CHAPTER 80

IMMUNODEFICIENCY DISEASES

Hans D. Ochs and Luigi D. Notarangelo

SUMMARY

Primary immune deficiency diseases (PIDDs) are characterized by increased susceptibility to infections, often associated with autoimmunity and inflammation and an increased risk of malignancies because of impaired immune homeostasis and surveillance. Depending on the nature of the immune defect, the clinical presentation of PIDD may vary and may include recurrence of upper and lower respiratory tract infections, invasive bacterial infections, purulent lymphadenitis, skin or deep abscesses, infections sustained by poorly virulent or opportunistic pathogens (*Pneumocystis jirovecii*, cytomegalovirus,

environmental mycobacteria, *Cryptosporidium*, *Giardia lamblia*), persistent or recurrent candidiasis, narrow susceptibility to a selective type of pathogens, autoimmunity, increased susceptibility to malignancies, and may be associated with typical signs of specific immunodeficiency syndromes.

With the exception of immunoglobulin (Ig) A deficiency and DiGeorge syndrome, PIDDs are generally rare, with a prevalence of approximately 1 in 10,000 to 1 in 50,000 of the general population. However, prompt recognition of PIDD is of importance, because diagnostic delay is associated with increased risk of death and of irreversible complications. Most forms of PIDD follow mendelian inheritance; however, some, like common variable immunodeficiency (CVID), have a multifactorial origin. In most cases, PIDDs present in childhood, but late presentations may occur or even predominate in some forms, such as CVID.

The diagnostic approach to PIDD is based on a detailed family and clinical history, physical examination and appropriate laboratory tests. Lymphopenia is characteristic of severe combined immune deficiency. Abnormalities affecting neutrophils can be observed in patients with disorders of neutrophil production (e.g., congenital neutropenia, leukocyte adhesion deficiency; Chap. 65) or function (e.g., chronic granulomatous disease; Chap. 66), respectively. Evaluation of serum immunoglobulin levels and of antibody responses to immunization antigens is of value for patients with a history of recurrent infections.

Acronyms and Abbreviations: AD, autosomal dominant; ADA, adenosine deaminase; AD-HIES, autosomal dominant hyperimmunoglobulin E syndrome; aHSCs, autologous hematopoietic stem cells; AID, activation-induced cytosine deaminase; AIRE, autoimmune regulator; ALPS, autoimmune lymphoproliferative syndrome; APECED, autoimmune polyendocrinopathy, candidiasis, and ectodermal dystrophy; APS, autoimmune polyglandular syndrome; AR-HIES, autosomal recessive hyperimmunoglobulin syndrome; AT, ataxia-telangiectasia; ATLD, ataxia-telangiectasia-like disorder; ATM, ataxia-telangiectasia mutated; BCG, bacillus Calmette-Guérin; *BLM*, the causative gene of Bloom syndrome; BS, Bloom syndrome; BTK, Bruton tyrosine kinase; C, complement; CARD, caspase recruitment domain-containing protein; CD40L, CD40 ligand; CHARGE, coloboma of the eye, heart defects, atresia of the nasal choanae, retardation of growth and/or development, genital and/or urinary abnormalities, and ear abnormalities and deafness; CID, combined immune deficiency; CMC, chronic mucocutaneous candidiasis; CMV, cytomegalovirus; CSR, class switch recombination; CTL, cytotoxic T lymphocyte; CTLA-4, cytotoxic T-lymphocyte antigen-4; CTPS1, cytidine 5-triphosphate synthase 1; CVID, common variable immunodeficiency; D, diversity; DC, dendritic cell; DGS, DiGeorge syndrome; DOCK8, dedicator of cytokinesis 8; EBV, Epstein-Barr virus; FHL, familial hemophagocytic lymphohistiocytosis; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; GS2, Griscelli syndrome type 2; HIES, hyperimmunoglobulin E syndrome; HLA, human leukocyte antigen; HLH, hemophagocytic lymphohistiocytosis; HPV, human papillomavirus; HSCT, hematopoietic stem cell transplantation; HSE, herpes simplex virus encephalitis; HSV, herpes simplex virus; IBD, inflammatory bowel disease; ICF, immunodeficiency with centromere instability and facial anomalies; IFN, interferon; Ig, immunoglobulin; IGF-1, insulin-like growth factor 1; IGHM, immunoglobulin heavy constant mu; IGLL1, immunoglobulin lambda-like polypeptide 1; IKK, I κ B kinase; IL, interleukin; IL-7R, IL-7 receptor; iNKT, invariant natural killer T cell; IPEX, immune dysregulation, polyendocrinopathy, enteropathy, X-linked; IRAK, IL-1 receptor-associated kinase; IRF8, interferon-regulated factor 8; ISG15, interferon-stimulated gene 15; ITCH, itchy E3 ubiquitin protein ligase;

ITK, interleukin-2-inducible T-cell kinase; IVIG, intravenous immunoglobulin; J, joining; JAK3, Janus-associated tyrosine kinase 3; LCK, lymphocyte-specific protein tyrosine kinase; LGL, large granular lymphocytic leukemia; LIG4, DNA ligase IV; LRBA, lipopolysaccharide responsive beige-like anchor; LYST, lysosomal trafficking regulator; MAGT1, magnesium transporter 1; MHC, major histocompatibility complex; MMF, mycophenolate mofetil; MonoMAC, monocytopenia, B-cell and NK-cell lymphopenia associated with mycobacterial, fungal, and viral infections; MSMD, mendelian susceptibility to mycobacterial disease; MyD88, myeloid differentiation factor 88; NBS, Nijmegen breakage syndrome; NEMO, nuclear factor- κ B essential modulator; NF, nuclear factor; NK, natural killer; NKT, natural killer T cell; ORAI1, calcium release-activated calcium channel protein 1; PI3K, phosphatidylinositol 3-kinase; PIDD, primary immune deficiency disease; PLDN, pallidin; PMS2, postmeiotic segregation increased 2 (*Saccharomyces cerevisiae*); PNP, purine nucleoside phosphorylase; *RAG1/2*, recombination activating gene 1/2; RMRP, ribonuclease mitochondrial RNA processing complex; SAP, signaling lymphocyte activation molecule (SLAM)-associated protein; SCID, severe combined immune deficiency; SHM, somatic hypermutation; SLAM, signaling lymphocyte activation molecule; SMARCAL1, switch/sucrose nonfermentable (SWI/SNF)-related matrix-associated actin-dependent regulator of chromatin subfamily A-like protein 1; SNP, single nucleotide polymorphism; STIM1, stromal interaction molecule 1; TAP-1/2, transport-associated protein 1/2; TCR, T-cell receptor; T_{EMRA}, T memory; TLR, toll-like receptor; TNF, tumor necrosis factor; TRAF, TRIF-related adaptor molecule; TREC, T-cell-receptor excision circle; TRIF, toll-interleukin 1 receptor domain-containing adaptor-inducing IFN- β ; TYK2, tyrosine kinase 2; UNG, uracil N-glycosylase; V, variable; VODI, venoocclusive disease with immunodeficiency; WAS, Wiskott-Aldrich syndrome; WASp, Wiskott-Aldrich syndrome protein; WHIM, warts, hypogammaglobulinemia, infections, myelokathexis; WIP, WASp-interacting protein; WRN, Werner syndrome, RecQ helicase-like; XHIGM, X-linked hyperimmunoglobulin M; XLA, X-linked agammaglobulinemia; XLP1 and XLP2, X-linked lymphoproliferative syndrome types 1 and 2; XLT, X-linked thrombocytopenia; ZAP-70, zeta-associated protein of 70 kDa.

The clinical presentation and the results of these screening evaluations may prompt additional laboratory testing. For instance, patients with a profound hypogammaglobulinemia and a history of recurrent infections should be tested for the presence of circulating B lymphocytes (CD19+ or CD20+ cells), which are absent or markedly reduced in X-linked agammaglobulinemia. On the other hand, early presentation with severe and/or opportunistic infections, especially if associated with lymphopenia, should prompt enumeration of lymphocyte subsets. A severe reduction of circulating CD3+ T cells is typically observed in severe combined immune deficiency, and may be associated with defects of B and/or natural killer cells. Deep bacterial infections, or infections sustained by *Aspergillus*, require evaluation of neutrophil count and function, to identify patients with congenital neutropenia and chronic granulomatous disease, respectively. Invasive recurrent infections sustained by *Neisseria* species are an indication for assessing complement levels and function. The complement component deficiencies may also lead to systemic lupus erythematosus-like features or other autoimmune disorders. Laboratory results should be compared to age-matched control values, as white blood cell counts, lymphocyte subsets, complement components, immunoglobulin levels, and antibody production (especially to polysaccharide antigens) undergo significant changes and progressive maturation in the first years of life. It is important to rule out secondary forms of immunodeficiency, such as human immunodeficiency virus infection, protein loss, and immunodeficiency secondary to use of immunosuppressive drugs, as well as anatomical and/or functional problems (e.g., asplenia) that may lead to increased susceptibility to infections.

Recognition of PIDDs is essential to start optimal therapies at an early age. These include immunoglobulin substitution for patients with antibody deficiency; allogeneic hematopoietic stem cell transplantation for patients with severe combined immune deficiency; and in some cases, gene therapy or enzyme replacement therapy may be considered. Antimicrobial prophylaxis and aggressive treatment of infections is necessary in most cases of PIDD. Some patients with significant immune dysregulation may benefit from immunosuppressive therapy.

This chapter focuses on defects that primarily affect T and B lymphocytes, the complement system, and innate immunity. It discusses specific immunodeficiency syndromes, reviews etiology and pathogenesis, clinical and laboratory features, treatment, and prognosis. Chapters 65 and 66 discuss in detail disorders of neutrophil number and function.

● PREDOMINANT ANTIBODY DEFICIENCIES

X-LINKED AND AUTOSOMAL RECESSIVE AGAMMAGLOBULINEMIA

Definition and Genetic Features

X-linked agammaglobulinemia (XLA) is the prototypic antibody deficiency characterized by profound hypogammaglobulinemia caused by a maturation defect in B-cell development.^{1,2} XLA, originally described in 1953, is one of the first primary immunodeficiencies in which the underlying defect, a mutation of Bruton tyrosine kinase (BTK) was identified. Autosomal recessive agammaglobulinemia, a variant form of agammaglobulinemia, has been reported in patients with a clinical phenotype resembling XLA including very low B-cell numbers and severe

bacterial infections but normal BTK.² Several responsible gene mutations have been identified, including those involving the B-cell receptor complex μ heavy chain (immunoglobulin heavy constant μ [IGHM]), the surrogate light chain component $\lambda 5$ (immunoglobulin lambda-like polypeptide 1 [IGLL1]), the signal transducer complex of the pre-B-cell receptors immunoglobulin (Ig) α (CD79a), Ig β (CD79b), and mutations in the B-cell adaptor molecule BLNK, the p85 α subunit of phosphatidylinositol 3-kinase (PI3K)³ and a dominant negative E47 mutation causing autosomal dominant agammaglobulinemia.⁴

Clinical Features

Because IgG is actively transported across the placenta, infants born with XLA have normal levels of IgG at birth and are frequently asymptomatic for the first few months of life. Following metabolism of the maternal antibodies, affected boys begin to develop recurrent infections usually between 4 and 12 months of age. In a review of 96 XLA patients, 20 percent experienced initial clinical symptoms after their first birthday and approximately 10 percent after 18 months of age.⁵ In an Italian study of 73 patients with mutation-verified XLA, the mean age of onset of symptoms was 2 years.⁶ The presenting symptoms vary greatly and may be mild or severe (Table 80-1). Otitis media and chronic sinusitis, pneumonia, pyoderma, and diarrhea are frequent clinical presentations. Serious complications include septicemia, meningitis, septic arthritis, and osteomyelitis. In young children with XLA, acute infections are often associated with neutropenia. Pyogenic bacteria, such as *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Staphylococcus aureus* are the most common pathogens observed in XLA. Opportunistic infections, such as *Pneumocystis jirovecii*, are rarely observed. Infections with *Ureaplasma urealyticum* have been reported in XLA patients with mycoplasma arthritis.⁷ Although resistance to viral infections is generally intact, XLA patients are unusually susceptible to enteroviruses such as echovirus, coxsackievirus, and poliovirus. Poliomyelitis after live-attenuated (Sabin) poliovirus vaccine, especially if given at a time when maternal antibodies had disappeared, is associated with high morbidity and mortality.⁵ Before the introduction of intravenous immunoglobulin (IVIG), XLA patients frequently developed chronic, disseminated echovirus and coxsackievirus infections presenting as meningoencephalitis, dermatomyositis/fasciitis, and hepatitis.⁸ Gastroenteritis caused by *Giardia lamblia*, *Campylobacter* species, or rotavirus is not uncommon and may be associated with malabsorption. Chronic intestinal inflammation resembling Crohn disease may develop in children and adults with XLA. Interestingly, an increased incidence of rectosigmoid cancer with high mortality has been reported.⁹ Pyoderma gangrenosum-like ulcers of the lower extremities have been observed to be caused by *Helicobacter* species.¹⁰

Laboratory Features

Most patients have markedly reduced levels of all classes of immunoglobulins; circulating B cells are less than 1 percent of total lymphocytes and tonsils are absent. Because of the maturation arrest at the pre-B-cell stage, very few B cells undergo differentiation into plasma cells. As a result, lymph nodes, lymphoid follicles, germinal centers, and intestinal mucosal biopsies lack plasma cells. As expected, specific antibodies to microorganisms or vaccines are markedly reduced or undetectable (Table 80-2).

BTK, a cytoplasmic protein tyrosine kinase known to interact with other cytoplasmic proteins, plays an important role in the pre-B-cell expansion and the survival of mature B cells by facilitating signaling through the B-cell antigen receptor. BTK is present in all hematopoietic cells except T cells, natural killer (NK) cells, and plasma cells. The presence of BTK in normal monocytes and platelets allows assessment of BTK in most XLA patients with low or absent

TABLE 80–1. Principal Clinical Features of Primary Immunodeficiency Disorders

Neutrophil Numerical or Functional Defects (See Chaps. 65, 66)	Antibody Deficiencies	Combined Immune Deficiencies	Complement Deficiencies
Severe bacterial and fungal infections	Recurrent bacterial infections after 4 to 6 months of age	Early onset respiratory and gut infections (bacterial, viral, fungal)	Recurrent or severe infections sustained by encapsulated pathogens
Skin or deep bacterial and fungal abscesses	Intestinal <i>Giardia lamblia</i> infection	Opportunistic infections	Recurrent <i>Neisseria meningitidis</i> infections
Infections sustained by unusual bacteria and fungi	Enteroviral meningoencephalitis	Persistent candidiasis	Autoimmune manifestations (systemic lupus erythematosus-like)
Colitis		Growth failure	Atypical hemolytic-uremic syndrome
			Recurrent angioedema (C1-INH deficiency)

BTK levels using flow cytometry, and to identify carrier females.¹¹ Sequence analysis of the *BTK* gene confirms the diagnosis of XLA and allows prenatal diagnosis. Autosomal recessive (and dominant) forms of agammaglobulinemia are rare and require sequence analysis of the genes listed above.

Treatment

Intravenous or subcutaneous IgG infusions at a dose of 400 to 600 mg/kg every 3 to 4 weeks are highly effective in preventing chronic infections in agammaglobulinemic patients. Prophylactic antibiotics are indicated in those with chronic lung disease. Adequate IVIG replacement has markedly reduced the incidence of enteroviral infections, but other complications, such as Crohn-like disease, are difficult to prevent, and progressive neurodegeneration has been observed in a small number of XLA patients without identification of an infectious agent.¹²

HYPERIMMUNOGLOBULIN M SYNDROMES

Definition and Genetic Abnormalities

Hyper-IgM syndromes are characterized by recurrent infections associated with low serum levels of IgG, IgA, and IgE, but normal or increased levels of IgM (see Table 80–2). They are the direct result of mutations affecting genes involved in B-cell activation, class switch recombination (CSR), and somatic hypermutation (SHM). Mutations in the genes encoding CD40 ligand (CD40L) or CD40 interfere with the triggering of events that lead to CSR and SHM. Mutations in the B-cell intrinsic enzymes, activation-induced cytosine deaminase (AID) and uracil N-glycosylase (UNG), directly affect CSR and SHM. Mutations in the *NEMO* gene (nuclear factor [NF]- κ B essential modulator), a protein crucial for NF- κ B activation, cause clinical features of anhydrotic ectodermal dysplasia with associated immune deficiency in males and incontinentia pigmenti in females.¹³ A novel B-cell-intrinsic CSR deficiency characterized by susceptibility to malignancies was found to be associated with mutations in the gene encoding the postmeiotic segregation increased 2 (*Saccharomyces cerevisiae*) (PMS2) component of the mismatch repair machinery.¹⁴ A subset of patients with ataxia telangiectasia present with elevated serum IgM and CSR deficiency.¹⁵

X-Linked Hyperimmunoglobulin M as a Result of CD40 Ligand Deficiency

Clinical Features In addition to recurrent bacterial infections, affected infants with X-linked hyperimmunoglobulin M (XHIGM) often present with interstitial pneumonia caused by *P. jirovecii* approximately 50 percent of affected males will develop neutropenia.¹⁶ Patients with XHIGM are at high risk of developing chronic *Cryptosporidium* infections complicated by ascending cholangiolitis and chronic liver disease. Progressive neurodegeneration in XHIGM patients similar to those with XLA has been reported.¹² Abortive germinal center formation and severe depletion of follicular dendritic cells of lymph nodes occurs. Affected patients are at risk to develop neoplasms, most often lymphomas, but also tumors of the biliary and gastrointestinal tract,¹⁷ which are rarely observed in other primary immunodeficiencies.

Laboratory Features Circulating lymphocyte subsets are present in normal numbers but B cells are predominantly naïve and few are of the switched memory B-cell subtype (IgD⁺, IgM⁺ CD27⁺).¹⁸ Lymphocyte proliferation in response to mitogens is normal, but responses to specific antigens are often reduced.¹⁹ XHIGM is caused by mutations in CD40L, a surface protein expressed by activated CD4⁺ lymphocytes. CD40L interacts with the CD40 membrane protein constitutively expressed by B cells, macrophages, and dendritic cells (DCs). The interaction of CD40L/CD40 sets in motion a signaling event that results in the expression of AID and UNG, and induces CSR and SHM. Mutations in CD40L are distributed throughout the gene and may result in nonfunctional or absent protein.¹⁶ Several patients with mild cases of XHIGM not treated with IVIG have developed chronic pure red cell aplasia as a result of persistent parvovirus B19 infection.²⁰

Treatment Prophylactic treatment with trimethoprim-sulfamethoxazole is indicated during infancy and childhood to prevent *P. jirovecii* pneumonia. Intravenous or subcutaneous immunoglobulin at doses similar to patients with XLA is used to prevent chronic infections, including parvovirus B19. Exposure to *Cryptosporidium* should be prevented by avoiding the use of potentially contaminated water. Because of the high incidence of serious complications and the unfavorable long-term outcome,²¹ allogeneic stem cell transplantation should be considered if an optimal donor can be identified. Severe and persistent neutropenia may

Autosomal Recessive Hyperimmunoglobulin M with CD40 Mutations

Autosomal recessive hyperimmunoglobulin M caused by mutations in CD40 have been reported, mostly in consanguineous families.^{16,22} Affected members have similar clinical and laboratory findings as those with CD40L mutations. Treatment and prognosis of CD40 deficiency is similar to XHIGM.

Autosomal Recessive Hyperimmunoglobulin M Syndrome Caused by an Intrinsic B-Cell Defect

Definition AID is expressed only in B cells undergoing CSR or SHM and is thought to affect DNA editing.²³ Because of milder symptoms, the diagnosis of AID deficiency is often established later in life.

Clinical Features AID-deficient patients present with recurrent bacterial infections, mostly affecting the upper and lower respiratory tract. In contrast to patients with XHIGM, AID-deficient individuals have an excellent long-term prognosis, especially if given IVIG prophylaxis. Most affected individuals present with striking lymphoid hyperplasia involving tonsils and lymph nodes as a result of marked follicular hyperplasia. The number of circulating T- and B-cell subsets are normal, including normal proportion of memory B cells; however, all CD27⁺ memory B cells fail to isotype switch and only express IgM and IgD. Mutations of *AID* affect the entire gene and include missense, nonsense mutations, and small deletions.

UNG is expressed in proliferating cells, including B cells undergoing CSR. Following AID-induced deamination of cytosine into uracil residues on single-stranded DNA, UNG deglycosylates and removes uracil residues, thus leading to a single-stranded DNA break. The repair of the DNA nick leads to successful CSR and SHM. Because AID and UNG are functionally closely linked, lack of UNG results in a clinical

phenotype similar to AID deficiency. The three UNG deficient patients reported to date have a history of frequent bacterial infections, lymphadenopathy, and an excellent response to IVIG therapy.²³

X-Linked Anhydrotic Ectodermal Dysplasia with Immunodeficiency Caused by Mutations in Nuclear Factor-κB Essential Modulator

Definition Anhydrotic (or hypohidrotic) ectodermal dysplasia is a rare syndrome with partial or complete absence of sweat glands, sparse hair growth, and abnormal dentition. A subset of these patients has an X-linked mode of inheritance and immunodeficiency characterized by low-serum IgG levels, variably elevated IgM levels, and decreased antibody responses. This syndrome results from mutations in the *IKBKG* gene encoding NEMO, a key subunit of I-κB kinase that regulates NF-κB dimerization and nuclear transfer.²⁴ Most affected boys have a hypomorphic NEMO mutation that allows some function, and present with bacterial (*S. pneumoniae*, *S. aureus*) and often atypical mycobacterial infections. Loss-of-function mutations cause the X-linked dominant condition of incontinentia pigmenti in females and are embryonically lethal in males. A similar phenotype with autosomal dominant inheritance is caused by gain-of-function mutations in *IKBA*.²⁵

Clinical Features A review of 72 individuals with NEMO mutations has demonstrated a wide spectrum of clinical phenotypes.²⁶ Thirty-two different mutations of NEMO were identified, with 70 percent being associated with ectodermal dysplasia, 86 percent with serious pyogenic infections, 39 percent with mycobacterial infections, 19 percent with serious viral infections, and 21 percent with inflammatory bowel disease. One-third of this cohort of NEMO patients died prematurely (mean age: 6.4 years).

Treatment Treatment with IVIG is useful but does not prevent the occurrence of serious complications. Symptomatic treatment depends on those complications.

COMMON VARIABLE IMMUNODEFICIENCY AND SELECTIVE IMMUNOGLOBULIN A DEFICIENCY

Definition

Common variable immunodeficiency (CVID) is a clinically and molecularly heterogeneous disorder, presenting at any age, but most often during adulthood. CVID is characterized by recurrent bacterial infections, hypogammaglobulinemia, and impaired antibody responses. Together with selective IgA deficiency, CVID is the most common primary immune deficiency, with an incidence of 1 in 10,000 individuals. Familial inheritance is observed in approximately 20 percent of cases and CVID and IgA deficiency may be present in the same families. In rare instances, patients with selective IgA deficiency may progress to CVID. Attempts have been made to associate CVID and IgA deficiency with genes located within the major histocompatibility complex (MHC) region on chromosome 6; however, no specific genes within this region have been identified. A small proportion of patients with CVID have been molecularly defined as having mutations in several genes involved directly or indirectly with B-cell differentiation, including *ICOS*, *TACI*, *BAFF*-receptor, *CD19*, *CD20*, *CD21*, and *CD81*.²⁷ The recent discovery of CVID-like phenotypes resulting from heterozygous mutations in *NF-κB2*^{28,29} and gain-of-function mutations in *PI3Kδ*,³⁰ and CVID with autosomal recessive inheritance as a result of mutations in protein kinase *Cδ*³¹ further support the idea that CVID is a heterogeneous primary immune deficiency disease (PIDD) with strong genetic roots. In addition, patients with mutations in *BTK*, *CD40L*, and *SH2D1A* have been mistakenly diagnosed as CVID.

Clinical Features and Treatment of Common Variable Immunodeficiency

The majority of CVID patients present with recurring sinopulmonary infections, most often bacterial pneumonia.^{27,32} If the diagnosis is delayed or if treatment is inadequate, bronchiectasis and chronic lung disease may develop. Gastrointestinal complaints are frequent and may be caused by chronic *G. lamblia* or *Campylobacter* infections, resembling chronic inflammatory bowel disease. Lymphoid hyperplasia of the small bowel is a frequent finding. Autoimmune disorders are common and may resemble rheumatoid arthritis, dermatomyositis, or scleroderma. In addition, CVID patients may develop autoimmune hemolytic anemia, autoimmune thrombocytopenia, autoimmune neutropenia, pernicious anemia, and chronic active hepatitis. Lymphadenopathy and splenomegaly are common, the result of follicular hyperplasia. Caseating granulomas of the lung, spleen, liver, skin, and other tissues may develop at any age, and a condition resembling sarcoidosis has been described. The cause of this devastating granuloma formation is unknown. A high incidence of lymphoma and gastrointestinal malignancies have been reported in older CVID patients,³³ with a 438-fold increase in the risk of lymphomas in affected women during the fifth and sixth decades.³⁴ Despite normal numbers of blood B lymphocytes and the presence of lymphoid cortical follicles, CVID patients have hypogammaglobulinemia that may be as profound as in XLA (see Table 80-2). Antibody responses to recall and to neoantigens are diminished and some CVID patients have decreased numbers of memory B cells, especially of switched memory B cells. A subset of CVID patients have a substantial T-cell deficiency characterized by decreased expression of *CD40L* by activated *CD4*⁺ T cells (without a mutation of *CD40L*) and by reversed *CD4*:*CD8* ratio. Treatment with IVIG substitution and prophylactic antibiotics is beneficial but often insufficient to prevent serious complications. Allogeneic hematopoietic stem cell transplantation (HSCT) is generally not recommended, except in patients with lymphoid malignancies. There is a rare association between immune

deficiency and thymoma, which is estimated to be present in 4 percent of patients with hypogammaglobulinemia.³⁵

Clinical Features and Treatment of Selective Immunoglobulin A Deficiency

The incidence of selective IgA deficiency, defined as IgA less than 5 to 10 mg/dL, differs greatly between ethnic groups, being highest in Scandinavia (1 in 396 in a Finnish study)³⁶ and lowest in Asian populations (1 in 14,000 in Japan).³⁷ Because secretory IgA is considered to be most important in protecting mucus surfaces, it is surprising that most IgA-deficient patients remain healthy. Other defense systems, for example, noncirculatory IgM or neutrophils, may compensate for this deficiency. Symptomatic individuals are not only IgA deficient, but often have deficient antibody responses to specific antigens. IgA deficiency may be associated with *IgG₂* and *IgG₃* deficiency and poor responses to polysaccharide antigens.³⁸ Selective IgA deficiency, if associated with symptoms, often leads to recurrent sinopulmonary infections and atopic symptoms including allergic conjunctivitis, rhinitis, and eczema. Food allergy may be more common in IgA-deficient patients and asthma associated with IgA deficiency appears to be more refractory to therapy. Gastrointestinal tract disorders include chronic giardiasis, malabsorption, celiac disease, primary biliary cirrhosis, pernicious anemia, and nodular lymphoid hyperplasia. A number of autoimmune diseases are associated with selective IgA deficiency, including rheumatoid arthritis, systemic lupus erythematosus, thyroiditis, myasthenia gravis, and ulcerative colitis.

A significant proportion of IgA-deficient individuals has anti-IgA antibodies in their serum and may react to blood products containing IgA, including IVIG preparations with low IgA content. However, patients with selective IgA deficiency who make normal IgG antibody do not need IVIG therapy.

The fundamental defect in selective IgA deficiency is the failure of IgA-bearing B lymphocytes to mature into IgA-secreting plasma cells. There is no specific treatment that would correct this problem. Intermittent or continuous prophylactic antibiotics may be helpful in patients with recurrent respiratory tract infections, who develop chronic symptoms of lung disease. On the other hand, if IgA deficiency is associated with poor antibody responses to selected antigens, for example, to polysaccharides, an attempt with IVIG substitution should be made.

LIPOPOLYSACCHARIDE RESPONSIVE BEIGE-LIKE ANCHOR DEFICIENCY

Lipopolysaccharide responsive beige-like anchor (LRBA) is a broadly expressed, cytosolic protein involved in endocytosis of ligand-activated receptors. LRBA deficiency is inherited as an autosomal recessive trait and is characterized by recurrent bacterial and viral infections, and prominent autoimmune manifestations, cytopenias, and inflammatory bowel disease, in particular.^{39,40} Hypothyroidism and myasthenia gravis have been also reported. Immunologic abnormalities include progressive hypogammaglobulinemia, impaired activation and decreased survival of T and B lymphocytes, reduced number of marginal zone-like and switched memory B cells, and defective autophagy.

SEVERE COMBINED IMMUNODEFICIENCIES

DEFINITION AND HISTORY

The first description of severe combined immunodeficiencies (SCIDs) dates back to 1950, when Glanzmann and Riniker described infants

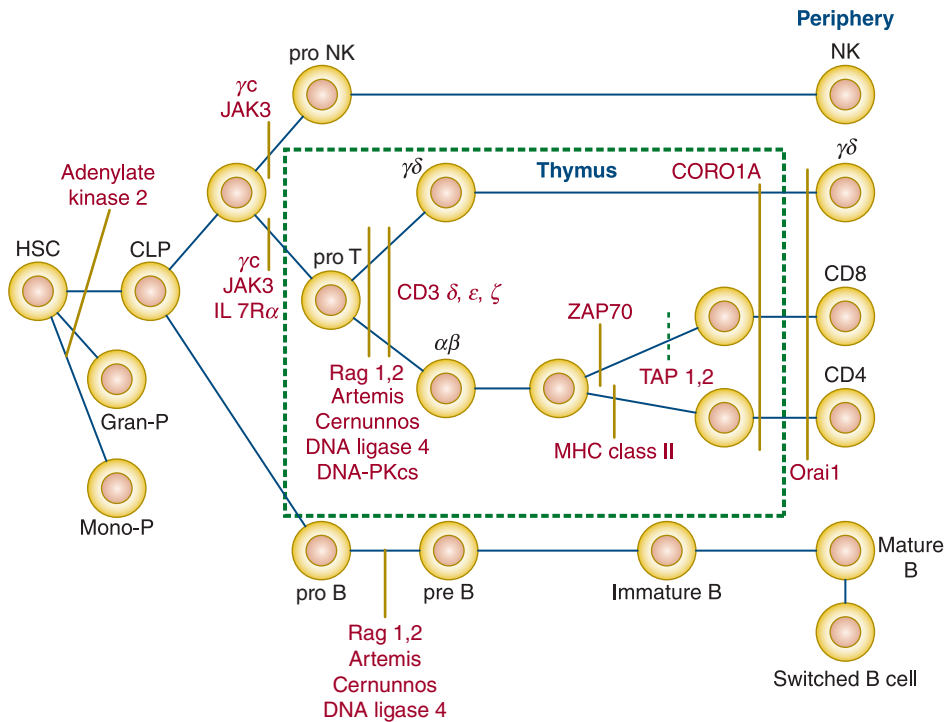

Figure 80–1. Disruption of the normal T-cell development by mutations of genes known to cause a severe combined immunodeficiency disease phenotype. B, B lymphocyte; CLP, common lymphocyte progenitor; γc , common gamma; Gran-P, granulocyte progenitor; HSC, hematopoietic stem cell; JAK3, Janus-associated tyrosine kinase 3; MHC, major histocompatibility complex; Mono-P, monocyte progenitor; NK, natural kill lymphocyte; Orai1, calcium release-activated calcium channel protein 1; T, T lymphocyte; TAP-1/2, transport-associated protein 1/2; ZAP70, zeta-associated protein of 70 kDa.

who died with overwhelming infections, intractable diarrhea, thrush, and profound lymphopenia.⁴¹ The SCID phenotype represents a heterogeneous group of genetic disorders that are characterized by a severe impairment of T-lymphocyte development and function (Fig. 80–1).^{42–44} Depending on whether the development of B and/or NK lymphocytes is also affected, SCID can be classified into four distinct immunologic phenotypes: (1) T⁺B⁺NK⁻ SCID (the most common variant); (2) T⁺B⁺NK⁺ SCID; (3) T⁻B⁻NK⁺ SCID; or (4) T⁻B⁻NK⁻ SCID (see Table 80–2). The term *combined immune deficiency* (CID) is used to define disorders with residual development and/or function of T lymphocytes. Unless treated by allogeneic HSCT or, in selected cases, by gene therapy or enzyme replacement therapy, SCID is inevitably fatal.

MOLECULAR DEFECTS AND PATHOGENESIS OF SEVERE COMBINED IMMUNE DEFICIENCY

SCIDs are mendelian disorders, and their overall prevalence is estimated to be approximately 1 in 50,000 births. In Western countries, the most common form of SCID is inherited as an X-linked trait; however, a variety of autosomal recessive forms are also known. SCID can be grouped in different categories that illustrate the various pathogenetic mechanisms involved in T-cell development.

Severe Combined Immune Deficiency as a Result of Increased Apoptosis of Lymphocyte Precursors

Adenosine Deaminase Deficiency Approximately 5 to 10 percent of infants with SCID have a deficiency of adenosine deaminase (ADA), the enzyme that converts adenosine and deoxyadenosine into inosine and deoxyinosine, respectively.⁴⁵ In the absence of ADA, high intracellular levels of adenosine, deoxyadenosine, and their toxic phosphorylated metabolites cause apoptosis of lymphoid precursors, and hence result in the virtual absence of T lymphocytes, that is usually associated with marked reduction of B and NK lymphocytes (T⁻B⁻NK⁻ SCID).⁴⁶ ADA-SCID is inherited as an autosomal recessive trait, and its clinical manifestations

extend beyond the immune system, reflecting the fact that ADA is a general housekeeping enzyme.

Purine Nucleoside Phosphorylase Deficiency Purine nucleoside phosphorylase (PNP) is another enzyme of the purine salvage pathway. PNP catalyzes the phosphorylation of inosine, guanosine, and deoxyguanosine.⁴⁵ In the absence of PNP, high intracellular levels of deoxyguanosine triphosphatase cause lymphoid and neuronal toxicity. Immature thymocytes are particularly susceptible to PNP deficiency. Accordingly, the immunologic phenotype of PNP deficiency is characterized by decreased T-cell counts, whereas B and NK lymphocytes are often unaffected.⁴⁷ PNP deficiency accounts for 1 to 2 percent of all forms of SCID, and is inherited as an autosomal recessive trait.

Adenylate Kinase 2 Deficiency Another rare variant of autosomal recessive SCID, reticular dysgenesis, is characterized by extreme lymphopenia, absence of neutrophils, and sensorineural deafness.⁴⁸ The disease is caused by mutations of adenylate kinase 2 that result in apoptosis of myeloid precursors of neutrophils, and of lymphoid progenitor cells.^{49,50}

Severe Combined Immune Deficiency as a Result of Defects of Cytokine-Mediated Signaling

Thymic T-cell progenitors depend on interleukin (IL)-7 for cell proliferation. The IL-7 receptor (IL-7R) is composed of an α chain (encoded by the *IL7R* gene) and a common γ chain (γc), that is shared also by IL-2R, IL-4R, IL-9R, IL-15R, and IL-21R,⁵¹ and is encoded by the *IL2RG* gene, located on the X chromosome. Cytokine-mediated signaling through γc -containing receptors involves activation of Janus-associated tyrosine kinase 3 (JAK3).⁵¹ In humans, defects of IL-7-mediated signaling abrogate T-cell development, whereas impaired signaling through IL-15R affects development of NK cells.⁵¹ X-linked SCID, caused by *IL2RG* mutations,⁵² represents approximately 30 percent of all cases of SCID, and is characterized by lack of T and NK lymphocytes but normal development of B cells (T⁺B⁺NK⁻ SCID). B-lymphocyte function, however, is severely compromised by both the lack of T-cell help and non-functional γc . JAK3 deficiency is inherited as an autosomal recessive

trait, and its phenotype is identical to that of X-linked SCID (T⁺B⁺NK⁻SCID).^{53,54} In contrast, autosomal recessive IL-7R deficiency caused by mutation of the α chain is characterized by the selective lack of T cells (T⁺B⁺NK⁺ SCID).⁵⁵

Severe Combined Immune Deficiency as a Result of Defective Signaling Through the T-Cell Receptor

One of the distinctive features of developing thymocytes is the expression of the pre-T-cell receptor (TCR), that is composed of a pre-T α chain, a TCR β chain, and the CD3 γ , δ , ϵ , and ζ chains. Signaling through the pre-TCR permits rearrangement of the TCR α chain and expression of a mature TCR $\alpha\beta$. Alternatively, thymocytes may express the $\gamma\delta$ chains of the TCR. Rearrangement of the TCR loci is accomplished by means of the V(D)J recombination, whereby the lymphoid specific recombination activating gene 1 (*RAG1*) and recombination activating gene 2 (*RAG2*) proteins mediate DNA cleavage at the variable (V), diversity (D), and joining (J) elements of the TCR loci. The DNA double-strand break of the coding ends is initially sealed as a hairpin, followed by nonhomologous endjoining via the nuclease Artemis (encoded by the *DCLRE1C* gene). Eventually, joining of coding (and signal) elements is mediated by a series of proteins, that include the Ku70/80 heterodimer, XRCC4, DNA ligase IV (LIG4), DNA-protein kinase catalytic subunit, and Cernunnos/XLF. Defects in V(D)J recombination affect both T- and B-cell development and hence cause T⁺B⁺NK⁺ SCID, because this process is also essential to mediate rearrangement of the immunoglobulin genes, a key step in B-cell development. *RAG1* or *RAG2* deficiencies account for 3 to 20 percent of all SCID cases in different series.^{42,56} Artemis (*DCLRE1C*),⁵⁷ DNA-protein kinase catalytic subunit,⁵⁸ LIG4,^{59,60} and Cernunnos/XLF⁶¹ deficiencies are less frequent and their cellular and clinical phenotypes extend beyond impaired T- and B-cell development, because enzymes that mediate DNA double-strand break repair are ubiquitously expressed, and their deficiency results in increased cellular radiosensitivity.⁵⁷⁻⁶¹ The phenotype of LIG4 deficiency can be extremely variable, from T⁺B⁺NK⁺ SCID to mild or no immunodeficiency, whereas Cernunnos/XLF deficiency is characterized by significant T-cell lymphopenia and progressive decrease in the number of B cells.

Defects of the CD3 δ , ϵ , or ζ chains affect signaling through the pre-TCR and the TCR and hence cause autosomal recessive T⁺B⁺NK⁺ SCID.⁶²⁻⁶⁴ In contrast, CD3 γ deficiency is associated with mild T-cell lymphopenia and a variable clinical phenotype.^{65,66}

Mutations of the TCR α constant (*TCRA*) gene cause impaired differentiation of T cells expressing TCR $\alpha\beta$.⁶⁷

Mutations of CD45, a pan-leukocyte tyrosine phosphatase that has been implicated in signaling through the TCR and the B-cell receptor, have been reported in few patients with T⁺B⁺NK⁺ SCID.^{68,69}

Clinical Features of Severe Combined Immunodeficiency Syndrome

Despite genetic heterogeneity, SCID is characterized by a consistent clinical phenotype. Interstitial pneumonia, often sustained by *P. jirovecii*, cytomegalovirus (CMV), adenovirus, parainfluenza 3 virus, respiratory syncytial virus, chronic diarrhea, failure to thrive, and persistent candidiasis are common features (see Table 80-1). Typically, infections develop in the first months of life. Skin manifestations (maculopapular rash, erythroderma, alopecia) are also common, especially in infants with maternal T-cell engraftment. Hypoplastic lymphoid tissue (tonsils, lymph nodes), and absence of a thymic shadow on chest radiography are characteristic.⁷⁰

Because of the inability to control replication of live microorganisms, administration of live-attenuated vaccines often leads to severe, life-threatening complications in infants with SCID.⁷¹

T-cell engraftment derived from maternal cells that cross the placenta occurs in more than 50 percent of infants with SCID. Most often asymptomatic, it may cause skin rash or, less frequently, typical graft-versus-host disease with generalized rash, liver disease, profuse diarrhea, jaundice, and severe hematologic abnormalities (thrombocytopenia, anemia, leukopenia) that are indicative of marrow damage.^{72,73} Transfusion of un-irradiated blood products often leads to fatal graft-versus-host disease.

Laboratory Features of Severe Combined Immunodeficiency Syndrome

An absolute lymphocyte count less than 2000/ μ L should prompt immediate investigation for SCID, regardless of the severity of clinical symptoms.⁴² Typically, infants with SCID have markedly reduced or absent circulating T cells which are unable to proliferate *in vitro* in response to mitogens and specific antigens.⁷⁴ However, T lymphocyte count may be preserved, at least in part, in SCID infants with maternal T-cell engraftment, with “leaky” variants of the disease,⁷⁴ or with somatic reversions that allow for some autologous T-cell development.⁷⁵ Finally, T-lymphocyte count can be normal or modestly reduced in patients with functional T-cell immunodeficiencies (see other combined immunodeficiencies; defective thymic development).

Maternal T-cell engraftment and “leaky” SCID with residual development of autologous T cells are characterized by the expression of the CD45R0 memory/activation antigen on the surface of circulating T lymphocytes (whereas most T cells in normal infants have a naïve CD45RA⁺ phenotype).

TCR excision circles, consisting of circularized signal joints, are a byproduct of V(D)J recombination and are exported to the blood by recent thymic emigrants. Levels of TCR excision circles in circulating lymphocytes are particularly high in newborns and infants, and progressively decline with age. Because TCR excision circles cannot be detected in infants with SCID, assessment of TCR excision circle levels by polymerase chain reaction has been successfully introduced for newborn screening for SCID.⁷⁶

Although the number of circulating B lymphocytes can vary depending on the nature of the genetic defect, serum immunoglobulin levels are low in infants with SCID (see Table 80-2). Normal serum IgG levels early in life reflect transplacental passage of maternal immunoglobulins. Antibody response to immunization antigens is abolished.

Eosinophilia may be observed in SCID, and IgE serum levels may be elevated in spite of hypogammaglobulinemia. Cytopenias, caused by infections or marrow damage, may also be present. Autoimmune hemolytic anemia is frequent in PNP deficiency.⁴⁷ Marrow abnormalities (dysplasia or aplasia) can be observed in ADA,⁷⁷ PNP,⁷⁸ Cernunnos/XLF,^{79,80} and LIG4⁸¹ deficiencies.

The diagnosis of ADA and PNP deficiency is facilitated by the demonstration of increased levels of deoxyadenosine triphosphate and deoxyguanosine triphosphate, respectively, in red blood cells.

Differential diagnosis of SCID includes secondary forms of immunodeficiencies, especially HIV infection, congenital rubella, and CMV infections, severe malnutrition, marrow failure syndromes,⁸² and defects of vitamin B₁₂ and folate metabolism.^{83,84}

Therapy, Course, and Prognosis of Severe Combined Immunodeficiency Syndrome

SCID is a medical emergency and is inevitably fatal if untreated. Confirmation of diagnosis by appropriate laboratory assays, referral to a tertiary care center, and aggressive treatment of infections should be immediately initiated in infants with possible SCID. High-dose intravenous sulfamethoxazole-trimethoprim (20 mg/kg) is effective in treating

P. jirovecii pneumonia. CMV should be treated with ganciclovir and adenoviral infections should be treated with cidofovir. Infants who have received bacillus Calmette-Guérin (BCG) vaccination at birth should receive isoniazid and rifampicin, regardless of the presence of overt signs of mycobacteriosis. Administration of IVIG and antimicrobial prophylaxis are necessary to reduce the risk of infections. Parenteral nutrition may be necessary, especially if chronic diarrhea and failure to thrive are present.

Survival, however, is ultimately dependent on immune reconstitution. Allogeneic HSCT was first performed in 1968 in an infant with X-linked SCID,⁸⁵ and is the treatment of choice. A multiinstitutional analysis of outcome of HSCT for SCID performed in North America in the period 2000 to 2009 demonstrates that survival following HSCT from a human leukocyte antigen (HLA)-identical sibling is as high as 97 percent.⁸⁶ T-cell-depleted transplantation from haploidentical donors results in a 79 percent 5-year-survival rate if no conditioning regimen is used. Importantly, survival is as high as 94 percent, regardless of donor type, if the transplant is performed within the first 3.5 months of age.⁸⁶ Moreover, 90 percent survival rate has been reported for older infants who received HSCT and did not have a prior history of infection.⁸⁶ For patients who do not have a matched sibling donor, use of pretransplantation conditioning regimen increases the chance of achieving more robust B-cell reconstitution, but this benefit must be balanced against toxicity of chemotherapy.⁸⁶ By contrast, HSCT from unrelated cord blood is associated with a lower survival rate (58 percent).⁸⁶

Failure to achieve sufficient T- and B-cell reconstitution is associated with prolonged morbidity after transplantation, but most patients with SCID enjoy good quality of life after transplantation.⁵⁶ However, neurologic complications and developmental problems after transplantation are more common in patients with SCID associated with increased radiosensitivity and in patients with defects of purine metabolism.^{56,87–89}

Enzyme replacement therapy offers rapid normalization of the toxic metabolites in ADA deficiency in those who do not have a matched donor, and may result in immune reconstitution and significant clinical improvement in patients with ADA deficiency, although T-cell counts often remain low.⁴⁵

Gene therapy is an attractive form of therapy for SCID patients who lack fully matched donors. Transplantation of gene-modified autologous hematopoietic stem cells (aHSCs) may lead to immune reconstitution without the risk of graft-versus-host disease. More than 40 patients with ADA deficiency have received gene therapy using non-myeloablative conditioning regimen and transfusion of aHSCs transduced with ADA-encoding retroviral vectors. All of these patients are alive, and approximately 75 percent of them have attained sufficient immune reconstitution.^{90–92}

Twenty patients with X-linked SCID received gene therapy with retroviral vectors in Paris and London, without conditioning regimen. Seventeen of them are alive (as of this writing) with robust T-cell immune reconstitution, but variable B-cell function.^{93,94} However, five patients developed leukemia as the result of insertional mutagenesis.^{95,96} This prompted development of novel, hopefully safer, vectors. A new multiinstitutional trial of gene therapy for X-linked SCID with a self-inactivating γ -retroviral vector is being conducted as of this writing. Of nine patients treated, eight are surviving, and seven have attained good T-cell reconstitution. No leukemic proliferations have been observed.⁹⁷ Variable, but often poor, B-cell reconstitution has been reported after gene therapy for X-linked SCID without conditioning. To overcome this problem, a new trial based on use of a self-inactivating lentiviral trial and reduced intensity conditioning is under way at the National Institutes of Health as of this writing.

OTHER COMBINED IMMUNODEFICIENCIES

In some cases, significant impairment of T-cell immunity is associated with residual development and/or function of T lymphocytes. These conditions are also known as CID to distinguish them from SCID, in which both T-cell development and function are abrogated. The clinical features of CID overlap with SCID, but also include autoimmunity and/or inflammatory manifestations reflecting unbalanced immune homeostasis. CID is caused by two main mechanisms: (1) hypomorphic mutations in SCID-causing genes that allow for some T-cell development; and (2) genetic defects that affect late stages in T-cell development or peripheral T-cell function.

OMENN SYNDROME

Definition

Originally described in 1965, Omenn syndrome is characterized by severe infections, associated with early onset diffuse rash or generalized erythroderma, alopecia, eosinophilia, lymphadenopathy, hepatosplenomegaly, hypoproteinemia with edema, and oligoclonal expansion of activated autologous T lymphocytes that infiltrate and damage target tissues.^{98,99}

Genetic Abnormalities

Various gene defects can cause this syndrome. Hypomorphic mutations in the *RAG1* and *RAG2* genes are most common,¹⁰⁰ but virtually any gene defect that severely impairs, but does not abolish, T-cell development may cause the disease.¹⁰¹

Pathophysiology

Defects of immunologic tolerance have been implied in the pathophysiology of Omenn syndrome. Thymic expression of AIRE (autoimmune regulator), a transcription factor involved in presentation of self-antigens and negative selection of autoreactive thymocytes, is reduced.¹⁰² Impaired generation of natural regulatory T cells, and homeostatic proliferation of T lymphocytes in a lymphopenic environment, may also play a critical role in the pathophysiology of the disease.¹⁰³

Laboratory Features

Laboratory investigations demonstrate that leukocytosis with eosinophilia and hypogammaglobulinemia are common findings, and that serum IgE is often elevated. The number of circulating T lymphocytes may vary, but they have a characteristic activated/memory (CD45RO+) phenotype. T cells have a restricted repertoire, and the distribution of CD4 and CD8 subsets is generally skewed. There is also a skewing to a T-helper (Th) type 2 (Th2) profile, with increased production of IL-4 and IL-5. The *in vitro* lymphocyte response to antigens is abrogated; responses to mitogens are variable, but in general are reduced.^{74,104} The number of circulating B and NK lymphocytes may vary, depending on the nature of the underlying genetic defect. Absence of invariant NK T cells has been reported in RAG-deficient Omenn syndrome.¹⁰⁵

Differential Diagnosis

Differential diagnosis includes maternal T-cell engraftment in patients with SCID, complete atypical DiGeorge syndrome, CHARGE syndrome (coloboma of the eye, heart defects, atresia of the nasal choanae, retardation of growth and/or development, genital and/or urinary abnormalities, and ear abnormalities and deafness), immune dysregulation-polyendocrinopathy-enteropathy-X-linked (IPEX) syndrome

and other conditions of neonatal erythroderma.^{106–109} Male infants with NEMO deficiency can also present with severe skin manifestations resembling Omenn syndrome.

Treatment

In preparation for allogeneic HSCT, the only curative treatment available,⁵⁶ patients require aggressive nutritional support, correction of hypoproteinemia, and treatment or prevention of infections with antibiotics, antifungals, and immunoglobulin replacement therapy. Immune suppression with steroids or cyclosporine is beneficial in controlling T-cell-mediated tissue damage.

DEFECTS OF T-CELL-RECEPTOR SIGNALING

Definition

TCR ligation promotes activation of the p56Lck kinase, which mediates phosphorylation of components of the CD3 complex. This allows recruitment and phosphorylation of the zeta-associated protein of 70 kDa (ZAP-70), activation of downstream signaling molecules, release of Ca²⁺ from intracellular endoplasmic reticulum stores, and initiation of Ca²⁺ influx. Mutations of lymphocyte-specific protein tyrosine kinase (LCK), ZAP-70, and of other TCR-associated signaling molecules (RHOH, MST1, IL-2-inducible T-cell kinase [ITK]) result in various forms of CID with dysfunctional T cells.^{110–115} Finally, PI3K, composed of a p110 δ and a p85 subunit, is involved in generation of phosphatidylinositol 4,5-triphosphate (PIP₃) and activation of mammalian target of rapamycin (mTOR) and AKT. Activating mutations of the *PI3KD* gene (encoding for the PI3K subunit p110 δ) results in increased activation-induced cell death of T lymphocytes, and consequently immunodeficiency.^{29,30}

Clinical and Laboratory Features

Patients with these disorders present with early onset and severe infections. Warts, molluscum contagiosum, infections caused by herpes viruses, and a high risk of Epstein-Barr virus (EBV)-driven lymphoproliferative disease have been reported in patients with LCK, RHOH, and MST1 deficiency, and with activating *PI3KD* mutations.^{29,30,110,113,114} Moreover, autoimmunity and lung granulomatous disease may also occur. From a laboratory standpoint, selective loss of CD8⁺ lymphocytes is observed in patients with ZAP-70 deficiency, and although the number of CD4⁺ lymphocytes is preserved, *in vitro* response to mitogens is markedly reduced, consistent with a signaling defect.^{111,112} Patients with LCK, RHOH, MST1, and ITK deficiency and with gain-of-function *PI3KD* mutations have a reduced number of naïve CD4⁺ T cells. Oligoclonality of the T-cell repertoire and an increased proportion of exhausted CD8⁺ T memory (T_{EMRA}) cells have been reported in these patients.^{29,30,107,113–115}

Differential Diagnosis

Differential diagnosis of ZAP-70 deficiency includes MHC class I deficiency and CD8 α deficiency, two conditions characterized by a severe reduction of CD8⁺ lymphocytes. Patients with CD8 α deficiency have an unusual population of CD3⁺ TCR $\alpha\beta$ ⁺ CD4⁻ CD8⁻ cells that have normal proliferative responses and usually survive to adulthood, although a late death from infections has been reported.^{116,117} The other defects of TCR signaling have an overlapping phenotype. Ultimately, biochemical and molecular tests are needed to define the diagnosis.

Treatment

The only curative treatment of this group of disorders is allogeneic HSCT. Treatment with rapamycin (an mTOR inhibitor) or phosphoinositide

3-kinase inhibitor may reduce lymphoproliferation and hepatosplenomegaly in patients with activating *PI3KD* mutations.^{29,30}

T-CELL IMMUNODEFICIENCIES WITH IMPAIRED NUCLEAR FACTOR- κ B ACTIVATION

Following TCR signaling, the complex composed of MALT1, BCL-10, and caspase recruitment domain-containing protein (CARD)-11 proteins is activated, resulting in recruitment of TRIF-related adaptor molecule (TRAF) 6 and activation of IKK, permitting nuclear translocation of the p50 and p65 subunits of NF- κ B and consequently induction of activation of NF- κ B-dependent genes. Mutations of *MALT1*,¹¹⁸ *CARD11*,^{119,120} and *IKBKB*¹²¹ (encoding for the IKK β component of the IKK complex) genes are associated with increased susceptibility to bacterial, viral and fungal infections. Although the number of circulating T lymphocytes is normal, generation of memory T cells is impaired and proliferative responses to CD3 stimulation are decreased. Patients with *CARD11* mutations have a block in B-cell development at the transitional stage,^{119,120} and virtual absence of class-switched memory B cells is observed in patients with *IKBKB* mutations.¹²¹

As reported above, mutations of the *IKBKG/NEMO* gene are responsible for X-linked immunodeficiency with ectodermal dysplasia, whose clinical manifestations may also include opportunistic infections, resembling CID. Finally, gain-of-functions mutations of the *IKBA* gene, that prevent phosphorylation and degradation of the IKB- α subunit of the IKB complex, cause T-cell immunodeficiency with ectodermal dysplasia. The immunologic phenotype includes deficiency of memory T cells, impaired *in vitro* proliferation of naïve T cells to TCR/CD3 stimulation, and hypogammaglobulinemia with inability to mount specific antibody responses.¹²² In addition to TCR signaling, activation of toll-like receptor (TLR) and tumor necrosis factor (TNF) pathways can also be compromised, causing increased susceptibility to a broad range of pathogens (pyogenic bacteria, mycobacteria, *Candida*, other opportunistic pathogens).¹²³

CORONIN-1A DEFICIENCY

Coronin-1A is an actin regulator that is predominantly expressed in hematopoietic cells, plays a key role in regulating T-cell survival and migration. Mutations affecting both alleles of the *CORO1A* gene have been reported in patients with CID and an increased risk of severe varicella and EBV lymphoproliferative disease.^{124,125} The immunologic phenotype includes naïve T-cell lymphopenia with normal numbers of B and NK cells, oligoclonal T-cell repertoire and reduced number of circulating invariant NKT (iNKT) cells and mucosa-associated invariant T (MAIT) lymphocytes. Immunoglobulin serum levels are low, and antibody responses to antigens are absent. The disease can be treated by allogeneic HSCT.¹²⁴

CD27 DEFICIENCY

The CD27 costimulatory molecule regulates survival and activation of T, B, and NK cells. CD27 deficiency is a CID with risk of EBV lymphoproliferative disease. *In vitro* T-cell proliferation to mitogens and antigens is reduced.¹²⁶ Immunoglobulin serum levels may be initially high, but patients eventually become hypogammaglobulinemic.

CTPS1 DEFICIENCY

Cytidine 5-triphosphate synthase 1 (CTPS1) is involved in *de novo* synthesis of cytidine 5-triphosphate (CTP), a nucleotide required for DNA and RNA metabolism. Impaired *de novo* synthesis of CTP causes a proliferation defect in both T and B lymphocytes. *CTPS1* mutations

have been identified in several infants from Northwestern England. The disease is characterized by severe bacterial and viral infections since early in life, and an increased risk of EBV-driven non-Hodgkin lymphoma. There are no extra-immune manifestations. Variable degrees of lymphopenia (especially of CD4⁺ cells), increased proportion of effector memory T cells and reduced *in vitro* proliferation to mitogens and antigens have been reported. Immunoglobulin levels may be normal, but specific antibody titers are reduced, and there is a low number of memory B cells.¹²⁷

MAJOR HISTOCOMPATIBILITY COMPLEX CLASS I DEFICIENCY

Definition

MHC class I deficiency is characterized by reduced expression of MHC class I molecules at the cell surface. The disease is inherited as an autosomal recessive trait, and may be caused by defects in the *TAP1*,¹²⁸ *TAP2*,¹²⁹ or *Tapasin*¹³⁰ genes. These defects interfere with intracellular transport of peptide antigens and their loading onto MHC class I molecules, and cell-surface expression of the complex.

Clinical and Laboratory Features

MHC class I deficiency manifests with recurrent respiratory infections in childhood, and chronic inflammatory lung disease and skin lesions, mimicking Wegener granulomatosis in patients with transporter-associated with antigen-processing (TAP)-1 and TAP-2 deficiencies.^{131,132} Chronic lung disease is a prominent cause of death. Glomerulonephritis and herpes zoster infections have been reported in Tapasin deficiency.¹³⁰

The number of circulating CD8⁺ T cells is reduced, because positive selection of CD8⁺ lymphocytes in the thymus depends on the recognition of MHC class I molecules. *In vitro* T-cell function is normal, which facilitates differential diagnosis with ZAP-70 deficiency in patients who have significantly reduced CD8⁺ cells. The NK cytolytic activity is usually significantly reduced (see Table 80–2). Serum immunoglobulin levels are variable.

Treatment

Prophylactic measures, similar to those used in cystic fibrosis, may be beneficial. Treatment of the granulomatous lesions is based on use of topical antiseptics; immunosuppressive drugs may worsen symptoms and should be avoided.

MAJOR HISTOCOMPATIBILITY COMPLEX CLASS II DEFICIENCY

Definition

MHC class II deficiency is defined by the lack of MHC class II expression and autosomal recessive inheritance. There is a higher prevalence in populations of North African origin. MHC class II deficiency is caused by mutations of transcription factors that bind to the proximal promoters of the MHC class II gene. Four different gene defects are known and include mutations of the *CIITA*, *RFXANK*, *RFX5*, and *RFXAP* genes.¹³³

Clinical and Laboratory Features

Typically, patients present early in life with increased susceptibility to bacterial, viral, and opportunistic infections. Severe lung infections, chronic diarrhea, and sclerosing cholangitis, often secondary to *Cryptosporidium* or CMV infection, are frequently observed. Less-severe presentations and survival into adulthood have been reported.¹³³

The number of circulating CD4⁺ T cells is markedly reduced, reflecting an impairment of positive selection in the thymus.

Delayed-type hypersensitivity responses are absent, but *in vitro* proliferative responses to mitogens are preserved. Hypogammaglobulinemia is common and poor antibody response to immunization antigens is consistently observed (see Table 80–2).¹³³ The diagnosis is based on demonstrating lack of MHC class II expression on monocytes, B lymphocytes and *in vitro* activated T cells. Differential diagnoses include HIV infection and idiopathic CD4 lymphopenia; however, in these conditions expression of MHC class II molecules is preserved.

Treatment and Course

MHC class II deficiency has a poor prognosis. If untreated, most patients die in infancy or childhood. Respiratory infections are the predominant cause of death. Liver failure is observed in patients who develop sclerosing cholangitis. Antibiotic prophylaxis and immunoglobulin replacement therapy, with adequate nutritional support, are required. HSCT is the only curative approach, but survival rate is lower than in other forms of CID and graft-versus-host disease is common, especially in patients with preexisting viral infections.¹³³

DEFECTS OF STORE-OPERATED CA²⁺ ENTRY

Calcium mobilization is a key event in the activation process of lymphocytes and nonimmune cells. Two molecules, calcium release-activated calcium channel protein 1 (ORAI1) and stromal interaction molecule 1 (STIM1), mediate the function of Ca²⁺ entry channels. ORAI1 is a ubiquitously expressed protein that constitutes the pore-forming subunits of the Ca²⁺ release-activated channels located in the cell membrane. STIM1 senses the Ca²⁺ concentration in the endoplasmic reticulum and activates Ca²⁺ release-activated channels. Mutations of both the *ORAI1* and *STIM1* genes in humans result in an autosomal recessive immunodeficiency with increased susceptibility to severe infections, especially from herpesviruses infections, associated with nonprogressive myopathy and ectodermal dysplasia. Manifestations of immune dysregulation (autoimmune cytopenias, hepatosplenomegaly) are common, especially in STIM1 deficiency.^{134,135} Although T-cell development is unaffected, *in vitro* proliferation of circulating T cells to mitogens and to a combination of phorbol ester and ionomycin is drastically reduced, and the Ca²⁺ influx following T-cell activation is absent. Lack of natural killer T (NKT) cells and functional defects of NK lymphocytes have been reported. In spite of hypergammaglobulinemia, specific antibody responses are typically absent. Allogeneic HSCT has been used in some patients to correct the defect.¹³⁵

DEFECTS OF MAGNESIUM TRANSPORTER 1

Mg²⁺ is an important second messenger in the immune system. Mutations of the X-linked magnesium transporter 1 (*MAGT1*) gene, that encodes for a protein that permits transport of Mg²⁺ across the cell membrane, cause immunodeficiency with increased susceptibility to bacterial and viral infections, and a high risk of EBV-driven lymphoproliferative disease.¹³⁶ Patients have CD4 lymphopenia, defective lymphocyte proliferation *in vitro* and impaired NK cytolytic function.¹³⁷

DEDICATOR OF CYTOKINESIS 8 DEFICIENCY

Dedicator of cytokinesis 8 (DOCK8) is an atypical guanosine triphosphatase (GTPase) that regulates cytoskeleton reorganization and intracellular signaling. Although it is broadly expressed, it plays a critical role in T, B, and NK lymphocytes. DOCK8 deficiency is inherited as an autosomal recessive trait, and is characterized by recurrent and severe bacterial, fungal, and viral infections, eczema and other manifestations of immune dysregulation, including autoimmune cytopenias. Cutaneous

viral infections (warts, molluscum contagiosum, herpes simplex) are especially common, but systemic viral disease (varicella, CMV, EBV) has been also reported. Cutaneous infections frequently evolve into squamous cell carcinoma. Vascular thrombosis in the central nervous system has been described in several patients.^{138,139} Multiple immunologic abnormalities have been reported,¹³⁸⁻¹⁴² including a variable degree of lymphopenia that affects especially naïve T cells, increased proportion of CD8⁺ T_{EMRA} cells, decreased *in vitro* proliferation to CD3 stimulation, impaired generation of Th17 cells, and defects of NK cytolytic function. Immunoglobulin levels are variable, but IgM serum levels are often low. B-cell response to TLR9 stimulation is defective, and specific antibody responses are blunted. Large, intragenic deletion of the gene has been frequently reported in affected patients,¹³⁹ and lack of DOCK8 protein expression can be demonstrated by flow cytometry.¹⁴³ The disease has a poor prognosis, but can be cured by allogeneic HSCT.¹⁴⁴ Good results have been reported in the treatment of severe herpetic infections with interferon (IFN)- α (see also “The Hyperimmunoglobulin E Syndromes” below).¹⁴⁵

COMBINED IMMUNODEFICIENCY WITH MULTIPLE INTESTINAL ATRESIA

Multiple intestinal atresia is a congenital disease characterized by atresias that may affect the gastrointestinal tract, from stomach to anus.¹⁴⁶⁻¹⁴⁹ In many cases, CID is associated, with reduced number of T (and in some patients, B) lymphocytes, impaired *in vitro* proliferation to mitogens, and profound hypogammaglobulinemia. A high risk of sepsis because of Gram-negative bacteria has been reported, but viral, fungal, and opportunistic infections are also common. The disease is inherited as an autosomal recessive trait and is caused by mutations of the tetratricopeptide repeat domain 7A (*TTC7A*) gene,^{146,147} which plays an important role in intestinal and immune homeostasis by maintaining cell polarity and regulation of cell survival, proliferation, adhesion, and migration.^{148,149} In the thymus, *TTC7A* is expressed both by thymic epithelial cells and by thymocytes.^{147,148} Multiple surgeries are often required to establish canalization of the gastrointestinal tract. Total parenteral nutrition often leads to severe liver disease, and combined small bowel and liver transplantation may be needed.¹⁵⁰ Most patients die early in life. Partial immune reconstitution has been reported in a few cases following HSCT.¹⁴⁷

VENOOCCLUSIVE DISEASE WITH IMMUNODEFICIENCY

Venoocclusive disease with immunodeficiency (VODI) is a congenital disorder characterized by liver abnormalities and immunodeficiency, with onset in the first months of life.¹⁵¹ Liver abnormalities include venoocclusive disease, fibrosis, hepatomegaly, and hepatic failure. Patients are prone to recurrent infections, sustained by viruses, bacteria, and opportunistic pathogens (*P. jirovecii*, *Candida*, CMV). Thrombocytopenia is frequent. Infections may precede development of liver abnormalities. Immunologic defects include low number of memory T and B lymphocytes, defective B-cell differentiation *in vitro* into antibody-secreting cells, and hypogammaglobulinemia.¹⁵¹ The disease is more common in the Lebanese population. It is inherited as an autosomal recessive trait and is caused by mutations of the *SP110* gene,¹⁵² which encodes for a nuclear body protein that acts as a transcription factor driving expression of genes with a retinoic acid response element. Treatment is based on immunoglobulin replacement therapy, prophylactic antibiotics, prompt treatment of infections, and ursodiol; however, the prognosis remains dismal. HSCT is the only curative approach, but the outcome is often problematic because of liver toxicity as a result of conditioning regimen.¹⁵³

DEFECTIVE THYMIC DEVELOPMENT

DIGEORGE SYNDROME (22q 11.2 DELETION SYNDROME)

Definition

The DiGeorge syndrome (DGS) is a developmental disorder caused by abnormal cephalic neural crest cell migration and differentiation in the third and fourth pharyngeal arches during early embryonic development.¹⁵⁴ The vast majority of patients with DGS have partial monosomy of human chromosome 22q11.2. However, a significant fraction (10 to 45 percent) of patients with DGS do not have a chromosome 22q11.2 deletion and some 2 percent have small deletions in chromosome 10p.

Clinical and Laboratory Features

The clinical phenotype of DGS consists of the triad congenital cardiac defects, hypocalcemia as a result of parathyroid insufficiency, and immune deficiency as a consequence of aplasia or hypoplasia of the thymus.¹⁵⁴ However, there is significant phenotypic variability. Cardiac defects (especially interrupted aortic arch type B and truncus arteriosus) occur in 50 to 80 percent of patients with 22q11.2 deletion. Hypocalcemia is observed in 50 to 60 percent, and may cause neonatal seizures. Facial dysmorphisms include micrognathia, hypertelorism, antimongoloid slant of the eyes, and ear malformations. A third of DGS patients have velopharyngeal incompetence, leading to feeding difficulties and speech delay; 10 percent have a cleft palate. As young adults, many develop social, behavioral, and psychiatric problems.

There is also significant variability of the severity of immunologic phenotype. Most patients have residual thymic tissue and hence mild to moderate T-cell lymphopenia (see Table 80-2). Approximately 1 percent of DGS patients lack T cells completely, resembling SCID (complete DGS). In some cases, generation of oligoclonal T cells that infiltrate target tissues is associated with generalized skin rash and lymphadenopathy, resembling Omenn syndrome. This phenotype is known as atypical complete DGS.¹⁵⁵ As in other cellular immunodeficiencies, patients with DGS have a high incidence of autoimmune diseases such as cytopenia and thyroiditis. A retrospective analysis of TCR excision circle (TREC) levels at birth in patients with DGS has shown that approximately 20 percent of them had low TRECs; these infants had lower CD8⁺ T-cell count and were more prone to viral infections than DGS infants with normal TREC levels at birth.¹⁵⁶

Treatment

Cardiovascular anomalies require prompt attention and hypocalcemia appropriate medical treatment. Depending on the extent of the immune deficiency, patients may require antibiotic prophylaxis or IVIG therapy. However, patients with complete DGS (including complete atypical phenotype) require more aggressive treatment. Allogeneic thymic transplantation may restore T-cell development and function in approximately 75 percent of these patients.¹⁵⁵ Unmanipulated marrow from matched donors can also lead to immune reconstitution by providing mature T lymphocytes contained in the graft.¹⁵⁷

COLOBOMA, HEART DEFECTS, ATRESIA OF THE CHOANAE, RETARDED GROWTH, GENITAL HYPOPLASIA AND EAR ANOMALIES SYNDROME

A syndrome with a severe T-cell defect, CHARGE is caused by heterozygous *de novo* mutations in the *CHD7* gene.¹⁵⁸ Circulating T lymphocytes are decreased in most CHARGE patients and respond poorly to mitogens.

CONGENITAL ALOPECIA AND ABSENCE OF THYMUS

Mutations of the *FOXP1* gene, encoding for a transcription factor that plays a critical role in development of thymic epithelial cells, causes thymic aplasia, associated with congenital alopecia, nail dystrophy, and a severe neural tube defect.¹⁵⁹ This phenotype is the equivalent of the mouse nude/SCID phenotype. Successful outcome has been reported after thymic transplantation.¹⁶⁰

PRIMARY IMMUNODEFICIENCY DISORDERS PRESENTING AS AUTOIMMUNE DISEASES

The concept of a link between immune dysregulation and autoimmunity has been strengthened by the discovery of distinct single-gene defects resulting in unusual susceptibility to autoimmune diseases. The three representative syndromes in this category include (1) IPEX, (2) autoimmune polyendocrinopathy, candidiasis, and ectodermal dystrophy (APECED), and (3) the autoimmune lymphoproliferative syndrome (ALPS).

IMMUNE DYSREGULATION, POLYENDOCRINOPATHY, ENTEROPATHY, X-LINKED SYNDROME

Clinical Findings

The most prominent IPEX symptoms include early onset diarrhea secondary to autoimmune enteropathy, eczematous dermatitis, multiple endocrinopathies including early onset insulin-dependent type 1 diabetes mellitus, thyroiditis, and, rarely, adrenal insufficiency. Autoimmune hemolytic anemia, thrombocytopenia, and neutropenia are common complications. Eczema is the most frequent pathology of the skin, but erythematous, psoriasiform dermatitis, and *alopecia universalis* have been reported. Autoimmune hepatitis is present in 20 percent of IPEX patients. Lymphadenopathy and hepatosplenomegaly are less common.¹⁰⁸ Loss of small bowel villi and lymphocytic infiltrates in the intestinal mucosa, the pancreas, thyroid, lung, and liver are commonly observed. Immunologic abnormalities include elevated serum IgA and IgE concentrations and the absence of CD4⁺CD25⁺ FOXP3⁺ regulatory T cells.

IPEX is caused by mutations in the *FOXP3* gene located in the centromeric region of the X chromosome.¹⁶¹ The transcription factor FOXP3 binds to more than 700 promoters and acts as a transcriptional repressor of the IL-2, IL-4, and IFN- γ promoters by interfering with the cytokine regulator, NFAT (nuclear factor of activated T cells).¹⁶² FOXP3 plays a crucial role in the generation of T-regulatory cells (Tregs) in the thymus.

Treatment

Immunosuppressive drugs such as cyclosporine, tacrolimus, sirolimus, and glucocorticoids provide temporary remission. Allogeneic HSCT can cure this disease.¹⁶³

IMMUNE DYSREGULATION, POLYENDOCRINOPATHY, ENTEROPATHY, X-LINKED-LIKE SYNDROMES

An IPEX-like phenotype has been associated with mutations in a number of genes, including *CD25*, *STAT5B*, *STAT1* (gain-of-function mutations) *STAT3* (gain-of-function) and *ITCH/AIP4*.

Cd25 Deficiency

CD25 (IL-2 receptor α chain) was found to be deficient in three infants from two unrelated families. Clinical features resemble those of both IPEX and SCID. CD25-deficient infants presented with severe chronic diarrhea, villous atrophy and autoimmune hepatitis at an early age.^{164,165} Early onset insulin-dependent diabetes was observed in one patient; all presented with eczema and developed autoantibodies, hepatosplenomegaly, lymphadenopathy, and lymphocytic infiltrates in the lung, gut, and liver.¹⁶⁵ However, CD25-deficient patients suffered from infectious complications more commonly observed in patients with SCID, including recurrent CMV pneumonitis, persistent thrush, and EBV infection. One patient was treated successfully with HSCT.¹⁶⁴

STAT5B Deficiency

The transcription factor STAT5B is activated/phosphorylated in response to growth hormone and the cytokines IL-2, IL-7, IL-15 and IFN- γ , and promotes the transcription of nonimmune and immune genes. STAT5B plays a crucial role in the transcription of insulin-like growth factor 1 (IGF-1), which is required for *in utero* and postnatal growth. In addition, STAT5B is required for the transcription of IL-2R α , a crucial component of the IL-2 receptor necessary for induction of FOXP3, which programs the development of Tregs in the thymus. The clinical phenotype of homozygous STAT5B deficiency reflects these molecular observations. Affected patients suffer from intrauterine and postnatal growth failure from lack of IGF-1 resulting in growth hormone insensitivity.¹⁶⁶ Moderate T and NK cell lymphopenia may be the cause of susceptibility to viral infections.¹⁶⁷ Importantly, STAT5B-deficient patients have reduced numbers of Tregs with low FOXP3 expression, and decreased suppressor function.¹⁶⁸ As a result of abnormal Treg homeostasis, STAT5B-deficient patients have immune dysfunction and multiple autoimmune problems, including arthritis, lymphocytic interstitial pneumonia, severe eczema, autoimmune thyroiditis, and idiopathic thrombocytopenic purpura.¹⁶⁹

STAT1 Gain-of-Function Mutations

Heterozygous mutations in STAT1 were recently identified in patients with chronic mucocutaneous candidiasis.¹⁷⁰ These mutations were within the coiled-coil and DNA-binding domains, leading to hyperphosphorylation of STAT1 in response to cytokines such as IFN- γ . Screening of a cohort of patients with IPEX-like symptoms who also had mucocutaneous fungal infections revealed heterozygous STAT1 gain of function mutations. The clinical characteristics included enteropathy with villous atrophy, type I diabetes, thyroiditis, eczema, short stature, vascular aneurysms and viral infections. FOXP3⁺ Treg numbers were within the normal range, and showed normal suppressive function.¹⁷¹ It has been hypothesized that effector cells may be less responsive to suppression as a result of excessive STAT1 activity.

STAT3 Gain-of-Function Mutations

A Finnish-British consortium discovered heterozygous gain-of-function mutations in several patients with short stature, polyendocrinopathy including type 1 diabetes starting at a very young age (*in utero* or before 3 weeks of age). The clinical phenotype included the presence of multiple autoantibodies, celiac disease or autoimmune enteropathy, eczema, thyroiditis, arthritis, autoimmune cytopenias and large granular lymphocytic (LGL) leukemia in one in five patients.¹⁷² Except for eczema, none of the patients with STAT3 gain-of-function mutations had the clinical features of autosomal dominant (AD) hyperimmunoglobulin E syndrome (HIES) as a result of heterozygous dominant negative STAT3 mutations, although the mutations, all missense, were located in the same domains (DNA binding, SH3 [Src homology 3], and transactivation) as those observed in AD-HIES. When studied for STAT3 activity

using a luciferase reporter assay gain-of-function mutations showed an increase, whereas those with heterozygous loss of function mutations causing AD-HIES had decreased activity.

Cytotoxic T-Lymphocyte Antigen-4 Haploinsufficiency

Cytotoxic T-lymphocyte antigen-4 (CTLA-4) is an inhibitory receptor expressed by T lymphocytes including Tregs, and by B cells. While CD28 transmits a stimulatory signal to lymphocytes, CTLA-4 provides an inhibitory signal.¹⁷³ CTLA-4 can also affect signaling in B cells by competing with CD28 for CD80/86 binding.

In a recent report, heterozygous mutations in the *CTLA4* gene were observed in members of four unrelated families suffering from multiple autoimmune diseases, recurrent infections, and lymphocytic infiltrates in a number of target organs.¹⁷⁴ Affected patients developed hypogammaglobulinemia, CD4 lymphopenia, progressive loss of circulating B cells and defective/dysregulated Treg cells. Reduced CTLA-4 expression in T cells, B cells, and Tregs, and increased T- and B-cell apoptosis are characteristic findings and may contribute to the clinical phenotype.

ITCH E3 Ubiquitin Protein Ligase Deficiency

The clinical features of ITCH E3 ubiquitin protein ligase (ITCH) deficiency caused by mutations in E3 ubiquitin ligase (*ITCH/AIP4*) include dysmorphic facial features, failure to thrive and developmental delay. In addition, immune dysregulation that is characterized by chronic interstitial pneumonitis, thyroiditis, type I diabetes, enteropathy, and hepatitis were common.¹⁷⁵ This is a rare syndrome observed in a single large Amish kindred with 10 affected family members. ITCH can affect T-cell energy in mice because of defective FOXP3 expression.¹⁷⁶

AUTOIMMUNE POLYENDOCRINOPATHY, CANDIDIASIS, AND ECTODERMAL DYSTROPHY SYNDROME

APECED is a rare autosomal recessive disorder, also known as autoimmune polyglandular syndrome (APS) type I. The incidence is high in certain isolated populations, for example, Finns, Iranian Jews, and Sardinians. Most patients with APECED present with chronic mucocutaneous candidiasis and endocrinopathies predominantly involving the parathyroid and adrenal glands, less frequently the thyroid and the pancreas. The syndrome is often associated with ectodermal manifestations such as dystrophic dental enamel and fingernails.¹⁷⁷ APECED results from mutations in the *AIRE* gene. *AIRE* expression is limited to medullary thymic epithelial cells which express MHC class II and the costimulatory molecule CD80. These cells are endowed with the remarkable ability to “promiscuously” express a wide variety of tissue-restricted antigens derived from nearly all organs in the body.¹⁷⁸ Expression of these organ specific proteins allows for the negative selection of autoreactive T cells or the generation of immunoregulatory FOXP3⁺ T cells in the thymus. A lack of *AIRE* function causes decreased expression of tissue-restricted antigens in the thymus, resulting in the escape of autoreactive T-cell clones into the periphery.¹⁷⁹ Autoantibodies against type I interferons,¹⁸⁰ and against IL-17A, IL-17F and/or IL-22,¹⁸¹ were detected at high titers in most patients. Treatment for APECED is largely supportive.

AUTOIMMUNE LYMPHOPROLIFERATIVE SYNDROME

Definition, Clinical Features, and Pathogenesis

ALPS is caused by defective apoptosis of lymphocytes, resulting in nonmalignant lymphadenopathy, hepatosplenomegaly, and autoimmune disorders, which most commonly include Coombs-positive

autoimmune hemolytic anemia, thrombocytopenia, and neutropenia. The incidence of lymphoma is estimated to be 9 percent in the National Institutes of Health cohort of 79 probands¹⁸² and consist of both Hodgkin and non-Hodgkin lymphoma. Both lymph nodes and spleen show pronounced hyperplasia and contain a CD3⁺ lymphocyte population of which a large proportion consists of TCRαβ⁺ CD4⁺CD8⁻ cells. This phenomenon is also observed in blood lymphocytes from ALPS patients in which the proportion of double-negative T cells is typically between 5 and 20 percent (range: 1.5 to 68 percent).¹⁸² Many of these cells express MHC class II and secrete high levels of IL-4, IL-5, and IL-10.

The FAS-mediated apoptosis pathway is important for the down-regulation of antigen-induced immune responses and the elimination of autoreactive lymphocytes. ALPS patients have mutations in genes required for “programmed cell death.” The most common defect involves heterozygous (dominant) mutations in the gene encoding the T-cell surface molecule FAS, also known as CD95 or TNFRSF6 (ALPS-FAS, formerly ALPS type Ia); rare patients with compound heterozygous or homozygous FAS-mutations (ALPS-FAS or type 0) have been reported. In some patients, somatic mutations of FAS have been identified in double-negative T cells (ALPS-sFAS or type 1m). A few families have been identified with mutations affecting the FAS ligand (CD95L; TNFSF6) which is responsible for ALPS-FASL or ALPS type Ib. Approximately 3 percent of ALPS patients have mutations in caspase 10 (ALPS-CASP10 or ALPS type II). Ten to 20 percent of patients with the ALPS phenotype do not have mutations in FAS, FASL, or caspases and are classified as ALPS-U or ALPS type III.¹⁸² Because three Fas molecules form a trimeric complex to interact with a FasL trimer, most families with ALPS have AD inheritance (dominant negative effect) with variable penetrance (mutations in caspase 8 and 10 are autosomal recessive).

Treatment

Immunosuppressive therapy including steroids, mycophenolate mofetil (MMF), and rituximab, has been used with variable success to treat autoimmune symptoms.¹⁸² A recent clinical trial with sirolimus achieved complete or near complete resolution of autoimmune cytopenia, colitis, lymphadenopathy, and splenomegaly and all patients had a reduction in double-negative T cells.¹⁸³ Splenectomy is recommended only in patients with excessively large spleens or splenic rupture and requires lifetime antibiotic prophylaxis. The long-term prognosis is guarded, but patients can achieve a normal life span.

OTHER WELL-DEFINED IMMUNODEFICIENCY SYNDROMES

WISKOTT-ALDRICH SYNDROME

Definition

The Wiskott-Aldrich syndrome (WAS) is a rare X-linked disorder characterized by thrombocytopenia (Chap. 117) and small platelets, eczema, recurrent infections, immunodeficiency, and a high incidence of autoimmune diseases and malignancies.¹⁸⁴ A classic WAS phenotype is generally associated with null-mutations of the gene that encode the WAS protein (WASp). WASp is the key regulator of actin polymerization in hematopoietic cells and has well-defined domains that are involved in cytoplasmic signaling, cell locomotion, and immunologic synapse formation. A milder phenotype, X-linked thrombocytopenia (XLT), is often associated with mutations that result in expression of mutated protein. XLT patients have either no or very mild eczema and few problems, if any, with infections, autoimmunity, and malignancy.¹⁸⁵ Amino acid substitutions within the GTPase-binding domain of WASp interfere with the intramolecular autoinhibitory mechanism, resulting

in gain-of-function–impaired actin polymerization, causing X-linked neutropenia (Chap. 65).¹⁸⁶

Clinical and Laboratory Features

By definition, WAS and XLT patients have congenital thrombocytopenia in the range of 20,000 to 60,000/ μ L and microplatelets, but normal numbers of megakaryocytes. Hemorrhagic problems may be mild, consisting of bruises and petechiae, or serious, including gastrointestinal and central nervous system hemorrhages. Patients with classic WAS are susceptible to bacterial, fungal, and viral infections.

Treatment

Patients may require antibiotic prophylaxis and IVIG replacement therapy. Immunosuppressive therapy may be needed if autoimmune symptoms occur. Splenectomy ameliorates the bleeding tendency by increasing the number of blood platelets. However, splenectomy substantially increases the risk of septicemia, sometimes in spite of antibiotic prophylaxis, and often results in fatal bacterial infections. Because of the poor long-term outcome of WAS, early allogeneic HSCT is the treatment of choice. The outcome is excellent if a matched-related or matched-unrelated donor can be identified, or if a partially matched cord blood unit is available.¹⁸⁷ Haploidentical transplantation is not recommended. Patients with XLT have an excellent prognosis, but may develop complications including serious bleeding, autoimmune diseases, and malignancies.^{144,185} Therefore, allogeneic HSCT for XLT may be considered if an appropriate donor is available. Because complete myeloid and lymphoid engraftment is required to correct all aspects of WAS/XLT, standard-conditioning using myeloablative protocols (busulfan, cyclophosphamide, with or without antithymocyte globulin) are required. A European followup study of WAS patients who received HSCT reports a strong association of autoimmunity with mixed chimerism, clearly demonstrating that reduced intensity conditioning is not sufficient.¹⁸⁸

WASp-INTERACTING PROTEIN DEFICIENCY

A syndrome exhibiting symptoms and laboratory abnormalities typical for classic WAS has been observed in a female infant with a homozygous nonsense mutation in *WIPF1* that encodes WASp-interacting protein (WIP). The patient presented at 11 days of age with eczema, thrombocytopenia (but normal platelet size) and infections.¹⁸⁹ Both WIP and WASp were absent in patient leukocytes, demonstrating that WIP is required for stabilization of WASp. The patient was successfully transplanted at age 4.5 months.

THE HYPERIMMUNOGLOBULIN E SYNDROMES

Autosomal Dominant Hyperimmunoglobulin E Syndrome

HIES (or Job syndrome) is a rare AD or sporadic multisystem immunodeficiency characterized by eczema, *S. aureus*-induced skin abscesses, recurrent pneumonia with abscess and pneumatocele formation, *Candida* infections, and skeletal and connective tissue abnormalities.¹⁹⁰ In 1966, two girls suffering from eczema, recurrent respiratory tract infections, and “cold” staphylococcus skin abscesses were described as having Job syndrome because of the phenotypic similarity to the biblical figure Job, who had been “smitten with sore boils from the soles of his feet unto his crown.”¹⁹¹ Subsequently, patients with similar clinical findings were reported to have very-high serum IgE concentrations¹⁹² and additional characteristic abnormalities were recognized, including distinct facial features, often described as “coarse,” hyperextensive joints, pathologic bone fractures, scoliosis, craniosynostosis, and retained primary teeth.^{193,194} Serum IgE levels of greater than 2000 IU/mL have been used as arbitrary diagnostic values, but often are greater than 10,000 IU/mL.

Other abnormal laboratory tests include eosinophilia, abnormal B-cell maturation and defective antibody responses to neoantigens,¹⁹⁵ chemotactic defects of neutrophils, and reduced lymphocyte proliferation to specific antigens.

Most patients with HIES were noted to arise sporadically from unaffected, healthy parents. With the advent of improved antibiotic therapy, patients survived into adulthood and had affected children, suggesting AD inheritance.¹⁹³ This observation was validated by the finding that heterozygous mutations of the gene encoding the transcription factor STAT3 are the cause of AD-HIES. All STAT3 mutations identified to date in patients with AD-HIES are either amino acid substitutions or in-frame deletions strongly supporting the concept that coexpression of wild-type and mutant STAT3 protein is required to cause the syndrome. The notable lack of nonsense or frameshift mutations strengthens the notion that AD-HIES is a result of a dominant-negative effect.^{196–198} The molecular analysis of a large cohort of patients (n = 38) with “classic” HIES and a score of greater than 40 points using the National Institutes of Health clinical scoring system, identified STAT3 mutations in all but one individual. The mutations clustered in three domains of the STAT3 protein known to have distinct functional characteristics, the DNA-binding, and the SH2 and the transactivation domains. This finding suggests that more than one molecular mechanism causes the AD-HIES phenotype. This notion is supported by the observation that mutations in the SH2 domain, but not those in the DNA-binding domain, affect tyrosine phosphorylation of STAT3, whereas mutations in the DNA-binding domain interfere with nuclear import and DNA-binding.¹⁹⁸ Because STAT3 plays a key role in the development of IL-17 producing Th17 cells, AD-HIES patients have a marked decrease in circulating Th17 cells.¹⁹⁹ Given that IL-17 plays an important role in host defense against extracellular bacteria and fungi and upregulates production of β defensins and S100 proteins by neutrophils,²⁰⁰ the absence of Th17 cells may directly affect susceptibility to *S. aureus* and *Candida albicans*.

Treatment

To prevent progressive lung destruction, prophylactic antibiotic therapy to decrease the frequency of *S. aureus* infections is important. Anti-fungal therapy is indicated to prevent recurrent *Candida* infections. A surgical approach to treating chronic lung disease should be avoided, if possible. Allogeneic HSCT has been performed in a few patients with variable benefits.^{201,202}

Autosomal Recessive Hyperimmunoglobulin E Syndromes

In 2004, a cohort of 13 patients from consanguineous families were reported to have marked eosinophilia, elevated serum IgE levels, eczema, skin abscesses, recurrent bacterial, fungal, and viral infections including herpes simplex, therapy-resistant molluscum contagiosum, and recurrent varicella zoster. Lymphopenia and decreased lymphocyte proliferation suggested a significant T-cell defect. In contrast to HIES caused by STAT3 mutations, autosomal recessive hyper-IgE syndrome (AR-HIES) patients frequently present with neurologic complications but do not develop skeletal abnormalities or postpneumonia pneumatoceles. Most have large deletions in the *DOCK8* gene, resulting in absent DOCK8 protein.^{138,139} (See DOCK8 deficiency in “Other Combined Immunodeficiencies” above.) Because of a high incidence of malignancies and early death, HSCT is recommended.²⁰³ A single adult patient with eczema; moderately elevated serum IgE; a history of bacterial (BCG complications, salmonellosis), fungal, and viral infections, including molluscum contagiosum; and a mild T-cell deficiency was found to have a mutation in tyrosine kinase 2 (TYK2), a receptor-associated cytoplasmic tyrosine kinase that plays an important role in multiple cytokine signaling of T cells.²⁰⁴

IMMUNOOSSEOUS DYSPLASIAS

Cartilage Hair Hypoplasia

Cartilage hair hypoplasia is an autosomal recessive condition characterized by short-limbed dwarfism and light-colored, hypoplastic hair.²⁰⁵ Patients may also present with marrow cell dysplasia, increased susceptibility to malignancies, Hirschsprung disease, defects of spermatogenesis, and a variable degree of immune deficiency (resembling SCID, Omenn syndrome, partial T-cell deficiency) or may have normal immune function.²⁰⁶ The rare disorder is more common in certain populations, such as the Amish and Finns, and is caused by mutations in the gene encoding for untranslated RNA component of the ribonuclease mitochondrial RNA processing (*RMRP*) complex, which is involved in cleavage of ribosomal RNA, processing of mitochondrial RNA, and cell-cycle control.²⁰⁷ Decreased numbers of T lymphocytes, especially of CD8+ cells, and impaired *in vitro* proliferative responses to mitogens have been reported and may be from reduced thymic output, cell-cycle abnormalities, and increased apoptosis.^{208,209} Impairment of cellular immunity may cause increased susceptibility to severe varicella or other viral diseases, and administration of live-attenuated viral vaccines should be avoided. Defects of humoral immunity are less frequent, and may contribute to recurrent infections. Autoimmune manifestations (hemolytic anemia, neutropenia, and thrombocytopenia) may also occur. Similar to what has been observed in other disorders of ribosomal biogenesis (Diamond-Blackfan anemia, Shwachman-Diamond syndrome), disturbances of hematopoiesis, such as anemia, leukopenia, thrombocytopenia, and marrow dysplasia, are frequent manifestations of cartilage hair hypoplasia. Allogeneic HSCT has been successfully used to correct those forms of cartilage hair hypoplasia presenting with a SCID or Omenn syndrome phenotype.²¹⁰

Schimke Syndrome

Schimke syndrome is an autosomal recessive condition characterized by dwarfism with short neck and trunk because of spondyloepiphyseal dysplasia, progressive renal impairment evolving to renal failure, facial dysmorphisms, lentigines, immunodeficiency (ranging from T-cell lymphopenia to SCID), and increased occurrence of marrow failure and of early onset arteriosclerosis associated with cerebral infarcts.²¹¹ Microcephaly and cognitive, motor, or social abnormalities have been reported in a significant proportion of the patients.²¹² The disease is caused by mutations of the switch/sucrose nonfermentable (SWI/SNF)-related matrix-associated actin-dependent regulator of chromatin subfamily A-like protein 1 (*SMARCA1*) gene that encodes for a chromatin remodeling protein.²¹¹ Recurrent infections of bacterial, viral, and fungal origin, and opportunistic infections (*P. jirovecii* pneumonia) are seen in half of the patients. Severe presentations lead to death in the first decade of life, and development of renal failure is common among those who survive. Combined HSCT and renal transplantation has been used to correct immune deficiency and renal problems.²¹³

WHIM SYNDROME

Warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) syndrome²¹⁴ is an AD disorder, caused by heterozygous mutations in the *CXCR4* gene that encodes for the receptor for the CXCL12 chemokine, involved in leukocyte trafficking.²¹⁵ The term *myelokathexis* indicates retention of mature neutrophils in the marrow. WHIM mutations result in truncation or structural abnormalities in the intracytoplasmic tail of CXCR4 that interfere with ligand-induced internalization and ultimately cause increased cellular responsiveness to CXCL12.²¹⁴

Patients with WHIM syndrome may present with early onset recurrent bacterial infections, but the clinical phenotype may vary greatly.²¹⁶ Warts, caused by human papillomavirus (HPV), tend to

develop in the second decade of life. Severe neutropenia contrasts with accumulation of mature neutrophils in the marrow. Spontaneous apoptosis of neutrophils has been reported.²¹⁷ Lymphopenia, including low B-cell numbers, is a frequent finding. Hypogammaglobulinemia of variable degree can be observed, and immunizations result in short-lived antibody responses and impaired class switch.²¹⁸ EBV-positive B-cell lymphoma can occur.

Immunoglobulin replacement therapy and antibiotic prophylaxis may reduce the incidence of infections. Recombinant G-CSF has been used to increase the absolute neutrophil count. Warts are resistant to local therapy and need to be monitored for neoplastic transformation.

● CHROMOSOMAL INSTABILITY SYNDROMES ASSOCIATED WITH IMMUNODEFICIENCY

Chromosomal instability syndromes have in common increased spontaneous or induced DNA breaks, susceptibility to infections secondary to immune deficiency, and an increased risk of malignancies. Disease-specific abnormalities involving growth and development, the central nervous system, and the skin provide useful diagnostic clues. The classic chromosomal instability syndromes include ataxia-telangiectasia (AT), Nijmegen breakage syndrome (NBS), Bloom syndrome (BS), and AT-like disorder (ATLD). The genes responsible for these syndromes protect human genome integrity by contributing to the complex task of double-strand break repair. Together with the proteins associated with Fanconi anemia, the gene products of the chromosomal instability syndromes form or regulate a large protein complex that is active in the surveillance and maintenance of genomic integrity.²¹⁹ The triad of immunodeficiency, neoplasia, and infertility is the direct consequence of defective double-strand break repair, and involves nonhomologous end-joining or homologous rejoining. Because nonhomologous end-joining is crucial for the generation of TCR diversity and polyclonal immunoglobulins, any interruption of this process will predictably result in defective adaptive immunity. Tumor development and infertility may be a direct consequence of defective DNA repair during mitotic recombination of lymphocytes, other somatic cells, or germ cells, respectively.

ATAXIA-TELANGIECTASIA

AT is a multisystem disorder, characterized by immunodeficiency, progressive neurologic impairment, and ocular and cutaneous telangiectasia.²²⁰

The immune deficiency in AT is highly variable, involving both cellular and humoral immunity. Respiratory infections are common and often result in chronic lung disease. Opportunistic infections are rare. The majority of AT patients have low or absent IgA and IgE, often combined with IgG₂ and IgG₄ deficiency.²²¹ Specific antibody responses may be depressed or normal. The number of circulating lymphocytes is often reduced, and proliferation in response to mitogens is variably depressed. Spontaneous cytogenetic abnormalities include chromosomal breaks, translocations, rearrangements, and inversions; these defects increase following *in vitro* exposure to radiation. The thymus is often small, showing marked paucity of thymocytes and absence of Hassall corpuscles. The most consistent laboratory abnormality, an elevation of serum α -fetoprotein, is diagnostic in adults and children older than age 8 months as it is not observed in the other chromosomal instability syndromes.

Cancer is the second most common cause of death, after infections.²²⁰ Most malignancies are non-Hodgkin lymphomas (40 percent),

leukemias (25 percent), and solid tumors (25 percent); 10 percent are Hodgkin lymphoma. In contrast to other immune deficiency syndromes with increased incidence of malignancies, the leukemias and lymphomas observed in AT are predominantly of T-cell origin. The solid tumors in AT patients include adenocarcinoma, dysgerminoma, gonadoblastoma, and medulloblastoma.

Cerebellar ataxia is the earliest clinical manifestation of AT and becomes evident when a child begins to walk at the end of the first year of life. The ataxic gait persists, and most patients never develop normal speech. Eventually, involuntary movements become a major handicap and the child may require a wheelchair by the end of the first decade of life. Cortical cerebellar degeneration involves primarily Purkinje and granular cells; progressive changes to the central nervous system also occur.

A variety of other features have been reported. Growth retardation is present in 30 percent of the patients. Female hypogonadism is common and associated with hypoplasia of the ovaries. Hypogonadism is also observed in male AT patients.

The AT gene (*AT mutated [ATM]*) encodes a large transcript that predicts a protein of 3056 amino acids.²²² ATM is a predominantly nuclear protein with a strong serine-threonine kinase activity. Its major function is to rapidly respond to the induction of double-stranded breaks in DNA. The activation of ATM leads to phosphorylation of an extensive array of target proteins, each of which plays a key role in a unique damage response pathway. Specifically, ATM is involved in cell-cycle checkpoint control and delays the passage of cells through the various phases of the cell cycle, allowing time for DNA damage repair. Additionally, ATM is functionally linked to telomere maintenance, a process crucial to aging and cancer.²²³ The more than 400 unique mutations of ATM described to date are distributed throughout the gene with a majority predicted to cause premature termination resulting in unstable truncated proteins.

AT patients should avoid X-radiation and chemotherapeutic agents. Treatment is symptomatic and includes prophylactic antibiotics for those with recurrent pulmonary infections and IVIG for those with antibody deficiency.

ATAXIA-TELANGIECTASIA-LIKE DISORDER

ATLD²²⁴ has many features of AT and is the result of mutations in the Mre11 protein, which is part of the DNA-repair complex (Mre11/Rad50/Nbs1).²²⁵ Affected patients have progressive ataxia, but show less-severe neurodegeneration and may be ambulatory until their early twenties. They do not develop telangiectasia and α -fetoprotein levels are normal. However, similar to AT, ATLD patients have increased spontaneous chromosomal abnormalities in blood lymphocytes and show increased radiation sensitivity.

NIJMEGEN BREAKAGE SYNDROME

NBS is characterized by short stature, microcephaly, a bird-like face, immunodeficiency, chromosomal instability, increased radiosensitivity, and a high incidence of malignancies.²²⁶ Although NBS shares many characteristics with AT and ATLD, it can be distinguished from these disorders by an absence of neurodegeneration, impressive microcephaly with mild to moderate mental retardation, and absence of telangiectasia.

Most NBS patients develop respiratory tract infections, including recurrent pneumonia that may result in bronchiectasis and premature death from respiratory failure. Both humoral and cellular immunity are defective and include hypogammaglobulinemia, except for normal or elevated IgM, abnormal antibody responses to protein and polysaccharide antigens, suggesting a defect in CSR, reduced numbers of T lymphocytes, and abnormal lymphoproliferation to mitogens and specific antigens.²²⁶

NBS lymphocytes show the typical features of chromosomal instability syndromes characterized by increased chromatid and chromosome breaks, rearrangement/translocations of chromosome 7 and 14, telomere fusions, radioresistant DNA synthesis, and hypersensitivity to ionizing radiation and radiomimetic agents.²²⁶

The extensive immunodeficiency and the chromosomal instability explain the high incidence of lymphoid malignancies, including non-Hodgkin lymphoma (both of B- and T-cell origin), lymphoblastic leukemia/lymphoma, and, less frequently, Hodgkin lymphoma and acute myeloblastic leukemia. Solid tumors are less frequent and include medulloblastoma and rhabdomyosarcoma. Because of hypersensitivity to radiation and radiomimetic/alkylating agents, tumor therapy is limited. Magnetic resonance imaging and ultrasound examinations are the preferred imaging techniques, rather than x-ray and CT scan. Prophylactic therapy with antibiotics and IVIG is indicated in patients with recurrent infections. Several patients have been successfully treated with allogeneic HSCT.²²⁷

BLOOM SYNDROME

BS is characterized by short stature, hypersensitivity to sunlight, increased susceptibility to infections, and a predisposition to early development of a variety of cancers.²¹⁹ Susceptibility to bacterial infections, affecting mainly the upper and lower respiratory tract, is associated with hypogammaglobulinemia and variable T-cell deficiency. Most affected patients have decreased fertility and some may develop early onset type II diabetes mellitus. By age 25 years, approximately half of the patients with BS will have developed one or more malignancies. Leukemia and non-Hodgkin lymphoma predominate during the first two decades; later, carcinoma affecting the colon, skin, and breast are common. The diagnosis of BS can be confirmed by demonstrating excessive numbers of sister-chromatid exchanges, increased chromatid gaps and breaks, and the presence of quadriradial configuration composed of two homologous chromosomes. The causative gene, *BLM*, encodes a 1417-amino-acid protein with homology to the RecQ family of helicases. This family of helicases includes the Werner syndrome, RecQ helicase-like (WRN) protein, which is mutated in Werner syndrome. *BLM* is a member of a group of proteins that associate with BRCA1 to form a large complex that co-localizes to large nuclear foci if cells are treated with agents that interfere with DNA synthesis. As part of this complex, *BLM* plays a role in sensing DNA damage and contributes to the maintenance and genomic integrity during the process of DNA replication and repair. More than 60 unique mutations in the *BLM* gene have been identified. The most common mutation is a 6-bp deletion/7-bp insertion in exon 10, which is the homozygous mutation causing BS in Ashkenazi Jews.

BS patients with significant antibody deficiency may benefit from antibiotic prophylaxis and IVIG therapy. Because of increased radiation sensitivity, exposure to any form of irradiation should be restricted.

RARE SYNDROMES WITH CHROMOSOMAL INSTABILITY

NBS-like phenotypes have been linked to mutations in *LIG4*, *RAD50*, and nonhomologous end-joining factor 1 (*NHEJ1*).²¹⁹ Other syndromes with chromosomal instability include Werner syndrome, Riddle syndrome and immunodeficiency with centromere instability and facial anomalies (ICF) syndrome.

● CYTOTOXICITY DISORDERS

Defense against viruses is primarily dependent on cell-mediated cytotoxicity. Cytotoxic T lymphocytes (CTLs) and NK cells are capable of killing virus-infected target cells using pore-forming perforin and

cytolytic granzymes A and B. Different genetic defects can affect various steps in the formation, intracellular transport, and delivery of cytolytic granules,^{228,229} and result in different defects of cell-mediated cytotoxicity, that include various forms of familial hemophagocytic lymphohistiocytosis (FHL), Chédiak-Higashi syndrome, Griscelli syndrome type II, and Hermansky-Pudlak syndrome type II. Overall, these disorders are characterized by increased susceptibility to severe viral infections that in some cases is associated with defects of hair and skin pigmentation, and neurologic problems. Dysregulation in CTL and NK homeostasis, with increased production of inflammatory cytokines and accumulation of activated lymphocytes, characterizes the two genetic variants of X-linked lymphoproliferative syndrome (XLP1 and XLP2).

FAMILIAL HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

FHL includes a group of genetically heterogeneous conditions that are characterized by the uncontrolled proliferation of activated lymphocytes and histiocytes that secrete large amounts of proinflammatory cytokines. This results in life-threatening manifestations, characterized by fever, hepatosplenomegaly, marrow infiltration and pancytopenia, and severe neurologic manifestations (Chap. 71).

There are at least five different forms of FHL, four of which have been defined at the molecular level. FHL2 is caused by mutations of the *PRF1* gene, which encodes perforin.²³⁰ FHL3 is caused by mutations in *UNC13D*, also known as Munc13–4.²³¹ FHL4 is caused by defects of the *STX11* gene, that encodes syntaxin 11,²³² whereas FHL5 is a result of mutations of the *STXBP2* gene, that encodes for Munc18–2, a protein that interacts with STX11.²³³ Each of these defects interferes with a specific step of the cytolytic machinery, and ultimately causes inefficient pathogen clearance, uncontrolled activation of CTLs, and release of IFN- γ and other inflammatory cytokines, resulting in recruitment and activation of macrophages, and inhibition of hematopoiesis.

Clinical and Laboratory Features

In approximately 85 percent of the cases, FHL becomes clinically evident within the first year of life,²³⁴ but late presentations may occur in patients with hypomorphic mutations.^{235–237} High fever, severe hepatosplenomegaly, lymphadenopathy, hemorrhagic manifestations as a result of thrombocytopenia, and edema are common. Neurologic symptoms, including seizures and decreased level of consciousness, may lead to long-term disability.²³⁸

The FHL diagnostic guidelines were updated in 2007.²³⁹ Anemia and thrombocytopenia are early signs followed by increased serum levels of triglycerides, bilirubin, liver enzymes, ferritin, and coagulation abnormalities. Hemophagocytosis can be observed in the marrow, lymph nodes, and cerebrospinal fluid, which often shows abundant mononuclear cells and increased proteins, even in the absence of overt neurologic symptoms. Immunologic findings include persistently impaired cytolytic activity of NK cells and elevated levels of inflammatory cytokines (IFN- γ , IL-1, IL-6, TNF- γ) in the blood. Monitoring circulating soluble CD25 (IL-2R α) is also useful as a measure of increased cellular activation.

Flow-cytometry enables analysis of perforin expression, which is absent except for hypomorphic mutations, and may thus facilitate diagnosis of FHL2. The diagnosis of FHL forms that are characterized by reduced NK cell degranulation (such as *UNC13D* and *STX11* defects) may be facilitated by the analysis of membrane expression of the lysosomal marker CD107a.²⁴⁰

Treatment and Prognosis

Without treatment, FHL is usually rapidly fatal. Treatment of active disease should focus on controlling or eliminating possible triggers (infections in particular), blocking T-cell activation, and stopping the hyperinflammatory cytokine response. To this purpose, antimicrobials, etoposide, immune suppression (antithymocyte globulin), cyclosporine, and dexamethasone are commonly used.^{239,241} Alemtuzumab has shown some efficacy in controlling etoposide-resistant forms.²⁴² However, relapses are common in FHL. Patients should be monitored carefully for reactivation of the disease, especially in the central nervous system. Administration of anti-IFN- γ monoclonal antibody has given interesting results in animal model of the disease,²⁴³ and is currently being tested in a clinical trial. Permanent cure for FHL can be only provided by allogeneic HSCT. A higher success rate is obtained when HLA-matched related or unrelated donors are available. Use of myeloablative conditioning regimen is associated with high transplantation-related mortality. Considering that partial chimerism is enough to achieve disease control,²⁴⁴ reduced intensity conditioning is being increasingly used, with promising results.²⁴⁵ Outcome of HSCT is worse if the disease is not in remission at the time of transplantation.

X-LINKED LYMPHOPROLIFERATIVE DISEASE

Definition and History

In 1975, Purtilo described a family in which numerous males in multiple generations presented with fulminant infectious mononucleosis, lymphoma, or hypogammaglobulinemia after primary EBV infection.²⁴⁶ XLP1 is caused by mutations in the *SH2D1A* gene^{247,248} that encodes an adaptor protein (SLAM [signaling lymphocyte activation molecule]-associated protein [SAP]) involved in T- and NK-cell signaling.²⁴⁹ Thus, defects of SAP drastically affect both T- and NK-mediated cytotoxicity.^{250–252} SAP also plays an important role in germinal center formation and antibody production by modulating development and function of follicular helper T cells.²⁵³ Finally, SAP is required for the development of iNKT cells, which are immunoregulatory cells that are involved in the responses to pathogens and cancer cells.²⁵⁴ In the absence of SAP, EBV and other virus infections result in dysregulated immune responses, because of persistent antigenic stimulation that leads to hyperactive cytotoxic T lymphocytes and macrophages, with increased production of IFN- γ .

However, not all males with X-linked lymphoproliferative syndrome (XLP) features have mutations in *SH2D1A* and mutations in another X-chromosome-associated gene (*XIAP*; X-linked inhibitor of apoptosis, also known as *BIRC4*) have been identified,²⁵⁵ resulting in XLP2.

Clinical and Laboratory Features

Although lymphoproliferative disease is observed in both XLP1 and XLP2, there are some important differences in the disease phenotype. Most often, XLP1 becomes clinically manifest following EBV infection in childhood, although later presentations are possible. Fulminant infectious mononucleosis has been observed in 50 to 60 percent of cases, and EBV-related lymphoma in 30 percent of the cases. Most lymphomas are of B-cell origin, and approximately half are of the Burkitt type. Persistent dysgammaglobulinemia, with low IgG and low to increased levels of IgM, is common among survivors. Other clinical manifestations of XLP1 include vasculitis, marrow aplasia secondary to hemophagocytic lymphohistiocytosis, and lymphoid granulomatosis.

Although less frequently encountered, other viral infections (CMV, other herpes viruses) may unmask the clinical phenotype of XLP1.²⁵⁶

Fulminant infectious mononucleosis is marked by a rapid increase of liver enzymes, followed by impaired coagulation, hepatic encephalopathy, and signs of hemophagocytic lymphohistiocytosis (HLH), associated with a high EBV viral load in the blood and other tissues. B-cell lymphomas carry monoclonal immunoglobulin gene rearrangements. Patients who develop dysgammaglobulinemia show impaired antibody responses. Antibody levels to the EBV nuclear antigen usually remain undetectable, even in patients who survive the acute EBV infection. In contrast, antibodies to the EBV viral capsid antigen can be low to elevated. During clinical manifestations of XLP, the proportion of CD8⁺ T cells carrying activation markers is increased and the number of memory (CD27⁺), and specifically switched memory (CD27⁺IgD⁻) B cells, is reduced. NK cell cytotoxicity is usually normal, when measured in a conventional K562 killing assay. However, NK cytolytic activity is markedly reduced in XLP1, when costimulation through CD244 is provided.²⁵⁰ Flow cytometry can be used to detect a lack of SAP protein expression in circulating T and NK lymphocytes in patients with XLP1.²⁵⁷

XLP2 often manifests with HLH, and EBV is a common trigger.²⁵⁸ However, some important differences exist in the phenotype of XLP2 versus XLP1. In particular, recurrent splenomegaly often associated with cytopenia and fever is preferentially observed in XLP2, and may represent an attenuated manifestation of HLH. By contrast, lymphoma, a common complication of XLP1, is not frequently observed in XLP2. Importantly, severe inflammatory bowel disease (IBD) has been reported in a significant proportion of patients with XLP2,^{258,259} and in some cases may represent the dominant clinical phenotype.²⁵⁹ Moreover, XLP2 may also manifest as delayed-onset Crohn disease.²⁶⁰ The occurrence of IBD in XLP2 may reflect the notion that the RING domain of XIAP is required for NOD2 signaling.²⁶¹

A flow-cytometry-based assay can be used to facilitate differential diagnosis of XLP1 and XLP2.²⁶²

Treatment and Prognosis

If untreated, approximately 70 percent of XLP1 patients die within 10 years of onset. The mortality rate is particularly high (96 percent) in patients who present with fulminant infectious mononucleosis.²⁶³ Allogeneic HSCT is the treatment of choice, yielding the best results when the transplant is performed early in life, prior to EBV infection. However, transplantation using reduced-intensity conditioning may permit correction of the disease in EBV-positive patients with severe organ toxicity.²⁶⁴ The use of anti-CD20 monoclonal antibody can reduce viral load and improve the clinical status, and anti-TNF- α therapy or etoposide may be beneficial in patients with active EBV infection and severe systemic inflammatory response.^{265–267} Administration of immunoglobulin may reduce the risk of infections, but does not prevent or attenuate the symptoms of primary EBV infection.

Similar survival rates have been reported in XLP2 and in XLP1.²⁵⁸ However, this figure does not take into account forms of XLP2 that may present with features other than HLH, and IBD in particular. Sulfasalazine, glucocorticoids, 5-amino salicylic acid, and anti-TNF medications have been used in the treatment of IBD in patients with XLP2, however the only curative approach is allogeneic HSCT. Use of myeloablative conditioning is associated with high mortality and toxicity rate, but good results have been reported with reduced intensity conditioning.²⁶⁸

CYTOTOXICITY DEFECTS ASSOCIATED WITH PIGMENTARY DILUTION DISORDERS

Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome is an autosomal recessive disorder characterized by immune dysregulation with impaired cellular cytotoxicity,

partial oculocutaneous albinism, platelet functional abnormalities, and neurologic involvement.²⁶⁹ The disease is caused by mutations in the *lysosomal trafficking regulator (LYST)* gene.²⁷⁰ LYST plays an important role in sorting of lysosomal proteins, and in docking and fusion of lysosomal vesicles.²²⁸

Patients are susceptible to recurrent pyogenic and viral infections. Bruises are common and reflect deficiency of the platelet specific granules responsible for secondary aggregation (Chap. 120). Both bacterial and viral infections may trigger the life-threatening “accelerated phase” of the disease, characterized by high fever, hepatosplenomegaly, coagulation abnormalities, increase of liver enzymes and bilirubin (with possible jaundice), edema, and neurologic symptoms, with seizures, ataxia, cranial nerve palsies, and peripheral neuropathy.²⁶⁹

Abnormally large granules in lymphocytes, neutrophils, platelets, melanocytes, and neurons represent a morphologic hallmark of the disease. Light microscopy examination of hair reveals large and evenly distributed granules of melanin. Reduced NK cytotoxic activity and prolonged bleeding time are typical findings.

Treatment requires control of infections, and immunosuppressive intervention during the accelerated phase. Allogeneic HSCT, best performed during remission, is the only permanent cure of the immunohematologic problems.²⁷¹ However, HSCT does not seem to prevent progressive neurologic involvement.²⁷²

Griselli Syndrome Type 2

Griselli syndrome type 2 (GS2) is an autosomal recessive syndrome characterized by immunodeficiency and hypopigmentation, and a variable degree of neurologic involvement.²⁶⁹ The presence of immune deficiency distinguishes GS2 from Griselli syndrome type 1 (GS1; marked by the association of partial albinism and neurologic involvement) and Griselli syndrome type 3 (GS3; with isolated hypopigmentation). GS2 is caused by mutations of the *RAB27A* gene,²⁷³ which encodes for a GTPase involved in intracellular transport of granules.

GS2 patients are highly susceptible to recurrent pyogenic infections and to episodes of “accelerated phase” of the disease, with typical features of HLH. Prominent hypopigmentation is a result of large clumps of melanin in the hair shafts. NK cytotoxicity is defective and CD107 expression at the cell membrane of NK lymphocytes is impaired upon coculture with target cells. Treatment is based on allogeneic HSCT, and promising results have been reported with reduced intensity conditioning.²⁷⁴

Hermansky-Pudlak Syndrome Type 2

This autosomal recessive disease is characterized by oculocutaneous albinism, bleeding tendency, recurrent infections, and moderate to severe neutropenia (Chap. 120).²⁶⁹ Bone anomalies (with dysplastic acetabula), facial dysmorphisms and development of pulmonary fibrosis are also part of the clinical phenotype. Hermansky-Pudlak type 2 is caused by mutations of the *AP3B1* gene that encode for the β_1 subunit of the AP-3 endosomal protein, which is required for sorting of lysosomal membrane proteins to the granules.²⁷⁵ Missorting of tyrosinase in melanocytes accounts for oculocutaneous albinism. Reduced platelet-dense granules and impaired platelet degranulation are responsible for increased susceptibility to bleeding. Absence of AP-3 leads to low intracellular content of neutrophil elastase in myeloid progenitors causing neutropenia. Even though CTL and NK cell cytolytic activity is defective,²⁷⁶ the risk of progression to HLH is lower than in Chédiak-Higashi syndrome or GS2.²⁷⁷ Consequently, preemptive use of HSCT is not justified.

Hermansky-Pudlak syndrome type 9 is caused by mutations of the pallidin (*PLDN*) gene, and is characterized by recurrent infections, partial albinism and nystagmus.²⁷⁸ NK cell cytolytic activity is impaired.²⁷⁹

● IMMUNODEFICIENCIES WITH SELECTIVE SUSCEPTIBILITY TO PATHOGENS

Although classical forms of PIDD are characterized by susceptibility to a broad range of pathogens, several disorders have been identified with selective susceptibility to certain microorganisms. Some of these diseases (e.g., mendelian susceptibility to herpes simplex virus encephalitis [HSE] or to pyogenic infections, especially *S. pneumoniae*) are the result of defects of innate immunity, in particular TLR signaling. Others (mendelian susceptibility to mycobacterial disease) involve defects of the IL-12/IFN- γ axis at the interface of innate and adaptive immunity. Susceptibility to recurrent meningitis caused by *Neisseria meningitidis* is discussed in “Genetically Determined Deficiencies of the Complement System” below.

IMMUNODEFICIENCIES WITH IMPAIRED SIGNALING THROUGH TOLL-LIKE RECEPTORS

TLRs are transmembrane proteins (Chap. 17) expressed on a variety of cell types that recognize pathogen-associated molecular patterns, such as lipopolysaccharide derived from Gram-negative bacteria, lipopeptide, double-stranded RNA that is generated during viral replication, viral single-stranded RNA, viral cytosine phosphate guanine DNA moieties, and flagellin. Although most TLRs are expressed at the cell surface, TLRs 7, 8, and 9 are expressed on the membrane of endosomal vesicles.²⁸⁰

The recognition of pathogen-associated molecular patterns by TLRs induces characteristic intracellular signaling.²⁸⁰ The classical pathway of TLR activation involves the adaptor molecules MyD88 (myeloid differentiation factor 88) and toll-IL-1R domain-containing adaptor protein (TIRAP), and the intracellular kinases IL-1R-associated kinase (IRAK)-4 and IRAK-1, ultimately resulting in the nuclear transfer of NF- κ B and the production of inflammatory cytokines (IL-1, IL-6, TNF- α , IL-12). TLRs 3, 7, 8, and 9 activate an alternative pathway that involves other adaptor molecules, such as TRIF, TRAF3, and the UNC-93B protein, and ultimately results in the induction of type 1 interferons (IFN- α/β). Deficiencies of IRAK-4, MyD88, TLR3, and UNC-93B have been identified in humans, and are associated with two distinct phenotypes.

Toll-Like Receptor Signaling Defects with Increased Susceptibility to Herpes Simplex Virus Encephalitis

Selective susceptibility to HSE is associated with monogenic disorders that affect TLR3,^{281,282} or components of the TLR3 signaling pathway, including UNC-93B,²⁸³ TRAF3,²⁸⁴ TRIF,²⁸⁵ and TBK1.²⁸⁶ The disease reflects a CNS-intrinsic defect of neurons and oligodendrocytes to produce type 1 IFN in response to herpes simplex virus (HSV).²⁸⁷

Because TLR3 recognizes double-stranded RNA and is normally expressed in CNS-resident cells, mutations of TLR3 or other components of the TLR3-dependent signaling pathway impair the response of these cells to actively replicating HSV-1. Because cellular responsiveness to type 1 IFN is intact in both UNC-93B-deficient and TLR3-deficient patients, the use of IFN- α along with acyclovir should be considered to treat HSE in these patients.^{281,287}

HSE may also be a result of null mutations of STAT1, a transcription factor that is activated upon interaction of type 1 IFN with their receptors, and is critical for the induction of IFN-responsive genes. However, these patients are also prone to other severe viral infections. Furthermore, because STAT1 is also involved in the response to IFN- γ ,

patients with null *STAT1* mutations are also at risk for mycobacterial disease.²⁸⁸

Other Immunodeficiencies with Increased Susceptibility to Viral Infections

Mutations of *STAT2*, leading to impaired response to IFN- α and IFN- β predispose to severe viral infections, including disseminated vaccine-strain measles.²⁸⁹

Skin warts caused by HPV infection are the hallmark of epidermodysplasia verruciformis. This disease is caused by mutations of the *EVER1* and *EVER2* genes.²⁹⁰ There is an increased risk of squamous cell carcinoma.

Toll-Like Receptor Signaling Defects with Increased Susceptibility to Pyogenic Infections

IRAK-4 and MyD88 deficiencies are characterized by recurrent and invasive pyogenic bacterial infections, particularly from *S. pneumoniae* and *S. aureus*.^{123,291,292} These infections are common especially during the first years of life (when lethality rate can be as high as 50 percent), but their frequency tends to decline with age.²⁹³ Fever and systemic inflammatory responses are absent or unusually modest, reflecting poor induction of inflammatory cytokines and reduced response through the IL-1R.

Use of antimicrobial prophylaxis is important to prevent invasive pyogenic infections, especially in childhood. Substitution therapy with immunoglobulins may be beneficial in patients with impaired antibody responses.

Defects Involving Other Pattern-Recognition Signaling Pathways with Increased Susceptibility to Fungal Infections

Several inborn errors of immunity have unraveled key mechanisms of defense against *Candida*. Chronic mucocutaneous candidiasis (CMC) is a common complication affecting patients with APECED; it results from a mutation in the transcription factor AIRE.¹⁷⁷ CMC also affects those with AD-HIES; in this case, it is a result of mutations in the transcription factor *STAT3*.¹⁹⁰ Autoantibodies to IL-17 are a common feature of APECED,^{181,294} and Th17 differentiation is impaired in HIES because of *STAT3* mutations. The Th17 cytokines IL-17A, IL-17F, and IL-22 induce the synthesis of chemokines that recruit neutrophils, and promote production of antimicrobial peptides from epithelial cells, thereby playing a key role in mucocutaneous resistance to *Candida* spp. Heterozygous, dominant negative mutations in *IL17F* gene, and biallelic loss-of-function mutations in the *IL-17RA* gene (encoding for the α chain of IL-17 receptor) have been linked with CMC.²⁹⁵ Furthermore, mutations of the *ACT1* gene²⁹⁶ (that encodes for an adaptor molecule that interacts with IL-17R) and gain-of-function *STAT1* mutations impairing Th17 immunity¹⁷⁰ are associated with CMC.

Mutations of the *CARD9* gene have been identified in patients with CMC or disseminated candidiasis, including infection of the brain.²⁹⁷ *CARD9* is recruited by Dectin-1, a transmembrane pattern-recognition receptor that senses the β -glucan component of fungal cell walls, and together with other cytoplasmic proteins, forms an intracellular signaling complex that leads to the nuclear import of NF- κ B and the induction of key cytokines including IL-1, IL-6, IL-23, and the generation of IL-17 cells, which are required to control antifungal immune responses. However, invasive fungal infections in *CARD9* deficiency are not restricted to *Candida*, but also include other species, such as *Exophiala*, an environmental black yeast with low virulence.²⁹⁸ Granulocyte macrophage-colony stimulating factor (GM-CSF) therapy resulting in complete clinical remission has been reported in one *CARD9*-deficient patient with relapsing *albicans* meningoencephalitis.²⁹⁹

MENDELIAN SUSCEPTIBILITY TO MYCOBACTERIAL DISEASE

The IL-12/IFN- γ axis is essential for controlling mycobacterial infections. Following phagocytosis of mycobacteria, macrophages secrete IL-12, a heterodimer composed of IL-12p40 and IL-12p70. IL-12 binds to the heterodimeric IL-12R (composed of IL12R β_1 and IL-12R β_2 chains) expressed by Th1 and NK cells. This results in activation of the JAK-STAT4 pathway, and ultimately in the production of IFN- γ , which binds to its receptor (comprising IFN- γ R1 and IFN- γ R2 chains) on the surface of macrophages, triggering a signaling cascade that involves the transcription factor STAT1 and induction of IFN- γ -responsive genes that are essential to contain the infection and kill the mycobacteria. A variety of defects along this pathway have been shown to account for mendelian susceptibility to mycobacterial disease (MSMD) in humans.³⁰⁰ The basis for increased susceptibility to mycobacterial disease in patients with NEMO deficiency was discussed in “X-Linked Anhydrotic Ectodermal Dysplasia with Immunodeficiency Caused by Mutations in Nuclear Factor- κ B Essential Modulator” above.

IL-12p40 Deficiency

Affected patients are at increased risk of childhood infections because of BCG and *Salmonella*; *Candida* infections have also been reported. Recurrence of *Salmonella* infection is common.³⁰¹ IL-12p40 can associate with IL-12p70 to form the IL-12 heterodimer, or with IL-23p19 subunit to form IL-23. Consequently, patients with IL-12p40 deficiency have defects in both IL-12 and in IL-23–dependent immunity, with the latter causing a Th17 deficiency. The clinical course is variable, with some genetically affected siblings being asymptomatic, but approximately 32 percent of symptomatic IL-12p40–deficient patients die prematurely of infections.³⁰¹ Treatment with antimicrobial drugs and IFN- γ has been tried with variable results.

IL-12R β_1 Deficiency

Autosomal recessive IL-12R β_1 deficiency is characterized by infections with mycobacteria of low virulence and *Salmonella* species.³⁰² However, infections with *Mycobacterium tuberculosis*, *Cryptococcus*, and disseminated coccidioidomycosis have also been reported.^{302–304} Unlike salmonellosis, mycobacterial infections tend not to recur and the overall prognosis is good. In most cases, IL-12R β_1 expression on the cell surface is absent, and *in vitro* IFN- γ production in response to IL-12 is abrogated. Treatment with appropriate antibiotics and IFN- γ is effective.

IFN- γ R1 and IFN- γ R2 Deficiencies

The genetic and biochemical pathophysiology of IFN- γ R1 and IFN- γ R2 deficiencies are remarkably complex. Autosomal recessive forms are most often associated with mutations that abrogate cell surface expression of IFN- γ R1 or result in the expression of receptors that do not bind IFN- γ . Partial autosomal recessive deficiency is the result of hypomorphic mutations, with residual IFN- γ binding and signaling.³⁰⁵ Dominant partial forms reflect the presence of heterozygous mutations in the cytoplasmic tail of IFN- γ R1, allowing the expression of mutant molecules on the cell surface (often in increased density because of defective receptor shedding) which are unable to mediate signal transduction.³⁰⁶

The severity of the clinical features reflects the nature of the biochemical defect.³⁰⁷ Patients with complete deficiency develop severe infections with environmental mycobacteria infections early in life, with lack of granuloma formation. Osteomyelitis caused by BCG or by environmental mycobacteria has been reported in several patients with dominant partial IFN- γ R1 deficiency.

Treatment of partial deficiency should be based on careful identification and typing of the mycobacterial strains and appropriate

antimicrobial therapy; addition of IFN- γ may be useful in patients with AD mutations in IFN- γ R1 who are able to express reduced amounts of normal IFN- γ R1 on the cell surface. Recessive forms are resistant to medical treatment. Although allogeneic HSCT may be curative, a high rate of graft failure has been observed³⁰⁸ as a consequence of the inhibitory effect of high levels of circulating IFN- γ .³⁰⁹

GATA2

The syndrome of monocytopenia, B-cell and NK-cell lymphopenia associated with mycobacterial, fungal and viral infections, also called MonoMAC syndrome or familial myelodysplasia/leukemia with lymphedema (Emberger) syndrome was first described in 2010.³¹⁰ One year later, heterozygous mutations in *GATA2* resulting in haploinsufficiency were identified as the molecular defect causing MonoMAC³¹¹ and Emberger syndrome.^{312,313}

GATA2 plays a role in the early development of lymphatics and their valves,³¹⁴ explaining the connection with Emberger syndrome. The transcription of *GATA2* occurs in early and undifferentiated hematopoietic cells, but also in somatic cells. Because of its progression to myelodysplastic syndrome or acute myeloid leukemia, mortality can be as high as 28 percent.³¹⁰ HSCT has successfully reversed clinical symptoms.³¹⁵

STAT1 Deficiency

Complete STAT1 deficiency causes increased susceptibility to viral infections and to mycobacterial disease with a severe clinical course and early death.²⁸⁸

Dominant partial STAT1 deficiency is caused by a heterozygous mutation that allows formation of the IFN- α/β -dependent ISGF3 transcription factor, but abrogates expression of the γ -activating factor, which is composed of STAT1 homodimers. Affected individuals have either a mild clinical course, characterized by selective susceptibility to mycobacterial infections, or are asymptomatic.³¹⁶

Partial autosomal recessive STAT1 deficiency is associated with impaired, but not abrogated, IFN- α/β and IFN- γ signaling, and occurrence of severe, but curable, intracellular bacterial and viral infections.³¹⁷

Heterozygous STAT1 gain-of-function mutations result in susceptibility to mycobacterial infections, candidiasis, and IPEX-like phenotype (see “Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-Linked–Like Syndromes” above).¹⁷¹

Other Genetic Disorders with Mendelian Susceptibility to Mycobacterial Disease

Interferon-regulated factor 8 (IRF8) is a transcription factor that regulates the differentiation of granulocytes and macrophages, and the development of DCs. IRF8 mutations in humans cause MSMD.³¹⁸ Two variants of the disease have been described: an autosomal recessive form characterized by extreme leukocytosis (up to $98 \times 10^9/L$ cells), marked expansion of lymphocytes and granulocytes, and absence of monocytes, myeloid DCs, and plasmacytoid DCs; and an AD variant, in which monocytes and DCs are present, but there is selective loss of IL-12–producing CD1c⁺ DCs. The clinical phenotype of autosomal recessive IRF8 deficiency is more severe, with early onset, failure to thrive, and disseminated BCG. HSCT is curative. The AD variant of the disease is characterized by disseminated but curable BCG infection.

The interferon stimulated gene 15 (ISG15) protein is an IFN- α/β -inducible, ubiquitin-like protein involved in ISGylation, but can be also secreted by granulocytes and act upon T and NK lymphocytes, inducing IFN- γ production. Inherited ISG15 deficiency causes severe MSMD, with disseminated BCG infection, which is responsive to antimycobacterial treatment.³¹⁹

● GENETICALLY DETERMINED DEFICIENCIES OF THE COMPLEMENT SYSTEM

The complement (C) system³²⁰ consists of the classical and alternative pathways and the membrane attack complex, and is composed of a series of plasma proteins that play an important role in host defense, inflammation, clearance of immune complexes and apoptotic cells, and induction of a normal humoral immune response (Chap. 19). Mutations in the classical pathway (C1q, C1r/C1s, C4, C2, and C3) result in pyogenic infections and autoimmune diseases. Mutations affecting the alternative pathway (factors B, D, properdin) result in meningococcal and pneumococcal sepsis. Mutations in the terminal components (C5–C9) are associated with an increased susceptibility to *Neisseria* species, especially meningococcal sepsis and meningitis. C1 inhibitor deficiency, an AD disorder, is the cause of hereditary angioedema. All other complement-component deficiencies have an autosomal recessive mode of inheritance with the exception of properdin deficiency, which is X-linked.

The most important screening tests for complement deficiencies are those using the assessment of the hemolytic function of both the classic and alternative pathways, CH50 and AH50, respectively. If both tests are normal, a complement deficiency is unlikely. If CH50 is absent and AH50 normal, a defect of C1, C4, or C2 is likely. Normal CH50 but absent AH50 suggests a defect of properdin or factor D. If both tests are abnormal, the defect most likely affects C3 to C8. Deficiency of C9 results usually in a CH50 value that is approximately half of normal. To pinpoint the specific complement component deficiency, immunochemical tests using component specific antibodies or functional assays using *in vitro* reconstitution of the hemolytic function are recommended. Mutations and single nucleotide polymorphisms (SNPs) in the complement regulatory proteins factor H and factor I are implicated in atypical hemolytic uremic syndrome and age-related macular degeneration.^{320,321} Treatment of complement-component deficiencies depends on the defect and may include frequent immunizations using the appropriate vaccines, antibiotic prophylaxis, and workup for sepsis if the clinical symptoms suggest bacterial infections. Autoimmune disorders are treated symptomatically, using the same immunosuppressive agents and antiinflammatory medications as those used in the general population. Management of angioedema has been revolutionized by C1 esterase inhibitor concentrate (Cinryze, Berinert), which is most effective for the treatment of acute attacks and by the kallikrein inhibitor Kalbitor (Dyax) and the bradykinin receptor antagonist Firazyr (Shire).

CHAPTER 81

HEMATOLOGIC MANIFESTATIONS OF ACQUIRED IMMUNODEFICIENCY SYNDROME

Virginia C. Broudy and Robert D. Harrington

SUMMARY

The prevalence of HIV in the United States continues to rise as a result of the combined effects of a declining HIV death rate, and a sustained rate of new infections. Furthermore, HIV-infected patients on antiretroviral therapy can expect to live nearly as long as uninfected persons (within 5 years) providing ample time for individuals to develop AIDS-associated and non-AIDS-associated hematologic and oncologic conditions. HIV-infected individuals remain at increased risk of AIDS-defining malignancies such as Kaposi sarcoma, aggressive non-Hodgkin lymphoma, primary central nervous

Acronyms and Abbreviations: ABVD, Adriamycin, bleomycin, vinblastine, dacarbazine; ADAMTS 13, a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13; AMC, AIDS Malignancy Consortium; ART, antiretroviral therapy; AVD, Adriamycin, vinblastine, dacarbazine; BEACOPP, bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine, procarbazine, prednisone; BFU-E, burst-forming unit–erythroid; CFU-GM, granulocyte-macrophage colony-forming unit; CFU-GEMM, granulocyte-erythrocyte-monocyte and megakaryocyte colony-forming unit; CHOP, cyclophosphamide, doxorubicin, vincristine, prednisone; CHORUS, Collaboration in HIV Outcomes Research/U.S. study; CMV, cytomegalovirus; CODOX-M/IVAC, cyclophosphamide, vincristine, doxorubicin, methotrexate/ifosfamide, mesna, etoposide, cytarabine; CRF, circulating recombinant form; CSF, cerebrospinal fluid; CTL, cytotoxic T-lymphocyte; DHHS, Department of Health and Human Services; EBV, Epstein-Barr virus; ECOG, Eastern Cooperative Oncology Group; EPOCH, etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin; ESHAP, etoposide, methylprednisolone, high-dose cytarabine, cisplatin; G6PD, glucose-6-phosphate dehydrogenase; HHV8, human herpesvirus-8; HPV, human papillomavirus; HSV, herpes simplex virus; HUS, hemolytic-uremic syndrome; hyperCVAD, cyclophosphamide, vincristine, doxorubicin, dexamethasone; IL, interleukin; IRIS, immune reconstitution inflammatory syndrome; ITP, idiopathic thrombocytopenic purpura; KICS, KSHV-associated inflammatory cytokine syndrome; KSHV, Kaposi sarcoma-associated herpesvirus; LDH, lactate dehydrogenase; LPS, lipopolysaccharide; MRI, magnetic resonance imaging; NHL, non-Hodgkin lymphoma; nRTI, nonnucleoside reverse transcriptase inhibitor; nRTI, nucleoside reverse transcriptase inhibitor; PCR, polymerase chain reaction; PET-CT, positron emission tomography–computed tomography; PrEP, preexposure prophylaxis; R-CHOP, rituximab plus CHOP; R-EPOCH, rituximab plus EPOCH; R-ICE, rituximab plus ifosfamide, carboplatin, etoposide; SEER, Surveillance, Epidemiology, and End Results Program; SIV, simian immunodeficiency virus; TTP, thrombotic thrombocytopenic purpura.

system lymphoma, and invasive cervical cancer and a number of non-AIDS-defining malignancies, including Hodgkin lymphoma, as well as anemia and thrombocytopenia. When individuals present with any of these hematologic or malignant illnesses it should be the standard of care to obtain HIV testing so as to provide optimal treatment to both the presenting illness and the HIV.

HISTORY AND HUMAN IMMUNODEFICIENCY VIRUS

HIV, the virus that causes AIDS, is a lentivirus that originated as a simian immunodeficiency virus (SIV) in chimpanzees and entered the human population in the early 20th century in equatorial Africa.^{1,2} First isolated in 1983,^{3,4} HIV-1 actually comprises four distinct viruses (types M, N, O, and P) that represent four separate transmission events that occurred between chimpanzees and humans, likely the result of predation of monkeys by humans and mucosal or nonintact skin contact with infected fluids. Group M, the viral type responsible for the HIV-1 pandemic, was detected in a tissue sample from 1959 and probably entered the human population in or around Kinshasa, Democratic Republic of Congo (then Leopoldville, Belgium Congo) between 1910 and 1930 based on phylogenetic analysis.² HIV-2 originated in West Africa, the result of cross-species transmission of SIV from sooty mangabeys to humans. Patients infected with HIV-2 progress more slowly and have lower plasma viral loads (often nondetectable) than those with HIV-1, reflective of the different virology and adaptation to humans of this SIV.⁵ Because of lower rates of replication and transmission, HIV-2 prevalence is declining and is being replaced by HIV-1 in countries where both viruses are endemic.^{5,6} Among those infected with HIV-1, group M is the globally predominant viral strain and is further divided into nine subtypes and many more recombinant viruses (circulating recombinant forms [CRFs]) with some geographic localization. Subtypes A and D predominate in East Africa; subtype C in South Africa, India, and Asia; subtype B in the Caribbean, the Americas, and Western Europe; and CRF01 in Southeast Asia.¹

EPIDEMIOLOGY, TRANSMISSION

The development of *Pneumocystis jiroveci* (*Pneumocystis carinii*) pneumonia and Kaposi sarcoma in previously healthy men who have sex with men on both coasts of the United States in 1981 represented the first clinical manifestations of HIV and the onset of the HIV-1 pandemic.⁷⁻⁹ Subsequent reports of similar illnesses in the sexual partners of index cases, injection drug users, patients with hemophilia and other transfusion recipients, infants born to infected mothers, and Haitian immigrants¹⁰⁻¹⁷ helped identify the routes of transmission as bloodborne, sexual, or vertical. With the discovery of HIV in 1983 and the subsequent development of serologic testing, more systematic detection of HIV infections became possible providing an understanding of the regional and global HIV epidemiology. While sexual contact between men was responsible for most infections in the United States, Northern Europe, Australia, and parts of Central and South America, heterosexual spread predominated in sub-Saharan Africa and injection drug use followed by sexual transmission was responsible for most infections in Southern and Eastern Europe and Southeast Asia.¹⁸ Transmission rates between individuals per incident/act is dictated by the viral load in the HIV-infected person,¹⁹ the presence of modifying factors such as concurrent ulcerative sexually transmitted diseases and the type of exposure.²⁰ Rates vary between 93 percent for blood transfusion from an infected person to less than 0.04 percent for oral sex. Estimated rates for mother-to-child transmission (in the absence of antiretroviral therapy [ART] prophylaxis) are 23 percent, for

needle sharing 0.63 percent, for needle stick 0.23 percent, for receptive anal intercourse 1.38 percent, for insertive anal intercourse 0.11 percent, for receptive vaginal intercourse 0.08 percent, and for insertive vaginal intercourse 0.04 percent.²⁰ In 2012 there were an estimated 35.3 million people living with HIV, including 2.3 million newly infected persons.²¹ Although the global incidence of HIV is thought to have peaked in 1997, the prevalence of HIV is increasing because of ongoing new infections and the shrinking death rate of those already infected and on ART (2.3 million deaths in 2005 versus 1.6 million deaths in 2012). The majority of HIV-infected persons (approximately 23 million) now live in sub-Saharan Africa with 4 million in Asia and Southeast Asia and roughly 3 million in the Americas and Caribbean.

● PATHOGENESIS

Eighty percent of HIV infections occur via mucosal transmission during sex²² when cell-free and cell-associated virions transverse the epithelium to gain access to macrophages, Langerhans cells, dendritic cells, and CD4-expressing T lymphocytes.²³ To infect most cells HIV must bind to CD4 and one of two major coreceptors (CCR5 or CXCR4); in most cases, CCR5-utilizing viral strains are those that are transmitted and predominate early in disease. Rare individuals who do not express CCR5 (homozygote for a 32 bp deletion mutation in the CCR5 gene) are highly resistant to HIV infection although they can be infected with isolates utilizing CXCR4. After transmission, low-level replication of HIV in tissue macrophages and dendritic cells can occur, but the key role these cells play is in trapping and trafficking virions and presenting them to CD4+ T lymphocytes within regional lymphatics (e.g., gut-associated lymphoid tissue and lymph nodes where the infection is amplified).²⁴ High-level viral replication proceeds within these local tissues leading to profound CD4+ T-cell depletion, establishment of a reservoir of latently infected memory T cells and eventually to high plasma levels of virus that are the hallmark of acute infection. The immune response to HIV is brisk but ineffective and may, in fact, fuel the infection because the expression of inflammatory cytokines²⁵ and migration of activated CD4+ T cells to the site of HIV-1 concentration provides additional activated cells that the virus coopts for its own replication.²⁶ The initial antibody response to HIV does not contain neutralizing antibodies; these develop only later, months after chronic infection is established. Furthermore, HIV escapes these antibodies by mutations within N-glycosylation sites that prevent antibody binding.²⁷ The CD8+ cytotoxic T-lymphocyte (CTL) cell response to HIV controls high-level viral replication during primary infection and establishes the viral “setpoint” or plasma level of HIV RNA in chronic infection. Evidence for the controlling anti-HIV effect of CD8+ T cells includes their detection immediately prior to peak viremia, the development of viral escape mutations^{28–30} and the requirement for CD8+ T cells to control SIV infection in Rhesus macaques.³¹ The rate of viral escape mutations slows during chronic infection^{32,33} and is not associated with further declines in viral load, reaching a stalemate where viral replication continues under the pressure of a slowly evolving CTL response leading to viral strains with reduced replication capacity.^{34–36} As important as the direct cytolytic effect of HIV on CD4+ T cells, the virus induces a state of chronic immune activation of both the adaptive and innate immune systems that is central to disease pathogenesis.^{37–41} Because the immune response to HIV is defective and does not clear the virus, the immune system remains continually activated with high rates of T-cell turnover that eventually leads to T-cell exhaustion and depletion. This is particularly evident in gut-associated lymphoid tissue where early T-cell losses alter the integrity of the mucosal border leading to microbial translocation and leakage of lipopolysaccharide (LPS) into the blood which, in turn, amplifies the state of immune activation.⁴² This persistent,

systemic inflammatory state leads to tissue fibrosis over time^{43,44} that is partly responsible for immune failure and the increased frequency of nonimmune, nontraditional chronic diseases that now plague an aging HIV population.⁴⁵

● CLINICAL FEATURES AND DISEASE PROGRESSION

Primary HIV infection that comes to medical attention presents as a febrile illness that may include headache, pharyngitis, lymphadenopathy, gastrointestinal symptoms, and rash and may be mistaken for mononucleosis or other nonspecific viral infections. Key to making the diagnosis is taking a history for HIV risk factors and obtaining appropriate laboratory testing (combined HIV Ag/Ab assays and plasma HIV RNA testing). However, in most cases, primary infection goes undiagnosed and patients are later identified in the chronic, asymptomatic phase of infection by routine screening or later still, after the development of symptoms that are often caused by opportunistic infections. Typically, the asymptomatic phase of chronic infection will last for 8 to 10 years, although there is great interindividual variation dictated by the effectiveness of the immune response in controlling HIV replication (the viral “setpoint,” see above). Long-term nonprogressors (those who maintain CD4+ T-cell counts >500 for 5 years without therapy) and elite controllers (those with low or nondetectable plasma HIV RNA without treatment) can live for decades with limited or no disease progression, while others with high viral setpoints in the range of 100,000 to >1,000,000 copies/mL can develop AIDS-defining illnesses quickly after primary infection. In untreated individuals CD4+ T-cell counts (typically at CD4 counts) typically decline by 50 to 100 cells/ μ L per year, taking 8 to 10 years before counts are in the range where symptoms develop (typically at CD4 count <500 cells/ μ L) or AIDS-defining illnesses occur (typically at CD4 count <200 cells/ μ L). Historically, opportunistic infections provided the first evidence for the existence of HIV and remain the most visible manifestation of infection in countries with limited access to ART and in individuals who are diagnosed late in the course of their disease. The development of opportunistic infections and AIDS-defining conditions is dependent on the virulence properties of the organism and the degree of host immune suppression. Pathogens with high virulence potential (e.g., *Mycobacterium tuberculosis*, *Salmonella* sp., the bacterial agents of community-acquired pneumonia) cause disease in patients without HIV and do so in HIV-infected persons regardless of CD4 count (although more severe and prolonged illness occurs with more profound immunodeficiency). Agents with more limited pathogenic potential typically cause disease at lower CD4 counts, for example, *P. jiroveci* at CD4 counts below 200 cells/ μ L, while those that rarely cause disease in immunocompetent persons, such as disseminated *Mycobacterium avium* complex, *Toxoplasma gondii* encephalitis, and JC virus (the agent of progressive multifocal leukoencephalopathy), typically occur only in those with very advanced HIV disease and CD4 counts less than 100 cells/ μ L or less than 50 cells/ μ L, respectively (Table 81–1 lists HIV staging; Table 81–2

TABLE 81–1. HIV Staging

HIV Stage	Description
0	Infection within the previous 6 months
1	CD4 count \geq 500 cells/ μ L (or \geq 26%)
2	CD4 count 200–499 cells/ μ L (or 14–25%)
3	AIDS-defining condition or CD4 count <200 cells/ μ L (or <14%)
Unknown	If none of the above apply

TABLE 81–2. Aids-Defining Conditions

Bacterial infections, multiple or recurrent*
Candidiasis of bronchi, trachea, or lungs
Candidiasis of esophagus†
Cervical cancer, invasive [§]
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month's duration)
Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 month
Cytomegalovirus retinitis (with loss of vision)†
Encephalopathy, HIV related
Herpes simplex: chronic ulcers (>1 month's duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 month)
Histoplasmosis, disseminated or extrapulmonary
Isosporiosis, chronic intestinal (>1 month's duration)
Kaposi sarcoma†
Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex*†
Lymphoma, Burkitt (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
<i>Mycobacterium avium</i> complex or <i>Mycobacterium kansasii</i> , disseminated or extrapulmonary†
<i>Mycobacterium tuberculosis</i> of any site, pulmonary, ^{†§} disseminated, [†] or extrapulmonary†
<i>Mycobacterium</i> , other species or unidentified species, disseminated† or extrapulmonary†
<i>Pneumocystis jirovecii</i> pneumonia†
Pneumonia, recurrent ^{†§}
Progressive multifocal leukoencephalopathy
<i>Salmonella</i> septicemia, recurrent
Toxoplasmosis of brain, onset at age >1 month†
Wasting syndrome attributed to HIV

*Only among children younger than age 13 years. (Centers for Disease Control and Prevention (CDC). 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. *MMWR Morb Mortal Wkly Rep* 1994;43(RR-12). Available at: <http://www.cdc.gov/mmwr/PDF/rr/rr4312.pdf>)

†Condition that might be diagnosed presumptively.

§Only among adults and adolescents older than age 13 years. (Centers for Disease Control and Prevention (CDC). 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. *MMWR Morb Mortal Wkly Rep* 41(RR-17):1–19, 1992.)

Data from Centers for Disease Control and Prevention (CDC): 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age. *MMWR Morb Mortal Wkly Rep* 1994;43(RR-12) (available at: <http://www.cdc.gov/mmwr/PDF/rr/rr4312.pdf>), and Centers for Disease Control and Prevention (CDC): 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. *MMWR Morb Mortal Wkly Rep* 41(RR-17):1–19, 1992.

TABLE 81–3. Examples of Common Opportunistic Infections By CD4 Count

CD4 Count	Opportunistic Infection or Condition
>500 cells/ μ L	Any condition that can occur in HIV-uninfected persons, e.g., bacterial pneumonia, tuberculosis, varicella-zoster, herpes simplex virus
350–499 cells/ μ L	Thrush, seborrheic dermatitis, oral hairy leukoplakia, molluscum contagiosum
200–349 cells/ μ L	Kaposi sarcoma, lymphoma
100–199 cells/ μ L	Pneumocystis pneumonia, <i>Candida</i> esophagitis, cryptococcal meningitis
<100 cells/ μ L	<i>Toxoplasma</i> encephalitis, disseminated <i>Mycobacterium avium</i> complex, progressive multifocal leukoencephalopathy, cytomegalovirus retinitis, primary central nervous system lymphoma, microsporidia

lists AIDS-defining conditions; and Table 81–3 lists common HIV-associated conditions by CD4 count). Prophylaxis against the development of these infections is provided when the infection is common and significant and when the prophylaxis is effective, inexpensive and well tolerated. (Table 81–4 lists the organisms and medications used for primary prophylaxis.) Tumors classified as AIDS-defining malignancies are Kaposi sarcoma, Burkitt lymphoma, immunoblastic lymphoma, primary CNS lymphoma and cervical cancer, as these were first identified at high rates among infected persons early in the epidemic. Many other cancers also occur at increased rates among HIV-infected patients because of a higher rate of traditional cancer risk factors and the long-term effects of immune dysregulation leading to decreased tumor surveillance and chronic systemic inflammation. Outside of the immune defects levied by HIV, the virus can directly or indirectly cause specific organ or tissue damage including the nervous system (causing cognitive impairment, dementia and peripheral neuropathy), cardiovascular system (HIV cardiomyopathy), kidney (HIV nephropathy), gastrointestinal system (HIV enteropathy and cholangiopathy), and can accelerate disease progression as a result of other infections, such as hepatitises

TABLE 81–4. Primary Prophylaxis

Infection	Criteria	Treatment
Pneumocystis pneumonia	CD4 <200 cells/ μ L or <14% or oral candidiasis or an AIDS-defining illness	Trimethoprim-sulfamethoxazole or dapsone or aerosolized pentamidine
Tuberculosis	Purified protein derivative >5 mm or + Interferon- γ release assay	Isoniazid (INH) + pyridoxine
Toxoplasmosis	Immunoglobulin G+ and CD4 <100 cells/ μ L	Trimethoprim-sulfamethoxazole or dapsone+ pyrimethamine+ leucovorin
<i>Mycobacterium avium</i> complex	CD4 <50 cells/ μ L	Azithromycin or clarithromycin

B and C.^{46,47} Finally, the long-term effects of chronic immune activation and persistent inflammation is likely a factor in the development of coronary artery disease,⁴⁵ chronic liver disease,^{47,48} and a hypercoagulable state^{49–51} that is only partly corrected by the initiation of ART. These “aging effects” of HIV are likely to dominate the health issues for infected persons now that opportunistic infections are readily treated or avoided altogether through a combination of prophylaxis and ART.

● THERAPY

The story of ART from the first reports that zidovudine had activity against HIV to the current formulary of drugs, including single-tablet, fixed-dose, once-daily formulations, is one of the great achievements in medicine. Early studies of zidovudine monotherapy demonstrated a delay to the development of AIDS and short-term mortality benefits but no long-term effect on survival; zidovudine also carried significant toxicity.^{52–57} Combination therapy with other nucleoside reverse transcriptase inhibitors (NRTIs) proved slightly more effective than zidovudine alone, but not until combination NRTI was used with a third drug from another class, first nonnucleoside reverse transcriptase inhibitors (NNRTIs)⁵⁸ and then protease inhibitors,^{59–62} were sustained viral suppression and substantive, dramatic improvements in survival realized.⁶³ The recommended time to initiate ART has evolved in response to studies demonstrating benefits of ART at high CD4 counts and improvements in drug tolerability and formulation. Current Department of Health and Human Services (DHHS) guidelines suggest that all HIV-infected persons be offered ART regardless of CD4 count, although the strength of evidence supporting this recommendation varies by CD4 count (Table 81–5 lists the criteria for initiating ART), while the World Health Organization sets a CD4 count threshold of 350 cells/ μ L for initiating ART in more resource-limited countries. The rationale for these expanded ART recommendations include the recognition that newer therapies are more convenient, have fewer adverse effects and are associated with lower rates of drug resistance. Furthermore, in addition to

improved all-cause survival, ART preserves renal function in those with HIV-associated nephropathy,⁶⁴ slows the progression of hepatic fibrosis in those coinfecting with hepatitis C,^{65–68} decreases (but does not normalize) markers of chronic inflammation⁶⁹ and may be associated with reduced cardiovascular disease,⁷⁰ prevents the development of HIV-associated dementia,^{71,72} and is highly effective in reducing mother-to-child^{73,74} and sexual transmission.^{19,22,75} Adverse effects related to ART do occur but are less common with current regimens and can usually be effectively managed with corrective treatments and by substitution of the offending drug with an alternative medication.^{76,77} Similarly, the presence or development of drug resistance can usually be overcome by the use of secondary or salvage ART regimens that are fully suppressive. At the current time, only rare patients who are fully adherent to ART fail to control HIV replication. Treatment of early and primary infection provides a unique opportunity to intervene and possibly alter the course of HIV infection. Several studies have demonstrated that treatment in early or primary HIV lowers the rate of disease progression if treatment is subsequently interrupted^{78–83} and may also limit the size of the latent HIV reservoir,^{84–87} the impediment to curing patients. One interesting group of 14 patients initiated ART during primary infection and stayed on treatment for a median of 3 years and then controlled HIV replication for a median of 7 years after ART interruption.⁸⁸ Finally, given the high viral loads typical of primary HIV, these patients are thought to be highly infectious; therefore identifying them and initiating treatment should prevent transmission to their uninfected partners. One consequence of initiating ART in the setting of a known or occult infection is the development of an acute inflammatory reaction as a result of reconstitution of the immune system in the presence of organisms or foreign antigens.^{89–93} The immune reconstitution inflammatory syndrome (IRIS) occurs in between 8 and 30 percent of patients who start ART, depending on the opportunistic infection and the timing of ART.⁹⁴ Risk factors for the development of IRIS include a low baseline CD4 count, more-severe disease and a short interval between treatment of the opportunistic infection and initiation of ART. The treatment of IRIS should include treatment of the underlying infection or condition, continued ART, and antiinflammatory medication, such as corticosteroids, depending on the severity of the reaction.⁹⁵

TABLE 81–5. Criteria for Initiating Antiretroviral Therapy

CD4 Count	Recommendation
<350 cells/ μ L	Start antiretroviral therapy (ART) (AI)
350–500 cells/ μ L	Start ART (AII)
>500 cells/ μ L	Start ART (BIII)
Clinical conditions favoring initiation of therapy regardless of CD4 count:	
<ul style="list-style-type: none"> • History of AIDS-defining illness (AI) • Pregnancy (AI) • HIV-associated nephropathy (AII) • Hepatitis B coinfection (AII) • Patients at risk of transmitting HIV to sexual partners (AI, heterosexuals; AIII, others) • Hepatitis C coinfection (BII) • Patients older than 50 years of age (BIII) 	

A, strong recommendation; B, moderate recommendation; C, optional recommendation; I, one or more randomized trials with clinical outcomes and/or validated laboratory end points; II, one or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; III, expert opinion.

● PREVENTION AND CURE

The future of the HIV epidemic will differ by region and be dictated by local public health responses, HIV testing rates, sociobehavioral prevention interventions, and access to ART. Expanded HIV testing is an essential element of any prevention campaign as an estimated 50 percent of all new infections originate from individuals unaware of their HIV status.⁹⁶ Behavioral interventions can have some preventative effect^{97–99} but biomedical methods have emerged as the most effective means to prevent new infections. Male circumcision can reduce female-to-male sexual transmission by 51 percent¹⁰⁰ and is being implemented on a population level in some African countries. ART administered peripartum will prevent most mother-to-child transmissions^{101,102} and fully suppressive ART provided throughout pregnancy essentially eliminates all infant infections.^{73,74} A prospective randomized trial of HIV-discordant couples demonstrated that ART provided to the HIV-infected partner was almost 100 percent effective in preventing transmission²² and other studies have shown that elements of ART given to HIV-negative but at-risk persons (preexposure prophylaxis [PrEP]) can prevent HIV acquisition when subjects are adherent to treatment.^{103–105} These studies point the way to the best strategies and interventions to curtail the HIV epidemic until an effective HIV vaccine is available.

The persistence of replication-competent but transcriptionally silent HIV proviral DNA in long-lived resting cells (the HIV latent

reservoir) is the impediment to cure for nearly all HIV-infected people.^{87,106–109} Although combination ART is highly effective at controlling HIV replication in activated cells, it has no effect on the latent HIV reservoir, which will persist as long as the cells harboring HIV survive. Because most HIV genomes reside in central and effector memory T cells that decay at a negligible rate, there is no possibility of cure with ART alone. The only individual cured of *chronic* HIV infection (Timothy Brown, the Berlin patient) developed acute myelogenous leukemia that was treated with high-dose conditioning and transplantation of HIV-resistant (CCR5D32/D32) allogeneic blood stem cells.¹⁰⁹ While this case provides proof-of-principle that the latent HIV reservoir can be eliminated by allogeneic hematopoietic cell transplantation, the approach is impractical for widespread application because of the high toxicity associated with this procedure, the morbidity of graft-versus-host disease, and the scarcity of CCR5D32/D32 donors. To date, most HIV cure efforts have focused on the strategy of reversing latency with the notion that once resting cells begin producing HIV they will be targeted by the immune system or die from apoptosis. However, early studies suggest that activating latent cells to express HIV does not reliably lead to their death and additional treatments including vaccination to boost cytotoxic responses will be needed.^{109A} Gene therapy is also being pursued as a means to control or cure HIV; specifically, DNA editing enzymes that disrupt CCR5 have been used to eliminate CCR5 expression in cells that are then expanded *ex vivo* and reinfused into patients, creating a population of HIV-resistant CD4+ T cells.^{110,111}

HUMAN IMMUNODEFICIENCY VIRUS–ASSOCIATED MALIGNANCIES

When AIDS was first identified as a clinical syndrome it was quickly appreciated that these patients were at greatly increased risk for certain types of malignancies, including Kaposi sarcoma, various types of non-Hodgkin lymphoma (NHL), and invasive cervical cancer. Each of these AIDS-defining cancers is frequently associated with an oncogenic virus (Table 81–6). As effective ART was developed and patients began living into their 50s, 60s, and 70s,^{112,113} it became apparent that many non-AIDS-defining malignancies were also more common in this population compared to HIV-uninfected patients. Anal cancer is 120-fold more common in people living with HIV, particularly among men who have sex with men. Hodgkin lymphoma incidence is increased approximately 20-fold, hepatocellular cancer fivefold, and the risk of lung cancer is increased twofold. In contrast, the risks of other common cancers, including breast cancer, prostate cancer, and colon cancer, are not increased in comparison to HIV-negative people.¹¹⁴ In the ART era, non-AIDS-defining malignancies comprise approximately half of the cancers in people living with HIV, and overall cancer causes approximately 25 to 33 percent of all deaths in HIV-infected

patients, supporting the importance of age-appropriate standard cancer screening.¹¹⁵

The Centers for Disease Control estimates that 20 percent of HIV+ people in the United States do not know that they are HIV+,¹¹⁶ and HIV testing is strongly recommended in all patients who present to the hematologist with NHL, Hodgkin lymphoma, or idiopathic thrombocytopenic purpura (ITP), or other malignancies.¹¹⁷ This recommendation is made because approximately 5 percent of those with diffuse large B-cell lymphoma and 22 percent of patients with Burkitt lymphoma in the United States are HIV+ (Fig. 81–1). These proportions vary substantially by demographic group¹¹⁸: among men, 10 percent of those with diffuse large B-cell lymphoma are HIV+, in contrast to 1 percent of women, and approximately 40 percent of those 30 to 59 years old with Burkitt lymphoma are HIV+. It is important to diagnose HIV infection when present, as effective treatment of HIV is essential for successful treatment of the malignancy or ITP.

HUMAN IMMUNODEFICIENCY VIRUS–ASSOCIATED DIFFUSE LARGE B-CELL LYMPHOMA

Among HIV+ patients in the United States, diffuse large B-cell lymphoma is now more common than Kaposi sarcoma, although Kaposi sarcoma remains the most common malignancy in people living with HIV worldwide.¹¹⁸ The pathophysiology of diffuse large B-cell lymphoma in HIV has been reviewed.^{119,120} In a recent case series, HIV+ patients presented with diffuse large B-cell lymphoma at a median age of 43 years, 2 decades younger than HIV– patients.¹²¹ Patients often present with a rapidly growing lymph node or extranodal mass, and frequently have B symptoms (drenching night sweats, fever, or loss of 10 percent of body weight). Involvement of extranodal sites, including the gastrointestinal tract, liver, CNS, lung, and other sites is common.^{121,122} Diagnosis is most commonly made by excisional lymph node biopsy. Evaluation should include careful examination of all lymph nodes sites, and the oral cavity. Standard staging with positron emission tomography–computed tomography (PET-CT), marrow evaluation, and lumbar puncture for cerebrospinal fluid cytology and flow cytometry¹²³ should be performed. Patients should be evaluated for hepatitis B prior to initiation of chemotherapy. If active hepatitis B is found (hepatitis B DNA+), it must be managed in the context of the HIV treatment, as several commonly used medications for hepatitis B are also active against HIV. Although initial studies in the pre-ART era focused on low-dose chemotherapy,¹²⁴ it is now appreciated that full-dose multi-agent systemic chemotherapy with appropriate supportive care using filgrastim or peg-filgrastim and prophylaxis against infectious complications, offers the best chance for permanent cure. Cohort studies show that the 5-year overall survival in the ART era is far better than the pre-ART era.¹²⁵ A National Cancer Institute study using six cycles of dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin (EPOCH), in which the initial cyclophosphamide dose was adjusted based on the CD4 count, and subsequent cycles cyclophosphamide dosing was adjusted based on the neutrophil nadir, showed an overall survival of 60 percent at 53 months (39 patients, 79 percent had diffuse large B-cell lymphoma, 18 percent had Burkitt lymphoma, and none were on ART during chemotherapy).¹²⁶ CD4 counts dropped by 190 cells/ μ L during chemotherapy, but recovered to baseline by 6 to 12 months following chemotherapy. All patients received *P. jiroveci* prophylaxis, and if CD4 counts were less than 100 cells/ μ L, *M. avium* complex prophylaxis. All patients also received filgrastim following each cycle of chemotherapy. This key study demonstrated that EPOCH is safe and effective in HIV+ patients with aggressive lymphoma. Outcomes differed markedly depending on the initial CD4 count: patients with an

TABLE 81–6. AIDS-Defining Malignancies and Oncogenic Viruses

AIDS-Defining Malignancy	Oncogenic Virus
Kaposi sarcoma	HHV8
Aggressive non-Hodgkin lymphoma	EBV, HHV8
Primary central nervous system lymphoma	EBV
Invasive cervical cancer	HPV

EBV, Epstein-Barr virus; HHV, human herpesvirus; HPV, human papillomavirus.

Figure 81-1. Number of AIDS-defining cancer cases in the United States in persons with and without AIDS by calendar year. (Reproduced with permission from Shiels MS, Pfeiffer RM, Hall HI, et al.: Proportions of Kaposi sarcoma, selected non-Hodgkin lymphomas, and cervical cancer in the United States occurring in persons with AIDS, 1980-2007. *JAMA* 13;305(14):1450-1459, 2011.)

initial CD4 count greater than 100 cells/ μ L had an 87 percent overall survival at 53 months, whereas those with CD counts of less than 100 cells/ μ L had a 16 percent overall survival at 53 months.¹²⁶ A larger multi-institution study done by the AIDS Malignancy Consortium (AMC-034) randomized patients to receive EPOCH with concurrent rituximab versus EPOCH with sequential rituximab (given weekly for 6 weeks following completion of EPOCH) in 101 patients with HIV-associated NHL (approximately 75 percent of the patients had diffuse large B-cell

lymphoma and 25 percent had mainly Burkitt lymphoma).¹²⁷ Administration of EPOCH with concurrent rituximab resulted in a high complete response rate (73 percent) in comparison to EPOCH with sequential rituximab (55 percent complete response rate). The National Cancer Institute evaluated short-course EPOCH with dose-dense rituximab (rituximab day 1 and day 5 of each cycle of EPOCH), and achieved an overall survival of 68 percent at 5 years in 33 patients with diffuse large B-cell lymphoma.¹²⁸ In this study, the initial cyclophosphamide dose

was 750 mg/m² (even in those patients with a low CD4 count) and was dose adjusted, depending on the neutrophil nadir, in subsequent cycles of EPOCH. Patients were treated to complete response plus one additional cycle. The majority (79 percent) of patients received three cycles of short-course EPOCH with dose-dense rituximab, and ART was suspended during chemotherapy because of concern about alteration in the pharmacokinetics or pharmacodynamics of the chemotherapy agents or overlapping toxicity. CD4 counts dropped a median of 64 cells/ μ L, and recovered to baseline by 6 to 12 months. Consistent with other studies, patients with initial CD4 counts of 100 cells/ μ L or greater had a much better 5-year overall survival (90 percent) than did the patients with a CD4 count of less than 100 cells/ μ L (20 percent). Cyclophosphamide, doxorubicin, vincristine, prednisone (CHOP) has also been studied in HIV+ patients with diffuse large B-cell lymphoma. In an AMC phase III multiinstitution clinical trial (AMC 010), patients with HIV-associated NHL (diffuse large B-cell lymphoma in 80 percent, Burkitt lymphoma in 9 percent) were randomized to six cycles of CHOP (n = 50) versus rituximab plus CHOP (R-CHOP) (n = 99), with all patients on ART.¹²⁹ The R-CHOP group also received three monthly doses of rituximab following completion of chemotherapy. Of note, the median CD4 count at enrollment was 133 cells/ μ L and 24 percent of the patients had advanced HIV with CD4 counts less than 50 cells/ μ L, so this was a fairly immunocompromised group of patients. Overall survival was identical with CHOP or R-CHOP, unlike HIV-negative patients in whom the addition of rituximab significantly improves outcome. In the AMC 010 clinical trial, there were significantly more deaths from infection in the R-CHOP arm in comparison to the CHOP arm, which offset the trend toward better control of lymphoma with R-CHOP. The majority of these infectious deaths occurred in patients with a CD4 count of less than 50 cells/ μ L, suggesting that rituximab should be used cautiously in immunologically vulnerable patients. As in studies of EPOCH, patients with a CD4 count greater than 100 cells/ μ L had a better overall survival than those with a lower CD4 count. Other reports suggest that R-CHOP treatment in HIV+ patients with diffuse large B-cell lymphoma is safe and effective,^{121,130} including in those with a low CD4 count.¹³¹ In a phase II study of modified R-CHOP in 40 patients with diffuse large B-cell lymphoma, pegylated liposomal doxorubicin was substituted for doxorubicin¹³² and the complete response rate was 48 percent, lower than what is reported with rituximab plus EPOCH (R-EPOCH) or R-CHOP. At the time of this writing, there are no phase III data comparing R-EPOCH to R-CHOP in HIV+ patients. Pooled analysis of two sequential AMC clinical trials, AMC 010 (99 patients on the R-CHOP arm) and AMC 034 (51 patients on the concurrent R-EPOCH arm) showed that the 2-year overall survival was approximately 50 percent with R-CHOP and approximately 65 percent with R-EPOCH (p < 0.01), suggesting superiority of R-EPOCH.¹³³ Similarly, a pooled analysis of 1546 patients enrolled in 19 prospective clinical trials, concluded that EPOCH was associated with a better overall survival than CHOP in patients with HIV-associated diffuse large B-cell lymphoma (hazard ratio 0.33, p = 0.03).¹³⁴ However these observations require validation in prospective randomized studies. For patients with relapsed or refractory HIV-associated diffuse large B-cell lymphoma, salvage regimens such as gemcitabine/dexamethasone/cisplatin¹³⁵ or etoposide, methylprednisolone, high-dose cytarabine, cisplatin (ESHAP)¹³⁶ can provide response rates of approximately 50 percent.

HUMAN IMMUNODEFICIENCY VIRUS-ASSOCIATED BURKITT LYMPHOMA

HIV-associated Burkitt lymphoma is approximately one-third as common as HIV-associated diffuse large B-cell lymphoma in the Western world, and occurs at a higher CD4 count.¹³⁷ In a Surveillance,

Epidemiology, and End Results (SEER) Registry-based study, there was an increase in the number of cases of Burkitt lymphoma in the United States in the late 1980s that is maintained to the present time (see Fig. 81-1), particularly in men, and is thought to be attributable to the HIV epidemic.¹³⁸ The pathogenesis of HIV-associated Burkitt lymphoma is similar to that of Burkitt lymphoma in HIV- people, and involves translocation of the *Myc* gene on chromosome 8 with one of the immunoglobulin genes on chromosomes, 2, 14, or 22, resulting in overexpression of *Myc*.¹³⁹ HIV-associated Burkitt lymphoma is an aggressive malignancy, and it is important to act decisively in these often very ill patients. More than 80 percent of patients with HIV-associated Burkitt lymphoma present with stage IV disease¹⁴⁰ and extranodal sites are often involved. Marrow, liver, gastrointestinal tract, kidney, and CNS involvement are common, with cranial nerve palsies a common feature of CNS involvement.¹⁴¹ The serum lactate dehydrogenase (LDH) is elevated in more than 80 percent of patients, often to high levels (greater than five-fold normal). A number of chemotherapy regimens have been studied in HIV+ patients with Burkitt lymphoma. As in the HIV- setting, CHOP is not adequate treatment for Burkitt lymphoma,^{140,142} and should not be used. Recent data show excellent outcomes with a variant of the R-EPOCH regimen.¹⁴³ In this single-institution, small prospective clinical trial, a total of 30 patients with Burkitt lymphoma were treated, including 11 who were HIV+ with a median CD4 count of 322 cells/ μ L. The short-course EPOCH-RR used in this clinical trial included two doses of rituximab per cycle of EPOCH, and a total of three or four cycles of EPOCH (to complete response plus one additional cycle), and included prophylactic intrathecal methotrexate. With a median follow up of 6 years, the overall survival of the HIV+ patients was 90 percent. The major toxicity was neutropenia in 31 percent of cycles of EPOCH-RR, and hospital admission for febrile neutropenia was required in 10 percent of cycles. This study showed that low-intensity therapy administered primarily in the outpatient setting can be effective for HIV-associated Burkitt lymphoma. Other studies of R-EPOCH that included a subset of patients with HIV-associated Burkitt lymphoma also report excellent outcomes with R-EPOCH.¹²⁷ Other regimens reported in patients with HIV-associated Burkitt lymphoma include cyclophosphamide, vincristine, doxorubicin, and dexamethasone (HyperCVAD) alternating with high-dose methotrexate plus cytarabine.¹⁴⁴ In this study, patients were very immunocompromised with a median CD4 count of 77 cells/ μ L; nevertheless, complete remission was achieved in more than 90 percent of patients, with 48 percent of patients alive at 2 years. Severe myelosuppression was universal, but infectious complications were similar to HIV- patients. In this small study, those on ART had a better outcome than those not on ART. Cyclophosphamide, vincristine, doxorubicin, methotrexate/ifosfamide, mesna, etoposide, cytarabine (CODOX-M/IVAC) has also been employed to treat HIV-associated Burkitt lymphoma,¹⁴⁵⁻¹⁴⁷ with 3-year overall survival of approximately 50 percent.¹⁴⁶ A retrospective review compared eight HIV+ patients who received CODOX-M/IVAC to 24 HIV- patients with Burkitt lymphoma¹⁴⁵. Patients had similar rates of myelosuppression, infection, and complete response regardless of HIV status. The LMB86 protocol (including high-dose methotrexate plus cytarabine) was used to treat HIV-related Burkitt lymphoma¹⁴¹ in a prospective single center study of 63 patients on ART. The complete response rate was 70 percent and the estimated disease-free survival at 2 years was 67 percent. This regimen was characterized by severe marrow toxicity, and more than 10 percent of patients died of regimen-related toxicity. Poor prognostic factors included a CD4 count of less than 200 cells/ μ L and an Eastern Cooperative Oncology Group (ECOG) performance status of greater than 2. Other intensive regimens have also been used, with 4-year overall survival of 70 percent, but with death in 11 percent from regimen-related toxicity.¹⁴⁸

HUMAN IMMUNODEFICIENCY VIRUS–ASSOCIATED PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMA

Primary CNS lymphoma in HIV+ patients is an Epstein-Barr virus (EBV)–related diffuse large B-cell lymphoma occurring in the brain, typically in patients with very advanced HIV: These patients usually have a CD4 count of less than 50 cells/ μ L, and often of less than 20 cells/ μ L.^{137,149–151} The epidemiology of primary CNS lymphoma illustrates the concept of specific types of lymphoma occurring at different levels of immunodepletion. The incidence of primary CNS lymphoma has declined markedly since the availability of ART (see Fig. 81–1).^{150,152} The pathophysiology of HIV-associated primary CNS lymphoma is related to EBV which is detectable in virtually all cases.¹³⁹ Primary CNS lymphoma should be considered in an HIV+ patient who presents with neurologic symptoms (confusion, cognitive decline, memory loss), headache, seizures, or ataxia. In one series, the most common symptom was headache, followed by memory loss, ataxia, and seizure.¹⁵³ Characteristic features on magnetic resonance imaging (MRI) of the brain include a single to several mass lesions in the subcortical white matter.¹⁵⁴ Anatomic sites commonly involved are predominantly the cerebral cortex and periventricular area, but the basal ganglia can be involved in up to one-third of cases. Cerebellar or brain stem involvement is rare.¹⁵⁰ A thorough physical exam for signs of systemic lymphoma is key, including a testicular exam as testicular lymphoma frequently involves the CNS. A slit-lamp exam to assess for vitreous disease should be done; this may assist in diagnoses of primary CNS lymphoma and may affect therapy. Evaluation with a chest, abdomen, and pelvic CT and a marrow aspirate and biopsy should be performed. If a lumbar puncture can be safely done, cerebrospinal fluid (CSF) should be sent for cytology and flow cytometry to evaluate for leptomeningeal involvement with lymphoma, and also for polymerase chain reaction (PCR) for EBV. Detection of EBV in the CSF supports, but does not confirm, the diagnosis of primary CNS lymphoma in these patients.¹⁵⁵ PET-CT of the brain can also help distinguish primary CNS lymphoma from other common causes of focal brain lesions in profoundly immunosuppressed patients with HIV, namely, cerebral toxoplasmosis and other infections.^{156,157} Evaluation of HIV+ patients with CNS mass lesions should include blood serology for toxoplasmosis, although a small percentage of patients with CNS toxoplasmosis will have negative serologies. Stereotactic brain biopsy should be performed if possible, but some lesions are not readily accessible to biopsy; in these cases, the diagnosis of primary CNS lymphoma may rest on CSF cytology, detection of EBV in the CSF, and the results of PET-CT. Because of the rarity of primary CNS lymphoma in the ART era, there are no large prospective clinical trial data to define optimal therapy. Case reports document long-term responses to initiation of ART as a sole intervention in a small number of patients who refused other therapy. All HIV+ patients with primary CNS lymphoma should be on effective ART. Systemic glucocorticoid treatment can temporarily ameliorate symptoms. Small retrospective series report that whole-brain radiation therapy can result in improved survival,¹⁴⁹ but approximately one-third of these patients had detectable leukoencephalopathy on followup. A large retrospective study found that treatment with whole-brain radiation therapy and/or chemotherapy was associated with a decreased risk of death,¹⁵¹ but this analysis is confounded by lack of information on performance status. Small numbers of patients have been treated with multiple cycles of high-dose methotrexate with leucovorin rescue, without radiation therapy, with prolonged survival and no cognitive dysfunction,^{158,159} and this may be a reasonable option in patients with good performance status. In the pre-ART era, median survival of the HIV+ patient with primary CNS lymphoma was approximately 2 months. The outcome has improved in

the present era, but remains inferior to that of patients without HIV.¹⁵³ The Center for AIDS Research database for 1996 to 2010 shows that the 2-year survival of HIV+ patients with primary CNS lymphoma was 24 percent, inferior to other major types of HIV-associated lymphoma (diffuse large B-cell lymphoma, Burkitt lymphoma, Hodgkin lymphoma).¹³⁷ Prior CNS opportunistic infection¹⁵¹ and poor performance status^{149,150} confer an increased risk of death.

HUMAN IMMUNODEFICIENCY VIRUS–ASSOCIATED PLASMABLASTIC LYMPHOMA

Described in 1997,¹⁶⁰ plasmablastic lymphoma is a rare and very aggressive B-cell NHL with plasmacytic differentiation that often involves the oral cavity, typically the gingiva and the palate. In the original report, 15 of the 16 cases were HIV+, and subsequent studies showed that plasmablastic lymphoma comprises approximately 2 to 3 percent of NHL in people living with HIV.¹⁶¹ A review of 112 cases of HIV-associated plasmablastic lymphoma showed that the median age of presentation was approximately 40 years, and the median CD4 count was approximately 180 cells/ μ L. Of the 112 patients, 58 percent had primary oral involvement. Other common sites of involvement were the gastrointestinal tract, the lymph nodes and skin, among other sites.¹⁶² In a recent series of 50 cases of plasmablastic lymphoma,¹⁶³ approximately 25 percent of the patients had oral cavity involvement, and extraoral involvement was common. Diagnosis requires biopsy. The pathology shows a monomorphic diffuse lymphoid infiltrate with cells resembling plasmablasts. The cells have a high proliferative rate with a Ki-67 often exceeding 90 percent, and are positive for plasma cell markers. CD20 is expressed in 2 percent or fewer of the cases and the majority of the cases (>80 percent) are EBV+. The differential diagnosis of an oral cavity lesion in a person with HIV includes odontogenic infection, squamous carcinoma, Kaposi sarcoma, and diffuse large B-cell lymphoma or Burkitt lymphoma.

Many of the patients with plasmablastic lymphoma have been treated with CHOP or with EPOCH, with poor outcome. In one retrospective series,¹⁶³ median overall survival was 11 months with no difference in outcome between CHOP versus more intensive chemotherapy (EPOCH, hyperCVAD, or other regimens). Data from the German AIDS Related Lymphoma Cohort Study in the ART era confirmed the poor outcome of these patients, with a median survival of 5 months.¹⁶⁴ There are no prospective clinical trials to define optimal treatment for patients with HIV-associated plasmablastic lymphoma. Case reports of individual patients suggest that bortezomib may have activity in these patients, and this should be explored in future clinical trials.^{165,166}

HUMAN IMMUNODEFICIENCY VIRUS–ASSOCIATED PRIMARY EFFUSION LYMPHOMA

Primary effusion lymphoma is an aggressive B-cell lymphoma characterized by lymphomatous effusions in body cavities, most commonly pleural effusion,^{167,168} followed by ascites and pericardial effusion or multiple body cavities; lymph nodes, marrow, and skin can also be involved. A solid variant of primary effusion lymphoma presents without effusion, but with lymph node, gastrointestinal, skin, or liver involvement has been reported.¹⁶⁹ Primary effusion lymphoma comprises approximately 4 percent of HIV-associated NHL¹⁷⁰ and occurs much more frequently in men than in women (10:1 ratio), usually associated with low CD4 counts (50 to 200 cells/ μ L).¹⁷¹ Of primary effusion lymphoma cases, 100 percent are human herpesvirus-8+ (HHV8+), and approximately 80 percent are EBV+. HHV8 plays a key pathophysiologic role, possibly by elaboration of a viral homologue of FLICE inhibitory protein and

a viral homologue of interleukin (IL)-6.¹²⁰ Other HHV8-related disorders include Castleman disease and Kaposi sarcoma, both of which may coexist with primary effusion lymphoma in a substantial proportion of patients.¹⁶⁸ Patients may present with dyspnea from pleural effusions or new-onset ascites. A high index of suspicion for lymphoma is needed so that appropriate samples are sent to Hematopathology for analysis. Primary effusion lymphoma cells have an immunoblastic, plasmablastic, or anaplastic appearance and are CD45+ and CD30+; CD20 is expressed less than 5 percent of the time. The malignant cells are latently infected with HHV8, which is detectable by immunocytochemistry. There are no large prospective studies of treatment of primary effusion lymphoma, a consequence of its rarity, and the majority of the available information is derived from retrospective case series. There are a few case reports of complete remission following initiation of ART without chemotherapy, and ART should be a component of the treatment plan. Patients have been treated with CHOP, EPOCH, and other regimens. Approximately 50 percent of patients with primary effusion lymphoma achieve a complete response, but relapse within the next few months is common, and the median survival is approximately 6 months, with most deaths a result of progressive lymphoma. In one series, poor prognostic features included an ECOG performance status greater than 2 and ART non-compliance. Promising preclinical data show that treatment with the anti-CD30 agent brentuximab vedotin¹⁷² or bortezomib with or without vorinostat¹⁷³ can decrease growth of primary effusion lymphoma cell lines and prolong survival in a mouse xenograft model.

Prognosis

As ART improves, the prognosis for patients with HIV-associated NHL is defined mainly by lymphoma-related features, and less by HIV.¹²¹ A retrospective review of patients with HIV-associated diffuse large B-cell lymphoma diagnosed in the pre-ART era (120 patients), and in the ART era (72 patients) showed a median survival of 8 months in the pre-ART era and 43 months in the ART era; this held true for each of the different International Prognostic Index groups.¹²⁵ Pooled data for 1546 patients with HIV-associated diffuse large B-cell lymphoma or Burkitt lymphoma who had been enrolled in phase II or phase III clinical trials was evaluated to identify treatment-related factors associated with overall survival. The use of rituximab was significantly associated with improved overall survival (hazard ratio 0.55, $p < 0.001$) for patients with a CD4 count of greater than 50 cells/ μL but not for those patients with CD4 counts of less than 50 cells/ μL . A focus on the 1059 patients with diffuse large B-cell lymphoma suggested that treatment with EPOCH resulted in a better overall survival (hazard ratio 0.33, $p = 0.031$) than treatment with CHOP. On multivariate analysis of R-EPOCH versus R-CHOP, the hazard ratio for overall survival was 0.34 favoring R-EPOCH, although this did not achieve statistical significance. An enhanced internal prognostic index based on 650 adults with *de novo* diffuse large B-cell lymphoma treated at seven National Comprehensive Cancer Network Cancer Centers in the rituximab era included a small portion of HIV+ patients.¹⁷⁴ Patients were risk stratified on an 8-point scale. Patients with a low score (0 to 1 points) had a 5-year overall survival of 96 percent; patients with a low intermediate score (2 to 3 points) had a 5-year overall survival of 82 percent; patients with a high intermediate score (4 to 5 points) had a 5-year overall survival of 64 percent, and patients with high risk (6 to 8 points) had an overall 5-year survival of 33 percent. This scale offered better risk stratification than the original International Prognostic Index, which was developed in the prereduction era. It is recommended that this enhanced International Prognostic Index be used as a guide, in addition to the very robust data that patients with CD4 counts of less than 100 cells/ μL at the time of diagnosis of lymphoma have a much worse outcome than those with higher CD4 counts.

HUMAN IMMUNODEFICIENCY VIRUS-ASSOCIATED HODGKIN LYMPHOMA

Hodgkin lymphoma tends to occur at moderate levels immunosuppression in HIV+ patients, unlike NHL, where the risk increases as the CD4 count decreases.¹⁷⁵ A retrospective cohort study from the Veterans Administration Clinical Case Registry from 1985 to 2010 showed that Hodgkin lymphoma was most common in patients with CD4 counts of 200 to 350 cells/ μL . The risk was highest in the first year after starting ART, and was lower in people with a greater percent of time with an undetectable viral load.¹⁷⁶ Data from 14 U.S. Cancer Registries representing 25 percent of the U.S. population was used to compare the clinical features of HIV+ and HIV- patients with Hodgkin lymphoma in the ART era.¹⁷⁷ In this study, Hodgkin lymphoma occurring in HIV+ people was shown to be a clinically aggressive disease. Of the 22,355 patients with Hodgkin lymphoma, 3.8 percent were HIV+. However this percentage varied depending on sex, ethnicity, and age. Prevalent HIV infection was higher in men (6 percent) than in women (1.2 percent), and among men in the 40- to 59-year-old age group, those newly diagnosed with Hodgkin lymphoma had a 14.2 percent chance of being HIV+. Non-Hispanic blacks with newly diagnosed Hodgkin lymphoma had a 16.9 percent chance of being HIV+ and Hispanics with newly diagnosed Hodgkin lymphoma had a 9.9 percent chance of being HIV+. Unlike NHL, the incidence of Hodgkin lymphoma is comparable in the pre- and post-ART era. The pathology of Hodgkin lymphoma in HIV+ cases differs from that of HIV- cases, with a higher percent of HIV+ patients having a more aggressive histology (mixed cellularity or lymphocyte depleted; Table 81-7). An HIV-AIDS cancer match study that linked HIV and cancer registry data found that an even higher percent of patients with HIV-associated Hodgkin lymphoma had mixed cellularity on biopsy (53.7 percent).¹⁷⁵ The Ann Arbor stage at diagnosis is higher in HIV+ Hodgkin patients than in HIV- cases, with 41.5 percent of those with HIV+ Hodgkin lymphoma having stage IV disease at presentation, compared to 17 percent of those with HIV- Hodgkin lymphoma (Table 81-7). B symptoms (drenching night sweats, fever, or loss of 10 percent of body weight) are also more common in HIV+ patients with Hodgkin lymphoma (Table 81-7).¹⁷⁷

A retrospective study of Adriamycin, bleomycin, vinblastine, and dacarbazine (ABVD) chemotherapy in 62 HIV+ patients newly diagnosed with advanced-stage Hodgkin lymphoma showed that ABVD and ART could be given safely together.¹⁷⁸ In this study, the median CD4 count at diagnosis was 129 cells/ μL , and all patients had stage III or stage IV Hodgkin lymphoma. Patients received ABVD with filgrastim support, as well as trimethoprim-sulfamethoxazole or pentamidine for *P. jiroveci* prophylaxis. The overall survival was 76 percent at 5 years, with treatment-related mortality of 10 percent. In a large retrospective study¹⁷⁹ of 93 HIV+ patients and 131 HIV- patients with Hodgkin lymphoma who were treated with ABVD, (HIV+ patients also received concomitant ART), those with stage I or II nonbulky disease received four cycles of ABVD plus involved field radiation therapy; the rest received six cycles of ABVD with involved field radiation therapy if bulky disease was present. All patients received prophylaxis for opportunistic infections. The HIV+ patients had more advanced-stage Hodgkin lymphoma and a worse International Prognostic Score¹⁸⁰; despite this the 5-year overall survival was 81 percent for the HIV+ patients compared to 88 percent for the HIV- patients, a nonsignificant difference. This retrospective case series demonstrated comparable overall survival in HIV+ and HIV- patients with Hodgkin lymphoma, and that ART could be given safely with ABVD chemotherapy.

The German HIV Related Lymphoma Study Group¹⁸¹ conducted a prospective multicenter study in which HIV+ patients with early stage favorable Hodgkin lymphoma were treated with two to four cycles of

TABLE 81-7. Characteristics of Hodgkin Lymphoma in HIV+ and HIV- Populations

	HIV+	HIV-

ABVD plus 30 Gy of involved field radiation therapy, while patients with early stage unfavorable Hodgkin lymphoma received four cycles of bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine, procarbazine, and prednisone (BEACOPP) baseline or four cycles of ABVD plus 30 Gy of involved field radiation therapy. More advanced-stage Hodgkin lymphoma patients received six to eight cycles of BEACOPP. Patients with advanced HIV infection (defined as two of the following: CD4 count <50 cells/ μ L, prior AIDS-defining opportunistic infection, performance status >2) were treated with six to eight cycles of ABVD. ART was used with chemotherapy. CD4 count decreased with chemotherapy, but recovered over the subsequent 6 to 9 months and treatment-related mortality was 5.6 percent, mainly from sepsis. Using this risk-adapted approach, the 2-year overall survival was 90.7 percent, comparable to HIV- patients with Hodgkin lymphoma.

Areas of controversy in treatment of Hodgkin lymphoma in HIV- patients include whether BEACOPP escalated is better than ABVD for advanced Hodgkin lymphoma.^{182–184} Until this controversy is settled, most authorities recommend using ABVD for patients with HIV-associated Hodgkin lymphoma. Brentuximab vedotin, an antibody-drug conjugate that targets CD30, has been combined with Adriamycin, vinblastine, and dacarbazine (AVD) to treat HIV- patients with Hodgkin lymphoma.¹⁸⁵ Whether brentuximab vedotin plus AVD will be effective for HIV+ patients with Hodgkin lymphoma is being addressed in a prospective phase II clinical trial being done by the AMC (AMC 085).

In the ART era, HIV+ patients with Hodgkin lymphoma have similar excellent outcomes with systemic chemotherapy as do

HIV- patients. This is corroborated by the SEER Study¹⁷⁷ in which the 5-year risk of death from Hodgkin lymphoma was 6.2 percent in the HIV+ patients and 9 percent in the HIV- patients. However, this interpretation is confounded by competing risks of death: the overall risk of death was higher in the HIV+ cohort, and the majority of the deaths were from HIV. Many¹⁷⁹ but not all¹⁸¹ studies conclude that the International Prognostic Score has predictive value for HIV+ patients with Hodgkin lymphoma.

Stem Cell Transplant

There is more than a decade of experience in high-dose therapy followed by autologous blood stem cell transplantation showing that this technique is feasible, safe, and effective in patients with HIV and NHL or Hodgkin lymphoma.^{186,187} Adequate numbers of blood stem cells can be mobilized in the majority of patients with HIV-associated NHL or Hodgkin lymphoma. A retrospective study of 155 patients with either NHL or Hodgkin lymphoma in the ART era showed that mobilization of greater than 2×10^6 CD34+ cells/kg was achieved in 73 percent of patients and greater than 5×10^6 CD34+ cells/kg was achieved in 48 percent. Factors reducing the chance of optimal mobilization included a low platelet count, a low CD4 count, and use of filgrastim alone, rather than chemotherapy plus filgrastim, to mobilize blood stem cells.¹⁸⁸

Studies of autologous blood stem cell transplantation in HIV+ patients with NHL (mainly diffuse large B-cell lymphoma) or Hodgkin lymphoma show that outcomes are similar to those reported for patients without HIV infection.^{189,190} The median time to neutrophil and platelet engraftment is 11 and 14 days, respectively. The risk for nonrelapse mortality is in the 5 to 8 percent range and the overall survival at 3 to 4 years after transplantation is approximately 50 percent.^{191–193} These patients were supported throughout the transplantation with ART, as well as with antibacterial, antifungal, and antiviral prophylaxis. The European group for Blood and Marrow Transplant performed a case-control study that included 53 HIV+ patients with either NHL (two-thirds of patients) or Hodgkin lymphoma (one-third of patients) that matched patients on the basis of histology, Ann Arbor stage, International Prognostic Index and disease status. The overall survival, progression-free survival, and relapse rates were similar in the HIV+ and the HIV- groups across all histologies and disease states. Nonrelapse mortality at 1 year was 8 percent in the HIV+ group and 2 percent in the HIV- group; the difference mainly was a result of early bacterial infections. Overall survival at 30 months was 59 percent for both HIV+ and HIV- patients with NHL, and the main cause of death in both HIV+ and HIV- patients was relapse. A single-institution matched case-control study of HIV+ and HIV- NHL patients showed nonrelapse mortality of 11 percent in the HIV+ group, and 4 percent in the HIV- group. Overall survival at 2 years was 75 percent for both the HIV+ and HIV- groups.¹⁹⁰ Thus, HIV status did not affect the outcome of autologous transplantation for NHL although there were more viral opportunistic infections, particularly cytomegalovirus (CMV), adenovirus, and varicella in the HIV+ population. The main cause of death was relapse and the major predictor of outcome in both groups was disease status at time of transplantation. Together these data suggest that long-term outcomes are similar in the HIV+ and HIV- patients who undergo autologous blood stem cell transplant in the setting of NHL or Hodgkin lymphoma and the reconstitution of neutrophils and platelets are similar in both groups.¹⁹⁴ Experience with allogeneic stem cell transplantation HIV+ patients is less extensive.^{195–197} This remains an area of intensive research, in part because of the report of cure of HIV in a patient who underwent allogeneic transplant to treat acute myeloid leukemia and received a donor graft that was homozygous for a deletion mutation eliminating the chemokine and HIV coreceptor CCR5.¹⁰⁹

Antiretroviral Therapy and Chemotherapy

Controversy persists regarding whether ART should be initiated or continued during multiagent systemic chemotherapy. In the pre-ART era, the outcomes for treatment of lymphoma in HIV+ patients were markedly inferior to the present era.¹²⁵ Some clinical trial groups stop or do not initiate ART during systemic chemotherapy,¹⁹⁸ whereas others continue ART or initiate ART after the first cycle of chemotherapy in those patients not on ART at time of lymphoma diagnosis.^{199,200} Certain classes of ART medications, notably protease inhibitors and nnRTIs can alter the metabolism of other medications primarily through inhibition or induction of the cytochrome P450 enzymes, potentially leading to higher or lower concentrations of other drugs (including chemotherapy agents).²⁰¹ Unfortunately, there are limited pharmacokinetic data from clinical trials to elucidate these potential drug interactions and their effects on drug levels. Chemotherapy agents eliminated by non-P450 routes are less likely to be affected by ART. A study of 154 HIV+ patients with a broad range of malignancies (many with hematologic malignancies) treated at the MD Anderson Cancer Center showed that clinically relevant drug interactions between ART and chemotherapy drugs were rare (4 percent of cases) and confined to the protease inhibitor class.²⁰² The nnRTIs and the integrase strand-transfer inhibitors had a better safety profile when combined with chemotherapy than did the protease inhibitors, in this retrospective series. Others have also found that protease inhibitors may exacerbate chemotherapy-induced neutropenia,²⁰³ although this is controversial.^{204,205} A retrospective review of 34 patients with diffuse large B-cell lymphoma showed similar complete response rates and toxicities in those receiving CHOP while also on an HIV protease inhibitor as those who were receiving a nonprotease inhibitor ART regimen.²⁰⁶ In another study of HIV+ patients with Hodgkin lymphoma receiving ABVD chemotherapy, the use of the protease inhibitor ritonavir appeared to increase the risk of peripheral neuropathy.²⁰⁷ More accurate information regarding drug interactions between ART and chemotherapy agents will become available through the AMC, which is currently conducting clinical trials in which patients are stratified by the type of ART and its potential for inducing or inhibiting cytochrome P450 enzymes, and obtaining detailed pharmacokinetic data. With the growing number of available ART agents, including integrase strand-transfer inhibitors, it is usually possible to adjust an ART regimen that minimizes potential drug interactions but still suppresses HIV replication throughout the course of chemotherapy.

A second issue is overlapping toxic effects between ART and chemotherapy drugs. Zidovudine causes marrow suppression, and should be avoided in patients receiving myelosuppressive chemotherapy. Didanosine and stavudine (older, infrequently used agents) cause peripheral neuropathy, and their use should be reconsidered in patients who will receive potentially neurotoxic chemotherapy. Atazanavir, a commonly prescribed protease inhibitor, causes unconjugated hyperbilirubinemia similar to Gilbert syndrome and can complicate the administration of some chemotherapy agents. However, if there is no other evidence of hepatotoxicity, chemotherapy can be given at standard doses. Earlier studies suggested some ART drugs (saquinavir, efavirenz, nelfinavir) might cause cardiac conduction abnormalities (prolongation of the electrocardiographic "QTc interval"), but this has not been confirmed in subsequent studies. If the patient is stable on ART with excellent HIV virologic control, a reasonable approach is to consult the infectious diseases physician who is managing the patient and also the chemotherapy pharmacist to identify potential drug interactions between ART and the planned chemotherapy, to adjust ART as necessary, and then proceed with chemotherapy with concurrent ART. If the patient is not on ART, it is reasonable to give one cycle of chemotherapy and then start ART with the second cycle of chemotherapy following

multidisciplinary consultation with the pharmacist and infectious diseases physician.

HUMAN IMMUNODEFICIENCY VIRUS-ASSOCIATED CASTLEMAN DISEASE

Castleman disease is a rare polyclonal lymphoproliferative disorder characterized by periodic flares (an inflammatory illness accompanied by lymphadenopathy and splenomegaly), and a high risk of progression to lymphoma.²⁰⁸ Castleman disease occurs with higher frequency in people living with HIV.²⁰⁹ The pathophysiology of Castleman disease is related to IL-6 (reviewed in Ref. 210). Virtually all patients with HIV-associated Castleman disease are infected with HHV8, whose viral genome encodes a viral homologue of IL-6. Sequential analysis of human IL-6, viral IL-6, and a variety of other cytokines in patients with HIV-associated Castleman disease during and after flares showed that either human IL-6, viral IL-6, or both were elevated during the flare and diminished during remission.²¹¹ IL-6 is a proinflammatory cytokine and stimulates polyclonal proliferation of B lymphocytes. Serologic evidence of HHV8 infection is present in 7 percent of healthy U.S. blood donors,²¹² but few healthy adults or HIV+ patients without Castleman disease, Kaposi sarcoma, or primary effusion lymphoma have detectable HHV8 virus in the blood. More than 80 percent of HIV+ patients with symptomatic multicentric Castleman disease have detectable HHV8 viremia, often at a high level.²⁰⁹ A retrospective analysis of 52 HIV+ patients with multicentric Castleman disease at time of presentation²¹³ showed that more than 50 percent of the patients had a prior diagnosis of Kaposi sarcoma, and 80 percent were on ART. The mean CD4 count at time of diagnosis of Castleman disease was 287 cells/ μ L, indicating that Castleman disease occurs in moderately immunocompromised patients. Symptoms at presentation included fever, lymphadenopathy, and splenomegaly in 98 to 100 percent, pulmonary symptoms in 60 percent, and edema in 40 percent of patients. A single-institution study of 113 patients with Castleman disease²¹⁴ also reported that approximately half of the patients had a prior diagnosis of Kaposi sarcoma. The median CD4 count in this study was 188 cells/ μ L. The ECOG performance status at diagnosis of Castleman disease was greater than 2 in 45 percent of patients, 36 percent had hemophagocytosis, and 30 percent required an ICU stay, illustrating how ill these patients often are. During a Castleman disease flare, patients may rapidly develop cytopenias: half the patients in this series had a hemoglobin of less than 8 g/dL and 29 percent had a platelet count of less than 150,000/ μ L. High C-reactive protein (often 10-fold higher than normal) and plasma HHV8 levels (median 30,000 copies/mL, range: 60 to 1 million copies/mL) are found during a flare,^{215,216} and these values can be helpful. Diagnosis requires a lymph node biopsy that is consistent with Castleman disease, ideally an excisional biopsy rather than a needle biopsy. The morphology of multicentric Castleman disease in HIV+ patients shows plasmablastic cells in the mantle zone of the follicles; HHV8 is detectable in the plasmablasts.²¹⁷ Often, lymph nodes diagnostic of Castleman disease also contain malignant appearing spindle cells characteristic of Kaposi sarcoma.

Castleman disease is rare, and treatment recommendations are largely based on case series and small clinical trials. Several clinical trials show that the anti-CD20 monoclonal antibody rituximab is very effective for treatment of Castleman disease. Prospective studies^{213,218,219} demonstrate that 375 mg/m² of rituximab administered intravenously weekly for 4 doses resulted in rapid symptomatic improvement, and 90 percent of patients achieved a response that lasted for more than 6 months. Clinical improvement with rituximab may begin within hours to days and is associated with diminished levels of serum IL-6.²²⁰ In one series of 113 HIV+ patients with multicentric Castleman disease, some

of whom received rituximab, the overall median survival was longer than 12 years with therapy; this is much improved in comparison to 20 years ago when Castleman disease was rapidly fatal.

Incipient flares of Castleman disease may be heralded by cytopenias, increased C-reactive protein, or by increased levels of HHV8 in the blood.²¹⁶ Serial studies of 52 HIV+ patients with multicentric Castleman disease showed that approximately 75 percent had elevated C-reactive protein and 90 percent had detectable plasma HHV8 during a flare, with a median HHV8 viral load of 27,000 copies/mL. HHV8 was detectable in 38 percent of patients during remission. If relapse occurs, patients can safely be retreated with rituximab.²²¹ Up to 20 percent of HIV+ patients with Castleman disease will develop lymphoma,^{208,214} often primary effusion lymphoma, plasmablastic lymphoma, or diffuse large B-cell lymphoma, but occasionally Hodgkin lymphoma, so it is important to consider this during followup. Use of rituximab to treat Castleman disease may decrease the risk of subsequent NHL.²¹⁴ In HIV+ patients with both Castleman disease and Kaposi sarcoma, Kaposi sarcoma may progress following treatment with rituximab.^{218,219,222} When Kaposi sarcoma involves a key clinical location such as the lungs, where progression might result in significant respiratory compromise, a regimen of rituximab plus liposomal doxorubicin can be considered to address both the Castleman disease flare and Kaposi sarcoma.²²³ R-CHOP or other multiagent systemic chemotherapy has also been used to treat Castleman disease, but given the excellent response to rituximab alone, R-CHOP is usually not necessary. An alternative therapeutic approach focuses on the central role of IL-6. A multiinstitution, randomized, placebo-controlled clinical trial of an anti-IL-6 monoclonal antibody siltuximab in 79 HIV- patients with Castleman disease showed a 34 percent response rate.²²⁴ Siltuximab was given IV every 3 weeks and can be administered long-term (up to 60 months).²²⁵ Siltuximab is FDA-approved for treatment of Castleman disease in HIV- patients but not in HIV+ patients. Tocilizumab, an anti-IL-6 receptor monoclonal antibody has been FDA-approved for use in rheumatoid arthritis. Tocilizumab had short-term effects in two HIV+ patients with Castleman disease, but both patients relapsed within 6 months and required subsequent treatment with rituximab.²²⁶ Tocilizumab is not FDA-approved for treatment of Castleman disease. Another approach to treatment of Castleman disease is to use antiviral therapy, such as ganciclovir, valganciclovir, foscarnet, cidofovir, or zidovudine, to suppress HHV8 replication.^{227,228} When 14 HIV+ patients with Castleman disease were treated with high-dose zidovudine plus valganciclovir, the C-reactive protein level, human IL-6 levels and HHV8 viral load improved. The median progression-free period was 6 months and the major toxicity was marrow suppression. However, until additional information is available from clinical trials, the data at this time most strongly support the use of rituximab as the backbone of treatment of Castleman disease.

KAPOSI SARCOMA-ASSOCIATED HERPESVIRUS-ASSOCIATED INFLAMMATORY CYTOKINE SYNDROME

A new syndrome termed Kaposi sarcoma-associated herpesvirus (KSHV)-associated inflammatory cytokine syndrome (KICS) is characterized by an inflammatory illness similar to a flare of Castleman disease, but without the pathologic diagnosis of Castleman disease.²²⁹⁻²³¹ Patients present with fever, sweating, anorexia, leukopenia, anemia, thrombocytopenia, hypoalbuminemia, and hyponatremia, and may also have dyspnea or abdominal pain. Four of the six patients in the original report also had severe manifestations of Kaposi sarcoma. Patients with KICS have a very high HHV8 viral load, similar to that seen in patients during a flare of multicentric Castleman disease. Levels of other cytokines, including human IL-6, viral IL-6, and IL-10, are similar in KICS

and multicentric Castleman disease patients, and much higher than in patients with isolated Kaposi sarcoma. Whether KICS represents a *form fruste* of multicentric Castleman disease, part of the clinical spectrum of Castleman disease, or a distinct clinical syndrome requires more investigation. There is scant information on treatment of KICS.

HUMAN IMMUNODEFICIENCY VIRUS-ASSOCIATED HEMOPHAGOCYTIC SYNDROME

Hemophagocytic syndrome is a rare and potentially fatal disorder characterized by excess immune activation that occurs with increased frequency in people living with HIV. An autopsy study in the pre-ART era identified hemophagocytosis in 20 percent of 56 patients who died of AIDS.²³² The pathogenesis of the hemophagocytic syndrome results from failure to regulate the immune response, resulting in excess activation of T lymphocytes, increased cytokine secretion, and hyperactivation of macrophages. There are primary and secondary forms of hemophagocytic syndrome. Secondary forms can occur in the setting of infection, hematologic malignancy, or autoimmune disease.²³³ In HIV+ patients, the hemophagocytic syndrome is usually secondary to a viral infection, either HIV itself or, more commonly, a member of the herpes virus family (EBV, CMV, HHV8), but can also occur in patients with Hodgkin lymphoma, NHL, or Castleman disease.²³⁴ A study of 58 HIV+ patients with hemophagocytic syndrome performed in the ART era²³⁴ showed that the median duration of HIV at the time of diagnosis was 4 years. Most patients were on ART, and the median CD4 count was 91 cells/ μ L, demonstrating advanced HIV disease. Patients with hemophagocytic syndrome are typically very ill: greater than 40 percent of the patients in this series required ICU care and 31 percent died within a year of diagnosis. The clinical features of hemophagocytic syndrome in HIV+ patients include fever, hepatosplenomegaly, and cytopenias. Patients often have a markedly elevated ferritin (greater than 10-fold the upper range of normal), coagulopathy, and increased triglycerides.²³⁴

The differential diagnosis of hemophagocytic syndrome in HIV+ patients includes a Castleman disease flare or KICS, and the clinical features of these syndromes may overlap. [Table 81-8](#) shows the diagnostic criteria for hemophagocytic syndrome. If an underlying trigger for the hemophagocytic syndrome is identified, specific therapy should be directed at the trigger. Treatment for hemophagocytic syndrome is standardized using the Histiocytosis Society 1994 protocol²³⁵ or the

TABLE 81-8. Diagnostic Criteria for Secondary Hemophagocytic Syndrome*

1. Fever $\geq 38.5^{\circ}\text{C}$
2. Splenomegaly
3. Cytopenias in at least 2 of 3 lineages (hemoglobin < 9 g/dL, platelets $< 100,000/\mu\text{L}$, neutrophils $< 1000/\mu\text{L}$)
4. Hypertriglyceridemia (fasting > 265 mg/dL) and/or low fibrinogen (< 150 mg/dL)
5. Hemophagocytosis found on biopsy of the marrow, spleen, lymph nodes, or liver
6. Low or absent natural killer cell activity
7. Ferritin > 500 mg/mL
8. Elevated soluble CD25

*Presence of 5 of these 8 criteria is required for diagnosis of hemophagocytic syndrome.

Adapted with permission from Henter JI, Horne A, Arico M, et al: HLH-2004: Diagnostic and therapeutic guidelines for hemophagocytic lymphohistiocytosis. *Pediatr Blood Cancer* 48(2):124-131, 2007.

Histiocytosis Society 2004 protocol²³⁶ (Chapter 71). Caution regarding interaction of cyclosporine with specific ART medications is warranted.

ANEMIA AND HUMAN IMMUNODEFICIENCY VIRUS

Anemia is common in people living with HIV. The multisite Adult and Adolescent Spectrum of HIV Disease Surveillance Project²³⁷ included approximately 32,000 HIV+ people living in the United States in the pre-ART era, 1990 to 1996. In this study, the first hemoglobin measured was less than 10 g/dL in 37 percent of men and 43 percent of women with clinical AIDS (an AIDS-defining illness). Even patients with a CD4 count of greater than 200 cells/ μ L and no AIDS-defining illness had a high prevalence of anemia: 28 percent of men and 31 percent of women had anemia defined as hemoglobin less than 14 g/dL for men or less than 12 g/dL for women. At the 1-year followup, the incidence of anemia was 3.2 percent for HIV+ people without immunologic or clinical AIDS, 12.1 percent for those with immunologic AIDS, and 36.9 percent for those with clinical AIDS. Notably, anemia was associated with a 1.5- to 2.5-fold increased risk of death during followup.²³⁷ One prospective study showed a moderate correlation between the hemoglobin and CD4 count at entry into the cohort, and found that initiation of ART could increase the hemoglobin value.²³⁸ Similarly, interruption of ART increased the risk of anemia.²³⁹ An investigation of 2056 HIV+ women at six sites in the United States showed that use of ART for as little as 6 months was associated with improvement of anemia,²⁴⁰ while several factors, including CD4 count less than 200 cells/ μ L, HIV viral load greater than 50,000 copies/mL, and mean corpuscular volume less than 80 fL were associated with decreased ability to correct the anemia. Anemia was identified as a key prognostic factor in large European and South African HIV+ cohorts.^{241,242} The Veterans Aging Cohort Study evaluated HIV+ patients who had been on ART for 1 year, to identify factors predictive of mortality.²⁴³ This study identified age, CD4 count, HIV viral load, hemoglobin, glomerular filtration rate, presence or absence of hepatitis C, and a composite measure of liver function as predictive factors for mortality. Even a mild decrease in the hemoglobin contributed significantly to mortality in this index. The Veterans Aging Cohort Study Index was subsequently validated in an independent cohort.²⁴⁴ Thus, even in the ART era, anemia is associated with a worse prognosis, independent of the traditional risk markers such as the CD4 count and the HIV viral load.

Pathophysiology of Anemia in Human Immunodeficiency Virus

There are many pathophysiologic causes of anemia in HIV+ people (Table 81-9), and often anemia in an individual is multifactorial in origin. Unique to HIV are the effects of the virus on hematopoiesis, including direct infection of hematopoietic progenitor cells (impairing their survival, proliferation, differentiation, and maturation), infection of marrow stromal cells (affecting their ability to support hematopoiesis in the marrow microenvironment²⁴⁵), and alterations in hematopoietic growth factor production or function. Additionally, HIV infection is associated with a chronic inflammatory state³⁸ that may also contribute to ineffective erythropoiesis. Markers of inflammation, including IL-6, are higher in HIV+ individuals than in their HIV- counterparts, and this holds true even for those on ART with an undetectable viral load.⁶⁹ Inflammation, in part mediated by IL-6, upregulates hepcidin, a key regulator of iron trafficking, and serum hepcidin levels are inversely correlated with CD4 counts.^{246,247}

Attempts to infect normal hematopoietic progenitor cells *in vitro* with HIV and studies of hematopoietic progenitor cells obtained from HIV+ patients initially suggested that HIV infection of hematopoietic

TABLE 81-9. Causes of Anemia in Human Immunodeficiency Virus

DECREASED PRODUCTION
HIV effect on hematopoiesis
Marrow infiltration (e.g., <i>Mycobacterium avium</i> complex, histoplasmosis, non-Hodgkin lymphoma, Hodgkin lymphoma)
Pure red cell aplasia (Parvovirus B19)
Drug suppression of hematopoiesis (e.g., Zidovudine)
Nutritional deficiency (e.g., vitamin B ₁₂ , folate, iron)
Inflammation
INCREASED DESTRUCTION
Thrombotic thrombocytopenic purpura
Immuno-hemolytic anemia
Glucose-6-phosphate dehydrogenase deficiency (e.g., dapsone, trimethoprim-sulfamethoxazole)
Hemophagocytic syndrome

Gastrointestinal bleeding (e.g., Kaposi sarcoma in gastrointestinal tract)

progenitor cells was an infrequent event. However, subsequent studies of HIV subgroup C (the subtype that predominates in African populations) showed that a proportion of burst-forming unit-erythroid (BFU-E), granulocyte-macrophage colony-forming units (CFU-GM), and granulocyte-erythrocyte-monocyte and megakaryocyte colony-forming units (CFU-GEMM) can be infected with HIV *in vitro*.²⁴⁸ The proportion of hematopoietic progenitor cells that could be infected with HIV subtype B (the predominant subtype in the United States and in Europe) was smaller (in the 1 percent range). Proviral HIV was detected by PCR in a small fraction of isolated CD34+ cells from some but not all HIV+ patients on ART with an undetectable viral load,²⁴⁹ suggesting that HIV can latently infect hematopoietic progenitor cells *in vivo*; similar results were obtained using CD133+ sorted marrow cells.²⁵⁰ Recent studies using a specific strain of humanized mice showed that some human CD34+, CD38+ intermediate progenitor cells could be infected with HIV *in vivo*, and that these progenitor cells when cultured *in vitro* had impaired growth, particularly in the erythroid and megakaryocytic lineages.²⁵¹

The normal response of the kidneys to a decline in hemoglobin is to produce more erythropoietin. However in HIV+ people, the incremental increase in erythropoietin is blunted.^{252,253} Additionally, antierythropoietin antibodies can be detected in a portion of HIV+ patients and are associated with increased risk of anemia.²⁵⁴ The antierythropoietin antibodies recognize a peptide that is needed for erythropoietin binding to the erythropoietin receptor. This peptide has sequence homology to an HIV protein, suggesting molecular mimicry as a potential mechanism for development of the antierythropoietin antibodies.²⁵⁵

A cross-sectional study of 200 HIV+ patients in San Francisco during the ART era suggested an association between low testosterone levels and anemia in men living with HIV.²⁵⁶ Hypogonadism is associated with weight loss, osteoporosis, and AIDS wasting syndrome, but whether testosterone treatment can correct anemia in these patients awaits further study.

Another, occasionally dramatic, cause of anemia in those living with HIV is pure red cell aplasia caused by parvovirus B19. Parvovirus

B19 is a small DNA virus that infects and lyses late human erythroid precursor cells,²⁵⁷ causing transient reticulocytopenia in immunocompetent patients. The clinical spectrum of parvovirus B19–related disease includes “slapped cheek rash” in children and arthralgias in adults, but most immunocompetent patients are asymptomatic. Patients with hemolytic anemia who depend on high production of reticulocytes may develop transient aplastic crisis following infection with parvovirus B19. Immunoincompetent individuals may not be able to mount an adequate antibody response to clear parvovirus B19 from the blood and marrow, resulting in sustained infection with reticulocytopenia and anemia. In a series of HIV+ patients with parvovirus B19–related anemia, the median CD4 count was 42 cells/ μ L, indicating that parvovirus B19–associated pure red cell aplasia is associated with advanced immunodeficiency.²⁵⁸ Characteristically, these patients have a normocytic anemia with virtual absence of reticulocytes, but normal white blood cells and platelets. Parvovirus immunoglobulin (Ig) G and IgM levels are generally not helpful in making the diagnosis, but PCR to detect parvovirus in the blood can be a reliable diagnostic test.²⁵⁹ Marrow evaluation may show characteristic giant proerythroblasts and markedly diminished late erythroid precursor cells, with full maturation of the myeloid and megakaryocytic lineages. Some patients respond to initiation of ART in addition to transfusion support, but the majority of patients require additional therapy. A high prevalence of antibodies to B19 parvovirus exists in the general population; therefore, pooled human IgG preparations are a rich source of antiparvovirus antibody. Infusion of human IgG results in clearance of parvovirus B19 from the blood and improved reticulocyte production and resolution of anemia in HIV+ patients with parvovirus B19–induced pure red cell aplasia.^{259,260} However, patients with a CD4 count of less than 80 cells/ μ L are prone to relapse within 6 months and may require retreatment.

Medications and Anemia

An important cause of anemia in people living with HIV is medications; both ART and medications used for prophylaxis against infections are implicated. Zidovudine can cause macrocytic anemia and leukopenia, and is not commonly used at present because of its toxicity. Stavudine is associated with anemia, although at lower rates than zidovudine.²⁶¹ Dapsone or trimethoprim-sulfamethoxazole, used for *P. jiroveci* prophylaxis, can cause hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Ganciclovir or valganciclovir, used to treat herpes simplex virus (HSV), Varicella-zoster, CMV, and sometimes HHV8, often cause pancytopenia. Trimethoprim-sulfamethoxazole can also cause myelosuppression and pancytopenia.

Treatment of Anemia

Initiation of ART is the optimal treatment for HIV-associated anemia. If a specific cause of anemia is identified, such as parvovirus B19, specific treatment can be provided. Early clinical trials demonstrated that erythropoietin treatment in anemic HIV+ patients taking zidovudine can improve the hemoglobin and decrease red blood cell transfusion requirements,²⁶² although responses were confined to patients with an endogenous erythropoietin level of 500 mU/mL or less.^{262,263} Since zidovudine is no longer commonly used as a component of ART, the use of erythropoietin has declined. Nevertheless, treatment of anemia caused by zidovudine in patients with HIV and an erythropoietin level of 500 mU/mL or less is an FDA-approved indication for erythropoietin. However, a Cochrane analysis²⁶⁴ that included six studies and more than 500 anemic HIV+ patients treated with erythropoietin or placebo concluded that erythropoietin did not reduce the risk of death and did not have a clear effect on quality of life. Additionally, erythropoietin has side effects including the potential to exacerbate hypertension,

increased risk of thrombosis, a very rare risk of pure red cell aplasia, and increased risk of tumor progression or recurrence in specific types of cancer, as well as high cost.

HUMAN IMMUNODEFICIENCY VIRUS–ASSOCIATED THROMBOTIC MICROANGIOPATHY

Early in the HIV epidemic, it was reported that HIV+ people are at increased risk of thrombotic microangiopathy, either thrombotic thrombocytopenic purpura (TTP) or hemolytic-uremic syndrome (HUS). In a retrospective survey of 1223 patients with clinical AIDS in the pre-ART era, 1.4 percent met criteria for thrombotic microangiopathy. However, a prospective cohort of 347 patients followed from 1997 to 2000 identified no patients with thrombotic microangiopathy, suggesting that the incidence may have declined as a result of effective ART.²⁶⁵ In support of this, a study done in the ART era followed 6022 HIV+ patients and found that 0.3 percent of patients developed thrombotic microangiopathy.²⁶⁶ The group with thrombotic microangiopathy had a lower mean CD4 count, a higher plasma viral load, and a higher incidence of clinical AIDS than did HIV+ patients without microangiopathy. Registries of patients with TTP have been used to investigate what fraction of the patients are HIV+; of 362 patients in the Oklahoma TTP/HUS registry from 1989 to 2007, 1.84 percent were HIV+ while the prevalence of HIV in the local community was 0.3 percent.²⁶⁷ In this study, several of the HIV+ patients were thought to have alternative causes of their microangiopathic hemolytic anemia, reinforcing the importance of a thorough consideration of the full spectrum of illnesses causing thrombotic microangiopathy, which may, in turn, affect the decision to use plasmapheresis/plasma exchange.²⁶⁷ One series of 24 HIV+ patients with TTP reported that these patients presented with a mean hemoglobin of 6.8 g/dL, a mean platelet count of 20,000/ μ L, a mean LDH of 4.5-fold normal, and a mean CD4 count of 236 cells/ μ L, and the majority had an HIV viral load of greater than 10,000 copies/mL. Patients were treated with prompt plasma exchange (mean of 13 treatments) and initiation of ART and achieved excellent outcomes comparable to HIV– patients with TTP, with death occurring in a single patient. However six of the 24 patients suffered relapse of TTP, often in the setting of increased viral load, and required retreatment.²⁶⁸ A study of patients enrolled in the French thrombotic microangiopathy (TMA) network revealed that 29 of 236 patients were HIV+. Of the HIV+ patients who had a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS 13) activity of less than 5 percent, outcome was very similar to HIV– patients with a low ADAMTS 13 activity. However the HIV+ patients with an ADAMTS 13 activity of greater than 5 percent tended to have far advanced HIV with a median CD4 count of 30 cells/ μ L, more infectious complications present at the diagnoses of thrombotic microangiopathy, multiple AIDS-associated complications, and a high mortality.²⁶⁹ Thus the outcome of TTP in HIV+ patients can be excellent in patients without advanced HIV when treated promptly with plasmapheresis/plasma exchange and ART.

HUMAN IMMUNODEFICIENCY VIRUS–ASSOCIATED THROMBOCYTOPENIA

In the pre-ART era, approximately 10 to 30 percent of people living with HIV had thrombocytopenia, defined as a platelet count of less than 150,000/ μ L, and thrombocytopenia was the initial manifestation of HIV in approximately 10 percent of patients. Those whose risk factor for HIV was intravenous drug abuse had a higher incidence of

thrombocytopenia, attributed to increased coinfection with hepatitis C and hepatic cirrhosis. A British study evaluated selective testing for HIV in patients who presented with specific medical conditions, including thrombocytopenia. They found an increased rate of HIV infection in patients presenting with thrombocytopenia,²⁷⁰ providing a rationale for including HIV testing in the evaluation of patients presenting with isolated thrombocytopenia. In the ART era, 26 percent of 5290 patients followed at the British Columbia Center for Excellence in HIV/AIDS had at least one platelet count less than 100,000/ μL , and 3 percent had at least one platelet count less than 20,000/ μL .²⁷¹ A study of the frequency and severity of thrombocytopenia in a large cohort of patients in the Collaboration in HIV Outcomes Research/U.S. study (CHORUS) included 6300 HIV+ people from 1997 to 2006²⁷² and found a prevalence of thrombocytopenia (platelet count <150,000/ μL) of 14 percent. However, this cohort excluded patients who had hepatitis C or hepatitis B infection, so the prevalence of thrombocytopenia would likely be higher if these patients had been included.²⁷² In this study, 3.1 percent of patients had a platelet count of 50,000/ μL or less, and 1.7 percent of patients had a platelet count of 30,000/ μL or less. The majority of patients with severe thrombocytopenia who had not started ART had a CD4 count greater than 200 cells/ μL , demonstrating that thrombocytopenia can occur prior to severe immunodepletion. These data are consistent with the findings of the British Columbia Center for Excellence in AIDS/HIV study, in which the CD4 count at diagnosis of ITP was 200 or greater in 72 percent of patients.²⁷¹

Mild thrombocytopenia also occurs during primary HIV infection, a time of unfettered HIV replication and intense immune activation. In one study of 957 patients evaluated during primary HIV infection, 9.7 percent had a platelet count of less than 150,000/ μL , 2.3 percent had a platelet count of less than 100,000/ μL , and none had a platelet count of less than 50,000/ μL .²⁷³ Of those who started ART, the time to platelet recovery was approximately 1 month. Of those who did not start ART, the time to platelet recovery was just under 2 months. Those who developed thrombocytopenia during acute HIV infection had a threefold higher incidence of developing a low platelet count in the next 3 years (13.3 percent) in comparison to those who maintained a normal platelet count throughout. Thus, most patients who develop thrombocytopenia during primary HIV infection recover quickly, even if ART is not started immediately. A study to evaluate the risk factors for HIV-associated thrombocytopenia included 73 HIV+ people with a platelet count of less than 100,000/ μL for 3 months matched to 73 nonthrombocytopenic controls. Identified risk factors were an HIV viral load of greater than 400 copies/mL, hepatitis C coinfection, and cirrhosis.²⁷⁴ The platelet count correlated inversely with the viral load in a study of 207 patients naïve to ART.²⁷⁵

Platelet kinetic studies demonstrate shortened platelet survival in HIV+ patients not on ART (92 hours) compared to HIV- healthy volunteers (198 hours).²⁷⁶ Even HIV+ patients with normal platelet counts had modestly diminished platelet survival in these studies as well as decreased platelet production in comparison to HIV- normal volunteers. As discussed above, some human hematopoietic progenitor cells can be infected with HIV *in vivo*, and these cells demonstrate impaired megakaryopoiesis *in vitro*.²⁵¹ Additionally megakaryocytes can be infected with HIV²⁷⁷ and these observations may contribute to the decreased production of platelets in the marrow of HIV+ individuals. The more frequent and severe thrombocytopenia seen in patients with HIV and hepatitis C coinfection can be explained by the increased risk of cirrhosis in people coinfecting with HIV and hepatitis C. The combined effects of diminished production of thrombopoietin, the major thrombopoietic growth factor, together with portal hypertension, splenomegaly, and sequestration of platelets in the enlarged spleen can result in severe thrombocytopenia. Patients with severe liver failure

TABLE 81–10. Pancytopenia in Human Immunodeficiency Virus

- Advanced HIV with high viral load
- Medication side effect
- Malignancy in the marrow
 - Non-Hodgkin lymphoma, Hodgkin lymphoma
- Infection in the marrow
 - *Mycobacterium avium* complex, histoplasmosis, cytomegalovirus, *Mycobacterium tuberculosis*
- Castleman disease
- Hemophagocytic syndrome
- Alcohol abuse
- Vitamin B₁₂ or folate deficiency

may also have a component of low-grade disseminated intravascular coagulation.

Evaluation of thrombocytopenia in HIV+ patients is similar to HIV- patients and should include a thorough history and physical exam looking for symptoms and signs of platelet-type bleeding, to assess the clinical severity of the thrombocytopenia. The blood film should be reviewed to confirm that the patient does have low platelets, rather than platelet clumping, and to evaluate for abnormalities in red blood cell and white blood cell numbers and morphology. If not already done, the patient should be tested for hepatitis C. The HIV viral load and CD4 count should be determined, as noncompliance or development of resistance to the current ART regimen can exacerbate HIV-associated thrombocytopenia. The patient should be asked what percent of the patient's HIV medications are taken, or alternatively how many missed doses the patient has had in the past month. The medication list, including nonprescription medications, naturopathic medications, and dietary supplements, should be thoroughly reviewed. The differential diagnosis for isolated thrombocytopenia includes HIV-associated ITP, hepatitis C-associated ITP, *Helicobacter pylori*-associated ITP, medication side effect, or antiphospholipid antibody syndrome. If the patient also has anemia, immunohemolytic anemia with ITP (Evans syndrome) or TTP should be considered. In a febrile and ill patient who has additional cytopenias, Castleman disease and hemophagocytic syndrome should be included in the differential diagnosis (Table 81–10).

Treatment of Human Immunodeficiency Virus–Associated Idiopathic Thrombocytopenic Purpura

ART improves the platelet count in patients with HIV-associated ITP over a period of approximately 3 months in the majority of patients.^{278–280} The primary treatment of HIV-associated ITP is initiation of ART if the patient is not on ART, and assessment of the effectiveness of ART if the patient is taking ART. Reasons for failure of ART include suboptimal compliance with the medications, as the ability of ART to control the HIV viral load is related to adherence.²⁸¹ Alternatively, the patient's HIV may have developed ART resistance which can be detected by resistance testing. Close communication between the hematologist and the infectious disease/HIV physician is essential for optimal management of these issues.

Because ART typically takes 3 months to improve the platelet count, additional interventions are needed if the patient is experiencing severe thrombocytopenia (platelets <20,000/ μL) or has platelet-type bleeding. If the patient is Rh+ and has an intact spleen, intravenous anti-D can be very effective.²⁸² In a study that included both HIV+ and

HIV- patients, treatment with intravenous anti-D increased the platelet count by an average of 45,000/ μ L in adults in both groups. In the majority of patients, the platelet increment lasted more than 21 days. The major side effect of anti-D treatment was a drop in the hemoglobin (average decrease in hemoglobin of 1 g/dL). Another approach is to use intravenous immunoglobulin although one study of immunoglobulin treatment reported a smaller increase in the platelet count (average of 29,000/ μ L), and a shorter duration of response (19 days) than was obtained with intravenous anti-D.²⁸³ Furthermore, intravenous anti-D may be less expensive than intravenous immunoglobulin. However, anti-D has the potential to cause significant hemolysis and has a “Black Box” warning because of this rare complication. Alternative approaches include the use of standard doses of prednisone or pulse dexamethasone, as in HIV- patients. Steroids are less attractive in HIV+ patients because of the potential to decrease CD4 counts, increase the risk of infection, and increase risk of Kaposi sarcoma progression. Splenectomy can be effective in HIV+ patients,²⁸⁴ but is rarely required. Case reports document the use of romiplostim or eltrombopag in HIV+ patients.^{285,286}

HIV+ patients with ITP should be counseled not to take aspirin or nonsteroidal antiinflammatory drugs or fish oil while severely thrombocytopenic, and educated on the symptoms of relapse of ITP (spontaneous nose bleeds, spontaneous large bruises, bleeding gums), and encouraged to report promptly for medical care should any of these occur. Most patients with HIV-associated ITP can be started on ART and treated with 1 or 2 doses of anti-D at 3-week intervals and will subsequently experience sustained platelet count response with effective control of HIV.

HUMAN IMMUNODEFICIENCY VIRUS-ASSOCIATED NEUTROPENIA

The prevalence of neutropenia (defined as a neutrophil count <1300/ μ L) in patients naïve to ART in Africa, Asia, the Americas, and the Caribbean was 14.3 percent,²⁸⁷ with the U.S. cohort having a slightly higher prevalence of approximately 16 percent. A multicenter prospective study of HIV+ women in the United States followed 1729 women²⁸⁸ and found that 7 percent had a pre-ART absolute neutrophil count of less than 1000/ μ L, and during 7.5 years of follow up 31 percent had an absolute neutrophil count of less than 1000/ μ L. Low CD4 count and high viral load were significant risk factors for development of neutropenia whereas initiation of ART correlated with resolution of neutropenia. Patients living with HIV may have neutropenia for a variety of reasons and neutropenia may be a component of pancytopenia (see Table 81–10) or occur as an isolated finding. As discussed in the section “Pathophysiology of Anemia in HIV” above, HIV has a multitude of effects on hematopoiesis, and the effects on progenitor cell survival, growth and differentiation and on the marrow microenvironment pertain to myelopoiesis as well as erythropoiesis and megakaryopoiesis. A study of 87 consecutive patients attending an HIV clinic who developed an absolute neutrophil count of less than 1000/ μ L showed that the vast majority were receiving at least one known myelosuppressive medication, and 59 of the 87 patients were receiving three or more myelosuppressive drugs. Many other medications are rare causes of neutropenia,²⁸⁹ illustrating the importance of drug-induced neutropenia in this population of patients.

Other causes of neutropenia reported in HIV+ patients include deficiency of vitamins such as folate or vitamin B₁₂, hepatitis C-associated autoimmune neutropenia, alcohol toxicity, and levamisole-adulterated cocaine, which can cause severe neutropenia (neutrophil counts as low as 0). Patients should be specifically asked about cocaine use if they are found to have severe neutropenia with normal hemoglobin and platelet count.²⁹⁰

CHAPTER 82

MONONUCLEOSIS SYNDROMES

Robert F. Betts

SUMMARY

The defining clinical features of a mononucleosis syndrome are fever and reactive lymphocytes in the blood. The two most common causes of mononucleosis are Epstein-Barr virus (EBV) and cytomegalovirus (CMV) infection. The clinical manifestations of EBV and CMV mononucleosis depend on a vigorous host response to the viral infection. Patients who become infected without a host response develop antibodies to the virus but no or minimal clinical manifestations. Several clinical similarities exist between EBV and CMV mononucleosis. Both infections have a febrile prodrome before the mononucleosis phase develops. Both infections can induce fever, an enlarged spleen, and an erythematous skin rash—the mononucleosis phase. The disease is self-limited in the vast majority of patients, although resolution may take several weeks, especially in older individuals. In both viral infections, lymphocytes represent greater than 50 percent of blood cells, and at least 10 percent are reactive lymphocytes. Differences in clinical and laboratory findings are observed. Severe pharyngitis and tender lymph node enlargement, often in several lymph node groups, occur in infection with EBV and perhaps with some unknown agents, but not to the same degree in infections with CMV. The majority of cases of EBV mononucleosis occur in teenagers and young adults, whereas CMV-induced disease occurs most commonly in adults in their 30s to 60s. A much larger percentage of adults have unrecognized primary infection with CMV than with EBV. EBV results in the development of heterophile antibodies, active against sheep and horse red cells among others, but this development does not occur in CMV. The pathway leading to lymphocytosis and reactive lymphocytes differs between the two agents. The B cell is infected in EBV infection which eventually may lead to hematologic malignancy, whereas the macrophage is infected in CMV. This may explain its important role after allogeneic transplantation. In both infections, the T lymphocyte is the reactive cell. Other agents, including *Toxoplasma gondii*, human immune deficiency virus type 1, and several other viruses, can cause a mononucleosis-like syndrome with reactive lymphocytes in the blood.

DEFINITION AND HISTORY

The first clinical description of what was probably infectious mononucleosis was published in 1885 when Pfeiffer¹ described a disorder termed *Drüsenfieber* (glandular fever). In 1920, Sprunt and Evans² introduced the term *infectious mononucleosis* for an acute, self-limited syndrome

Acronyms and Abbreviations: CMV, cytomegalovirus; EA, early antigen; EBNA, Epstein-Barr nuclear antigen; EBV, Epstein-Barr virus; NK, natural killer; PCR, polymerase chain reaction; PTLT, posttransplantation lymphoproliferative disease; VCA, virus capsid antigen.

of mononuclear leukocytosis in febrile patients. In 1932, Paul and Bunnell³ showed that the sera from patients with infectious mononucleosis agglutinated red cells from sheep and horses, a reaction that was termed the *heterophile antibody test*. Paul was investigating heterophile antibodies in human sera that reacted with sheep red blood cells. These antibodies were unrelated by phylogenetic features to the antigen with which they reacted, the so-called Forssman antigen. He found that the highest titer had developed in the serum of an individual recovering from infectious mononucleosis. Davidson showed that serum, after absorption by guinea pig kidney cells, no longer reacted with sheep or horse cells. This absorption of these antibodies made this test very specific for Epstein Barr virus (EBV) infection.⁴ In 1964, Epstein, Ashong, and Barr reported the isolation of a virus from the cells of a patient with African Burkitt lymphoma and hence the derivation of its name, EBV. The etiologic role of EBV in infectious mononucleosis was discovered serendipitously in the laboratory of Gertrude and Werner Henle.⁵ A technician in their laboratory whose serum had been negative for EBV antibodies and was used as a seronegative control was discovered to be EBV antibody-positive after she recovered from infectious mononucleosis. The association later was confirmed in seroepidemiologic studies of college students.⁶⁻⁹

Much of the clinical nature and the incubation period of mononucleosis were documented by Hoagland¹⁰ in studies of cadets at West Point. He established that oral transmission was the principal route of viral transmission, which led to mononucleosis being dubbed the “kissing disease.” He also noted that cadets developed the disease approximately 6 weeks after they returned from their vacation.¹¹

Although EBV is the most common cause of infectious mononucleosis, other agents produce a febrile syndrome with a blood lymphocytosis that mimics some aspects of EBV mononucleosis.

ETIOLOGY AND PATHOGENESIS

The infectious mononucleosis syndrome is most commonly caused by one of two members of the herpes virus family: EBV or cytomegalovirus (CMV). Occasionally the HIV and, less commonly, the parasite *Toxoplasma gondii* produce a febrile illness with lymphocytosis. Other viral agents produce a febrile syndrome with a blood lymphocytosis, but only infrequently (Table 82-1). For both EBV and CMV mononucleosis, the T-lymphocyte response to the infected target cell, resulting in reactive lymphocytosis, is a hallmark of the disease. The difference is that for EBV, the B lymphocyte is the cell that becomes infected and thus the target of the responding T lymphocyte, whereas it is the macrophage/monocyte lineage that is infected by CMV, which engenders the T-lymphocyte response.^{13,14}

EPIDEMIOLOGY OF EPSTEIN-BARR VIRUS AND CYTOMEGALOVIRUS

Some similar and several distinct epidemiologic and clinical differences exist between EBV and CMV infection. Both EBV and CMV infect young children.¹⁵ Those who develop EBV infection at a very young age (1 to 5 years) have an illness similar to other illnesses occurring during their youth. CMV infection presents similarly, but in the young patients there is low-grade fever, mild elevation in liver function, and, quite often, lymphadenopathy. The latter seldom occurs in older people with primary CMV infection.

If an individual escaped EBV infection when he or she was young, it is very common for the individual to develop infection during the teen and young adult years, that is, between the ages of 12 and 25 years.⁸ By contrast, CMV infection is uncommon in that age range but begins

to increase in frequency after the age of 25 years.^{16,17} Primary CMV infection is also far more common than EBV in those older than 50 years of age.¹⁶ Between the ages of 12 and 25 years, the classic mononucleosis illness develops in the majority of those with primary EBV infection.⁸ In the few older individuals in whom EBV occurs, clinical illness that develops resembles the clinical illness that occurs in those with new CMV infection.¹⁸ Congenital infection with EBV occurs,¹⁹ but it occurs only in babies of mothers who were infected with EBV during pregnancy and it is very uncommon. By contrast, it is estimated that 1 to 2 percent of all livebirths have CMV congenital infection. Furthermore, it occurs associated with primary infection in mothers; it also occurs in babies of mothers who were seropositive preconception.²⁰ CMV infection of the monocyte/macrophage²¹ helps explain its role in disease following solid-organ transplant. Because latent CMV is present in all solid organs of those with previous CMV infection, when immunosuppression is administered latent CMV is reactivated. EBV infection posttransplantation occurs only in those recipients who have not been infected before transplantation and, as with CMV, the EBV is reactivated in the donor organ.²²

● EPSTEIN-BARR VIRUS MONONUCLEOSIS

VIROLOGY AND PATHOGENESIS

EBV is a DNA virus of the Gammaherpesvirinae subfamily. The virus is estimated to infect 90 percent of the world's population. In the process of this infection, the EBV intercalates itself primarily into the long-lived memory B cell, not the naïve B cell,²³ and thereafter establishes lifelong residence in its host. Early after infection, the virus is continuously shed into oral secretions. The virus then usually undergoes latency, but it may be reactivated periodically.²⁴

Following primary infection, varying severity of disease ensues. Infection occurs via virus attachment to the cell surface CD21 glycoprotein, a 140-kDa complement receptor type 2. Infection induces polyclonal proliferation of infected B cells in the nodes in the pharynx. There is increasing evidence that host genetic factors predict the severity and duration of disease following primary EBV infection.^{25,26} Specifically, the interferon (IFN)- γ +874T/A or the interleukin (IL)-10 -592C/A polymorphisms are the important genetic factors. Using measures of severity of illness such as fatigue, myalgia, and height of fever, individuals who have the IFN- γ +874TT (high interferon production) allele have a striking increase in the risk of experiencing these severe manifestations compared to those with IFN- γ +874 A and IL-10 -592.²⁴ When a subject's blood monocytes are tested in vitro, the high-risk group has

a higher production of IFN- γ in stimulated cells.²⁷ Other factors in host response, which include the height of the virus load in the blood, the number of CD8+ cells, and the T-cell granzyme expression in the CD8+ cell also have been described as contributing to disease severity.²⁸ As a corollary to this, variability in the symptoms, signs, physical findings, and laboratory abnormalities occurs in primary infection.^{28,29} At the time serology confirms evidence of primary infection, some, but not all individuals with primary infection, have classic symptomatic disease.^{28,29} In those who develop the classical syndrome, T lymphocytes recognize viral replicative antigens on the infected B cell as foreign, and an exuberant polyclonal cytotoxic T-cell response ensues. The proliferative rate of CD8+ T cells is estimated to be approximately 50 percent of this population of cells proliferating per day. This translates into a population doubling time of 1.5 days so that 5×10^9 CD8+ T cells per day appear in the blood. The later rate of appearance is two orders of magnitude greater than normal.³⁰ The surface activation marker SLAM (signaling lymphocyte activation molecule)-associated protein (SAP) on T lymphocytes stimulates cell activation in response to a signal from CD244 and CD150 (SLAM) on the T-cell surface.³¹ In the healthy individual, this process subsides over days to weeks. In parallel, the signs and symptoms of the infection subside, although fatigue may persist for a longer period of time.

EPIDEMIOLOGY

There is an apparent seasonal pattern with its peak incidence in the summer. Close person-to-person contact is required for transmission to a susceptible individual.²⁹ Subclinical primary infection²⁸ or frequent asymptomatic reactivation of EBV in the previously infected individual provides an opportunity for transmission at all ages. Although, transmission from breast milk or from the cervix occurs, it is very uncommon.³² Nonetheless, nearly everyone in the developing world is infected by age 5 years and mononucleosis is rarely seen. Similar rates of infection occur in the lower socioeconomic class in the developed world. In the upper socioeconomic strata of the developed world, the majority of persons avoid infection when they are young. However, between the ages of 12 and 25, infection is very common. Characteristically, primary infection occurs in an individual a few months after the individual develops a relationship with someone who has latent infection.^{24,28} Transmission occurs from a virus-positive asymptomatic individual who transmits his or her virus to a previously uninfected person. Individuals who are raised in more protected environments may reach their 30s before they are infected. If both individuals in an initial relationship are seronegative, years may pass before they become infected. Individuals who are seropositive usually do not develop clinical disease upon reexposure, although a second infection with a different strain may occur.³³⁻³⁵

CLINICAL MANIFESTATIONS

Clinical manifestations vary by age.^{15,18,36-41} When young children acquire illness they develop a typical childhood illness of upper respiratory infection (43 percent), otitis media (29 percent) pharyngitis (21 percent), gastroenteritis (7 percent), or typical mononucleosis (<10 percent). Rashes and/or periorbital swelling occur more frequently in younger children than in the teens. In the age group 12 to 25 years, many, but not all, present with the classical presentation of infectious mononucleosis. However, there are a substantial proportion of newly infected individuals who have minimal or very mild disease.^{28,29} Furthermore, evidence of virus in the blood may be present for several days before disease appears.²⁸ For those who present with the classical disease of infectious mononucleosis, the earliest manifestations of disease develop 35 to 42 days after the individual develops infection (Table 82-2). Infection occurs via virus attachment to the cell-surface CD21 glycoprotein, a 140-kDa complement receptor type 2. Infection

induces polyclonal proliferation of infected B cells in the nodes in the pharynx. Initial symptoms are lassitude and fever with no evidence of lymphocytosis or pharyngitis. Fever results from infection and proliferation of the B lymphocytes. From the nodes in the pharynx, the infected cells make their way into the circulating lymphocyte pool.^{42,43} Although the duration of virus in the blood is much shorter than it is in the secretions, it is the movement into the blood that leads to the manifestation of the disease. Subsequent, massive T-cell response to the neoantigens on the infected B lymphocyte is evident by the lymphocytosis with reactive blood lymphocytes and other disease manifestations. The pharyngitis that develops is a result of the T-cell response to the infected B cells that are found in Waldeyer ring in the tonsils. Sometimes enlargement of the tonsils occurs to the extent that they touch each other in the midline. Blood lymphocytosis occurs in response to the virus in the blood. Periorbital swelling, which occurs in mononucleosis, is an important clue to the diagnosis, even in young adults. Other manifestations include lymphadenopathy, hepatitis and splenic enlargement. (Table 82-2).^{8,28} Although the liver is not an organ rich in lymphocytes and hepatocytes are not damaged by the infection, CD4+ and CD8+ lymphocytes are trapped in that organ and their release of cytokines contributes to the inflammation in the liver and the changes in liver function that occur.⁴⁴ However, hyperbilirubinemia is very uncommon. The frequency of each clinical finding of the typical syndrome in newly infected patients is variable (Table 82-3).^{28,29} The disease abates with the occurrence of a T-cell-mediated counterresponse to the virus-induced initial polyclonal B-cell proliferation. During this time, dramatic clinical improvement can occur in 24 to 48 hours. Subsequently, EBV remains in the patient's B cells throughout life, but expresses only Epstein-Barr nuclear antigen-1 (EBNA-1), which does not elicit a T-cell response because of a glycine-alanine repeat that inhibits its processing.⁴⁵

Group A streptococcus is found in the pharynx occasionally (3 to 4 percent of cases) in concert with an EBV primary infection. Although treatment of the streptococcus eradicates the organism, the severe pharyngitis changes little, and the disease follows its usual course. Thus, treatment should be administered only if the test result for β -streptococcus is positive. If a penicillin congener is used, quite often, but not always, a rash develops^{46,47} and the patient is labeled "penicillin allergic." The patient should be reevaluated after the mononucleosis resolves to determine if the patient has a true allergy.

There are exceptions to the usual situation of most people becoming infected by age 25 years. The first is found in a woman who is protected by her family from intimate male contact. She avoids infection until she is married at which time she may become infected from her husband. The second situation occurs when a long-term relationship is established when a couple is young. If they are both seronegative, infection does not occur. When they reach parenting age or older, they become infected by a child or a grandchild. When that occurs, the presentation is less likely to include lymphadenopathy and pharyngitis (see Table 82-3).^{18,40,41} Fever almost always occurs and abdominal pain, hepatomegaly, and abnormal liver function develops in most. Older adults are less likely to develop lymphocytosis, they have fewer reactive lymphocytes, and splenomegaly is less evident. This leads to the clinical impression of infiltrative hepatic disease or cholecystitis. The illness at this age may be very protracted.

LABORATORY FINDINGS

Antibody Responses

By week three of a mononucleosis caused by primary EBV infection, an heterophile antibody response will occur in approximately 85 percent of patients. The test is called the monospot test and may be falsely negative, especially in young children.^{36,48}

The infection of B cells results in their production of a variety of antibodies against uninvolved infectious agents. The B-cell clones expanded, non-specifically, result in antibodies against *Chlamydia*, *Borrelia burgdorferi*, the yellow fever virus, and many other infectious agents. If the patient's febrile illness is considered a fever of unknown origin, diagnostic conclusions may be misleading. A variety of other antibodies against antigens that are not those of infectious agents also are produced because of polyclonal B-cell activation. These include antiplatelet, anti-red cell (anti-i cold agglutinin), and antinuclear antibodies.

At the time clinical disease is evident, both immunoglobulin (Ig) G and IgM antibodies to Epstein-Barr virus capsid antigen (VCA) usually are detectable. Later, antibody to early antigen (EA) develops. A small proportion of individuals will also have developed antibody to EBNA-1 on presentation. However, usually EBNA-1 antibody does

not appear until the recovery phase of the illness. For those patients suspected of having infectious mononucleosis but who do not develop heterophile antibody, detection of IgG and IgM antibody to VCA with the absence of EBNA-1 antibody leads to the diagnosis.⁴⁹ A real-time positive polymerase chain reaction (PCR) is sometimes useful.⁵⁰

Reactive Lymphocytosis

Expansion of cytotoxic T lymphocytes produces lymphocytosis. Reactive lymphocytes are larger than the lymphocytes normally found in the blood (Fig. 82-1). They may have a vacuolated cytoplasm, lobulated and eccentrically placed nucleus, and a cell membrane that often is indented by neighboring erythrocytes. A more darkly staining peripheral cytoplasm, called "skirting," occurs. Reactive lymphocytes are a hematologic hallmark of infectious mononucleosis, but they are not always found²⁹ and are not pathognomonic. They also are found in CMV infection, roseola (caused by human herpes virus-6), viral hepatitis, toxoplasmosis, rubella, mumps, and drug reactions.

Sheets of lymphocytes are noted on a stained slide preparation of tonsillar exudate. The immunophenotype of lymphocytes in mononucleosis syndromes assessed by multiparametric flow cytometry has confirmed that lymphocytosis results from CD8+ T cells. CD4+ T

Figure 82-1. A-D. Blood films from patients with Epstein-Barr virus–induced mononucleosis. These reactive lymphocytes exhibit the characteristic changes seen in patients with infectious mononucleosis: large lymphocytes with abundant cytoplasm. The cytoplasmic margin often spreads around (is indented by) neighboring red cells and the margin may take on a densely basophilic coloration (skirting). This type of reactive T lymphocyte may be seen in a variety of diseases and is not a specific change but is characteristic and helpful in pointing to the diagnosis in concert with other characteristic clinical findings. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

cells and B cells are not increased. In EBV mononucleosis, the notable populations increased are CD8+CD57- and CD3+ $\gamma\delta$ + T cells.⁵¹ If β -streptococcal infection accompanies the EBV infection segmented neutrophils may be present in the tonsillar exudate.

Other Blood Test Abnormalities

Liver function abnormalities are common, especially elevated serum alkaline phosphatase and γ -aminotransferase. There is no or only slight elevation of bilirubin. Studies in Israel have found a higher frequency of hyperbilirubinemia (15 percent), a lower incidence of leukocytosis (46 percent), and elevated liver enzymes (58 percent) than previously reported. The differences may be geographical or genetic.²⁹

COURSE AND PROGNOSIS

Complications of Epstein-Barr Virus Mononucleosis

Hematologic Virtually all subjects with acute mononucleosis develop a mildly decreased platelet count (see Table 82-2). More-severe hematologic complications occur infrequently, but include severe immune thrombocytopenia with petechiae, immune hemolytic anemia, immune-mediated granulocytopenia, and aplastic anemia.⁵²⁻⁶⁰ Uncommonly, the splenomegaly that accompanies the lymphoid proliferation accentuates an underlying, previously undiagnosed, hereditary spherocytosis.⁶⁰ Splenic rupture is estimated to occur in 1 to 5 per 1000 cases. It is the leading cause of death from EBV mononucleosis.^{61,62} Avoidance of athletic activities is prudent until the signs of the disease have disappeared and the spleen has returned to normal size.⁶²

Neurologic Neurologic complications include Guillain-Barré syndrome, acute encephalitis, acute disseminated encephalomyelitis (Alice-in-Wonderland syndrome), acute cerebellar ataxia, viral meningitis, transverse myelitis, and cranial nerve palsies.^{57,58,63-65} There is evidence that antibody to gangliosides plays a role in the pathogenesis of Guillain-Barré syndrome. Neurologic complications may occur in the absence of clinical mononucleosis. Diagnosis of EBV-induced neurologic disease requires obtaining specific antibodies to EBV (see "Antibody Responses" above) and a positive PCR for EBV in the cerebrospinal fluid.⁶³ Neurologic disease can be associated with primary infection, reactivated infection or chronic EBV infection.⁶³ Table 82-2 lists other complications.

Chronic Fatigue Fatigue is a very prominent feature of acute infectious mononucleosis. Most recover from this fatigue fairly quickly but a few remain fatigued for a very long period of time. The source of this fatigue is not certain but there is evidence that dysfunction of the midbrain plays a role.^{68,69} Furthermore, there are genetic factors that are present in those who remain fatigued. Limited information suggests improvement in some with antiviral treatment.⁶⁹

Multiple Sclerosis There are reports indicating that EBV infection is linked to the development of multiple sclerosis.^{70,71} Further studies to clarify which molecular mechanisms link the immune response to a natural infection of humans with EBV to the subsequent development of chronic inflammatory damage to the CNS are required to explain this relationship.

Systemic Lupus Erythematosus and Rheumatoid Arthritis There are epidemiologic links between previous infection with EBV and development of systemic lupus erythematosus (SLE).⁷² Not unexpectedly, virtually everyone with SLE has had previous infection with EBV. Therefore, the link may be fortuitous. Alternatively, a history of infection with EBV might lead to induction of autoimmunity.^{73,74} There has also been a suggested relationship between increased viral load in rheumatoid arthritis leading to expansion of CD8+ cells and its consequences.⁷⁵

Chronic Progressive Epstein-Barr Virus Infections, T-Cell or Natural Killer-Cell Lymphoproliferation, Lymphoma, and Hemophagocytic Syndrome Chronic EBV infection is a rare outcome of primary EBV infection, notable in persons with an immunodeficiency state.^{76,77} In chronic EBV infection, fever, marrow hypoplasia, interstitial pneumonia, hepatosplenomegaly, persistent hepatitis often to the point of hepatic failure, lymphadenitis, and uveitis are frequent clinical manifestations. These findings may persist for months or years and eventuate in a high fatality rate.⁷⁵ EBV antibodies may be very elevated (VCA in excess of 1:5120, anti-EA greater than 1:640) but with no detectable EBNA-1 antibody. A persistently elevated blood PCR for EBV is a feature. The more-severe form of this manifestation may evolve into a natural killer (NK)- or T-cell lymphoproliferative disease that ranges from chronic to fulminant.⁷⁸ Alternatively, EBV hemophagocytic syndrome may develop. The latter is a severe multiorgan, inflammatory disease provoked by massive cytokine elaboration. In some case, clonal proliferation induced by EBV develops (Chap. 71).⁷⁸⁻⁸¹

OTHER EPSTEIN-BARR VIRUS-ASSOCIATED DISEASE PROCESSES

Neoplastic Potential of Epstein-Barr Virus

EBV was the first human tumor virus identified⁸² from the cultured cells of a patient with African Burkitt lymphoma. EBV can confer unlimited proliferative potential of infected B lymphocytes in culture.⁸³ EBV has since been associated with tumors other than Burkitt lymphoma, including some patients with Hodgkin lymphoma (Chap. 97). Although proof of causality still eludes investigators, there is an intriguing relationship between EBV and Hodgkin lymphoma.⁸⁴⁻⁸⁷ EBV is detectable in the neoplastic B cells (Reed-Sternberg cells) of a significant percent of patients with Hodgkin lymphoma. The etiologic role of EBV in this setting is unknown.⁸⁴⁻⁸⁷

There is also a relationship between EBV and lymphoma in immune-deficient individuals including the posttransplantation lymphoproliferative disease (PTLD).⁸⁸ Recipient PTLD is a more serious problem than donor PTLD⁸⁹ and investigators avoid certain immunosuppressive programs if there is a risk of PTLD.⁹⁰ Use of positron emission tomography helps determine who of those at risk for PTLD have evidence for disease.⁹¹ X-chromosome-linked lymphoproliferative disease,⁹² T-cell and NK-cell lymphomas that follow chronic EBV infection,⁹³⁻⁹⁵ nasopharyngeal carcinoma in patients in the Far East,⁹⁶ the latter disease generating efforts to develop a vaccine,⁹⁷ leiomyoma and leiomyosarcoma in patients with HIV infection or immunodeficiency posttransplantation,⁹⁸ and a small fraction of cases of gastric carcinoma⁹⁹ are each associated with EBV infection (Table 82-4). In three types of lymphomas, Burkitt, Hodgkin, and PTLD, the cell that mutates to produce the clonal disease is a germinal center B cell with a circular viral genome in the tumor cells that expresses the EBV-encoded latent genes.¹⁰⁰

In the case of PTLD, the most characteristic clinical setting involves an EBV seronegative person receiving an organ from an EBV seropositive donor.⁸⁹ EBV is latent in the B lymphocytes of the transplanted marrow or solid organ. Immunosuppression allows reactivation of the latent virus. Because basiliximab, calcineurin inhibitor, sirolimus, and glucocorticoids seem to increase the frequency of PTLD, that regimen is avoided where the potential for PTLD is present.⁹⁰ Because the recipient is not immune, there is no T-cell response and the B cells may proliferate unchecked, sometimes eventuating in PTLD. In the EBV-seronegative recipient who develops PTLD posttransplantation, this disease usually develops within the first posttransplantation year

TABLE 82-4. Special Problems with Epstein-Barr Virus or Cytomegalovirus Infection

Oral hairy leukoplakia ¹⁰²	

and often within the first few months. The abnormally proliferating cell almost always is a B cell and the process at an early stage may be monoclonal. In the initial states, the disease may respond to lowering of immunosuppressive medications. Although administration of antiviral prophylaxis seems to lower the frequency of development of the disease, once the disease develops, antiviral agents are ineffective.¹⁰¹ When disease develops, in addition to reduction in immunosuppression, administration of anti-CD20 therapy with rituximab is used. Occasionally, PTLD occurs in a person who is EBV antibody-positive pretransplantation. When this occurs, the onset is usually greater than 1 year posttransplantation.

In young males with an X-linked lymphoproliferative syndrome, primary EBV infection leads to unabated B-cell proliferation and evolution into a frank B-cell lymphoma, the so-called Duncan syndrome.⁹² These young males do not develop a T-cell response and hence do not develop mononucleosis. Although control of this effect of EBV infection by treatment with antiviral agents and/or chemotherapy has been attempted, the Duncan syndrome usually is fatal.

Oral hairy leukoplakia, a characteristic white lingual lesion with hairy projections, occurs in patients with HIV infection. It is caused by EBV infection of the lingual epithelium.¹⁰²

FUTURE THERAPEUTIC APPROACHES TO EPSTEIN-BARR VIRUS INFECTION AND NEOPLASIA

Because of the severe consequences of EBV infection, several approaches to preventing or treating these disorders are underway, such as an EBV

vaccine,¹⁰³ adoptive transfer of activated cytotoxic T cells,¹⁰⁴ and the development of peptides that inhibit viral replication.¹⁰⁵

CYTOMEGALOVIRUS MONONUCLEOSIS

HISTORY

The early description of CMV-related disease was that of an uncommon congenital syndrome with abnormal liver function and thrombocytopenia leading to petechiae.¹⁰⁶ Subsequently, it was recognized that previously healthy young children with a primary infection with CMV¹⁰⁷ had prolonged abnormal liver function, hepatosplenomegaly, lymphocytosis, and thrombocytopenia. Later, primary CMV infection was linked to a febrile mononucleosis syndrome.¹⁰⁸

EPIDEMIOLOGY

In the developing world, CMV infects the majority of individuals by the age of 5 or 6 years. Three factors contribute to this. In those societies, mothers are still in their teen years when they deliver their children. These young women have active CMV virus in their cervix that has persisted since they were younger. The cervical virus is aspirated by the child during the birthing process. Transmission to the newborn also occurs through breast milk. In addition, all of these young children play together when they are young and virus is transmitted readily to those who have avoided earlier infection. Infection at the time of birth from the cervical virus or shortly after birth from breast milk or another child does not lead to any known consequences. However, congenital infection occurs in all populations. For less-than-clear reasons, a seropositive mother may deliver a child who has become infected in utero.¹⁰⁹ In the developing world, most often it occurs in the babies whose mothers are seropositive before they become pregnant and the disease in the new born is not clinically obvious at birth.¹⁰⁹ These children, who have asymptomatic congenital infection, may develop unilateral or bilateral hearing deficits later. Congenital CMV infection in the babies of seropositive women and may account for a significant number of people with hearing loss.¹⁰⁹

In the developed world, first children often have parents who have not had CMV infection. If primary infection occurs in the mother at or near the time of impregnation in anticipation of the second child, severe congenital infection may develop.¹¹⁰ It is not clear which of the several possible factors contribute to why that child acquires congenital CMV infection and more study is required to lead to intelligent management decisions.

Presence of CMV in oral secretions and in urine in children living together in families where there is known CMV has been recognized for many years.¹⁰⁷ The source of the virus is not entirely clear. It is not always certain whether these children acquired infection at birth or from breast milk and they continue to have active infection or whether it is resulting from transmission among children. The latter is suspected but not proven.

It is strongly suspected that when a CMV-infected child comes in contact with a CMV-seronegative grandparent, primary infection in that grandparent may occur. This can be associated with CMV disease in the older person, although the development of disease associated with the infection is uncommon.¹⁸ Very little is known about the risk of CMV-infected semen in those undergoing heterosexual intercourse. However, there is a very high frequency of CMV infection in young homosexual males. Almost all active homosexual young men are seropositive to CMV by age 20 years, which contrasts to only 20 percent of heterosexual young men. Presumably that 20 percent of heterosexual men were infected as children.

CLINICAL MANIFESTATIONS

In most cases, the new infection with CMV is clinically silent. However, some newly infected individuals will develop high fever (40°C often), weight loss, and associated malaise and myalgia.¹¹¹ Abnormal liver function and a palpable spleen similar to that seen with EBV occur. A left shift in the differential white count may occur initially, evidenced by a higher proportion of band neutrophils. The incidence of lymphadenopathy is much higher in the young than in the older person with primary CMV. Infection occurs in the older individual because they have not been infected during their younger years (Tables 82–2 and 82–3 list additional clinical and laboratory findings). Because no classic manifestation, such as severe exudative pharyngitis, develops, CMV is not considered in the differential diagnosis. Instead, it is assumed that the patient has a bacterial infection and antibiotics are administered. How frequently this occurs is uncertain but administration of a β -lactam antibiotic may be associated with development of a rash and the mistaken impression that the recipient is allergic to penicillin. Because the disease occurs in the older population, including those older than age 50 years, the causes of fever of unknown origin often are pursued in an expensive evaluation prior to the diagnosis. A number of the laboratory and physical findings raise many diagnostic possibilities. Development of antinuclear factor and thrombocytopenia (Table 82–5) often erroneously leads to the diagnosis of a collagen vascular disease. The presence of splenomegaly raises the question of lymphoma.

LABORATORY FINDINGS

The cell that becomes infected initially is not the B lymphocyte but a cell in the monocyte–macrophage lineage and it is that cell or cells to which the T-lymphocyte responds.^{112,113} Lymphocytosis that develops is indistinguishable from that of EBV-induced disease. In some patients, neutrophilia with band forms occurs early in the infection. In addition, because the incubation period is 30 to 40 days, IgG and IgM antibodies to CMV have already developed when the disease first becomes manifest. The PCR of a blood sample for CMV usually is positive, and CMV can be isolated from specimens of urine or saliva. Liver function abnormalities (see Tables 82–2 and 82–3) include bilirubin elevation. Jaundice may occur in up to 25 percent of these ill patients.¹⁸ Prolonged illness and severe fatigue is quite common in this subset of ill individuals.

TABLE 82–5. Laboratory Findings in Mononucleosis

Complication	Epstein-Barr Virus	Cytomegalovirus
Heterophile antibody	+++	–
Lymphocytosis	+++	++
Reactive lymphocytes	+++	++
Abnormal liver function	++	++
Antinuclear factor	+	+
Cold agglutinins	+	+
Cryoglobulins	+	+
Decreased platelets	++	+

+++ , Characteristic; ++ , common; + , occurs.

COMPLICATIONS

Hemolytic anemia and thrombocytopenia occur in primary CMV infection and are other findings that may lead the clinician initially to consider a diagnosis of lymphoma. There are a variety of pathogenic factors, which explain these hematologic changes. The most prominent neurologic complication is Guillain-Barré syndrome and, less commonly, transverse myelitis and aseptic meningitis (see Table 82–3). Antibody that develops to CMV-infected cells cross reacts with GM₂ antigen that may explain the development of Guillain-Barré syndrome.^{66,67} This antibody can be absorbed with CMV-infected fibroblasts but not by uninfected fibroblasts.

Because it is not the B cell that is the target of infection, but the monocyte–macrophage lineage,^{112,113} evolution to unrestrained B-cell replication, lymphoma, and PTLTD do not occur.

CYTOMEGALOVIRUS IN TRANSPLANTATION

CMV does not predispose to hematologic malignancy. However, it plays a critical role in all of the transplantation settings, with some very similar findings in lung and allogeneic hematopoietic stem cell transplants. It is rare in autologous hematopoietic stem cell transplantations, but can occur and be a serious infection (Chap. 23 discusses CMV infection in allogeneic hematopoietic stem cell transplantation).

In all solid-organ transplantations, there are three potential types of infection that can occur because of CMV.^{114–116} The monocyte–macrophage cells in all solid organs, for example, heart, kidney, pancreas, and liver of CMV-seropositive individuals, harbor CMV that can be reactivated. The CMV-seronegative recipient who receives an organ from a CMV-positive donor can develop a primary infection when the CMV reactivates from the donor organ. Because this occurs when the recipient is receiving immunosuppression, this is the most serious clinical problem.^{115,116} The classic situation occurs when a parent, who is older and has developed infection in the past, donates a kidney or a segment of their liver containing CMV to their child.¹¹⁶ A second possibility is that the CMV in the seropositive recipient, even when the donor is CMV-seronegative, can be reactivated. Because it is the recipient's own latent CMV that is reactivated, the clinical manifestations of infection usually are mild or absent.¹¹⁶ The third occurs when both the donor and the recipient are both CMV-seropositive. Clinical disease can sometimes occur, but its severity is difficult to predict. Clinical disease consists of fever, liver function abnormalities, and inflammatory bowel changes. Prior to the availability of antiviral agents, most patients who developed primary CMV infection did well.¹¹⁶ In solid-organ transplantation patients, in the majority of situations, immunosuppressive therapy starts with the transplantation and then is maintained for prolonged periods.

CMV pulmonary problems occur mainly in lung and allogeneic hematopoietic stem cell transplantations. One contributing factor is that an ideal *in vitro* growth system for CMV is pulmonary macrophages obtained by bronchoalveolar lavage (BAL) from humans.¹¹⁷ That raises the question, does the CMV grow well in the pulmonary macrophage *in vivo*? Does latency in the macrophage–monocyte cellular system from which it reactivates play an important role in lung and allogeneic hematopoietic stem cell transplant patient populations?^{118–120} It is in that setting that the infected macrophage is either occurring in a foreign tissue, the lung transplant, or is being seen as foreign by the allogeneic hematopoietic stem cell cellular derivatives.

In patients receiving an allogeneic hematopoietic stem cell transplant, the immunosuppressive regimen is of relatively short duration, unless the patient develops graft-versus-host disease compared to that for solid-organ recipients. If both the recipient and the donor are CMV-seronegative, posttransplantation, CMV infection does not

develop.¹²¹ In the allogeneic hematopoietic stem cell transplantation setting, if the recipient is CMV-seronegative and the donor is positive for CMV, infection occurs often, but not in everyone. Although pulmonary involvement is most common, the retina and gastrointestinal tract also can be involved. Because the donor cells are not exposed to immunosuppressive medication, other factors need to come into play for CMV infection to become manifest. The other possible matches with respect to CMV are that the recipient is CMV-seropositive and the donor is negative, or both the recipient and the donor are seropositive. If the recipient is seropositive and has been repeatedly exposed to therapeutic regimens in the process of treatment for the recipient's underlying disease, reactivation of CMV could occur before the recipient undergoes transplantation. It would be a "self-vaccination" process for some. One needs to consider whether serious infection with CMV is a major problem in allogeneic hematopoietic stem cell transplantations, or whether it is the interaction between the virus, the pulmonary macrophage, and the host.¹¹⁷⁻¹²⁰ CMV continues to be a problem, but there are now preliminary studies of a CMV DNA vaccine that are promising.

Two approaches have been taken to manage CMV infection for solid-organ recipients. The first is to provide anti-CMV antiviral agents when the donor, the recipient, or both are CMV-seropositive. Antiviral prophylaxis is initiated at transplantation and continued for up to 120 days thereafter. The second is to provide CMV antiviral prophylaxis only for those situations where the donor is seropositive and the recipient is seronegative. For other situations, weekly monitoring for CMV by PCR is done. If that result is positive, the subject is treated for approximately 1 month. In those who undergo specific monitoring, fewer people receive anti-CMV antiviral drugs and for those who do, the duration is shorter. It also makes the best sense as those recipients who were seropositive pre-solid-organ transplantation have a very low frequency of disease.¹¹⁶

For solid-organ transplantations, clinical illness caused by CMV and rejection of the transplanted organ are difficult to differentiate. Fever develops in the recipient when they begin to mount an immune response. Because the cells in the transplanted organ are now "more foreign" than they were prior to virus reactivation, an immune response occurs directed at the infected monocyte. Although both hepatic and gastrointestinal changes occur, mononucleosis usually does not. There is the potential for rejection of the donated organ. Reactivation of one's own latent CMV in a solid-organ recipient does not lead to a problem.¹¹⁶ On occasion, reactivation of CMV in the donor organ in a previously seropositive recipient can lead to illness.

Other infectious problems develop in solid-organ recipients. It is proposed that reactivation of the CMV in the macrophage system inhibits the protective function of that system. In the lung where inhalation of potentially infectious agents occurs continuously, new infection can develop because of impairment of the protective action of the macrophages or the neutrophils.^{122,123} In addition, a number of organisms can, in the case of renal transplantation, be transplanted with the kidney. Besides the viruses discussed above, these can include bacteria, yeast, and parasites, such as *Strongyloides* sp.

When fever develops there is a tendency for the transplantation physician to increase immunosuppression under the assumption that rejection is occurring. If the fever is a result of development of primary infection with CMV, the immunosuppressive therapy leads to permanent interference with development of posttransplantation immunity to the CMV. That, in turn, leads to life-long continued problems with CMV infection.

One of the other confusing features for the transplantation physician has stemmed from the common practice to provide ganciclovir prophylaxis to prevent CMV infection posttransplantation to everyone (see above). Those who are seronegative, receive an organ from a seropositive donor, and receive ganciclovir that suppresses reactivation

from that organ. When the ganciclovir is discontinued, CMV sometimes reactivates from that organ and primary infection can develop several months later. When this happens, patients present with fever and diarrhea and often have a negative blood CMV by PCR. CMV-induced bowel disease develops because the colonic mucosal cells, as noted previously, are targets for primary infection and virus replication. However, because the blood PCR for CMV is negative, the diagnosis eludes the transplant clinician until colonoscopy and biopsy are carried out.

There are other clinical settings where CMV may play a role. There are hints that HIV patients with pneumocystis pneumonia who also have CMV secretions do less well than those who simply have pneumocystis pneumonia.¹²⁴ In the intensive care unit, CMV reactivation may occur in the very ill nonimmunosuppressed patient. It is uncertain what role the virus plays in this setting.

● PRIMARY HIV INFECTION MONONUCLEOSIS

An acute syndrome develops very frequently at the time of development of primary infection with HIV.¹²⁴⁻¹²⁷ The frequency with which the HIV mononucleosis syndrome develops is uncertain, but for this discussion the difference in features is more important. The acute retroviral syndrome must be recognized for both the patient's health and the public health. Fever is sudden in onset, followed by sore throat, lymphadenopathy, tonsillar hypertrophy, painful oral ulcerations, conjunctivitis, and rash. Nausea, vomiting, and diarrhea also occur. Leucopenia, thrombocytopenia, a relative increase in band neutrophils, and a small proportion of reactive lymphocytes usually can be identified on the blood film. Although absolute lymphocytosis is uncommon, the syndrome is referred to as *HIV mononucleosis*. Uncommonly, patients may also develop a heterophile antibody.¹²⁶ Among a group of 563 heterophile antibody-positive patient samples retrospectively tested for HIV-1 RNA and p24 antigen, approximately 1 percent had evidence of primary HIV-1 infection.¹²⁶ In another study, none of 132 cases was positive.¹²⁷ Because in this situation, anti-HIV antibody response has not yet developed, HIV load in the blood should be measured by PCR to make a diagnosis of HIV infection. Usually, viral load is very high (greater than 50,000 viral particles per milliliter of blood). Early treatment may reduce the incidence of HIV-1 complications (Chap. 81). Acute HIV-1 infection may be particularly contagious.¹²⁸ Discussion of the findings with the patient may prevent transmission to a sexual partner.^{124,128}

● OTHER AGENTS LINKED TO A MONONUCLEOSIS SYNDROME

Human herpes virus-6 occasionally has been associated with a mononucleosis-type syndrome as has metapneumonia virus (see Table 82-1).^{129,130} Hepatitis A and rubella virus infection have produced the typical blood lymphocytic changes. Pharyngitis is not a prominent feature in patients infected with *T. gondii*. Lymphocytosis is mild, and liver functions are normal even when the liver is enlarged. Usually, toxoplasmosis presents as posterior cervical lymphadenopathy. In the United States, exposure to oocysts from cat feces is the primary route of infection. In other countries, ingestion of partially cooked meat, especially from sheep, is a route of infection. The IgM immunofluorescent antibody test for *T. gondii* is useful in diagnosing the disease.

Cat scratch disease, *Corynebacterium diphtheriae* pharyngitis, infection with brucellosis, or lymphoma can be mistaken for mononucleosis. Other, as yet unidentified, agents probably produce the classic syndrome as laboratory studies for all of the known infectious agents,

including EBV and CMV, are negative in a small percentage of typical mononucleosis cases.

● DIFFERENTIAL DIAGNOSIS OF MONONUCLEOSIS SYNDROMES

At a very young age, EBV and CMV mimic each other. They present as one of the many febrile illnesses in young children.¹⁵ The difference here is that the children with CMV present with abnormal liver function tests.¹⁰⁷ The importance of documenting primary CMV is that with this information, one can develop a strategy to prevent transmission to a pregnant woman when she might not be immune. By so doing, a severe congenital CMV infection may be avoided.¹¹⁰ The latter possibility is much more likely in the developed world, because only 20 to 30 percent of women have been infected with CMV before they reach reproductive age. In the older teenage child, both EBV and CMV may cause the mononucleosis syndrome but EBV is far more common. If exudative pharyngitis or lymphadenopathy is present then it is most likely to be EBV. If the patient has intraoral ulcers tests for HIV should be done.

In the sexually active teen, both EBV and HIV testing should be done but CMV remains a possibility.¹⁰⁸ Simultaneous infection with EBV and HIV has occurred, although this, too, is very uncommon. Presence of heterophile antibody strongly supports EBV, although these have been reported in HIV.¹²⁷ In adults in their 30s or 40s, mononucleosis more likely results from infection with CMV than EBV because almost all individuals have been infected with EBV by age 25 years. Furthermore, absence of exudative pharyngitis points to CMV, but HIV also should be considered in this age group. Patients infected with either CMV or HIV can present with blood neutrophilia with an increased proportion of band neutrophils. Rash or aseptic meningitis is more common in patients infected with HIV than CMV. In the middle-aged patient, primary CMV infection is by far the most important possibility, although the unusual individual who has escaped infection with EBV earlier in life may present with EBV with clinical manifestations similar to patients with primary CMV infection at that age.^{18,40,41}

● THERAPY

For the majority of patients with primary CMV or EBV infection, treatment is supportive. Salicylates or other analgesics are appropriate for control of fever, headache, and sore throat. Contact sports should be avoided until the spleen has returned to normal size because splenic rupture can occur in the first few weeks after diagnosis. The vast majority of subjects improve and have resolution of most symptoms. Almost half of patients recovering from EBV mononucleosis still feel fatigued at 60 days and a small percent at 6 months. Severe fatigue can persist after CMV mononucleosis as well.

Antiviral therapy may be considered in special settings for treatment of EBV mononucleosis. The nucleoside analogue acyclovir blocks EBV replication by inhibition of viral DNA polymerase and can prevent viral shedding from the oropharynx.^{131,132} However, acyclovir has little if any effect on the course of mononucleosis, presumably because the disease at that point results from the immunopathologic process and not viral proliferation. Antiviral therapy may be useful in chronic aggressive EBV infection and in EBV infection posttransplantation.

Glucocorticoids have been used for management of specific complications. Their specific benefit is difficult to determine because glucocorticoids often are started late in the clinical course, when immunologic reaction to infection is leading to improvement. One carefully controlled trial showed little benefit from glucocorticoids in EBV mononucleosis, and the treated group did less well at 30 days than the

placebo group.¹³³ Nevertheless, treatment with glucocorticoid is reasonable when the tonsils are touching in the midline when airway obstruction is imminent. Prednisone 40 to 60 mg/day is given for 7 to 10 days, then rapidly tapered once a clinical response is achieved. Urgent tonsillectomy and adenoidectomy may be required.^{134,135} The same prednisone regimen is used for severe immune hemolytic anemia, severe symptomatic immune thrombocytopenia, neurologic complications, pancreatitis, and myocarditis.

The same dose of glucocorticoid has been used for the hematologic or neurologic complications of CMV mononucleosis. Results of ganciclovir 5 mg/kg/day given intravenously for 14 days for severe CMV mononucleosis occasionally have been dramatic. However, ganciclovir is seldom used because of the potential long-term risk to spermatogenesis (aspermia) or potentially on female fertility. Thus, when the disease appears to be self-limited, many physicians do not treat it. Therapy that already was started is stopped after a few weeks. Antiretroviral therapy has been suggested for severe HIV primary disease.

Acyclovir use for other manifestations of EBV infection not resulting from host response but from a high titer of EBV replication, such as oral hairy leukoplakia of AIDS, rapidly resolves lingual lesions.¹³⁶ However, treatment with acyclovir does not appear to be effective for the carrier state.¹³⁷

● MONONUCLEOSIS IN PREGNANCY CYTOMEGALOVIRUS AND EPSTEIN-BARR VIRUS INFECTION

For CMV, immunity does not necessarily protect against congenital infection.¹⁰⁹ CMV viruria at birth occurs in babies of mothers known to be seropositive before they became pregnant. Some viruric children whose mother is seropositive at conception go on to develop unilateral or bilateral hearing loss. The reason for the susceptibility to this type of infection in the apparently immune mother is not clear. If primary CMV infection occurs during gestation the baby can have very severe disease. Microcephaly, mental retardation, cataracts, hepatosplenomegaly, and fetal loss or postnatal death have can occur.¹¹⁰ When EBV mononucleosis occurs during pregnancy, severe abnormalities similar to those as described for CMV have occurred (see Table 82-4).^{138,139} Ganciclovir for congenital CMV infection in a very young child is being studied for those who are viruric at birth. Antiviral therapy with famciclovir or valacyclovir has been used for EBV primary infection during pregnancy, but the number of patients treated is too small to draw conclusions.

HIV INFECTION

Primary infection with HIV during pregnancy may not be recognized because HIV antibody is absent early in infection and the antibody screening process is performed at the first prenatal visit. If suspicion of HIV infection is raised during pregnancy and the antibody test for HIV is negative, then viral load should be measured. If positive, antiretroviral therapy for the mother to prevent HIV transmission to the fetus or newborn is indicated.¹⁴⁰

TOXOPLASMA INFECTION

T. gondii producing primary infection during pregnancy can lead to congenital abnormalities. Although no controlled trials are available, treatment of the mother with pyrimethamine plus sulfonamides or spiramycin may eradicate parasites from the infant and the placenta.^{141,142}

CHAPTER 83

CLASSIFICATION AND CLINICAL MANIFESTATIONS OF THE CLONAL MYELOID DISORDERS

Marshall A. Lichtman

SUMMARY

The clonal myeloid neoplasms result from acquired driver and cooperating mutations within a multipotential marrow cell, or sometimes, perhaps, a stem cell. Translocations, inversions, duplications (e.g., trisomy, tetrasomy), and deletions of chromosomes can result in (1) the expression of fusion genes that encode oncogenic fusion proteins or (2) the overexpression or underexpression of genes that encode molecules critical to the control of cell growth, programmed cell death, cell differentiation and maturation, or other regulatory pathways. Gene sequencing has also identified relevant somatic mutations in cases without an overt cytogenetic abnormality. The different mutations may result in phenotypes that range from mild impairment of the steady-state levels of blood cells, insignificant functional impairment of cells, and a modest effect on longevity to severe cytopenias and death in days, if the disorder is untreated. The somatically mutated multipotential cell from which the clonal expansion of neoplastic hematopoietic cells derives acquires the features of a stem cell and retains the ability, with varying degrees of imperfection, to differentiate and mature into each blood cell lineage. A particular disease in this spectrum of phenotypes may have altered blood cell concentrations and cell structural and functional abnormalities, and these may range from minimal to severe, involving several blood cell lineages. The effect on any one lineage occurs in an unpredictable way, even in subjects within the same category of disease. The resulting phenotypes are, therefore, innumerable and varied. In polycythemia vera or essential thrombocythemia, differentiation and subsequent maturation of unipotential progenitor cells results in blood

cells nearly normal in appearance and function, but their level in the blood is excessive. Moreover, overlapping features are common, such as thrombocytosis as a feature of polycythemia vera, essential thrombocythemia, primary myelofibrosis, and chronic myelogenous leukemia. The clonal (refractory) anemias may be accompanied by functionally insignificant or very severe neutropenia or thrombocytopenia or sometimes thrombocytosis. These findings reflect the unpredictable expression of the mutant multipotential hematopoietic cell's differentiation and maturation capabilities for which the genetic explanations are not well defined. The mutant cell of origin takes on the features of a (leukemic) stem cell, responsible for sustaining the disease process. Tight relationships between the genetic alteration and phenotype occur in only a few circumstances, and even these are imperfect, for example, $t(9;22)(q34;q11)(BCR-ABL1; p210)$ with chronic myelogenous leukemia and $t(15;17)(q22;q21)(PML-RAR\alpha)$ with acute promyelocytic leukemia. However, most patients can be grouped into a classic diagnostic designations listed in Table 83–1. The mutant stem cells that maintain the clone may undergo further somatic mutations over time resulting in a more aggressive phenotype, notably acute leukemia, usually of the myeloid type. An important feature of the clonal myeloid diseases is the potentially reversible suppression of normal (polyclonal) stem cells by the clonally expanded neoplastic cells. The coexistence of normal polyclonal stem cells and their competition with the neoplastic clone forms the basis for the remission-relapse pattern seen in acute myelogenous leukemia after intensive chemotherapy and the reappearance of polyclonal, normal hematopoiesis in patients with chronic myelogenous leukemia after tyrosine kinase BCR-ABL inhibitor therapy. This reciprocal relationship between the leukemic clonal and polyclonal normal stem cells may be mediated by the effects of the mass of neoplastic cells (inhibitory cytokine elaboration) and/or to the effect of the neoplastic clone on the stem cell niche and the resulting disturbance of stromal cell support for normal stem cell function.

A wide array of clonal (neoplastic) syndromes or diseases can result from somatic mutations in a multipotential hematopoietic progenitor cell (Table 83–1). This mutated neoplastic cell behaves like a hematopoietic stem cell (albeit, a cancer or leukemia stem cell), in that it is self-replicating, can differentiate, and feed progenitor cells into the various hematopoietic lineages. These leukemic, unipotential progenitors can undergo varying degrees of maturation to phenocopies of mature blood cells. Strong circumstantial evidence has existed for a myelogenous leukemia stem cell for approximately 60 years. This concept has been buttressed by experimental verification of such cells by transplantation of the human disease into immunodeficient mice¹ and by techniques to isolate and characterize their stem cell phenotype.^{2,3} Although most attention has been given to the leukemic stem cell in acute myelogenous leukemia (AML) and chronic myelogenous leukemia (CML), it is very likely that a similar cell underlies (initiates and sustains) each of the phenotypically distinctive clonal myeloid diseases.

The clonal myeloid diseases can be grouped, somewhat arbitrarily, by their degree of malignancy, using the classic terminology of experimental carcinogenesis, which considers the degree of loss of differentiation and maturation potential and the rate of progression of the disease. Thus, myeloid malignancies can be viewed in the spectrum of minimally to severely deviated neoplasms (leukemias). The term *deviation* refers to the relationship of the disease in question to normal cellular differentiation and maturation and the regulation of cell population homeostasis (birth and death rates). This terminology has been used here to array the diagnostic categories of clonal hematopoietic diseases into a

Acronyms and Abbreviations: *ABL1*, Abelson murine leukemia viral oncogene homologue 1; *ALL*, acute lymphocytic leukemia; *AML*, acute myelogenous leukemia; *BCR*, breakpoint cluster gene; *CALR*, calreticulin gene; *CD*, cluster of differentiation; *CEPBA*, CCAAT/enhancer-binding protein *a* gene; *CML*, chronic myelogenous leukemia; *FGFR*, fibroblast growth factor receptor; *FLT-3*, FMS-like tyrosine kinase 3; *G-banding*, Giemsa banding; *GPI*, glycosylphosphatidylinositol; *inv*, inversion; *JAK2*, Janus kinase 2; *miRNA*, microribonucleic acid; *MPL*, myeloproliferative leukemia virus gene; *NPM1*, nucleophosmin 1 gene; *PDGFR*, platelet-derived growth factor receptor; *PNH*, paroxysmal nocturnal hemoglobinuria; *t*, translocation; *WHO*, World Health Organization.

^aThe World Health Organization includes these disorders under the rubric of the “Myelodysplastic Syndromes,” the classification of which is discussed in Chap. 87.

^bThe World Health Organization includes these three disorders under the rubric of the “Myeloproliferative Syndromes.”

^cAcute eosinophilic leukemia is rare. Most cases are subacute or chronic and formerly were included in the category of the hypereosinophilic syndromes.

^dRare cases of acute basophilic leukemia are *BCR*-rearrangement-negative and are variants of acute myelogenous leukemia. Most cases have the *BCR* rearrangement and evolve from chronic myelogenous leukemia (Chaps. 63, 88, and 89).

^eSee Chap. 63.

^fSee Chap. 71.

^gThe World Health Organization has designated these subtypes as separate entities. They also have phenotypes listed under phenotypic variants.¹ For example, approximately 90 percent of cases of t(8;21) AML are of the phenotype acute myelogenous leukemia with maturation. Occasional cases are of the phenotypes acute myeloblastic leukemia (no evidence of maturation) or acute myelomonocytic leukemia. Inv(16) is usually an acute myelomonocytic leukemia but can be of other phenotypes, and t(15;17) invariably manifests itself as an acute promyelocytic leukemia.

^hApproximately 10 percent of cases of acute myeloblastic leukemia may be biphenotypic (myeloid and lymphoid CD markers on individual cells) when studied with antimyeloid and antilymphoid monoclonal antibodies (Chap. 88).

framework related to their pathogenesis for the reader. This approach is an effort to encourage thinking about these somewhat arbitrary diagnostic categories in pathobiologic terms and not just as a list of conditions or by epiphenomena such as disturbed morphology of blood cells that is shared to varying degrees in all categories of these disease (e.g., the dysmorphia of primary myelofibrosis is as dramatic as that of clonal cytopenias or oligoblastic myelogenous leukemia, so-called myelodysplastic syndromes.)

● MINIMAL-DEVIATION CLONAL MYELOID DISORDERS

The neoplasms in this category in Table 83–1 retain a higher degree of differentiation and maturation capability and permit median life spans measured in decades without treatment or with minimally toxic treatment approaches.⁴ Use of the term *minimal-deviation* should not be construed as indicating these conditions do not have morbidity, shorten life, and have other consequences to the patient. The term is used relative to AML, in which differentiation and maturation and regulation of cell proliferation and cell death are profoundly disturbed, and in which expected life span is measured in days to weeks, if untreated. The minimal-deviation clonal myeloid diseases include one group in which late precursor apoptosis (ineffective myeloproliferation) is characteristic (the clonal cytopenias) and one group in which proliferation is exaggerated and cellular maturation approximates normal (effective myeloproliferation).

PRECURSOR APOPTOSIS PROMINENT

The clonal (refractory) anemias and bi- and tricytopenias are characteristic of this category. Cytopenias resulting from exaggerated apoptosis of marrow late precursors (referred to as “ineffective hematopoiesis”) are a principal feature of this subgroup of clonal hematopoietic multipotential cell diseases. A common additional characteristic is variable dysmorphogenesis of blood cells. The blood cell abnormalities, characteristic of the clonal anemias, bicytopenias, or pancytopenia, include abnormalities of (1) red cell size (macrocytosis, anisocytosis), shape (poikilocytosis), and cytoplasm (basophilic stippling), (2) neutrophil nuclear or organelle structure (cytoplasmic hypogranulation, nuclear hypolobulation or hyperlobulation and condensation), and (3) platelet variation in size (megathrombocytes) and granulation (hypogranulation or abnormal granulation). These structural changes are the result of neoplasia. Abnormal maturation of blood cells may also lead to biochemical and functional alterations of the cells, such as disturbed hemostasis, despite adequate platelet numbers, and dysfunctional phagocytes. Dysmorphic changes in marrow precursors are evident, also (Chap. 87). Ineffective erythropoiesis, the intramedullary, apoptotic death of late erythroblasts before they reach full maturation and release, is a common feature, a major factor in development of anemia. Ineffective granulopoiesis and thrombopoiesis also occur, resulting in varying degrees of neutropenia and thrombocytopenia, despite a cellular marrow.

There is no clinical distinction in the presenting manifestation or the course of clonal anemia with less than 15 or equal to or greater than 15 percent pathologic sideroblasts in the marrow,⁵ not surprisingly, as there is no pathobiologic basis for this arbitrary boundary. Therefore, this distinction nonsideroblastic vis-à-vis sideroblastic clonal (refractory) anemia has no nosologic or clinical utility, although the World Health Organization (WHO) has retained it.⁶ Indeed, the clonal anemias frequently have some degree of pathologic sideroblasts in the marrow, and, thus, usually have some degree of sideroblastic erythropoiesis. Another important feature of these syndromes is that there is

no quantitative evidence of leukemic blast cells in marrow or blood. If marrow blasts are elevated above the normal upper limit of 2 percent, the disorder should be considered oligoblastic myelogenous leukemia (synonym: *refractory anemia with excess blasts*; see “Moderately Severe-Deviation Disorders” below).

The WHO has defined “AML” as having equal to or greater than 20 percent leukemic blast cells in marrow; whereas, a marrow with fewer blasts (5 to 20 percent) is referred to as refractory anemia with excess blasts (e.g., one of the myelodysplastic syndromes). The use of an arbitrary boundary of 20 percent blasts has no pathobiologic basis.^{7,8} In addition, the use of less than 5 percent of blasts as a threshold to distinguish clonal anemia (refractory anemia) from oligoblastic myelogenous leukemia (refractory anemia with excess blasts) is an anachronism that dates back approximately 60 years to a time when supportive care was inadequate for children undergoing newly developed multi-drug chemotherapy for acute lymphoblastic leukemia (ALL). At that time, the mid-1950s, there was no accessibility to platelet transfusions. There were very limited antibiotic options and no antifungal agents. There were no venous access devices. The risk of death during prolonged posttherapy marrow aplasia was substantial and it was not yet evident that intensive antileukemic therapy would produce a net benefit to the children so treated. In children with ALL, there were often occasional residual atypical lymphoid cells in the marrow after treatment. To deal with these circumstances an arbitrary threshold of less than 5 percent atypical lymphoid cells (suspected blasts) was used as a measure of successful induction therapy to avoid an unnecessarily long period of posttreatment–induced aplasia.⁷ That boundary, however, was not intended to be a threshold to be used at the time of diagnosis. The normal myeloblast percentage is a very tightly regulated variable (mean: 1.0; SD: 0.4). In severe inflammatory states with leukemoid reactions, the marrow myeloblast percent is usually decreased because in this circumstance precursor cell expansion in the postblast cell myelocyte pool is greater. Three or 4 percent blast cells in the marrow at the time of presentation or suspected relapse should not be considered “normal” and is usually evidence of leukemic hematopoiesis. Indeed, in the presence of an established clonal myeloid disorder (e.g., clonal anemia), any percentage of blast cells, no matter how low the percentage is presumably part of the clone and thus “leukemic.” Not surprisingly, sophisticated multicolor flow analysis has found immunophenotypic abnormalities in such blast cells indicating that they are not “normal” blasts.⁹

In no other cancer is the diagnosis defined by the proportion of cancer cells in histologic or cytologic examinations. Thus, using equal to or greater than 20 percent blasts as the basis for diagnosis of AML versus myelodysplasia represents an aberration in cancer diagnosis and has no pathophysiologic basis.^{7,8} Indeed, studies have shown that there are no differences in the presenting hematologic findings or a series of prognostic genetic markers, for example, the FMS-like tyrosine kinase 3 (*FLT-3*) gene mutation in patients with 10 to 19 percent versus 20 to 30 percent marrow leukemic myeloblasts at the time of diagnosis.⁷ The patient's disease features are the same regardless of whether they have 10 or 30 percent blast cells in the marrow at diagnosis; prognosis was correlated with patient age at diagnosis and the cytogenetic risk category and not the blast count. Moreover, several phenotypes of AML may have less than 20 percent blasts at diagnosis (e.g., acute promyelocytic leukemia, acute monocytic leukemia, acute myelomonocytic leukemia, and others).

The term *hematopoietic dysplasia*, later simplified to *myelodysplasia*, has become ensconced as the category into which clonal anemia, clonal multicytopenia, and oligoblastic myelogenous leukemia (refractory anemia with excess blasts) have been grouped. In strict pathologic terms, a dysplasia is a polyclonal, and thus nonmalignant, change in the cells of a tissue.^{8,10} These myeloid syndromes are clonal, often have

aneuploid or pseudodiploid cells in the clone, are the result of the expansion of a somatically mutated cell, and can be associated with significant morbidity and premature death; thus, they are neoplasias not dysplasias. They demonstrate clonal (genomic) instability, and each has a propensity to evolve into AML at a rate that far exceeds the incidence of the disease in the general population. The term *myelodysplasia* was proposed at a conference in Paris in 1976 at a time when prominent dysmorphogenesis and cytopenias were thought to be the singular abnormalities and arguments existed as to whether some of these syndromes without increased blast cell percentages represented a preneoplastic (preleukemic) condition.¹¹ They have long been established as neoplastic (a spectrum of minimal-deviation to severe-deviation leukemias)—indeed, those with overt leukemic hematopoiesis (quantitatively increased leukemic blast cell counts), which made up approximately 50 percent of cases, were known at the time to be neoplasms—but the terminology has not been rectified.

OVERPRODUCTION OF CELLS PROMINENT

Polycythemia vera (Chap. 84) and essential thrombocythemia (Chap. 85) are clonal myeloid disorders so named because of the overaccumulation of red cells, and often neutrophils, and platelets in the blood in polycythemia, and of platelets, and to a lesser extent neutrophils, in thrombocythemia.¹² Each cell lineage is affected in each disorder, reflecting a multipotential hematopoietic cell origin, but the magnitude of the effect on each lineage differs. The decrease in red cell production in essential thrombocythemia usually is slight to mild. Polycythemia vera and essential thrombocythemia do not show morphologic evidence of leukemic hematopoiesis; the proportion of blast cells in the marrow is never increased above normal, and blast cells are never present in the blood. Hematopoietic differentiation and maturation are maintained. These are minimal-deviation neoplasms. These disorders do not have a specific cytogenetic abnormality, but approximately 95 percent of cases of polycythemia and approximately 50 percent of cases of essential thrombocythemia have an acquired mutation in the Janus kinase 2 (*JAK2*) gene. In thrombocythemia, 25 percent of patients have wild-type *JAK2* genes and mutations in the calreticulin (*CALR*) gene. A few percent of patients with thrombocythemia have nonmutated *JAK2* and *CALR* but a mutation in the myeloproliferative leukemia virus gene (*MPL*; Chaps. 84 and 85).^{13,14} Several studies of comparative survival of the chronic myeloproliferative neoplasms have been reported.^{4,15–18,18a} In the most comprehensive study of survival as of this writing, patients with essential thrombocythemia have only slightly decreased survival than expected over 10 years of observation, but this widens somewhat over longer periods. The difference in survival of patients with primary myelofibrosis is dramatically less than expected for age- and gender-matched unaffected persons and the survival of patients with polycythemia vera is intermediate (Table 83–2).^{18a}

MODERATE-DEVIATION CLONAL MYELOID DISORDERS

Primary myelofibrosis (Chap. 86) and CML (Chap. 89) classically share the features of overproduction of granulocytes and platelets and impaired production of red cells. In contrast to the minimally deviated clonal myeloid neoplasms, CML and primary myelofibrosis may have a small to moderate proportion of leukemic blast cells in marrow and blood. The most constant feature in primary myelofibrosis is the abundance of neoplastic, dysmorphic megakaryocytes and the resultant predisposition to marrow reticulin and collagen fibrosis, osteosclerosis, extramedullary fibrohematopoietic tumors, splenomegaly, and teardrop-shaped red cells (dacryocytes) in every oil immersion field on the blood film. The megakaryocytic abnormalities are so dominant and consistent in this disorder that it could be considered chronic megakaryocytic leukemia.¹⁹ The cells in this disorder have no specific cytogenetic change, but approximately 50 percent of cases carry a mutation in the *JAK2* gene and approximately one-third have wild-type *JAK2* but a mutation in the *CALR* gene (Chap. 86).^{13,14} These two mutations give primary myelofibrosis a genetic kinship with polycythemia vera and essential thrombocytosis. They are often referred to as “the myeloproliferative neoplasms,” but virtually all clonal myeloid diseases are fundamentally myeloproliferative as the term refers, principally, to marrow hematopoiesis. The clinical behavior of primary myelofibrosis is, in most cases of a progressive neoplasm with morphologic evidence, of lower-level leukemic hematopoiesis and with a median survival significantly less than polycythemia vera or essential thrombocythemia. Primary myelofibrosis is another misnomer perpetuated in the WHO classification. The fibrosis is secondary to cytokines released by neoplastic (leukemic) megakaryocytes (an epiphenomenon) and it is the only cancer in the medical lexicon named after connective tissue fibers and not the cells in which the cancer arises.¹⁹

In contrast to primary myelofibrosis, CML has a rearrangement of the breakpoint cluster (*BCR*) gene on chromosome 22. The shortening of the long arm of chromosome 22 gives it the designation of the Philadelphia chromosome, now called the Ph chromosome. It can be identified by Giemsa (G)-banding cytogenetic studies in approximately 90 percent of patients with CML. This mutation is caused by and is a reflection of the translocation t(9;22)(q34;q11)(*BCR-ABL1* [Abelson murine leukemia viral oncogene homologue 1]). The *BCR-ABL1* fusion in CML cells can be found in virtually all cases studied by fluorescence *in situ* hybridization or the polymerase chain reaction. Only approximately 4 percent of patients with a phenotype indistinguishable from *BCR*-rearrangement-positive CML do not have the rearrangement (see Table 83-1 and Chap. 89). An unrelenting increase in the white cell (granulocyte) count, anemia, splenomegaly, and a progressive course are common features of CML. Blast cells are very slightly increased in marrow

TABLE 83–2. Comparative Survival Among Persons with Myeloproliferative Neoplasms

Years of Survival	Percent (%) of Cohort Alive			
	Expected	Essential Thrombocythemia	Polycythemia Vera	Primary Myelofibrosis
5	90	90	85	55
10	85	80	70	30
15	75	70	45	30
20	65	50	30	15
25	55	40	20	10

Data from Tefferi A, Guglielmelli P, Larson DR, et al: Long-term survival and blast transformation in molecularly annotated essential thrombocythemia, polycythemia vera, and myelofibrosis. *Blood* 2014 Oct 16;124(16):2507–2513.

and in the blood in patients with these two disorders, although this is a function of time of diagnosis in relation to the time of onset. CML, if untreated, has a very high propensity to progress through clonal evolution to acute leukemia.

Primary myelofibrosis terminates in acute leukemia in approximately 15 percent of patients. Median life span in these disorders is measured in years, but is significantly decreased compared to age- and gender-matched unaffected cohorts. Therapy is required in all cases of CML, and in most, but not all, cases of primary myelofibrosis at the time of diagnosis. Both diseases can be cured by allogeneic hematopoietic stem cell transplantation. Median life span is projected to be increased by decades in CML as a result of the introduction of tyrosine kinase inhibitors, which results in involution of the malignant clone, restoration of polyclonal normal hematopoiesis, and a reduction in the risk of transformation to an accelerated phase of the disease and to acute leukemia in many patients (Chap. 89).²⁰ A significant median prolongation of life (e.g., approximately median 2 years) result from JAK inhibitors in poor-prognosis primary myelofibrosis (Chap. 86).

Chronic neutrophilic leukemia, chronic eosinophilic leukemia, systemic mastocytosis, and chronic basophilic leukemia are included in this category. Chronic basophilic leukemia is a rare disease (Chap 89).²¹ Chronic neutrophilic leukemia is uncommon but well described and defined (Chap. 89). Chronic neutrophilic leukemia is associated with a mutation in the colony-stimulating factor 3 receptor gene (*CSF3R*) alone (approximately 30 percent of cases), or a combination of mutated *CSF3R* and a SET binding protein gene (*SETBP1*) mutation (approximately 60 percent of cases) or the *JAK2*^{V617F} mutation alone (approximately 10 percent of cases). Chronic eosinophilic leukemia represents cases previously called hypereosinophilic syndrome with evidence of clonal hematopoiesis involving eosinopoiesis. Some cases are associated with a rearrangement of the platelet-derived growth factor receptor- β (*PDGFR*- β) gene (these are indicted in Table 83-1) because they are specifically responsive to the tyrosine kinase inhibitor imatinib mesylate or to a congener (Chaps. 62 and 89). Chronic clonal eosinophilia also may be associated with a *PDGFR*- α gene rearrangement, but histopathologic examination of the marrow also may be consistent with systemic mastocytosis with eosinophilia, with sheets of spindle-shaped mast cells and intense eosinophilia in blood and marrow. This rearrangement is usually the result of a *FIP1L1*-*PDGFR*- α fusion gene. Identification of this fusion gene in cases of mastocytosis with eosinophilia is important because of the sensitivity of the gene product to imatinib mesylate (or a congener). The mutation is inferred by a deletion in the *CHIC2* gene found using fluorescence *in situ* hybridization, which narrowly separates *FIP1L1* and *PDGFR*- α at chromosome 4q band 12. The cryptic deletion involving *CHIC2* is too small to be seen on standard G-banding. A clonal myeloid syndrome that includes eosinophilia and a translocation between 8p11, at the site of the tyrosine kinase domain of the fibroblast growth factor receptor-1 (*FGFR1*) gene, and several different partner chromosomes, is not responsive to imatinib mesylate. Systemic mastocytosis may have several types of *KIT* gene mutation; *KIT*^{V560G} is sensitive to imatinib mesylate and *KIT*^{D816V} is insensitive to imatinib but may be responsive to second-generation tyrosine kinase inhibitors. *PDGFR*- α mutations also may be present in the cells of patients with systemic mastocytosis and be responsive to imatinib mesylate (or a congener).²²

MODERATELY SEVERE-DEVIATION CLONAL MYELOID DISORDERS

These disorders fall into a group that progresses less rapidly than acute leukemia and more rapidly than CML.^{23,24} They have a predisposition

to develop with a granulocytic and monocytic phenotype, either morphologically or cytochemically. These diseases include oligoblastic myelogenous leukemia (refractory anemia with excess blasts), chronic myelomonocytic leukemia, and juvenile myelomonocytic leukemia. Occasional patients have an atypical or unclassifiable syndrome. The “unclassifiable syndrome” designation is used for uncommon cases that do not fall into a classical or easily classifiable designation and usually are seen in patients older than age 70 years.

The subacute syndromes produce more morbidity than do the chronic syndromes, and patients have a shorter life expectancy. These are leukemic states that have low or moderate concentrations of leukemic blast cells in marrow and often blood, anemia, often thrombocytopenia, and usually prominent monocytic maturation of cells (Chap. 88). The oligoblastic myelogenous leukemias compose approximately 50 percent of the cases that have been grouped under the title *myelodysplastic syndromes*. In all other malignancies, the presence of tumor cells determines the diagnosis, such as carcinoma of the colon or the uterine cervix, whether *in situ*, invasive, or metastatic. Use of the percentage of tumor (leukemic blast) cells as a threshold for the diagnosis of leukemia versus “dysplasia” is not consistent with usual practice; hence, the preference for oligoblastic myelogenous leukemia rather than myelodysplasia for patients with a quantitative increase in blast cells (>2 percent blasts), cytopenias, and dysmorphic cell maturation.⁸ Moreover, CML, chronic neutrophilic leukemia, chronic myelomonocytic leukemia, acute promyelocytic leukemia, and several other subtypes of AML invariably have fewer than 20 percent blasts in the marrow. Thus, the criteria used in the WHO classification system for clonal myeloid diseases have internal inconsistencies that can be dealt with by experts but are confusing to the less experienced and are not unifying.

A group of clonal myeloid diseases are referred to as atypical myeloproliferative disease or atypical CML (aCML) in the WHO classification. They are usually seen in older patients (>65 years), have a relatively low myeloblast percentage in marrow (<5 percent) and blood, and have an elevated white cell count ranging between 15 and $100 \times 10^9/L$, but which may be higher. They have anemia and thrombocytopenia and often splenomegaly. The blood and marrow usually have a progressively increasing proportion of promyelocytes and myelocytes as well as neutrophils, superficially simulating the appearance of CML, hence the use of the designation “aCML.” These cases never have a rearrangement in the *BCR* gene, are not responsive to tyrosine kinase inhibitors, and have a poor prognosis with a median survival of approximately 15 to 20 months. Because the granulocytic series often has some dysmorphism (e.g., acquired Pelger-Huët nuclear anomaly), the WHO seems reluctant to call it an atypical myeloproliferative disorder, which should be done as aCML is an inadvisable term. Their inconsistency is evident in the classification of primary myelofibrosis as a myeloproliferative disorder despite florid dysmorphism of all three major lineages. Dysmorphism is a feature of most neoplastic cells, of considerable diagnostic utility, of interest cytologically, but an epiphenomenon not central to the pathobiology of the neoplasm. Atypical myeloproliferative disease (aCML) has a relatively high frequency of *CSF3R* gene mutations, akin to chronic neutrophilic leukemia. Because the mutant gene is thought to cause dysregulation evidenced by *myeloproliferation* and exaggerated neutrophil counts, it underlines the preferred terminology.

SEVERE-DEVIATION CLONAL MYELOID DISORDERS

Morphologic, histochemical, immunocytologic, and cytogenetic characteristics of cells in the blood and marrow provide the major basis for the diagnosis and classification of AML and its subtypes

(Chaps. 11 and 88). Correlation among observers and between the morphologic method of classification and the monoclonal antibody reactivity-dependent classification of AML is imperfect.²⁵⁻²⁷ The approach that uses morphology, immunocytochemistry, and the immunophenotype is the most inclusive because virtually all cases can be placed into a morphologic subtype. Because immunophenotyping is a standard procedure in most clinical hematopathology laboratories, the results are readily available. Classification by cytogenetics is more limited because approximately 45 percent of cases of AML do not have a discernible cytogenetic abnormality by G-banding and many cases have different infrequent abnormalities, making this approach complex. Hundreds of unique patterns of cytogenetic abnormalities have been reported in cells of patients with AML, including unbalanced structural abnormalities, such as loss of part or all of chromosome 5 or 7, numerical abnormalities, such as an additional chromosome 8 (e.g., trisomy 8), or unbalanced and balanced structural abnormalities, such as translocation between chromosomes 8 and 21 or 15 and 17, or between chromosome 11 and many chromosome partners, or any one of numerous other abnormalities involving other chromosomes.²⁸ Despite this heterogeneity, knowing the cytogenetic alteration is useful for estimating the probability of entering a sustained remission (risk category). For example, AML patients whose cells contain t(8;21), t(15;17), t(16;16), or inv(16) (approximately 20 percent of cases considering all age groups) are more likely to enter a prolonged remission or be cured with therapy. The cytogenetic findings may influence the drugs used for remission-induction therapy. Notably, patients with t(15;17) AML (approximately 7 percent of all new AML cases in the United States and twice that frequency in China) uniquely require use of all-*trans*-retinoic acid and arsenic trioxide to result in the best long-term outcome and, in many cases, a cure. Thus, combining light microscopy of blood and marrow with immunocytochemistry and cell-flow analysis immunophenotyping to designate the phenotypic subtype, supplemented by cytogenetics or molecular diagnostic methods, currently is the best approach to categorization of the AML subtype. The polymerase chain reaction may be particularly useful for determining subclinical (minimal) residual disease and monitoring therapy in cases in which an appropriate genetic marker is available, such as the t(8;21) or t(15;17) (Chaps. 88 and 89).

Gene expression profiling using chips containing tens, hundreds, or thousands of relevant genes can be used to further genotype and subclassify AML into prognostic groups.^{29,30} One would predict, based on cytogenetics, a large and diverse group of gene expression profiles for cases of AML. In one study of 200 cases of AML, some of 270 mutated genes among nine genes families (i.e., transcription factor, tumor-suppressor, signaling pathway, nucleophosmin encoder, DNA-methylation-related, chromatin-modifying, myeloid transcription factor, cohesion complex, and spliceosome-complex genes) were found in at least two cases.³¹ Genetic analysis is currently most useful in analyzing cases with prior stratification by some relevant variable. For example, a study of patients with AML who have normal karyotypes by standard cytogenetic methods (e.g., G-banding) has identified two groups by hierarchical gene clustering with significantly different survival after current therapy.³² Patients with AML whose cells contain a *FLT-3* internal tandem duplication also can be stratified into more discriminating prognostic groups using hierarchical gene cluster analysis.³³ Gene expression profiling can identify groups of patients with AML who have covert gene abnormalities, such as a mutation in the DNA methyltransferase gene (*DNMT3A*) or the nucleophosmin 1 (*NPM1*) gene. The former gene encodes one of a family of enzymes that catalyze the transfer of a methyl group to DNA, using *S*-adenosyl methionine as the methyl donor; and, the latter gene encodes a protein that shuttles between the nucleus and cytoplasm. Gene expression studies in AML are important because they (1) identify genes that cooperate or interact to result in a fully malignant

phenotype, (2) provide potential new targets for therapy, (3) help identify patients who might benefit from early hematopoietic stem cell transplantation, (4) may be used to measure minimal residual disease,³⁴ and (5) may permit analysis of the mutational evolution from the earliest neoplastic cell without malignant potential to cells with additional mutations capable of developing lethal clones.³⁵

Another molecular technique applied to understanding the molecular pathology of AML and to defining prognostic groups is the leukemic cell microribonucleic acid (miRNA) signature.^{36,37} The miRNAs are small (19 to 25 nucleotides), noncoding RNAs that regulate messenger RNA stability and its translation into protein. miRNA signatures can be analyzed by polymerase chain reaction technology of RNA samples from leukemic cells and compared to normal or compared among different categories of AML cases. For example, miRNA analysis can distinguish among cytogenetically normal cases of AML as to their expression of different genes that influence prognosis, such as *NPM1* and the CCAAT/enhancer binding protein α gene (*CEPBA*). Specific microribonucleic acids (miRNAs) may regulate lineage differentiation of stem cells, indicating critical roles for these molecules in the regulation of hematopoiesis and in leukemogenesis.³⁸ Prognostic group stratification of AML, at the moment, has value principally in assessing the utility of using allogeneic hematopoietic stem cell transplantation as an early therapy. It also may inform the therapist about considering a clinical trial of new therapeutic combinations, if the prognostic indicators suggest use of cytarabine and an anthracycline regimen, as the backbone of therapy, is unlikely to be successful and the patient is not a candidate for allogeneic hematopoietic stem cell transplantation (Chap. 88).

● TRANSITIONS AMONG CLONAL MYELOID DISEASES

Patients with minimal-, moderate-, and moderately severe-deviation clonal myeloid disorders have an increased likelihood of progressing to florid (polyblastic) AML, with a frequency ranging from approximately less than 1 percent of patients with paroxysmal nocturnal hemoglobinuria, approximately 10 percent of patients with clonal anemia, approximately 35 percent of patients with clonal bi- or tricytopenia, and as many as 66 percent of patients with oligoblastic myelogenous leukemia.³⁹ Approximately 30 percent of patients within the spectrum of clonal cytopenia to oligoblastic myelogenous leukemia (myelodysplastic syndromes) develop AML when the WHO boundary of equal to or greater than 20 percent blast cells is applied.³⁹ Approximately 15 percent of patients with polycythemia vera evolve to a syndrome indistinguishable from primary myelofibrosis and the same evolution can occur in patients with essential thrombocythemia.^{40,41} Occasional cases of apparent essential thrombocythemia or rare cases of primary myelofibrosis can evolve into polycythemia vera. Apparent essential thrombocythemia with cells containing the *BCR-ABL1* fusion gene may progress to CML or acute blast crisis of CML.

Approximately 5 percent of patients with essential thrombocythemia develop AML over 20 years of observation, but this rises to 10 percent over 25 years.^{18a} Approximately 12 percent of patients with polycythemia vera evolve to AML over 20 years of observation.^{18a} Approximately 20 percent of patients with primary myelofibrosis progress to overt AML over 10 years of observation.^{18a} Virtually all patients with CML have the potential to progress to acute leukemia of any subtype, including in about a quarter of cases to lymphoid phenotypes, although in some cases the patient enters an accelerated phase that behaves like oligoblastic leukemia before it progresses to acute leukemia. The accelerated phase of CML is associated with inadequate response to therapy, progressive anemia, bone pain, enlarging spleen,

thrombocytopenia, among other changes (Chap. 89). The progression from chronic to accelerated phase or blast phase of CML, however, has been delayed in the majority of patients by the application of tyrosine kinase inhibitor therapy during the chronic phase of the disease. Determining the frequency of evolution to AML in those patients with CML who enter a complete molecular remission with tyrosine kinase inhibitors must await observations over the next decade.

This process of clonal evolution is an intrinsic feature of the genomic instability of clonal myeloid diseases. The practice of calling the result of this process “secondary AML” is obfuscating. This choice of terms is notable in the case of myelodysplastic syndrome, which is “leukemia” at the time of diagnosis. (Leukemia is defined as the neoplastic transformation of a primitive multipotential hematopoietic [myeloid] cell.) The neoplastic transformation has occurred and the progression to a more advanced myeloid neoplasm is a process quite different from the secondary AML that occurs as a result of recent chemotherapy for a lymphoma or an unrelated cancer (e.g., breast cancer). When there is progression to AML from a previously diagnosed clonal myeloid disease, it should be designated as clonally evolved AML (ceAML). This distinction is important because an effort to develop methods to prevent clonal evolution is very likely to be different from methods to prevent true secondary leukemia.

● PATHOGENESIS OF CLONAL MYELOID DISEASES

In AML, a sequence of mutations in a single multipotential cell results in a clone that is severely defective and contains precursor cells that are largely unable to mature.^{42,43} Proliferation of primitive progenitors is excessive when considered in absolute terms, that is, the total number of blast cells proliferating. AML is a clinical disease with many forms of morphologic expression. This variation of phenotype is consistent with the large number of genetic lesions identified and the behavior of the leukemic stem cell, which is capable of differentiation into all the blood cell lineages (Fig. 83-1). Hence, the asymmetrical and uncoordinated differentiation and maturation of leukemic progenitor cells may allow one or another cell type to predominate.⁴⁴ The different morphologic or cytogenetic variants of AML are each rapidly progressive, however, if not treated successfully (Chap. 88).

Important epiphenomena are related to certain morphologic types of AML, such as tissue infiltration, including into the central nervous system in monocytic leukemia, disseminated intravascular coagulation, fibrinolysis, and hemorrhage in promyelocytic leukemia, and to a lesser extent in monocytic leukemia, hepatosplenomegaly (eosinophilic

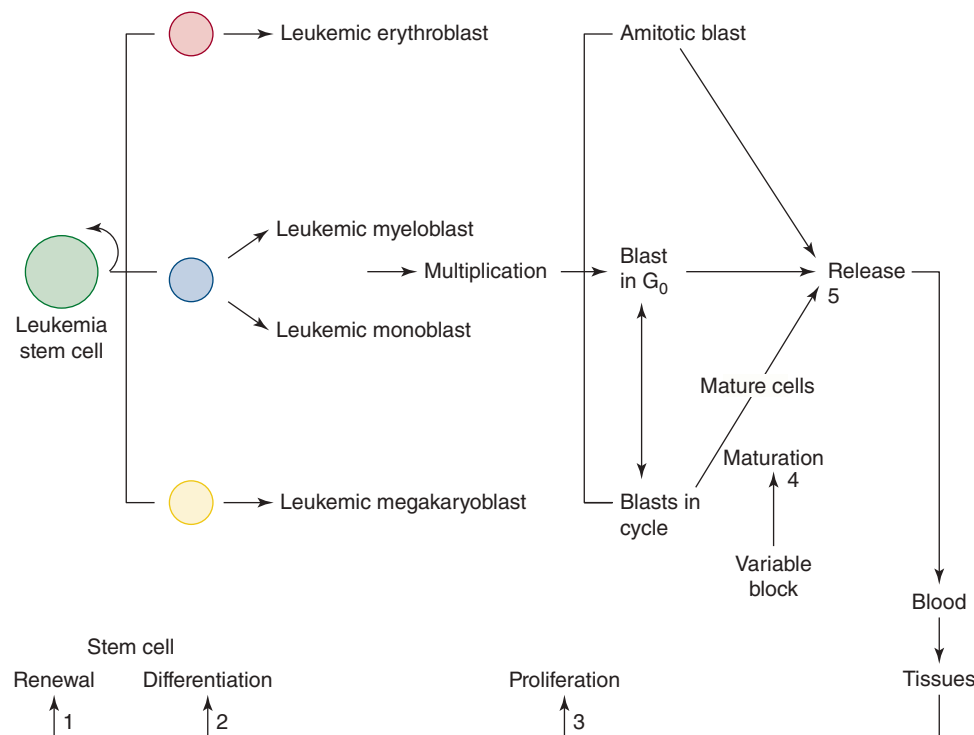

Figure 83-1. Leukemic hematopoiesis in acute myelogenous leukemia. The malignant process evolves from a single mutant multipotential cell. This cell on the basis of a sequence of somatic mutations becomes a leukemia stem cell with a growth advantage in relationship to normal pluripotential stem cells. This cell originates at either level 1 or level 2 or level 3 in Fig. 83-2. Whether all cases of acute myelogenous leukemia originate in the pluripotential stem cell pool is still under study (see text). This cell is capable of multivariate commitment to leukemic erythroid, granulocytic, monocytic, and megakaryocytic progenitors. In most cases, granulocytic and monocytic commitment predominates, and myeloblasts and promonocytes or their immediate derivatives are the dominant cell types. Leukemic blast cells accumulate in the marrow. The leukemic blast cells may become amitotic (sterile) and undergo programmed cell death, may stop dividing for prolonged periods (blasts in G_0) but have the potential to reenter the mitotic cycle, or may divide and then undergo varying degrees of maturation. Maturation may lead to mature cells, such as red cells, segmented neutrophils, monocytes, or platelets. A severe block in maturation is characteristic of AML, whereas a high proportion of leukemic primitive multipotential cells mature into terminally differentiated cells of all lineages in patients with CML. The disturbance in differentiation and maturation in myelogenous leukemia is quantitative, thus many patterns are possible. At least five major steps in hematopoiesis are regulated: (1) stem cell self-renewal, (2) differentiation into hematopoietic cell lineages (e.g., red cells, granulocytes, monocytes, platelets), (3) proliferation (cell multiplication), (4) maturation of progenitor and precursor cells, and (5) release of mature cells into the blood. These control points are defective in acute myelogenous leukemia. Premature or delayed apoptosis of cells may be another key abnormality contributing to premature cell death or cell accumulation.

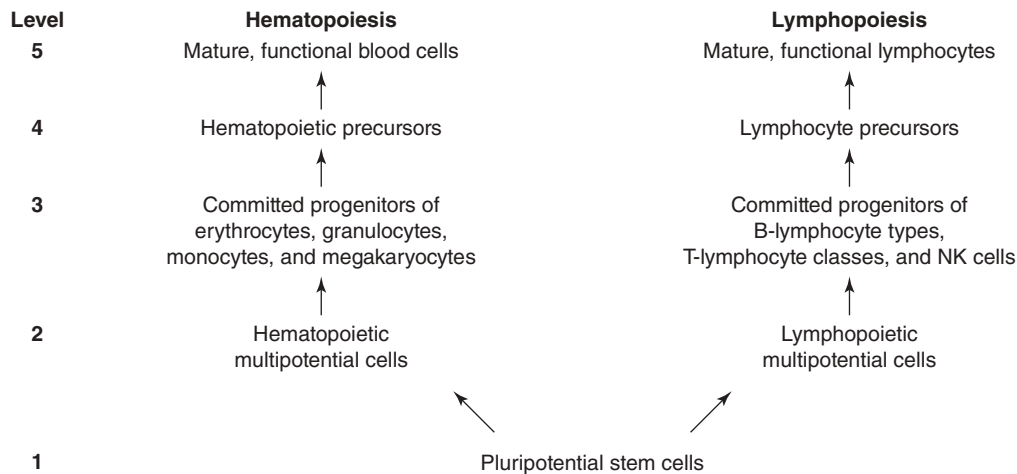

Figure 83–2. Differentiation and maturation of hematopoietic stem cells. The functioning stem cell pool is thought to be at *level 1*, the pluripotential (lymphohematopoietic) stem cells. In healthy humans, two multipotential progenitor cell pools are operative (*level 2*). The multipotential progenitors differentiate further to unipotential progenitors, which are sensitive to specific cytokines (*level 3*). The committed progenitor cells are referred to as colony-forming units or colony-forming cells because they form clonal colonies of cells in semisolid medium in the presence of the appropriate growth factors. These growth factors are capable of inducing proliferation and maturation of the committed progenitor cells so that they achieve *level 4*, at which the first morphologically identifiable marrow precursors have developed, such as myeloblasts, proerythroblasts, promonocytes, megakaryocytes and, ultimately, *level 5*, the mature, functional blood cells. NK, natural killer.

leukemia), mediator-release syndromes (basophilic or mast cell leukemia), predisposition to myeloid sarcomas (AML with t[8;21] or inv[16] cytogenetic abnormalities), and intense marrow fibrosis (megakaryocytic leukemia) (Chap. 88).

In CML, injury to a single cell results in a clone in which there is an enormous expansion of progenitors for granulocytic and, often, megakaryocytic cells. Erythropoiesis is effective but decreased. Unlike AML, maturation of progenitor cells in CML is nearly normal; hence, the predominant leukemic cells in the blood are postmitotic, mature, or partially matured cells, such as late myelocytes and segmented neutrophils, monocytes, erythrocytes, and platelets. This process of multilineage differentiation and maturation to cells with virtually normal function accounts for the relative infrequency of hemorrhage or recurrent infection in the chronic phase of CML.

Because hematopoiesis is generated by a leukemic stem cell that has functional analogies to a normal multipotential hematopoietic cell, erythropoiesis, thrombopoiesis, and granulopoiesis are leukemic in most patients with AML, CML, and other clonal myeloid diseases. Thus, identical clonal cytogenetic abnormalities are present in erythroblasts, megakaryocytes, and granulocyte precursors in cases of AML so studied (Chap. 88) and in all cases of CML with a BCR-rearrangement (Chap. 89).

● PHENOTYPE OF MYELOID CLONAL DISEASES AS A RESULT OF THE MATRIX OF DIFFERENTIATION AND MATURATION

The phenotype of clonal myeloid diseases is a reflection of a neoplastic stem cell's capability to differentiate into abnormal committed progenitor cells and the ability of those progenitor cells to mature into identifiable cells of the erythroid, granulocytic (neutrophilic, basophilic, mastocytic, eosinophilic), monocytic, dendritic, and megakaryocytic cell lineages (Fig. 83–3).^{42,45,46}

Under normal circumstances, hematopoietic differentiation represents the irreversible change from a multipotential cell to multiple, unipotential lineage progenitors. Maturation represents the physical and chemical changes from a unipotential progenitor through a sequence of precursors to the fully mature and functional blood cell, including progression from a burst-forming unit–erythroid to proerythroblast to erythrocyte; from a colony-forming unit–granulocyte to myeloblast to segmented neutrophil; from a colony-forming unit–eosinophil to a segmented eosinophil; from a colony-forming unit–basophil to a mature basophil; from a colony-forming unit–mast cell to a mature mast cell; from a colony-forming unit–monocyte-macrophage to promonocyte to monocyte to macrophage or dendritic cell; and from a colony-forming unit–megakaryocyte to a diploid megakaryoblast to the polyploidy, platelet-forming megakaryocyte (Chap. 18). A matrix, which is composed of the options of commitment to different lineages and the progressive stages of maturation at which partial or complete arrest can occur, results in the potential for a wide array of morphologic syndromes by which a leukemic stem cell can dominate hematopoiesis (see Fig. 83–2).

In the clonal myeloid diseases in which differentiation and maturation capability are retained, one of the cell lines—for example, erythrocytes, granulocytes, monocytes, or platelets—tends to accumulate in the blood more prominently and results in a phenotypic expression of the disease that determines the nosology (e.g., exaggerated blood platelet accumulation and essential thrombocythemia). In AML, the phenotypic expression may be predominantly myeloblastic (granuloblastic), erythroid, monocytic, megakaryocytic, or combinations thereof. Certain patterns are favored. In AML, myelocytic leukemia, monocytic leukemia, or a mosaic of the two cell types (myelomonocytic leukemia) are more common than erythroid or megakaryocytic leukemia. Eosinophilic, basophilic, and dendritic cell leukemias are rare. However, AML usually has a disturbance in all cell lines. In myeloblastic or myelomonocytic leukemia, overt, qualitative abnormalities of erythroblasts and megakaryocytes may occur. The prevalence of the abnormalities in the latter two lineages may not be great enough or evident enough for the observer to designate a case as erythroid or megakaryocytic leukemia. In the latter two cases, identification of markers unique for erythroid

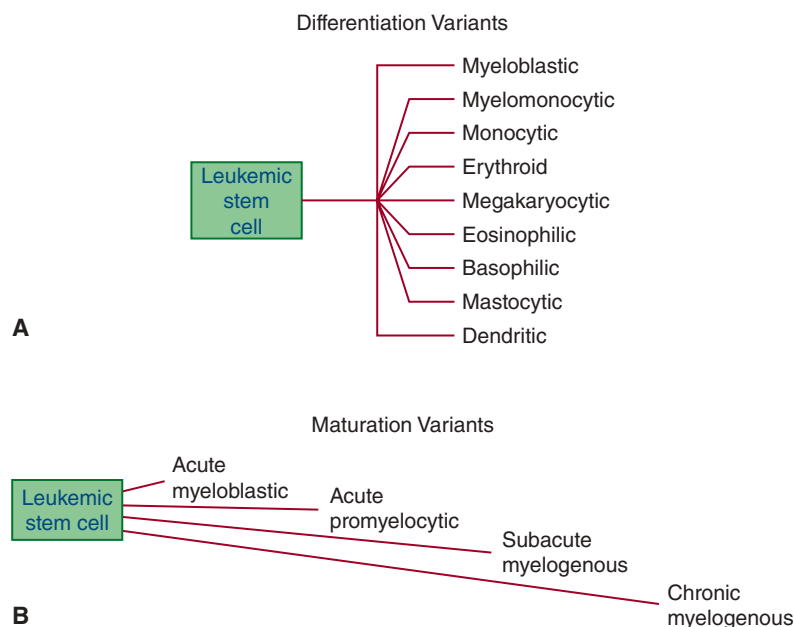

Figure 83-3. Phenotypic subtypes of acute myelogenous leukemia. Acute myelogenous leukemia has variable morphologic expression and a variable degree of maturation of leukemic cells into recognizable precursors of each blood cell type. This phenotypic variation results because the leukemic lesion resides in a multipotential cell normally capable of all the hematopoietic lineage commitment decisions. **A.** Morphologic variants of AML can be considered differentiation variants in which the cells derived from one of the options of commitment accumulate prominently (e.g., leukemic erythroblasts, leukemic monocytes, leukemic megakaryocytes). **B.** Acute myeloblastic leukemia, promyelocytic leukemia, subacute myelogenous leukemia, and chronic myelogenous leukemia can be considered maturation variants in which blocks at different levels of maturation may be present or do not exist (e.g., CML).

(e.g., cluster of differentiation [CD] 71) or megakaryocytic cells (e.g., CD41, CD42, or CD61), rather than reliance solely on light microscopy, has increased the frequency of identification of these variants.

The continuum of maturation can be completely or partially blocked at various levels, leading to morphologic variants such as acute myeloblastic, acute promyelocytic, AML with maturation, and CML.

● PLURIPOTENTIAL STEM CELL POOL AS SITE OF THE NEOPLASTIC EVENTS

Evidence points to a lesion in the multipotential hematopoietic cell pool in most of the clonal myeloid diseases, explaining the involvement of erythropoiesis, granulopoiesis, monopoiesis, and thrombopoiesis. Debate continues whether the cell of origin is a pluripotential (lymphohematopoietic) stem cell or a somewhat more differentiated multipotential cell.^{47,48} (Chapter 88 provides a more detailed discussion of this topic.) In CML patients, the mutation is thought to be in the pluripotential stem cell; in other syndromes, evidence for involvement of B, T, and natural killer (NK) lymphocytes is variable. B lymphocytes are derived from the clone in some cases. Evidence that affected T lymphocytes undergo apoptosis before entering the blood in patients with CML may explain the absence of clonal markers in T lymphocytes in some cases of CML and other clonal myeloid disorders.⁴⁹

PROGENITOR CELL LEUKEMIA

Analysis of cases of AML in informative girls (young women) and older women who were heterozygous for X chromosome-linked gene products isotypes A and B of the enzyme glucose-6-phosphate dehydrogenase indicated that the AML clone in the young women was restricted to the granulocyte-monocyte pathway, whereas monoclonality was expressed in all hematopoietic cell lines in the older women. This approach had been validated in prior studies of CML and AML, using enzymes or chromosome markers.^{50,51} These findings supported the possibility that a leukemic transformation in young patients can occur in progenitor cells (e.g., colony-forming unit—granulocyte-monocyte; level 3 in Fig. 83-2) and result in a true acute “granulocytic”

leukemia. If progenitor cell myelogenous leukemia is common in younger patients, this pattern might explain their better response to treatment. In a subset of patients with acute monocytic leukemia,⁵² t(8;21) AML,⁵³ and t(15;17) AML,⁵⁴ studies indicated that the leukemia derives from the neoplastic transformation of a more differentiated progenitor cell not the pluripotential lymphohematopoietic stem cell. The acute transformation of CML also appears to occur in a granulocyte-monocyte progenitor (Chap. 89).

More sophisticated approaches to the site of the lesion in mouse models of AML have indicated that disorders like acute promyelocytic leukemia for which there is evidence in humans that it may originate in a more differentiated progenitor, such as the granulocyte-monocyte colony-forming cell,⁵⁴ places the neoplastic event(s) in a much earlier multipotential (?stem) cell.⁵⁵ Indeed, some experts have concluded that all clonal myeloid neoplasms originate in a mutated lymphohematopoietic stem cell, whereas others do not feel the evidence is either consistent or conclusive and that either a stem cell or an early multipotential progenitor cell could be the site of the transformation.

● QUANTITATIVENESS OF CLONAL MYELOID DISEASES

The mutational lesions of the primitive hematopoietic multipotential cell compartment are qualitative in the sense that a distinct alteration from normal is seen in the function of that cell pool. The alteration reflects an acquired change in the genome of one primitive hematopoietic cell. This qualitative change, however, is such that the mutant multipotential cell can express all or some of the normal differentiation and maturation options. This expression can mimic closely the differentiation (commitment) and maturation expected of normal hematopoietic cells, as occurs in CML, essential thrombocythemia, and polycythemia vera. Most cases tend to conform to readily recognized patterns, but the opportunity for a large number of variations on the most common themes is possible. Thus, some mixed and “in-between” syndromes occur in which features of ineffective hematopoiesis and myeloproliferation of different cell lineages are present. For example, extreme thrombocytosis, usually confined to essential thrombocythemia, may accompany CML, primary myelofibrosis,

or clonal bicytopenia with thrombocytosis. Erythrocytosis may rarely accompany CML. Atypical myeloproliferative syndromes or other clonal myeloid diseases may have mixtures of anemia, granulocytopenia, and thrombocytosis or of anemia, granulocytosis, and thrombocytopenia rather than pancytopenia. Qualitative abnormalities of red cell, granulocyte, or platelet structure or function may be more or less prominent in a given patient. For example, qualitative abnormalities of erythroblast development may result in acquired α -thalassemia (acquired hemoglobin H disease), especially in patients with primary myelofibrosis, or occasionally other clonal myeloid diseases. In AML, unusual patterns of phenotypic expression occur frequently. For example, prominent leukemic erythroblasts and monocytes or eosinophils and monocytes may be seen in patients. So much opportunity for variation in disease expression exists among patients with AML that observation of patients in whom the phenotype of their leukemic cells is identical to the phenotype of other patients is unusual. Choice of treatment is little affected by these variations. Decisions about whether to treat and which drugs to use are greatly influenced by whether a patient has a chronic, subacute, or acute clonal myeloid disease; by the rate of progression of the disease; by the extent of the leukemic blast cell infiltrate; by the cytogenetic findings; and by the severity of the cytopenias. The experienced diagnostician and therapist usually can identify variants as a clonal myeloid disorder and can manage the disorder as dictated by their manifestations regardless of their precise subclassification.

● INTERPLAY OF CLONAL AND POLYCLONAL HEMATOPOIESIS

Although potentially curative chemotherapy of myelogenous leukemia was introduced in the mid-20th century to kill “the last leukemic cell,” two important factors were not explicitly appreciated. The first was whether residual normal stem cells coexisted in marrow to restore polyclonal (normal) hematopoiesis if ablation of the leukemia was accomplished. The second was whether, given the estimates of 1 trillion leukemic cells in a patient, the therapist had to eliminate all the leukemic cells to achieve a cure. A corollary of the latter was whether the disease was the result of a leukemic stem cell and, if so, was the undifferentiated replicates of the leukemic stem cell the only cells that mattered, ultimately, in the eradication process. We know that remissions result from sufficient suppression of the leukemic population by intensive chemotherapy to permit restitution of polyclonal hematopoiesis by normal stem cells (Fig. 83–4).⁵⁶ Why monoclonal leukemic hematopoiesis is so difficult to subdue, even temporarily, with intensive chemotherapy (pre-tyrosine kinase therapy) in the chronic myeloid neoplasms (e.g., CML) compared to the acute myeloid neoplasms (AML) is unclear. Prolonged remission (longer than 3 years) may occur in some cases of AML with late relapse occurring from the same clone, suggesting a new symbiotic relationship occurs after intensive therapy that suppresses the growth potential of leukemic cells for an extended period of time. A role for the patient's immune system in such protracted remissions has been hypothesized and forms the basis for attempts to manipulate cellular and innate immunity in an attempt to improve therapeutic results.

● CLINICAL MANIFESTATIONS

DEFICIENCY, EXCESS, OR DYSFUNCTION OF BLOOD CELLS

Alterations in blood cell concentration are the primary manifestations of clonal hematopoietic disorders. The clinical manifestations of deficiencies or excesses of individual blood cell types are described in the chapters

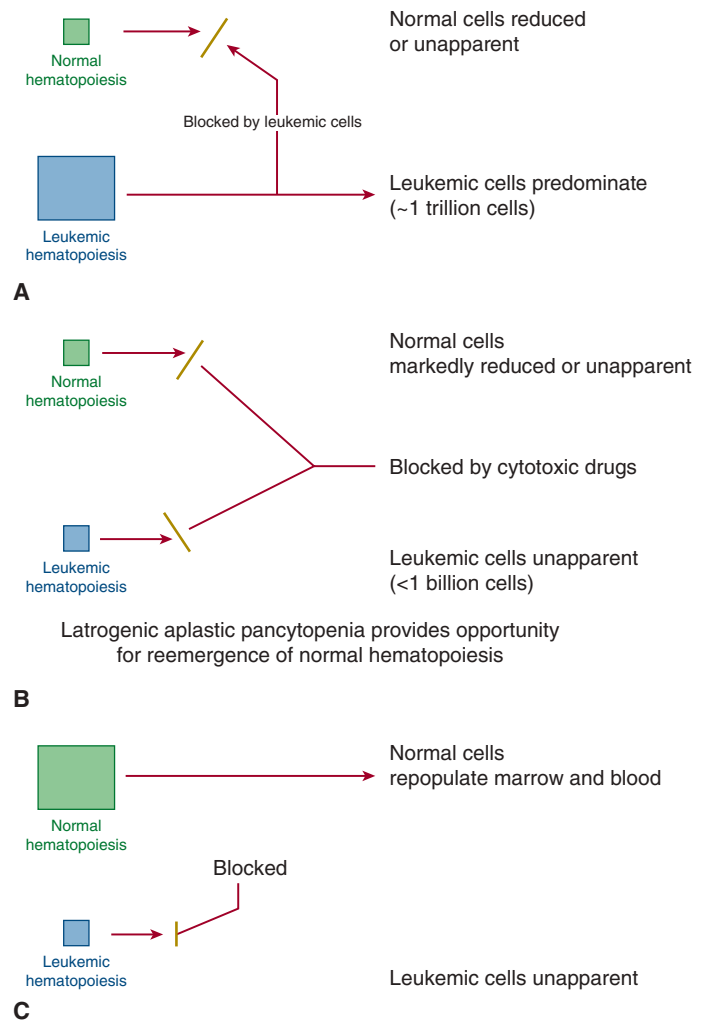

Figure 83–4. Remission–relapse pattern of acute myelogenous leukemia. **A.** Acute myelogenous leukemia at diagnosis or in relapse. Monoclonal leukemic hematopoiesis predominates. Normal polyclonal stem cell function is suppressed. **B.** Following effective cytotoxic treatment leukemic cells are unapparent in marrow and blood. Severe pancytopenia exists as a result of cytotoxic therapy. The reduction in leukemic cells can release inhibition of normal polyclonal stem cell function. **C.** If reconstitution of normal hematopoiesis ensues, a remission is established and blood cells return to near normal as a result of the recovery of polyclonal hematopoiesis. This relapse–remission pattern has not been seen, generally, in the subacute and chronic myeloid leukemias treated with similar chemotherapy. Either it has not been possible to minimize the leukemic cell population with cytotoxic therapy to a point at which polyclonal hematopoiesis is restored or some other factors inhibit normal stem cell recovery. The principal exception is the effect of BCR-ABL1 inhibitor therapy in which suppression of BCR-ABL1–positive cells in CML can be achieved with return of polyclonal hematopoiesis. Uncommon examples of tyrosine kinase inhibitor responses in myeloid neoplasms with *PDGFR* or certain *KIT* mutations may also show this pattern. In a proportion of cases, BCR-ABL1 transcripts (minimal residual disease) can be detectable along with normal, polyclonal hematopoiesis (mosaic hematopoiesis). (Reproduced with permission from Lichtman MA: *Interrupting the inhibition of normal hematopoiesis in myelogenous leukemia: A hypothetical approach to therapy*. *Stem Cells* 18(5):304–306, 2000.)

on clinical manifestations of disorders of erythrocytes (Chap. 34), granulocytes (Chap. 64), monocytes (Chap. 69), and platelets (Chap. 116).

Several clonal hematopoietic diseases frequently manifest as qualitative abnormalities of blood cells. Abnormal red cell shapes,

red cell or granulocyte enzyme deficiencies, abnormal neutrophil granules, bizarre nuclear configurations, disorders of neutrophil chemotaxis, phagocytosis or microbial killing, giant platelets, abnormal platelet granules, and disturbed platelet function can occur in some patients with oligoblastic myelogenous leukemia and primary myelofibrosis. In oligoblastic myelogenous leukemia, the effects of severe cytopenia usually dominate. In primary myelofibrosis and essential thrombocythemia, functional platelet abnormalities may contribute to the hemorrhagic diathesis, especially if surgery or injury occurs. Paroxysmal nocturnal hemoglobinuria is a hematopoietic multipotential cell disease resulting from a somatic mutation of the *PIG-A* gene on the active X chromosome. The mutation causes a highly specific alteration in blood cell membranes, a deficiency in the glycosylphosphatidylinositol (GPI) anchor, with decreased cell-surface CD59, rendering the blood cells exquisitely sensitive to complement lysis. In its classic form, chronic hemolytic anemia is coupled with mild decreases in neutrophil and platelet counts but depressions in hematopoiesis often occur (hypoplastic marrow; Chap. 40). Patients with CML or polycythemia vera usually do not have clinically significant functional abnormalities of cells, although in polycythemia vera, neutrophils often are activated with heightened metabolic rates and enhanced phagocytosis.

Secondary clinical manifestations occur as a result of the proliferation and accumulation of the malignant (leukemic) cells.

EFFECTS OF LEUKEMIC BLAST CELLS

Extramedullary Tumors

Myeloid (granulocytic) sarcomas (also called *chloromas* or *myeloblastomas*) are discrete tumors of leukemic cells that form in skin and soft tissues, breast, periosteum and bone, lymph nodes, mediastinum, lung, pleura, gastrointestinal tract, gonads, urinary tract, uterus, central nervous system, and virtually any other site (Chap. 88).⁵⁷⁻⁵⁹ They can develop in patients with AML or the accelerated phase of CML and, occasionally, may be the first manifestation of AML, preceding morphologic evidence of the disease in marrow and blood by months or, sometimes, years. AML with the t(8;21) and inv(16) has a predisposition to form myeloid sarcomas, although other AML types may also. Myeloid sarcomas can be mistaken for large cell lymphomas because of the similarity of the histopathology in biopsy specimens from soft tissues. In the past, approximately 50 percent of cases that occur in the absence of blood and marrow involvement initially were misdiagnosed, usually as lymphoma.⁵⁷ The presence of eosinophils or other granulocytes in the mass may arouse suspicion of a myeloid sarcoma; however, immunohistochemistry should be used on such lesions to identify myeloperoxidase, lysozyme, CD117, CD61, CD68/KP1, and other relevant CD markers of myeloid cells. One of four histopathologic patterns usually is evident by immunocytochemistry: myeloblastic, monoblastic, myelomonoblastic, or megakaryoblastic.

More diffuse collections of leukemic promonocytes or monoblasts can invade the skin, gingiva, anal canal, lymph nodes, central nervous system, or other tissues of patients with AML of the monocytic subtype and may form tumors in those locations. Leukemic monocytes tend to mature to the point at which they develop many of the cytoplasmic and membrane features required for motility and tissue entry.⁶⁰⁻⁶² Moreover, leukemic monocytes proliferate and survive in tissues for long periods. Consequently, this AML phenotype has a higher frequency of overt infiltrative tissue lesions than do other forms of AML.

Extramedullary tumors may usher in the accelerated phase of CML. These tumors may be composed of myeloblasts or lymphoblasts, although in each case the Ph chromosome or the *BCR-ABL1* fusion is present in the cells, indicating the extramedullary Ph-positive

lymphoblastomas are the tissue variant of the predisposition of CML to transform into a terminal deoxynucleotidyl transferase-positive lymphoblastic leukemia in approximately 30 percent of patients who enter blast crisis (Chap. 89).

Release of Procoagulants and Fibrinolytic Activators

Microvascular thrombosis is a feature of AML of the promyelocytic type, although thrombosis can occur in other forms of acute leukemia, especially in cases with elevated white cell counts or monocytic phenotypes.^{63,64} The leukemic promyelocytes liberate tissue factor and other procoagulants, giving rise to disseminated intravascular coagulation, and annexin II, which augments conversion of plasminogen to plasmin and contributes to the activation of fibrinolysis (Chaps. 88, 129, and 135). Each mechanism contributes to hypofibrinogenemia and hemorrhage. Thrombin generation may mediate the microvascular thrombotic aspect of this process, which can occur in acute promyelocytic, acute monocytic, or acute myelomonocytic leukemia, either before or after cytotoxic treatment.^{65,66} The increased fibrinolytic activity further complicates coagulopathy in patients with promyelocytic leukemia.

Large-vessel arterial thrombosis is very rare as a presenting feature or complication of leukemia but has occurred in the setting of hyperleukocytosis and as a presenting feature of acute promyelocytic leukemia.^{67,68}

The plasma levels of protein C antigen, functional protein C, free protein S, and antithrombin are decreased in some patients with AML. Although these changes are particularly notable in acute promyelocytic leukemia, they occur occasionally in other morphologic variants of AML. The changes are not related to liver disease or white cell count.^{69,70}

Hyperleukocytic Syndromes

A proportion of patients with AML (5 to 15 percent) and CML (10 to 20 percent) manifest extraordinarily high blood leukocyte counts.⁷¹⁻⁷⁵ These patients present special problems because of the effects of blast cells in the microcirculation of the lung, brain, eye, ear, and penis, and the metabolic effects that result when massive numbers of leukemic cells in blood, marrow, and tissues are simultaneously killed by cytotoxic drugs. Cell concentrations greater than 100,000/ μL ($100 \times 10^9/\text{L}$) in AML and greater than 300,000/ μL ($300 \times 10^9/\text{L}$) in CML usually are required to produce such problems. In CML, the manifestations of hyperleukocytosis are usually reversed by cytoreduction and may not portend a poor outcome with anti-tyrosine kinase therapy. In AML, intracerebral hemorrhage and the impairment of pulmonary function are the most serious manifestations in predicting early death.^{74,75} A respiratory distress syndrome attributed to pulmonary leukostasis occurs in some patients with acute promyelocytic leukemia after all-*trans*-retinoic acid therapy.⁷⁶ The syndrome is usually, but not always, associated with prominent neutrophilia.

The viscosity of blood is related to the total cytocrit and usually is not increased in hyperleukocytic leukemias because the reduced hematocrit compensates for increased leukocrit. This compensatory change is invariably present in AML. In CML there is a very close negative correlation of hematocrit with leukocrit, preventing an increase in bulk viscosity.⁷¹ Occasional patients with hyperleukocytic CML who are transfused initially with red cells may have a blood viscosity increased above normal.

Pathologic studies of patients who have died with hyperleukocytosis have identified leukoocclusion and vascular invasion in small vessels of the lung, brain, or other sites. Because viscosity in the microcirculation is a function of the plasma viscosity and the deformability of individual cells in capillaries, leukocytes should transiently raise the viscosity in such small channels. Flow in microvascular channels decreases if poorly deformable blast cells enter capillary channels.⁷⁷

TABLE 83-3. Clinical Features of the Hyperleukocytic Syndrome

- I. Pulmonary circulation
 - A. Tachypnea, dyspnea, cyanosis
 - B. Alveolar–capillary block
 - C. Pulmonary infiltrates
 - D. Postchemotherapy respiratory dysfunction
- II. Predisposition to tumor lysis syndrome
- III. Central nervous system circulation
 - A. Dizziness, slurred speech, delirium, stupor
 - B. Intracranial (cerebral) hemorrhage
- IV. Special sensory organ circulation
 - A. Visual blurring
 - B. Papilledema
 - C. Diplopia
 - D. Tinnitus, impaired hearing
 - E. Retinal vein distention, retinal hemorrhages
- V. Penile circulation
 - A. Priapism
- VI. Spurious laboratory results
 - A. Decreased blood partial pressure of oxygen (P_{O_2}); increased serum potassium
 - B. Decreased plasma glucose; increased mean corpuscular volume, red cell count, hemoglobin, and hematocrit

With high leukocyte counts, chronically reduced flow may reduce oxygen transport to tissues because the probability of leukocytes being in microchannels should increase as a function of white cell count. Moreover, trapped leukemic cells have an oxygen consumption rate that contributes to deleterious effects in the microcirculation. Leukocyte aggregation, leukocyte microthrombi, release of toxic products from leukocytes, endothelial cell damage, and microvascular invasion can contribute to vascular injury and flow impedance. Adhesive interactions between leukemic blast cells and endothelium may also be involved but have not been defined.

High leukemic blast cell counts in AML and CML may be associated with pulmonary, central nervous system, special sensory, or penile circulatory impairment (Table 83-3). Sudden death can occur in patients with hyperleukocytic acute leukemia as a result of intracranial hemorrhage.^{74,75} Hyperleukocytosis can be treated initially with hydration, leukapheresis, and/or cytotoxic therapy, usually hydroxyurea (Chaps. 88 and 89). In patients with CML, leukapheresis reverses the hyperleukocytic syndrome and can reduce the extent of cytotoxic-induced hyperuricemia, hyperkalemia, and hyperphosphatemia by reducing tumor cell mass before hydroxyurea therapy. Hydroxyurea may follow as, or soon after, the tumor cell burden is decreased. Unfortunately, the specific effect of leukapheresis, hydroxyurea therapy, or cranial irradiation in patients with hyperleukocytic AML on duration of survival appears to be negligible.⁷³⁻⁷⁵

THROMBOCYTHEMIC SYNDROMES: HEMORRHAGE AND THROMBOPHILIA

Hemorrhagic or thrombotic episodes can develop during the course of essential thrombocythemia or thrombocythemia associated with other clonal myeloid diseases.⁷⁶⁻⁷⁸ Arterial vascular insufficiency and venous thromboses are the major vascular manifestations of thrombocythemia.

Peripheral vascular insufficiency with gangrene and cerebral vascular thrombi can develop. Thrombosis of superficial or deep veins of the extremities occurs frequently.⁷⁹ Mesenteric, hepatic, portal, splenic, or penile venous thrombosis can ensue. Patients with essential thrombocythemia who have the *CALR* mutation have a significantly lower risk of thrombotic disease than those with a *JAK2* or *MPL* mutation.⁸⁰ Hemorrhage is an occasional manifestation of thrombocythemia and can occur concomitantly with thrombotic episodes. Gastrointestinal hemorrhage and cutaneous hemorrhage, the latter especially after trauma, happen most frequently, but bleeding from other sites also can result (Chap. 85).

Procoagulant factors, such as the content of platelet tissue factor and blood platelet neutrophil aggregates, are more frequent in patients with essential thrombocythemia than normal subjects and are more frequent among patients with the *JAK2*^{V617F} mutation than patients with the wild-type gene.^{79,81}

Thrombotic complications occur in approximately 40 percent of patients with polycythemia vera.^{79,82} The presence of homozygosity for the *JAK2* mutation as a result of uniparental disomy in as many as one-third of patients with polycythemia vera increases the risk of thrombosis. Erythrocytosis and thrombocytosis may interact and cause hypercoagulability, especially in the abdominal venous circulation. A syndrome of splanchnic venous thrombosis associated with endogenous erythroid colony growth, the latter characteristic of polycythemia vera, but without blood cell count changes indicative of a myeloproliferative disease, has accounted for a high proportion of patients with apparent idiopathic hepatic or portal vein thrombosis.^{83,84} These cases may have blood cells with the *JAK2* gene mutation without a clinically apparent myeloproliferative phenotype.⁸⁵

Nearly half of patients with paroxysmal nocturnal hemoglobinuria have thrombosis, especially in the venous system. Thrombosis of the veins of the abdomen, liver, and other organs, characteristic complications of paroxysmal nocturnal hemoglobinuria, may result from a complex thrombophilic state related to nitric oxide depletion, formation of prothrombotic platelet microvesicles, the dysfunction of tissue factor pathway inhibitor, and other factors.^{86,87} Thrombosis is more common in paroxysmal nocturnal hemoglobinuria (PNH) patients with the classical hemolytic syndrome than in those with the PNH-aplastic anemia hybrid (Chap. 40).

SYSTEMIC SYMPTOMS

Fever, weight loss, and malaise occur as early manifestations of AML. At the time of diagnosis, low-grade fever is present in nearly 50 percent of patients.⁸⁸ Although minor infections may be present, severe systemic infections are relatively uncommon at the time of AML diagnosis.⁸⁹ However, fever during cytotoxic therapy, when neutrophil counts are extremely low, nearly always is a sign of infection. Fever also may be a manifestation of the acute leukemic transformation of CML and can occur in patients with oligoblastic myelogenous leukemia (refractory anemia with excess blasts).

Weight loss occurs in nearly 20 percent of patients with AML.⁸⁹ Loss of well-being and intolerance to exertion may be disproportionate to the extent of anemia and may not be corrected by red cell transfusions. The pathogenesis of these effects is unknown.

METABOLIC SIGNS

Hyperuricemia and hyperuricosuria are common manifestations of AML and CML. Acute gouty arthritis and hyperuricosuric nephropathy are less common. If therapy is instituted without a reduction in plasma uric acid and without adequate hydration, saturation of the urine with uric acid can lead to precipitation of urate (gravel) and obstructive uropathy. If the uropathy is severe, urine flow can be obliterated,

and renal failure ensues. Hyponatremia can occur in AML, and in some cases results from inappropriate antidiuretic hormone secretion. Hyponatremia also can result from an osmotic diuresis of urea, creatinine, urate, and other substances released from blast cells and wasting muscles. Hypernatremia is rare but may be seen in cases with central diabetes insipidus. Hypokalemia is commonly seen in AML⁸⁹⁻⁹¹ and is thought to be caused by injury to the kidney by increased plasma and urine lysozyme and subsequent kaliuresis. Hypokalemia is related to excessive urinary potassium loss, but the correlation with lysozymuria is imperfect. Other mechanisms probably are responsible in most cases, including osmotic diuresis and tubular dysfunction. Kaliuretic antibiotics, often administered to patients with AML, may accentuate the hypokalemia. Hyperkalemia is very unusual, but may be seen with tumor lysis syndrome. Hypercalcemia occurs in occasional patients with AML. Several causes have been proposed, including bone resorption as a result of leukemic infiltration. This explanation is in keeping with the normal serum inorganic phosphate in most patients. Occasional patients with hypercalcemia, and hypophosphatemia can have ectopic parathyroid hormone secretion by leukemic blast cells. Hypophosphatemia also can occur because of rapid utilization of plasma inorganic phosphate in some cases of myelogenous leukemia with a high blood blast cell count and a high fraction of proliferative cells. Hyperphosphatemia is uncommon, except as a reflection of the tumor lysis syndrome. Approximately 10 percent of persons with AML show varying degrees of tumor lysis syndrome in the week after onset of therapy, reflected in at least doubling of baseline creatinine, and increases in serum phosphate (>1.6 mmol/L [>5 mg/dL]), uric acid (>416 mmol/L [>7 mg/dL]), or potassium (>5 mmol/L [>5 mEq/L]).⁹² Hypomagnesemia is common as a result of low intake coupled with gastrointestinal loss and a shift of magnesium to the intracellular compartment.

Acid-base disturbances occur in approximately 25 percent of patients, the majority having respiratory or metabolic alkalosis.⁹¹ The latter may be secondary to volume depletion, upper gastrointestinal fluid loss, and hypokalemia. Lactic acidosis also has been observed in association with AML, although the mechanism is obscure. True hypoxia can result from the hyperleukocytic syndrome as a consequence of pulmonary vascular leukostasis (see also "Factitious Laboratory Results" below).

Increased serum concentrations of lipoprotein (a) and decreased concentrations of both low-density and high-density lipoproteins have been observed in a high proportion of patients with AML.⁹³ The increased level of lipoprotein (a), which returns to normal after successful treatment, correlates with the presence of leukemic blast cells. Serum prolactin also is increased in some patients with AML.⁹⁴ Leukemic blast cells may be an ectopic source of this hormone.⁹⁴

Colony-stimulating factor-1 is elevated in a variety of lymphoid and hemopoietic malignancies, including AML and CML.⁹⁵ The malignant cells have been proposed as the source of excess cytokine.

FACTITIOUS LABORATORY RESULTS

Elevations of serum potassium levels have resulted from the release of potassium from platelets or, less often, leukocytes in patients with myeloproliferative diseases and extreme elevations in those blood cell concentrations. If blood is collected in a tube that contains an anticoagulant and the plasma is removed after high-speed centrifugation, the potassium concentration is normal. Glucose can be falsely decreased, especially because autoanalyzer techniques call for omission of glycolytic inhibitors such as sodium fluoride in collection tubes. Blood with high leukocyte counts, if it stands prior to separation of the plasma, may have a significant amount of glucose metabolism by leukocytes. Factitious hypoglycemia also can occur as a result of red cell utilization

of glucose, especially in polycythemic patients. True hypoglycemia has been observed rarely in patients with leukemia. Arterial blood oxygen content also can be lowered spuriously as a result of *in vitro* utilization by large numbers of leukocytes, while the anticoagulated blood awaits measurement.

SPECIFIC ORGAN INVOLVEMENT

Clonal myeloid diseases lead to disturbances principally in marrow, blood, and spleen. Although clusters of cells may be found in all organs, major infiltrates and organ dysfunction are unusual. In AML and the acute blastic phase of CML, clinically significant infiltration of the larynx, central nervous system, heart, lungs, bone, joints, gastrointestinal tract, genitourinary tract, skin, or virtually any other organ can occur.

Splenomegaly

In AML, palpable splenomegaly is present in approximately one-third of cases, but usually is slight in extent. In the chronic myeloproliferative diseases, palpable splenomegaly is present in a high proportion of cases (polycythemia vera ~80 percent, CML ~90 percent, primary myelofibrosis ~100 percent). In essential thrombocythemia, splenic enlargement is present in approximately 30 percent of patients. A predisposition to silent splenic vascular thrombi, infarction, and subsequent splenic atrophy, analogous to that occurring in sickle cell anemia, is postulated as the cause of the lower frequency of splenic enlargement in essential thrombocythemia. Early satiety, left-upper-quadrant discomfort, splenic infarctions with painful perisplenitis, diaphragmatic pleuritis, and referred shoulder pain may occur in patients with splenomegaly, especially in the acute phase of CML and in primary myelofibrosis. In primary myelofibrosis, the spleen can become enormous, occupying the left hemiabdomen. Blood flow through the splenic vein can be so great as to lead to portal hypertension and gastroesophageal varices. Usually, reduced hepatic venous compliance also is present (Chap. 86). Bleeding and, occasionally, encephalopathy can result from portal-systemic venous shunts.

Marrow Necrosis

Extensive marrow necrosis, an uncommon event, can occur in any clonal myeloid disease, especially AML, and less often, primary myelofibrosis, CML, essential thrombocythemia, and polycythemia vera. Bone pain and fever are the most common initial findings. Anemia and thrombocytopenia are very common, as are nucleated red cells and myelocytes in the blood (leukoerythroblastic reaction).^{96,97} Marrow aspiration does not result in a useful sample but biopsy early in the process usually shows hypocellularity with loss of marrow cell structural definition (blurred staining of residual cells), evidence of cell necrosis, gelatinous transformation of marrow, and, often, an amorphous eosinophilic material throughout. The mechanism is thought to be microvascular dysfunction. Restitution of marrow and repopulation of hematopoietic tissue often may follow. The prognosis is a function of the underlying disease.

CHAPTER 84

POLYCYTHEMIA VERA

Jaroslav F. Prchal and Josef T. Prchal

SUMMARY

Polycythemia vera (PV) is classified in the group of Philadelphia chromosome–negative myeloproliferative neoplasms (MPNs) that also includes essential thrombocythemia (ET) and primary myelofibrosis (PMF). Chronic myelogenous leukemia was historically classified as a MPN, but is now considered a separate entity. PV is an acquired primary clonal polycythemic disorder. Primary polycythemias result from abnormal intrinsic properties of erythroid progenitors that proliferate independently or excessively in response to extrinsic regulators; low serum erythropoietin is their hallmark. PV is the most common primary polycythemia. It arises from mutation(s) of a pluripotent hematopoietic stem cell, which results in excess production of erythrocytes and variable overproduction of granulocytes and platelets. It is often accompanied by splenomegaly. Most patients with PV have a somatic mutation of the Janus-type tyrosine kinase-2 gene (*JAK2*) that is detectable in blood myeloid cells. The mutation results in constitutive hyperactivity of JAK2 kinase stemming from loss-of-function of its negative regulatory domain. The most common mutation is *JAK2*^{V617F}, which is present in virtually all cases of PV; a small minority of PV patients have a mutation in other parts of *JAK2* (exon 12). The *JAK2*^{V617F} mutation is also found in many patients with ET and myelofibrosis (MF), albeit at lower frequency (55 percent in ET and 65 percent in MF). As with other clonal hematologic disorders, PV can undergo a clonal evolution to PMF (*JAK2*^{V617F}-positive) or acute leukemia (either *JAK2*^{V617F}-negative or positive). In virtually all *JAK2*^{V617F}-positive PV patients, at least some progenitors exist that become homozygous for the *JAK2*^{V617F} mutation by uniparental disomy-acquired mitotic recombination. The majority of these progenitors account for the erythropoietin-independent erythroid colonies detected *in vitro* by clonogenic burst-forming unit–erythroid assay. The *JAK2*^{V617F} mutation is often not the initial cause of clonal proliferation, but may be preceded by other germline and somatic mutation(s) (e.g., *TET2*).

Acronyms and Abbreviations: AML, acute myelogenous leukemia; BFU-E, burst-forming unit–erythroid; ECLAP, European Collaboration on Low-Dose Aspirin in Polycythemia Vera; EEC, endogenous erythroid colony; ELN, European Leukemia Net; ET, essential thrombocytosis; HDAC, histone deacetylase; HU, hydroxyurea; IFN- α , interferon- α ; IWG-MRT, International Working Group for Myeloproliferative Neoplasms Research and Treatment; JAK2, Janus-type tyrosine kinase 2; MDS, myelodysplastic syndrome; MF, myelofibrosis; MPN, myeloproliferative neoplasm; PCR, polymerase chain reaction; PEG-IFN, pegylated interferon; PFCP, primary familial and congenital polycythemia; PMF, primary myelofibrosis; PV, polycythemia vera; SNP, single nucleotide polymorphism; UPD, uniparental disomy; TET2, a homologue of chromosome 10-11 translocation; WHO, World Health Organization.

Arterial and venous thromboses are a major cause of morbidity and mortality in PV, and a small proportion of patients develop secondary myelofibrosis (sometimes called the *spent phase*) and/or an invariably fatal acute leukemic transformation. Myelosuppressive therapy has been an effective mode of therapy, with drugs such as hydroxyurea, busulfan, pipobroman, and radioactive phosphorus useful in controlling proliferation of all blood cell lineages. However, while myelosuppressive therapy controls the cellular proliferation and decreases the incidence of thrombotic complications, many of these drugs have leukemogenic potential. In contrast, pegylated interferon- α may lead to complete hematologic remission and restoration of polyclonal hematopoiesis and avoid the leukemogenic complications. Targeted therapy with JAK2 kinase inhibitors is currently being evaluated in clinical trials and, thus far, have been found effective in decreasing the need for phlebotomies, decreasing the number of white cells and splenomegaly, and improving the patient's quality of life.

DEFINITION AND HISTORY

The term *polycythemia*, denoting an increased amount of blood, has traditionally been applied to those conditions in which the mass of erythrocytes is increased. In polycythemia vera (PV), an increase in the erythroid mass is frequently accompanied by an increase in neutrophils and platelets. For a classification of the polycythemias, see Chap. 57 and Chap. 34, Table 34–2. Although several clinical stages of PV are recognized (masked PV, plethoric phase, stable phase, transformation, spent phase, and acute leukemia), it is not clear whether these stages represent a sequential progression of the disease or whether all patients progress through all stages.

PV, the sole clonal form of primary polycythemia, was first described in 1892 by Vaquez.¹ In 1903, Osler reviewed four of his own PV cases and an additional five cases from the literature and wrote, “The condition is characterized by chronic cyanosis, polycythemia, and variable moderate enlargement of the spleen. The chief symptoms have been weakness, prostration, constipation, headache, and vertigo.”² The increased proliferation of granulocyte precursors and megakaryocytes was first described by Türk in 1904.³

EPIDEMIOLOGY

A recent analysis of 20 studies of PV patients from around the world revealed an annual incidence rate of 0.84 cases per 100,000 people, with no bias for gender.^{4,5} The true incidence may be higher, as many cases are asymptomatic and thus not diagnosed. Testing for the Janus-type tyrosine kinase 2 (*JAK2*)^{V617F} mutation can uncover hidden cases of PV among subjects with thrombosis or concomitant iron deficiency. The incidence of PV may be higher among Ashkenazi Jews.^{6,7}

Although most patients with PV do not have a history of polycythemia in the family, familial incidence of the disorder is known to occur^{8–10} and is very likely underreported. In a large Swedish study of more than 25,000 first-degree relatives of 11,000 myeloproliferative neoplasm (MPN) patients, the incidence of MPNs were five to seven times higher in relatives than in controls.¹¹ In familial cases of PV, an inherited predisposition, perhaps in the form of a germline mutation, presumably facilitates the acquired somatic mutation(s) necessary for disease onset.^{9,12}

ETIOLOGY AND PATHOGENESIS

PV arises from the neoplastic transformation of a single normal hematopoietic pluripotent cell, which acquires a selective proliferative and survival advantage, resulting in the development of a variable degree

of clonal hematopoiesis. Once large enough, the clone then suppresses and replaces normal polyclonal hematopoiesis. The clonal origin of PV has been demonstrated in women heterozygous for a polymorphic X-chromosome marker such as, glucose-6-phosphate dehydrogenase¹³ as well as by more modern clonality assays (Chap. 10).¹⁴ In both cases, all hematopoietic cell lineages⁹ express either one isoform of the enzyme, or some polymorphic allele encoded by the maternal or paternal X chromosome, whereas T lymphocytes and nonhematopoietic cells are a mosaic of both enzyme types.

In vitro marrow- or blood-derived erythroid colonies of PV patients arise from both normal burst-forming unit-erythroid (BFU-E) precursors and BFU-E precursors that are erythropoietin-independent. Erythropoietin-independent BFU-E precursors form so-called endogenous erythroid colonies (EECs),¹⁵⁻¹⁸ a characteristic feature of PV. The fibroblasts that accumulate in the marrow of patients with PV as the disease progresses are not part of the abnormal PV clone. Rather, they seem to accumulate in response to cytokines released by megakaryocytes and other cells (Chap. 86).¹⁹

Other abnormalities that have been described include decreased levels of a platelet thrombopoietin receptor,²⁰ deregulation of bcl-x, an inhibitor of apoptosis,²¹ increased expression of protein tyrosine phosphatase activity by red cell precursors,²² and acquired loss-of-heterozygosity of chromosome 9p as a result of uniparental disomy (UPD).⁹ This last observation was one of two routes that led to the discovery of the *JAK2* 2343G > T mutation encoding the V617F mutation located on chromosome 9p,^{12,23} which has improved our understanding of disease pathogenesis, improved the specificity of diagnosis, and led to an explosion of research in MPN (see “*JAK2*^{V617F} Mutation” below).

There are no specific karyotypic markers occurring with high frequency in PV. Fewer than 25 percent of patients have karyotypic abnormalities at diagnosis,²⁴⁻²⁹ but the incidence rises with the increasing duration of the disease,^{25,30} suggesting that karyotypic abnormalities represent secondary genetic events.³¹ Cytogenetic abnormalities may potentially herald transformation from PV to myelofibrosis, acute myeloid leukemia, or a myelodysplastic syndrome, but as of now, these associations are weak.²⁹

JAK2^{V617F} MUTATION

JAK2 kinase is present in all hematopoietic cells and is essential for proliferative intracellular signaling in response to a variety of hematopoietic growth factors (Chaps. 34 and 57). The V617F mutation was first identified in PV in 2004,²³ and was simultaneously reported by several laboratories.³²⁻³⁴ The V617F mutation is present in virtually all patients with PV and in more than 50 percent of patients with essential thrombocytosis (ET; Chap. 85) and myelofibrosis (MF; Chap. 86); rarely is it found in the minority of patients with other myeloproliferative disorders.^{35,36} In PV (unlike in ET), it is often in its associated homozygous form as a result of UPD, at least in some of the progenitors.^{26,37} Patients bearing homozygous *JAK2*^{V617F} tend to have a longer duration of disease,³³ higher hemoglobin levels, and increased incidence of pruritus³⁸ and are more likely to transform to post-PV MF (Chap. 86).³⁹ The *JAK2*^{V617F} allele burden in PV may also be correlated with increased spleen volume, increased leukocytosis, and severity of MF.³⁹⁻⁴² It should be noted, however, that PV patients can achieve a complete hematologic remission without a significant molecular response (i.e., a decrease in *JAK2*^{V617F} allele burden).⁴³ In some of the rare PV patients who are *JAK2*^{V617F}-negative, a different *JAK2* mutation is present in exon 12.⁴⁴ Several different *JAK2* exon 12 mutations, including missense mutations, insertions, and deletions, have been described. Patients with exon 12 mutations may present with different clinical manifestations from those with the classic *JAK2*^{V617F} mutation: erythrocytosis only, higher

hemoglobin, and differences in marrow morphology.⁴⁵ Disease course and clinical outcome, however, are similar.⁴⁶

Studies of families of MPN patients, in which several different MPNs occur in a single pedigree,⁴⁷ indicate that *JAK2* mutations may not be solely responsible for the disease phenotype and may not even represent the disease-initiating event. A number of compelling lines of evidence support this conclusion. First, in familial PV, there is no clear linkage between the disease and chromosome 9p, the genetic site of *JAK2*, suggesting an independent germline predisposition to PV.¹² Second, in familial PV, affected members can be either *JAK2*^{V617F}-positive or -negative.⁴⁸ Third, acquisition of the *JAK2*^{V617F} mutation may be a late genetic event.⁴⁹ Fourth, in sporadic PV, only a proportion of clonal PV cells are *JAK2*^{V617F}-positive.³⁷ And fifth, acute leukemic transformation of any *JAK2*-positive MPN, including PV, is frequently negative for the *JAK2*^{V617F} mutation.^{35,50} These diverse observations strongly suggest that the somatic mutation of the *JAK2* gene is not the initiating or sole pathogenic process in PV, but in most patients is essential for the clinical phenotype of PV. The pathways leading to acquisition of the *JAK2*^{V617F} mutation, homozygosity of *JAK2*^{V617F}, and participation of many other genes in the 9p UPD region may have phenotypic and prognostic significance.^{51,52} Additional prognostic significance can be ascertained by analysis for clustering of specific genes.⁵³

A genomic chromosome 9p functional variant might also be relevant to the pathogenesis of *JAK2*^{V617F}. Independent occurrence of the *JAK2*^{V617F} mutation on different haplotypes was found, although a specific constitutional inherited *JAK2* haplotype (GGCC, 46/1), associated with the *JAK2*^{V617F} somatic mutation, was found in most *JAK2*^{V617F}-positive individuals.⁵⁴ The risk of acquiring a *JAK2*^{V617F}-positive MPN is three to four fold higher in patients with the *JAK2* GGCC (46/1) haplotype.⁵⁴⁻⁵⁷ This GGCC haplotype of *JAK2* also confers susceptibility to *JAK2* exon 12 mutation-positive PV.⁵⁵ These studies suggest that pre-*JAK2* hypermutability events exist and that germline genetics play an important role in the early pathogenesis of MPNs.

OTHER MUTATIONS

In addition to the important role of *JAK2*^{V617F} and other *JAK2* mutations in the etiology of PV and other MPNs, mutations in other genes may be important to the full genesis of these disorders.

TET2 is a homologue of the gene originally discovered at the chromosome ten-eleven translocation (TET) site in a subset of patients with acute leukemia. *TET2* mutations were found in hematopoietic cells from a significant proportion of patients with PV and other MPNs.^{58,59} It has been established that *TET2* loss-of-function mutations originate in pluripotent hematopoietic stem cells but seem to favor myeloid rather than lymphoid proliferation, and that in many patients both *TET2* alleles were affected. However, studies in familial PV demonstrated that the *TET2* mutation is often not disease-initiating, as the *TET2* mutations differ among affected relatives and, in some instances, the *TET2* mutations followed, rather than preceded, the appearance of *JAK2*^{V617F}.⁶⁰ Additionally, recurrent *TET2* mutations have been reported in elderly patients with clonal hematopoiesis but no evidence of hematological malignancy.⁶¹ Several additional genes commonly bear mutations in PV patients, including *ASXL1*, *DNMT3A*, and *IDH1/2*.^{62,63} The quantitative proportion of clones carrying different mutations may change during disease progression.⁶⁴

AUTOIMMUNITY AND CHRONIC INFLAMMATION

Although *JAK2* kinase is clearly involved in the pathogenesis of PV, immune dysfunction and chronic inflammation may also be implicated. A history of any autoimmune disorder is associated with a 20 percent

increased risk of developing an MPN,⁶⁵ and chronic inflammation is suggested to contribute to mutagenesis and clonal evolution in PV.^{66–68} A recent molecular profiling study found that a number of immune and inflammatory genes were either up- or downregulated in PV patients, among them interleukin-10, interleukin-4, complement 5, short pentraxin C-reactive protein, fibrinogen, orosomucoid, and transforming growth factor- β_1 .⁶⁹ The dysregulation of immune and inflammatory genes in PV may represent an additional avenue for future therapeutic development.

CLINICAL FEATURES

SIGNS AND SYMPTOMS

PV usually has an insidious onset, most commonly during the sixth decade of life, although onset may occur from childhood to old age.⁷⁰ Presenting signs and symptoms may include headache, plethora, pruritus, thrombosis, and gastrointestinal bleeding, but many patients are diagnosed because elevated hemoglobin, and sometimes other cell counts, are found on a periodic medical examination. Others cases may be uncovered during investigation for blood loss, iron-deficiency anemia, or thrombosis. Symptoms are reported by at least 30 percent of patients at the time of diagnosis; other patients may admit to symptoms on direct questioning. The most common symptoms, in decreasing order of frequency, are headache, fatigue, weakness, pruritus, dizziness, and night sweats, but these symptoms are more likely in those PV patients transforming to MF (Chap. 86).⁷⁰

PV generally occurs in older patients, a population who may already have an elevated rate of vascular abnormalities (e.g., coronary artery disease). Development of PV represents an additional increase in the risk of vascular events.

Thrombosis and Hemorrhage

Thrombotic episodes are the most common and most important complication of PV,^{71–73} occurring in approximately one-third of PV patients.⁷⁴ From one-half to three-quarters of these events are arterial⁷⁵; ischemic strokes and transient ischemic attacks account for the majority of arterial complications. In some studies, 40 to 60 percent of patients develop at least one thrombotic event over a period of 10 years, the annual incidence being approximately equal throughout this period.⁷⁶ However, in prospective studies, thrombosis was most common just prior to and during the first few years after diagnosis.^{74,77,78} The most common serious complication is a cerebrovascular accident, which accounts for approximately one-third of thrombotic events, followed in frequency by myocardial infarction, deep vein thrombosis, and pulmonary embolism.⁷⁶ The allelic burden of the *JAK2*^{V617F} mutation has been correlated with activation of thrombotic pathways in PV patients,^{79,80} although this idea is not universally accepted.³⁹

Bleeding and bruising is a common complication of PV, occurring in approximately one-quarter of patients in some series.⁷⁴ Although such episodes are usually minor (e.g., gingival bleeding, nose bleeding, easy bruising), serious gastrointestinal and other hemorrhagic complications with a fatal outcome can also occur.^{31,75,81,82}

Hepatic Vein Thrombosis (Budd-Chiari Syndrome) Budd-Chiari syndrome is a catastrophic and often fatal complication of PV. In one series, it occurred in 10 percent of 140 PV patients,⁸³ but was less common in a European collaborative study.⁷⁵ Budd-Chiari syndrome is caused by a thrombosis in the hepatic venous outflow, leading to ischemia from reduced perfusion through hepatic arterioles and necrosis of hepatocytes. Budd-Chiari syndrome may present as ascites with or without right-upper-quadrant abdominal pain, hepatosplenomegaly, and jaundice.

Budd-Chiari syndrome may be the first clinical manifestation of PV; endogenous erythroid colony formation and *JAK2*^{V617F} mutation have been described in many of these patients before any clinical evidence of polycythemia.^{84,85} PV is the most frequent underlying disease associated with Budd-Chiari syndrome. The association of Budd-Chiari syndrome and PV is so strong that many experts advocate screening for PV with *JAK2*^{V617F} mutation analysis in all patients who present with hepatic vein thrombosis.^{86,87} Budd-Chiari syndrome is a serious condition, often requiring a liver transplant for treatment.^{85,88,89}

Cutaneous Findings

Pruritus occurs in approximately 40 percent of PV patients.⁹⁰ It is usually aggravated by bathing or showering (aquagenic pruritus), and may be so severe it markedly compromises the quality of life of the patient.^{82,91} It has been attributed to increased numbers of mast cells in the skin⁹² and to elevated histamine levels,⁹³ although these associations were not found in other studies.⁹⁴

Several PV patients have developed the dermatologic disorder, acute febrile neutrophilic dermatosis (i.e., Sweet syndrome).^{95,96}

Erythromelalgia

Erythromelalgia is a syndrome characterized by warmth of the extremities; painful, reddened digits; a burning sensation; and erythema of the fingers, hands, and feet (Fig. 84–1) that is associated with thrombocytosis. It characteristically responds rapidly to low-dose aspirin therapy. In severe cases, it results in ischemic necrosis of the digits and may lead to their amputation. This syndrome occurs in less than 5 percent of PV patients.^{75,81} It is not specific to PV or other MPNs, and in one series of 168 patients with erythromelalgia, less than 10 percent had PV.⁹⁷ A causative role for transient microvascular occlusion by platelet aggregates has been proposed (Chap. 112).^{98,99}

Abdominal Findings

Portal hypertension, varices, and abdominal pain are not uncommon,¹⁰⁰ and are often caused by unrecognized splenic or hepatic vein thromboses. The occurrence of Budd-Chiari syndrome is noted above (see “Hepatic Vein Thrombosis [Budd-Chiari Syndrome]” above). The incidence of peptic ulcer is four to five times greater than in the general population.¹⁰¹ Gastrointestinal bleeding may be the first presenting symptom of PV, with iron deficiency caused by gastrointestinal blood loss frequently masking erythrocytosis.⁸⁷

Cardiovascular Findings

Cardiovascular complications include angina, myocardial infarction, and congestive heart failure, related to a predisposition to thrombosis in the coronary circulation.^{31,75,77}

Pulmonary Hypertension

Pulmonary hypertension occurs in a higher than expected frequency in patients with PV. The suggested etiologies include smooth muscle hyperplasia induced by the release of platelet-derived growth factor from activated platelets, obstruction of pulmonary circulation by megakaryocytes, extramedullary hematopoiesis, and unrecognized recurrent thrombotic events.^{102,103} None of these etiologies are clearly established.

Neurologic Findings

Neurologic symptoms such as dizziness and headache are very common in PV.^{31,75,77,81,104} Spinal cord compression secondary to extramedullary hematopoiesis has been documented.¹⁰⁵

Findings in Other Organ Systems

The increased nucleic acid turnover that results from the excessive proliferation of marrow cells often leads to an increase in blood uric acid concentration; gout can be exacerbated in some patients.³¹

Figure 84-1. **A.** Patient with erythromelalgia of hand and fingers. **B.** Erythromelalgia of feet and toes that progressed to necrosis and amputation of the toes. (Used with permission of Steven Fruchtman, MD, Allos Therapeutics, Princeton, New Jersey.)

SPECIAL CONSIDERATIONS

Surgery

More than 75 percent of patients with uncontrolled PV develop complications during or after major surgery because both bleeding and thromboses are common.^{82,106} Thus, it is advised to normalize blood counts and blood volume before surgical interventions, which may lower the frequency of intraoperative and postoperative complications.

Pregnancy

Chapter 8 discusses the complications of PV in pregnancy.

SPENT PHASE OF POLYCYTHEMIA VERA

The spent phase of PV, also referred to as post-PV MF, is a frequent and often terminal complication of the disease.^{75,78,107} It is characterized by a combination of anemia (non-iron deficiency), progressive increase of splenic size (Fig. 84-2), and marrow fibrosis (Chap. 86). The spent phase may first be noticed when phlebotomy requirements decrease. Thrombocytosis and granulocytosis (often with immature myeloid cells) are common. In a minority of cases, thrombocytopenia and granulocytopenia may occur. Affected individuals are frequently symptomatic with anemia, bleeding, splenic enlargement with early satiety, and/

Figure 84-2. Patient with spent phase of PV with a massive increase of splenic size (**A**) and surgically removed spleen (**B**). (Used with permission of Steven Fruchtman, MD, Allos Therapeutics, Princeton, New Jersey.)

or upper abdominal pain secondary to splenic infarcts. Most patients become dependent on transfusions or erythropoietin therapy.^{31,75,77,81,107} Development of the spent phase is associated with an increased risk of leukemic transformation^{31,108}; in the PV Study Group-01 study, the incidence of acute leukemia was 24 percent in PV patients with MF, compared to 7 percent in those without MF, although it should be noted that a sizable number of the patients in this study had been treated with alkylating agents or ³²P.⁷⁸ Therapy, including use of JAK2 inhibitors, is described in Chap. 86.

LEUKEMIC AND MYELODYSPLASTIC TRANSFORMATION OF POLYCYTHEMIA VERA

Patients with PV have an increased risk of developing leukemia.^{71,82} This contrasts with other nonclonal polycythemic disorders, wherein progression to leukemia is not part of the disease process. Acute leukemia, usually myelogenous, is an invariably fatal complication of PV. A European multicenter observational study of 1638 patients reported a 6.3 percent relative risk of developing leukemia within 10 years after the diagnosis of PV.⁷⁵ Different treatments can also influence the risk of transformation from PV to leukemia. In the PV Study Group-01 randomized trial, the incidence of acute leukemia at 18 years of followup was 1.5 percent on the phlebotomy-only treatment arm, 10 percent on the ³²P treatment arm, and 13 percent on the chlorambucil treatment arm.⁸¹ In a more recent study of 1638 patients, the risk of transformation to acute myelogenous leukemia (AML) or a myelodysplastic syndrome (MDS) in PV patients also varied by treatment. Treatment-specific risk of transformation, ordered by increasing risk, was: phlebotomy (hazard ratio [HR]: 0.91), hydroxyurea (HR: 1.09), interferon (INF)- α (HR: 1.24), busulfan (HR: 8.64), pipobroman (HR: 4.32), and ³²P (HR: 8.96).¹⁰⁹ Leukemic transformation was not significantly different between phlebotomy, hydroxyurea, and INF- α treatments.¹⁰⁹

Acute leukemia as the terminal PV event may arise from either the JAK2^{V617F}-positive clone or, more frequently, from a hematopoietic cell that does not carry the JAK2 mutation.^{35,47,50}

LABORATORY FEATURES

BLOOD FINDINGS

Erythrocytes

The hemoglobin concentration, erythrocyte count, and hematocrit are usually increased, and the mean cell volume is usually low-normal or low in untreated patients, and low in patients who have undergone phlebotomies or had gastrointestinal bleeding episodes. Red cells are hypochromic and microcytic, with morphology characteristic of iron deficiency. Although increased hemoglobin is generally a diagnostic feature of PV, at times the hemoglobin level may be low, normal, or borderline, a condition termed “masked” PV.^{110–112}

The appearance of significant aniso- and poikilocytosis and tear-drop cells (dacryocytes; Chap. 31) heralds the onset of the spent phase and post-PV MF (Chap. 86).

Red Cell Mass Determination

The Polycythemia Vera Study Group employed the direct determination of red cell mass as the *sine qua non* of the diagnosis of PV for all patients entered into their studies.⁷⁶ Some believe that even in the routine clinical setting, this procedure should be performed on all patients to establish a diagnosis of PV.^{76,113} Unfortunately, the determination of red cell mass is expensive, requires the use of radioactive isotopes in patients, and, when performed by the inexperienced, is often inaccurate.¹¹⁴ Red cell mass determination is not useful in distinguishing PV

from secondary polycythemia because the red cell mass is increased in both disorders. The principal value of red cell mass determination is to distinguish apparent or spurious polycythemia from PV and secondary polycythemia.^{110,111} It could also be useful in distinguishing cases of masked PV from ET.¹¹⁵ The availability of the JAK2 assay has made red cell mass determination only rarely important.

Leukocytes

Absolute neutrophilia occurs in approximately two-thirds of PV patients.⁷⁰ Occasional myelocytes and metamyelocytes are present in the blood, and considerable degrees of cell immaturity are present in patients with longstanding, advanced disease. Again, these abnormalities herald the onset of the spent phase (Chap. 86). Basophilia occurs in approximately two-thirds of patients with uncontrolled disease.^{31,81,116} In PV, the proportion of activated neutrophils is increased,¹¹⁷ and it is possible that neutrophils may be an important factor in PV-associated thrombosis.¹¹⁸

The leukocyte alkaline phosphatase level is elevated in approximately 70 percent of patients with PV,⁷⁰ but this assay has now become largely obsolete.

Platelets

The platelet count is increased in approximately 50 percent of PV patients at the time of diagnosis, and in approximately 10 percent of patients it is greater than $1000 \times 10^9/L$.⁷⁰ There are no consistent abnormalities of thrombopoietin levels in PV patients.¹¹⁹ A significant proportion of PV patients first present with isolated thrombocytosis without elevated hemoglobin, especially if the patient has a reason for iron deficiency, and are sometimes misdiagnosed with essential thrombocythemia.¹²⁰

Qualitative platelet abnormalities have been described which may play a role in the pathogenesis of thrombotic and hemorrhagic events. *In vitro* spontaneous platelet aggregation is accelerated. On the other hand, patients with MPNs often display a nearly pathognomonic defect in the primary wave of platelet aggregation induced by epinephrine (Chaps. 112 and 121).¹²¹

There are a number of additional platelet abnormalities associated with PV, including increased platelet thromboxane A₂ generation¹²² and increased excretion of thromboxane metabolites.¹²³ Platelet factor-4 levels are elevated.¹²⁴ Platelet survival may be shortened.^{124,125} Fibrinogen binding after stimulation with a platelet-activating factor is diminished,¹²⁶ and there is reduced expression of the thrombopoietin receptor.²⁰ However, none of these changes are specific for PV. In a prospective study, a *PLA2* polymorphism of the platelet glycoprotein IIIa was associated with an increased risk of arterial thrombosis in PV patients,¹²⁷ although this conclusion remains controversial.

Platelet counts greater than 1000 to $1500 \times 10^9/L$ are associated with progressive decrease of von Willebrand factor (an acquired, type 2 von Willebrand disease) and increased risk of bleeding, but not of thrombosis.¹²⁸

Plasma

Serum lysozyme levels are slightly increased in some patients,¹²⁹ and because of increased leukocyte turnover and increased levels of B₁₂ binding protein, serum B₁₂ determination is usually increased.¹³⁰ Hyperuricemia, a consequence of hyperproliferative myelopoiesis, is frequently encountered.³¹

JAK2^{V617F} AND EXON 12 MUTATIONS

JAK2 G1849T Creating V617F

Mutations within the JAK2 gene cause deregulation of the hematopoietic process, which is expressed in a wide spectrum of disorders

involving the expansion of erythrocytes, granulocytes, or leukocytes. The primary lesion associated with these disorders was discovered in exon 14: A single nucleotide change *JAK2* G1849T resulting in the amino acid substitution V617F. Detection of the *JAK2*^{V617F} mutation provides a qualitative diagnostic marker for the identification of the Philadelphia-chromosome-negative subgroup of MPNs, and differentiates them from congenital and acquired reactive hematopoietic disorders. In general, the *JAK2*^{V617F} allele burden is lower in ET patients than in either PV or primary myelofibrosis (PMF).^{131,132} In many, but not all, *JAK2*^{V617F}-positive PV patients, at least some progenitors exist that became homozygous for the *JAK2*^{V617F} mutation by UPD acquired by mitotic recombination.^{37,133}

Allele-specific polymerase chain reaction (PCR) is widely used for single nucleotide polymorphism (SNP) genotyping; the technique is based on amplification of DNA by an allele-specific primer matching the polymorphism at the 3' position. This approach is directly applicable to analysis of *JAK2*^{V617F} because the mutation (*G1849T*) is analogous to a SNP. To improve the specificity, sensitivity, and reliability for quantitating the *JAK2*^{V617F} allele burden, two modifications of technique were incorporated: Inclusion of a second mismatch at the -1 position, and substitution of a modified locked nucleic acid at the -2 position. A study comparing 11 different techniques was undertaken and carried out in 16 laboratories using various testing platforms.¹³⁴ Although five of the 11 techniques were similarly reliable for quantification of *JAK2*^{V617F} loads that were equal to or greater than 1 percent of total *JAK2*^{V617F}, the allele-specific quantitative PCR technique could detect 0.2 percent of *JAK2*^{V617F}.

The majority of laboratories analyze quantitative assays of *JAK2*^{V617F} allele burden from (clonal) granulocytes; nonquantitative analyses use total leukocytes, whole blood, or marrow for screening. A proportion of *JAK2*^{V617F}-negative assays are positive using sensitive quantitative analyses.¹³⁴ Plasma has been used for detection of the *JAK2*^{V617F} DNA and mRNA mutation and zygosity state,^{135,136} but plasma analysis is not reliable.¹³⁷

JAK2 Exon 12 Mutations

Although the most common *JAK2* mutation is a single SNP in exon 14, many MPN cases negative for the exon 14 *JAK2*^{V617F} mutation may carry one of a number of mutations in exon 12. Almost 40 different mutations in exon 12 have been identified within codons 536 to 547, including substitutions, deletions, and duplications.^{45,138-142} In addition to the various mutations observed in this region, the proportion of mutations within a given sample may be small and therefore difficult to detect in the high background of a normal sequence.⁴⁵ *JAK2* exon 12 mutations have been observed primarily in younger patients and in patients with isolated erythrocytosis, and thus may represent a somewhat different phenotype from *JAK2*^{V617F}-positive PV.

ERYTHROPOIETIN LEVELS

PV is distinguished by the fact that erythroid cells proliferate even in the absence of normal levels of erythropoietin; thus, one would expect that at high hematocrit levels, the production of erythropoietin would be inhibited and serum levels consequently reduced. Indeed, several studies have documented serum erythropoietin levels below the normal reference range in patients with PV.¹⁴³⁻¹⁴⁵

Patients with secondary polycythemia usually have normal to elevated erythropoietin levels, although considerable overlap exists in the range of erythropoietin levels between patients with PV and those with secondary polycythemia rendering the test of marginal value in distinguishing between diagnostic possibilities.^{144,146} An elevated erythropoietin level generally excludes the diagnosis of PV, but a low erythropoietin

level is not pathognomonic of PV; patients with primary familial and congenital polycythemia (PFCP) have levels of erythropoietin that are as low or lower than in PV,¹⁴⁷ and instances of normal erythropoietin levels occur in PV patients without apparent explanation. The latter is more likely to occur in PV patients with exon 12 *JAK2* mutations.⁴⁴

ERYTHROID COLONY CULTURES

In vitro assays of erythroid progenitor cells permit the study of their responsiveness to erythropoietin. In PV patient samples, erythroid BFU-E progenitors grow in culture without added erythropoietin,¹⁷ forming colonies that are termed EECs. Detection of EECs in cultures of blood or marrow had previously been the most specific test for PV.^{12,14,148} In one study, all patients with PV, but none with secondary or other causes of polycythemia, formed EECs *in vitro*.¹⁴⁹ Rare EECs may, at times, be observed in PFCP and in congenital disorders of hypoxia sensing, but unlike EECs in PV, these are abrogated by pretreatment with erythropoietin and erythropoietin receptor-blocking antibodies.^{150,151}

In experienced hands, the EEC assay is a specific and sensitive means for detecting PV. It may be useful in diagnosing patients with unusual presentations of PV, such as Budd-Chiari syndrome,^{85,89,152,153} isolated thrombocytosis, or the rare *JAK2*^{V617F}-negative PV patient. It has not been fully standardized, however, and is expensive and laborious, so it is now used primarily in a research setting where it remains informative.

MARROW FINDINGS

In PV, the marrow is characteristically hypercellular, with an increase in erythroid and granulocytic precursor cells and megakaryocytes. Whereas marrow morphology is part of the World Health Organization (WHO) diagnostic criteria of PV,¹⁵⁴ the morphologic features have not yet been validated and may be subject to inter- and intraobserver variation. Marrow morphology in patients with *JAK2* exon 12 mutations may be subtly different, with subtle or no megakaryocytic clustering and a lack of panmyelosis.^{45,155} Absent or decreased iron stores are seen in the marrow of most PV patients. Various cytogenetic findings have been reported,¹⁵⁶ but they are not sufficiently specific to be of diagnostic utility (Chap. 13).

CLONALITY IN FEMALE SUBJECTS USING ASSAYS EMPLOYING X-CHROMOSOME-BASED POLYMORPHISM

PV results from an acquired mutation in a pluripotent hematopoietic stem cell. Clonality studies based on the phenomenon of X-chromosome inactivation¹⁵⁷ show that red cells, granulocytes, platelets, monocytes, and B lymphocytes are all part of the neoplastic clone.^{13,158} The majority of T lymphocytes and natural killer cells are polyclonal, but a small proportion of these cells are also derived from the PV clone³; this is presumed to be the result of the presence of long-lived, normal T cells that preceded the development of the clone and younger, clonal cells. Unfortunately, the applicability of X-chromosome inactivation for the differential diagnosis of PV is hampered by the many methodologic and conceptual differences that have drawn conflicting conclusions.¹⁵⁹ Some of these discrepancies result from using two different approaches¹⁶⁰ to distinguish the active from inactive X-chromosomes (Chap. 10).¹⁶¹⁻¹⁶⁴ In a study of approximately 100 female PV patients, their reticulocytes, platelets, and granulocytes were always clonal, with the exception of a few patients who converted to polyclonal hematopoiesis after therapy with IFN- α .¹⁴

DIFFERENTIAL DIAGNOSIS

Also refer to Chap. 34, Table 34–2, and Chap. 57, Fig. 57–6.

PV has to be differentiated from spurious polycythemia, secondary polycythemias, congenital disorders of hypoxia sensing, and primary congenital polycythemias. The differential diagnostic task has been facilitated by the discovery of the *JAK2*^{V617F} mutation that is present in 95 percent or more of all PV patients.^{165,166} Thus, the majority of PV patients can be diagnosed with a complete blood count repeated twice and molecular studies to confirm the presence of the *JAK2*^{V617F} mutation.

For the remainder of polycythemic patients, additional diagnostic measures need to be undertaken. These may include measuring serum erythropoietin level, measuring venous oxygen saturation to calculate hemoglobin P50, measuring arterial oxygen saturation (less than 92 percent suggests cardiac or pulmonary etiologies), abdominal CT scan (to exclude renal, hepatic, and cerebral tumors), brain magnetic resonance imaging (to rule out a cerebellar hemangioblastoma), and detailed family studies.

If a diagnosis at this point has not yet been made, the patient could be referred to a specialized center for further testing. These studies may include measuring changes in serum erythropoietin levels after phlebotomies, red blood cell and plasma volume studies (to diagnose spurious polycythemia or masked PV), genomic sequencing studies, testing for *JAK2* exon 12 mutations, and *in vitro* studies for EECs. The latter two are used to diagnose *JAK2*^{V617F}-negative PV patients (<5 percent of all PVs).

Distinguishing between PV and other polycythemic disorders may, at times, be challenging. Although the diagnosis of PV may be straightforward if patients have the classic features of PV as defined by the most recent WHO guidelines,¹⁵⁴ patients often present with an incomplete phenotype. Some of the clinical and laboratory features that can be helpful for differential diagnosis are summarized in Chap. 34, Table 34–2 and Chap. 57, Fig. 57–6. While the current WHO diagnostic criteria (presented in Table 84–1)¹⁵⁴ represent an improvement over previous guidelines, they do not necessarily discriminate between individual MPNs,¹⁶⁷ and are still a matter of some debate.^{168,169} Children with PV are especially unlikely to fit the most recent WHO criteria.¹⁷⁰ Most importantly, often laborious and time-consuming efforts to rule

out congenital polycythemia should always be undertaken in patients with atypical presentations; however, the presence of polycythemia in other relatives does not rule out PV.

TREATMENT

The major causes of morbidity and mortality in PV are an increased incidence of vascular complications (i.e., thrombosis and/or hemorrhage), and progression to MF or acute leukemia/myelodysplasia. In the first randomized trial of PV patients, a history of previous thrombosis, age, treatment with phlebotomies, and rate of phlebotomies contributed to the increased risk of thrombosis.⁷⁶ Presently, the age of the patient (>60 years) and previous thrombotic events are universally acknowledged major risk factors for major vascular complications in PV.⁷¹

Thus, PV patients are classified as low risk or high risk, with age greater than 60 years and previous thrombotic events (including transient ischemic attacks) defining the high-risk category. The assigned risk classification has a major impact on therapeutic decisions, as high-risk patients are treated with cytoreductive therapies. Other risk factors may also play a role in the pathogenesis of thrombosis, such as hypertension, diabetes, or smoking,¹⁷¹ as well as leukocytosis^{172–176} and *JAK2*^{V617F} mutational allele burden.^{80,177} There is a need for prospective clinical studies with stratification of patients according to these criteria, but until such evidence is available, patients with high leukocyte levels and/or high *JAK2*^{V617F} mutational allele burden should be managed according to conventional criteria.

An elevated platelet count does not increase the risk of thrombosis, but it may increase the risk of hemorrhage.¹²⁸ Bleeding is more frequent in patients with platelet counts in excess of $1500 \times 10^9/L$, thought to be the result of an acquired type 2 von Willebrand disease.

Treatment of PV depends on risk evaluation at diagnosis and evolution of the disease over time. Treatment should be given both to alleviate symptoms and prevent complications. Updated consensus-based guidelines for the management of PV and other major MPNs were published by a panel of experts formed by European LeukemiaNet (ELN).¹⁷⁸ Response criteria by which new therapies are evaluated were also updated to facilitate direct comparison of therapeutic efficacy across clinical trials (Table 84–2).¹⁷⁹ This joint effort between ELN and the International Working Group for Myeloproliferative Neoplasms Research and Treatment (IWG-MRT) provides updated guidelines incorporating assessment of clinical, hematologic, and histologic response, as well as symptoms, disease progression, and vascular events.¹⁷⁹

It is useful to consider treatment for the *plethoric* and *spent* phases separately. In the plethoric phase, the mainstay of therapy remains non-specific myelosuppression, which many practitioners supplement with phlebotomies.^{82,178,180} Additional measures prevent thrombotic events (i.e., aspirin) and relieve symptoms. Promising therapies include pegylated interferon (PEG-IFN) preparations and *JAK2* inhibitors; these are, at the time of this writing, being evaluated by prospective randomized trials. A minority of patients (i.e., low-risk patients) can be treated with phlebotomies and low-dose aspirin alone. PV patients in the spent phase may be treated with a number of therapies (Chap. 86), which may include hydroxyurea, transfusion, erythropoiesis-stimulating drugs, *JAK2* inhibitors, splenectomy, or allogeneic stem cell transplantation; only *JAK2* inhibitors have been proven to be beneficial in prospective trials.²³⁵

THE PLETHORIC PHASE

Treatment of PV patients in the plethoric phase of the disease is aimed at reducing marrow proliferation and blood counts, thereby ameliorating symptoms and decreasing the risk of thrombosis and bleeding.^{180,181} This

TABLE 84–1. World Health Organization Criteria for the Diagnosis of Polycythemia Vera, 2008

MAJOR CRITERIA	
1	Hgb >18.5 g/dL (men), >16.5 g/dL (women) or Hgb >17 g/dL (men), >15 g/dL (women) if associated with a sustained increase of ≥ 2 g/dL from baseline that cannot be attributed to correction of iron deficiency
2	Presence of <i>JAK2</i> ^{V617F} or similar mutation
MINOR CRITERIA	
1	Marrow trilineage myeloproliferation
2	Subnormal serum EPO level
3	EEC growth

EEC, endogenous erythroid colony; EPO, erythropoietin; Hgb, hemoglobin.

A diagnosis of PV requires the presence of both major criteria and one minor criterion, or the first major criterion and two minor criteria.

TABLE 84–2. Response Criteria for Polycythemia Vera¹⁷⁹

A. CLINICAL RESPONSE	
Response	Criteria
Complete remission	
A	Durable* resolution of disease-related signs including palpable hepatosplenomegaly, large improvement in symptoms, [†] AND
B	Durable* blood count remission, defined as hematocrit lower than 45% without phlebotomies; platelet count $\leq 400 \times 10^9/L$, white blood cell count $< 10 \times 10^9/L$, AND
C	Without progressive disease, and absence of any hemorrhagic or thrombotic event, AND
D	Marrow histologic remission defined as the presence of age-adjusted normocellularity and disappearance of trilinear hyperplasia, and absence of $>$ grade 1 reticulín fibrosis.
Partial remission	
A	Durable* resolution of disease-related signs including palpable hepatosplenomegaly, large improvement in symptoms, [†] AND
B	Durable* blood count remission, defined as hematocrit lower than 45% without phlebotomies; platelet count $\leq 400 \times 10^9/L$, white blood cell count $< 10 \times 10^9/L$, AND
C	Without progressive disease, and absence of any hemorrhagic or thrombotic event, AND
D	Without marrow histologic remission defined as persistence of trilinear hyperplasia.
No response	Any response that does not satisfy partial remission.
Progressive disease	Transformation into post-PV myelofibrosis, myelodysplastic syndrome or acute leukemia.
B. MOLECULAR RESPONSE [‡]	
Response	Criteria
Complete response	Eradication of a preexisting abnormality
Partial response	$\geq 50\%$ decrease in allele burden, in patients with $\geq 20\%$ allele burden at baseline

*Lasting at least 12 weeks.

[†]Large improvement in symptoms (≥ 10 -point decrease) in MPN Symptom Assessment Form total assessment score.

[‡]Evaluation requires analysis in blood granulocytes. Molecular response is not required for assignment as complete response or partial response.

is best accomplished by myelosuppressive drugs and, in some patients, combination therapy consisting of myelosuppression, phlebotomies, and platelet-reducing agents and/or IFN- α . Table 84–3 summarizes the advantages and disadvantages of various forms of therapy for PV.

Myelosuppression

Myelosuppression decreases blood counts, decreases the risk of vascular events, and ameliorates symptoms, thus increasing an overall sense of well-being. Although there may be an impression that it increases patients' long-term survival, there are no long-term clinical studies to document this.

TABLE 84–3. Treatment of Polycythemia Vera

Treatment	Advantages	Disadvantages
Phlebotomy	Low Risk. Simple to perform.	Does not control thrombocytosis or leukocytosis.
Hydroxyurea	Controls leukocytosis and thrombocytosis as well as erythrocytosis.	Continuous therapy required. Long-term leukemogenic potential is not completely known.
Busulfan	Easy to administer. Prolonged remissions.	Overdose produces prolonged marrow suppression. Risks of leukemogenesis, long-term pulmonary and cutaneous toxicity.
³² P	Patient compliance not required. Long-term control of thrombocytosis, leukocytosis, and erythrocytosis.	Expensive and relatively inconvenient to administer. Likely leukemogenic risk.
Chlorambucil	Easy to administer. Good control of thrombocytosis and leukocytosis.	High risk of leukemogenesis.
Interferon	Low leukemogenic potential. Beneficial effect on pruritus. Potential deep suppression of the polycythemic clone.	Inconvenient to administer (injectable), costly, and adverse effects are common.
Anagrelide	Selective effect on platelets.	Selective effect on platelets.
JAK2 Inhibitors	Decreased need for phlebotomy. Improvement in quality of life.	Clinical trials experience only. Long-term benefits are unknown.

Hydroxyurea Hydroxyurea (HU) is the most common myelosuppressive agent used in the treatment of PV.^{182,183} HU is an effective therapy for controlling erythrocyte, leukocyte, and platelet counts, and it decreases the risk of thrombosis during the first few years of therapy when compared to an historical cohort treated with phlebotomy alone.⁷⁸ Because its suppressive effect is of short duration, continuous rather than intermittent therapy is required. Because it is short acting, it is relatively safe to use even when excessive marrow suppression occurs, as blood counts rise within a few days of decreasing the dose or stopping the drug. Several groups have investigated the effects of HU on JAK2^{V617F} allele burden, and as of yet, the results have been conflicting.^{184–187} Interestingly, it has been suggested that the JAK2^{V617F} allele burden in PV may be a reliable predictor of response to HU, and of the HU dose necessary to control the disease.¹⁸⁸

The leukemogenic risk of HU has been an ongoing debate for many years. Because HU is not an alkylating agent, it has less potential to cause acute leukemic transformation than other myelosuppressive agents, but its leukemogenicity was questioned in some historical studies. A large meta-analysis of patients with sickle cell disease did not find an increased risk of the development of acute leukemia following HU treatment.¹⁸⁹ Two large studies in PV have also suggested a similar

low risk associated with HU; analysis of 1638 PV patients enrolled in a prospective observational study¹⁰⁹ and 1545 patients followed under IWG-MRT¹⁹⁰ did not find an increased incidence of leukemic or myelodysplastic transformation with HU treatment.

Unfortunately, despite its safety and effectiveness, approximately 10 percent of PV patients develop HU resistance or intolerance (i.e., skin ulcers or gastrointestinal intolerance).^{191–193} Resistance to HU is correlated with decreased survival and a higher rate of transformation to AML or MF.¹⁹¹ Effective alternative treatments are available.

Busulfan Busulfan is a useful second-line agent in patients whose disease is difficult to control or who have adverse reactions to HU. The administration of busulfan is a convenient and effective means for treating PV. The marrow suppression produced by this drug is long-lasting and, as a consequence, it can be given intermittently at a dose of 2 to 8 mg daily for a period not exceeding several weeks; blood counts continue to fall for several weeks after drug administration is discontinued. The disease is usually controlled for many months or even years. In one large study, the median first remission duration of busulfan-treated patients was 4 years.¹⁹⁴ The prolonged depression of marrow activity brought about by busulfan is its major advantage in the treatment of PV, but it also poses a hazard of long-term pancytopenia. The incidence of transformation to leukemia may be increased with busulfan treatment. In a large study of 1638 PV patients, busulfan was one of the agents which was associated with an increased rate of transformation to AML/MDS.¹⁰⁹ When tested as a second-line therapy, busulfan robustly reduces the *JAK2*^{V617F} allelic burden and causes a complete hematologic response in the majority of patients,^{195,196} but also has a higher rate of transformation to leukemia compared to first-line busulfan treatment.¹⁹⁶

Radioactive Phosphorus ³²P therapy was one of the first effective modes of treatment used in PV. Extensive investigations of the long-term outcome of treatment with ³²P have been documented.^{76,197} Satisfactory control of the disease usually can be achieved with initial doses of 2 to 4 mCi. It is rarely used at present, but it may be the treatment of choice for older patients and patients who may be difficult to follow.^{198,199}

Interferon Since the pioneering work of Silver,²⁰⁰ IFN- α treatment has been confirmed to result in clinical and hematologic remission in PV in more than a dozen studies.^{201–204} Although these studies have many design similarities, they do not lend themselves to accurate meta-analysis; various formulations of IFN were used (INF- α 2a and - α 2b, PEG-INF- α 2a, and - α 2b, human leukocyte IFN), and heterogeneous criteria were employed to measure response. Nevertheless, it is clear that IFN- α effectively decreases many PV symptoms, including pruritus, results in a hematologic response in approximately 80 percent of patients, and decreases the need for phlebotomies in approximately 60 percent of patients.^{201–204}

In addition to clinical and hematologic responses, administration of IFN- α has led to a decrease in *JAK2*^{V617F} allelic burden^{43,205,206} and conversion from clonal to polyclonal hematopoiesis¹⁴ in the small number of patients studied thus far. Two comparisons of IFN- α 2b and HU suggest that IFN- α 2b may cause a greater molecular and hematologic response than HU in PV patients.^{207,208}

However, IFN- α has significant adverse effects. Approximately 25 percent of patients with PV and ET given IFN- α discontinue treatment, half of them within the first year. The hematologic toxicities include anemia, thrombocytopenia, and neutropenia. Other potential untoward effects of IFN- α include depression, mood changes, disabling fatigue, skin toxicity, hair loss, nausea, diarrhea, weight loss, liver function abnormalities, and cardiac and neurologic toxicity. Immunologic abnormalities in the form of autoimmune processes (e.g., hypothyroidism, autoimmune hemolytic anemia, polyarthritis, glomerulonephritis, connective tissue diseases, and asymptomatic antinuclear antibodies) may be consequences of IFN therapy.²⁰⁹ Conceivably, the development

of IFN-induced autoimmune processes reflects the immunomodulatory activity of the drug, through which at least part of its antitumor activity is mediated.

A pegylated version of IFN- α (PEG-IFN- α) is better tolerated than standard IFN- α and requires less frequent administration.²¹⁰ A number of phase II trials have shown that PEG-IFN- α 2a induces a complete hematologic response in the vast majority of patients and a reduction in *JAK2*^{V617F} allelic burden in some.^{211–215} Using *JAK2*^{V617F} as a molecular marker, a French group studied 40 PV patients treated with PEG-IFN- α 2a; 95 percent of evaluable patients had a complete hematologic remission, 90 percent had a decrease in *JAK2*^{V617F} allelic burden, and in 20 percent the *JAK2*^{V617F} allelic burden became undetectable.²¹⁴ However, the experience of the authors of this chapter is that we have not seen any true molecular remission in our therapy of more than 50 PV subjects and always detect a small level of *JAK2* mutant in those considered in “molecular remission,” albeit it at times at levels of less than 0.2 percent.

Although IFN- α and PEG-IFN- α can be used as first-line therapy in PV, they are more often used as second-line treatments.¹⁹³ PEG-IFN- α is the drug of choice in pregnant patients (Chap. 8).

Phlebotomy

Often, the initial treatment for patients with uncomplicated PV is phlebotomy.^{31,197} Together with low-dose aspirin, it is at present the recommended therapy for low-risk PV cases.

When phlebotomy is instituted, the hemoglobin may be reduced to normal or near-normal values by the removal of 450 mL of blood at one time every 2 to 4 days; smaller amounts should be removed from patients who weigh less than 50 kg. Patients with impaired cardiovascular function are better treated with smaller phlebotomies at more frequent intervals.

Phlebotomy is an effective way by which to lower or normalize the elevated blood viscosity of patients with PV. The reduction of hemoglobin levels may result in improvement of symptoms such as headaches or feeling of increased pressure. However, it does not reduce the leukocyte or platelet count, nor does it affect pruritus or gout. Iron deficiency and resulting microcytosis are usual consequences of repeated phlebotomies. An iron-deficient state may help control hemoglobin concentration in the long run, but it may increase platelet counts and fatigue in some patients. Judicious use of oral iron replacement therapy may improve the fatigue associated with iron deficiency without significantly increasing hematocrit.

A randomized study^{76,216} of a small number of PV patients comparing phlebotomy to other treatments indicated that the survival of patients treated only with phlebotomy was slightly better than for patients treated with chlorambucil, and no worse than those given ³²P. Patients undergoing phlebotomy did suffer more thrombotic episodes than patients treated with myelosuppressive therapy, although this risk seemed limited to the first 3 years of therapy.⁷⁸ This documented increased risk of thrombosis associated with phlebotomy was balanced by a lower incidence of acute leukemia late in the patient's course. There was no correlation between platelet count and development of thrombotic complications.²¹⁶

The rationale for phlebotomy in patients with PV is based on a widely quoted study that suggested the risk of thrombosis in PV was proportional to the elevation in hematocrit.²¹⁷ Although the underlying mechanisms causing thrombosis in PV are not fully understood, hematocrit is unlikely to be the only, or even a major risk factor, as the risk of thrombosis is not elevated in patients with non-PV polycythemia or in patients with secondary polycythemia caused by chronic exposure to high altitude, Eisenmenger syndrome,²¹⁸ or other cyanotic heart diseases.^{219,220} In patients with Chuvash polycythemia, the risk of stroke is similar regardless of whether hematocrit is controlled by phlebotomies (Chap. 37). Furthermore, the European Collaboration on Low-Dose

Aspirin in the Polycythemia Vera study (ECLAP), which included 1638 patients from 12 countries and 94 centers, found no difference in thrombotic complications for patients with hematocrits in the range of 40 to 55 percent.²²¹ An important attempt to clarify this issue was a prospective study of the effect of hematocrit in PV patients, as evaluated by univariate analysis, which reported that patients treated with phlebotomies had a decreased rate of thrombosis.²²² However, patients in the high-hematocrit group received less HU than those in the low-hematocrit group and had higher levels of leukocytes, both independent correlates of thrombotic risk.²²³

Anagrelide

Anagrelide can be used in PV for thrombocytosis, as an adjunct to other treatments. Among 113 PV patients with thrombocytosis, the administration of anagrelide produced a platelet response in 85 cases (75 percent).²²⁴ The starting dose was 0.5 or 1.0 mg given four times daily, and a response was noted in most patients within 1 week. The average dose required to control the platelet count was 2.4 mg per day. Adverse events included headache, palpitations, diarrhea, and fluid retention, and were occasionally sufficiently severe to require discontinuation of the treatment.²²⁵ In patients with ET (Chap. 85), a randomized trial in the United Kingdom indicated superior results for HU plus aspirin compared to anagrelide plus aspirin for control of elevated platelet count, MF, and hemorrhagic complications.²⁶ However, a later randomized trial showed a noninferiority of anagrelide to HU.²²⁶

Symptomatic Therapy for Pruritus

Although some symptoms of PV can be controlled using phlebotomy, control of pruritus is at times achieved using myelosuppression. Pruritus is a major symptom of PV and, in some patients, it is nearly intolerable. When marrow proliferation is well controlled, pruritus becomes milder or disappears entirely. Because bathing or showering usually intensifies the itching, the term *aquagenic pruritus* is often used. Some level of control of pruritus may be achieved by moisturization of the skin. Photochemotherapy with psoralens and ultraviolet light can be helpful.²²⁷ Antihistamines are often given, but are usually not very effective, and neither is aspirin.²²⁸ Both IFN- α ²²⁹⁻²³¹ and the JAK2 inhibitors provide a generally effective treatment modality to alleviate pruritus.^{232,233}

Aspirin

Because thromboembolic episodes represent a major source of morbidity and mortality in patients with polycythemia, aspirin is an important drug in the arsenal of treatment modalities for PV.

The results of early trials using 300 mg of aspirin daily showed an increase in the incidence of bleeding without a measurable impact on the incidence of thrombotic episodes.²³⁴ Subsequently, several studies showed positive benefits of aspirin use in PV. A pilot-controlled trial found that low-dose aspirin was well tolerated by PV patients and fully inhibited synthesis of the platelet aggregating compound thromboxane, but not the endothelial cell protectant prostacyclin.²³⁵ An ECLAP study showed that daily low-dose aspirin decreased arterial and venous thromboses, albeit incompletely.⁷⁵ Because thrombotic complications were not completely prevented, this study suggested that only a minor fraction of thromboses are attributable to platelets, and additional pathogenetic pathways in PV should be investigated. The increased risk of bleeding with high platelet counts and associated acquired von Willebrand disease is discussed in the preceding section entitled Platelets; aspirin should not be used when the platelet count exceeds 1000 to 1500 $\times 10^9/L$.

JAK2 Inhibitors

JAK2 inhibitors represent a promising new therapeutic avenue that arose with the discovery of abnormal JAK-STAT signaling in MPNs.²³⁶

Currently available JAK2 inhibitors target the catalytic site of the enzyme and therefore inhibit both wild-type and mutant forms of JAK2, as well as variable inhibition of JAK1, JAK3, and other kinases. A number of JAK2 inhibitors are in clinical testing for PV,^{236,237} including ruxolitinib (INCB018424), which is effective and FDA approved for use in patients with PMF.²³⁸⁻²⁴¹ Ruxolitinib is an oral JAK1/JAK2 inhibitor that has been shown effective in preclinical testing with PV primary cultures²⁴² and in phase II trials in HU-intolerant or refractory PV patients,^{233,243,244} ruxolitinib effectively reduced PV-associated symptoms, such as night sweats, pruritus, and bone pain, within 4 weeks, decreased spleen size to nonpalpable in 44 percent of patients by week 24, induced a complete hematologic response in 59 percent of patients, and reduced the *JAK2*^{V617F} allelic burden by equal to or greater than 50 percent within the first 3 years of treatment in 24 percent of patients.²³³ Phase III trial showed that patients with HU-intolerant or refractory PV treated with ruxolitinib have a decreased requirement for phlebotomy, decreased spleen size, and improvement in other PV-associated symptoms.²³²

Despite the encouraging advances with JAK2 inhibitors, modulation of the JAK2 pathways may not be the sole optimal treatment for PV and other MPNs. *JAK2*^{V617F} may not be the disease-initiating step in patients with MPNs,^{37,245} and additional mutations may require specific therapeutic targeting. Additionally, disease progression is characterized by clonal heterogeneity and genetic instability.²⁴⁶ Better characterization of the pathogenesis of PV is needed to facilitate further therapeutic developments.

Epigenetic Modulation

A high incidence of mutation in genes involved in epigenetic modification in MPNs (i.e., *TET2*, *DNMT3A*, *IDH1/2*, *PRC2*, *ASXL1*) provides potential targets for therapy.^{247,248} One currently used approach in cancer treatment is interference of histone acetylation, as the acetylation status of histones can alter DNA-protein and protein-protein interactions.²⁴⁹ The expression levels of histone deacetylases (HDAC) were found to be altered in all three major MPNs,²⁵⁰ which has made HDAC inhibitors a new therapy of interest in PV. For instance, Givinostat is an HDAC inhibitor which specifically inhibits the proliferation of *JAK2*^{V617F}-positive cells compared to normal cells²⁵¹ by inhibiting hematopoietic transcription factors NFE2 and c-MYB.²⁵² It has been found to reduce splenomegaly and pruritus in Phase II trials with PV patients.^{253,254}

Summary of Therapeutic Approach

The current approach for the management of the majority of PV patients (i.e., high risk) who are not participating in a clinical trial is a combination of therapeutic and preventative approaches:

1. Myelosuppression with HU daily, both as initial therapy (1500 mg qd) and long-term treatment (500 to 2000 mg qd), aiming to maintain neutrophil counts at low-normal levels. In addition, some patients will require the use of phlebotomies and/or anagrelide to maintain hemoglobin and platelet levels in normal ranges. Myelosuppression can also be achieved by other agents such as IFN- α or PEG-IFN- α . PEG-IFN- α is better tolerated than IFN- α and is the most effective therapy, but it is not as well tolerated as HU.
2. Low-dose aspirin at 80 mg qd (or 100 mg outside of North America) is given to all patients without history of major bleeding or gastric intolerance, or those with platelets over 1000 to 1500 $\times 10^9/L$.
3. Medication to control pruritus and gout may be added if required.
4. Judicious use of phlebotomies in patients with hematocrits greater than 45 to 55 percent and in patients who find phlebotomy relieves their symptoms, such as headaches, difficulty concentrating, and fatigue.

THE SPENT PHASE

Sometimes after only a few years and usually after 15 years or more, erythrocytosis in patients with PV gradually abates in the absence of iron deficiency, phlebotomy requirements decrease and cease, and anemia develops. During this “spent” phase of the disease, marrow fibrosis becomes more marked and the spleen often becomes greatly enlarged (see Fig. 84–2A). Instead of phlebotomies, transfusions or erythropoietin may be required in such patients.²⁵⁵ The platelet count may remain high or may decline, even to pronounced thrombocytopenic levels. Marked leukopenia or leukocytosis may occur, and immature granulocytes may appear in the blood. At this point, the disease closely mimics PMF (Chap. 86) and is termed post-PV MF. Treatment of this phase of the disease is difficult and requires the judicious use of a combination of therapeutic approaches, including HU, erythropoiesis-stimulating drugs, transfusions, JAK2 inhibitors, and/or allogeneic stem cell transplantation.

Splenectomy

Splenectomy may be warranted (see Fig. 84–2B), particularly in patients with severe fatigue and cytopenias, and in those where a greatly enlarged spleen produces physical discomfort and postprandial fullness.²⁵⁶ However, a large Mayo Clinic series reported significant morbidity and mortality associated with splenectomy at this stage of the disease.²⁵⁷

Hematopoietic Stem Cell Transplantation

Nonmyeloablative allogeneic stem cell transplantation should be considered for otherwise healthy PV patients in the spent phase, even in the seventh decade of life (Chap. 23).^{255,258,259} Transplantation is the treatment of choice in patients with early signs of MDS/AML transformation, and the only treatment offering the possibility of a cure.²⁶⁰ The rate of relapse and nonrelapse mortality following allogeneic stem cell transplantation is negatively associated with increased age, a matched but unrelated donor, and a diagnosis of AML.²⁶⁰

COURSE AND PROGNOSIS

PV is a chronic disease that runs a course over many years. Thrombotic complications, discussed in the preceding sections, are the dominant cause of morbidity and mortality in patients with PV. In contrast to other polycythemic disorders, PV has an increased risk and increased mortality resulting from development of acute leukemia.

The Polycythemia Vera Study Group⁷⁶ found that the median survival from the beginning of treatment was 13.9 years for those treated by phlebotomy alone, 11.8 years for ³²P-treated patients, and 8.9 years for chlorambucil-treated patients. Thrombosis was the most common cause of death, accounting for 31 percent of fatalities. Nineteen percent of patients died of acute leukemia, 15 percent from other neoplasms, and approximately 5 percent each from hemorrhage or development of the spent phase.

There is excess mortality attributable to thrombotic complications and acute leukemia transformation as a direct consequence of PV.⁷⁵ Acute leukemia occurs even in patients who have been treated only by phlebotomy, although its incidence is increased by the various forms of cytotoxic therapy employed. While AML is most common, acute lymphoid leukemia²⁶¹ and chronic neutrophilic leukemia²⁶² have occurred as well. The IWG-MRT reported a rate of transformation to leukemia of 2.3 percent at 10 years and 5.5 percent at 15 years,¹⁹⁰ but a unified scoring system that predicts the likelihood of transformation is yet to be developed.^{263,264}

Although it has been suggested that the overall survival of PV patients is near normal,^{265,266} a number of other studies have found

Figure 84–3. Survival of PV patients stratified by prognostic low-risk (blue), intermediate-risk (green), and high-risk (red) groups. Patients are scored based on three risk criteria: venous thrombosis (1 point), a leukocyte count $\geq 15 \times 10^9/L$ (1 point), and age (≥ 67 years: 5 points, 57–66 years: 2 points). The sum of these points classifies patients as prognostic low risk (0 points), intermediate risk (1–2 points) or high risk (≥ 3 points). (Reproduced with permission from Tefferi A, Rumi E, Finazzi G, et al: *Survival and prognosis among 1545 patients with contemporary polycythemia vera: An international study*. *Leukemia* 27(9):1874–1881, 2013.)

reduced survival of PV patients compared to controls.⁴ A recent study of 1545 patients by the IWG-MRT found that survival for PV patients was negatively correlated to leukocytosis, older age, venous thrombosis, and atypical karyotype. The median overall survival ranged from 10.9 and 27.8 years for different PV prognostic risk groups (Fig. 84–3).¹⁹⁰

CHAPTER 85

ESSENTIAL THROMBOCYTHEMIA

Philip A. Beer and Anthony R. Green

SUMMARY

Essential thrombocythemia is a clonal stem cell disorder characterized by an overproduction of platelets and associated with mutations in the *JAK2*, *CALR*, or *MPL* gene. Complications include thrombosis (predominantly arterial), hemorrhage, and progression to myelofibrosis or acute myeloid leukemia. Diagnosis requires exclusion of reactive thrombocytosis and other myeloid malignancies associated with a raised platelet count. Therapy is aimed at reducing thrombotic complications and includes modification of known cardiovascular risk factors and antiplatelet therapy for the majority of patients. Those at high risk of thrombosis are also considered for cytoreductive therapy with agents such as hydroxyurea, anagrelide or interferon- α . Although the majority of patients can expect to live for many years, mortality rates are increased compared to the general population as a consequence of disease complications.

DEFINITION AND HISTORY

Essential thrombocythemia (ET), one of the myeloproliferative neoplasms (MPNs), is a clonal hematopoietic stem cell disorder characterized by thrombocytosis and associated with thrombotic and hemorrhagic complications. First recognized as a specific disease entity in 1934¹ and as a clonal disorder in 1981,² ET shares clinical and pathologic similarities with other MPNs, particularly polycythemia vera (PV) and primary myelofibrosis (PMF).

EPIDEMIOLOGY

The annual incidence of ET is in the order of 1 to 2.5 per 100,000 per population and appears slightly more common in females.^{3,4} Patients may present at any age, although ET is largely a disorder of later life with a peak incidence between the ages of 50 and 70 years. Presentation in childhood is rare but well recognized.

ETIOLOGY

Little is known about the precise etiology of this disorder, although environmental factors such as exposure to radiation have been implicated in the genesis of other MPNs.⁵ Both registry data and kindred

studies suggest a familial tendency to develop MPNs, including ET.^{6,7} This predisposition appears to be explained in part by inheritance of a specific haplotype that contains the Janus family of tyrosine kinases type 2 (*JAK2*) gene.⁸

PATHOGENESIS

ET is characterized by hyperactive cytokine signaling which in 50 to 60 percent of cases is the result of somatic mutations targeting components of signaling pathways, including the *JAK2* gene or the thrombopoietin receptor gene (*MPL*). Mutations in calreticulin gene (*CALR*) are present in the majority of *JAK2/MPL*-wild-type patients, leaving approximately 10 percent of ET patients without a mutation in any of these genes (*JAK2/MPL/CALR*-wild-type or "triple-negative" patients). A minority of ET patients also harbor mutations in transcriptional regulation pathways (Fig. 85-1).

A *JAK2*^{V617F} mutation is found in approximately 50 percent of patients with ET.⁹ *JAK2*, a cytoplasmic tyrosine kinase, forms a complex with and is essential for signaling by the erythropoietin and thrombopoietin receptors^{10,11}; *JAK2* also contributes to signaling by the granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, and interferon- γ receptors.¹² Cytokine binding leads to a conformational change in the *JAK2*-receptor complex, with consequent activation of *JAK2* kinase activity and recruitment of downstream signaling pathways.^{10,13,14} The *JAK2*^{V617F} mutation alters a critical residue within the autoinhibitory pseudokinase (JH2) domain, resulting in increased *JAK2* basal kinase and downstream signaling activity.¹⁵ The cellular consequences of mutant *JAK2* expression include increased proliferation, cytokine hypersensitivity, cytokine-independent differentiation, and inhibition of apoptosis.⁹ The central role of *JAK2* in erythropoiesis is highlighted by a *JAK2* knockout mouse, which dies in midgestation from severe anemia.¹² In addition, mice engineered to express the *JAK2*^{V617F} allele recapitulate features of human ET or PV.¹⁶

Acquired mutations in *MPL* are found in 4 percent of ET patients, the majority of whom are *JAK2*-wild-type, and a similar proportion of those with PMF, but not in patients with PV.^{17,18} These mutations alter residues in the juxtamembrane (*MPL*^{W515}) or transmembrane (*MPL*^{S505N}) regions and lead to constitutive activation of the receptor complex.^{19,20} Expression of the *MPL*^{W515L} allele in a mouse model recapitulated features of human ET and PMF.²¹ Occasional patients with ET, as well as PV and PMF, harbor loss of function mutations in *SH2B3* which encodes LNK, an important negative regulator of *JAK/STAT* (signal transducer and activator of transcription) signaling.²²

The majority of ET patients without a signaling pathway mutation harbor a somatic mutation in *CALR* (encoding calreticulin). *CALR* mutations are found in 15 to 35 percent of ET patients and a similar proportion of those with PMF but not in PV. Calreticulin is a key endoplasmic reticulum protein with calcium buffering and protein chaperone activity.²³ Although *CALR*-mutant patients generally lack mutations in *JAK2* or *MPL*, they nonetheless show signaling pathway activation, suggesting an as yet undetermined role for *CALR* in cytokine signaling.²⁴⁻²⁶

Mutations targeting pathways implicated in the control of gene transcription are found in a minority of patients with ET, as well as those with PV, PMF and other myeloid neoplasms (see Fig. 85-1B). These mutations, which may coexist with mutations in *JAK2*, *MPL*, or *CALR*, target genes involved in DNA methylation (*TET2*, *IDH1/2*, *DNMT3A*), histone modification (*EZH2*) or RNA splicing (*SF3B1*).²⁷ In addition to its roles in cytokine signaling, *JAK2* has also been shown to translocate to the nucleus where it acts as a mediator of gene transcription through the direct modification of histone proteins. Whereas nuclear translocation of wild-type *JAK2* appears to be activation-dependent,

Acronyms and Abbreviations: AML, acute myeloid leukemia; *CALR*, calreticulin gene; CML, chronic myeloid leukemia; ET, essential thrombocythemia; *JAK2*, Janus family of tyrosine kinases type 2; *MPL*, the thrombopoietin receptor; MPN, myeloproliferative neoplasm; PCR, polymerase chain reaction; PMF, primary myelofibrosis; PV, polycythemia vera; RARS-T, refractory anemia with ringed sideroblasts and thrombocytosis; *STAT*, signal transducer and activator of transcription.

CLINICAL FEATURES

SYMPTOMS AND SIGNS

ET is often diagnosed following the incidental finding of a high platelet count, although a proportion of patients present with thrombotic or hemorrhage complications. A detailed clinical history and physical examination are necessary to exclude causes for a reactive thrombocytosis. Approximately 10 percent of ET patients have a mild degree of palpable splenomegaly at diagnosis,³⁰ although significant splenic enlargement should raise the possibility of another MPN such as PMF or chronic myeloid leukemia (CML).

THROMBOSIS

Thrombotic complications are the major source of morbidity and mortality in ET, with a prospective study indicating a cumulative incidence of 24 percent over 27 months for untreated high-risk patients.³¹ Arterial thrombosis predominates, affecting the central nervous system (stroke, transient ischemic attack) and cardiovascular system (myocardial infarction, unstable angina, peripheral arterial occlusion).^{30,31}

Erythromelalgia, a distinct clinicopathologic syndrome caused by occlusion of small blood vessels, is manifest by discomfort and burning sensations in the fingers or toes, sometimes accompanied by mottling or discoloration of the skin.³² Venous events mainly comprise deep vein thrombosis and pulmonary embolism. Involvement of unusual sites such as hepatic, portal or mesenteric veins also occurs and may precede the onset of clinically overt ET (Fig. 85-2A). In one series, half of all patients presenting with hepatic vein thrombosis and a normal blood count tested positive for the *JAK2*^{V617F} mutation, and a quarter of these subsequently developed a clinically overt MPN, most commonly ET.³³

The strongest predictive factors for thrombotic complications are older than 60 years of age or a history of previous thrombosis.³⁴ The platelet count and leucocyte count at diagnosis are poor predictors of thrombotic risk.³⁵ Meta-analysis confirmed detection of a *JAK2*^{V617F} mutation as a risk factor for both arterial and venous thrombosis.^{36,37} Other reported risk factors include predisposition to cardiovascular disease or increased marrow fibrosis at diagnosis.³⁸

HEMORRHAGE

Serious bleeding is less common than thrombosis and mainly affects the nasal and buccal mucosa and the gastrointestinal tract, although central nervous system hemorrhage may occur.^{30,31} ET patients often demonstrate prolongation of the bleeding time and various abnormalities of

Figure 85–2. Morphologic features of essential thrombocythemia. **A.** Contrast-enhanced abdominal computed tomography (CT) scan showing features of established hepatic vein thrombosis in a 53-year-old female, including hypertrophy of the caudate lobe (*arrow*) with atrophy of the remaining liver and surrounding ascites; the spleen is of normal size. Hematoxylin and eosin (H&E)-stained marrow trephine biopsy showing normal cellularity and increased megakaryocytes with occasional hyperlobulated forms (*inset*). Although the patient was $JAK2^{V617F}$ -positive, other investigations performed at this time, including blood count, red cell mass and cytogenetic analysis, were normal. **B.** Marrow aspirate from a $JAK2^{V617F}$ -positive essential thrombocythemia (ET) patient showing large, hyperlobulated megakaryocytes (slide stained with Wright-Giemsa). **C.** Marrow trephine biopsy samples from patients with ET (slide stained with H&E).

in vitro coagulation studies, including abnormal platelet aggregation or loss of large von Willebrand factor multimers; however, the relationship of these findings to episodes of clinical bleeding is unclear.³⁹ In a prospective study, rates of major hemorrhage were increased in patients with increased marrow fibrosis at diagnosis³⁸ and in those with an increased platelet or leucocyte count during followup.³⁵

MYELOFIBROTIC TRANSFORMATION

Evolution to myelofibrosis is seen in a proportion of ET patients, although the reported prevalence varies widely, reflecting differences in study design, therapeutic intervention and diagnostic criteria for post-ET myelofibrosis (Chap. 86). Retrospective studies suggest that

disease duration is a major predictor of progressive disease, with rates of myelofibrosis in the first decade after diagnosis of 3 to 10 percent rising to 6 to 30 percent in the second decade.^{34,40} The presence of marrow fibrosis at diagnosis also appears to presage progression to myelofibrosis,³⁸ although the predictive value of other histologic features of early stage PMF, such as megakaryocyte dysplasia, remains controversial.⁴¹ Mutations in $JAK2$,^{42,43} MPL ,^{17,18} or $CALR$ ^{44,45} appear to lack prognostic significance. A prospective study of high-risk ET patients indicated increased progression to myelofibrosis with anagrelide therapy, with a 5-year cumulative incidence of 7 percent for anagrelide plus aspirin versus 2 percent for hydroxyurea plus aspirin-treated patients.³⁰ The clinical consequences of post-ET myelofibrosis are similar to *de novo* myelofibrosis, and the conditions are managed in the same way.

LEUKEMIC TRANSFORMATION

Progression to acute myeloid leukemia (AML) occurs in a small minority of patients, with retrospective studies suggesting a prevalence of 1 to 2.5 percent in the first decade after diagnosis, 5 to 8 percent in the second decade, and continuing to rise thereafter.^{34,40,46} Therapeutic heterogeneity in these studies, however, renders their findings difficult to interpret. Studies in PV demonstrated a significantly increased risk of AML in patients receiving genotoxic agents such as radioactive phosphorus, chlorambucil, or busulphan.^{47,48} The potential leukemogenicity of hydroxyurea remains controversial (see “Choice of Cytoreductive Agent” below). Importantly, transformation to leukemia has been reported in the absence of any cytoreductive therapy,^{49,50} indicating that AML is part of the natural history of this disorder.

Therapy of post-ET AML is often limited by the older age of the affected patients, in whom palliative treatment may be the most appropriate strategy. Overall the prognosis of secondary AML is poor (Chap. 88). Younger patients who do achieve remission with AML induction therapy may be considered for allogeneic hematopoietic stem cell transplantation.

LABORATORY FEATURES

An unexplained and persistently raised platelet count generally warrants further investigation (Fig. 85–3). Establishing a diagnosis of ET requires exclusion of both reactive conditions and other myeloproliferative or myelodysplastic disorders that may present with an isolated thrombocytosis (Tables 85–1 and 85–2).

HEMATOLOGIC AND BIOCHEMICAL PARAMETERS

An elevated platelet count is invariably present and may be only slightly increased (e.g., $\geq 400 \times 10^9/L$) or massively elevated into the millions $\times 10^9/L$. Thus, the degree of thrombocytosis varies markedly between patients. The white count may be slightly to mildly elevated but usually not above $20 \times 10^9/L$ as a result of neutrophilia. The hemoglobin concentration may be normal or mildly reduced. If occult bleeding has been present, the hemoglobin may be further decreased and indications of iron deficiency may be evident in the red cells (microcytosis and hypochromia; see “Differential Diagnosis” below). Examination of the blood film often reveals large platelets which may stain poorly, and is useful in excluding features of PMF such as teardrop cells (dacryocytes) or circulating immature granulocyte precursors.

SERUM CHEMICAL FINDINGS

Levels of thrombopoietin are normal or slightly elevated in ET and have no diagnostic utility. ET patients may show a spurious increase in serum potassium level as a result of *in vitro* activation of platelets and leukocytes during processing of serum; this phenomenon can be circumvented by using a plasma sample for biochemical analysis.

MOLECULAR TESTING

Molecular testing for genetic mutations has become the investigation of choice for patients with an unexplained and persistent increase in platelet count (see Fig. 85–3). A reasonable approach is to screen all patients for the *JAK2*^{V617F} mutation, following by screening for mutations in *CALR* and uncommon *MPL* in negative cases. Suitable techniques include allele-specific or real-time polymerase chain reaction (PCR) for *JAK2*^{V617F}, pyrosequencing or high-resolution melt curve

analysis for *MPL*, and fragment length analysis for *CALR* exon 9.^{25,51} In the absence of marrow cytogenetic analysis, molecular testing for the *BCR-ABL1* fusion gene is also recommended to exclude CML. Screening for additional mutations (e.g., *TET2*) is currently of uncertain utility in routine clinical practice.

MARROW STUDIES

Marrow aspiration and trephine biopsy is particularly recommended in suspected cases of ET that are negative for a relevant somatic mutation. Marrow studies may also be useful in cases showing atypical clinical or laboratory features (for example, palpable splenomegaly, unexplained anemia or blood film abnormalities) or in the context of a clinical study. The marrow aspirate in ET often shows large hyperlobulated megakaryocytes (see Fig. 85–2B), and iron staining may be helpful in excluding iron deficiency or the presence of ringed sideroblasts (see “Differential Diagnosis” below). The marrow trephine biopsy typically shows an increase in megakaryocyte frequency with megakaryocyte clustering and nuclear hyperlobulation in the absence of significant reticulin fibrosis (see Fig. 85–2C). Cellularity is usually normal or slightly increased, but occasional cases may show a hypocellular marrow, for example, a proportion of those with mutations in *MPL*.^{17,18}

Chromosomal analysis, by G-banding or *in situ* fluorescent hybridization, is helpful in suspected cases of ET lacking a relevant somatic mutation, primarily to exclude lesions associated with other myeloid disorders such as t(9:22) (CML) or deletions of chromosome 5q (“5q-minus syndrome”; Chap. 87). Other karyotypic abnormalities, mainly comprising deletions of chromosomes 20q or 13q or additional copies of chromosomes 8 or 9, are found in approximately 5 percent of ET patients and establish the existence of clonal hematopoiesis.

DIFFERENTIAL DIAGNOSIS

REACTIVE THROMBOCYTOSIS

A secondary increase in platelet count, initiated by cytokines such as interleukin-6 and directly driven by the induction of hepatic thrombopoietin production is associated with a number of infectious, inflammatory and malignant disorders (see Table 85–2; Chap. 119). In reports of unselected patients attending various hospital departments, an increased platelet count was attributable to reactive causes in more than 80 percent of cases; the degree of thrombocytosis did not permit distinction between a clonal versus a reactive pathogenesis.^{52,53}

FAMILIAL THROMBOCYTOSIS

Familial thrombocytosis is a rare disorder caused by mutations in the thrombopoietin gene, *MPL*, or other unknown genes. Changes in the 5′-untranslated region or splice donor/acceptor sites of the thrombopoietin gene are associated with increased translation of thrombopoietin and consequent thrombocytosis.⁵⁴ These alleles are dominantly inherited and have not been seen in clonal MPNs.⁵⁵ A dominantly inherited, activating *MPL* allele (*MPL*^{S505N}) has been reported in Japanese and Italian kindreds.⁵⁴ Of interest, this allele has also been reported as a somatic mutation in patients with a clonal MPN.¹⁷ Several different inherited *JAK2* alleles have been reported in families with autosomal dominant thrombocytosis (including *JAK2*^{R564Q}, *JAK2*^{V617I}, *JAK2*^{R867Q}, and *JAK2*^{S755R/R938Q}).^{56,57} Although complicated by occasional thrombotic or bleeding episodes, the clinical phenotype of familial thrombocytosis is relatively mild, although exceptions occur.⁵⁴ The genetic cause underlying a subset of familial cases remains to be elucidated.

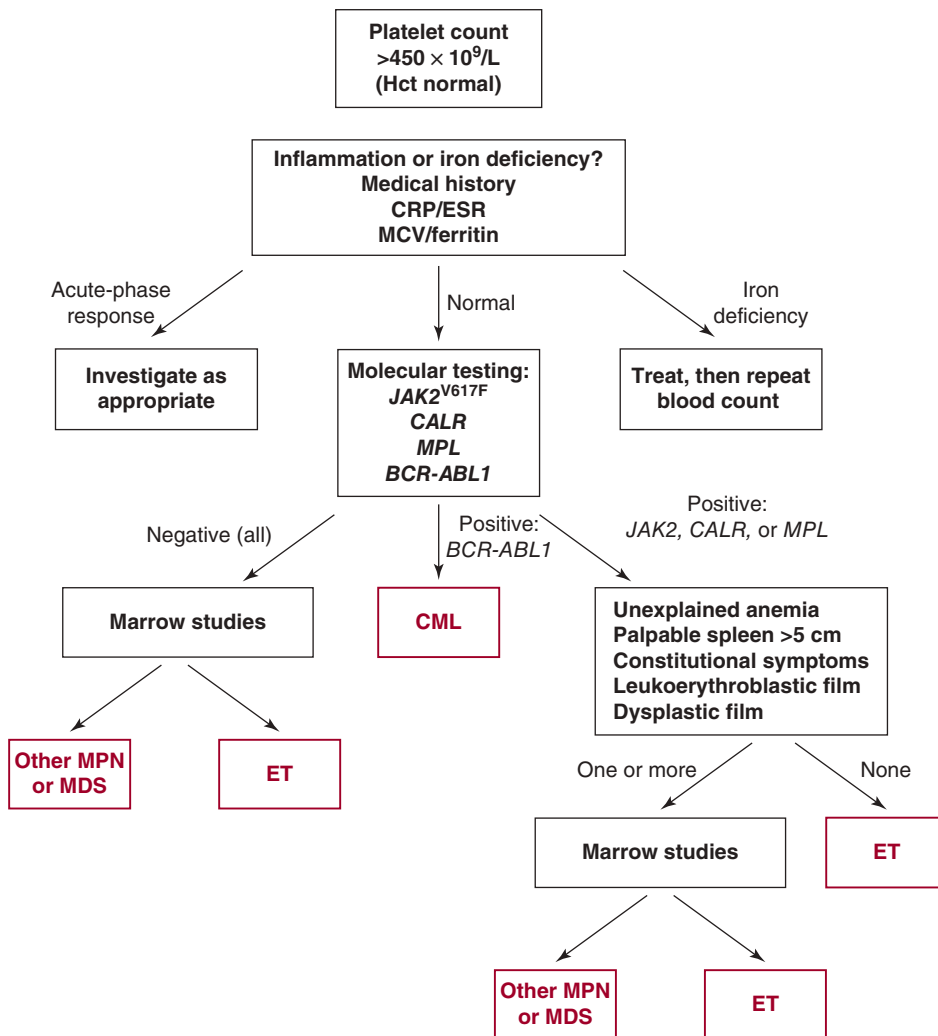

Figure 85-3. Investigation of patients with thrombocythemia. Algorithm outlining the investigation of a patient with an unexplained and persistently raised platelet count.

POLYCYTHEMIA VERA

PV (Chap. 84) is often associated with thrombocytosis, and may present with a normal hemoglobin level in the presence of iron depletion, mimicking ET, although in such cases the mean corpuscular volume is usually decreased. In addition, ET and PV form a phenotypic spectrum, resulting in diagnostic difficulties in a subset of patients. There are inherent limitations to the utility of continuous variables, such as hematocrit, to make this distinction, as the group of patients with intermediate values

will inevitably include both disorders (Fig. 85-4). Controversy persists over how to best distinguish these two conditions.⁵⁸

TABLE 85-1. Diagnostic Criteria for Essential Thrombocythemia

Diagnosis requires A1 to A3 or A1 + A3 to A5

A1 Sustained platelet count $>450 \times 10^9/L$

A2 Presence of an acquired pathogenic mutation (e.g., in *JAK2*, *CALR*, or *MPL*)

A3 No other myeloid malignancy, especially polycythemia vera, primary myelofibrosis, chronic myeloid leukemia, or myelodysplastic syndrome

A4 No reactive cause for thrombocytosis and normal iron stores

A5 Marrow studies showing increased megakaryocytes displaying a spectrum of morphology with prominent large hyperlobulated forms; reticulin is generally not increased

PRIMARY MYELOFIBROSIS

PMF may present with an isolated thrombocytosis, but palpable splenomegaly, circulating teardrop red cells and progenitor cells, and marrow fibrosis are usually present (Chap. 86). An area of ongoing controversy relates to the 15 to 20 percent of ET patients who harbor distinct marrow morphology, coined *prefibrotic PMF*, at diagnosis in the absence of other features to indicate PMF. Although such patients have higher rates of myelofibrotic transformation, thrombosis, and hemorrhage, their overall survival is not different from other patients with ET.⁵⁹ A second area of controversy relates to the suggestion that marrow trephine appearances can distinguish ET and prefibrotic PMF from the early stages of PMF⁶⁰; however, the reproducibility and clinical utility of this distinction is unclear.^{41,58}

CHRONIC MYELOID LEUKEMIA

Occasional patients with CML present with an isolated thrombocytosis. Such cases are predominantly female with absent or minimal splenomegaly and a normal or marginally elevated white cell count, often without basophilia or circulating myeloid progenitors.⁶¹ Marrow studies, however, are usually informative, showing small hypolobulated megakaryocytes typical of CML, and not the large hyperlobulated forms observed

in ET. Given the significant impact of tyrosine kinase inhibitors on the prognosis of CML, it is important that this unusual presentation is not overlooked. It is therefore recommended that suspected cases of ET that are negative for a relevant somatic mutation undergo molecular analysis of blood for the BCR-ABL1 fusion gene. Marrow aspiration, biopsy and G-banding cytogenetic analysis, may be useful in a specific case.

MYELODYSPLASIA

Thrombocytosis, usually in association with anemia, may be seen in the myelodysplastic disorder associated with an isolated deletion of chromosome 5q (“5q-minus syndrome”). Although often increased in

number, the megakaryocytes are generally small and hypolobulated,⁶⁰ in contrast to the large hyperlobulated forms typical of ET. A raised platelet count is also a feature of refractory anemia with ringed sideroblasts and thrombocytosis (RARS-T), and may be associated with thrombotic complications. Approximately half of patients with RARS-T harbor a $JAK2^{V617F}$ mutation or, rarely, a mutation in *MPL*.

PATHOGENETIC RELATIONSHIP OF ESSENTIAL THROMBOCYTHEMIA TO OTHER MYELOPROLIFERATIVE NEOPLASMS

Polycythemia Vera

The same $JAK2^{V617F}$ mutation is present in the vast majority of patients with PV (Chap. 84) and in approximately half of those with ET, raising questions as to how a single mutation is commonly associated with apparently distinct clinical phenotypes. Clones that are homozygous for the $JAK2^{V617F}$ mutation (arising by a mitotic recombination event termed *uniparental disomy*; Fig. 85–5) are larger and more frequent in patients with PV compared with ET,^{62,63} suggesting a role for increased JAK2-STAT5 signaling in driving erythrocytosis. In support of this hypothesis, in both mouse and human model systems strong JAK2-STAT5 activation drives erythropoiesis whereas weaker activation favors a megakaryopoiesis.^{16,64,65} Other contributing factors include the effects of patient gender⁶³ and modulation of STAT1 signaling.⁶⁶

Myelofibrosis and Accelerated Phase Disease

A proportion of patients diagnosed with ET experience progression to an accelerated phase characterized by increasingly disordered hematopoiesis. The phenotypic manifestations are variable and include hyperproliferation, myelodysplasia, or, most commonly, myelofibrosis. Myelofibrotic transformation of ET, characterized by marrow fibrosis, extramedullary hematopoiesis and marrow failure, is clinically indistinguishable from PMF (Chap. 86), suggesting PMF may represent presentation with accelerated phase disease. Consistent with this, patients with PMF may have thrombocytosis for many years prior to diagnosis, suggestive of undiagnosed ET.⁵⁸

The prevalence of mutations in *JAK2*, *CALR*, or *MPL* is similar in ET compared to myelofibrosis; however, karyotypic abnormalities are present in up to 50 percent of myelofibrosis patients (Chap. 86) compared to only approximately 5 percent of patients in ET, indicating a greater degree of genetic instability. In addition, mutations in genes implicated in transcriptional regulation (including *ASXL1*, *IDH1/2*, and *EZH2*) appear more common in patients with PMF compared with ET. Together, these findings suggest that progression to advanced phase disease arises through a process of clonal evolution driven by the acquisition of additional genetic events or epigenetic alterations; to date, however, no combination of genetic events has been shown to reliably

Figure 85–4. Distribution of diagnostic hematocrit levels in a cohort of 243 patients with $JAK2^{V617F}$ -positive disease (essential thrombocythemia or polycythemia vera).

Figure 85-5. Mitotic recombination leads to duplication of the $JAK2^{V617F}$ mutation, resulting in a V617F-homozygous subclone.

distinguish ET from PMF. Constitutive activation of JAK2 has been implicated as a driver of clonal progression, as expression of mutant JAK2 leads to the accumulation of reactive oxygen species, increased DNA damage, and aberrant DNA repair.⁶⁷⁻⁷⁰

Blastic Phase Disease

For a minority of patients with ET, their disease terminates in AML, also referred to as blastic phase. In some patients, the disease phenotype shows a stepwise transition from ET to PMF to AML, thus mimicking the triphasic disease pattern of CML observed in the preimatib era (Chap. 89). In other cases, AML arises directly following ET.⁷¹

The mutational profile of blastic phase disease shares some similarities with *de novo* AML. Mutations in transcriptional control pathways (including *TET2*, *ASXL1*, *EZH2*, and *IDH1*) are more common in blastic phase than in the early disease phases. In addition, mutations are seen in DNA repair and cellular differentiation pathways (including *TP53*, *RUNX1*, and *IKZF1*) which are rarely mutated in early stage MPNs. In contrast to *de novo* AML, balanced chromosomal translocations are rare in post-MPN AML.⁷²⁻⁷⁴ Of note, patients with $JAK2^{V617F}$ -positive ET may develop AML that is negative for the *JAK2* mutation.^{49,71}

THERAPY

MODIFICATION OF CARDIOVASCULAR RISK FACTORS

Established risk factors for cardiovascular disease, such as hypertension, diabetes, smoking, hypercholesterolemia, and obesity, should be identified and treated appropriately. The broad efficacy of the cholesterol-lowering statin drugs in the prevention of atherosclerotic disease has raised the possibility that such agents may be useful in ET, although this has yet to be tested in a prospective study.

ANTIPLATELET THERAPY

A large randomized trial in PV demonstrated a reduction in thrombotic events in those taking low-dose aspirin (100 mg daily) without a concomitant increase in the risk of hemorrhage.⁷⁵ Although retrospective studies have suggested a similar protective effect in ET,³² prospective trials have not been performed. Based on current evidence, aspirin is recommended for all ET patients unless contraindicated. Although there are few data concerning the use of newer antiplatelet agents such as clopidogrel in ET, their proven track record in preventing complications of atherosclerotic disease suggests they may be appropriate for patients unable to tolerate aspirin.

CYTOREDUCTIVE THERAPY

Indications to Treat

A prospective randomized trial demonstrated a clear role for cytoreductive therapy with hydroxyurea in reducing thrombotic events in high-risk ET patients (age >60 years or history of prior thrombosis), approximately 70 percent of whom were also receiving antiplatelet

TABLE 85-3. Risk Stratification for Patients with Essential Thrombocythemia

High Risk	No High-Risk Features	
	Low Risk	Intermediate Risk
Age >60 years	Age <40 years	Age 40–60 years
Prior thrombosis		
Platelets >1500 × 10 ⁹ /L		

agents.³¹ Although retrospective studies suggest that thrombotic complications in those younger than 60 years of age without additional risk factors may be no higher than controls, prospective data are lacking. Patients with ET are currently stratified on the basis of their risk of thrombotic complications (Table 85-3), with cytoreductive therapy likely to benefit high-risk patients. Patients without high-risk features can be divided into low risk (age less than 40 years) and intermediate risk (age 40 to 60 years). Cytoreductive therapy is unlikely to offer a significant protective effect for those with low-risk disease, in whom the *a priori* risk of thrombosis is small. There is currently little evidence available to guide treatment decisions in the intermediate-risk group. The ongoing PT-1 trials (<http://www.haem.cam.ac.uk/primary-thrombocythaemia/>), comprising a randomized trial of hydroxyurea and aspirin versus aspirin alone for intermediate-risk patients and an observational study of low-risk patients treated with aspirin alone, will provide prospective data to help clarify therapeutic decisions for these patients. Although the degree of thrombocytosis is not a reliable indicator of thrombotic risk, many physicians consider cytoreductive therapy in patients with a very high platelet count (e.g., greater than 1500 × 10⁹/L).

Once cytoreductive therapy is instituted, dose adjustment is recommended to keep the platelet and leucocyte counts within the normal range.³⁵

Choice of Cytoreductive Agent (Table 85-4)

Choices of first and second line therapies for patients with ET are summarized in Table 85-4). Hydroxyurea, a ribonucleotide reductase inhibitor also known as hydroxycarbamide, is widely regarded as first-line therapy for patients requiring treatment, and is the only cytoreductive agent proven to reduce thrombotic events in a randomized controlled trial.³¹ Major complications of this drug include reversible myelosuppression and ulceration of the buccal mucosa or lower leg. Although hydroxyurea appears nonleukemogenic when used to treat sickle cell

TABLE 85-4. Choice of Cytoreductive Agent in Essential Thrombocythemia

Age Group	First Line	Second Line
<40 years old	Interferon- α	Hydroxyurea Anagrelide
40–60 years	Interferon- α Hydroxyurea	Anagrelide
>60 years	Hydroxyurea	Anagrelide Pipobroman* Busulphan* Radioactive phosphorus*

*These agents increase the frequency of transformation to acute leukemia in PV studies and their use is only recommended in patients older than 75 years of age after careful consideration on a case-by-case basis.

disease,⁷⁶ controversy remains about potential leukemogenicity in the MPNs. Some studies suggest an increased risk of acute leukemia in hydroxyurea-treated ET patients,^{77,78} but others have failed to observe this association.^{79,80} Problems with these studies include small patient numbers, inclusion of patients who have received multiple cytotoxic agents, lack of proper controls, retrospective data collection, and relatively short followup. Of note, analysis of blood cells from sickle cell and MPN patients receiving hydroxyurea showed equivalent rates of DNA mutations to normal controls, suggesting that the mutagenic potential of hydroxyurea is low.⁸¹ At present it is not clear whether hydroxyurea used as a single agent is associated with an increased risk of acute leukemia; however, any increased risk is likely to be small and should be balanced against the reduction in thrombotic complications.

Anagrelide, a quinazoline derivative, reduces the platelet count by inhibition of megakaryocyte differentiation. Although the white cell count is unaffected, anemia is common and often progressive.³⁸ Up to a third of patients cannot tolerate anagrelide because of side effects, many of which result from its vasodilatory and positive inotropic actions including palpitations and arrhythmias, fluid retention, heart failure and headaches. Use of this drug requires particular caution in elderly patients or those with preexisting cardiac disease. Although anagrelide is not cytotoxic, and therefore unlikely to be leukemogenic, the PT-1 randomized trial demonstrated that anagrelide plus aspirin was inferior to hydroxyurea plus aspirin in high-risk ET patients. In this study, anagrelide-treated patients experienced reduced event-free survival ($p = 0.03$) with higher rates of arterial thrombosis ($p = 0.004$), major hemorrhage ($p = 0.008$) and progression to myelofibrosis ($p = 0.01$), despite equivalent control of the platelet count, although rates of venous thrombosis were decreased ($p = 0.006$).³⁰ In contrast to hydroxyurea, anagrelide therapy was also associated with an increase in marrow reticulin over time.³⁸ Comparison of patients in the PT-1 (comparison of hydroxyurea versus anagrelide) and Italian (comparison of hydroxyurea versus no cytoreductive therapy) prospective studies suggests that anagrelide does provide partial protection from thrombosis,⁸² and therefore may be suitable as second-line therapy for patients in whom hydroxyurea therapy is inadequate or not tolerated. It has been suggested that the results of the ANAHYDRET trial (comparing hydroxyurea to anagrelide) show that anagrelide is not inferior to hydroxyurea in the treatment of ET.⁸³ However, the number of patients enrolled, duration of followup, and primary end points recorded were relatively small (Table 85–5) and as such this trial was not powered to see the differences observed in the PT-1 study. In addition, the ethical basis for performing noninferiority trials may be questioned.⁸⁴

Recombinant interferon- α is effective at controlling the platelet count in ET, although there is little direct evidence of efficacy in prevention of thrombosis. Treatment is often associated with significant side effects, including flu-like symptoms and psychiatric disturbance that may mandate cessation of therapy. As this agent is free from leukemogenic or teratogenic effects,⁸⁵ interferon- α is often used for younger patients or during conception and pregnancy. The adverse side-effect profile, however, means that it is generally avoided in older patients. Pegylated interferon- α , for which less-frequent administration is required, may be more convenient but the side-effect profile appears similar to the native compound.

Radioactive phosphorus and alkylating agents such as busulphan are effective at controlling the platelet count, but are associated with an increased risk of progression to acute leukemia, particularly when used sequentially with hydroxyurea, and thus should be avoided in younger patients. Both radioactive phosphorus and busulphan can be given intermittently with long intervals between doses, and may be useful in treating older patients who are unable to attend the clinic on a regular basis. Pipobroman, a piperazine derivative, is effective at reducing

*82.2 percent of patients met WHO 2001 diagnostic criteria for ET.

the platelet count in ET, although there is little direct evidence for efficacy in thrombosis prevention. However, studies of patients with PV have indicated that long-term use of this agent is associated with an increased risk of developing leukemia.^{80,86}

The identification of mutations in *JAK2* and studies highlighting a central role for increased *JAK2* activity in the pathogenesis of the MPNs have driven the rapid development of targeted *JAK2* inhibitors (e.g., ruxolitinib). Randomized trials indicate a role for these agents in relieving symptoms and possibly prolonging survival in patients with PMF.^{87,88} Although early phase clinical trials have demonstrated efficacy in reducing the platelet count in patients with ET, their place in routine management has yet to be defined.

SPECIAL CONSIDERATIONS

Conception and Pregnancy

First trimester fetal loss complicates up to 50 percent of pregnancies in ET patients, with other complications such as intrauterine growth retardation, stillbirth, and preeclampsia also occurring more frequently. Such complications occur irrespective of the platelet count prior to conception but may be more prominent in those with *JAK2*^{V617F}-positive disease. Whether the use of aspirin or cytoreductive agents can improve pregnancy outcome is uncertain, with studies reporting contradictory results.⁸⁹ However, a large meta-analysis of preeclampsia patients without ET suggested that aspirin use in pregnancy is safe for both mother and fetus,⁹⁰ and it therefore seems reasonable to consider its use for all pregnant ET patients. Although hydroxyurea has been used during pregnancy, usually without adverse effects for mother or fetus, it is teratogenic in various non-human mammals⁹¹ and should be avoided if possible. Anagrelide can cross the placenta with unknown effects on fetal development and should also be avoided. Interferon- α is nonteratogenic⁸⁵ and is the agent of choice for patients with high-risk disease

TABLE 85–6. Risk Factors for Complications in Essential Thrombocythemia

[¶]Compared with hydroxyurea.

should cytoreductive therapy be required during pregnancy. Although studies in ET patients are lacking, thromboprophylaxis appears safe in pregnancy (e.g., with low doses of low-molecular-weight heparin),⁹² and may be considered for patients with a history of thrombosis or pregnancy loss; in those with prior thrombosis, treatment should be continued for 6 weeks postpartum. Pregnant ET patients should ideally be managed in a center where regular fetal monitoring can be performed, with good communication between the obstetric, hematology, and anesthetic departments. Pregnancy does not appear to affect the natural history of the disease, although the platelet count often falls during gestation. In animal studies, hydroxyurea is associated with reduced spermatogenesis and genetic damage to spermatogonia.⁹¹ Male patients requiring cytoreductive treatment should therefore consider interferon- α therapy prior to attempted conception.

Surgery

Although thrombotic and bleeding complications appear increased in ET patients undergoing surgical procedures, it is not clear whether these risks can be ameliorated by specific therapeutic interventions. In general, antiplatelet agents should be stopped 7 to 10 days prior to major surgery or surgery to critical sites, and recommenced as soon as the surgeon is confident of secure hemostasis. Postoperative thromboprophylaxis should be administered according to local protocols. For patients receiving cytoreductive therapy, control of blood counts should be optimized preoperatively and interruptions in therapy kept to a minimum. For patients not receiving treatment, temporary cytoreductive therapy may be considered on a case-by-case basis, taking into account the individual's thrombotic risk profile, the degree of thrombocytosis, and the nature of the surgery.

Splenectomy in ET patients generally results in an increase in the platelet count and also in increased thrombotic and hemorrhagic complications. Normalization of the platelet count is therefore advisable for all ET patients prior to elective splenectomy. Thromboprophylaxis and daily monitoring of blood counts is recommended during the postoperative period.

COURSE AND PROGNOSIS

There is a lack of good quality prospective data concerning long-term survival in ET. Data from cancer registries and retrospective studies indicate that overall survival is reduced compared with population controls.^{93–95} This excess mortality results from disease complications such as thrombosis and transformation to PMF or AML. However,

management paradigms have changed significantly over the last 10 to 20 years, including more aggressive intervention to prevent thrombosis and decreasing use of leukemogenic agents. These changes, which may be related to observed improvements in patient outcomes in recent years,⁹⁴ render some long-term followup studies difficult to interpret.

A number of predictive factors for thrombotic complications have been identified (Table 85–6), the best established of which are age older than 60 years or a history of previous thrombosis. Factors independently associated with decreased overall survival in ET include history of prior thrombosis, anemia and leukocytosis,⁹³ the latter two factors likely representing markers of more advanced disease. Additional factors associated with an increased risk of thrombosis include predisposition to atherosclerotic disease (diabetes, hypertension, hypercholesterolemia, or tobacco use), presence of a *JAK2*^{V617F} mutation or increased marrow fibrosis at diagnosis (see section “Thrombosis”). At the present time, age older than 60 years or history of previous thrombosis are generally considered to mandate cytoreductive therapy in ET patients. Whether additional factors, such as presence of a *JAK2* mutation, can be used to improve patient stratification is yet to be tested formally in a clinical trial.

In contrast to thrombotic complications, there are few identifiable factors that predict for progression to PMF or acute leukemia. The incidence of both complications increases progressively with disease duration. Choice of therapy also plays a role, with anagrelide increasing the risk of myelofibrotic transformation compared to hydroxyurea³⁰ and genotoxic agents increasing the risk of leukemia, especially when used sequentially with hydroxyurea. Marrow fibrosis at diagnosis was associated with an increased risk of subsequent PMF in a prospective study,³⁸ but other markers, including the presence of different somatic mutations, have failed to show a consistent association with either myelofibrotic or leukemic transformation.

CHAPTER 86

PRIMARY MYELOFIBROSIS

Marshall A. Lichtman and Josef T. Prchal

SUMMARY

Primary myelofibrosis is one of several disorders in the spectrum of clonal myeloid diseases, malignant diseases that originate in the clonal expansion of a single hematopoietic multipotential cell reprogrammed by several somatic mutations. It is one of the eight neoplasms, including polycythemia vera and essential thrombocythemia, classified as a myeloproliferative disease by the World Health Organization. Approximately 90 percent of cases have a mutation in the Janus kinase 2 (*JAK2*) gene (~50 percent), the calreticulin (*CALR*) gene (~35 percent), or the thrombopoietin receptor (*MPL*) gene (~4 percent). The disease is characterized, classically, by anemia, mild neutrophilia, thrombocytosis, and splenomegaly. Occasional cases may present with bi- or tricytopenias (~15 percent). Immature myeloid and nucleated red cells, teardrop-shaped erythrocytes, and large platelets (megakaryocyte cytoplasmic fragments) are characteristic features of the blood film. The marrow contains an increased number of neoplastic dysmorphic megakaryocytes and increased reticulin fibers and, often later, collagen fibrosis. This reactive, polyclonal fibroplasia is the result of cytokines (e.g., transforming growth factor- β) released locally by the numerous neoplastic megakaryocytes. Osteosclerosis, also, may be present. The disease may be complicated by (1) portal hypertension and gastroesophageal varices as a result of a very large splenic blood flow and loss of compliance of hepatic vessels, (2) extramedullary fibrohematopoietic tumors that can develop in any tissue and lead to symptoms by compression of vital structures, and (3) abdominal vein thrombosis (Budd-Chiari syndrome). Newly developed *JAK2* inhibitors are now first-line therapy for splenomegaly and constitutional symptoms (fever, night sweats, and weight loss). Other treatment has included hydroxyurea for thrombocytosis and massive splenomegaly, androgens, erythropoietin, or red cell transfusions for severe anemia, local irradiation of fibrohematopoietic tumors or of a massive, symptomatic spleen, or splenectomy for severe cytopenias, if splenic effects are not controlled by *JAK2* inhibitors. Portosystemic shunt surgery may be required for gastroesophageal variceal bleeding. In younger patients, allogeneic hematopoietic stem cell transplantation can be curative and nonmyeloablative transplantation has been successful, at least up to age 60 years. The disease may remain indolent for years or may progress rapidly by further deterioration in hematopoiesis, by massive splenic enlargement and its sequelae, or by transformation to acute myelogenous leukemia.

Acronyms and Abbreviations: AML, acute myelogenous leukemia; bFGF, basic fibroblast growth factor; bp, base pair; *CALR*, calreticulin gene; CD, cluster of differentiation; CML, chronic myelogenous leukemia; FISH, fluorescence *in situ* hybridization; G6PD, glucose-6-phosphate dehydrogenase; G-CSF, granulocyte colony-stimulating factor; IL, interleukin; *JAK2*, Janus kinase 2 gene; *MPL*, thrombopoietin receptor gene; MRI, magnetic resonance imaging; PDGF, platelet-derived growth factor; TGF, transforming growth factor; TNFR, tumor necrosis factor receptor.

DEFINITION AND HISTORY

Primary myelofibrosis is a chronic clonal myeloid neoplasm characterized by (1) anemia; (2) neutrophilia and thrombocytosis or, in a minority, thrombocytopenia and leukopenia; (3) splenomegaly; (4) immature granulocytes, increased cluster of differentiation (CD) 34+ cells, erythroblasts, and teardrop-shaped red cells in the blood; (5) marrow fibrosis; and (6) osteosclerosis. The disorder originally was described by Heuck¹ in 1879 under the title “Two Cases of Leukemia and Peculiar Blood and Bone Marrow Findings.” In his monograph, Silverstein traced the history of the concepts set forth during the first half of the 20th century to explain the pathogenesis of this disease, including its origin in the marrow, the appearance of extramedullary hematopoiesis, and the relationship of fibrosis to hematopoietic changes.² The disease occurs, often, *de novo* but can develop as a later phase of polycythemia vera (Chap. 84), essential thrombocythemia (Chap. 85), or, rarely, chronic myelogenous leukemia (Chap. 89), or an atypical myeloproliferative disease (Chap. 89). It may be preceded by a prefibrotic phase (see “Special Clinical Features: Prefibrotic Primary Myelofibrosis” below). Numerous designations for the disease have been proposed or used, and different names were preferred in different countries.³ *Primary myelofibrosis* has been designated the most recent “official” name of the disease by a working group on classification of the World Health Organization.³ This compromise selection is unfortunate as the fibrosis is secondary, not primary, and the choice omits focusing on the central pathologic change: a clonal myeloid disease with the singular finding of neoplastic (dysmorphic) megakaryocytopoiesis.⁴ It is a disease of cells, not fibers, and is the only cancer in the medical lexicon not so designated; rather, it is named for an epiphenomenon in the extracellular matrix.

The discovery that the mutated Janus kinase 2 (*JAK2*) gene mutation can play a role in the causation and behavior of several myeloproliferative diseases⁵ and that approximately 50 percent of cases of primary myelofibrosis have a mutation of the *JAK2* gene⁶ or, far less commonly, thrombopoietin receptor (*MPL*) gene has led to better understanding of the pathogenesis of the disease and its relationship to other myeloproliferative diseases. The *JAK* signaling pathways also represent an important new target for therapy. The subsequent observation of mutations of the calreticulin (*CALR*) gene in approximately 70 percent of patients without a *JAK2* or *MPL* mutation has provided deeper insights into the pathogenesis of myelofibrosis, the opportunity to examine interactions among somatic mutations in the cells of patients, and the opportunity for new therapeutic approaches (see “Etiology and Pathogenesis” below).⁷

EPIDEMIOLOGY

INCIDENCE

Age and Sex

Primary myelofibrosis characteristically occurs after age 50 years.^{2,8–16} The median age at diagnosis is approximately 65 to 70 years,^{8,12–14,17} but the disease also can occur in neonates and children.^{2,12,14,18–20} In infants, the disorder can mimic the classic disease or show certain features but not others, such as absence of hepatosplenomegaly.¹⁹ Familial infantile myelofibrosis mimics the adult disease and in some cases is transmitted by autosomal recessive inheritance.^{20–23} The occurrence of primary myelofibrosis in children usually is in the first 3 years of life.^{20,24,25} In young children, girls are afflicted with the disease twice as frequently as boys.¹⁹ In young and middle-age adults, the disease is similar to that in older subjects, although the proportion of indolent cases may be higher.^{18,20,26} In adults, the disease occurs with about equal frequency in men and women.^{8,12–16} Like virtually all clonal myeloid diseases,²⁷ primary myelofibrosis can cluster in families, suggesting transmission of

an unidentified predisposition gene.^{28–30} A large Swedish study found a significant relative risk (five- to sevenfold) for a familial occurrence of another myeloproliferative disease neoplasm, although not specifically primary myelofibrosis. The latter finding may relate to the small number of cases of primary myelofibrosis in that study.¹⁷ The incidence of the disease is approximately 0.5 cases per 100,000 population per year in northern European countries.^{31–34} A survey in Olmstead County, Minnesota reported an incidence of 1.5 case per 100,000 population per year and a median age of onset of 67 years,³⁵ similar to other studies (see above in this section).

ETIOLOGY AND PATHOGENESIS

EXOGENOUS FACTORS

Exposure to high concentrations of benzene^{36–38} or very-high-dose ionizing radiation³⁹ preceded the development of primary myelofibrosis in a very small number of cases in the past. Epidemiologic studies have not determined a relative risk of myelofibrosis after high-dose benzene exposure. Lower-level benzene exposure was not found to be associated with the risk of myeloproliferative disease in a comprehensive study.⁴⁰ Thus, the few case reports must be viewed with caution in assessing causation. Benzene in exposures greater than 40 to 200 ppm-years is associated with an increased relative risk of acute myelogenous leukemia (AML),^{41,42} but not of chronic myelogenous leukemias (CMLs; Chap. 89). These levels of exposures are far above the current levels permitted by the Occupational Safety and Health Administration.

IMMUNE MECHANISMS

Reports of myelofibrosis in patients with lupus erythematosus, have suggested the possibility of immunologic-mediated hyperplasia of marrow connective tissue (see “Immune and Inflammatory Manifestations” below).² These forms of myelofibrosis are different from the monoclonal multipotential hematopoietic cell disease, which is the principal type considered in this chapter.

CLONAL MYELOID DISEASE, ANIMAL MODELS, AND ACTIVATING MUTATIONS

The disease arises from the neoplastic transformation of a single hematopoietic multipotential cell, a conclusion derived from the presence of clonal cytogenetic abnormalities in patients with an identifiable chromosomal abnormality and in studies in women with primary myelofibrosis who also were heterozygous for isotypes A and B of glucose-6-phosphate dehydrogenase (G6PD).^{43,44} Although the nonhematopoietic tissues of these patients expressed both isotypes, each patient had blood cells with only one G6PD isotype. The findings strongly imply the blood cells of each patient arose from only one transformed stem cell. Furthermore, chromosome studies of colonies of hematopoietic progenitor cells in primary myelofibrosis established that the same clonal cytogenetic abnormality is present in erythroblasts, neutrophils, macrophages, basophils, and megakaryocytes.⁴⁵ These studies were confirmed by (1) examining X-linked restriction fragment length polymorphisms in women with primary myelofibrosis with heterozygosity for X chromosome-linked genes^{46,47} and (2) verifying the presence of a mutation of codon 12 of the N-RAS gene in five blood cell lineages of a patient with the disease.^{48,49} Lymphocyte derivation from the clone has been noted using mutation in codon 12 of the RAS gene as the marker.⁴⁸ Using fluorescence *in situ* hybridization (FISH) analysis, T and B lymphocytes were found to be derived from clonal expansion of a multipotential hematopoietic cell in three of four patients with primary myelofibrosis with a 13q- or 20q- clonal cytogenetic abnormality.⁵⁰ Primary myelofibrosis

can be distinguished from secondary myelofibrosis in women by clonality studies.⁵¹ The discovery of the *JAK2*^{V617F} mutation has permitted this marker to be used in assessing clonality (as will mutations in *CALR* and *MPL* as their determination reaches the clinic). Mutated *JAK2*-containing cells were identified in all blood lineages of patients with primary myelofibrosis and in the common multipotential hematopoietic cell.⁵²

The neoplastic hematopoietic stem cells in primary myelofibrosis containing the *JAK2*^{V617F} mutation behave differently from the same cell population in polycythemia vera when studied in nonobese, diabetic, severe combined immunodeficient mice. Although studied in a non-human environment, the findings are consistent with the presence of *JAK2*^{V617F} mutations in three phenotypically different myeloproliferative diseases: polycythemia vera, essential thrombocythemia, and primary myelofibrosis.⁵³

Animal models allowed the derivation of the murine myeloproliferative leukemia (*mpl*) virus, carrying the oncogene *v-mpl*, which in mice produced a syndrome having features of a mixed idiopathic myelofibrotic-polycythemic disorder (Chap. 111).⁵⁴ The availability of *v-mpl* led to the isolation of the thrombopoietin receptor and its ligand thrombopoietin.⁵⁵ Later models of myelofibrosis and osteosclerosis, mimicking some of the important features of human primary myelofibrosis, were induced in mice by retroviral-mediated overexpression of thrombopoietin.^{56,57} The concomitant high levels of fibroblastic factors (transforming growth factor [TGF]- β_1 and platelet-derived growth factor [PDGF]) resulted in intense fibrosis.⁵⁸ In this model, increased osteoprotegerin was thought to be the principal cause of osteosclerosis.⁵⁹ The disease was cured by murine hematopoietic stem cell transplantation.⁵⁶ These findings were extended and led to the discovery of the human analogue of *v-mpl*, *c-MPL* that encodes the human thrombopoietin receptor. Two gain-of-function somatic mutations, *MPL*^{W515L} and *MPL*^{W515K}, were found to be associated with primary myelofibrosis and essential thrombocythemia.^{60,61} These gain-of-function mutations may also be germline and in such a case are associated with familial (hereditary) thrombocytosis.⁶²

A syndrome in mice that results from the *GATA-1* (low) mutation also leads to a phenotype that closely simulates human myelofibrosis. The mice gradually develop anemia, teardrop poikilocytes, myeloid immaturity, marrow fibrosis, extramedullary hematopoiesis, and overexpression of profibrotic cytokines in marrow.⁶³ *GATA-1* is a transcription factor required for normal megakaryocyte development. *GATA-1* deficiency in mice leads to increased megakaryocytic proliferation, followed by myelofibrosis and osteosclerosis, as a result of exaggerated elaboration of fibroblast-inducing and osteoblast-stimulating factors.^{64,65}

The discovery in 2005 that an activating somatic G→T point mutation (V617F) in *JAK2* was associated with the three major myeloproliferative diseases—polycythemia vera, essential thrombocythemia, and primary myelofibrosis—has rapidly led to a fuller understanding of the pathogenesis of these diseases.^{48,66} A dominant, gain-of-function mutation in the gene *JAK2* residing on chromosome 9p24, which encodes the *JAK2* tyrosine kinase, is present in approximately 50 percent of patients with primary myelofibrosis, in approximately 95 percent of patients with polycythemia vera (Chap. 84), and in approximately 60 percent of patients with essential thrombocythemia (Chap. 85), but is absent in healthy individuals.^{67,68} In confirmation, the expression of the mutated human *JAK2* gene transferred into mice can induce a myeloproliferative disease with features characteristic of the human disorders.^{69–74} Homozygosity results from allelic duplication as a result of uniparental disomy of chromosome 9p, not loss of the normal allele corresponding to the mutation.⁷²

It is not yet precisely known how *JAK2*^{V617F}, the most prevalent mutation, links the three diseases and what modifiers explain the dramatically different phenotype and expected survival of the patients with

polycythemia and primary myelofibrosis. At least four other modifying factors have been proposed to account for the different phenotypes and the apparent absence of the mutation in a high proportion of patients with primary myelofibrosis: (1) gene dosage, (2) germline modifiers, (3) predisposition alleles, and (4) additional somatic mutations.^{66,68,73} An example of each influence follows. There is an increasing *JAK2*^{V617F} allele burden from essential thrombocythemia, to polycythemia vera, to primary myelofibrosis.⁷⁴ For example, the *JAK2*^{V617F} allele burden may be a key determinant of the degree of myeloproliferation and myeloid metaplasia reflected by significantly higher levels of white blood cell counts, CD34+ cell counts, lower platelet counts, and a higher frequency of splenomegaly in homozygous polycythemia vera patients compared to their heterozygous counterparts. These findings are consistent with *JAK2*^{V617F}-positive chronic myeloproliferative disorders as a biologic continuum with phenotypic presentation in part influenced by *JAK2*^{V617F} mutational load.⁷⁴ Myeloproliferative neoplasm predisposition alleles could provide a selective advantage for the development of mutations in the *JAK2* signaling pathway. A number of pre-*JAK2* alleles, which arise in cells prior to *JAK2* mutation, may contribute to the phenotype displayed.⁶⁸

A mutation in the thrombopoietin receptor gene, *MPL*, (*MPL*^{515L/K}) has been found in some mutant *JAK2*-negative patients with primary myelofibrosis. The finding of an activating *JAK2* (~50 percent of patients) or *MPL* (~4 percent of patients) mutation, which employs *JAK2* for signaling, reinforces the critical role of unregulated activation of the JAK-STAT (signal transducer and activator of transcription) signaling pathway in the pathogenesis of primary myelofibrosis.⁷⁵⁻⁷⁷ Using next-generation gene whole-exome sequencing, primary myelofibrosis patients who did not have mutated *JAK2* or *MPL* genes (approximately half of all patients) were only found to have an occasional somatic mutation.⁷⁸

It came as a surprise that nearly a decade after the description of the *JAK2* mutation in primary myelofibrosis and related myeloproliferative diseases, two groups reported, simultaneously, the presence of *CALR* mutations in approximately 70 percent of patients with primary myelofibrosis who did not carry the *JAK2* or *MPL* mutations (35 percent of total population).^{79,80} The *CALR* mutations were either from deletions or insertions, explaining the failure to identify them by Sanger sequencing technology. The 52-bp deletion (type 1 mutation) or 5-bp insertion (type 2 mutation) are the most frequent types, accounting for approximately 85 percent of the *CALR* mutations. The *CALR* mutations are missense for the gene's final domain, encoding the calcium binding site.

Patients with primary myelofibrosis and *JAK2*, *CALR*, or *MPL* mutations may have an additional two to four somatic mutations. Some of the principal genes mutated are *TET2*, *ASXL1*, *DNMT3A*, *EZH2*, and *IDH1*, which are implicated in epigenetic regulation, and *TP53* and *CBL*.⁷ As many as five somatic mutations could be identified in 3 percent of patients, whereas 12 percent of patients with primary myelofibrosis did not have an identifiable somatically mutated gene, using targeted next-generation whole-exome gene sequencing.⁷ However, the proportion of these additional somatic mutations was less than that detected by similar studies in polycythemia vera,⁸¹ suggesting that these sequencing technologies, capable of uncovering only approximately 1 percent of the genome, may leave unidentified additional somatic and germline mutations present in a much greater proportion of primary myelofibrosis patients.

Isolated genetic findings in individual patients have included (13q14) deletions, mutation or overexpression of the retinoblastoma gene,^{82,83} *NF1* (17q11) deletions,⁸⁴ *RAS* mutations in approximately one in 20 patients studied, and occasional patients with mutations in *KIT*.⁷¹ Uniparental disomy has been found on chromosomes 9p (site of *JAK2*, creating a second allele of V617F) and 1p.⁸³

HMG2, a gene on chromosome 12, normally is not expressed in humans and is implicated in mesenchymal tumors. *HMG2* was expressed in 12 of 12 patients with idiopathic myelofibrosis studied, implying that, if confirmed, expression of this gene in myeloid cells may play a role in the disease.⁸⁷

CENTRALITY OF CD34+ CELL EGRESS AND NEOPLASTIC MEGAKARYOCTOPOIESIS

Neoplastic megakaryopoiesis is the most prominent alteration in this clonal myeloid disease and is responsible for most of its major manifestations. Constitutive mobilization and circulation of CD34+ cells are prominent features of the clonal expansion. This phenomenon, probably, is the result of epigenetic methylation of the *CXCR4* promoter, a resultant decrease in *CXCR4* mRNA, decreased expression of *CXCR4* on CD34+ cells, and their resultant enhanced migration into the blood in primary myelofibrosis patients.⁸⁵

Circulating CD34+ cells in patients with primary myelofibrosis generate about 24-fold the number of megakaryocytes in culture than do CD34+ cells from normal subjects, express increased levels of BCL-XL, and have delayed apoptosis.^{86,87} Media conditioned with CD61+ cells (presumptive megakaryocytes) elaborated greater quantities of growth factors and proteases, including TGF- β and metalloprotease-9, than did CD61+ cells generated from normal CD34+ cells.

Circulating CD34+ cells in patients with primary myelofibrosis also had a higher expression of eight genes (*CD9*, *GAS2*, *DLK1*, *CDH1*, *WT1*, *NFE2*, *HMG2*, and *CXCR4*) than did normal CD34+ cells. These genes or subsets of them are likely related to disease pathogenesis and were shown to be related to specific manifestations in patients (e.g., increased expression of *CD9* and *DLK1* with platelet count and *WT1* with severity score).⁸⁸

ENHANCED ANGIOGENESIS AND SPLENIC ENDOTHELIAL CELLS

Microvessel density and marrow blood flow are increased in patients with myelofibrosis. These changes may be related to an increase in circulating endothelial cell progenitors.⁸⁹ The endothelial cells examined by laser microdissection, cell sorting, or cell culture from spleen capillaries and splenic vein contained the *JAK2*^{V617F} mutation in 12 of 18 patients studied who had the mutation in their granulocytes. A definitive explanation for this finding has not been established.⁹⁰

DYSFUNCTION OF HEMATOPOIESIS

Neoplastic myeloproliferation usually is the dominant marrow abnormality in the granulocytic and megakaryocytic lineages resulting in intensely cellular marrows and mild to moderate blood granulocytosis and thrombocytosis. Hypocellular hematopoiesis, resulting from exaggerated apoptosis of very early precursors, can be present initially or emerge later, leading to granulocytopenia and/or thrombocytopenia. Anemia is a frequent finding and results from a combination of decreased erythropoiesis, shortened red cell survival, and the effects of splenomegaly on the distribution of red cells in the circulation. Hemolysis can be a prominent factor in some cases. Neoplastic megakaryocyte expansion and intense dysmorphogenesis of megakaryocytes are constant features of the disease. Even in intensely fibrotic marrows with severe decreases in erythroid and granulocytic precursors, clusters of megakaryocytes are easily found interspersed between collagen bundles. The term *megakaryocytic myelosis*, one of the many synonymous terms for the disease, exemplifies the constancy of this finding. The dominance of megakaryopoiesis may relate to the average fivefold

overexpression of *FKBP51* in megakaryocytes in primary myelofibrosis and the marked predisposition of CD34+ cells to differentiate into megakaryocytes (see “Centrality of CD34+ Cell Egress and Neoplastic Megakaryocytopoiesis” above). *FKBP51* increases resistance to apoptosis, possibly by an effect through the calcineurin pathway.⁹¹ Thus, the designation “chronic megakaryocytic leukemia” would be a more accurate designation for primary myelofibrosis, if one used an internally consistent classification.⁷ Although elevated levels of thrombopoietin (and interleukin [IL]-6 and IL-11) are found in the serum of patients with primary myelofibrosis, their etiologic role in the human disease is unresolved.⁹² A marked increase in the thrombopoietin receptor MPL is observed on the platelets and megakaryocytes of a proportion of patients with primary myelofibrosis.⁹³ Despite the animal models of thrombopoietin-induced myeloproliferation and osteomyelofibrosis and the apparent abnormality of MPL receptor sites on human megakaryocytes, autonomous megakaryocyte growth, characteristic of human primary myelofibrosis marrow in culture, has not been associated with either an autocrine effect of MPL ligand (thrombopoietin) or of a mutation in *MPL*.

FIBROPLASIA

Four of the five major types of collagen⁹⁴ are present in normal marrow: type I in bone, type III in blood vessels, and types IV and V in basement membranes. The fine reticulin fibers that appear after silver impregnation of marrow are principally type III collagen. They do not stain with trichrome dyes. The thicker collagen fibers are principally type I collagen and stain with trichrome dyes, but do not impregnate with silver. The amount of the very fine fibrous network barely perceptible in normal marrow that is stained by silver impregnation techniques⁹⁵ increases in the marrow of patients with primary myelofibrosis (Table 86-1 and Fig. 86-1C).⁹⁶ The fibrous network contains collagen and occasionally progresses to include thick collagen bands that are evident with trichrome stains. Collagen types I, III, IV, and V are increased in myelofibrosis, but type III collagen is increased uniformly and preferentially.⁹⁷⁻¹⁰⁴ The latter occurrence accounts for the increased plasma concentration of procollagen III aminoterminal peptide, a component of collagen type III, which is cleaved during collagen biosynthesis.^{96,101,102} Serum prolyl-hydroxylase and marrow and plasma fibronectin also increase in patients with idiopathic myelofibrosis or myelofibrosis from other causes.^{98,99} Several other matrix materials are increased in marrow or plasma (Tables 86-1 and 86-2).¹⁰⁵⁻¹¹⁹

Marrow fibrosis in primary myelofibrosis is most closely correlated with increased neoplastic and dysmorphic megakaryocytes in the marrow. Even densely fibrotic marrow with little residual granulopoiesis or erythropoiesis usually has numerous megakaryocytes scattered throughout the fibrotic areas.^{96,120} The increased pathologic emperipoiesis (the entry of neutrophils and other marrow cells into the canalicular system of megakaryocytes), evident in human primary myelofibrosis and in mouse models, suggests this may be an additional mechanism of α -granule injury and release of TGF- β and PDGF.¹²¹ Animal models also indicate that marrow monocytes and macrophages may play a subsidiary role in the induction of fibrosis.¹²¹⁻¹²³ Secretion of PDGF, basic fibroblast growth factor (bFGF), and TGF- β from monocytes that are part of the clone have the potential to act as myeloproliferative growth factors and profibrotic cytokines.¹¹⁴

The increased content of marrow collagen types I and III results from release of fibroblast growth factors, which include PDGF,^{123,124} epidermal growth factor,¹²⁶ endothelial cell growth factor,¹²⁶ TGF- β ,^{114,127,128} and bFGF,^{114,129} each of which is present in megakaryocyte α granules. Other factors, such as tumor necrosis factor α , IL-1 α , IL-1 β , and lysyl oxidase, which can be released from marrow cells, also can stimulate

fibroblasts.¹³⁰⁻¹³² Platelet factor 4, also derived from megakaryocytes, inhibits collagenase and could contribute to collagen accumulation,¹²⁰ although studies showing a poor correlation between plasma platelet factor 4 concentration and marrow fibrosis have dampened enthusiasm for the role of this factor.¹³³ Substance P, a peptide that acts as a neurotransmitter and a modulator of immune and hematopoietic functions, is increased in the fibrotic marrow and colocalizes with fibronectin. It is angiogenic and is a fibroblast mitogen.¹¹⁵ Its precise role in the complex interactions among fibroblasts, cytokines, and matrix protein deposition is not clear. The high urinary excretion of platelet-derived calmodulin, a putative fibroblast growth factor, in patients with myelofibrosis has added this compound to the array of factors that may contribute to the fibroplasia.¹³⁰ The plasma level of matrix metalloproteinase III is decreased and the level of tissue inhibitor of metalloproteinase is increased in patients with idiopathic myelofibrosis.¹³⁴ The expression of matrix metalloproteinase-14 in marrow increases by nearly two orders of magnitude as fibroplasia progresses during the course of the disease; and, megakaryocytes and endothelial cells are the major sources of this protein.¹⁰⁷ Neutrophil collagenase (matrix metalloproteinase-8) content is decreased early in the disease.¹⁰⁷ Bone morphogenetic proteins (BMPs) also are implicated as a contributory factor in fibroplasia. BMP1, BMP6, BMP7, and BMP-receptor 2 are increased in marrow in myelofibrosis as a result of release from megakaryocytes and stromal cells. These proteins are activators of latent TGF- β_1 and processors of collagen precursors. In addition, TGF- β_1 induces release of BMP6.¹⁰⁸

This complex combination of alterations contributes to matrix deposition. The pathogenetic role of released growth factors in

TABLE 86-2. Diagnostic Findings in Primary Myelofibrosis

PREFIBROTIC STAGE

Anemia may be absent or mild
 Leukocytosis may be absent or slight
 Thrombocytosis is invariable
BCR-ABL fusion gene absent
 Presence of *JAK2*, *CALR*, or *MPL* mutations indicative of diagnosis of myeloproliferative disease (one of these mutations present in ~90% of patients)
 Cellular marrow with mild increase in granulopoiesis; increased megakaryocytes, clusters of very dysmorphic megakaryocytes and megakaryocytic nuclei; no to very slight increase in reticular fibers on silver stain
 Palpable splenomegaly infrequent
 Absent or slight anisopoikilocytosis including teardrop red cells

FULLY DEVELOPED STAGE

Marrow reticulin fibrosis plus or minus collagen fibrosis
BCR-ABL fusion gene absent
JAK2, *CALR*, or *MPL* mutation in approximately 90% of patients
 Splenomegaly
 Anisopoikilocytosis with teardrop red cells in virtually every oil immersion field
 Immature myeloid cells in blood
 Increased CD34+ cells in blood
 Nucleated red cells in blood
 Marrow usually hypercellular but invariably has increased megakaryocytes, clusters of highly dysmorphic megakaryocytes, and megakaryocyte bare nuclei regardless of overall marrow cellularity

fibroplasia is not completely understood. Generalizations from *in vitro* experiments or correlation between two variables provide only a limited perspective. For example, TGF- β can stimulate or inhibit fibroblast growth, depending on the repertoire of other growth factors in the environment.^{127,128}

Fibroplasia is associated with an increase in the number and size of marrow sinuses,¹¹¹ the number of endothelial cells,¹³⁵ an increase in vascular volume in the marrow,¹⁰⁶ and an increase in blood flow through the marrow.^{136,137} These processes are responsible for the increase in marrow collagen types IV and V and laminin synthesized by endothelial cells in the marrow of patients.¹²⁶

The fibroblastic proliferation in marrow is not an intrinsic part of the abnormal clonal expansion of hematopoiesis.¹³⁸ In cases of primary myelofibrosis in which G6PD isoenzyme studies or chromosome karyotyping establish monoclonal growth of hematopoietic cells, marrow fibroblasts contain both G6PD isoenzymes and do not share the clonal chromosome abnormality.¹³⁹ The findings strongly imply that the fibroblasts differentiate from a primordial cell different from the neoplastic hematopoietic stem cell in primary myelofibrosis and that fibroblast proliferation and enhanced collagen synthesis are secondary results of abnormal hematopoiesis.

EXTRAMEDULLARY HEMATOPOIESIS

Extramedullary hemopoiesis is almost always present in liver and spleen, where it contributes to organ enlargement.⁸⁻¹⁰ Escape of progenitor cells from marrow and their lodgment in other organs contributes to extramedullary blood cell formation. Reversion of the liver and spleen to their fetal hematopoietic functions (metaplasia) is not a major factor in extramedullary hematopoiesis, and quantitatively significant, effective hematopoiesis does not occur outside of the marrow (see also "Extramedullary (Fibrohematopoietic) Tumors" below).

CLINICAL FEATURES

PRESENTING SYMPTOMS

Some patients are asymptomatic at the time of diagnosis; in which case the disease is detected by medical examination for an unrelated reason. In symptomatic patients, fatigue, weakness, shortness of breath, pruritus, and palpitations are nonspecific but frequent complaints.^{9–13} Fatigue is the most frequent self-reported complaint and is disproportionate to the degree of anemia. Weight loss is common, but anorexia is less so, and fever and night sweats may occur. The term *constitutional symptoms*, often used in studies of the response to treatment of myelofibrosis, refers specifically to the aggregate occurrence of fever, weight loss, and night sweats.¹⁴⁰ A dragging sensation in the left upper abdomen caused by an enlarged spleen or early satiety from encroachment of the spleen on the stomach may occur. Severe left upper quadrant or left shoulder pain can occur from splenic infarction and perisplenitis. Patients may report unexpected bleeding. Occasionally, bone pain is prominent, especially in the lower extremities. Fever, weight loss, cachexia, night sweats, and bone pain are more frequent later in the course of the disease and are related to the increase in circulating inflammatory cytokines that are a key feature of the disease (see “Immune and Inflammatory Manifestations” below).

PRESENTING SIGNS

Hepatomegaly is detectable in two-thirds of patients, and splenomegaly is present on palpation or imaging studies in almost all patients at the time of diagnosis.^{8–12} The spleen is mildly enlarged in one-fourth, moderately enlarged in half, and massively enlarged in approximately one-fourth of patients. Muscle wasting, peripheral edema, and purpura are present infrequently. Bone tenderness may be present. The latter signs may develop in a larger proportion of patients over the course of the disease.

Neutrophilic dermatosis, a syndrome that closely mimics the raised and tender plaques of Sweet syndrome, may occur.^{141–143} It can be the presenting or a significant complicating feature, and can progress to bullae or pyoderma gangrenosum.^{141,144} The dermatopathology of neutrophilic dermatosis is different from leukemia cutis and is unrelated to infection or vasculitis. The predominant histologic lesion is an intense polymorphonuclear neutrophilic infiltrate.

Skin infiltrates related to hematopoietic cells (leukemia cutis) are uncommon.¹⁴⁵ These cutaneous lesions may have myeloid cells with giant cells carrying CD61 markers characteristic of megakaryocytes.^{146,147} Skin lesions representing cutaneous fibrohematopoietic tumors may occur.

SPECIAL CLINICAL FEATURES

Prefibrotic Primary Myelofibrosis

The presenting findings of the clonal myeloid diseases are changing because of more and earlier access to healthcare in industrialized countries (see Table 86–2). A subset of patients, perhaps as many as 25 percent, with primary myelofibrosis present without overt reticulin fibrosis in the marrow.^{148,149} Blood hemoglobin may be normal and white cell count mildly elevated. The classic findings of frequent teardrop red cells, myelocytes, and nucleated red cells in the blood film and palpable splenomegaly often are absent. Thrombocytosis is a constant finding. Essential thrombocythemia is closely simulated, but observation eventually shows evolution to primary myelofibrosis. The most important distinction with essential thrombocythemia is the nature of the megakaryocytic expansion.¹⁵⁰ In primary myelofibrosis, bizarre changes are evident with wide variation in megakaryocyte size, from very small to giant

size cells. Nuclear lobulation is abnormal, with bulky multilobulation, hypolobulation, and free megakaryocyte nuclei in the marrow spaces. In essential thrombocythemia, megakaryocytes are increased but they do not display the dysmorphia observed in myelofibrosis. The prefibrotic disease usually evolves into fully developed myelofibrosis over a period of years. Investigators, evaluating histopathology in a blind fashion, have confirmed the entity of prefibrotic myelofibrosis and this abnormality predicts for progression to an overt primary myelofibrosis and, thus, has an impact on the risk of progression to acute leukemia and prognosis in general.¹⁵¹

Extramedullary (Fibrohematopoietic) Tumors

The appearance of symptoms or signs leading to (1) identification of a mass on imaging regardless of location, (2) appearance of signs or symptoms of an effusion in the thorax or abdomen, (3) unexpected neurologic signs, or (4) another finding that appears unexpected in a patient with primary myelofibrosis should be considered a fibrohematopoietic (extramedullary) tumor(s) until proven otherwise. Foci of hematopoiesis may become clinically apparent as fibrohematopoietic tumors in the adrenal glands,^{152,153} renal parenchyma,^{154–156} and lymph nodes.^{157–159} Tumors composed of hematopoietic tissue, sometimes with intense fibrosis, can develop in the bowel,^{160–163} breast,^{164–166} liver,^{167,168} lungs,^{169–171} mediastinum,¹⁷² pleura and mesentery,^{169,171,173} skin,^{174,175} synovium,¹⁷⁶ thymus,¹⁶⁹ thyroid,¹⁷⁷ thorax,¹⁷⁸ prostate,¹⁷⁹ spleen,¹⁸⁰ or urinary tract.^{178,181–184}

Extramedullary hematopoiesis in the intracranial or intraspinal epidural space can lead to serious neurologic complications, including subdural hemorrhage,¹⁸⁵ delirium,^{185,186} increased intracranial pressure,¹⁸⁷ orbital apex syndrome,¹⁸⁸ papilledema,¹⁸⁹ cerebral tumor,¹⁹⁰ coma,¹⁹¹ motor and sensory impairment,^{192,193} spinal cord compression,^{194,195} and limb paralysis.^{195,196} Intraspinal myelography,^{193–199} computed axial tomography,^{185,187,191–197,199} positron emission tomography after ⁵²Fe infusion,¹⁸⁶ and magnetic resonance imaging (MRI)^{198,199} each has been used to define the location and nature of the masses.

Hematopoietic foci on serosal surfaces can produce effusions, sometimes massive, in the thorax,^{178,180} abdomen,^{172,173,201,202} and pericardial space.^{203–206} The effusion fluid often contains megakaryocytes, immature granulocytes, and, occasionally, erythroblasts.^{207–209} Splenectomy is sometimes followed by extramedullary hematopoietic tumors in soft tissues,²¹⁰ in body cavities, or on serosal surfaces,²⁰⁹ perhaps as a result of an increase in circulating hematopoietic progenitors²¹¹ and loss of the filtration function of the spleen. In rare cases, extramedullary soft-tissue megakaryoblastic tumors simulate the myeloid sarcoma (synonyms: chloroma, granulocytic sarcoma) of other types of myelogenous leukemia.^{212,213}

Portal Hypertension and Varices and Pulmonary Arterial Hypertension

In patients with primary myelofibrosis, there can be a massive increase in splenoportal blood flow and a decrease in hepatic vascular compliance or the presence of hepatic vein thrombosis, either of which can result in severe portal hypertension, ascites, esophageal and gastric varices, intraluminal gastrointestinal bleeding, and hepatic encephalopathy.^{214–216} The hepatic venous pressure gradient, normally less than 6 torr, is markedly elevated.²¹⁷

Perisinusoidal fibrosis,^{218–220} collagen bundles in the spaces of Disse,²¹⁹ perisinusoidal fibroplasia,^{218–221} and foci of hematopoietic cells^{219,222} appear to contribute to the decreased sinusoidal compliance. Portal vein thrombosis is a complication of primary myelofibrosis and occasionally precedes disease onset.²²³

Rarely, portal hypertension is accompanied by pulmonary hypertension and may result from pulmonary fibrosis¹⁷¹ or hydrodynamic

factors.²²⁴ Pulmonary arterial hypertension, also, may be the principal problem.^{225,226} Although as many as one-third of patients with primary myelofibrosis have an elevated systolic pulmonary artery pressures (>35 torr), the fraction that is symptomatic is very small. Elevated vascular endothelial growth factor (VEGF) levels, elevated circulating endothelial cells, and elevated marrow microvessel density in patients suggest that proangiogenic factors may contribute to the hypertension.²²⁷ Contrariwise, secondary myelofibrosis with polyclonal hematopoiesis and normal blood CD34 cell concentrations frequently occurs in patients with primary pulmonary hypertension.²²⁸

Immune and Inflammatory Manifestations

Abnormalities of humoral immune mechanisms have been observed in up to half of patients with primary myelofibrosis.^{229–234} The array of immune products and events reported includes anti-red cell antibodies,^{233–237} antiplatelet antibodies,^{238,239} antinuclear antibodies,^{229,230,234} elevated plasma-soluble IL-2 receptor,²⁴⁰ anti-Gal (galactoside determinants) antibodies,²⁴¹ anti- γ -globulins,^{229,230,234} antiphospholipid antibodies,^{234,242} antitissue or organ-specific antibodies,^{231,233} and circulating immune complexes,^{234,243–245} as well as complement activation,^{234,246} immune complex deposition,²³¹ interstitial immunoglobulin deposition,²³¹ increased numbers of marrow plasmacytoid lymphocytes,^{231,243} and development of amyloidosis.^{244–247}

Inflammatory cytokines, including IL-1 β , IL-6, IL-8, tumor necrosis factor (TNF)- α , TNF receptor II (TNFR II), and C-reactive protein also are markedly elevated and play a role in the constitutional symptoms seen in patients with progressive disease,²⁴⁸ which explains the often rapid, symptomatic improvement in patients treated with JAK2 inhibitors before splenic size is reduced.

Occasional reports of nonclonal secondary myelofibrosis associated with lupus erythematosus,^{249–254} vasculitis,²⁵⁵ polyarteritis nodosa,^{234,255} ulcerative colitis,²⁵⁶ scleroderma,²⁵⁷ biliary cirrhosis,^{237,258,259} Sjögren syndrome,²⁶⁰ and acute reversible myelofibrosis responsive to glucocorticoids,²⁶¹ although fundamentally different processes from primary myelofibrosis, have raised the possibility that immune mechanisms play a role in the development of marrow fibrosis in some circumstances.

Bone Changes

A large proportion of patients have osteosclerosis at diagnosis or develop osteosclerosis during the course of the disease,^{11–15,262–265} as reflected by increased bone density on imaging studies and histomorphometric analysis of a bone biopsy (Table 86–3).^{263–268} The proximal femur and humerus, pelvis, vertebrae, ribs, and skull may be involved. MRI can uncover evidence of new bone formation and periosteal thickening. Lumbar spine dual-energy x-ray absorption studies and quantitative computed tomography provide evidence for increased bone formation, bone thickening, and higher proportions of cancellous and of woven bone.^{268,269} Osteolytic lesions are rare²⁷⁰ and may reflect a myeloid sarcoma.²⁷¹ Periostitis, although infrequent, can lead to debilitating bone pain.²⁷²

Thrombosis

The risk of arterial and venous thrombosis is elevated in patients with primary myelofibrosis, although not to the degree seen in polycythemia vera or essential thrombocythemia.²⁷³ Approximately 10 percent of patients with myelofibrosis will develop a significant thrombotic event during the first 4 years of the disease. The two principal risk factors are an elevated leukocyte count and age, but not platelet count.²⁷⁴ In a large multicenter study of 707 patients with primary myelofibrosis, thromboses occurred in 7.2 percent of patients over the period of observation, or 1.8 percent patient-years. The combination of the *JAK2* mutation, leukocytosis, and age predicted the highest incidence of thrombosis.²⁷⁵

TABLE 86–3. Serum, Urine, and Bone Changes Reflecting Osteosclerosis^{243,244}

- Increased serum alkaline phosphatase
- Increased serum bone GLA-protein
- Increased serum carboxytelopeptidase
- Increased urinary deoxypyridinoline
- Increased bone density by dual-energy x-ray absorption
- Increased bone density by quantitative computed tomography
- Histomorphometry
 - Increased percentage of cancellous bone volume to tissue volume
 - Increased bone formation and resorption (high turnover)
 - Increased trabecular plate thickness
 - Increased percentage of woven bone volume
 - Increased percentage of fibrous area
- No evidence of mineralization defect

The cardiovascular risk factor, such as hypertension, hypercholesterolemia, or smoking, further increase thrombotic risk. Multiple thrombotic episodes may occur; and, the thrombotic event may occur at or just before diagnosis.

Noncirrhotic splanchnic vein thrombosis includes hepatic vein thrombosis (Budd-Chiari syndrome) and portal vein thrombosis, which may occur with minimal evidence of a clonal myeloproliferative disease. In the past marrow examination or evidence of erythropoietin-independent colony growth was used to determine if an occult or incipient myeloproliferative disease may underlie the thrombosis. Now *JAK2* mutational analysis can be done and is positive in 35 percent of seemingly idiopathic hepatic vein thrombosis and 25 percent seemingly idiopathic portal vein thrombosis.²⁷⁶ Presumably, future use of *CALR* gene mutational analysis will increase the proportion of cases of hepatic vein thrombosis indicative of an underlying occult myeloproliferative disease.

LABORATORY FEATURES

BLOOD CELL COUNTS AND MORPHOLOGY

The range of values for blood cell counts at the time of diagnosis is very broad. Normocytic–normochromic anemia is present in most, but not all, patients (see Table 86–2).^{8–10,273–280} Mean hemoglobin concentration in a series of patients at diagnosis was approximately 9 to 12 g/dL (range: 4–20 g/dL).^{8–16,279,280} Anisocytosis and poikilocytosis are a constant finding. In all cases, teardrop-shaped red cells (dacryocytes) are present in sufficient number to be found in every oil immersion field (see Fig. 86–1). Nucleated red cells are present in the blood film of most patients and average 2 percent of nucleated cells (range: 0 to 30 percent). The percentage of reticulocytes is mildly increased but may vary widely in a given case. A decreased blood hemoglobin may be attributed in part to the expansion of plasma volume and a higher than normal proportion of the red cell volume in an enlarged spleen. Ineffective erythropoiesis can result in a decrease in red cell mass.²⁷⁷ Erythroid hypoplasia is present in many patients.^{281,282} In some patients, hemolysis may be prominent, and polychromatophilia and very elevated reticulocyte counts can occur.^{278,279} The antiglobulin (Coombs) test usually is negative, but red cell autoantibodies can develop and lead to immune-mediated hemolysis,^{234–236,283} which rarely has been a presenting finding of the disease.²³⁶ Occasional patients have had a positive acid hemolysis and

sucrose hemolysis test, reflecting a concurrent clone of cells consistent with paroxysmal nocturnal hemoglobinuria.²⁸⁴ Acquired hemoglobin H disease, coincident with typical white cells and platelet changes of myelofibrosis, can occur²⁸⁵ and results in hemolysis, hypochromic-microcytic red cells, marked poikilocytosis, and hemoglobin H inclusions that stain with brilliant cresyl blue. Red cell aplasia, in association with primary myelofibrosis, has been observed.^{280,286}

The total white cell count usually is usually moderately elevated as a result of granulocytosis.^{8–16} The mean total blood white cell count was 10,000 to 14,000/ μ L (10 to 14 $\times 10^9$ /L) in four large studies. Neutropenia, however, is present in approximately 20 percent of patients at the time of diagnosis.^{8–16} The range of white cell counts was 400 to 237,000/ μ L (0.4 to 237.0 $\times 10^9$ /L) at the time of diagnosis.^{8–15,278,279} Myelocytes and promyelocytes are present in small proportions in the blood film in most patients, and a low proportion of blast cells (0.5 to 2.0 percent) may be found in the blood film. The blood blast cells range from 0 to 20 percent at the time of diagnosis. In patients with blast counts at the high end, which is unusual at presentation, the disease merges with or may progress rapidly to AML. Hypersegmentation, hyposegmentation (acquired Pelger-Huët anomaly), and abnormal granulation of neutrophils may be present.^{8–16} Neutrophil alkaline phosphatase scores may be elevated (25 percent of patients) or decreased (25 percent of patients).²⁸⁷ The percentage of basophils may be slightly increased.²⁷⁹ The mean platelet count in patient series ranges from 175,000 to 580,000/ μ L (175 to 580 $\times 10^9$ /L) at the time of diagnosis. Individual platelet counts can range from 15,000 to 3,215,000/ μ L (15 to 3215 $\times 10^9$ /L).^{8–16,278,279} The platelet count is elevated above the normal upper limit in approximately 40 percent of patients.²⁷⁹ Mild to moderate thrombocytopenia is present in approximately one-third of patients at the time of diagnosis, particularly if splenomegaly is massive. Giant platelets and abnormal platelet granulation in the blood film are characteristic features of the disease.

Approximately 10 percent of patients present with pancytopenia because of severe impairment of hematopoiesis affecting each cell lineage, coupled with sequestration in a massively enlarged spleen. Pancytopenia usually is associated with intense marrow fibrosis.

Increased concentrations of multipotential,^{288,289} granulocytic,^{290,291} monocytic,²⁹¹ erythroid,²⁹² and megakaryocytic²⁹³ progenitor cells are present in the blood of patients, as measured by clonogenic assays in semisolid cultures. The frequency of hematopoietic progenitor cells in the blood is correlated with the extent of marrow reticular fiber density.²⁹³ Megakaryocytes also are present in the systemic venous blood.²⁹⁴ An increase in blood CD34+ cells is very characteristic of primary myelofibrosis, and the concentration of these cells lends weight to the diagnosis. The height of the CD34+ cell count is correlated with the extent of disease and disease progression. Greater than 15 $\times 10^6$ /L blood CD34+ cells is virtually diagnostic of primary myelofibrosis, and patients with greater than 300 $\times 10^6$ /L CD34+ cells have more rapid progression of disease than patients with fewer CD34+ cells.²⁸⁹

Endothelial progenitor cells (CD34+CD133+ and VEGF receptor 2–positive cells) are significantly higher in the blood of primary myelofibrosis patients than of normal subjects.⁸⁹

Mild lymphocytopenia resulting from decreased CD3+, CD4+, CD8+, and CD3–/CD56+ T cells is the rule.²⁹⁵

FUNCTIONAL ABNORMALITIES OF BLOOD CELLS

The neutrophils of some patients have impaired phagocytosis, oxygen consumption, nitroblue tetrazolium reduction, and hydrogen peroxide generation, and decreased myeloperoxidase^{296,297} and glutathione reductase activities.²⁹⁷ CD34+ cells have impaired *in vitro* differentiation to

natural killer cells, which appears to be related to a dysregulation in control of IL-15.²⁹⁸

Bleeding time can be prolonged disproportionately to the platelet count.^{299,300} Platelet abnormalities include impaired aggregation in response to epinephrine, depletion of dense granule adenosine diphosphate content,³⁰¹ decreased platelet lipoyxygenase pathway activity,³⁰² and others.^{303,304} The correlation of bleeding or thrombosis with platelet functional abnormalities is weak.^{303,304} The lupus anticoagulant has been present, rarely.²⁴²

MARROW EXAMINATION

Morphology

In the fibrotic phase, marrow aspiration often is unsuccessful because of the fibrosis.^{8–16,96,97} The marrow biopsy specimen usually is cellular and shows granulocytic and megakaryocytic hyperplasia (see Fig. 86–1).^{8–16,288,289} Erythroid cells may be decreased, normal, or increased in number. Silver stain usually shows an increase in reticular fibers, and in half of patients a striking increase in reticular fibers is seen.²⁸⁹ Hematoxylin and eosin stains of the biopsy specimen may show mild collagen fibrosis; occasionally the fibrosis is extreme (see Fig. 86–1). Collagen fibrosis may be more evident using a Gomori trichrome stain with which collagen characteristically stains green. In intensely fibrotic marrows, cellularity may be markedly decreased but megakaryocytes usually remain evident.²⁸⁹ Giant megakaryocytes and micromegakaryocytes, abnormal nuclear lobulation, and naked megakaryocyte nuclei are present.^{8–16,305} Thrombopoietin receptors are decreased on megakaryocytes and platelets.⁹³ Granulocytes may show hyperlobulation and hypolobulation of the nucleus, acquired Pelger-Huët anomaly, nuclear blebs, and nuclear-cytoplasmic maturation asynchrony.³⁰⁶ Clusters of blasts and CD34+ cells are often present. Dilated marrow sinusoids are common. Intrasinusoidal, immature hematopoietic cells, and megakaryocytes are present.⁹⁸ As a reflection of the high blood flow to marrow-bearing bone and the widened sinusoidal system, microvessel density is significantly increased in approximately 70 percent of patients.^{306,307} Histomorphometric analysis of marrow biopsies permit detection of osteosclerosis.^{263,265,266} Grading of the degree of myelofibrosis has used the Bauermeister scale,³⁰⁸ which assesses fibrosis on a scale of 0 to 4, and the revised European grading scale of 0 to 3.³⁰⁹ Digital imaging may be used for less subjective, quantitative grading of fibrosis or osteosclerosis, if its utility is confirmed in additional studies.³¹⁰

The marrow in the pre-fibrotic stage usually has no or slight reticular fibrosis. The marrow is cellular and there is often an increase proportion of late neutrophil precursors (myelocytes, metamyelocytes, bands). Myeloblasts and CD34+ cells are inconspicuous. Erythropoiesis may be slightly decreased. Increased and abnormal megakaryocytopoiesis is the hallmark of this phase. Clusters of megakaryocytes are present. Megakaryocytes are large and admixed with small megakaryocytes. Nuclei are often ballooned and have scalloped margins. Bare megakaryocyte nuclei are present. Megakaryocyte involvement is facilitated by staining the marrow with a megakaryocyte marker such as CD61.

Cytogenetic Findings

Chromosome abnormalities of hematopoietic cells are evident in approximately 40 percent of patients at the time of diagnosis.^{311–316} The most frequent findings are partial trisomy 1q, interstitial deletion of a segment of the long arm of chromosome 13, del(13)(q12–22), which bears the retinoblastoma gene,^{312–314,317} del 20q, and trisomy 8.³¹⁸ Involvement of chromosome 5, 6, 7, 9, 13, 20, or 21 occurs with heightened frequency.³¹⁸ The 5q– abnormality is more prevalent in primary myelofibrosis than any other chronic myeloproliferative disorder. Abnormality of chromosome 12 resulting from several translocations or deletion or

inversion occurs in approximately 3 percent of patients.³⁰¹ The del(13) and der(6)t(1;6)(q21–23;p21.3) are associated with myelofibrosis but are not exclusively seen in patients with primary myelofibrosis.³²⁰ Aneuploidy as a result of monosomy or trisomy is common. Pseudodiploidy, manifested by partial deletions and translocations, occurs. Patients with the clinical features of typical primary myelofibrosis very rarely have the Philadelphia (Ph) chromosome in their marrow cells.³²¹ Approximately 15 percent of patients present with unfavorable karyotypes, including three or more abnormalities, +9, -7/7q-, 5/5q-, i(17q), inv(3), 12p-, or 11q23. An unfavorable karyotype is associated with a sixfold greater risk of acute leukemic transformation than a favorable karyotype.³²² With increasing knowledge of the chromosomes commonly affected, interphase FISH of blood cells is used to look for prevalent abnormalities, compensating for the technical difficulties of harvesting cell suspensions, given the intense marrow fibrosis.³¹⁴ Clonal chromosomal abnormalities found in hematopoietic cells have not been observed in marrow fibroblasts.¹³⁹

Magnetic Resonance Imaging

Marrow fibrosis alters the hyperintensity of T1-weighted images that normally results from marrow fat. As cellularity and fibrosis progress, hypointensity of T1-weighted and T2-weighted images develops. MRI does not distinguish between primary myelofibrosis and secondary causes of fibrosis,^{264,323,324} but the clinical distinctions usually are very evident from the results of prior physical, blood, and marrow examinations and the evidence for mutations in *JAK2*, *CALR*, or *MPL*. Patchy or diffuse osteosclerosis is a common finding, as are “sandwich vertebrae,” so called because of marked radiodensity of superior and inferior margins of the vertebral body. MRI can identify the uncommon periosteal reactions that usually occur in the distal femur, proximal tibia, or ankle. The reactions represent expansion of marrow cellularity into normally inactive regions of long bones or extramedullary space-occupying lesions of fibrohematopoietic tissue.²⁶⁴ The findings of sodium fluoride (¹⁸F) positron emission tomography can be virtually specific for osteosclerosis of primary myelofibrosis.³²⁵

PLASMA AND URINE CHEMICAL CHANGES

Serum levels of uric acid, lactic dehydrogenase, bilirubin, alkaline phosphatase, and high-density lipoprotein frequently are elevated.^{8–16} Serum cholesterol is often decreased and is a negative prognostic factor.^{326–328} Serum levels of albumin and cholesterol frequently are decreased.³²⁹ Hypocalcemia³³⁰ or hypercalcemia³³¹ may occur. Plasma levels of thrombopoietin and IL-6 are elevated but do not correlate with either platelet or megakaryocyte mass.^{332,333} Elevated thrombopoietin is not explained by increased marrow hematopoietic or stromal cell production.³³⁴ Serum-soluble IL-2 receptor³³⁵ and serum VEGF³³⁶ levels are increased. Urinary excretion of calmodulin is approximately three times normal.¹³⁰ The serum contains evidence of increased collagen (see Table 86–1) and bone (see Table 86–2) synthesis.

DIFFERENTIAL DIAGNOSIS

CML (Chap. 89) should be considered in the differential diagnosis of primary myelofibrosis. In CML, the white cell count is usually greater than 30,000/ μ L (30×10^9 /L) in almost all patients and greater than 100,000/ μ L (100×10^9 /L) in half of patients. In myelofibrosis, the white cell count usually is less than 30,000/ μ L (30×10^9 /L) at the time of diagnosis. In CML, red cell shape usually is normal or slightly perturbed. In myelofibrosis, teardrop poikilocytes are present in every oil immersion field and exaggerated anisocytosis and anisochromia are often prominent. The marrow in CML shows intense granulocytic hyperplasia, with

almost 100 percent cellularity and usually no or very slight fibrosis.³³⁷ In myelofibrosis, the marrow has mildly increased cellularity or is hypocellular, with moderate to marked reticulin fibrosis. Occasionally, patients with CML develop intense marrow fibrosis and dysmorphic blood cell changes that make distinction between the two diseases difficult on merely morphological grounds.³¹⁹ However, the Ph chromosome or the *BCR-ABL* fusion gene is present in CML and is absent in primary myelofibrosis; whereas, the *JAK2*^{V617F} or the *CALR*, or the *MPL* mutation is present in approximately 90 percent of cases of primary myelofibrosis and absent in CML. Most cases are readily separable based on the aforementioned distinctions.

Patients with primary myelofibrosis may have pancytopenia or bicytopenia and in that respect mimic patients with oligoblastic myelogenous leukemia (myelodysplasia [MDS]; Chap. 87). Contrariwise, patients with oligoblastic leukemia rarely have intense fibrosis.³³⁸ Prominent splenomegaly is expected in patients with primary myelofibrosis but not in patients with oligoblastic myelogenous leukemia, which helps to distinguish the former from the latter patients. The absence of a high frequency of teardrop-shaped red cells, nucleated red cells, and striking anisopoikilocytosis in the blood film mitigates against primary myelofibrosis.

Because some patients with primary myelofibrosis have platelet counts greater than 450,000/ μ L (450×10^9 /L), the diagnosis of primary thrombocythemia may be considered. Moreover, some patients may be in transition from thrombocythemia to myelofibrosis. The anisopoikilocytosis, nucleated red cells, and myeloid immaturity in the blood film characteristic of myelofibrosis are not present in patients with thrombocythemia. Marrow fibrosis usually is insignificant in thrombocythemia, and splenic enlargement often is absent or slight. For these reasons, a clear distinction usually exists between the two disorders.^{279,339} The prefibrotic phase of primary myelofibrosis may mimic essential thrombocythemia, but the more prominent splenomegaly and the more disordered and characteristic dysmorphic megakaryopoiesis in primary myelofibrosis can be used to distinguish the two entities by an experienced hematopathologist.³⁴⁰ Careful observation of disease evolution is, also, important.³⁴¹

Hairy cell leukemia (Chap. 93), when associated with shape abnormalities of red cells, pancytopenia, splenomegaly, and fibrotic marrow, can closely mimic primary myelofibrosis.^{336,342} Usually, careful scrutiny of the blood and marrow by microscopy, histochemistry, and cell immunophenotype shows evidence of the abnormal mononuclear (hairy) cells characteristic of the disease.

Hepatic disease can be associated with cytopenias and splenomegaly, although the specific blood and marrow findings usually make the distinction with primary myelofibrosis obvious. In a review of 170 cases of splenomegaly in a county hospital, hepatic disease was the second most common cause of massive splenomegaly after primary myelofibrosis.³⁴³

Primary autoimmune myelofibrosis is characterized by intense marrow fibrosis and an increase in marrow polyclonal T and B lymphocytes.^{344,345} Serologic or clinical evidence of lupus erythematosus or other connective tissue diseases is absent, giving primary autoimmune myelofibrosis a definitive diagnostic niche. Cytopenias that occur may be immune mediated (e.g., immune hemolytic disease), and the blood cell findings (anisopoikilocytosis, nucleated red cells, myeloid immaturity) characteristic of primary myelofibrosis usually are absent. The marrow may be cellular with increased megakaryocytes, but strikingly dysmorphic megakaryocytopoiesis is absent. Splenomegaly, a nearly constant feature of primary myelofibrosis, usually is absent. Polyclonal hyperglobulinemia may be present.

Patients with sporadic idiopathic or familial pulmonary hypertension have significant marrow fibrosis. They can be distinguished from

patients with primary myelofibrosis with pulmonary hypertension by the latter's high-circulating CD34+ cell count, the presence of clonal platelets and granulocytes, a high frequency of dacryocytes in the blood film, and a *JAK2*^{V617F} mutation.³⁴⁶

Metastatic carcinoma, especially derived from carcinoma of breast or prostate^{347–352} or disseminated mycobacterial infection,^{353,354} can induce reactive marrow fibrosis and occasionally simulate primary myelofibrosis. Demonstration of metastatic carcinoma cells or mycobacteria in the marrow indicates the etiology. Other disorders reported with secondary myelofibrosis include mastocytosis,^{355–358} angioimmunoblastic lymphadenopathy,³⁵⁹ angiosarcoma,³⁶⁰ lymphoma,^{361–363} multiple myeloma,^{364–366} renal osteodystrophy,³⁶⁷ hypertrophic osteoarthropathy,³⁶⁸ gray platelet syndrome,³⁶⁹ systemic lupus erythematosus,^{251–254} polyarteritis nodosa,²⁵⁶ hypereosinophilic syndrome,^{370,371} kala azar,³⁷² primary thrombocytopenic purpura,³⁷³ thrombotic thrombocytopenic purpura,³⁷⁴ tretinoin administration,³⁷⁵ neuroblastoma,³⁷⁶ giant lymph node hyperplasia,³⁷⁷ vitamin D-deficiency rickets,^{378–381} Langerhans cell histiocytosis,³⁸² acute promyelocytic leukemia,^{383,384} and malignant histiocytosis.³⁸⁵ Correction or amelioration of the primary disorder can lead to disappearance of the marrow fibrosis.

Lymphoma,^{386,387} chronic lymphocytic leukemia,^{388,389} hairy cell leukemia,^{342,390} systemic mastocytosis,³⁹¹ macroglobulinemia,³⁹² amyloidosis,^{244,245} myeloma,^{393,394} malignant teratoma,³⁹⁵ and essential monoclonal gammopathy³⁹⁶ can coincide with primary myelofibrosis.

TRANSITIONS TO AND FROM MYELOFIBROSIS AMONG CLONAL HEMOPATHIES

All clonal hematopoietic diseases (AML, CML, oligoblastic myelogenous leukemia [MDS], lymphomas) may have increased marrow reticular fibers but only infrequently have collagen fibrosis.³⁹⁷ Acute megakaryoblastic leukemia is accompanied by intense marrow fibrosis (Chap. 88). Approximately 15 percent of patients with polycythemia vera, whether treated by phlebotomy, alkylating agents, or ³²P, develop a clinical state indistinguishable from primary myelofibrosis during 20 years of observation (Chap. 84).^{398–400} Essential thrombocythemia may evolve into a myelofibrotic stage, estimated to occur in approximately 7 percent of cases (Chap. 85). This estimate is complicated by the question of whether some cases of essential thrombocythemia actually were distinguished as early (prefibrotic) primary myelofibrosis.^{340,341} Sideroblastic anemia has progressed to primary myelofibrosis.⁴⁰¹ Rarely, primary myelofibrosis reverts to polycythemia vera, with disappearance of marrow fibrosis.^{402,403} Even more rarely, primary myelofibrosis, carrying the *JAK2* mutation, has undergone clonal evolution to BCR-ABL-positive CML or vice versa.^{404,405}

THERAPY

DECISION TO TREAT

A proportion of asymptomatic patients remains stable for years and they do not require specific treatment. Constitutional symptoms, anemia, thrombocytopenia, and splenomegaly are the principal initial reasons for therapy. A hemoglobin less than 10 g/dL,^{12,14,20} a white count less than 4000/ μ L (4.0×10^9 /L) or greater than 30,000/ μ L (30.0×10^9 /L),¹³ a platelet count under 100,000/ μ L (100×10^9 /L), and blood blasts above 1 percent of total leukocytes^{12,20,406} predict more rapid progression of disease. In addition, patients may have a loss of sense of well-being, fatigue, night sweats, loss of weight, low-grade fever, and loss of functionality as a result of the accompanying elaboration of inflammatory cytokines.

Staging protocols may be useful in comparing concurrent and sequential clinical trial results (see “Course and Prognosis” below). In an individual patient under the care of a clinician experienced in the disease, following the disease for evidence of progression is a very important additional factor in determining the timing of treatment, even in patients deemed at higher risk by formulaic techniques, especially before introducing allogeneic stem cell transplantation with its morbidity and potential mortality in this age group.

RED CELL TRANSFUSION

Patients with severe anemia or with moderate but symptomatic anemia may require periodic red cell transfusions (Chap. 138). Alternative mechanisms for raising the blood hemoglobin concentration include use of recombinant erythropoietin and androgen therapy.

RECOMBINANT HUMAN ERYTHROPOIETIN FOR ANEMIA

Serum erythropoietin levels usually are appropriate to the severity of anemia in patients with myelofibrosis.⁴⁰⁷ Thus, use of erythropoietin for anemia is, usually, disappointing. In some studies, patients selected by their inappropriately low serum erythropoietin levels (<125 U/L) for the degree of anemia, beneficial effects can result.^{408,409}

ANDROGENS AND GLUCOCORTICOIDS FOR ANEMIA

Severe anemia may improve with androgen therapy in some patients.⁴¹⁰ Testosterone, oxymetholone, and fluoxymesterone have been used but have virilizing effects. In addition, they have the potential for hepatic injury and other side effects. Danazol, 600 to 800 mg/day orally for up to 6 months, can be used. The drug is tapered to the minimum effective dose or discontinued if no significant response occurs. Improvement may be limited to a decreased frequency of red cell transfusion. Androgens often are used after splenectomy if anemia returns and requires transfusion of red cells. They are more effective in splenectomized patients or those with less splenic enlargement. Patients undergoing androgen therapy should have periodic assessment of liver size by physical examination, measurement of liver function tests, and, if appropriate, ultrasonographic imaging to detect liver injury (e.g., peliosis) or tumors.⁴¹¹ Evaluation of male patients for prostatic enlargement or cancer is prudent before starting androgen therapy. Patients with significant hemolytic anemia may benefit from glucocorticoid therapy. Prednisone 25 mg/m² per day orally can be tried. If tolerated, the dose can be continued for 1 to 2 months and then tapered gradually. In children, high-dose glucocorticoid therapy can ameliorate marrow fibrosis and improves hematopoiesis.^{412,413}

DRUG THERAPY FOR MYELOPROLIFERATION, SPLENOMEGALY, OR CYTOPENIAS

A variety of drugs have been used for treatment of massive splenomegaly, thrombocytosis, or constitutional symptoms.

JAK2^{V617F} Kinase Inhibitors

Because *JAK2* mutations and the resulting effects on JAK-STAT signaling are thought to be a key factor in the clonal expansion leading to primary myelofibrosis in at least 50 percent of patients, an effort to synthesize and test inhibitors of the mutant *JAK2* protein product were conducted.⁴¹⁴ Early studies of the *JAK2* kinase inhibitor TG101209, an oral, bioavailable small molecule, and a potent inhibitor of *JAK2* kinase, showed its ability to inhibit *JAK2*^{V617F}-dependent phosphorylation of

STAT3 and STAT5, inhibit colony growth of cells harboring *JAK2* and *MPL* mutations, and to have therapeutic effects in a nude mouse model of *JAK2*^{V617F}-induced myeloproliferative disease.⁴¹⁵ The effects of several *JAK2* inhibitors have been described.^{416–418} Although their effects are somewhat different, the most striking and consistent effect with each agent is a decrease in spleen size and reversal of constitutional symptoms. They often suppress blood cell counts, and thrombocytopenia can be dose-limiting. At least initially, the anemia worsens although this laboratory deterioration may be transient, lasting only for few months. Typically, in spite of progression of anemia, most treated patients report decreased fatigue. The reduction in large spleen size and the improvement in the quality of life of many patients have been dramatic and were similar in those with and without a *JAK2* mutation. This effect may be explained by the drug's ability to inhibit *JAK1* and *JAK2* isoforms, the former having a role in cytokine elaboration. These agents may decrease morbidity and mortality, prolonging survival (see "Course and Prognosis" below).^{419–423}

In 2011, ruxolitinib, an oral *JAK2* inhibitor, was approved by the FDA for use in patients with intermediate or high-risk myelofibrosis. It decreases spleen size, fatigue, night sweats, pruritus, and red cell transfusion requirements, and can result in weight gain in a significant proportion of patients. The principal dose-limiting side effect is a decreased platelet count. Although some patients may have worsened anemia or neutropenia, the net effect often was beneficial, with improvement in fatigue and other symptoms. Headache, dizziness, and diarrhea also may occur but are usually manageable without discontinuing the drug. After 6 months of treatment approximately 40 percent of treated patients have a significant decrease in spleen size and constitutional symptoms. The initial drug trials were limited to patients with a platelet count at the initiation of ruxolitinib therapy of $100 \times 10^9/L$; however, newer studies using lower starting doses of ruxolitinib and gradually incrementing those doses have indicated that patients with platelet counts of between 50 and $100 \times 10^9/L$ may receive similar benefits from carefully incremented drug doses. Table 86–4 shows a suggested approach to initial dosage. Of all available therapeutic modalities for primary myelofibrosis, ruxolitinib is the only therapy that has shown benefit in clinical trials that included a comparison group given a placebo.

Hydroxyurea

Hydroxyurea is a commonly used agent for exaggerated accumulation of platelets, occasional very high leukocyte counts, troublesome areas of extramedullary hematopoiesis, and symptomatic splenomegaly.^{424–426}

TABLE 86–4. Guideline for Initial Oral Ruxolitinib Dose in Primary Myelofibrosis

Platelet Count	Dose
$>200 \times 10^9/L$	20 mg twice daily
$100\text{--}200 \times 10^9/L$	15 mg twice daily
$50\text{--}100 \times 10^9/L$	5 mg twice daily (increasing each month by 5 mg daily until maximal splenic size reduction, only if platelet count stays above $40 \times 10^9/L$) [*]

^{*}Drug not FDA approved for starting platelet counts of 50 to $100 \times 10^9/L$. If platelet count decreases while on ruxolitinib therapy, dose reduction should be made in relation to level of platelet count. The drug should not be administered if platelet counts falls to less than $50 \times 10^9/L$. Therapists should consult more detailed guidelines, *Prescribing Information*, published by Incyte, for use of ruxolitinib (Jakafi) (revised November 2011).

Hydroxyurea can, inconsistently, decrease the size of the spleen and liver, decrease or eliminate constitutional symptoms of night sweats or weight loss, and occasionally lead to an increase in hemoglobin concentration, a decrease of platelet counts, and a decrease in the degree of marrow fibrosis. Patients with myelofibrosis often do not have the marrow tolerance to chemotherapy of patients with other chronic myeloproliferative diseases. Hydroxyurea can be administered in doses of 0.5 to 1.0 g/day or 1 to 2 g orally two to three times per week, depending on the level of pretreatment blood cell counts. Patients should be evaluated for dose adjustment at least every week for 1 month and, if appropriate, eventually extended to evaluation every 3 months. Although alkylating agents, especially busulfan and other cytotoxic agents, have been used successfully, they have largely been replaced by hydroxyurea. Use of alkylating agents has resurfaced with the suggestion that melphalan or busulfan may be useful as therapy.^{427,428}

Thalidomide and Lenalidomide

Thalidomide is poorly tolerated at optimal doses of approximately 800 mg/day. Most patients receive about half that amount and are tapered to the lowest effective dose. One study of 14 patients found the drug was not beneficial and had high toxicity rates.⁴²⁹ Other studies found some decrease in spleen size and improvement in blood hemoglobin and platelet counts in a minority of patients receiving up to 600 mg/day.^{430,431} In subsequent studies, lower doses of thalidomide (50 mg/day) coupled with prednisone were more tolerable and resulted in improvement of anemia and thrombocytopenia in about half of patients, with sustained improvement in some patients after treatment was stopped.⁴³² The thalidomide congener lenalidomide may supersede thalidomide use. Lenalidomide has provided responses in a significant minority of patients.^{433–436} The drug can result in marked improvement in hemoglobin concentration or avoidance of a requirement for transfusion (22 percent of patients treated), improvement in platelet count (50 percent of patients treated), and decrease in spleen size (33 percent of patients treated). Neutropenia and thrombocytopenia were the most troubling side effects.⁴³³ The drug has also been useful in patients with primary myelofibrosis who have a 5q– cytogenetic abnormality.^{435,436} Another thalidomide congener, pomalidomide, has completed a phase 3 trial and has not been shown to decrease transfusion requirements.⁴³⁷

Cyclosporine, Etanercept, Imatinib Mesylate, and Tipifarnib

Cyclosporine has been used to achieve a serum level of 100 to 200 ng/mL in severely anemic patients with evidence of immune abnormalities (positive Coombs test, antinuclear antibodies).⁴³⁸ Three of six patients responded with an increased hemoglobin concentration. Cyclosporine has been used with apparent success in a single patient with myelofibrosis and red cell aplasia.⁴³⁹

TNF- α has been proposed as a target to inhibit its possible effects in the pathogenesis of primary myelofibrosis.⁴⁴⁰ Of 20 patients treated with soluble TNF- α receptor (etanercept), 12 had improvement in constitutional symptoms (fever, night sweats, fatigue, weight loss), and four had improved blood counts and decreased spleen size.^{441,442}

Imatinib mesylate for treatment of myelofibrosis has been examined on empirical grounds and has been largely ineffective in influencing the disease course.^{442,443} Modest doses have not been well tolerated, and responses have been infrequent and insubstantial.

The farnesyl transferase inhibitor tipifarnib is not well tolerated.⁴⁴⁴ Although it may decrease spleen size, it has shown no advantages over hydroxyurea.

Interferons

Interferon- α and interferon- γ act synergistically to inhibit myeloproliferation.⁴⁴⁵ Interferon- α has been used extensively for treatment of CML

prior to the availability of mutant tyrosine kinase (BCR-ABL) inhibitors (Chap. 89). Interferon- α has not been used extensively in primary myelofibrosis, but has been useful for treatment of splenic enlargement, bone pain, and thrombocytosis in select patients.⁴⁴⁶ Trials comparing interferon therapy with hydroxyurea or other therapy have not been reported.⁴⁴⁷ Hydroxyurea is easier to use (oral versus parenteral) and has less-frequent and less-severe side effects than interferon, especially in older patients. A polyethylene glycol conjugated interferon- α preparation may prove more practical and tolerable for use in patients with myelofibrosis. Although largely ineffective in later stages of myelofibrosis, it has shown efficacy in the early myeloproliferative stage of primary myelofibrosis with mild to moderate marrow fibrosis.^{448–451}

Serosal Implants

Cytarabine Ascites resulting from peritoneal hematopoietic implants has been treated with intraperitoneal cytarabine.⁴⁵² Intrasplicenic cytarabine administered via a splenic artery catheter has resulted in significant improvement in a patient (see also “Radiotherapy” below).⁴⁵³

IMMUNE-RELATED FIBROSIS

Intravenous Immunoglobulin

Although autoimmune or systemic lupus erythematosus-related myelofibrosis has responded to glucocorticoids or intravenous immune globulin^{251,254} and a variety of other fibrotic disorders occasionally respond,⁴⁵⁴ primary myelofibrosis does not have a sustained response to such therapy because the fundamental lesion is the hematopoietic multipotential cell neoplasm, neoplastic megakaryocytosis, severe megakaryocytic dysmorphia, and cytokine release with resultant fibrogenesis and, sometimes, osteogenesis.

BISPHOSPHONATES FOR BONE DISEASE

Debilitating bone pain can be a vexing problem in some patients with osteosclerosis and periostitis. Dramatic improvement in bone pain and hematopoiesis after etidronate 6 mg/kg per day on alternate months⁴⁵⁵ or clodronate 30 mg/kg per day for several months, during which marked improvement was still present 33 months later,⁴⁵⁶ highlight the potential usefulness of this family of drugs for bone symptoms.⁴⁵⁷

RADIOTHERAPY

Radiotherapy can be useful for patients with primary myelofibrosis in several situations. For example, in the presence of severe splenic pain (splenic infarctions) or massive splenic enlargement with contraindication to splenectomy (e.g., thrombocytosis), repeated doses of 0.5 to 2.0 Gy to the spleen can ameliorate the pain.⁴⁵⁸ Splenic radiation can result in further cytopenias or worsening cytopenias, especially thrombocytopenia, referred to as an abscopal effect on marrow production, perhaps because of the circulation of large numbers of CD34+ cells exposed in the spleen. Other situations in which radiation may be useful are ascites resulting from myeloid metaplasia of the peritoneum,⁴⁵⁹ focal areas of severe bone pain (periostitis or the osteolysis of a myeloid sarcoma),^{272,458,460} and extramedullary fibrohematopoietic tumors,^{157,458} especially of the epidural space.¹⁹¹ Low-dose radiation to the liver for symptomatic hepatomegaly and ascites provides only short-term relief.^{458,461} Low-dose radiotherapy to the lung has been used successfully to palliate the effects of pulmonary hypertension thought to result from extensive extramedullary hematopoiesis in the organ. Low-dose radiotherapy has relieved signs of respiratory insufficiency, especially hypoxemia,²²⁶ but in several unreported instances known to the authors, this approach has led to deterioration of pulmonary function.

SPLENECTOMY

Splenectomy has been important in the management of primary myelofibrosis.⁴⁶² The major indications for splenectomy include (1) painful enlarged spleen (~50 percent of patients), (2) excessive transfusion requirements or refractory hemolytic anemia (~25 percent of patients), (3) portal hypertension (~15 percent of patients), and (4) severe thrombocytopenia (~10 percent of patients).

Patients who have a prolonged bleeding time or coagulation times are at serious risk for hemorrhage with surgery and should not undergo the procedure unless the abnormalities can be corrected by platelet transfusion and factor replacement therapy. Evidence of low-grade intravascular coagulation, such as elevated D-dimer levels, may require prophylactic heparin therapy and platelet transfusion should excessive bleeding occur.

Removal of the spleen in patients with primary myelofibrosis may be difficult. Usually the spleen is adherent to neighboring serosal surfaces and structures (e.g., inferior surface of left hemidiaphragm) and has numerous collateral vessels and very dilated splenoportal arteries and veins. Immediate postoperative mortality is a function of surgical experience and skill and of the rapidity of recognition of postoperative complications. In experienced hands, perioperative mortality is approximately 10 percent. Postoperative morbidity from hemorrhage, subphrenic hematoma, subphrenic abscess, injury to the tail of the pancreas, pancreatic fistulas, or portal vein stump or mesenteric vessel thrombosis occurs in approximately 30 percent of patients. Infection, especially, pneumonia occurs in approximately 10 percent of patients. Later postoperative changes include liver enlargement (sometimes massive), extramedullary hematopoietic tumors, thrombocytosis, and a decrease in teardrop-shaped red cells. Leukemic blast transformation occurs in approximately 15 percent of patients after splenectomy. Hydroxyurea or aspirin and anagrelide may be useful for exaggerated thrombocytosis (Chap. 85). The morbidity and mortality from splenectomy and the modest extension of life have led to increasing conservatism regarding its use. However, splenectomy can improve the condition for which it was performed in approximately 50 percent of patients. Median survival after splenectomy has been approximately 18 months.

PORTAL-SYSTEMIC VASCULAR SHUNT SURGERY

Circulatory dynamic studies are performed at the time of surgery in patients undergoing operation for portal hypertension and bleeding varices or refractory ascites. In patients in whom the hepatic wedge pressure elevations result from markedly increased blood flow from the spleen to the liver, the preferred treatment procedure for portal hypertension is splenectomy. In patients who have portal hypertension resulting from intrahepatic block or hepatic vein thrombosis and who have a hepatic venous pressure gradient well above the upper limits of normal (6 torr), a splenorenal shunt can be performed⁴⁶³ or, to avoid abdominal surgery, a transjugular intrahepatic portosystemic shunt can be used.^{464,465} Variceal sclerotherapy or variceal ligation has been used to treat bleeding varices resulting from portal hypertension.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

Marrow transplantation is the only curative approach to primary myelofibrosis. Marrow transplantation therapy has been used increasingly in younger patients with a poor prognosis (e.g., severe anemia and leukopenia or exaggerated leukocytosis) who have a histocompatible sibling.^{466–473} The median age in most studies is approximately 50 years, whereas the median age of all patients is approximately 70 years.³²²

Patients engraft at a rate similar to the rate of patients with hematologic diseases without marrow fibrosis (Chap. 23). The decision to use full-conditioning allogeneic transplantation is a function of the patient's age (<50 years), the severity of the blood cell and marrow abnormalities, and the likelihood of a protracted indolent course without transplantation. Younger patients, especially those younger than age 50 years, with a DNA-based matched sibling donor, progressive disease, and poor prognostic findings, such as hemoglobin less than 10 g/dL, blast cells greater than 1 percent of blood cells, unfavorable cytogenetics (e.g., abnormalities involving chromosome 5, 7, or 17, or cells with three or more abnormalities) are usually considered for transplantation. Although a large spleen may slightly delay the expression of donor granulopoiesis, on average the results in patients with a spleen is the same as those who had prior splenectomy.^{471,474} In addition, the latter procedure incurs significant risk of morbidity or mortality.

Patients younger than age 50 years who are transplanted with stem cells from a matched sibling donor have a lower posttransplantation mortality and have better outcomes than those older than age 50 years.⁴⁶⁰ Transplant-related mortality using full-conditioning regimens is approximately 35 to 40 percent and 5-year survival is approximately 50 percent in patients younger than 50 years of age.

Donor lymphocyte infusion in patients who have lost donor dominance of hematopoiesis and a return of myelofibrosis can result in regression of fibrosis and return to normal hematopoiesis for at least 6 and 20 months at the time of reporting.^{475,476}

In *JAK2*^{V617F}-positive patients, real-time polymerase chain reaction analysis can permit a sensitive determination of residual *JAK2*^{V617F}-positive cells after transplantation. In a study of patients receiving low-intensity conditioning, 17 of 21 patients became *JAK2*^{V617F}-negative, and in one case donor lymphocyte infusion eliminated *JAK2*^{V617F}-positive cells.⁴⁷⁷

The option of nonmyeloablative transplantation in older patients is gaining favor.^{470,471,478-482} Several reports of lower posttransplantation mortality and salutary outcomes have led some to consider this approach as the preferred approach in patients older than 50 years of age, and perhaps in younger patients as well. One study showed that the outcome of nonmyeloablative transplantation was dramatically better than myeloablative transplant.⁴⁷⁰ The study compared 17 patients receiving a myeloablative conditioning regimen and 10 receiving nonmyeloablative conditioning. The median age was 50 years (age range: 5 to 63 years) at transplantation. After a median followup of 55 months, 20 patients were alive. The transplantation-related mortality was 10 percent in the nonmyeloablative group and 30 percent in the myeloablative group. There was no difference in survival for high- or low-risk patients or between sibling and unrelated donor transplantations. This study confirmed prior smaller comparisons of myeloablative and nonmyeloablative stem cell transplantation.⁴⁸³

A large cooperative study of reduced conditioning transplantation found the most favorable results in transplants using matched-related donors and in intermediate stage disease.⁴⁸²

Autologous blood stem cells mobilized with granulocyte colony-stimulating factor (G-CSF) and administered after busulfan conditioning produced clinical benefit, including improved erythropoiesis, improved platelet counts, and decreased splenic size, in a plurality of 21 patients with primary myelofibrosis whose age range was 45 to 75 years. The 2-year actuarial survival rate was 61 percent.⁴⁸⁴

COURSE AND PROGNOSIS

The rate of disease progression is associated with at least 16 variables measured at the time of diagnosis, namely: (1) older age; (2) severity of anemia; (3) exaggerated leukocytosis (>25 × 10⁹/L) or leukopenia

(<4.0 × 10⁹/L); (4) constitutional symptoms of fever, sweating, or weight loss at the time of diagnosis; (5) proportion of blast cells in the blood (≥1 percent); (6) male gender; (7) severity of thrombocytopenia; (8) proportion of CD34+ cells in the blood; (9) the presence of the V617F mutation in *JAK2*; (10) monocytosis; (11) a decreased proliferating cell nuclear antigen index and a decreased apoptotic index by *in situ* end labeling; (12) degree of liver enlargement; (13) extent of marrow fibrosis; (14) postsplenectomy spleen histology; (15) *WT1* expression in CD34+ cells; and (16) certain clonal cytogenetic abnormalities, especially involving chromosome 5, 7, or 17, or with three or more abnormalities. Abnormalities such as 13q or 20q did not affect patient survival compared to those patients without cytogenetic alterations.

Each retrospective study has found a different subset of these factors to be significant prognostic factors. The most consistent predictive variables appear to be advanced age, severity of anemia, and higher-risk clonal cytogenetic abnormality at the time of diagnosis, each of which represents a poor prognostic indicator.^{8,12,14,16,312,314,485-490}

In a study of more than 1000 consecutive cases of myelofibrosis at seven centers, among which the median survival was 69 months, variables (1) through (5) (listed above) proved to be the most useful in dividing patients into four risk-factor categories. Shorter survival was observed in patients who were older than age 65 years, had a hemoglobin concentration less than 10 g/dL, a leukocyte count greater than 25 × 10⁹/L (25,000/μL), a blood blast cell count equal to or greater than 1 percent, and constitutional symptoms. The patients were assigned to a risk group based on the number of risk factors present. If no risk factors were present, risk was low; if one factor was present, risk was low-intermediate; if two risk factors were present, risk was high-intermediate; and if three or more risk factors were present, risk was high. The application of these variables could distinguish among patients with low risk with a survival of 135 months, low-intermediate risk with a survival of 95 months, high-intermediate risk with a survival of 48 months, and high risk with a survival of 27 months.⁴⁹¹ Overall, the 5-year survival of patients with primary myelofibrosis is approximately 40 percent of the survival expected for healthy age- and sex-matched controls.⁴⁹²

Some data suggest that the use of *JAK2* inhibitors in the treatment of primary fibrosis may not only decrease symptomatology and spleen size, but may prolong survival.^{493,494} An analysis of 100 patients receiving ruxolitinib compared to 350 carefully matched patients who did not receive ruxolitinib showed a median 18-month prolongation in survival in patients with poorer prognosis disease. At the upper range some patients had a 4- to 5-year prolongation of life.⁴⁹⁴ In addition, the clinical improvement in vitality and functionality can be dramatic.

The major causes of death are infection, hemorrhage, postsplenectomy mortality, and acute leukemic transformation.⁴⁹⁵⁻⁴⁹⁹ Acute leukemia occasionally is preceded by the development of myeloid sarcomas.^{35,460,499,500} Evolution of the disease to acute lymphocytic leukemia or lymphoma may occur.^{501,502} An increased risk of progression to leukemia has been reported in splenectomized patients.⁵⁰³ Progression to acute leukemia is associated with a blast count greater than 3 percent and a platelet count less than 100,000/μL (100 × 10⁹/L) at the time of diagnosis. Treatment with erythropoietin or androgens is associated with increased risk of progression to acute leukemia, as well.⁵⁰⁴ The administration of *JAK2* inhibitors may provide improved efficacy for the treatment of AML evolving in patients with primary myelofibrosis. Rare spontaneous remissions of apparent primary myelofibrosis are documented.^{505,506}

A variety of gene mutations have been associated with prognosis in patients with primary myelofibrosis, either overall survival or risk of conversion to acute myelogenous leukemia. These include the following gene mutations: *IDH*, *EZH*, *ASXL1*, and *SRSF2*.^{507,508} The A3669G (rs6198) single nucleotide polymorphism of the glucocorticoid receptor

contributes to the erythrocytosis in polycythemia and contributes to the risk of evolution to AML.⁵⁰⁹ About 5 to 10 percent of patients with primary myelofibrosis do not have a mutation in *JAK2*, *CALR*, or *MPL*. These so-called “triple-negative” patients with myelofibrosis appear to have a less favorable prognosis as do those whose neoplastic cells have wild type *CALR* and an *ASXL1* mutation.^{509A}

Primary myelofibrosis in infants and children has a more varied pathobiology than in adults. Patients have been followed for decades without requiring significant treatment,⁵¹⁰ and spontaneous remission has been described.⁵¹¹ Because of its variable course, conservative management may be appropriate while the course of the disease is followed.

CHAPTER 87

MYELODYSPLASTIC SYNDROMES

Rafael Bejar and David P. Steensma*

SUMMARY

Myelodysplastic syndromes (MDS) are a heterogeneous group of clonal hematopoietic neoplasms defined by morphologic dysmorphia, one or more blood cytopenias, and an increased risk of clonal evolution to acute myelogenous leukemia (AML). These disorders can occur at any age but have an incidence that rises exponentially after age 40 years with a median age at diagnosis of 72 years. Most cases are acquired *de novo* through the accumulation of somatic mutations, although a small fraction arises after exposure to DNA damaging agents, such as chemotherapy and radiation. A minority of cases are the result of inherited mutations that predispose to the development of MDS and related myeloid disorders. Subtypes of MDS are largely defined by clinical features and range from refractory cytopenias (typically including anemia) to oligoblastic myelogenous leukemia with an increase in marrow myeloblasts (5 to 19 percent). Cases with 20 percent or more myeloblasts in the marrow (an arbitrary boundary) or specific chromosomal translocations are defined as AML. The diagnostic criteria for MDS include dysmorphogenesis in one or more blood cell lineages, often resulting in exaggerated apoptosis during later stages of maturation. Poikilocytosis, anisocytosis, anisochromia, and

Acronyms and Abbreviations: AHSCT, allogeneic hematopoietic stem cell transplantation; ALIP, abnormal localized immature precursor; ALL, acute lymphocytic leukemia; AML, acute myelogenous leukemia; ATG, antithymocyte globulin; ATRA, all-trans-retinoic acid; aUPD, acquired uniparental disomy; CALGB, Cancer and Leukemia Group B; CDR, commonly deleted region; CLL, chronic lymphocytic leukemia; CMML, chronic myelomonocytic leukemia; ESA, erythropoiesis-stimulating agent; FAB, French-American-British; FPD, familial platelet disorder; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HLA, human leukocyte antigens; IDH, isocitrate dehydrogenase; IL, interleukin; IPSS, International Prognosis Scoring System; IPSS-R, International Prognosis Scoring System Revised; LGL, large granular lymphocyte; MAP, mitogen-activated protein; M-CSF, monocyte colony-stimulating factor; MDS, myelodysplastic syndrome; MDS/MPN, myelodysplastic syndrome/myeloproliferative neoplasm; miRNA, microRNA; NCI, National Cancer Institute; NK, natural killer; PLK, polo-like kinase; PRC, protein-repressive complex; RA, refractory anemia; RAEB, refractory anemia with excess blasts; RAEB-t, refractory anemia with excess blasts in transformation; RARS, refractory anemia with ring sideroblasts; RARS-t, refractory anemia with ring sideroblasts and thrombocytosis; RBC, red blood cell; SEER, Surveillance, Epidemiology and End Results; snRNP, small nuclear ribonucleoprotein complex; TET, ten-eleven translocation; TGF, transforming growth factor; TNF, tumor necrosis factor; WT, Wilms tumor; WHO, World Health Organization.

basophilic stippling are features of the abnormal red cells. The marrow usually contains increased erythroid precursors with dysmorphic features, including nuclear distortions and scanty, poorly hemoglobinized cytoplasm or macroerythroblasts. Pathologic ring sideroblasts are a common feature used to define particular subtypes of MDS. Neutrophils may have bilobed or hypersegmented nuclei and hypogranulated cytoplasm in association with increased marrow granulocyte precursors. Giant and microcytic platelets, sometimes with abnormal or absent granulation, in the blood are associated with megakaryocytic hyperplasia and atypical lobulation of the nucleus, megakaryocyte clustering, and decreased marrow megakaryocyte size. Clonal cytogenetic abnormalities occur in approximately 50 percent of patients, typically as recurrent deletions of entire chromosomes or chromosomal segments. Trisomy 8 is the only frequent copy number gain and recurrent translocations are rare. Various prognostic models for MDS incorporate cytogenetic abnormalities along with marrow blast proportion and blood cytopenias to predict the mortality and risk of clonal evolution to AML. The selection and timing of therapy for MDS is largely driven by risk stratification. Newer prognostic scoring systems have begun to consider somatic mutations as markers of disease-associated risk as pathogenic driver mutations can be identified in almost all cases of MDS and several lesions have a prognostic significance that is independent of other known risk factors. As detectable somatic events, driver mutations are markers of clonal hematopoiesis and could help establish the diagnosis in some cases. Recurrent somatic mutations identify the heterogeneous molecular pathways frequently disordered in MDS. These include mutations in multiple components of the RNA splicing machinery, several epigenetic regulators of DNA methylation and histone modifications, various hematopoietic transcription factors, and growth factor signaling pathway members among others. Certain mutations are tightly associated with clinical features including ring sideroblasts, chromosomal instability, and severe cytopenias. Current treatment guidelines for MDS are based on clinical risk assessments and generally do not consider genetic abnormalities. The exception are cases with del(5q) and noncomplex karyotypes that have a high rate of deep and sustained responses to the immunomodulator drug lenalidomide. Many patients with lower-risk MDS may not require treatment. Others may benefit from hematopoietic growth factor support or immune suppression with antithymocyte globulin and a calcineurin inhibitor, depending on specific clinical features. Higher-risk MDS is typically treated with one of the hypomethylating agents, azacitidine or decitabine, and eligible patients are evaluated for hematopoietic allogeneic hematopoietic stem cell transplantation, the only potentially curative treatment for MDS. Despite these treatment options, outcomes for persons with MDS remain poor overall. Novel therapies targeting recently identified molecular pathways have been developed and are being pursued in clinical trials.

DEFINITION

Myelodysplastic syndromes (MDS) represent a collection of hematopoietic neoplasms characterized by abnormal differentiation, dysmorphology, and resultant blood cytopenias. The hallmarks of these clonal disorders include exaggerated apoptosis of hematopoietic precursors in the marrow, common chromosomal abnormalities, frequent somatic gene mutations, and a variable predilection to undergo clonal evolution to acute myelogenous leukemia (AML). The clinical course of patients with MDS is variable and ranges from relatively indolent clonal cytopenias (e.g., refractory anemia) with a low rate of AML transformation, to more aggressive disease defined by an increased proportion of marrow

*We acknowledge Drs. Marshall Lichtman and Jane Liesveld who wrote this chapter in previous editions of this text. We have retained sections of their previous chapter.

myeloblasts, oligoblastic myelogenous leukemia (refractory anemia with excess blasts), and a greater risk of progression to AML.

Despite their phenotypic variability, MDS share a common pathophysiology. They are neoplasms derived from the clonal expansion of a somatically mutated, multipotent hematopoietic progenitor cell. A wide range of genetic aberrations can contribute to the development and progression of MDS and these somatic mutations can exist in an even greater variety of combinations. The specific profile of genetic lesions present in a given case contributes to the eventual disease phenotype.

MDS are closely related to other myeloid neoplasms such as AML and some myeloproliferative neoplasms. The *dysmorphia of neoplasia* (commonly referred to as *dysplasia* in describing MDS) refers to the abnormal morphology than can be observed in neoplastic mature blood cells and maturing marrow erythroid, granulocytic, and megakaryocytic precursor cells, and is one of the distinguishing characteristics of MDS. The dysmorphia is essential in diagnosis, but is an epiphenomenon. The essential abnormality is the neoplastic transformation of a primitive multipotential myeloid cell. A lower fraction of myeloblasts in the marrow is a reflection of its being at the less-severe end of the spectrum of myelogenous leukemia and is a feature of the diagnosis, creating an arbitrary division between MDS and AML. The diagnostic criteria that separate various myeloid neoplasms (and MDS subtypes) from each other are somewhat ambiguous because they are so closely related. This is evident at the molecular level where no particular genetic abnormality or mutation profile is entirely unique to MDS. Both somatic mutations and chromosomal abnormalities found in MDS are observed in related disorders, albeit often with different frequency. RNA splicing factors and epigenetic regulators are the most common classes of genes affected by mutations in MDS followed by mutations in transcription factors, tyrosine kinase signaling genes, and *TP53*. MDS should be thought of as a minimal to moderately deviated neoplasm in the spectrum of myelogenous leukemias (Chap. 83).

A minority of MDS cases are attributable to prior exposure to DNA-damaging agents, including chemotherapy, high-dose ionizing radiation, and benzene-containing compounds. The latter external factor requires an exposure of sufficient duration and magnitude to be considered causal, rare now in countries with regulations regarding the content of benzene in products such as paints and solvents. Cigarette smoking is considered a risk factor for AML by the U.S. Public Health Service and, presumably, this should apply to MDS, although it has not been studied as extensively. Other chemical exposures have not been established as causative agents by the International Agency for Research on Cancer. A small number of patients come from families with a high penetrance of MDS and related myeloid disorders or have an inherited or congenital syndrome predisposing to MDS. Although rare, identification of the genetic abnormalities in many of these cases has informed our understanding of the molecular pathophysiology of MDS in general. Yet, the vast majority of MDS cases are age-related without a clear precipitating factor. Although MDS can occur at any age, including rare pediatric forms, its incidence increases exponentially after 40 years of age, making it one of the most common myeloid neoplasms of older adults. This pattern is related to the evidence that somatic mutations in primitive hematopoietic cells increase significantly with age.¹

HISTORY

MDS have historically been subject to confusing and shifting terminology and definitions related to incomplete biologic understanding of disease.^{2,3} With the advent of routine molecular analysis of primary patient samples and increasing insight into disease pathobiology, classification of MDS is likely to evolve from the current systems based on cytologic morphology and enumeration of marrow and blood cell

subsets to nosology based on DNA mutation patterns, clonal architecture, and predicted evolution to AML.⁴

Although anemia had been recognized since the early 19th century as a specific deficiency of red cells (also known as “colored corpuscles,” a term that distinguished these cells from leukocytes in the era before histological stains), marrow biopsies were not regularly performed on living patients until after the 1920s.⁵ Therefore, conditions such as MDS that are associated with and defined by specific marrow findings could not be described as distinct syndromes until the first half of the 20th century. Still, early suggestive reports can be found in the medical literature: a 1907 report by Luzzatto of megaloblastic “pseudo-aplastic anemia,”⁶ for example, could have included MDS cases.

In the mid-1920s, Di Guglielmo in Naples described a group of marrow disorders associated with bizarrely shaped erythrocytes and cytopenias, which in some cases ultimately proved fatal.⁷ For many years thereafter, a heterogeneous group of marrow disorders associated with anemia and erythroid dysmorphism were called “Di Guglielmo syndrome” by hematologists, a term that was used variably and is still employed occasionally as an eponymous description of erythroleukemia (AML M6). Some cases of Di Guglielmo syndrome would be called MDS today.

The first MDS-specific term familiar to contemporary hematologists, “refractory anemia,” was coined in the 1930s to describe patients who had unexplained anemia as a consequence of marrow underproduction and who failed to respond to treatment with the available hematinics: iron salts and the liver extract found by Minot and Murphy in the early 1920s to cure pernicious anemia.^{8,9} It is not clear how many of the 100 cases of refractory anemia in the classic 1938 series of Rhoads and Barker in New York City actually had MDS—many appear to have had anemia of chronic disease from infections or associated malignancies, such as Hodgkin lymphoma—but this term and its cognate, “refractory cytopenias,” are still used today to describe some of the lower-risk forms of MDS with blast proportions less than 5 percent.^{9,10}

In 1942, Chevallier and colleagues in France discussed syndromes they labeled as “odo-leukemias.”¹¹ The French investigators chose the Greek word *odo*, meaning threshold, to highlight disorders on the threshold of leukemia, and proposed *leucoses* as a generic term for the leukemias so that marked variations in white cell counts and other highly variable presenting features would not engender inappropriate terminology. However, this proposal was neglected, in part because the paper was published in French and there was no international network of hematologists with which to discuss such concepts in the 1940s.

Despite such provincialism, the idea that what would later be known as MDS could precede and terminate in AML soon made its way in the English medical literature. In 1949, Hamilton-Paterson in London used the term *preleukaemic anemia* to describe patients with refractory anemia antecedent to AML.¹² In 1953, Block and coworkers in Chicago expanded the concept to include cytopenias of all lineages and described cases that closely fit with our current concepts of a clonal myeloid hemopathy prior to evolution to overt AML.¹³ In 1956, Björkman in Malmö, Sweden described four cases of idiopathic refractory sideroblastic anemia, one of which terminated in AML.¹⁴ Descriptive terms, such as *herald state of leukemia*, *refractory anemia*, *sideroachrestic anemia*, *pancytopenia with hyperplastic marrow*, and others, were coined to describe the various hematopoietic derangements that preceded the onset of florid AML. By the 1970s, the relationship of acquired idiopathic cytopenias to the subsequent onset of AML had become broadly appreciated, although such cases were still thought to be rare. In a 1973 review, Saarni and Linman found only 143 cases of “preleukemic anemia” in the medical literature.¹⁵

In 1970, Dreyfus proposed the designation “les anémies réfractaires avec excès de myeloblasts” (i.e., refractory anemia with excess

myeloblasts) and in 1976 he and colleagues proposed a preliminary classification of these syndromes. Dreyfus published a paper in which refractory anemia with an excess of myeloblasts was amplified, parenthetically, as smoldering acute leukemia.^{16,17} The synonym, *oligoblastic leukemias*, had been used also to describe those cases with low proportions of leukemic myeloblasts and relatively protracted courses.^{18,19}

In 1975, at a conference held in Paris, Bessis and Bernard used the term *hematopoietic dysplasia*, later shortened to *myelodysplasia*, for the group of disorders having a more indolent course than AML. The concept that neoplasia is a tissue abnormality defined by its origin in the mutation(s) within a single cell (monoclonality) and that dysplasia is a polyclonal tissue change, not neoplasia, was ignored and took a back seat to the participants' primary interest in the dysmorphia of cells that characterized most of these syndromes, hence the application of the term *dysplasia*, which has become entrenched.

In the year following the Paris conference, a group of seven hematopathologists from France, the United States, and England—the “French-American-British (FAB) Co-Operative Group”—instituted the classification of acute leukemia,¹⁹ developed by Dalton and Dacie, and called it the FAB classification.²⁰ In the FAB classification, acute leukemia was defined by the presence of 30 percent blasts in the marrow; the original report also included two preleukemic syndromes that should be distinguished from acute leukemia, refractory anemia with excess blasts (RAEB), and chronic myelomonocytic leukemia (CMML), defined by greater than 1000/ μ L of blood monocytes. Because most patients with preleukemia do not go on to develop leukemia, the FAB group proposed the term “dysmyelopoietic syndrome” as an alternative to preleukemia.²⁰ A few years later, “dysmyelopoietic syndrome” was revised to become the “myelodysplastic syndrome(s)” still used today.

The 1976 FAB classification included only two subtypes of dysmyelopoietic syndromes, but in 1982 the FAB proposed a specific MDS classification that included five entities: refractory anemia (RA), refractory anemia with ring sideroblasts (RARS), RAEB (defined by 5 to 19 percent marrow blasts), refractory anemia with excess blasts in transformation (RAEB-t, defined by 20 to 29 percent marrow blasts), and CMML.²¹ The 1982 FAB classification, while not without limitations, proved influential and was the basis of subsequent classifications of MDS and related disorders by the World Health Organization (WHO). Subsequent developments in prognostic scoring systems and biologic understanding of MDS are described below.

CLASSIFICATION

A classification of MDS and related disorders was defined by the WHO in 2001 and revised in 2008. It includes six major subtypes of disease distinguished by the type and number of dysplastic lineages, the proportion of marrow blasts, and in one subtype, the presence of a specific chromosomal abnormality, del(5q). These subtypes include (1) refractory cytopenia with unilineage dysplasia (RCUD), which is typically RA, (2) RARS, (3) RA with ringed sideroblasts and thrombocytosis (RARS-t), (4) MDS with isolated del(5q), (5) refractory cytopenia with multilineage dysplasia, (6) RAEB (type 1 or type 2 depending in the proportion of marrow or blood blasts), and (7) unclassifiable MDS (Table 87-1). MDS patients with 20 to 29 percent marrow blasts, previously defined as RAEB-t, are considered to have AML in the WHO classification. However, this sharp cutoff is arbitrarily defined. In practice, patients with blast proportions in this range have comparable outcomes to patients with RAEB-2, including similar rates of benefit from MDS-directed therapy.

The boundaries between subtypes involving percentages of myeloblasts or ring sideroblasts are also arbitrarily defined. Patients may see their disease classification change over time as a result of clinical

TABLE 87-1. World Health Organization Classification of the Myelodysplastic Syndromes

1. Refractory cytopenia with unilineage dysplasia (RCUD)
Dysplasia in $\geq 10\%$ of cells from a single myeloid lineage
<5% marrow blasts, <1% blood blasts, and no Auer rods
<15% of erythroid precursors are ring sideroblasts
Most often is refractory anemia (RA) but can be refractory neutropenia (RN) or refractory thrombocytopenia (RT) in rare cases
2. Refractory anemia with ring sideroblasts (RARS)
Isolated erythroid dysplasia
<5% marrow blasts, <1% blood blasts, and no Auer rods
 $\geq 15\%$ of erythroid precursors are ring sideroblasts
The cutoff for ring sideroblasts is arbitrary and does not reflect the clinical behavior of this subtype as accurately as the frequently associated mutations of SF3B1
3. Myelodysplastic syndromes (MDS) associated with isolated del(5q)
5q31 deletion as the sole chromosomal abnormality
Normal to increased megakaryocytes with hypolobated nuclei
Normal to increase platelet count
<5% marrow blasts, <1% blood blasts, and no Auer rods
This subtype overlaps with, but is not entirely synonymous with the “5q-minus syndrome” recognized prior to the establishment of the WHO classification system for MDS
4. Refractory cytopenia with multilineage dysplasia (RCMD)
Dysplasia in $\geq 10\%$ of cells from two or more myeloid lineages
<5% marrow blasts, <1% blood blasts, and no Auer rods
Blood monocyte count $<1 \times 10^9/L$
5. Refractory anemia with excess blasts (RAEB)
Type 1: 5–9% marrow blasts, <5% blood blasts, and no Auer rods
Type 2: 10–19% marrow blasts, 5–19% blood blasts, or Auer rods
Blood monocyte count $<1 \times 10^9/L$
6. Unclassifiable MDS (MDS-U)
Minimal dysplasia in the presence of a clonal cytogenetic lesion considered presumptive evidence of MDS
<5% marrow blasts, <1% blood blasts, and no Auer rods

NOTE: Other acute and chronic clonal myeloid diseases are categorized in Chap. 83, Table 83-1.

progression or response to therapy. Clonal cytopenias with dysmorphia may also be present in patients with myeloproliferative features such as thrombocytosis or monocytosis. CMML, for example, was previously considered an MDS subtype in the FAB classification, but is now recognized as a myelodysplastic/myeloproliferative neoplasm (MDS/MPN) overlap syndrome. Some patients diagnosed with MDS may have their diagnosis change to CMML once their monocyte count exceeds $1 \times 10^9/L$. Similarly, RARS may be reclassified as RARS-t, if the platelet count rises above $450 \times 10^9/L$. CMML, RARS-t, and related MDS/MPN subtypes are discussed separately in Chap. 89 with the chronic myelogenous leukemias.

Classification systems for MDS have descriptive merit, but do not capture many disease variables with clinical significance. The WHO subtypes of MDS identify patients with similar prognoses because

patients with multilineage dysplasia and increasing blast percentages are at higher risk of AML transformation and death. However, dedicated prognostic models that include features not considered by the WHO classification system are better suited for the estimation of disease risk. Similarly, WHO-defined subtypes do not necessarily share common pathogenic elements or identify groups of patients most likely to respond to particular therapies. Our greater understanding about the underlying molecular abnormalities that occur in MDS demonstrate how clinically defined subtypes are genetically very heterogeneous. It is likely that future classification systems will consider somatic mutations in MDS driver genes, genes responsible for the clonal outgrowth and the eventual development of disease, as a basis for defining disease subtypes.

● EPIDEMIOLOGY

INCIDENCE BY AGE, SEX, AND OCCUPATION

The incidence and prevalence of MDS have been difficult to establish, in part because patients are not consistently reported to central cancer registries.^{22–24} Only since 2001 has the United States (U.S.) National Cancer Institute (NCI) Surveillance, Epidemiology and End Results (SEER) database included MDS cases (Fig. 87–1).²⁵ In 2003, approximately 10,000 new cases were reported to NCI SEER, most “unclassified” (i.e., not distinguished as lower- or higher-risk).²⁵ Improved methods of case ascertainment using claims-based data suggest a high rate of unreported cases and also indicate that MDS is one of the most common hematological malignancies.²⁶

Claims-based data suggest that conservatively, at least 30,000 new cases annually are diagnosed in the United States.²⁷ It is likely that many additional elderly patients with unexplained cytopenias have MDS, but are incompletely evaluated because of severe comorbid conditions limiting life expectancy, clinician oversight of blood test results, or a sense of nihilism. Rates of MDS are similar in Western Europe and the United States.²⁸

In certain Asian countries and Eastern Europe, MDS is diagnosed at a younger age on average than in the United States and Western Europe.^{29–31} The subtypes of MDS that are diagnosed in different regions of the world are also distinct^{32,33}; for instance, for unclear reasons RARS is rare in Japan compared to the West.³⁴ Exposure to ionizing radiation from the 1945 Hiroshima and Nagasaki atomic bomb explosions continues to be associated with an increased MDS risk among exposed Japanese more than 50 years after the events.³⁵

The median age at MDS diagnosis in the United States is approximately 71 years.³⁶ Onset of MDS before the age of 50 years is uncommon, except in cases preceded by irradiation or cytotoxic chemotherapy given for another malignancy.^{37–39} MDS, as defined by the WHO classification, occurs in children ages 5 months to 15 years at a rate of approximately one per 1 million children per year. In contrast to adults, most pediatric cases are oligoblastic myelogenous leukemia (RAEB); clonal sideroblastic anemia is rare.^{40,41} A proportion of childhood cases evolve from inherited predisposing diseases, such as Down syndrome and Fanconi anemia, or are associated with germline *GATA2* or *RUNX1* mutations.^{42–44} Some cases of Fanconi anemia first present in adulthood as MDS, often in the absence of typical dysmorphology.⁴⁵ Dyskeratosis congenita and other telomeropathies can also end in MDS, but many

Figure 87–1. The annual incidence of myelodysplastic syndrome shown by age. There is an exponential (approximately linear on semilogarithmic plot) increase in incidence from age 40 years on. In persons younger than age 40 years, the incidence is so low that it is aggregated as <40 years. (Data from the United States National Cancer Institute, Surveillance, Epidemiology, and End-Results Program.)

congenital marrow failure syndromes such as Diamond-Blackfan anemia or Shwachman-Diamond syndrome do not carry an increased MDS risk.⁴⁶

With the exception of the 5q-minus syndrome, males are affected with MDS up to 1.5 times as often as females.⁴⁷ Case-control studies of possible occupational or environmental associations have provided many possible candidates as contributors to MDS, but none other than benzene (exposure of ≥ 40 parts per million [ppm]-years) has been observed consistently.⁴⁸⁻⁵¹ Cigarette smoking, and a family history of hematologic malignancy also seem plausible risk factors.⁵² Chemicals other than benzene have not been established as causative factors by epidemiologic studies that fully meet the guidelines proposed by Bradford Hill for causation by an external factor. Moreover, given the requirement for biologic plausibility, such chemicals should be shown to induce the specific driver mutations required to cause MDS.

ETIOLOGY AND PATHOGENESIS

ETIOLOGY

The etiologic factors that increase the incidence of MDS are similar to the factors affecting the incidence of AML (Chap. 88). Exposure to prolonged or high levels of benzene,^{34,35} chemotherapeutic agents, particularly alkylating agents and topoisomerase inhibitors,³⁶⁻⁴³ and radiation^{44,45} increases the risk of these clonal hemopathies. These agents may cause DNA damage, impair DNA repair enzymes, and induce loss of chromosome integrity. Most cases of secondary or posttreatment MDS occur in patients treated for a lymphoma or a solid tumor. Increasing reports of MDS as a complication of treatment of myeloid diseases, such as acute promyelocytic leukemia, may reflect a second clonal myeloid disease from another primitive hematopoietic cell injured during therapy.⁴³ The increased life span of patients with acute promyelocytic leukemia and other cancers after effective therapy may make these events more common. More common environmental exposures, such as cigarette smoke, may contribute to the likelihood of developing MDS.

Inherited diseases, such as Fanconi anemia, known to predispose to AML development occasionally evolve instead into a clonal myeloid hemopathy (see Chap. 88, Table 88-1).⁴⁶ Other syndromes, of either a familial (inherited) or spontaneous nature, have been associated with a high risk of developing myeloid neoplasms. Germline mutations of the hematopoietic transcription factor *RUNX1* are associated with a familial platelet disorder with predisposition to AML (FPD-AML). Affected individuals often have qualitative and quantitative platelet abnormalities that precede the development of a more aggressive myeloid neoplasm such as MDS or AML. Transformation typically occurs in the third decade of life, but penetrance is variable between individuals and kinships. The long latency prior to progression suggests that the acquisition of additional cooperating mutations is required for transformation. Somatic *RUNX1* mutations are also common in *de novo* and therapy-related MDS cases highlighting the oncogenic driver nature of these abnormalities. In contrast, somatic mutations of Fanconi anemia genes are extremely rare in MDS. Congenital *FANC* mutations may instead cause DNA damage and accelerated exhaustion of normal stem cells allowing mutant clones to expand more readily. Similarly, inherited CCAAT/enhancer binding protein alpha (*C/EBPA*) mutations, often associated with eosinophilia, typically predispose to AML without an MDS-like clinical phase and are only rarely found as somatic mutations in MDS.

Congenital mutations of another hematopoietic transcription factor, *GATA2*, have been linked to familial MDS.⁵³ The syndromic manifestations of germline *GATA2* mutations are highly varied and can include lymphedema, cutaneous warts, sensorineural hearing loss,

pulmonary alveolar proteinosis, and disseminated nontuberculous mycobacterial infections.^{54,55} Several distinct clinical syndromes that include subsets of these features are now known to be caused by germline *GATA2* mutations. These include Emberger syndrome comprising MDS, verrucae, and congenital lymphedema, as well as the MonoMAC syndrome comprising monocytopenia and nontuberculous mycobacterial infections.⁵⁵⁻⁵⁸ Not all patients show overt syndromic features prior to developing MDS, even as adults, and several pediatric marrow failure syndromes can be associated with germline *GATA2* mutation in the absence of syndromic features.⁵⁹

The combined incidence of familial (<2 percent) and therapy-related MDS (~5 to 10 percent) pales in comparison to the frequency of *de novo* MDS that has age as its dominant predisposing factor. This may be simply a matter of probability, with aged stem cells being more likely to have acquired somatic driver mutations. It may also reflect age-related changes in the microenvironment or stem cell epigenetic state as hematopoietic stem cells from elderly persons without disease are known to have an exaggerated myeloid differentiation bias.⁶⁰ In concert, age-related drop out of normal hematopoietic stem cells could lead to oligoclonal, or even monoclonal, hematopoiesis derived from stem cells with weakly selective abnormalities that then serve as fertile ground for cooperating MDS-related somatic mutations.⁶¹

PATHOGENESIS

MDS arise from the clonal expansion of a mutated multipotential hematopoietic cell. For patients without excess blasts, the cell of origin is presumed to be a lymphohematopoietic pluripotential stem cell based on the presence of disease-associated driver mutations in cells that share the surface protein immunophenotype of functionally defined stem cells.⁶² Subsequent evolution measured by the acquisition of additional mutations takes place in this cellular compartment and can occur in more differentiated progenitors, if they confer the capacity for sustained self-renewal. Evidence for the clonal nature of MDS is supported by studies of skewed X-chromosome inactivation in female patients heterozygous for glucose-6-phosphate dehydrogenase isoenzymes. The hematopoietic progenitors,^{63,64} and sometimes B lymphocytes,⁶⁵ of such patients had only one isoenzyme present, supporting the concept of clonal expansion of a neoplastic early progenitor cell. Subsequent studies confirm the presence of acquired chromosomal abnormalities and somatic mutations in hematopoietic progenitors as well as in B and T lymphocytes in some, but not all, cases.^{62,66-72}

This process of clonal expansion takes place in the context of the marrow microenvironment and host immune response (Chap. 5). These features extrinsic to the cells in the neoplastic clone generate the selection pressures that drive disease evolution and can significantly influence the clinical manifestations of MDS.

The hallmark of clonal hematopoiesis is the presence of a somatic genetic abnormality. Approximately 50 percent of patients with MDS will have a grossly abnormal karyotype, typically in the form of a partial or total chromosomal deletion. A fraction of the remaining cases with a "normal" karyotype will have cryptic cytogenetic abnormalities that can include small microdeletions and areas of copy number neutral loss of heterozygosity. This latter phenomenon occurs by mitotic recombination during cell division and results in acquired uniparental disomy (aUPD) where both copies of a large chromosomal segment appear to be derived from a single parent. The most common somatic genetic lesions in MDS are mutations of individual genes. More than 50 recurrently mutated genes have been identified with nearly all patients harboring one or more such mutations (Table 87-2).

The recurrent nature of many of these genetic events has helped identify molecular mechanisms associated with the development and

TABLE 87-2. Recurrently Mutated Myelodysplastic Syndrome Genes

	Mutated Gene	Frequency in MDS (%)	Prognostic Value	Additional Information
Splicing	<i>SF3B1</i>	20–30	Favorable	Strongly associated with ring sideroblasts
	<i>SRSF2</i>	10–15	Adverse	More frequent in CMML
	<i>U2AF1</i>	8–12	Adverse	Associated with del(20q)
	<i>ZRSR2</i>	5–10	?	
Epigenetic regulators	<i>TET2</i>	20–25	Neutral	More frequent in CMML
	<i>DNMT3A</i>	12–18	Adverse	
	<i>IDH1/IDH2</i>	<5	?	
	<i>ASXL1</i>	15–25	Adverse	More frequent in CMML
	<i>EZH2</i>	5–10	Adverse	More frequent in CMML
	<i>ATRX</i>	<2	?	Associated with ATMDS
	<i>KMD6A</i>	<2	?	
Transcription	<i>RUNX1</i>	10–15	Adverse	Familial in rare cases
	<i>GATA2</i>	<2	?	Commonly familial, rarely somatic
	<i>ETV6</i>	<5	Adverse	Rarely translocated in MDS
	<i>PHF6</i>	<2	?	
	<i>TP53</i>	8–12	Adverse	Associated with complex karyotypes
Cohesins	<i>STAG2</i>	5–10	?	
	<i>RAD21</i>	<5	?	
	<i>SMC3</i>	<2	?	
	<i>SMC1A</i>	<2	?	
Signaling	<i>NRAS/KRAS</i>	5–10	Adverse	More frequent in CMML
	<i>JAK2</i>	<5	Neutral	Enriched in RARS-t
	<i>CBL/CBLB</i>	<5	Adverse	More frequent in CMML
	<i>PTPN11</i>	<2	Adverse	More frequent in JMML, can be germline
Others	<i>GNAS/GNB1</i>	<2	?	G-protein signalling pathway
	<i>BRCC3</i>	<2	?	DNA repair pathway
	<i>PIGA</i>	<2	?	Cause of PNH clones
	<i>TERT/TERC</i>	<2	?	Can be germline
	<i>FANC</i> genes	<2	?	Typically germline

ATMDS, acquired thalassemia and myelodysplastic syndrome; CMML, chronic myelomonocytic leukemia; JMML, juvenile myelomonocytic leukemia; MDS, myelodysplastic syndrome; PNH, paroxysmal nocturnal hemoglobinuria; RARS-t, refractory anemia with ringed sideroblasts and thrombocytosis.

progression of MDS. Many of these lesions are associated with particular clinical phenotypes, including differences in disease manifestation, response to therapy, risk of AML transformation and overall survival. However, the use of genetic features to classify disease subtypes or personalize the care of individual patients is still rudimentary.

Cytogenetics

Chromosomal amplifications and translocations are relatively rare events in MDS compared with other hematologic malignancies. The most frequent chromosomal abnormalities seen in MDS, present in nearly half of all cases, are deletions of chromosomal segments or loss of entire chromosomes (monosomies). Several such lesions are recurrent and typically involve commonly deleted regions that are presumed to harbor one or more tumor-suppressor genes. Identifying individual gene drivers from these regions has been challenging because of the large amount of genomic territory that they encompass and the

likelihood that multiple gene losses cooperate to generate a disease-related phenotype.⁷³ However, MDS-related chromosomal abnormalities do have important clinical significance. For example, they can establish the presence of clonal hematopoiesis and in the appropriate context, can serve as presumptive evidence of MDS. Chromosomal abnormalities are key elements in the determination of prognosis and in the case of del(5q), can predict response to a particular treatment.

Del(5q) Deletion of the long arm of chromosome 5 is the most common karyotypic abnormality observed in MDS, occurring in 15 percent of cases, half of which have several other karyotype abnormalities. Studies examining the breakpoints of deletions across multiple patients have identified two commonly deleted regions (CDRs), one on 5q31.1 and the other at 5q32–33.3. Patients with del(5q) often have deletions that encompass both CDRs and can include proximal and distal chromosomal regions as well. Larger deletions that include more proximal genes, like *APC*, and more distal genes, like *NPM1*, are much more

Figure 87-2. Composite from marrow films of patient with the 5q⁻ syndrome. Characteristic hypolobulated megakaryocytes. **A.** Monolobed megakaryocyte. **B.** Bilobed megakaryocyte. Lobes connected by a nuclear bridge. **C.** Bilobed megakaryocyte. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

common in higher-risk MDS and AML where del(5q) is considered an adverse cytogenetic abnormality.⁷⁴ In MDS, smaller deletions that include the 5q32–33.3 region are associated with a more favorable prognosis and a marked sensitivity to treatment with lenalidomide. Such patients with a sole del(5q) abnormality and no excess blasts represent the only genetically defined MDS subtype in the WHO classification system. Some of these patients have characteristics of the “5q-minus syndrome,” which is characterized by dyserythropoietic anemia, micro-megakaryocytes with a preserved or elevated platelet count, female predominance, and lower risk of transformation to AML (Fig. 87–2).

The pathogenic mechanisms associated with del(5q) are not completely understood. Patients with del(5q) do not routinely carry point mutations on the remaining intact 5q arm, suggesting that the inactivation of classic tumor-suppressor genes is not responsible for the selective advantage associated with this lesion.⁷⁵ Instead, haploinsufficiency of genes lost in the deleted regions of chromosome 5q is largely responsible for the disease phenotype. For example, deletion of the ribosomal subunit gene *RPS14* creates dyserythropoiesis mediated by TP53 activation in differentiating erythroid cells analogous to that seen in congenital haploinsufficient ribosomopathies such as Diamond-Blackfan anemia.^{76–79} Isolated mutations or deletions of *RPS14* are not known to occur in MDS, suggesting that loss of this gene may influence the clinical presentation of MDS, but is not directly responsible for its development. Instead, codeleted genes must be drivers of transformation and several candidates have been proposed. These include microRNA (miRNA) genes 145 and 146a involved in the regulation of innate immune signaling and megakaryocyte differentiation,^{80–82} a mitochondrial heat shock protein *HSPA9*,^{83,84} and the zinc finger transcription factor *EGR1*.^{85,86} Several other genes, both in and out of the CDRs, have been implicated in the pathogenesis of MDS, including *MAML1*, a coactivator of the Notch signaling pathway, and the casein kinase gene, *CSNK1A1*.^{74,87}

A del(5q) is frequently found as one of several chromosomal abnormalities in patients with complex disease karyotypes (defined as three or more chromosomal abnormalities).⁸⁸ In this context, it is associated with an adverse prognosis, a poor response to lenalidomide, and frequently cooccurs with mutations of *TP53* or abnormalities of 17p where *TP53* resides.^{89–92} The association between del(5q) and *TP53* lesions occur more often than predicted by their independent incidences alone, suggesting pathogenic cooperation between these abnormalities.⁸⁶ Even in cases of isolated del(5q), small subclonal *TP53* mutations can be found in 15 to 20 percent of cases. These patients appear to have a greater than predicted risk of AML transformation and inferior responses to treatment with lenalidomide.^{93–95}

Monosomy 7 and Del(7q) Abnormalities of chromosome 7 are prognostically adverse lesions found in approximately 5 percent of MDS patients, often as part of a complex karyotype. Studies indicate that isolated monosomy 7 is a more adverse abnormality than isolated del(7q),

and both occur more frequently (~50 percent) in patients with prior exposure to alkylating agents.^{88,89,96} Several distinct CDRs have been reported, including regions 7q22, 7q32–34, and 7q36.^{97–99} The relative pathogenic contribution of deletions in each of these regions is not well understood.

Several recurrently mutated genes reside on chromosome 7q. The histone methyltransferase gene, *EZH2*, is located on 7q36 and is mutated in approximately 6 percent of MDS cases.^{100–102} In some patients, an *EZH2* mutation is accompanied by aUPD of 7q, but most *EZH2* mutant patients do not have –7 or del(7q) and most patients with these chromosomal lesions do not harbor *EZH2* mutations. In AML, the *MLL3* gene, also located at 7q36, has been proposed as a haploinsufficient driven of disease.¹⁰³ More proximal lies *CUX1*, a 7q22 gene implicated in MDS pathogenesis, which, like *EZH2*, is associated with a poor prognosis when mutated.¹⁰⁴ Inactivating mutations of *CUX1* tend to be heterozygous, suggesting that haploinsufficiency of this gene found in 7q22 might be a disease driver.¹⁰⁴ However, deletion in mice of the region syngeneic to 7q22 produced no discernable phenotype.¹⁰⁵

Trisomy 8 This is the only large-scale amplification frequently encountered in MDS, present in approximately 5 percent of cases. It is also highly nonspecific as it can occur in patients with myeloproliferative neoplasms, acute myeloid leukemia, and even aplastic anemia. Trisomy 8 is associated with an intermediate prognosis and is often acquired late in the disease course.¹⁰⁶ In some cases, it may be acquired in myeloid progenitors as opposed to more pluripotent CD34+CD38–CD90+ stem cells where the MDS-initiating clone is presumed to have developed.¹⁰⁷ How trisomy 8 leads to a selective growth advantage is not well understood. Progenitor cells with trisomy 8 express high levels of apoptosis-related genes and demonstrate dysregulation of immune response genes. Patients can harbor T cells that preferentially suppress trisomy 8 progenitor cells, particularly in response to overexpression of Wilms tumor 1 (*WT1*), which is upregulated in trisomy 8 cells.^{108,109} These findings may indicate selective pressure from the immune system on the disease clone with potential for collateral autoimmune suppression of normal hematopoiesis. Patients with trisomy 8 may benefit from immune suppression even if the aneuploid clone expands after response to treatment.¹¹⁰ Other autoimmune phenomena, such as Behçet disease, have been associated with trisomy 8 MDS.^{111–113}

Del(20q) This abnormality is another nonspecific, yet recurrent, chromosomal abnormality found in approximately 2 percent of MDS cases. As an isolated lesion it is associated with disease risk comparable to that of MDS patients with normal karyotypes.^{114,115} However, del(20q) may be acquired late in the course of disease, indicating clonal progression and a more adverse prognosis.¹¹⁶ A CDR on 20q has been defined, but no single gene has been identified as the pathogenic driver responsible for the recurrent selection of del(20q) clones in MDS.^{117,118} Candidate disease genes on 20q include *MYBL2*,^{119,120} which lies within

the CDR, and *ASXL1*,^{121,122} which lies outside the CDR and is mutated in a large fraction of MDS patients with or without del(20q). Patients with del(20q) appear more likely to have thrombocytopenia and are enriched in mutations of the splicing factor gene *U2AF1*.^{123,124}

Loss of Y The isolated loss of the Y chromosome is a rare recurrent abnormality observed in just over 2 percent of males with MDS. Like the del(20q) abnormality, -Y is associated with the same cytogenetic risk as patients with normal karyotypes.¹¹⁴ It has been argued that -Y is not a pathogenic lesion in MDS, but instead an age-related event that can occur in men without cytopenias.^{125,126} However, the presence of -Y as a somatic change is indicative of oligoclonal, if not monoclonal hematopoiesis and is therefore consistent with the diagnosis of MDS in a cytopenic patient. The larger the -Y clone, the more likely that evidence of an underlying neoplasm like MDS will be found.¹²⁷ Other genetic abnormalities, including mutations in ten-eleven translocation 2 (*TET2*) and *DNMT3A* have also been identified in elderly patients without cytopenias or other evidence of hematologic disease, yet these are considered pathogenic lesions in MDS. It is unclear if cytopenic patients with these markers of clonality, such as -Y, and insufficient evidence for an MDS diagnosis have comparable prognoses to patients with MDS.

Chromosome 17 Abnormalities Including del(17p) A small fraction of MDS patients will have an abnormality of chromosome 17, typically in the context of a complex karyotype. The *TP53* gene is located on 17p13.1 in a region that is recurrently deleted in those rare patients with either del(17p) or monosomy 17. One copy of 17p is typically retained in these cases suggesting that total loss of this region is not tolerated. However, the *TP53* gene on the remaining chromosome is often mutated leaving no wild-type protein. Patients with chromosome 17 abnormalities typically have a poor prognosis, particularly in the presence of a *TP53* mutation. The 17p region can be effectively lost in patients with an isochromosome 17p abnormality [i(17q)], occurring in just under 1 percent of cases. While these lesions predict a high rate of leukemic transformation, they are rarely associated with a coexisting *TP53* mutation.¹²⁸ Instead, they are often found to cooccur with mutations of *SETBP1*, abnormalities that are found more often in patients with both dysplastic and proliferative disease features.¹²⁹

Complex and Monosomal Karyotypes MDS karyotypes can be defined by the number of abnormalities present instead of focusing on the specific regions involved. Complex karyotypes are defined as having three or more cytogenetic abnormalities of any sort and are strongly associated with an adverse prognosis. In the International Prognosis Scoring System-Revised (IPSS-R), complex karyotypes are further separated in those with exactly three abnormalities and those with four or more, with the latter group having the highest associated disease risk. Monosomal karyotypes are defined as the loss of two or more entire chromosomes or the deletion of a single chromosome and the presence of another structural cytogenetic abnormality. Monosomal karyotypes are not necessarily complex and complex karyotypes are not necessarily monosomal, but in practice, there is substantial overlap between the two. The most frequent abnormalities seen in both monosomal and complex karyotypes involve chromosomes 5 and 7. The IPSS-R considers complex, but not monosomal karyotype as an independent risk factor and there has been ambiguity about whether complex versus monosomal karyotypes are better predictors of disease risk.¹³⁰⁻¹³³

Approximately 50 percent of patients with complex karyotypes have a concomitant *TP53* mutation and account for the majority of patients with mutations of this gene.¹³⁴ The incidence of *TP53* mutation is particularly high when the complex karyotype includes del(5q) as an associated abnormality.^{90,92,135} The adverse prognostic significance associated with complex karyotypes may be largely driven by their frequent association with *TP53* mutations.^{134,136} Complex karyotype MDS patients with intact *TP53* have a median overall survival comparable

to that of patients with noncomplex karyotypes, whereas those with a *TP53* mutation have a significantly shorter overall survival.¹³⁴ Patients with complex karyotypes on average have fewer mutations in genes other than *TP53*.

Somatic Mutations

Acquired mutations of individual genes are significantly more common than karyotypic abnormalities in patients with MDS. Chromosomal rearrangements detected by standard cytogenetic techniques are present in just under 50 percent of cases and more sensitive techniques with greater resolution can uncover small scale or copy number neutral abnormalities in an additional 25 percent. However, recurrent mutations of single genes can be identified in more than 80 percent of patients with MDS using targeted sequencing techniques and are likely to be found in all cases studied with whole-genome approaches. Unlike most chromosomal abnormalities that span large regions of the genome containing many candidate disease genes, most recurrent mutations affect the coding sequence of single genes, identifying them and their associated molecular pathways as pathogenic drivers. As of this writing, there are more than 50 genes known to be recurrently mutated in patients with MDS. A handful of these genes are mutated in a significant fraction of cases (10 to 35 percent) with several others in the 5 to 10 percent range. But the majority of recurrently mutated genes are found only rarely, encompassing fewer than 5 percent and, generally, less than 1 percent of cases. In some instances, these rare mutations occur in genes, like the splicing factors *U2AF2* or *SFI* that are in the same family as more commonly mutated genes. In other cases, the infrequently mutated genes, like *GNAS* and *GNB1*, represent their own molecular pathways suggesting that clonal myelodysplasia is a phenotypic manifestation that can be caused by a variety of pathogenic mechanisms. The large number of potentially mutated genes and multitude of ways in which they can be combined result in a staggering number of possible genetic profiles. The apparent cooperativity between some lesions and the mutual exclusivity of other limits this variability to some extent, but still allows for tremendous complexity at the genetic level. As a determinant of disease phenotypes, this variation likely explains much of the clinical heterogeneity seen in patients with MDS.¹³⁷

Not all somatic mutations have equal pathogenic or clinical significance. Any patient with clonal hematopoiesis will harbor a large number of acquired mutations throughout their genome. The vast majority of these are incidental mutations acquired over the lifetime of the particular stem cell that eventually grew to clonally dominate hematopoiesis, most of which occurred prior to its expansion. These preceding mutations are not related to the development of disease and are distributed randomly, typically in noncoding and nonconserved areas of the genome, suggesting that they have no positive or negative selective significance. Collectively, these nonrecurrent mutations without pathogenic significance are described as *passenger mutations* because their presence in the expanded clone is only because they happen to coexist with much rarer *driver mutations*, responsible for the clonal outgrowth and the eventual development of disease. Driver mutations are typically recurrent and predicted to have pathogenic consequences like the alteration of a protein coding sequence or changes in the expression of one or more disease-related genes. Driver mutations can be early transformative events, in which case they would be found in every subsequent disease cell derived from that clone, or they can be late events, often associated with progressive disease. Some genes, like splicing factors, are predominantly mutated early and are typically found as part of the dominant disease clone. Other genes, like *NRAS* and *SETBP1*, are typically secondary mutations acquired later in the disease course and are often found as emergent subclones that may expand in size during progression.^{90,138,139}

Somatic mutations can have important clinical implications for patients with MDS and the physicians who treat them, but their interpretation can be challenging. Several factors may influence the clinical significance or recurrent gene mutations. These include the type of mutation present (e.g., missense, nonsense, splicing, or frameshift), the configuration of the mutations (e.g., homozygous, heterozygous, hemizygous, or compound heterozygous), the fraction of disease cells that contain the mutations (i.e., presence in the dominant clone versus a subclone), the mutations that coexist in that patient and if these mutations are in the same clone or a sister clone, and whether mutations add information above and beyond what can be learned by looking at more readily accessible clinical variables like age, blast proportion, and blood counts. Despite these complexities, there are several scenarios in which specific gene mutations can inform the clinical care of patients with clonal cytopenias like MDS.

Splicing Factors The most frequently mutated class of genes in patients with MDS encode splicing factor proteins involved in the excision of introns and the ligation of exons from maturing pre-mRNA strands. There are at least eight recurrently mutated splicing factor genes identified in MDS and nearly two-thirds of patients will carry at mutation of a member of this gene family.¹⁴⁰ Splicing factor mutations are largely mutually exclusive. Patients with one splicing factor mutation rarely have a mutation in another suggesting that these lesions are either not tolerated in combination or, more likely, have a common mechanism of action. Thus, a disease stem cell that acquires a second splicing factor mutation would gain no selective advantage and may well develop a selective disadvantage as a consequence of that second mutation. Despite a presumed common pathogenic role, patients with mutations in different splicing factor genes often have very disparate clinical phenotypes.¹³⁷ This is partially because disease manifestations are often determined by the effect of driver mutations in the differentiating progeny of disease stem cells. Some may induce profound dysplasia while others promote lineage-specific proliferation, for example. Different splicing factor mutations may also be associated with certain clinical phenotypes because of their distinct patterns of comutation with other MDS-related genes.^{90,135,141} These comutations may, for example, drive the disease manifestations or prognosis. If there is a common mechanism by which splicing factor mutations drive the development of MDS, it is not yet well understood. These mutations are not unique to MDS as they can be found in other malignancies, including some solid tumors, where they occur at low frequency. Several studies have identified changes in splicing efficiency and gene expression associated with splicing factor mutations, but these effects are subtle and do not readily identify a downstream pathogenic mechanism.

SF3B1 is the most frequently mutated splicing factor gene and encodes the U2 small nuclear riboprotein complex (snRNP) subunit responsible for branch site recognition. Mutations of *SF3B1* are present in 20 to 30 percent of patients and are the only somatic mutations associated with a favorable prognosis. The pattern of mutation of *SF3B1* suggests an oncogenic gain or change of function for its encoded protein. Mutations are always heterozygous to an intact wild-type allele and are relatively conservative missense substitutions at very specific hotspots.¹⁴² These mutations occur in the middle of several consecutive HEAT protein domains of which the K700E substitution is the most common, accounting for more than half of all mutations of *SF3B1*. Clinically, mutations of *SF3B1* are very tightly associated with the presence of ring sideroblasts (Fig. 87-3). More than 85 percent of patients with RARS or RARS-t will have an *SF3B1* mutation. These mutations are common in patients with other subtypes of MDS, like refractory cytopenia with multilineage dysplasia, when ring sideroblasts are present. *SF3B1* mutations have been associated with a more favorable prognosis but it is unclear if this is independent of other known risk factors.

For example, *SF3B1* mutant patients are less likely to have cytogenetic abnormalities, including complex karyotypes, and are less likely to have other mutations in genes associated with a poor prognosis. Only mutations in *DNMT3A* cooccur with *SF3B1* mutations more often than would be predicted by chance alone, suggesting a cooperative interaction between these lesions.^{90,141} *SF3B1*-mutant MDS may represent its own nosologic entity based on its common clinical features and patterns of comutation regardless of WHO subtype.¹³⁷ Mutation of *SF3B1* is also common in chronic lymphocytic leukemia (CLL) where it occurs in 15 to 20 percent of cases (Chap. 92). However, in contrast with MDS, these mutations in CLL are often subclonal or acquired after initial diagnosis and are associated with treatment resistance and a poor prognosis.¹⁴³ *SF3B1* hotspot mutations are enriched in uveal melanoma and can be found in various other solid tumors at lower frequency, demonstrating that it is not a tissue-specific oncogene.^{144,145}

SRSF2 is the second most frequently mutated splicing factor, present in 10 to 15 percent of MDS and 40 percent of CMML cases. It encodes a serine-arginine-rich protein that interacts with the U2 and U1 components of the spliceosome. The predominant mutation in this gene is a missense substitution of the proline at codon 95, although small insertions and deletions at this position that conserve the reading frame have also been reported. As with *SF3B1*, mutations are heterozygous to a wild-type allele suggesting a very specific gain or change of function. *SRSF2* mutations cooccur with mutations of several other genes, such as *TET2*, *ASXL1*, *CUX1*, *IDH2*, and *STAG2*, many of which are also enriched in patients with CMML.⁹⁰ *SRSF2* mutations are generally associated with an inferior prognosis.

U2AF1 is the third frequently mutated splicing factor, present in approximately 12 percent of patients. Like *SF3B1* and *SRSF2*, mutations are heterozygous to a wild-type allele and occur as missense mutations at fixed hotspots. The affected amino acids at codons 34 and 157 are in the zinc finger DNA-binding regions of the protein.^{140,146} *U2AF1* encodes an auxiliary factor in the U2 spliceosome responsible for the recognition of the AG splice acceptor dinucleotide at the 3' end of introns. *U2AF1* mutations appear to affect splicing in reporter assays and transgenic mouse models, but how these changes confer a selective advantage to mutant cells is not well understood.^{140,147} Clinically, *U2AF1* mutations are associated with shorter overall survival and increased risk of transformation to acute leukemia.¹⁴⁸ Patient with del(20q) may be enriched for *U2AF1* mutations.¹²³ Several additional splicing factors can be mutated in MDS, including *ZRSR2*, *SF1*, and *U2AF2*.¹⁴⁰ Most of these appear to harbor loss-of-function mutations, but remain largely exclusive of mutations in other splicing factors, suggesting a shared pathogenic mechanism.

Epigenetic Regulators

Epigenetic changes, defined as heritable covalent modifications of chromatin that do not alter the DNA base sequence, play a role in the development of MDS and other malignancies. Methylation of cytosine residues in DNA represents one form epigenetic modification that can be dysregulated in MDS. Specifically, patients may have global DNA hypomethylation, but will demonstrate hypermethylation in specific regions such as the CpG islands (areas rich in CG dinucleotides) found at or near gene promoters. These epigenetic marks have been associated with a closed chromatin configuration and relative silencing of nearby genes. The simplistic explanation is that aberrant DNA methylation leads to the pathogenic silencing of critical tumor-suppressor genes and is, therefore, oncogenic. Hypomethylating agents, which are inhibitors of the DNA methyltransferases that catalyze cytosine methylation, have been presumed to undo the silencing of these tumor-suppressor genes leading to therapeutic benefit. However, it is not certain that hypomethylating agents work in this way. It is known that several genes involved

Figure 87-3. Blood and marrow films from patients with clonal cytopenias (myelodysplastic syndromes). **A.** Blood film. Anisocytosis. Poikilocytosis with occasional fragmented cells. Marked anisochromia with marked hypochromia, mild hypochromia and normochromic cells. **B.** Blood film. Marked anisocytosis. Mild anisochromia. Poikilocytes with occasional fragmented cells and oval and elliptical cells. Two polychromatophilic macrocytes. **C.** Blood film. Striking anisocytosis with giant macrocytes and microcytes. Poikilocytes with tiny red cell fragment and elliptocyte. **D.** Blood film. Mild anisocytosis. Ovalocytes and elliptocytes. Dacryocyte. Hyposegmented neutrophil with poor granulation. **E.** Blood film. Marked anisocytosis (macrocytes and microcytes). Ovalocytes and elliptocytes. Acquired Pelger-Hüet nuclear anomaly (classic pince-nez shape) in neutrophil. **F.** Blood film. Mild anisocytosis. Abnormal neutrophil with ring nucleus. **G.** Blood film. Anisochromia. Stomatocytes. Abnormal neutrophil nuclei with hyperlobulation and hyperchromatic staining. Note abnormal elongated nuclear bridge in neutrophil on left. **H.** Blood film. Atypical platelets. Two macrothrombocytes with excess cytoplasm and atypical central granules. Anisocytosis (conspicuous microcytes). Anisochromia (conspicuous hypochromic cells). Poikilocytosis with occasional fragmented red cells. **I.** Marrow film. Wright stain. Trilobed megakaryocyte. Wright stain. Macroerythroblasts. **J.** Marrow films. Prussian blue stain. in the regulation of DNA methylation are mutated in a large proportion of patients with MDS as are genes involved in the regulation of DNA-associated histone modifications. Together these epigenetic regulators form the second largest class of genes mutated in MDS. Unlike the splicing factors, most mutated epigenetic regulator genes are not exclusive of each other and frequently coexist.

DNMT3A This gene encodes a *de novo* DNA methyltransferase and is the only DNA methyltransferase gene frequently mutated in MDS. It

is mutated in approximately 15 percent of cases in a pattern that suggests a resultant loss of function.^{149,150} Mutations can include frameshifts and premature stop codons, as well as missense mutations spread throughout the length of the gene. The one exception is a high frequency of missense mutations at the hotspot codon 882, which have been shown to impair catalytic activity.¹⁵¹ As with nearly all of the genes mutated in MDS, *DNMT3A* mutations are not unique to these disorders and can be found in AML, myeloproliferative neoplasms (MPNs), and even

lymphoid malignancies. Mouse models of *Dnmt3a* loss demonstrate hematopoietic stem cell expansion with impaired differentiation. Dysplasia and leukemic transformation do not occur in this mouse model, suggesting that *DNMT3A* loss is sufficient to provide a stem cell growth advantage, but insufficient to cause an MDS or AML disease phenotype. This is consistent with the finding that somatic *DNMT3A* mutations can be found in persons without cytopenias or other elements of disease.¹⁵² Therefore, cooperating mutations or microenvironmental changes are likely necessary determinants of disease. Mutations of *DNMT3A* are found most often in patients with normal karyotypes and cooccur with *SF3B1* mutations more often than expected by chance.^{90,153} *DNMT3A* mutations in MDS patients appear to confer a poor prognosis.^{150,154}

TET2 The second member of the ten-eleven translocation gene family, *TET2*, is among the most frequently mutated MDS genes present in 20 to 30 percent of cases, and in more than 40 percent of patients with CMML. It encodes a methylcytosine oxygenase that converts 5-methylcytosine (5-mC) in to 5-hydroxymethylcytosine (5-hmC) using iron and α -ketoglutarate (α KG) as cofactors.¹⁵⁵ The *TET2* enzyme can further oxidize 5-hmC into 5-formyl- and 5-carboxycytosine (5-fC and 5-caC, respectively).¹⁵⁶ This may represent a mechanism for the active demethylation of cytosines as 5-caC can be decarboxylated to form cytosine or treated as a mismatched nucleotide by the base excision DNA repair pathway. Mutations in *TET2* are typically truncating or clustered in regions that encode catalytic domains indicating an associated loss of function. Mutations are often compound heterozygous or in areas of aUPD on chromosome 4q, resulting in no viable wild-type allele.¹⁵⁷ Patients with *TET2* mutations demonstrate increased global DNA methylation, lower levels of 5-hmC and are more likely to have an elevated monocyte count.^{158,159} Mouse models of *Tet2* loss show a similar phenotype with increased stem cell and progenitor numbers, impaired differentiation, and myeloid skewing of hematopoiesis.^{160–163} As with *DNMT3A*, *TET2* mutations can also be found in various myeloid and lymphoid malignancies, as well as in persons with clonal hematopoiesis and no hematologic disease.¹⁵² Clinically, *TET2* mutations are not likely drivers of MDS prognosis and have variably been associated with favorable, neutral, or poor outcomes.^{134,164,165}

IDH1 and IDH2 Only mutations in the isocitrate dehydrogenase genes 1 and 2 (*IDH1* and *IDH2*, respectively) are exclusive of *TET2* mutations, suggesting that they share a common pathogenic mechanism. Mutations of these *IDH* genes are common in AML and gliomas, but relatively rare in MDS, comprising approximately 5 percent of cases. Oncogenic *IDH* mutations are always heterozygous missense mutations of specific codons that result in an important change of enzyme function. Instead of converting isocitrate to α KG while generating an nicotinamide adenine dinucleotide phosphate (NADPH) from nicotinamide adenine dinucleotide phosphate–positive (NADP⁺), the mutant forms of *IDH1* and *IDH2* catalyze the conversion of α KG to 2-hydroxyglutarate (2-HG) while oxidizing NADPH to NADP⁺.¹⁶⁶ The 2-HG produced is considered an *oncometabolite*, which can interfere with the activity of α KG-dependent oxygenases, including the *TET* family of genes, prolyl hydroxylases, collagen synthesis enzymes, and various histone demethylases.^{167–171} Mouse models of leukemic *IDH* mutations in the hematopoietic system share several features with *Tet2*-null mice, including global DNA hypermethylation and increased proportions of early progenitor cells.¹⁷² In MDS, the clinical significance of *IDH* mutations is mixed and may depend on the nature of the mutation.¹⁷³ Inhibitors of the neomorphic activity of mutant *IDH* enzymes represent promising therapies as the effects of 2-HG exposure appear to be reversible.¹⁷⁴

EZH2 and Other Rare Mutations Several regulators of histone modifications are recurrently mutated in MDS and MDS/MPN disorders. These include the histone methylase *EZH2*, which encodes the catalytic subunit of the protein-repressive complex 2 (PRC2) responsible

for methylating lysine 27 on histone 3 (H3K27). The H3K27 methyl mark is associated with closed chromatin and reduced expression of neighboring genes. Loss-of-function mutations in *EZH2*, present in 6 percent of MDS, are associated with a poor prognosis in a manner that is independent of common prognostic scoring systems.^{100,102,134} This is largely because *EZH2* mutations are not strongly associated with adverse clinical features such as increased proportions of blasts, complex karyotypes, or severe cytopenias.¹⁴¹ Other members of the PRC2, *EED* and *SUZ12*, can also be mutated in very rare cases of MDS.¹⁷⁵ Loss of PRC2 activity may, in part, promote the development and progression of MDS through derepression of *HOX* genes, which are often upregulated or aberrantly expressed in self-renewing leukemic cells.¹⁷⁶

ASXL1 *ASXL1* is a frequently mutated MDS gene believed to be an epigenetic “reader” capable of binding to specific histone marks through its highly conserved PHD domain. Mutations of *ASXL1*, present in 20 percent of MDS and 40 percent of CMML, are largely heterozygous truncating mutations in its terminal exon. These lesions are associated with a poorer prognosis than predicted by common clinical assessments alone.^{134,177,178} *ASXL1* interacts directly with the PRC2, directing the activity of *EZH2* to specific genomic regions. Loss of *ASXL1* is associated with absent H3K27 trimethylation at the *HOXA* gene cluster.¹⁷⁹ *ASXL1* mutations may cooperate with mutations in various other genes such as *SRSF2*, *U2AF1*, *TET2*, and *NRAS*, as mutations of these genes cooccur more often than predicted by chance alone.⁹⁰ In patients with germline mutations of the transcription factor *GATA2*, somatic *ASXL1* mutation appears to be a common concurrent event at the time of MDS or AML development.^{180,181}

Mutated Transcription Factor Genes Mutations of hematopoietic transcription factors in MDS are typically somatic events, but can be present in the germline either as inherited or spontaneous congenital events in rare cases. *RUNX1* is the most frequently mutated transcription factor in MDS. This gene, previously known as *AML1*, encodes the alpha core binding transcription factor subunit and is altered in many myeloid and lymphoid malignancies. In the acute leukemias, *RUNX1* is a frequent translocation partner with other genes such as *RUNX1T1* (previously known as *ETO*) as part of t(8;21) in AML and with *ETV6* in (previously known as *TEL*) as part of t(12;21) in acute lymphocytic leukemia (ALL). *RUNX1* is mutated in 10 to 15 percent of MDS where it is associated with a poor prognosis, increased rates of leukemic progression, and thrombocytopenia.^{134,135} Mutations can affect one or both alleles and often involve the DNA-binding *RUNT* domain or truncate the more distal protein interaction domain.^{182–184} Persons with congenital mutations of *RUNX1* can have an autosomal dominant FPD-AML characterized by numerical and functional platelet abnormalities that precede transformation to AML by many years. Penetrance of FPD-AML is variable and the long latency to transform indicates the need to acquire cooperating mutations.^{43,185,186} Mutations of *C/EBPA* can also cause familial propensity for AML in an autosomal dominant fashion, but are very rare mutations in MDS as somatic or inherited abnormalities.¹⁸⁷

ETV6 The ets-like transcription factor 6, *ETV6*, is frequently rearranged, deleted, or mutated in hematologic malignancies. In MDS, *ETV6* mutations are present in approximately 5 percent of cases, where they are independently associated with shorter overall survival and progressive disease.^{134,188}

GATA2 Germline *GATA2* mutations are responsible for several different congenital syndromes with overlapping features including a predisposition to marrow failure, MDS, and AML.^{53,58,189,190} Familial *GATA2* mutations can manifest as the monoMAC syndrome, characterized by monocytopenia and mycobacterial infections; Emberger syndrome, characterized by congenital lymphedema and risk of developing MDS; or as a deficiency in monocytes, B and natural killer (NK) lymphocytes, and dendritic cells.¹⁹¹ Patients can also have sensorineural

hearing loss, alveolar proteinosis, and dermatologic abnormalities. Penetrance is variable and patients with one syndrome often will have features of the others. Several cases of congenital neutropenia or apparently *de novo* MDS in childhood have been ascribed to germline *GATA2* mutations in the absence of other syndromic features.⁵⁶ However, unlike *RUNX1* and *ETV6* mutations, mutations of *GATA2* are only very rarely somatic events.

TP53 *TP53* mutations are present in approximately 10 percent of MDS cases and are strongly associated with a poor prognosis independent of other risk factors.¹³⁴ Most patients with mutations of *TP53* will have a complex karyotype and tend to have fewer point mutations in other typical MDS genes. Patients with del(5q) are more likely to have a *TP53* mutation, particularly in the context of a complex karyotype, suggesting pathologic synergy between these abnormalities.^{90,135} Unfortunately, treatment with either hypomethylating agents or allogeneic hematopoietic stem cell transplantation (AH SCT) fails to rescue the adverse outcomes associated with mutations of *TP53*.^{192–194}

Mutations of Growth Factor Signaling Pathway Genes Mutations of receptor tyrosine kinase genes are common in proliferative myeloid disorders, such as *FLT3* in AML, *KIT* in mast cell neoplasms, and of the receptor gene *MPL* in MPN, but only rarely present in MDS. Instead, several genes encoding downstream signaling proteins are more frequently mutated in MDS. Many of these mutations are associated with proliferative features and often presage more advanced disease or progression to secondary AML. Signaling pathway mutations are typically mutually exclusive, indicating some redundancy in function and are more common in CMML where monocytic proliferation is a defining feature. In MDS, these mutations are frequently present in minor disease subclones demonstrating that they were acquired later in the course of disease. Despite their small abundance, signaling pathway mutations are often predictive of transformation and shorter overall survival.^{195,196}

Activating *NRAS* mutations are the most common in this category, but found in only 5 to 10 percent of cases. These lesions are associated with excess blasts and thrombocytopenia.¹³⁴ The E3-ubiquitin ligase CBL regulates tyrosine kinase receptors by marking them for degradation.¹⁹⁷ *CBL* mutations that impair this function are found in 3 to 5 percent of MDS cases and are associated with monocytosis.^{198,199} Somatic mutations of the tyrosine phosphatase encoded by *PTPN11* are seen in very rare cases of MDS and CMML, but are more common in juvenile myelomonocytic leukemia where mutations are often germline lesions and part of a congenital syndrome.^{200,201} Other genes that are very rarely but recurrently mutated in this pathway include *KRAS*, *BRAF*, *KIT*, and *CBLB*.

The V617F mutation in *JAK2* is found in 3 to 5 percent of patients with MDS and is exclusive of other signaling pathway mutations. However, it does not appear to have prognostic significance and is not associated with an increased red cell mass as it is in polycythemia vera.¹³⁴ This is likely because *JAK2* mutations in MDS are often late events and coexist with other genetic lesions that result in dysplasia, limiting the production of mature red cells. *JAK2* mutations are enriched in patients with RARS-t, and MDS/MPN overlap disease.²⁰² Half of these patients will carry a *JAK2*^{V617F} mutation. This is roughly the same proportion observed in patients with essential thrombocythemia (ET); leading to the speculation that RARS-t is a “frustrated” form of ET with dysplasia caused by the other mutations like those in *SF3B1* associated with ring sideroblasts.²⁰³ Approximately 5 percent of RARS-t patients will instead have a mutation in *MPL*, which is similar to the rate at which it occurs in ET as well (Chap. 85).

Cohesin Genes *RAD21*, *STAG2*, *SMC3*, and *SMC1A* are recurrently mutated members of the cohesin gene family. Collectively, they are mutated in approximately 10 percent of MDS cases, where they may

be associated with a poor prognosis.^{204,205} Cohesins bind to chromatin in a large complex believed to protect chromatid structure and shepherd chromosomes through mitosis. However, mutations of this complex are not associated with chromosomal instability in MDS. Instead, they identify patients more likely to have multilineage dysplasia.¹³⁷ The pathogenic mechanism of cohesin mutations in myeloid disorders remains poorly understood.

Other Classes of Mutated Genes Several other classes of genes are recurrently mutated in MDS, including DNA repair enzymes, RNA helicases, and members of the G-protein signaling pathway. The long tail of recurrent, but rarely mutated genes in MDS suggest that dysplasia is common final phenotype that can be caused by a variety of different pathogenic abnormalities, each with their own degree of severity, risk of progression, and variation in clinical presentation.

Microenvironmental Changes

Not all abnormalities identified in the marrow of patients with MDS are intrinsic to the clonal cells that give rise to the disease. There are many microenvironmental alterations that contribute to the distorted hematopoiesis that is characteristic of MDS. Marrow cytokine levels are altered in many cases. Circulating monocyte colony-stimulating factor (M-CSF) is increased in some patients with MDS, AML, and other hematologic malignancies.²⁰⁶ Interleukin (IL)-1 α and granulocyte-macrophage colony-stimulating factor (GM-CSF) levels have been undetectable in most patients. IL-6, granulocyte colony-stimulating factor (G-CSF), and erythropoietin concentrations have been variable. Tumor necrosis factor (TNF) concentrations have been inversely related to hematocrit.²⁰⁷ Stem cell factor, a multilineage hematopoietin, can be decreased in some patients.²⁰⁸

The neoplastic clone may induce activation of the innate immune system. Loss of miRNAs 145 and 146a from the CDR of chromosome 5q lead upregulation of toll-interleukin receptor adaptor protein (TIRAP) and tumor receptor-associated factor (TRAF) 6, members of the innate immune signaling pathway downstream of toll-like receptors.⁸⁰ Toll-like receptors may also be targets of somatic mutations leading to nuclear factor (NF)- κ B activation.²⁰⁹ Myeloid-derived suppressor cells, distinct from the clonal disease cells, may contribute to the altered cytokine microenvironment and promote disordered hematopoiesis.²¹⁰

Dysregulation of the adaptive immune system has also been described. CD40 expression on monocytes is increased, as is CD40L on T lymphocytes, and has been postulated as being a contributing factor to hematopoietic failure in some patients with less-advanced disease.⁸⁶ Many patients with MDS will demonstrate oligoclonal T-cell expansion with skewing of V β -subunits of the T-cell receptor similar to that seen in aplastic anemia.²¹¹ In patients that respond to immunosuppressive therapy, this oligoclonality of T cells may be normalized.²¹² There likely exists substantial pathogenic overlap between aplastic anemia and hypoplastic MDS. Immunosuppression can improve hematopoiesis in both disorders, both can exhibit paroxysmal nocturnal hemoglobinuria (PNH) clones, and both can have somatic mutations typical of MDS (Chap. 35).²¹³ Large granular lymphocyte (LGL) leukemia can cause immune cytopenias and LGL cells are present in some cases of both MDS and aplastic anemia. These lymphocytes can carry somatic mutations of *STAT3* indicating their clonal nature, distinct from the MDS clone.²¹⁴

CLINICAL FEATURES

SYMPTOMS AND SIGNS

Patients can be asymptomatic or, if anemia is more severe, can have pallor, weakness, loss of a sense of well-being, and exertional dyspnea.²¹⁵ Fatigue is a major complaint that is not necessarily related to degree

of anemia.²¹⁶ A small proportion of patients have infections related to severe neutropenia or neutrophil dysfunction, or hemorrhage related to severe thrombocytopenia or platelet dysfunction at the time of diagnosis. Patients with severe depressions of neutrophil and platelet counts at diagnosis usually have more advanced disease. Rarely, patients have fever unrelated to infection. Arthralgia is the initial complaint in some patients. The presentation, infrequently, can mimic a rheumatologic disease. Hepatomegaly or splenomegaly occurs in approximately 5 or 10 percent of patients, respectively.

LABORATORY FEATURES

BLOOD

Red Cells

Anemia is present in greater than 85 percent of patients.^{217–219} In approximately 4 percent of patients, the anemia results from erythroid aplasia.²²⁰ Mean cell volume often is increased. Red cell shape abnormalities include oval, elliptical, teardrop, spherical, and fragmented cells. Red cell findings occur in a spectrum. Some patients have only slight anisocytosis. Elliptical red cells sometimes dominate. Basophilic stippling of red cells occurs (see Fig. 87–3). Nucleated red cells are seen in the blood film in approximately 10 percent of cases. Reticulocyte counts are low for the degree of anemia. Other abnormalities of red cells occur, such as an increased proportion of hemoglobin F²²¹ and decreased red cell enzyme activities, especially acquired pyruvate kinase deficiency.²²² Hemolysis has occurred in some patients with the latter deficiency. Enhanced sensitivity of membranes to complement²²³ and modification of red cell blood group antigens may be observed.²²⁴ Acquired hemoglobin H disease, a rare superimposition, results in red cell morphology similar to thalassemia (microcytosis, anisocytosis, basophilic stippling, poikilocytosis with target cells, fragmented cells, and teardrop cells). Intracellular precipitates of β -chain tetramers (identified by crystal violet stain) reflect an acquired decrease in the rate of α -chain synthesis in erythroblasts.^{225–227} The decrease in α -globin-chain synthesis is profound, involves each of the four α -chain loci, and results from a transcription abnormality. No gross alterations in genes (e.g., insertions, deletions) are seen in these cases.²²⁷ Acquired hemoglobin H disease in this setting has been dubbed the α -thalassemia–myelodysplastic syndrome and is the consequence of acquired mutations in *ATRX*, the gene associated with the X-linked α -thalassemia/mental retardation (*ATR-X*) syndrome.²²⁵

Granulocytes and Monocytes

Neutropenia is present in approximately 50 percent of patients at the time of diagnosis.²²⁸ The proportion of monocytes often is increased, and monocytosis per se can be the dominant manifestation of the hematopoietic abnormality for months or years.^{229–231} Morphologic abnormalities of neutrophils can occur, sometimes resulting in the acquired Pelger-Huët anomaly (see Fig. 87–3E). In this condition, neutrophils have very condensed chromatin and unilobed or bilobed nuclei that often have a pince-nez shape. The neutrophils may be in the process of apoptosis.²³² Ring-shaped nuclei also can occur in neutrophils (see Fig. 87–3F).²³³ Neutrophil alkaline phosphatase activity is decreased in some patients.²³⁴ Expression of normal surface antigens on neutrophils and monocytes is decreased, and abnormal surface antigen expression occurs in some cases.²³⁵ Defective primary granules of abnormal size and shape with decreased myeloperoxidase content can be present.²³⁶ Specific neutrophil granules are often decreased in number, producing hypogranular cells.²³⁷ Neutrophil granule membranes frequently are deficient in glycoproteins.²³⁸ Chemotactic, phagocytic,

and bactericidal capability may be impaired.^{239–241} Formyl-leucyl-methionyl-phenylamine receptor signaling and actin polymerization can be abnormal.^{242,243} Muramidase (lysozyme) activity in blood and urine may be increased, reflecting granulocytic hyperplasia, heightened monocytopoiesis, and monocyte turnover.

Platelets

Approximately 25 to 50 percent of patients have mild to moderate thrombocytopenia at the time of diagnosis.^{228,234} Mild thrombocytosis also can occur.^{228,234} Platelets may be abnormally large, have poor granulation, or have large, fused central granules (see Fig. 87–3H).^{244,245} Abnormal platelet function can contribute to a prolonged closure time, easy bruising, or exaggerated bleeding. Decreased platelet aggregation in response to collagen or epinephrine is a frequent functional abnormality.²⁴⁶

Lymphocytes

Patients with clonal hemopathies may have immunologic deficiencies, such as a decrease in NK cells in the blood but no decrease in LGLs,^{247–250} a decrease in helper T lymphocytes,²⁴⁸ and a decrease in Epstein-Barr virus receptors on B lymphocytes.^{248–251} Antibody-dependent cellular cytotoxicity is normal.²⁴⁸ Thymidine incorporation after mitogenic stimulation^{252,253} and colony growth of T lymphocytes are decreased.²⁴⁸ Lymphocytes may have an increased sensitivity to irradiation.²⁵³ The defects in lymphoid cells could reflect the level of the somatic mutation in a primitive multipotential cell in different cases. Intrinsic, rather than secondary, alterations in lymphocytes are determined by whether no lymphocytes are generated from the clone, B cells are part of the clone, or B and T cells are part of the clone.²⁵⁴ Clonally derived, CD8+CD57+CD244+CD28–CD62L– T lymphocytes are present in marrow and to a lesser extent in blood in approximately 50 percent of patients, independent of type of MDS, age, and sex of the patient,^{255,256} as are NK and B cells (see “Pathogenesis” above).²⁵⁶

PLASMA ABNORMALITIES

Serum iron, transferrin, and ferritin levels may be elevated as a result of anemia and the shift of erythron iron to plasma and storage compartments. Lactic dehydrogenase and uric acid concentrations can be increased as a result of ineffective hematopoiesis and a high death fraction of maturing marrow precursors. Monoclonal gammopathy, polyclonal hypergammaglobulinemia, and hypogammaglobulinemia each occur with increased frequency.^{257,258} The frequency of autoantibodies was increased in one report²⁴⁰ but not in another.²⁵⁸ β_2 -Microglobulin serum levels are increased in proportion to the prognostic category of the disease.²⁵⁹

MARROW

Cellularity

Marrow cellularity usually is normal or increased.^{234,260,261} Cellularity is decreased in approximately 15 percent of cases²⁶⁰ and may simulate hypoplastic or aplastic anemia.²⁶² However, islands of dysmorphic cells, especially atypical megakaryocytes, usually are present (see Fig. 87–3L). An increased proportion of blast cells in this setting suggests hypoplastic myelogenous leukemia (Chap. 88).

Erythropoiesis

Erythroid hyperplasia is frequent. Very large or small erythroblasts, nuclear fragmentation, stippled erythroblasts, and poor hemoglobinization may be seen.^{234,260,261} Proerythroblasts may be present in excess, and the marrow may lack normal clusters or islets of erythroblasts.

Erythroblasts may resemble megaloblasts that have nuclear-cytoplasmic maturation asynchrony, nuclear fragmentation, or cytoplasmic nuclear remnants. The asynchrony is manifest morphologically by nuclear immaturity with prominent euchromatin in cells with more advanced cytoplasmic maturation. This pattern is referred to as *megaloblastoid erythropoiesis* (see Fig. 87–3I). Erythroid aplasia seen in occasional cases results in a hypocellular marrow.²²⁰

Pathologic sideroblasts may be identified when the marrow is stained with Prussian blue stain (see Fig. 87–3J and K). The sideroblasts include erythroblasts with an increased number and size of siderosomes (cytoplasmic ferritin-containing vacuoles), referred to as *intermediate sideroblasts*, or erythroblasts with mitochondrial iron aggregates that take the form of a partial or complete circumnuclear ring of iron globules, referred to as *ring sideroblasts*. Macrophage iron often is increased. Ring sideroblasts are uncommon or present only in very low proportions in clonal myeloid disorders other than RA.

Granulopoiesis

Granulocytic hyperplasia is frequent.^{228,234,260,261} Marrow monocytes may be increased in number. Abnormalities of granulocytes include hypogranulation, a monocytoid appearance of neutrophilic granulocytes, and the acquired Pelger-Huët nuclear abnormality of neutrophils.^{232,263} Progranulocytes and myelocytes may be increased. The proportion of blast cells is not increased in clonal hemopathies that are categorized as RA (defined as <5 percent); although, a blast percentage of greater than 2 percent should be considered oligoblastic leukemia and is recognized as having prognostic risk. Marrow biopsy may show abnormal localized immature precursors (ALIPs),^{264,265} which are clusters of immature myeloid, CD34+ cells²⁶⁶ located centrally rather than subjacent to the endosteum. These clusters of atypical cells are present in almost all cases of oligoblastic leukemia where blast cells compose 3 percent or more of nucleated marrow cells (RAEBs) and in approximately one-third of patients with RA, suggesting these patients have a disorder closely approaching oligoblastic leukemia. Patients with this abnormality are more prone to develop overt AML. Vascular endothelial growth factor and its receptor are expressed on cells forming ALIP clusters and have been proposed as providing an autocrine loop to promote leukemia progenitor cell formation.²⁶⁷ The number of plasma cells may be slightly increased. Marrow basophilia or eosinophilia occurs in approximately one in seven patients and is associated with a higher probability of evolution to AML.²⁶⁸

Thrombopoiesis

Megakaryocytes are present in normal or increased numbers.^{234,260,261} Micromegakaryocytes (dwarf megakaryocytes) may occur.^{261,269,270} Megakaryocytes with unilobed or bilobed nuclei may be increased, and hypersegmented and hyposegmented megakaryocytes may be present (see Fig. 87–3L). Clusters of megakaryocytes may be seen. Megakaryocytes may be distributed laterally from their usual parasinusoidal location.²⁷¹

Fibrosis and Angiogenesis

An increase in reticulin and collagen fibers of varying degree is common (approximately 15 percent of cases), especially in oligoblastic myelogenous leukemia.²⁶⁶ When fibrosis is prominent, the disorder can resemble primary myelofibrosis, although, in contrast to the latter, splenomegaly usually is not marked and mutations of *CALR*, *JAK2*, or *MPL*, genes frequently truncated in primary myelofibrosis and ET, are extremely rare.²⁷² Because primary myelofibrosis is an oligoblastic leukemia with striking dysmorphogenesis of cells, some confusion in classification with other fibrotic clonal myeloid disorders may occur.²⁷³ Marrow fibrosis is correlated with higher blast counts and poor-risk cytogenetics.²⁶⁶ Some physicians have proposed a category of myelofibrotic myelodysplasia,

but all clonal myeloid diseases, including AML, chronic myelogenous leukemia, and CMML may have within their spectrum of expression occasional cases with intense myelofibrosis. Like numerous other epiphenomena that occur in the expression of hematopoietic stem cell diseases, extending the general classifications is not warranted.

Increased angiogenesis is a feature of MDS. Microvessel density increases with more advanced stages of the disease.²⁷⁴ Mast cell frequency and mast cell tryptase activity are highly correlated with microvessel density.²⁷⁵ Circulating endothelial cells are also increased in concentration in patients with MDS and their concentration is correlated with marrow neoangiogenesis (microvessel density).²⁷⁶

THERAPY-RELATED MYELOYDYSPLASTIC SYNDROMES

Therapy-related MDS are increasing in frequency as the use of intensive chemotherapy and radiation increases in other solid tumors and lymphoma.^{277–284} These cases have a poor prognosis and are not included in either the original IPSS or the revised IPSS-R. Cellular abnormalities of chromosomes 5, 7, and 8 are common in these cases.²⁸⁵ MDS following breast cancer is associated with older age, presence of other cancers, and multiple first-degree relatives with cancer.²⁸⁶ As compared to patients with myeloma or germ cell tumors, patients with lymphoma undergoing autologous stem cell transplantation have a higher incidence of treatment-related MDS. In this group, pretransplantation therapy, total-body irradiation, and other transplantation-related factors play a role, as do inherited polymorphisms in genes governing drug metabolism and DNA repair.²⁸⁷ Therapy-related MDS has been reported after high-dose melphalan for myeloma treatment, particularly in patients treated with lenalidomide.²⁸⁸

Accelerated telomere shortening precedes development of therapy-related myelodysplasia after autologous transplantation for lymphoma.²⁸⁹ Treatment-related MDS is managed as are *de novo* cases of MDS, but are very refractory to treatment. AH SCT can result in long-term disease-free survival, but most patients with therapy-related MDS are not candidates because of advanced age, comorbidities, or the inability to control the primary cancer.²⁹⁰

DIAGNOSTIC CRITERIA FOR MYELOYDYSPLASTIC SYNDROMES

The current diagnostic criteria for MDS are well defined, but can be difficult to apply in practice. Many diagnostic elements, such as the extent of dysplasia in the marrow and the quantification of blasts, are subjective measures associated with high rates of interobserver variability.^{291,292} Current guidelines require a blast proportion of 5 percent or greater in the marrow as definitive evidence for MDS absent other criteria and this threshold distinguishes RAEB from other MDS subtypes. However, more than 2 percent marrow blasts is abnormal and likely evidence of oligoblastic leukemia. This lower threshold is recognized as prognostically adverse in the IPSS-R. Even when dysplasia is clearly present, benign and potentially reversible causes of morphologic abnormalities must be excluded (Table 87–3). The presence of acquired chromosomal abnormalities is indicative of clonal hematopoiesis and can aid in the diagnostic evaluation. Specific karyotypes found more commonly in patients with MDS serve as presumptive evidence of the disorder in patients with clinically meaningful cytopenias and insufficient dysplasia to meet the morphologic criteria for diagnosis. Somatic mutations, which are more frequent than chromosomal abnormalities may soon be formally used in this manner to aid the diagnosis of MDS.

TABLE 87-3. Diagnostic Criteria for Myelodysplastic Syndromes⁵⁷⁷

Presence of one or more otherwise unexplained cytopenias*		
Hemoglobin <11 g/dL		
Absolute neutrophil count <1500/μL		
Platelet count <100,000/μL		
Presence of one or more myelodysplastic syndrome (MDS) decisive criteria		
>10% dysplastic cells in erythroid, myeloid, and/or megakaryocyte lineages		
5 to 19% marrow blasts		
Evidence of a cytogenetic abnormality typical for MDS [†] :		
-7 or del(7q)	del(12p) or t(12p)	t(1;3)(p36.3;q21.1)
-5 or del(5q)	del(9q)	t(2;11)(p21;q23)
i(17q) or t(17p)	idic(X)(q13)	inv(3)(q21q26.2)
-13 or del(13q)	t(11;16)(q23;p13.3)	t(6;9)(p23;q34)
del(11q)	t(3;21)(q26.2;q22.1)	
Exclusion of alternative diagnosis that explain blood and marrow findings		
No AML-defining criteria (e.g., t[8;11], i[16], t[16;16], t[15;17], or erythroleukemia)		
No other hematologic disorders (e.g., acute lymphocytic leukemia, aplastic anemia, or various lymphomas)		
Not explained by		
<ul style="list-style-type: none"> • HIV or other viral infection • Deficiencies of iron or copper • B₁₂, folate, or other vitamin deficiency • Medications (e.g., methotrexate, azathioprine, or chemotherapy) • Alcohol abuse (typically heavy and prolonged usage) • Autoimmune conditions (e.g., immune thrombocytopenia purpura, immune hemolytic anemia, Evans syndrome, Felty syndrome, or systemic lupus erythematosus) • Congenital disorders (e.g., Fanconi anemia, Diamond-Blackfan anemia, and Shwachman-Diamond syndrome, etc...) 		

*Present for 6 months or longer, if there is no typical cytogenetic abnormality identified.

†The list of cytogenetic abnormalities shown in this Table was taken from reference 578 and reiterated here.

CLINICAL PROGNOSTIC SCORING SYSTEMS

The estimation of prognosis is an integral element in the care for patients with MDS. It sets expectations for patients about their disease and helps physicians weigh the risks and benefits of specific treatments versus observation alone. Historically, they have been used to describe participants with MDS in clinical trials, which has allowed for comparison among studies. The most prevalent prognostic model in clinical use is the IPSS, first published in 1997. This model was created by examining 816 MDS patients at the time of their diagnosis. Patients with therapy-related MDS, proliferative CMML, and those who received disease-modifying therapy, such as AHSC, were excluded. The IPSS considered three major risk markers: the percentage of blasts in the marrow, the presence of specific cytogenetic abnormalities, and the number of cytopenias present in the blood. These elements were weighted as shown in Table 87-4 to assign patients to one of four IPSS risk groups

TABLE 87-4. International Prognostic Scoring System for Myelodysplastic Syndromes⁵⁷⁹

Score Value	0	0.5	1.0	1.5
Prognostic Variables				
Marrow Blasts (%)	<5	5–10		11–20
Karyotype	Good	Intermediate	Poor	
Cytopenias	0, 1	2, 3		

Risk groups: Low, 0; intermediate-1, 0.5–1.0; intermediate-2, 1.5–2.0; high, ≥2.5. Survival for each risk group is displayed in Table 87-5.

Karyotype: Good score, -Y, del(5q); poor score, complex abnormalities and chromosome 7 abnormalities; intermediate score, all other abnormalities. See “Marrow: Cytogenetics” in text above for further details.

Cytopenias: anemia, hemoglobin <10 g/dL; neutropenia, absolute neutrophil count <1.8 × 10⁹/L; thrombocytopenia, platelet count <100 × 10⁹/L.

with significant differences in overall survival and risk of clonal evolution to AML (Table 87-5). The IPSS was an extremely useful tool that gained wide acceptance in clinical practice and is incorporated into clinical practice guidelines published by the National Comprehensive Cancer Network and European LeukemiaNet.^{293,294} However, the IPSS has several limitations that include consideration of blast proportions that were later redefined by the WHO classification system as AML and a propensity to underestimate risk in patients with severe cytopenias. Several subsequent prognostic models that improve upon the IPSS have been published and validated, but have generally not been widely adopted in routine clinical practice.^{295–297}

The IPSS-R, published in 2012, addresses most of the limitations of the IPSS and provides improved prognostic accuracy over the IPSS and subsequent models.^{298–300} The IPSS-R examined clinical data from 7012 MDS patients at the time of their diagnosis (Table 87-6). Like the IPSS, the IPSS-R excluded patients with proliferative CMML or therapy-related disease and censored patients if and when they received disease-modifying therapy. The IPSS-R differs from the IPSS in that it includes a much broader range of cytogenetic abnormalities which are given greater weight in the overall risk calculation. The IPSS-R refines the marrow blast percentages to exclude patients with 20 percent or greater blasts and considers each type of cytopenia as an independent risk factor weighted by severity. Based on the total risk score, patients are assigned to one of five risk groups instead of the four used by the IPSS. The risk score can be adjusted for age to take this variable into account. Patients assigned to the “very low” and “low risk” groups are considered to have lower-risk MDS whereas those in the “high” or “very high” groups have higher-risk disease. Patients in the intermediate category may be treated as lower or higher risk based on other prognostic factors such as serum ferritin and serum lactate dehydrogenase (LDH) which are not formally considered in the model.

The IPSS-R has been validated and shown to apply in contexts for which it was not originally defined. This includes risk stratification at times other than diagnosis, use in patients who go on to receive disease-modifying treatment, and use in patients undergoing AHSC.^{299,301–303} It is important to note that the median overall survival for patients stratified by the IPSS and IPSS-R represent estimates based on patients who did not receive disease-modifying therapy. Patients who respond to active treatments may, in fact, have a greater expected median survival than predicted by these scoring systems. Currently, somatic mutations are not considered by any prognostic scoring system in widespread

TABLE 87-5. Survival of Patients Based on the International Prognostic Scoring System

IPSS Group at Diagnosis	No. of Patients	2-Year Survival	5-Year Survival	10-Year Survival	15-Year Survival
Low	267	85%	55%	28%	20%
Intermediate-1	314	70%	35%	17%	12%
Intermediate-2	179	30%	8%	0	–
High	56	5%	0	–	–

IPSS, International Prognostic Scoring System.

clinic use even though these lesions have been shown to have independent prognostic significance. Future prognostic models are likely to combine clinical and molecular information to refine the prediction of prognosis in MDS.

TREATMENT OF MYELODYSPLASTIC SYNDROMES BASED ON PROGNOSTIC SCORE

Therapeutic decisions in patients with MDS patients can be based on the predicted evolution of disease, as measured by prognostic tools such as the IPSS and IPSS-R.³⁰⁴ Lower-risk patients are commonly treated with lower-intensity therapies such as hematopoietic growth factors or immunomodulatory agents, while use of hypomethylating

agents, cytotoxic agents, or AHSCT is typically reserved for higher-risk patients.^{305–307} In addition, two biomarkers—the presence of del(5q) in lower-risk patients with anemia, and the serum erythropoietin level in anemic patients—are strong enough predictors of treatment response as to permit selection or avoidance of individual drugs (i.e., the use of lenalidomide³⁰⁸ or erythropoiesis-stimulating agents,³⁰⁹ respectively). While other predictive biomarkers in MDS have been proposed, such as *TET2* and *DNMT3A* mutation status as predictors of the likelihood of response to hypomethylating agents^{194,310,311}; patient age, marrow hypocellularity or human leukocyte antigen (HLA) DR-B15 status and response to immunosuppressive therapy³¹²; serum thrombopoietin and intensity of platelet transfusion requirements and response to thrombopoietin agonist romiplostim³¹³; or flow cytometry patterns and response to erythropoiesis-stimulating agents³¹⁴, these are not strong enough predictors of response to specific therapies to influence management

TABLE 87-6. Revised International Prognostic Scoring System for Myelodysplastic Syndromes⁸

Cytogenetic Groups		IPSS-R Karyotype Abnormalities			
Very good	del(11q), –Y				
Good	Normal, del(20q), del(5q) alone or with 1 other anomaly, del(12p)				
Intermediate	+8, del(7q), i(17q), +19, +21, any single or double abnormality not listed, or two or more independent clones				
Poor	der(3q), –7, double with del(7q), complex with 3 abnormalities				
Very poor	Complex with >3 abnormalities				
IPSS-R Parameter	Categories and Associated Scores				
	Very Good	Good	Intermediate	Poor	Very Poor
Cytogenetic Risk Group	0	1	2	3	4
Marrow blast %	≤2	>2–<5	5–10	>10	
	0	1	2	3	
Hemoglobin (g/dL)	≥10	8–<10	<8		
	0	1	1.5		
Platelet count (× 10 ⁹ /L)	≥100	50–<100	<50		
	0	0.5	1		
Neutrophil count (× 10 ⁹ /L)	≥0.8	<0.8			
	0	0.5			
IPSS-R Risk Group	Total Score	% of Patients	Median Survival, Years	25% with AML, at Years	
Very low	≤1.5	19	8.8	NR	
Low	>1.5–3	38	5.3	10.8	
Intermediate	>3–4.5	20	3	3.2	
High	>4.5–6	13	1.6	1.4	
Very high	>6	10	0.8	0.73	

AML, acute myelogenous leukemia; IPSS-R, International Prognostic Scoring System–Revised; NR, not reached.

These data were found in Ref 298 and reiterated in this table.

decisions. Patients with *TP53* mutations may comprise a special group, as they have such a poor outlook with conventional therapies that either clinical trial enrollment or palliative care may be most appropriate for individuals with a *TP53* mutant genotype.^{315,316}

The calculated prognostic score should not be the sole guide to treatment of a patient, as many patients deviate from the average expectation of disease behavior. The prognostic scores are based on the average behavior of large numbers of patients without confidence intervals to show the degree of variation, which is substantial. Unexpected progression or evolution of disease may also necessitate changes in treatment approach, and patients' comorbid conditions may preclude use of specific therapies (e.g., renal failure requires dose adjustment or avoidance of lenalidomide). There is also uncertainty among clinical investigators about the optimal therapeutic approach in many situations, such as for IPSS lower-risk patients with severe cytopenias other than anemia, anemic IPSS lower-risk patients without del(5q) and with a serum erythropoietin level greater than 500 U/L, and IPSS higher-risk patients who are not transplant candidates and for whom azacitidine and decitabine have failed.³¹⁷

Measurement of treatment response in a clinical trial usually involves comparison to the 2006 International Working Group (IWG) response criteria.³¹⁸ Although IWG response criteria focus on improvements in specific measurable and objective variables such as hemoglobin level, the number of abnormal metaphases on karyotyping, and marrow blast proportion, surveys have shown that what matters most to patients is decreased symptoms,^{319,320} improved quality of life,^{321–323} avoidance of hospitalization and extended survival, which overlap with but are not identical to numerical disease measurements. Economic considerations also determine clinical care patterns, and the high cost of MDS care is a burden for many patients.³²⁴

THERAPEUTIC APPROACHES TO PATIENTS WITH LOWER-RISK DISEASE

All patients, regardless of risk score, deserve “best supportive care.” Supportive care consists of improving quality of life by treatment of cytopenias or their complications (e.g., dyspnea, bleeding, infection) and providing ongoing psychosocial support, while monitoring the patient's clinical status at intervals.³²⁵ The inclusion of palliative care can be very helpful to many patients, especially those at higher-risk and does not imply the cessation of treatment. Counseling by experienced palliative care physicians can provide patients with important support in their understanding of the best ways to manage their disabilities and to make therapeutic decisions.

Red Cell Transfusion

Red blood cell (RBC) transfusions should be administered for symptomatic anemia. Often patients will tolerate hemoglobin levels lower than 8 g/dL, but the level at which symptoms develop varies from patient to patient. Higher thresholds have been suggested to prevent cardiac consequences of prolonged anemia,^{326,327} while lower thresholds have been recommended based on superior outcomes with restrictive RBC transfusion strategies in inpatient populations^{328–330} and the need to preserve the blood supply. Patients with MDS may receive hundreds of units of RBCs over the course of their illness.^{331,332}

Platelet Transfusion

Thrombocytopenia is common in MDS and has a higher prevalence in higher-risk IPSS categories.³³³ Furthermore, many therapies used in MDS may worsen thrombocytopenia. Hemorrhage is the second most common cause of death in patients with MDS.³³³ Platelet transfusions may be required if the platelet count falls below 10×10^9 cells/L or at

higher levels if the patient is actively bleeding. Antifibrinolytic agents, such as aminocaproic acid or tranexamic acid, can be used in patients who have mucosal bleeding despite platelet transfusion or to decrease the need of platelet transfusions.⁹³ This strategy is especially effective in patients with urinary bleeding or bleeding from arteriovenous malformations of the gut.

Antimicrobial Agents

Febrile events are common in higher-risk syndromes because of the frequency of moderately severe neutropenia and functional disorders of neutrophils and monocytes. Also, chemotherapy is more likely to be used in these situations, inducing severe neutropenia. Appropriate cultures and use of broad-spectrum antibiotics until and if a specific organism is found is important, with subsequent therapy tailored to microbiologic data. Chapter 24 discusses an approach to febrile neutropenia. The use of prophylactic antimicrobial agents in neutropenic patients is of uncertain usefulness in MDS, but may help prevent infections in those who have had previous problems with recurrent infection.³³⁴ In this setting, levofloxacin and acyclovir are the best studied.³³⁵ Prophylactic antifungal agents are used more frequently in AML patients, and some guidelines recommend posaconazole or voriconazole in MDS patients who have prolonged neutropenia and are at increased risk for fungal infections or who are undergoing induction chemotherapy.^{336–339}

Erythropoiesis-Stimulating Agents

RBC transfusion dependency negatively influences clinical outcomes in MDS.³⁴⁰ RBC transfusion dependence is a marker of more severe marrow failure, increased risk of transformation to AML, and increased iron overload from repetitive transfusions. Less-well-defined immunomodulatory effects of transfusions may contribute to poor outcomes.³⁴¹ In contrast, some studies found that neither the serum ferritin nor the number of RBC transfusions were associated with survival in clonal sideroblastic anemia.^{342,343}

Erythropoiesis-stimulating agents (ESAs), such as recombinant human erythropoietin analogues, can be used to treat anemia in patients who are transfusion-dependent, if the serum erythropoietin level is lower than optimal for the hemoglobin level. Responses are best in patients with low serum erythropoietin levels,³⁰⁹ normal blast counts, lower IPSS scores,³⁴⁴ normal cytogenetics,³⁴⁵ lower levels of inflammatory cytokines,³⁴⁶ absence of aberrant marker expression by flow cytometry,³¹⁴ and in patients who do not require regular RBC transfusions.^{309,347} Hemolysis and deficiencies of iron, vitamin B₁₂, or folate should be excluded as a cause of anemia before ESA therapy is started. Iron stores should be kept replete during ESA therapy.^{348,349}

Epoetin alfa at a dose of 150 to 300 U/kg per day three times per week or single weekly doses of 40,000 to 60,000 U are effective.^{350–362} There is no increase in response with doses exceeding 60,000 U weekly.³⁵⁸ In clinical practice, weekly epoetin is more commonly administered than three times per week, a dosing schedule that was developed in the hemodialysis setting. Darbepoetin alfa in various schedules of administration (e.g., 500 mcg fixed dose once every 3 weeks) has also been found effective in increasing hemoglobin levels and in enhancing quality of life.^{363,364} Meta-analysis has confirmed erythropoietic response rates are similar for those treated either with epoetin alfa or with the longer-acting darbepoetin alfa.³⁶⁵

The probability of a response to ESA therapy increases modestly with duration of therapy, but from a practical standpoint it is difficult to obtain reimbursement to continue patients on ESA treatment beyond 12 weeks in the absence of an objective response.³⁶⁶ Unlike in patients with solid tumors or renal failure, there is no evidence that ESAs increase thromboembolic disease or accelerate progress to leukemia, but followup in studies to date have been short.³⁶⁷ Several series have

reported increased survival in ESA-treated patients compared to controls.^{344,368} There is evidence that marrow erythroid cells of MDS patients who respond to erythropoietin have a different gene expression pattern than do those of nonresponders.³⁶⁹

Filgrastim (G-CSF) combined with erythropoietin may produce a response more frequently than with an ESA alone, perhaps as a result of lineage crosstalk of growth factors at the progenitor cell level.^{360,370} This combination does not appear to affect the risk of leukemic transformation and may have a positive impact on survival in those with low transfusion needs.³⁷¹

Granulocyte-Stimulating Factors

Infection is the major cause of mortality in MDS.³⁷² Both neutropenia and granulocyte dysfunction contribute to the risk of infection.^{373,374} Granulocyte transfusions are of little utility,³⁷⁵ and, unfortunately, randomized, double-blind studies have not shown that any cytokine prolongs survival or reduces morbidity in MDS.³⁷⁶ Treatment with GM-CSF (sargramostim) or G-CSF (filgrastim) increases neutrophil counts and function in some patients, but this is inconsistent.^{360,377,378} G-CSF receptor expression on hematopoietic progenitor cells may be low in some patients with MDS and prevents response to endogenous or exogenously administered G-CSF.³⁷⁹ Rare remissions have been reported in hypoplastic AML/MDS with G-CSF alone.³⁸⁰

The most common adverse effects of G-CSF and GM-CSF include bone pain, low-grade fevers, and soreness at the injection site. Rare serious complications such as splenic rupture, have been reported with use of G-CSF.³⁸¹ Pegfilgrastim may allow less-frequent dosing than filgrastim, but is poorly studied in MDS, in which leukemoid reactions and splenic ruptures have been described.^{376,382,383} G-CSF is not generally recommended for those with intermediate-2 risk or high-risk IPSS scores because of the risk of leukemoid reactions.³⁸⁴ In one review, 22 of 83 reported cases of MDS treated with G-CSF or GM-CSF had an increase in marrow blast percentage, and AML evolved in 12 of 69 patients. An increased percentage of abnormal macrophages has been reported during G-CSF therapy.³⁸⁵ Use of these agents without chemotherapy in oligoblastic leukemias carries a risk of promoting expansion of leukemic blast cells.³⁸⁶ Combinations of growth factors alone with maturing agents (so-called differentiating therapy) such as retinoic acid have not significantly improved response or survival rates.^{387,388}

Platelet and Megakaryocyte Growth Factors

Low-dose IL-11 (oprelvekin), a megakaryocyte growth factor, was studied in patients with symptomatic thrombocytopenia associated with marrow failure syndromes including MDS, but efficacy was low and adverse effects such as fluid retention and atrial dysrhythmias were common.^{389,390} Although this drug is approved by the FDA, it is rarely used and uncommonly reimbursed by third-party payers.

Initial development of thrombopoietin analogues was halted in the 1990s,³⁹¹ but newer thrombopoietin-receptor agonists have shown efficacy in MDS. Romiplostim (formerly AMG-531), a peptibody that stimulates the thrombopoietin receptor (c-Mpl), can decrease thrombocytopenia and reduce platelet transfusion needs and clinically significant bleeding events in patients with MDS and severe thrombocytopenia, including both those who are receiving no treatment and those who are receiving therapy with azacitidine, lenalidomide or decitabine.³⁹²⁻³⁹⁵ The optimal MDS romiplostim dose determined by early clinical studies, 750 mcg subcutaneously once weekly, is higher than that required for immune thrombocytopenia. Eltrombopag, an orally administered small molecule c-Mpl agonist, has also shown efficacy in early phase MDS studies.^{376,396-400}

Although there was initially concern about AML progression with romiplostim therapy as some leukemic blasts express functional

c-Mpl, a randomized study comparing romiplostim to placebo in lower-risk patients showed no increase in AML progression in patients receiving active treatment, although this study was stopped early by its Data Safety Monitoring Committee because of concern about such progression.⁴⁰¹ Another theoretical risk based on thrombopoietin-overexpressing murine models, marrow reticulin formation, appears to be uncommon in immune thrombocytopenia (ITP), but has not been systematically investigated in romiplostim-treated patients with MDS.⁴⁰² A model to predict response to romiplostim based on platelet transfusion need and serum thrombopoietin (TPO) level that parallels the similar model for ESAs based on RBC transfusion and serum erythropoietin (EPO) level has recently been developed.³¹³ The pathophysiology of ITP overlaps that of MDS, and other treatments for ITP such as rituximab or γ -globulin may be beneficial in cases of lower-risk MDS where the degree of thrombocytopenia is disproportionate to other cytopenias.

Iron-Chelation Therapy

The magnitude of risk from iron overload in patients with receiving frequent RBC transfusions compared to the risk of death intrinsic to the disease and the utility of chelation therapy is one of the most controversial areas in MDS clinical management.⁴⁰³⁻⁴⁰⁶ Claims-based data suggest increased risk of complications in transfused patients with MDS, but correlation does not prove causation and patients at higher risk of complications may have been more likely to be transfused (e.g., diabetic patients might have had more renal insufficiency and insufficient EPO production, rather than repeated transfusion causing pancreatic islet injury via hemosiderosis and inducing diabetes mellitus).^{407,408} Retrospective comparisons suggest superior outcomes in chelated patients compared to unchelated patients, but are subject to confounding by patient selection bias.⁴⁰⁹⁻⁴¹²

Despite the absence of high-quality evidence from prospective trials, numerous consensus guidelines have been published regarding the treatment of iron overload in MDS.⁴¹³ These guidelines make general recommendations about iron monitoring and chelation in RBC transfusion-requiring patients, but emphasize that there is no prospectively validated threshold for either the number of units of transfused blood or the level of serum ferritin that should trigger iron chelation, as patients accumulate iron at different rates and serum ferritin is sensitive to other influences such as inflammation. Most guidelines take into account the patient's candidacy for AHSCT,⁴¹⁴ life expectancy, and evidence of iron-related organ damage.^{415,416} Several guidelines use a serum ferritin greater than 1000 mcg/L and a transfusion history of 20 to 30 RBC units as a threshold for starting iron-chelation therapy, but this strategy is not validated. The use of T2^{*}/R2^{*} magnetic resonance imaging techniques may allow noninvasive assessment of organ iron deposition,^{331,332,417} but it is not clear whether labile plasma iron levels or total-body iron burden poses a greater risk.^{418,419}

Both deferoxamine given subcutaneously or intravenously and deferasirox given orally are available for chelation therapy in MDS patients. Deferasirox rapidly reduces labile plasma iron and mobilizes iron stores and is more convenient than deferoxamine, but in both U.S. and European studies, one-half of patients discontinued deferasirox therapy within a year of study enrollment because of disease progression or adverse effects (renal insufficiency, rash, and gastroenterologic distress).^{418,420} There are several reports of improved hematopoiesis in chelated patients.^{421,422}

Low-Dose Cytarabine

Since the early 1980s,⁴²³⁻⁴²⁵ low-dose cytarabine at doses of 5 to 20 mg/m² per day by subcutaneous injection every 12 hours for 8 to 16 weeks or by continuous intravenous infusion has been used in MDS in lieu of intensive chemotherapy.⁴²⁶⁻⁴²⁹ Although this approach

leads to remission in approximately 10 to 20 percent of patients with MDS, the median duration of remission is less than 1 year, and survival has not been prolonged nor has AML progression been delayed compared with supportive care alone.⁴³⁰ Moreover, low-dose cytosine arabinoside usually is cytotoxic, inducing marrow hypoplasia and worsening cytopenias. Although occasional reports of remission following low-dose cytarabine have been consistent with an effect on leukemia cell maturation, most patients experience suppression of the malignant cell clone, leading to marrow repopulation with polyclonal hemopoiesis. This treatment approach is used less often since the advent of other FDA-approved agents for MDS, especially as azacitidine treatment is associated with superior overall survival compared to cytarabine,⁴³¹ but may still have a role in some patients.⁴³²

Immunosuppressive Therapy: Cyclosporine and Antithymocyte Globulin

In some patients with MDS, autoreactive T-lymphocyte-mediated inhibition of hematopoiesis occurs and contributes to cytopenias.⁴³³ In such patients, cytopenias may be ameliorated by treatment with immunosuppressive agents directed at T cells such as antithymocyte globulin (ATG) or calcineurin inhibitors.²¹² In patients who recover effective hematopoiesis after immunosuppressive treatment, the V β (T-cell receptor- β) spectra-type representative of clonal or oligoclonal T-cell populations typically reverts to normal patterns. In one older study, a nonclonal X-chromosome inactivation pattern in the marrow, as assessed by the human androgen receptor gene assay and the phosphoglycerated kinase-1 assay, was associated with a response to ATG.⁴³⁴ This finding was attributed to incomplete clonal expansion, with ATG improving normal hematopoiesis by relieving the immunologic pressure on the remaining normal progenitors. Other investigators have postulated that responses may result from suppression of interferon- γ secretion by CD4+ T cells regardless of clonality.⁴³⁵

Some series in MDS have reported response rates to ATG of 15 to 60 percent and longer survival times in patients who respond.^{436–438} The mortality with ATG-based therapy is higher in MDS patients than in aplastic anemia.⁴³⁹ With cyclosporine alone, responses seem to be less common than with ATG-based regimens and mostly consist of minor hematologic improvements.^{440,441} There are case reports of responses to tacrolimus.⁴⁴²

HLA-DR15 (DR2) is overrepresented in MDS and predicts a response to immunosuppressive therapy.^{312,443} In one series of 60 patients who were treated with ATG and cyclosporine, 60 percent had hematologic improvement, and more responders had good karyotype or HLA-DRB1 1501.^{312,313} Most of the patients in this series had RA and an IPSS score of intermediate-1. In a series of 129 patients who were treated with immunosuppressive therapy at a single institution, 30 percent had either a complete or partial response; younger patient age and intermediate-1 or low-risk IPSS score favored survival.¹¹⁰

In some series a hypocellular marrow has predicted a higher likelihood of response, analogous to the response to immunosuppressive therapy in aplastic anemia, but this has not been consistent.^{439,441,444} Younger age, normal karyotype or trisomy 8, lack of transfusion dependence, and the presence of either a PNH clone⁴⁴⁵ or HLA-DR15 have predicted response to immunosuppressive therapy, but none is a robust biomarker.³¹²

Not all groups have seen success with immunosuppressive therapy approaches. One study of ATG was stopped early because of lack of efficacy and development of adverse reactions.⁴⁴⁶ Other studies also have reported lack of efficacy of single-agent cyclosporine.⁴⁴⁷

Among highly selected patients seen at the National Institutes of Health, the anti-CD52 monoclonal antibody alemtuzumab was associated with a response rate exceeding 90 percent in IPSS Intermediate-1 risk patients.⁴⁴⁸ However, these patients were 20 years younger than the

median age for MDS diagnosis (median age of approximately 50 years) and most were women with a normal karyotype, suggesting that they were not representative of the typical MDS patient seen in most clinics.

Immunomodulatory Agents: Thalidomide and Lenalidomide

The immunomodulatory drug (IMiD) thalidomide induced hematopoietic responses in 20 to 25 percent of patients with MDS at doses ranging from 50 to 800 mg per day, but thalidomide is difficult to tolerate (especially at higher doses) because of neuropathy, rashes, and constipation; in addition, risk of teratogenicity limited distribution of the drug.^{449,450} Although thalidomide was initially promoted as an angiogenesis inhibitor following a vogue for such therapies in the 1990s, more recent data indicate that thalidomide's effects depend on modulation of the activity of cereblon, a component of an E3 ubiquitin ligase complex.⁴⁵¹ Alteration of ubiquitination by IMiD therapy has pleiotropic effects, such as alteration of transcription factors, and downstream effects on levels of cytokines and immune cell subsets.^{452–455}

Lenalidomide, a thalidomide analogue with a more favorable risk-to-benefit ratio than the parent compound, induces improvement in approximately 85 percent of patients with lower-risk MDS associated with deletion of chromosome 5q, and results in RBC transfusion independence in almost 70 percent of patients.^{308,456} The median hemoglobin increment in responding patients is 5.4 g/dL and responses last a median of more than 2 years. A randomized trial of a starting dose of 5 mg/day versus 10 mg/day showed a higher cytogenetic response rate with the higher dose; in that study, there was no increase in AML risk compared to placebo.⁴⁵⁷ Most responses occur in the first 8 weeks. Neutropenia and thrombocytopenia can be adverse effects of lenalidomide, but treatment-emergent cytopenias correlate with response.⁴⁵⁸ Pretreatment thrombocytopenia, in contrast, is associated with lower response rate.

The results with lenalidomide therapy are less favorable if chromosome 5q is absent; patients with normal karyotype and lower-risk MDS have approximately a 25 percent response rate with a median response duration of less than 1 year.⁴⁵⁹ Case reports suggest patients with trisomy 13 may respond favorably.⁴⁶⁰ Another thalidomide derivative, pomalidomide, has activity in primary myelofibrosis but has not yet been studied in MDS.

Antitumor Necrosis Factor Therapy

Patients with MDS overlap with the anemia of chronic inflammation in that they often have elevated levels of inflammatory cytokines such as TNF- α , which inhibit hematopoiesis. Whereas both thalidomide and lenalidomide indirectly lower TNF levels, strategies more directly inhibiting TNF also have been pursued. The soluble TNF receptor fusion protein etanercept (p75 TNFR:Fc), FDA approved for rheumatoid arthritis, has produced mixed results in MDS. In one pilot series, moderate improvement in cytopenias was noted,⁴⁶¹ whereas in another trial, no responses were noted in 10 patients.⁴⁶² In another pilot study of 3 months duration, one of 16 enrolled patients became transfusion-independent temporarily.⁴⁶³ There is a report of two patients who had sustained erythroid responses during treatment with the chimeric anti-TNF- α monoclonal antibody infliximab, which also decreased the percentage of apoptotic cells in the marrow.⁴⁶⁴ Etanercept has been combined with ATG⁴⁶⁵ and with azacitidine,⁴⁶⁶ but the independent contribution of etanercept to the responses observed is unclear.

Other Treatment Options in Low- or Intermediate-1-Risk Patients

A number of miscellaneous therapies have been tried for lower-risk patients with MDS by analogy with other diseases such as inflammatory anemias or promyelocytic leukemia, or based on theoretical constructs.

There are anecdotes of hematopoietic responses to vitamin K₂ (menatetrenone), for unclear reasons.^{467,468} Glucocorticoids, vitamin A analogues (retinoids), vitamin D analogues such as dihydroxyvitamin D₃, the polar-planar solvent hexamethylene bisacetamide, the antioxidant amifostine, and interferon are among other agents that can induce *in vitro* maturation of mouse and human leukemic cells but have limited clinical activity.^{469–471} Glucocorticoids can induce neutrophil increment via demargination, but this does not prevent infections and there is at least some reason for concern about increased risk of fungal infections.^{472,473} Use of *cis*-retinoic acid, isotretinoin, or all-*trans*-retinoic acid (ATRA) has produced only slight, transient (few weeks) improvement in a very small proportion of patients with oligoblastic leukemia.^{474,475}

Arsenic trioxide, used as a single agent or in combination with other therapies, results in responses in up to 20 percent of cases.^{472,476–478} Lower-risk MDS patients were most likely to show benefit in one arsenic study.⁴⁷⁹ The mechanism of action of arsenic in MDS is unclear.

Bortezomib, a proteasome inhibitor that indirectly targets NF- κ B, has limited activity in MDS as a single agent but might be useful in combination.^{480–482} The AKT/mTOR (mammalian target of rapamycin) pathway is active in MDS, but there are no data on treatment with mTOR inhibitors.^{483,484}

For those patients who are unlikely to respond to the therapies described above or for those for whom such treatments have been attempted and failed, treatments more commonly used for higher-risk MDS such as azacitidine or decitabine can be used. In those not responding to these approved agents, AHSCT or other investigational options can be considered (see below).

A number of novel agents are currently undergoing clinical trials for patients with lower risk MDS for whom ESAs and other agents have failed. For instance, a multicenter trial of sotatercept, a soluble activin receptor type 2A immunoglobulin (Ig) G-Fc fusion protein that acts as a ligand trap for members of the transforming growth factor beta (TGF- β) superfamily, is ongoing in MDS.⁴⁸⁵ The dual p38 mitogen-activated protein (MAP) kinase/Tie2 kinase inhibitor Arry-614 was associated with hematologic improvements in patients for whom hypomethylating agents have failed yet who still meet IPSS criteria for lower-risk disease.⁴⁸⁶ Although activating kinase mutations are rare in MDS and kinase inhibitors such as imatinib have not shown efficacy in MDS with the exception of the rare CMML-like syndrome associated with t(5;12) and translocation of a gene encoding platelet-derived growth factor,^{487,488} several other kinase inhibitors besides Arry-614 are also being studied. The glutathione analogue TLK199 (ezatiostat hydrochloride [Telintra]) had some activity in lower-risk MDS and restored sensitivity to lenalidomide in some patients who had lost response, but development of this agent appears to have been abandoned.^{489–491}

THERAPY FOR PATIENTS WITH HIGHER-RISK DISEASE

Hypomethylating Agents (DNA Methyltransferase Inhibitors): Azacitidine and Decitabine

Recognition of the high prevalence of DNA cytosine methylation abnormalities in MDS, including hypermethylation and consequent silencing of expression of tumor-suppressor genes, contributed to clinical development of DNA hypomethylating agents.^{492,493} Another factor in development of these agents was the detection *in vitro* of the potential for DNA hypomethylating agents to induce differentiation of immature hematopoietic cells, including neoplastically transformed cells.^{388,494,495}

5-Azacytidine (azacitidine) is an azo-substituted pyrimidine analogue that is primarily incorporated into RNA. It can be converted to a deoxynucleotide by ribonucleotide reductase and incorporated into DNA where it binds to and irreversibly inhibits the enzyme DNA

methyltransferase 1, reduces cytosine methylation, and induces maturation of some leukemic cell lines. In addition to epigenetic changes, azacitidine also is an antiproliferative drug, alters NF- κ B and other signaling pathways, alters expression of cell-surface antigenic epitopes that can stimulate a regulatory T-cell immunologic response, and retains some cytotoxic activity akin to low-dose cytarabine as measured by induction of γ H2AX (a marker of DNA strand breaks).^{496–499} Administration of the drug and its congener decitabine has resulted in improvement of some patient's MDS, and these agents are also active in AML.^{500–502}

Azacitidine is typically administered at a dose of 75 mg/m² once per day given subcutaneously for 7 consecutive days each month. In a cooperative group randomized study conducted in the 1990s (Cancer and Leukemia Group B [CALGB] 9221), azacitidine was superior to supportive care in terms of hematopoietic improvement and AML progression.⁵⁰³ Quality of life was also enhanced.^{323,503} Complete responses were seen in approximately 15 percent of azacitidine-treated patients, and nearly 50 percent of patients had hematologic improvement, reduction of blasts, decrease in abnormal metaphases on cytogenetic analysis, or some combination of those changes.⁵⁰⁴ Ninety percent of responses were seen by cycle six of therapy, although a few patients responded to further cycles beyond six.⁵⁰⁵ In another series, subclasses of MDS did not predict for response to azacitidine therapy.⁵⁰⁶ Consequently, azacitidine was approved by the FDA in 2004 for treatment of all FAB subtypes of MDS.

In a randomized multicenter study of higher-risk MDS patients where azacitidine was compared to the physician's choice of one of three conventional care regimens that included supportive care, low-dose cytarabine treatment, or intensive induction chemotherapy, azacitidine increased survival by a median of 9 months compared to standard care regimens (24 vs. 15 months).⁵⁰⁷ This was the first agent shown in a randomized fashion to extend survival in MDS.

Treatment with azacitidine can usually be accomplished on an outpatient basis, and the efficacy of intravenous administration seems to be similar to that with subcutaneous drug delivery.⁵⁰⁸ An oral formulation of azacitidine is being studied.⁵⁰⁹ Other schedules of administration to accommodate outpatient therapy have been reported to have benefit but have not been directly compared to the 75 mg/m² daily dose for 7 days every 4 weeks.⁵¹⁰ Adverse events associated with azacitidine include treatment-emergent cytopenias, skin rash, injection site soreness (which may respond to evening primrose oil⁵¹¹), mucositis, renal insufficiency (uncommon), and gastrointestinal upset.

5-Aza-2'-deoxycytidine (decitabine) is also FDA approved for all MDS risk categories. Although also a 5-azo-substituted pyrimidine nucleoside analogue that inhibits DNA methyltransferase, decitabine differs from azacitidine in that it is primarily incorporated into DNA, has a distinct profile of sensitive cell lines among the NCI-60 panel compared to azacitidine (more similar to cytarabine), and may work faster.⁵¹² In one study, 90 percent of patients had responded by the end of cycle four of decitabine therapy, compared to cycle six with azacitidine, but this was a cross-study comparison and not randomization.⁵¹³ Seventeen percent of patients in one series had a major cytogenetic response on an intention-to-treat basis after a median of three courses.⁵¹⁴ The median duration of cytogenetic response was 7.5 months in all IPSS groups.⁵¹⁵ Patients who responded had improved survival compared with patients in whom the cytogenetically abnormal clone persisted. While decitabine was initially developed using a 3-day, nine-dose inpatient schedule, a 5-day intravenous administration schedule for outpatient use was found to be optimal in one series, which compared several doses and schedules; examination of optimal doses and schedules continues.^{516–518} Decitabine also has cytotoxic activity like cytarabine, but may work at least partly through demethylation, as it has resulted in demethylation of a hypermethylated *INK4B* gene in patients.⁵¹⁹ Treatment-emergent

demethylation is associated with clinical responses, although it is unclear whether the same cells are being compared pre- and posttreatment, and clonal shift could account for these results.⁵²⁰ Adverse events associated with decitabine are similar to those observed with azacitidine. Oligodeoxynucleotide antisense approaches to DNA methyltransferase-1 inhibition are also being explored in MDS.⁵²¹

Therapy with demethylating agents in patients who are not suitable candidates for AHSCT usually continues for as long as it seems like the patient is deriving benefit and as long as the drug is well tolerated. For patients who are going to AHSCT, these agents may be helpful as a bridge to transplant, and retrospective studies show that pretransplant treatment with azacitidine is at least as effective as treatment with induction chemotherapy.⁵²²

Histone Deacetylase Inhibitors

Inhibitors of histone deacetylation exhibit *in vitro* synergy with hypomethylating agents and have clinical activity in MDS, albeit limited, when they are used as single agents. This class of drugs is under active investigation at many centers.^{523,524} Numerous agents are being studied and include valproic acid,^{525,526} vorinostat (SAHA), mocetinostat (MGCD0103),⁵²⁷ panobinostat (LBH589),⁵²⁸ pracinostat and others. Belinostat had no activity.⁵²⁹ Randomized trials combining histone deacetylation inhibitors with DNA methyltransferase inhibitors are ongoing, such as the U.S.–Canadian Intergroup study S1117, which compares azacitidine monotherapy to azacitidine plus lenalidomide⁵³⁰ and azacitidine plus vorinostat.^{531,532} In a randomized cooperative group trial of azacitidine with or without entinostat (MS-275), the combination arm was not associated with an increase in response rate but was associated with more adverse events, including fatigue and thrombocytopenia.⁵³³

Failure of Hypomethylating Agents

In higher-risk patients whom azacitidine or decitabine has failed, overall life expectancy is less than 6 months and patients who receive only supportive/palliative care have a life expectancy of only 3 to 4 months.^{534,535} Novel approaches are needed for this group of patients. A randomized trial of rigosertib, an injectable phosphatidylinositol-4,5-bisphosphate 3-kinase (PI3K) kinase/polo-like kinase 1 (PLK-1) inhibitor, in higher-risk patients for whom azacitidine or decitabine had failed showed no survival benefit of the active agent compared with low-dose cytarabine or supportive care controls.⁵³⁶ An oral formulation of rigosertib is being studied in lower-risk patients.⁵³⁷

A new dinucleotide decitabine-guanosine hypomethylating agent with increased resistance to cytidine deaminase degradation, SGI-110, has activity in relapsed/refractory patients.^{538,539} The quinolone derivative vosaroxin, the nucleoside analogue sapacitabine, and inhibitors of PLK-1, such as volasertib, are also undergoing clinical trials in this setting.

Intensive Chemotherapy Similar to That Used for Acute Myelogenous Leukemia

Intensive chemotherapeutic regimens containing standard doses of cytarabine, an anthracycline, with or without etoposide (Chap. 88) result in remission in fewer than 20 percent of patients with high-risk MDS, primarily because of incomplete hematopoietic recovery or recovery with dysplastic/leukemia cells, and are no longer commonly used. The advanced age of many patients with MDS and the high frequency of cardiac, renal, immunologic, and other organ system impairment in most patients are thought to be largely responsible for the poor outcome. In a randomized trial of patients with WHO-defined AML and up to 30 percent blasts (oligoblastic leukemia), azacitidine was superior to a daunorubicin and cytarabine induction regimen.⁵⁴⁰

Patients who are younger than age 60 years have higher remission rates with AML-like regimens—rates up to 50 percent⁵⁴¹—and can be considered for intensive therapy, but this is usually only done as a bridge to AHSCT. Patients older than age 60 years have a median survival of only 9.5 months with this approach and the survival is reduced to 4 months in those with unfavorable karyotypes, indicating a lack of benefit in this group.⁵⁴² In addition to the standard combination of anthracycline and cytarabine, other regimens, such as liposomal daunorubicin and topotecan with or without thalidomide, did not result in clinical benefit in patients with AML or high-risk MDS.⁵⁴³ The so-called FLAG-Ida regimen (fludarabine, cytarabine, idarubicin, and G-CSF) resulted in 53 percent complete remissions and 11 percent improvement in 45 patients with high-risk myeloid malignancies, 13 of whom had MDS.⁵⁴⁴ CPX-351, a liposomal nanoparticle with cytarabine and daunorubicin in a fixed 5:1 ratio is currently being studied in patients with AML arising from MDS and may be more effective than standard anthracycline-based regimens.

Allogeneic Hematopoietic Stem Cell Transplantation

AHSCT has been used to treat various types of MDS in patients ranging in age from 1 month to older than 70 years.^{545,546} AHSCT remains the only treatment that can cure patients with the disease. Conditioning regimens have consisted of cyclophosphamide plus irradiation, fludarabine and busulfan, fludarabine and melphalan, or busulfan plus cyclophosphamide. Most patients have received transplants from histocompatible sibling donors, but the use of unrelated donors and of cord blood and haploidentical donors has increased. Patients with higher-risk karyotypes and more advanced disease do more poorly with transplantation, as do those with certain higher-risk genotypes such as a *TP53* mutation. Despite the increased age of donors and recipients and increased use of unrelated donors, transplantation outcomes in MDS are improving, in part as a result of molecular tissue typing and better supportive care.⁵⁴⁷ Numerous factors such as disease stage, patient age, comorbidities, prior therapies, type of donor, and source of stem cells need to be considered when recommending AHSCT to MDS patients.

AHSCT for MDS should be performed before the disease progresses to AML, but modeling of data from the International Bone Marrow Transplant Registry suggests that patients (age 60 to 70 years) with lower-risk disease have net loss of life whether fully myeloablative conditioning or reduced-intensity conditioning is used.^{548,549} When T-cell depletion is used to prevent graft-versus-host disease, the best outcomes occur in those who are transplanted while in remission, because T-cell depletion diminishes the graft-versus-leukemia effect.⁵⁵⁰

Poor-risk cytogenetic patterns may increase risk of relapse but not of nonrelapse mortality, but elevated pretransplant serum ferritin is correlated with less-favorable outcomes.^{414,551} In one retrospective series, blast percentage less than 5 percent at time of transplantation was the best predictor of improved disease-free survival, and myeloablative conditioning was associated with lower relapse risk but could not overcome the unfavorable effect of increased disease burden.⁵⁵² Patients with secondary MDS have comparable outcomes after AHSCT as those with *de novo* MDS when high-risk cytogenetics are considered.^{553,554} Pretransplantation neutropenia is also associated with inferior outcomes as a result of infection-related mortality.⁵⁵⁵ Prior therapy with demethylating agents does not appear to increase the toxicity of transplantation and whether it will improve outcomes by decreasing disease burden has yet to be studied systematically.^{556,557} Posttransplantation therapy with azacitidine and decitabine is also being explored, either as maintenance therapy, in an attempt to augment graft-versus-leukemia effect, or in an attempt to stave off imminent relapse.^{496,558}

The morbidity and mortality of various transplantation approaches for MDS remain high—at least 20 percent of patients—and currently

most patients are not candidates for any form of transplantation because of advanced age or comorbid conditions. Outcomes are similar for those treated with myeloablative and reduced-intensity conditioning.⁵⁵⁹ For those patients who relapse after AHSCT, outcomes are grim. Salvage therapy with donor lymphocyte infusions, second transplantations, or other immunologic manipulations may be feasible, but less than 10 percent of patients will experience prolonged disease-free survival.^{560,561}

Autologous Stem Cell Infusion

Patients with oligoblastic leukemia have been infused with their own stem cells after intensive chemotherapy.^{562–564} This strategy is rarely used in the present era. In MDS, autologous transplantation is limited by contamination of the stem cell product with a repopulating leukemic cell and the absence of a graft-versus-leukemia effect. In selected patients, peritransplantation mortality with intensive therapy and stem cell rescue has been approximately 10 percent, and approximately 50 percent of selected patients had extended survivals.⁵⁶⁵ The more advanced the disease at the time of treatment, the worse the outcome. With the increasing use of reduced-intensity AHSCT, autologous stem cell transplantation has been used less often. An antecedent diagnosis of RAEB had no influence on mobilization of blood stem cells and hematopoietic recovery after autologous stem cell transplantation for acute myeloid leukemia.⁵⁶⁶

Other Cytotoxic Drugs

Hydroxyurea and low-dose etoposide are useful in controlling leukemic cell proliferation but usually produce only partial responses in higher-risk MDS and do not influence survival duration.^{567,568} Occasional patients have achieved remissions with etoposide (50 mg as a 2-hour infusion, two to seven times weekly for 4 weeks; or 100 mg/day orally for 3 days and then 50 mg twice weekly).⁵⁶⁸ Low-dose melphalan,⁵⁶⁹ gemcitabine,⁵⁷⁰ irinotecan (CPT-11), a DNA topoisomerase I inhibitor,⁵⁷¹ troxacitabine, an enantiomer of cytarabine,^{572,573} and weekly doses of oral idarubicin⁵⁷⁴ have each resulted in responses in some patients. Clofarabine, a purine nucleoside analogue, also has activity in MDS, although renal insufficiency and hepatotoxicity limit its use to patients who require cytoreduction prior to transplant.⁵⁷⁵

Future Approaches

The FDA has not approved any new drugs for MDS therapy since 2006, and currently available therapies will lose effectiveness in the majority of patients within 2 to 3 years after treatment initiation. Unfortunately, targetable constitutively activating kinase mutations are rare in MDS, and for many MDS-associated mutations summarized above, including those that alter transcriptional regulation or pre-mRNA splicing, it is not clear how best to develop targeted therapy. In addition, clonal heterogeneity and the clonal architecture of MDS mean that currently it is often not known which mutations are early initiating events and which are later events important only for survival of a subclone.⁵⁷⁶ The advent of high-throughput techniques for genetic analysis and improved understanding of disease biology may lead to development of new, more effective approaches in the future.

CHAPTER 88

ACUTE MYELOGENOUS LEUKEMIA

Jane L. Liesveld and Marshall A. Lichtman

SUMMARY

Acute myelogenous leukemia (AML) is the result of a sequence of somatic mutations in a primitive multipotential hematopoietic cell. Exposure to radiation, chronic exposure to high doses of benzene, and chronic inhalation of tobacco smoke increase the incidence of the disease. Obesity has been found to be an endogenous risk factor. A small but increasing proportion of cases develop after a patient with lymphoma, a nonhematologic cancer, or an autoimmune disorder is exposed to intensive chemotherapy, especially with alkylating agents or topoisomerase II inhibitors. The mutant (leukemic) hematopoietic cell acquires the features of a leukemic stem cell capable of self-renewal and desultory differentiation and maturation. It gains a growth and survival advantage in relationship to the normal polyclonal pool of hematopoietic stem cells. As the progeny of this mutant, now leukemic, multipotential cell proliferates to form approximately 10 to 100 billion or more cells, normal hematopoiesis is inhibited, and normal red cell, neutrophil, and platelet blood levels fall. The resultant anemia leads to weakness, exertional limitations, and pallor; the thrombocytopenia to spontaneous hemorrhage, usually in the skin and mucous membranes; and the neutropenia and monocytopenia to poor wound healing and minor infections. Severe infection usually does not occur at diagnosis, but often does if the disease progresses because of lack of treatment or if chemotherapy intensifies the decrease of blood neutrophil and monocyte levels. The diagnosis is made by measurement of blood cell counts and examination of blood and marrow cells and is based on identification of

leukemic blast cells in the blood and marrow. The diagnosis of the myelogenous form of acute leukemia is confirmed specifically by identification of myeloperoxidase activity in blast cells or by identifying characteristic cluster of differentiation (CD) antigens on the blast cells (e.g., CD13, CD33). Because the leukemic stem cell is capable of imperfect differentiation and maturation, the clone may contain cells that have the morphologic or immunophenotypic features of erythroblasts, megakaryocytes, monocytes, eosinophils, or, rarely, basophils or mast cells, in addition to myeloblasts or promyelocytes. When one cell line is sufficiently dominant, the leukemia may be referred to by that lineage: for example, acute erythroid, acute megakaryocytic, acute monocytic leukemia, and so on. Certain cytogenetic alterations are more frequent; these abnormalities include t(8;21), t(15;17), inversion 16 or t(16;16), trisomy 8, and deletions of all or part of chromosome 5 or 7. A translocation involving chromosome 17 at the site of the retinoic acid receptor- α (*RAR- α*) gene is uniquely associated with acute promyelocytic leukemia. AML usually is treated with cytarabine and an anthracycline antibiotic, although other drugs may be added or substituted in poor-prognosis, older, refractory, or relapsed patients. The exception to this approach is the treatment of acute promyelocytic leukemia with all-*trans*-retinoic acid, arsenic trioxide, and sometimes an anthracycline antibiotic. High-dose chemotherapy and either autologous stem cell infusion or allogeneic hematopoietic stem cell transplantation may be used in an effort to treat relapse or patients at high risk to relapse after chemotherapy treatment. The probability of remission in acute myelogenous leukemia ranges from approximately 80 percent in children to less than 25 percent in octogenarians. The probability for cure decreases from approximately 50 percent in children to virtually zero in octogenarians.

DEFINITION AND HISTORY

Acute myelogenous leukemia (AML) is a clonal, malignant disease of hematopoietic tissues that is characterized by (1) accumulation of abnormal (leukemic) blast cells, principally in the marrow, and (2) impaired production of normal blood cells. Thus, the leukemic cell infiltration in marrow is accompanied, nearly invariably, by anemia and thrombocytopenia. The absolute neutrophil count may be low or normal, depending on the total white cell count.

The first well-documented case of acute leukemia is attributed to Friedreich,¹ but Ebstein² was the first to use the term *acute leukämie* in 1889. This work led to the general appreciation of the clinical distinctions between AML and chronic myelogenous leukemia (CML).³ In 1878, Neumann,⁴ who proposed that marrow was the site of blood cell production, first suggested that leukemia originated in the marrow and used the term *myelogene* (myelogenous) leukemia. The availability of polychromatic stains, as a result of the work of Ehrlich,⁵ the description of the myeloblast and myelocyte by Naegeli,⁶ and the earliest appreciation of the common origin of red cells and leukocytes by Hirschfeld⁷ laid the foundation for our current understanding of the disease.

Although Theodor Boveri proposed a critical role for chromosomal abnormalities in the development of cancer in 1914, a series of technical developments in the 1950s was needed to permit informed examination of the chromosomes of human cancer cells. Thereafter, the discovery that a G group chromosome consistently had a foreshortened long arm in the cells of patients with CML (Philadelphia chromosome) supported the concept that chromosome abnormalities may be specifically linked to a cancer phenotype. This finding was followed by the introduction of banding of chromosomes, which enhanced the specific

Acronyms and Abbreviations: ALL, acute lymphocytic leukemia; AML, acute myelogenous leukemia; APL, acute promyelocytic leukemia; ATRA, all-*trans* retinoic acid; CBF, core binding factor; CD, cluster of differentiation; ceAML, clonally evolved acute myelogenous leukemia; CEBPA, CCAAT-enhancer binding protein A; CML, chronic myelogenous leukemia; CNL, chronic neutrophilic leukemia; DNMT, DNA methyltransferase; FAB, French-American-British classification; FISH, fluorescence *in situ* hybridization; FLT, Fms-like tyrosine kinase; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-monocyte colony-stimulating factor; GVHD, graft-versus-host disease; HLA, human leukocyte antigen; HSC, hematopoietic stem cell; IDH, isocitrate dehydrogenase; ITD, internal tandem duplication; MDR, multidrug resistance; MDS, myelodysplastic syndrome; NPM1, nucleophosmin-1 mutation; OS, overall survival; PAS, periodic acid-Schiff; PCR, polymerase chain reaction; P-gp, permeability glycoprotein; ppm, parts per million; PTD, partial tandem duplication; RAR, retinoic acid receptor; RT, reverse transcriptase; RUNX, runt-related transcription factor; SAHA, suberoylanilide hydroxamic acid; t, translocation; TdT, terminal deoxynucleotidyl transferase; TET, ten-eleven translocation; TKD, tyrosine kinase domain; TMD, transient myeloproliferative disease; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor; WBC, white blood cell; WHO, World Health Organization; WT, Wilms tumor.

identification of individual chromosomes and the point at which they break in the formation of a translocation, inversion, or deletion. This technologic advance unleashed the power of cancer cytogenetics and initiated an era of leukemia study based not solely on the appearance of cells under the microscope (phenotype) but also by their chromosomal or genetic abnormality (genotype).⁸ The completion of the human genome project further enhanced the specificity of the identification of gene alterations.⁹ These advances permitted (1) more precise understanding of the molecular pathology of specific leukemia subtypes, (2) improvement of diagnostic and prognostic methods for the study of AML, and (3) identification of molecular targets for therapy.

The introduction to the clinic by Holland, Ellison, and colleagues¹⁰ of arabinosyl cytosine (cytarabine) in the late 1960s as the first potent drug for treatment of AML, followed by their introduction of the combination of 7 days of cytosine arabinoside and 3 days of daunorubicin in the early 1970s (the “7 plus 3 regimen”)¹¹ opened the era of effective therapy for AML. This drug combination or its congeners remains the mainstay of treatment over 4 decades later.¹² The description of allogeneic marrow (stem cell) transplantation as a curative therapy for AML by Thomas and colleagues¹³ in 1977 ushered in the era of hematopoietic stem cell (HSC) transplantation as a modality to cure eligible patients with AML.

ETIOLOGY AND PATHOGENESIS

ENVIRONMENTAL FACTORS

Table 88-1 lists the major conditions that predispose to development of AML. Only four environmental factors are established causal agents: high-dose radiation exposure,^{14,15} chronic, high-dose benzene exposure (≥ 40 parts per million [ppm]-years),¹⁶⁻¹⁸ chronic tobacco smoking,¹⁹ and chemotherapeutic (DNA-damaging) agents.²⁰⁻²² Most patients have not been exposed to an antecedent causative factor. Exposure to high-linear energy transfer radiation from α -emitting radioisotopes such as thorium dioxide increases the risk of AML.²³ Case-control studies have sometimes found a relationship between AML and organic solvents, petroleum products, radon exposure, pesticides, and herbicides, but these data have been inconsistent, have shown no association in other studies, and have not reached a level comparable to the strong association that exists for high-dose benzene, high-dose external irradiation, and certain chemotherapeutic agents. There is a significant association between tobacco smoking and AML with a relative risk of about 1.5 to 2.0.^{24,25} Although formaldehyde has been suspected of being a leukemogen, detailed analysis has not supported this contention.^{26,27}

An endogenous factor that increases risk is obesity. Studies in North America show an increased risk of AML in men and women with elevated body mass index, and this is particularly notable for acute promyelocytic leukemia. The precise mechanisms are still unclear but may be related, in part, to elevated leptin levels, decreased adiponectin levels, shortened telomeres, and as yet unknown factors in obese subjects.²⁸

EVOLUTION FROM A CHRONIC MYELOID NEOPLASM

AML may develop from the progression of other clonal disorders of a multipotential hematopoietic cell, including CML, chronic myelomonocytic leukemia, chronic neutrophilic leukemia (CNL), polycythemia vera, primary myelofibrosis, essential thrombocythemia, and clonal cytopenia or oligoblastic myelogenous leukemia. The latter two are considered forms of myelodysplastic syndrome (MDS) (see Table 88-1). Clonal progression occurs as a result of genomic instability and the acquisition of additional mutations, although with a different

probability of occurrence in each chronic myeloid neoplasm (Chap. 83). The frequency of clonal progression to AML is enhanced by radiation or chemotherapy in patients with polycythemia vera (Chap. 84) or essential thrombocythemia (Chap. 85).²⁹ Although some refer to this as secondary AML, it should be called clonally evolved AML (ceAML) to distinguish it from secondary AML that results from radiation or chemotherapy given to patients who do not have a precedent clonal myeloid disease. In the population of patients with preceding clonal myeloid neoplasms, a myeloid leukemic clone already exists and is not induced secondarily. Evolution to AML represents the natural history of the neoplasm, albeit sometimes accelerated by various external mutagens.

AGING AND ACUTE MYELOGENOUS LEUKEMIA—RELEVANT SOMATIC MUTATIONS

Very low copy number gene mutations characteristic of leukemia or lymphoma have been detected in the blood of healthy individuals. An analysis of blood cell DNA sequence data has identified 77 blood cell-specific mutations in cancer-associated genes, the majority being associated with advanced age. A large majority of these mutations were from 19 leukemia and/or lymphoma-associated genes, and nine were recurrently mutated (*DNMT3A*, *TET2*, *JAK2*, *ASXL1*, *TP53*, *GNAS*, *PPM1D*, *BCORL1*, and *SF3B1*). Additional mutations were found in a very small fraction of blood cells. Comparison of these findings to mutations in hematologic malignancies identified other recurrently mutated genes.

The blood cells of more than 2 percent of individuals (5 to 6 percent of people older than 70 years) contain mutations that may represent premalignant events that can cause clonal hematopoietic expansion. These events may, in part, explain the age-dependent incidence of AML (Fig. 88-1).^{29a}

PREDISPOSING DISEASES

Patients who develop AML may have an antecedent predisposing non-myeloid disease, such as aplastic anemia (poly- or oligoclonal T-cell disorder), myeloma (monoclonal B-cell disorder),^{30,31} or, rarely, AIDS (HIV-induced polyclonal T-cell disorder).³² An association between Langerhans cell histiocytosis, immune thyroid diseases, and familial polyendocrine disorder and AML has been reported.³³⁻³⁶ A number of inherited conditions carry an increased risk of AML (see Table 88-1).³⁷⁻⁸⁰ In the inherited syndromes, at least several pathogenetic types of gene alterations are represented: (1) DNA repair defects, for example, Fanconi anemia; (2) susceptibility genes favoring a second mutation, for example, familial platelet syndrome; (3) tumor-suppressor defects, for example, dyskeratosis congenita; and (4) unknown mechanisms, for example, ataxia-pancytopenia (See Tables 35-8 and 35-9 in Chap. 35 for further details of each pathogenetic process). There is evidence from central registry studies that any disorder that results in chronic immune stimulation, such as infection or autoimmune diseases may be associated with AML and MDS.⁸¹ The prevalence of essential monoclonal gammopathy is not increased in AML patients.⁸²

Figure 88-1. The annual incidence of acute myelogenous leukemia as a function of age. There is a relatively small increase to approximately 1.5 cases per 100,000 persons in the first year of life, representing congenital, neonatal, and infant AML. The incidence falls to a nadir of 0.4 new cases per 100,000 persons over the first 10 years of life and then rises again to 1 case per 100,000 in the second decade of life. From approximately 25 years of age, the incidence increases exponentially (log-linear) to approximately 25 cases per 100,000 population in octogenarians.

MOLECULAR PATHOGENESIS

The Leukemia Stem Cell

AML results from a series of somatic mutations in a primitive hematopoietic multipotential progenitor cell or, very occasionally, a more differentiated, more lineage-restricted progenitor cell.^{83,84} Some cases of monocytic leukemia, promyelocytic leukemia, and AML in younger individuals may arise in a progenitor cell with lineage restrictions (progenitor cell leukemia).^{85–87} Other morphologic phenotypes and older patients likely have a disease that originates in a primitive multipotential cell. In the latter case, all myeloid blood cell lineages can be derived from the leukemic stem cell because it retains the ability for some degree of differentiation and maturation (Chap. 83). Because the T lymphocytes, B lymphocytes, and natural killer cells in cases of AML, often, have not carried a cytogenetic abnormality as did the myeloid cells, claims of origin in the pluripotential lymphohematopoietic cell have been ambiguous. The most compelling data indicate that the bulk of AML cases arise from one of two predominant CD34+ cell populations: CD34+CD45RA+CD38–CD90– (multipotential myeloid progenitor) or CD34+CD38+CD45RA+CD110+ (granulocyte-monocyte progenitor). Both of these cell populations correspond to normal hematopoietic progenitor cells and not the normal pluripotential lymphohematopoietic stem cell.^{86,88} This finding was confirmed by showing that the two leukemic cell populations were more similar to the corresponding normal progenitor populations than to pluripotential lymphohematopoietic stem cells by microarray gene expression analysis.⁸⁸ The AML stem cell arises from somatic mutations in one of these populations in most, but not all, cases of AML. Because progenitor cells are not self-renewing, the somatic mutations transform the normal progenitor cell to an AML stem cell capable of sustaining the disease and transplanting it into immunosuppressed (NOD/SCID/IL2R γ null) mice.

Preleukemic Stem Cells

There is, also, experimental evidence that some cases of AML can arise from the accumulation of genetic and epigenetic changes in normal pluripotential HSCs.⁸⁹ Through single-cell analysis, it has been shown that clonal progression of multiple mutations occurs in the HSC of some AML patients.⁹⁰ These HSCs have been given the name “preleukemic HSCs” and it is proposed that AML progresses from such cells carrying founder mutations. These are thought to form a reservoir after therapy that can lead to relapse.⁸⁹ An HSC with DNA methyltransferase 3A (*DNMT3A*) mutants was found to have multilineage repopulation advantage over nonmutated HSCs in xenografts, establishing their identity as preleukemic HSCs. These cells can be found in remission marrow samples of patients with AML.⁹¹ Genes that regulate DNA methylation such as *DNMT3A*, ten-eleven translocation (*TET*) 2, and isocitrate dehydrogenase (*IDH*) 1 and 2 promote self-renewal and block differentiation of stem and progenitor cells. Acquisition of these mutations in an HSC can lead to their clonal expansion resulting in a preleukemia stem cell population.⁹²

Mutational History

Genome sequencing in AML cells shows that most mutations occur at random before acquisition of the initiating driver mutation, giving each clone a mutational history. The founding clone may acquire additional mutations, yielding subclones that contribute to disease progression or relapse.⁹³ When copy number aberrations and copy-neutral loss-of-heterozygosity gene mutation profiles are analyzed in AML cases at diagnosis and at relapse, the relapsed leukemia always reflects reemergence of the founder clone. In persistent AML cases, sometimes two coexisting dominant clones can be seen, one chemotherapy-sensitive and one chemotherapy-resistant, suggesting that refractory or relapsed

AML cases represent incomplete eradication of founder clones and not emergence of unrelated clones.⁹⁴

Role of Telomeres

AML with multiple chromosome aberrations is always characterized by critically short telomeres. Age-related critical telomere shortening may have a role in generating chromosome instability in AML pathogenesis.⁹⁵ Leukemic cells show variable reduction in length of telomeric DNA, and telomere length in blood cells during remission is greater.⁹⁶

Somatic Mutations

Somatic mutation results from a chromosomal translocation in a large fraction of patients.⁹⁷ The translocation results in rearrangement of a critical region of a protooncogene. Fusion of portions of two genes often does not prevent the processes of transcription and translation; thus, the fusion oncogene encodes a fusion protein that, because of its abnormal structure, disrupts a normal cell pathway and predisposes to a malignant transformation of the cell. The mutant protein product often is a transcription factor or an element in the transcription pathway that disrupts the regulatory sequences controlling growth rate or survival of blood cell progenitors and their differentiation and maturation.^{97–99} Examples of genes often mutated are core binding factor (*CBF*), retinoic acid receptor- α (*RAR- α*), *HOX* family, mixed-lineage leukemia (*MLL*), and others. *CBF* has two subunits: *CBF- β* and runt-related transcription factor 1 (*RUNX1*, formerly *AML1*). Approximately 10 percent of AML cases have translocations involving one or the other of these latter two genes (*CBF- β* and *RUNX1*), although the percentage varies depending on the patient's age at onset. In patients younger than age 50 years, the frequency is approximately 20 percent. In patients older than age 50 years, the frequency is approximately 6 percent. *CBF* activates genes involved in myeloid and lymphoid differentiation and maturation. These primary mutations are not sufficient to cause AML. Additional activating mutations, for example, in hematopoietic tyrosine kinases Fms-like tyrosine kinase (*FLT3*) and *KIT* or in *N-RAS* and *K-RAS*, are required to induce a proliferative advantage in the affected primitive cell. Other protooncogene mutations that occur in leukemic cells involve *FES*, *FOS*, *GATA-1*, *JUN B*, *MPL*, *MYC*, *p53*, *PU.1*, *RB*, *WT1* (Wilms tumor 1), *WNT*, *NPM1*, *CEPBA* (CCAAT-enhancer binding protein A), and other genes. Their interaction with loss-of-function mutations in hematopoietic transcription factors probably causes the acute leukemia phenotype characterized by a disorder of proliferation, programmed cell death, differentiation, and maturation. Because the mutant stem or early progenitor cell can proliferate and retains the capability to differentiate, a wide variety of phenotypes can emerge from a leukemic transformation.

EFFECT OF MOLECULAR AND CYTOGENETIC MARKERS ON DISEASE PROGRESSION AND THERAPEUTIC RESPONSIVENESS

Gene Markers

AML is a heterogeneous disease, and the extent to which cytogenetic and molecular markers define severity and influence treatment decisions is a rapidly changing arena of investigation as a result of continued refinements in correlating individual or a combination of mutations on disease progression. Using molecular markers to predict disease course in AML is complicated because these are incompletely determined, and they often interact. Several risk scores based on chromosome and molecular markers have integrated factors such as age and white blood cell (WBC) count into the scoring systems.^{100,101} Others have identified common gene signatures that can be independent predictors of disease progression or therapeutic response and provide a structure for risk

stratification. Some of these signatures have 24 genes,¹⁰² and some have a seven gene-epigenetic score.¹⁰³ Some have relied on genetic profiling,¹⁰⁴ some on expression of a subset of molecular mutations,¹⁰⁵ and some have combined epigenetic and genetic markers.¹⁰⁶ Prognostic models of AML based solely on molecular markers have been proposed. In one, *PML-RAR α* or *CEPBA* double mutations were very favorable (overall survival [OS] at 3 years of 83 percent), *RUNX1-RUNX1T1*, *CBFB-MYH11*, or *NPM1* (nucleophosmin-1 mutation) without *FLT3-ITD* (OS of 62.6 percent), intermediate with no mutation allowing assignment to other groups (OS of 44 percent), *MLL-PTD* or *RUNX1*, or *ASXL1* mutation (OS of 22 percent), and very unfavorable, *TP53* mutation (OS at 3 years, 0 percent).

Chromosome Markers

In general, those patients with changes involving CBF, that is, t(8/21), inv(16), t(16;16), or t(15;17), a feature of acute promyelocytic leukemia (APL), are considered predictors of a more favorable outcome. Those with complex karyotype, 11q23, t(6;9), abnormalities of chromosome 5 or 7 or inv3 (t3;3) are associated with a poor outcome. The remainder of cytogenetic abnormalities and those patients with a normal karyotype are considered of intermediate risk.¹⁰⁷ These are determined by the behavior of the average of very large groups of patients and confidence intervals are not calculated. Patients with favorable cytogenetic patterns may have poor outcomes and those with less favorable patterns may do better than anticipated.

Deletions of all or part of a chromosome (e.g., chromosome 5, 7, or 9) or additional chromosomes (such as trisomy 4, 8, or 13) are common cytogenetic abnormalities (Chap. 11), although the specific causative oncogenes or tumor-suppressor genes in these latter circumstances have not been defined. Deletions in chromosomes 5 and 7 and complex cytogenetic abnormalities are associated with a worse prognosis and are increased in frequency in older patients and cases of AML following cytotoxic therapy compared to *de novo* cases.¹⁰⁸ Because the genes residing on the undeleted homologous segment of chromosome 5 are not mutated, an epigenetic lesion, such as hypermethylation of a gene allelic to one on the deleted segment on chromosome 5, may contribute to the leukemogenic event.

In APL, *PML-RAR- α* fusion protein represses retinoic acid-inducible genes, which prevent appropriate maturation of promyelocytes. The induced disruption, which involves corepressor-histone deacetylase complexes, results in the leukemic phenotype (see "Acute Promyelocytic Leukemia" below).^{109,110}

Patients with CBF leukemias are younger on average and in addition to t(8;21) or inv(16)/t(16;16) may have *RUNX1/RUNX1T1* and *CBFB/MYH11* oncogenes.¹¹¹ The cure rate in these so-called good-risk patients is only approximately 55 percent, however. Patients with CBF leukemias expressing *KIT* have a worse prognosis.¹¹² In the case of inv(16)/t(16;16), different fusion transcripts can be formed, and these may have associated with *KIT* mutations and other abnormal chromosomal associations with differing prognosis, possibly from activation of caspase activity.¹¹³ Secondary genetic changes in inv(16) or t(16;16) cases may have an impact on prognosis. *RAS*, *KIT*, *FLT3*-internal tandem duplication (ITD), and *FLT3-TKD* each affect prognosis. *FLT3-TKD*, trisomy 8, age, and therapy-related AML were associated with worse prognosis.¹¹⁴ In t(8;21) leukemias, epigenetic silencing of *microRNA-193a* activates the PTEN/PI3K signaling pathway,¹¹⁵ and wild-type *RUNX1* can attenuate nuclear factor-kappaB (NF- κ B) signaling, events not present in the t(8;21) translocation leukemias.¹¹⁶

3q Abnormalities *EVII* and *MDS1/EVII* expression in AML is associated with poor prognosis and is a distinct entity. These chromosome 3 abnormalities are found in only approximately 4 percent of AML cases. These include inv(3) or t(3;3), t(3q26), t(3q21), and other

miscellaneous 3q abnormalities.¹¹⁷ These generally have an unfavorable prognosis.¹¹⁸

Monosomal Karyotype A monosomy has been associated with decreased chance of achieving remission or of survival, especially when combined with *TP53* mutations.^{119,120}

OTHER ACQUIRED MUTATIONS

Approximately 45 percent of AML cases have a normal karyotype. Sequencing has shown that mutations in *NPM1*, *DNMT1*, *FLT3*, *KIT*, *CEBPA*, *TET2*, and others may have diagnostic and prognostic implications. When genomes of APL with a known founder event (*PML-RAR α*) are sequenced and compared with normal karyotype AML and exomes of HSCs from normal donors, most mutations in AML genomes are random events that occurred in HSC before the initiating mutation occurred. As the clone expands, one or two additional, cooperating mutations may result in development of a leukemia, and these clones may acquire additional mutations, leading to subclones.¹²¹ DNA sequences of leukemia cell and normal skin cell genomes of a patient with AML showed 12 acquired mutations within coding sequences of genes and 532 somatic point mutations in conserved or regulatory portions of the genome.¹²² When whole-genome or whole-exome sequencing was performed in 200 AML cases, it was found that an average of only 13 mutations occurred in the genes. Only a total of 23 genes were mutated. There were nine categories of genes thought relevant for pathogenesis: (1) transcription-factor fusions, (2) nucleophosmin, tumor-suppressor, (3) DNA methylation-related, (4) signaling, chromatin-modifying, (5) transcription-factor, (6) cohesion-complex, and (7) spliceosome-complex genes. Many of these genes had patterns of cooperation and mutual exclusivity.¹²³ Table 88-2 lists commonly mutated genes in cytogenetically normal AML in order of decreasing frequency.

Nucleophosmin-1 Mutations *NPM1* mutations are the most frequent genetic alterations in AML, found in approximately half of patients with a normal karyotype.^{124,125} The mutation in exon 12 results in loss of the residue that requires its binding to nucleoli such that the *NPM1* protein is abnormally localized to the cytoplasm.¹²⁶ Studies show that mutant *NPM1* without *FLT3-ITD* represents a favorable prognostic marker.¹²⁷ *NPM1* mutations also have a favorable prognostic impact in older patients.¹²⁸ Mutated regions of *NPM1* elicit T-cell responses which might indicate that immunotherapy could have a role in these mutated cases.¹²⁹

FLT3 Mutations *FLT3* encodes a tyrosine kinase receptor in normal myeloid and lymphoid progenitors. ITD of *FLT3* on chromosome 13 occurs in approximately 25 percent of adult AML cases, but occurs more frequently in cases of AML with normal cytogenetic patterns, monocytic phenotype, and *PML-RAR- α* or *DEK-CAN* translocations.^{124,125,130} The *FLT3-ITD* mutation confers a poor prognosis if the ratio of mutant to wild-type expression is high.¹³⁰⁻¹³² *FLT3-ITD* expression is often higher at relapse.¹³³ *FLT3-ITD* upregulates *MCL-1* to promote survival of AML stem cells through signal transducer and activator of transcription (STAT) 5 activation.¹³⁴ *FLT3-ITD* adversely affects the outcome of an allogeneic stem cell transplant, but more than half of patients harboring this mutation who receive transplants can survive leukemia free for 2 or more years.¹³⁵ Point mutations in the tyrosine kinase domain (TKD) of *FLT3* (*FLT3-TKD*) mutations occur in approximately 6 percent of AML cases and have little impact on outcomes.¹³⁶

DNMT3A Mutations The *DNMT3A* gene encodes a DNA methyltransferase isoform. The process of DNA methylation involves the addition of a methyl group on a cytosine residue at a C-G site. If this methylation happens in the promoter region of a coding gene, the gene will be silenced. The DNMT enzymes contribute to leukemogenesis by mediating tumor suppressor gene silencing.¹³⁷ *DNMT3A* mutations have been found in approximately 20 percent of AML patients with normal

TABLE 88-2. Commonly Mutated Genes In Cytogenetically Normal Acute Myelogenous Leukemia

Mutated Gene	Approximate Frequency in AML with Normal Karyotype (%)	Implication	Comments	References
<i>NPM1</i>	50	More-favorable outcomes	Most frequently mutated gene in AML. Allogeneic transplantation not needed in first remission if this mutation occurs in absence of mutated <i>FLT3-ITD</i>	124–129
<i>FLT3 ITD</i>	40	Less-favorable outcomes		124, 125, 130–137
<i>DNMT3A</i>	20	Less-favorable outcomes	Seen more often in AML patients with normal cytogenetics. Mutant <i>NPM1</i> , <i>FLT3-ITD</i> , and <i>IDH1</i> have been found more frequently in AML patients with <i>DNMT3A</i> mutations compared to those with wild-type <i>DNMT3A</i>	137–143
<i>RUNX1</i>	15	Less-favorable outcomes		144–149
<i>TET2</i>	15	Less-favorable outcomes	Coincidence of mutated <i>TET2</i> with <i>NPM1</i> mutation in the absence of <i>FLT3-ITD</i> mutation predicts a less-favorable outcome	150–153
<i>CEBPA</i>	15	More-favorable outcomes	Only cases with double mutations associated with favorable outcomes	124, 154–157
<i>NRAS</i>	10	Little effect on prognosis		144
<i>IDH1 or IDH2</i>	10	Little effect on outcomes	More frequent in AML patients with normal cytogenetics. Frequently associated with <i>NPM1</i> . Adverse prognostic factor if present with mutated <i>NPM1</i> without <i>FLT3-ITD</i> . Serum 2-hydroxyglutarate levels indicate high probability of <i>IDH</i> mutation	138, 158, 159–164
<i>MLL-PTD</i>	8	Less-favorable outcomes		144
<i>WT1</i>	6	Less-favorable outcomes	More frequent in females than in males (6.6 vs. 4.7%; $P = 0.014$) and in patients <60 than in patients >60 years ($P < 0.001$)	166, 167
<i>FLT3-TKD</i>	6	Little effect on outcomes	May appear after use of <i>FLT3-ITD</i> inhibitor	132, 136

Gene frequencies are approximations with some variation from study to study. Outcome statement does not reflect effect of interacting mutations unless otherwise noted in comments. Outcome statements are based on consensus and vary from one study to another.

AML, acute myelogenous leukemia; *CEBPA*, CCAAT/enhancer binding protein alpha; *DNMT3A*, DNA methyltransferase 3A; *FLT*, FMS-like tyrosine kinase; *IDH*, isocitrate dehydrogenase; *ITD*, internal tandem duplication; *MLL*, myeloid-lymphoid (mixed-lineage) leukemia; *NPM*, nucleophosmin; *PTD*, partial tandem deletion; *RAS*, rat sarcoma; *RUNX*, Runt-related transcription factor; *TET*, ten-eleven translocation; *TKD*, tyrosine kinase domain; *WT*, Wilms tumor.

cytogenetic patterns.¹³⁸ These cases more frequently had mutations in *NPM1*, *FLT3*, and *IDH1* genes as well.¹³⁹ *DNMT3A* mutations are associated with a poorer prognosis^{139–142} and their significance appears to be age-dependent.¹⁴³ The R882 mutation was associated with adverse prognosis in older patients, and non-R882 mutations with adverse prognosis in younger patients.

***RUNX1* Mutations** The *RUNX1* gene is located on chromosome 21q22 and is involved in hematopoiesis at all stages through its interaction with *CBFβ*. It acts as an activator or repressor of numerous genes, including transcription factors.^{144,145} In *de novo* AML, *RUNX1* mutations were found with normal and noncomplex karyotypes. They were sometimes associated with *MLL-PTD* (partial tandem duplication [PTD]) and *FLT3-ITD*, and they were associated with a poor prognosis independent of other molecular mutations.¹⁴⁶ Another group found these mutations in 5.6 percent of cases, associated with cytogenetically normal AML and an association with *MLL-PTD* mutations, refractory disease, and, as an independent risk factor, an inferior relapse-free survival and overall survival. The use of allogeneic HSC transplant did have a

favorable impact in such cases.¹⁴⁷ Another series found *RUNX1* mutations to be twice as common in older than younger patients with normal cytogenetics, and to have an adverse outcome effect in both age groups. Mutated blasts had molecular signatures suggesting origin in a primitive hematopoietic cell.¹⁴⁸ *RUNX1* mutations have been found to cooperate with granulocyte colony-stimulating factor receptor (CSFR) mutations in congenital neutropenia to lead to acute leukemia or MDS.¹⁴⁹

***TET2* Mutations** The *TET2* protein inactivation may occur through a loss of function mutation, deletion, or through *IDH1/2* mutations. It is a member of a family of dioxygenases that catalyze conversion of 5-methyl-cytosine to 5-hydroxymethyl-cytosine and promote DNA demethylation. *TET2* has many roles in normal hematopoiesis, and knockout mice show that it is a tumor suppressor, which haploinsufficiency initiates myeloid transformations.¹⁵⁰ *TET2* mutations are found in approximately 25 percent of patients and in those who have mutated *CEBPA* and/or mutated *NPM1* without a *FLT3/ITD* mutation.^{151,152} Patients with AML and a *TET2* mutation had a shorter event-free and overall survival compared with patients who were *TET2* wild-type. They

did not predict for outcomes in those with cytogenetically normal AML and with wild-type *CEBPα*, *NPM1*, and/or *FLT3/ITD*.¹⁵³ Whether these patients would benefit from alternate therapies, such as hypomethylating agents or HSC transplantation, has not been determined.

CEBPα Mutation *CEBPα* is a leucine zipper transcription factor involved in myeloid differentiation. Mutations have been described in approximately 10 percent of AML patients.¹²⁴ Single or double mutations can occur, and these rarely are associated with *FLT3/ITD* or with *NPM1* mutations. *CEBPα*-double, but not *CEBPα*-single, mutation patients had a significantly better overall survival at 8 years than wild-type, *CEBPα*-single, or *CEBPα*-double and *FLT3/ITD*-positive patients.¹⁵⁴ A multivariate analysis found that only double-mutant *CEBPα* was associated with a favorable event-free, relapse-free, and overall survival. Double-mutant cases were also associated with a unique gene signature as compared with single-mutant cases.^{155,156} Some AML patients with *CEBPα*-double mutations harbor *TET2* and *GATA2* mutations, which can affect prognostic outlook unfavorably with *TET2* or favorably with *GATA2* mutations.¹⁵⁷

IDH1 and IDH2 Mutations The IDHs catalyze oxidative decarboxylation of isocitrate into α -ketoglutarate. The nicotinamide adenine dinucleotide phosphate–dependent IDH1 enzyme is encoded by the *IDH1* gene on chromosome 2q33.3, and the nicotinamide adenine dinucleotide phosphate–dependent IDH2 enzyme is encoded by the *IDH2* gene on chromosome 15q26.1.¹⁵⁸ Mutations in *IDH1* (R132) or *IDH2* (R172) occur in 10 percent of AML patients.^{158,159} Both were found to adversely impact relapse-free survival and overall survival. Multivariate analysis showed that *IDH* mutation conferred an adverse impact in those patients with an *NPM1* mutation without *FLT3-ITD*. Favorable genotype cytogenetically normal AML is therefore defined as *NPM1* or *CEBPα* mutation with neither a *FLT3-ITD* nor an *IDH1* mutation. An *IDH1* mutation was also associated with a higher relapse rate and shorter overall survival.¹⁶⁰ Another group found a higher frequency of *IDH1* and *IDH2* mutations in cytogenetically normal AML. Both were found to have an unfavorable impact on outcome.¹⁶¹ *IDH1* was exclusive of other mutations. Serum 2-hydroxyglutarate production has been found to predict for the presence of *IDH1/2* mutations.^{162,163} A level of 700 mg/mL was found to discriminate mutated from nonmutated cases, and those with levels greater than 20 ng/mL at the time of remission had shorter overall survival.¹⁶³ Mutant *IDH1* has been found to accelerate cell-cycle transition and to activate mitogen-activated protein kinase signaling. Mutant *IDH1* can be inhibited, suggesting this may be a therapeutic target.¹⁶⁴

WT1 Mutations Mutations of the *WT1* gene have been reported in approximately 5 to 10 percent of cytogenetically normal patients with AML.¹⁶⁵ Some studies suggest association with a poor prognosis, but others have not. *WT1* SNP rs 16754 was associated with a favorable risk, but acquired mutations did not affect the development of complete remission, relapse-free survival, or overall survival.¹⁶⁶ A study of *WT1* mutations in older patients with cytogenetically normal AML also showed poor treatment response across all age-groups and association with a distinct gene expression signature.¹⁶⁷

Prognostic Impact of Other Molecular Abnormalities

Other methodologies to evaluate genomic aberrations have been reported to have prognostic importance beyond the impact of the individual mutations described above and in Table 88–2. Abnormal genome-wide single nucleotide polymorphisms have adverse prognosis in patients with AML and a normal karyotype.¹⁶⁸ Expression signatures of cytokines and chemokines have an independent prognostic impact in AML.¹⁶⁹ Profiling transcriptional pathways may have prognostic importance in AML as well.¹⁷⁰

There is also interplay among molecular aberrancies in AML. These include: (1) gene interaction with a microRNA; for example,

BAALC and *miR-3151* in cytogenetically normal AML,¹⁷¹ (2) distinct patterns of dual or multiple gene mutation patterns that have prognostic impact,¹⁷² and (3) concurrence of somatic mutations and transcriptional regulators such as interaction between *ERG* expression and a heptad of transcriptional factors¹⁷³ that maintains a stem cell-like signature. Furthermore, interactions between genetic and epigenetic changes (DNA methylation, histone acetylation, histone methylation, and others) are anticipated to have prognostic impact.^{174,175}

DEREGULATED SIGNALING PATHWAYS

The mutations in AML result in deregulation of any of several signal transduction pathways, which disrupt pathways that ensure the normal behavior of (1) differentiation and maturation, (2) proliferation, and (3) survival signals in hematopoietic cells. The pathways involved are myriad, but several represent the majority of cases such as the (1) PI3K-AKT, (2) RAS-RAF-MEK-ERK, and (3) STAT3 signaling sequences.¹⁷⁶ The expectation is that a relative small number of downstream signaling pathways mediate the leukemogenic effect of gene mutations, making the potential targets for therapy less diffuse than suggested by the number of gene mutations involved in AML.

MODE OF INHERITANCE

In most cases, little evidence is seen for a strong influence of inherited factors. The identical twin of a child with acute leukemia has a heightened risk of developing the disease. However, the risk appears to be related to intraplacental metastasis and thus falls to the risk of a non-identical sibling after the first few years of life.^{177,178} The risk of AML in a nonidentical sibling in the United States is elevated, perhaps two-fold to threefold, compared to the risk of AML in unrelated American children of European descent younger than age 15 years.^{177,179} A registry study in Sweden showed no significant aggregation in relatives of patients with AML. An increased risk of AML/MDS was found among relatives of patients diagnosed at younger than age 21 years (relative risk 6.5).¹⁸⁰ Clusters of AML cases in families have been documented, but their frequency is low.⁵⁸ Clusters of AML in unrelated persons in a community are uncommon and, when investigated, usually prove to be a chance occurrence. Heritable *GATA2* mutations may be associated with familial MDS and AML,¹⁸¹ and loss-of-function germline *GATA2* mutations (the MonoMAC [monocytopenia and mycobacterial infections] syndrome) may be associated with primary lymphedema and a predisposition to AML (Emberger syndrome).^{182–184} Mutations of *CEBPα* have been found in familial AML.¹⁸⁵ In one study of 27 families with familial MDS/AML, genetic characterization could be shown in 10 (four with *GATA2* mutations, five with telomerase mutations, and one with mutated *RUNX1*).¹⁸⁶ Mutations in telomerase RNA (*TERC*) or telomerase reverse transcriptase component (*TERT*) are also associated with familial AML.^{185,187}

EPIDEMIOLOGY

AML is the predominant form of leukemia during the neonatal period but represents a small proportion of cases during childhood and adolescence. Approximately 20,000 new cases of AML occur annually, representing approximately 35 percent of the new cases of leukemia in the United States each year. Approximately 12,000 patients with AML in the United States die each year as a result of the disease. The incidence rate of AML is approximately 1.5 per 100,000 in infants younger than 1 year of age, decreases to approximately 0.4 per 100,000 children ages 5 to 9 years, increases gradually to approximately 1.0 persons per 100,000 population until age 25 years, and thereafter increases exponentially until the rate reaches approximately 25 per 100,000 persons

in octogenarians (see Fig. 88–1). The exception to this exponential age-related increase in incidence is APL, which does not change greatly in incidence with age.¹⁸⁸

AML accounts for 15 to 20 percent of the acute leukemias in children and 80 percent of the acute leukemias in adults. It is slightly more common in males. Little difference in incidence is seen between individuals of African or European descent at any age. A somewhat lower incidence is seen in persons of Asian descent.¹⁸⁹ An increase in the frequency of AML is seen in Jews, especially those of Eastern European descent. The acute promyelocytic variant of AML is somewhat more common in Latinos.^{190,191} In a large population study of 426,068 patients treated with chemotherapy for malignancy, 301 AML cases occurred, 4.7 times the number expected. Over time (1975 to 2008), the risks increased for non-Hodgkin lymphoma, declined for ovarian cancer and myeloma, and were heterogeneous for breast and Hodgkin lymphoma, reflecting changing treatment patterns.¹⁹²

CLASSIFICATION

Variants of AML can be identified by morphologic features of blood films using polychromatic stains and histochemical reactions,¹⁹³ monoclonal antibodies against surface markers,¹⁹⁴ or by the presence of specific chromosome translocations or other molecular changes as discussed above.^{104,105} The epitopes on the progenitor cells of several phenotypic variants overlap, and several monoclonal antibodies are required to make specific distinctions among cell types (Table 88–3; see also “Morphologic Variants of Acute Myelogenous Leukemia” below). Correlation between morphologic and immunologic phenotyping of AML is poor. However, poor correlation is expected because morphologic phenotyping is more subjective, given to observer variation, and is based on qualitative factors, whereas the immunologic phenotyping, which characterizes surface molecular features, is more accurate and reproducible. The correlation is improved only somewhat if morphology and histochemistry are coupled.¹⁹⁵ Gene-expression profiling is early in its use as a classification technique for AML but will be more specific and informative than current methods.^{104,105} The outcome will depend on the simplification and automation of such techniques, and the availability of drugs that make such distinctions in the prognostic category of practical utility. Chapter 83 contains the classification of morphologic

variants of AML (see Chap. 83, Table 83–1 and Fig. 83–3). A cogent argument has been made that, for practical purposes, a classification that initially considers morphologic phenotype and immunophenotype is advisable. Cytogenetics, molecular genetics, gene-expression profiling, and other considerations can, and should, be layered on as available and useful in influencing therapy, and these features are starting to be incorporated into the World Health Organization (WHO) Classification of AML.¹⁹⁶ It is anticipated that molecular classifications will continue to evolve and dominate clinical decision making in the future.¹⁰⁵

CLINICAL FEATURES

SIGNS AND SYMPTOMS

General

Signs and symptoms that signal the onset of AML include pallor, fatigue, weakness, palpitations, and dyspnea on exertion. The signs and symptoms reflect the development of anemia; however, weakness, loss of sense of well-being, and fatigue on exertion can be disproportionate to the severity of anemia.^{197–201}

Easy bruising, petechiae, epistaxis, gingival bleeding, conjunctival hemorrhages, and prolonged bleeding from skin injuries reflect thrombocytopenia and are frequent early manifestations of the disease. Very infrequently, gastrointestinal, genitourinary, bronchopulmonary, or CNS bleeding occurs at the onset of disease.

Pustules or other minor pyogenic infections of the skin and of minor cuts or wounds are most common. Major infections, such as sinusitis, pneumonia, pyelonephritis, and meningitis, are uncommon presenting features of the disease, partly because absolute neutrophil counts less than $0.5 \times 10^9/L$ are uncommon until chemotherapy starts. With intensification of neutropenia and monocytopenia after chemotherapy, major bacterial, fungal, or viral infections become more frequent. Anorexia and weight loss are frequent findings. Fever is present in many patients at the time of diagnosis.^{200,202–204} Palpable splenomegaly or hepatomegaly occurs in approximately one-quarter of patients.^{197,198,201} Lymphadenopathy is extremely uncommon,^{201,205,206} except in the monocytic variant of AML.²⁰⁷

SPECIFIC ORGAN SYSTEM INVOLVEMENT

Leukemic blast cells circulate and enter most tissues in small numbers. Occasionally, biopsy (or autopsy) uncovers marked aggregates or infiltrates of leukemic cells. Collections of such cells may cause functional disturbances. Extramedullary involvement is most common in monocytic or myelomonocytic leukemia.^{208,209}

Skin involvement may be of three types: nonspecific lesions, leukemia cutis, or granulocytic (myeloid) sarcoma of skin and subcutis.^{210–213} Nonspecific lesions include macules, papules, vesicles, pyoderma gangrenosum, vasculitis,^{214–216} neutrophilic dermatitis (Sweet syndrome),²¹⁷ cutis verticis gyrata,²¹⁸ and erythema multiforme or nodosum.^{211,212} Skin involvement preceding marrow and blood involvement or relapse occurs, but is rare.^{219–222}

Sensory organ involvement is very unusual, but retinal, choroidal, iridial, and optic nerve infiltration can occur.²²³ Otitis externa and interna, inner ear hemorrhage, and mastoid tumors with seventh nerve involvement may be presenting signs.^{224–226}

The gastrointestinal tract may be involved at any point, but functional disturbances are unusual.^{227,228} The mouth, colon, and anal canal are sites of involvement that most commonly lead to symptoms. Oral manifestations may prompt the patient to visit the dentist. Gingival or periodontal infiltration and dental abscesses may lead to an extraction, followed by prolonged bleeding of an infected tooth socket.²²⁹ Ileotyphlitis (enterocolitis), a necrotizing inflammatory lesion involving the

TABLE 88–3. Immunologic Phenotypes of Acute Myelogenous Leukemia

Phenotype	Usually Positive
Myeloblastic	CD11b, CD13, CD15, CD33, CD117, HLA-DR
Myelomonocytic	CD11b, CD13, CD14, CD15, CD32, CD33, HLA-DR
Erythroid	Glycophorin, spectrin, ABH antigens, carbonic anhydrase I, HLA-DR, CD71 (transferrin receptor)
Promyelocytic	CD13, CD33
Monocytic	CD11b, 11c, CD13, CD14, CD33, CD65, HLA-DR
Megakaryoblastic	CD34, CD41, CD42, CD61, anti-von Willebrand factor
Basophilic	CD11b, CD13, CD33, CD123, CD203c
Mast cell	CD13, CD33, CD117

terminal ileum, cecum, and ascending colon, can be a presenting syndrome or occur during treatment.^{230–233} Fever, abdominal pain, bloody diarrhea, or ileus may be present and occasionally mimic appendicitis. Intestinal perforation, an inflammatory mass, and associated infection with enteric gram-negative bacilli or clostridial species often are associated with a fatal outcome. Isolated involvement of the gastrointestinal tract is rare.^{234,235} Proctitis, especially common in the monocytic variant of AML, can be a presenting sign or a vexing problem during periods of severe granulocytopenia and diarrhea.²²⁷

The *respiratory tract* can be involved by infiltrates or tumors, leading to laryngeal obstruction, parenchymal infiltrates, alveolar septal infiltration, or pleural seeding. Each of these events can result in severe symptoms and radiologic findings.^{236–240}

Cardiac involvement is frequent but rarely causes symptoms. Symptomatic pericardial infiltrates, transmural ventricular infiltrates with hemorrhage, and endocardial foci with associated intracavitary thrombi can occasionally cause heart failure, arrhythmia, and death.²⁴¹ Infiltration of the conducting system or valve leaflets or myocardial infarction has occurred.²⁴²

The *urogenital system* can be affected. The kidneys are infiltrated with leukemic cells in a high proportion of cases, but functional abnormalities are rare. Hemorrhage in the pelvis or collecting system is frequent.^{243,244} Cases of vulvar, bladder neck, prostatic, and testicular involvement have been described.^{245–247}

Osteoarticular symptoms may occur. Bone pain, joint pain, and bone necrosis can occur, and, rarely, arthritis with effusion is present.²⁴⁸ Crystal-induced arthritis of either calcium pyrophosphate dihydrate (pseudogout) or monosodium urate (gout) may be responsible for the synovitis in some cases.²⁴⁹

Central or peripheral *nervous system* involvement by infiltration of leukemic cells is very uncommon, although meningeal involvement is an important consideration in the treatment of the monocytic type of AML.^{250,251} An association of CNS involvement and diabetes insipidus in AML with monosomy 7²⁵² and inversion of chromosome 16^{253,254} has been reported.

MYELOID (GRANULOCYTIC) SARCOMA

Myeloid sarcoma (synonyms: granulocytic sarcoma, chloroma, myeloblastoma, monocytoma) is a tumor composed of myeloblasts, monoblasts, or megakaryocytes.^{255–260} The tumor may occur as an extramedullary mass without evidence of leukemia in blood or marrow, so-called nonleukemic myeloid sarcomas, or in association with AML. When the tumor appears as an isolated lesion, it initially may be misdiagnosed as extranodal lymphoma because they look like lymphoid cells on biopsy.²⁵⁷ They may be found in virtually any location, including the skin; orbit; paranasal sinuses; bone; chest wall; breast; heart; gastrointestinal, respiratory, or genitourinary tract; central or peripheral nervous system; or lymph nodes and spleen. The tumors originally were called *chloromas* because of the green color imparted by the high concentration of the enzyme myeloperoxidase present in myelogenous leukemic cells. Biopsy specimens are positive for chloracetate esterase, lysozyme, myeloperoxidase, and cluster of differentiation (CD) markers of myeloid cells. When myeloid sarcomas are the initial manifestation of AML, the appearance of the disease in the blood and marrow may follow weeks or months later. Abnormalities in chromosome 8 are the most frequent cytogenetic disturbance in myeloid sarcomas.²⁵⁸ Systemic chemotherapy, rather than local therapy, should be used for treatment, although the long-term outcome in such cases usually is poor.^{260–262} Patients having AML with t(8;21) or inv16 have a propensity to develop extramedullary leukemia,^{263–266} and such patients with myeloid sarcomas have a poorer outcome after treatment than those who do not have extramedullary lesions.^{263,265}

LABORATORY FEATURES

BLOOD CELL FINDINGS

Anemia is an almost constant feature.^{197–201} Red cell life span may be mildly shortened, but the principal cause of anemia is inadequate production of red cells. The reticulocyte count usually is between 0.5 and 2.0 percent. Occasionally patients have rapid destruction of autologous and transfused red cells as a result of an unknown mechanism, referred to as milieu hemolysis. The presence of red cell autoantibodies (positive direct antiglobulin test) is very uncommon and may be non-specific (anti-C₃), perhaps related to circulating immune complexes. Red cell morphology is mildly abnormal, with exaggerated variation in cell size and occasional poikilocytes. Nucleated red cells or stippled erythrocytes may be present. Less often, extreme abnormalities of red cell size, shape, and hemoglobin content occur (AML with trilineage dysmorphism), but these changes are seen more often in oligoblastic myelogenous leukemia (Chap. 87).

Thrombocytopenia is nearly always present at the time of diagnosis. The mechanism of thrombocytopenia is a combination of inadequate production and decreased survival of platelets. More than half of patients have a platelet count less than $50 \times 10^9/L$ at the time of diagnosis.²⁶⁷ Giant platelets and poorly granulated platelets with functional abnormalities can occur.²⁶⁸ Defects in platelet aggregation and 5-hydroxytryptamine release are frequent.²⁶⁸

The total leukocyte count is less than $5 \times 10^9/L$ in approximately half of patients at the time of diagnosis.^{197–201} The absolute neutrophil count is less than $1 \times 10^9/L$ in more than half of cases at diagnosis.^{97–201} Patients with very elevated total leukocyte counts have a low proportion of mature neutrophils but may have a normal absolute neutrophil count. Hypersegmented, hyposegmented, and hypogranular mature neutrophils may be present. Cytochemical abnormalities of blood neutrophils include low or absent myeloperoxidase or low alkaline phosphatase activity.²⁶⁹ Defects in phagocytosis or microbial killing are common.^{270,270A}

Myeloblasts almost always are present in the blood but may be infrequent in severely leukopenic patients. Diligent search may uncover the myeloblasts, or examination of a white cell concentrate (buffy coat) may permit their identification. Classic leukemic blast cells are agranular, but mixtures of immature cells, including agranular and slightly granular cells ranging up to overt progranulocytes, can occur. Auer rods are elliptical cytoplasmic inclusions approximately 1.0 to 1.5 μm long and 0.5 μm wide that derive from azurophilic granules (Fig. 88–2B). The inclusions are present in the blast cells of approximately 15 percent of cases. When present, the inclusions are found in only a small percentage of blast cells when examined with polychrome stains.¹⁹³ An exception is APL, in which a higher proportion of cells have Auer rods and some have multiple (bundles) of rods (faggot cells). This finding can be dramatic if peroxidase stain is used to highlight the Auer rods.

MARROW FINDINGS

Morphology

The marrow always contains leukemic blast cells. From 3 to 95 percent of marrow cells are blasts at the time of diagnosis or relapse (see Fig. 88–2A). The WHO has invoked an arbitrary threshold of 20 percent of marrow nucleated cells being blast cells to distinguish polyblastic AML (≥ 20 percent blasts) from oligoblastic myelogenous leukemia (< 20 percent blasts).^{197–201} The latter situation is referred to as refractory anemia with excess blasts, a MDS (Chap. 87). The WHO choice of ≥ 20 percent blasts is an arbitrary standard as acute monocytic leukemia, APL, acute erythroid leukemia, and other variants often have less than 20 percent blast cells at the time of diagnosis,²⁷¹ and if any blasts are found with a case of AML in which the cells have a t(8;21) or other CBF inversions or

Figure 88-2. Blood and marrow images of major subtypes of acute myelogenous leukemia. **A.** Blood film of acute myelogenous leukemia (AML) without maturation (acute myeloblastic leukemia). Five myeloblasts are evident. High nuclear-to-cytoplasmic ratio. Agranular cells. Nucleoli in each cell. **B.** Blood film. AML without maturation (acute myeloblastic leukemia). Three myeloblasts, one containing an Auer rod. **C.** Marrow film. AML with maturation. Three leukemic myeloblasts admixed with myelocytes, bands, and segmented neutrophils. **D.** Blood film. Acute promyelocytic leukemia. Majority of cells are heavily granulated leukemic promyelocytes. **E.** Blood film. Acute promyelocytic leukemia. Myeloperoxidase stain. Intensely positive. Numerous stained (black) granules in cytoplasm of leukemic progenulocytes. **F.** Blood film. Acute myelomonocytic leukemia. Double esterase stain. Leukemic monocytic cells stained dark blue and leukemic neutrophil precursors stained reddish-brown. **G.** Marrow film. AML with inv16. Note high proportion of eosinophils in field. Note myeloblasts with very large nucleoli at upper right. Also, intermediate leukemic granulocytic forms. **H.** Blood film. Acute monocytic leukemia. Leukemic cells have characteristics of monocytes with agranular gray cytoplasm and reniform or folded nuclei with characteristic chromatin staining. This case had hyperleukocytosis as evident by leukemic monocyte frequency in the blood film. **I.** Blood film. Acute erythroid leukemia. Note population of extremely hypochromic cells with scattered bizarre-shaped poikilocytes admixed with normal-appearing red cells. **J.** Marrow film. Acute erythroid leukemia. Giant erythroblasts with multilobulated nuclei. **K.** Marrow film. Acute erythroid leukemia. Note giant trinucleate erythroblast and other leukemic erythroblasts with periodic acid–Schiff–positive cytoplasmic staining (reddish granules). **L.** Marrow section. Acute megakaryoblastic leukemia. Marrow replaced with atypical two- and three-lobed leukemic megakaryocytes with bold nucleoli. **M.** Marrow film. Acute megakaryoblastic leukemia. Marrow replaced with atypical megakaryocytes and megakaryoblasts with cytoplasmic disorganization, fragmentation, and budding. **N.** Marrow film. Acute megakaryoblastic leukemia. Marrow replaced with atypical megakaryocytes and megakaryoblasts staining for platelet glycoprotein IIIa (reddish-brown). Platelets in background also stained. **O.** Marrow section. Acute megakaryoblastic leukemia. Argentophilic (silver) stain shows marked increase in collagen, type III fibrils (marrow reticulin fibrosis), characteristic of this AML subtype. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

translocations, AML is the diagnosis. Moreover, relapse of AML can be identified at any increase in blast count >2 percent. In addition, patients with oligoblastic leukemia with 10 to 19 percent marrow leukemic blast cells are identical in all other phenotypic findings and survival to those with 20 to 29 percent marrow blast cells. Any distinctions between the two groups in survival are a function of age, cytogenetic risk category, and molecular features, not the blast count.²⁷² This arbitrary boundary prevents patients, otherwise suitable, to enter clinical trials.

Myeloblasts are distinguished from lymphoblasts by any of three pathognomonic features: reactivity with specific histochemical stains; Auer rods in the cells (see Fig. 88-2B); or reactivity with a panel of monoclonal antibodies against epitopes present on myeloblasts (e.g., CD13, CD33, CD117) (see Table 88-3). Leukemic myeloblasts give positive histochemical reactions for myeloperoxidase, Sudan black B, or naphthyl AS-D-chloroacetate esterase stains. Auer rods can be found in the marrow blast cells in approximately one-sixth of cases. Blast cells may express granulocytic (CD15, CD65) or monocytic (CD11b, CD11c, CD14, CD64) surface antigens. They typically do not express either lymphoid surface markers or membrane or cytoplasmic immunoglobulin. No immunoglobulin gene rearrangement or T-lymphocyte receptor gene rearrangement is evident with molecular probes (see “Hybrid and Mixed Leukemias” below). In a proportion of otherwise typical cases of AML, the cells may contain terminal deoxynucleotidyl transferase (TdT).^{273,274} Variations in marrow findings are discussed below in “Morphologic Variants of Acute Myelogenous Leukemia.” Normal erythropoiesis, megakaryocytopoiesis, and granulopoiesis are decreased or absent in the marrow aspirate. The biopsy may contain residual islands of erythroblasts or megakaryocytes. Dysmorphic changes in hematopoietic cells, including very small or large erythroblasts with nuclear fragmentation or binucleation or delayed nuclear condensation; small or monolobed megakaryocytes; or hypogranulated, bilobed, or monolobed neutrophils, may occur in 30 to 50 percent of patients with *de novo* AML.²⁷⁵ Marrow reticulin fibrosis is common but usually is slight to moderate except in cases of megakaryoblastic leukemia, in which intense fibrosis is the rule.²⁷⁶ Increased blood vessel density (angiogenesis) is present in the marrow of patients with AML compared to normal subjects.^{277,278} Various angiogenic factors, including vascular endothelial growth factor (VEGF), basic fibroblast growth factor, angiogenin, and angiopoietin-1, are increased. VEGF detected histochemically in human marrow is closely correlated with the prevalence of leukemic myeloblasts in the various AML subtypes.²⁷⁹ AML cytogenetic variants may result in marrow basophilia (usually t(6;9))²⁸⁰ or marrow eosinophilia (usually inv16 or t(16;16)).²⁸¹

Cytogenetic and Genic Features

An abnormal number (aneuploidy) or structure (pseudodiploidy) of chromosomes or both are evident in approximately 55 percent of cases.²⁸²⁻²⁸⁵ The most prevalent abnormalities are trisomy 8, monosomy 7, monosomy 21, trisomy 21, and loss of an X or Y chromosome. However, any chromosome can be rearranged, added, or lost (Chap. 13). In cases of AML following chemotherapy or radiotherapy, loss of part or all of chromosomes 5 and 7 are a common features,²⁸⁶⁻²⁸⁸ as are the cytogenetic findings noted above for AML, occurring *de novo*. Table 88-4 lists the most frequent abnormalities and translocations seen in AML.^{282,283,286-308} The t(8;21) and inv(16) confer a more favorable outcome on average. t(15;17) confers a highly favorable prognosis. Deletion of all or part of chromosomes 5 and 7 or the presence of complex changes (greater than 3 abnormalities) confers an unfavorable prognosis. Other findings (e.g., normal karyotype, +8, 11q23) generally confer an intermediate prognosis (Chap. 13 has further details and discussion regarding impact of specific translocations).²⁸²⁻²⁸⁴

Approximately 45 percent of cases of AML contain cells that are cytogenetically normal. When five genes—*NPM1*, *FLT3*, *CEPBA*, *MLL*, and *NRAS*—were examined in 872 adults who were younger than 60 years of age with a normal karyotype, approximately 85 percent had a mutation in at least one of these genes. Mutations in *NPM1* or *CEPBA* were associated with more favorable outcomes, analogous to the category of favorable cytogenetics noted above. The microarray expression signature in patients with AML younger than age 60 years who have cytogenetically normal cells but high-risk molecular features, especially *FLT3-ITD* and/or wild-type *NPM1* expression, is correlated with outcome of therapy (see “Effect of Molecular and Cytogenetic Markers on Disease Progression and Therapeutic Responsiveness” above and Table 88-2). MicroRNAs regulate gene expression and the downregulation of the microRNA-181 family predicts a poor outcome. The microRNAs studied also revealed several important gene families that appear to be involved in the pathogenesis of AML, including genes involved in innate immunity (e.g., toll-like receptors and interleukin-1 β expression and regulation).³⁰⁹ (Chapters 13 and 83 provide further discussion of gene-array profiling and microRNA analysis and the section “Other Acquired Mutations” on molecular pathogenesis has a more detailed discussion of specific molecular markers.) Microarray-based gene-expression profiling is anticipated to become more important in precise diagnosis and subclassification of AML in the future.³¹⁰

PLASMA CHEMICAL FINDINGS

Prior to treatment, mild to moderate increases in serum uric acid and lactic dehydrogenase levels are frequent. Both levels are higher in myelomonocytic and monocytic AML than in other AML phenotypes.^{200,201} Occasional patients have very elevated uric acid levels, which usually occur after chemotherapy if proper precautions are not taken (e.g., hypouricemic agents and hydration therapy).³¹¹ Abnormalities of sodium, potassium, calcium, or hydrogen ion concentration are infrequent and usually mild.^{312,313} Severe hyponatremia associated with inappropriate antidiuretic hormone secretion has occurred at presentation.^{312,313} Severe hypernatremia as a consequence of diabetes insipidus can be an initial event.³¹⁴ Hypokalemia is a more frequent finding at presentation and is related to kaliuresis, although the reason for the proximal renal tubular dysfunction is unclear.^{312,313,315} The hypokalemia can be severe and often is worsened by the effects of treatment, especially use of kaliuretic antibiotics.³¹⁵ Factitious elevations in serum potassium levels have been reported in patients with hyperleukocytosis as a result of leakage from white cells *in vitro*.^{316,317} Factitious hypoglycemia and spurious hypoxia from the effects of high blast cell counts in blood can occur.^{314,318}

The presence of hypercalcemia is multifactorial,³¹⁹ but cases with increased ectopic parathormone-like activity in the plasma have been described.³²⁰ Severe lactic acidosis prior to treatment has been reported.^{312,321,322} Hypophosphatemia as a result of phosphate uptake by leukemic cells can occur.³²³ Ectopic adrenocorticotrophic hormone secretion,³²⁴ circulating immune complexes,³²⁵ and abnormal concentrations of coagulation factors or their inhibitors³²⁶ may be present.

Although prothrombin and partial thromboplastin times usually are normal or near normal, abnormal concentrations of coagulation factors are frequent. Elevations of platelet factor 4 and thromboxane B₂ occur often.³²⁷ Decreases in α_2 -antiplasmin, protein C, and antithrombin III levels are frequent³²⁷ and may be associated with venous thrombosis.³²⁸ APL and acute monocytic leukemia are associated with hypofibrinogenemia and other indicators of activation of coagulation or fibrinolysis (see “Morphologic Variants of Acute Myelogenous Leukemia” below).³²⁹

TABLE 88-4. Clinical Correlates of Frequent Cytogenetic Abnormalities Observed in Acute Myelogenous Leukemia

Chromosome Abnormality	Genes Affected	Clinical Correlation
Loss or gain of chromosome		
Deletions of part or all of chromosome 5 or 7	Not defined	Frequent in patients with acute myelogenous leukemia (AML) occurring <i>de novo</i> and in patients with history of chemical, drug, or radiation exposure and/or previous hematologic disease. ^{282,283,286,287}
Trisomy 8	Not defined	Very common abnormality in acute myeloblastic leukemia. Poor prognosis, often a secondary change. ^{283,289}
Translocation		
t(8;21) (q22;q22)	<i>RUNX1(AML1)</i> – <i>RUNX1T1(ETO)</i>	Present in ~8% of patients <50 years old and in 3% of patients >50 years old with AML. ²⁸⁸ Approximately 75% of cases have additional cytogenetic abnormalities, including loss of Y in males or X in females. Secondary cooperative mutations of <i>KRAS</i> , <i>NRAS</i> , <i>KIT</i> common. Present in ~40% of myelomonocytic phenotype. Higher frequency of myeloid sarcomas. ^{263–266}
t(15;17) (q31; q22)	<i>PML-RAR-α</i>	Represents ~6% of cases of AML. ²⁸⁸ Translocation involving chromosome 17, t(15;17), t(11;17), or t(5;17) is present in most cases of promyelocytic leukemia. ^{290,291}
t(9;11); (p22; q23)	<i>MLL</i> (especially <i>MLLT3</i>)	Present in ~7% of cases of AML. Associated with monocytic leukemia. ^{292,293} 11q23 translocations in 60% of infants with AML and carries poor prognosis. Rearranges <i>MLL</i> gene. ^{292–296} Many translocation partners for 11q23 translocation. ^{295–298} <i>MLL1</i> , <i>MLL4</i> , <i>MLL10</i> may also result in AML phenotype.
t(9;22) (q34; q22)	<i>BCR-ABL1</i>	Present in ~2% of patients with AML. ^{299,300}
t(1;22)(p13;q13)	<i>RBM15-MKL1</i>	<1% of cases of AML. Admixture of myeloblasts, megakaryoblasts, micromegakaryocytes with cytoplasmic blebbing, dysmorphic megakaryocytes. Reticulin fibrosis common. ³⁰¹
t(10;11) (p12-13;q14-21)	<i>PICALM-MLLT10</i>	Outcome similar to that of intermediate prognosis group; more extramedullary disease and CD7 expression. ³⁰²
Inversion		
Inv(16) (p13.1;q22) or t(16;16) (p13.1;q22)	<i>CBF-β MYH11</i>	Present in ~8% of patients <50 years of age and in ~3% of patients >50 years of age with AML ²⁸⁸ ; often acute myelomonocytic phenotype; associated with increased marrow eosinophils; predisposition to cervical lymphadenopathy, ³⁰³ better response to therapy. ^{304–307} Predisposed to myeloid sarcoma.
Inv(3) (q21q26.2)	<i>RPN1-EVI1</i>	~1% of cases of AML. Approximately 85% of cases with normal or increased platelet count. Marrow has increased dysmorphic, hypolobulated megakaryocytes. Hepatosplenomegaly more frequent than usual in AML. ³⁰⁸

SPECIAL CLINICAL FEATURES

Hyperleukocytosis

Leukocyte count is an independent prognostic factor in the outcome of AML treatment.³³⁰ Approximately 5 percent of patients with AML develop signs or symptoms attributable to a markedly elevated blood blast cell count, usually greater than $100 \times 10^9/L$ (Chap. 83).³³¹ Several subsets of AML are associated with a greater likelihood of presenting with hyperleukocytosis. These include acute myelomonocytic, acute monocytic, the microgranular variant of APL, and AML with inv16,11q23 rearrangements, or FLT3-ITD. The circulations of the CNS, lungs, and penis are most sensitive to the effects of leukostasis. Intracerebral hemorrhage from vascular occlusion, invasion, and disruption, sometimes complicated by thrombocytopenia and vascular insufficiency are the most virulent manifestations of the syndrome.^{332–336} Dizziness, stupor, dyspnea, and priapism may occur. Diabetes insipidus is another association.^{337,338} Other severe organ involvement also may occur infrequently. A high early mortality in patients with AML correlates with hyperleukocytosis greater than $100 \times 10^9/L$.^{334,335,339,340} Chemotherapy in hyperleukocytotic patients may lead to a pulmonary leukostatic syndrome, presumably from the effects of rigid, effete blast cells, or the discharge of large amounts of cell contents and resultant cell aggregation or other effects.^{341–343} Larger-vessel vascular occlusion as a result of white thrombi or masses of leukemic cells is rare.^{344,348} The

upregulation of endothelial cell intercellular adhesion molecule-1 and of leukemic blast cell lymphocyte function-associated antigen-1 may mediate the vessel wall interaction contributing to leukostasis.³⁴⁹

Hypoplastic Leukemia

Approximately 10 percent of patients with AML present with a syndrome that includes pancytopenia, often with inapparent blood blast cells, and absence of hepatic, splenic, or lymph nodal enlargement.^{350–352} If one corrects for the decrease in marrow cellularity with age, hypoplastic AML occurs in approximately 2 percent of cases.³⁵³ Approximately 75 percent of these patients are men older than 50 years of age. Marrow biopsy is hypocellular, which is the unusual feature of the syndrome, but leukemic blast cells are evident and present in a proportion of 10 to 90 percent of marrow cells. Response to intensive chemotherapeutic treatment, often with low-dose cytarabine because of the patients' very advanced age, has been relatively good, and 3-year survival rates are approximately the same as the rates of other age-matched patients.³⁵⁴

Oligoblastic Myelogenous (Subacute, Smoldering, Low-Infiltrate, Pauciblastic) Leukemia

Not infrequently, usually in patients older than 50 years of age, myelogenous leukemia is manifested by anemia and often thrombocytopenia. The leukocyte count may be low, normal, or increased, and a small proportion of blast cells are present in the blood (0 to 15 percent) and

marrow (3 to 19 percent). Such cases have been referred to as *oligoblastic myelogenous leukemia*, *subacute*, or *smoldering leukemia*,³⁵⁵ or classified as a MDS, particularly refractory anemia with excess blasts. The clinical course of the untreated disease can be protracted. The disease has a high morbidity and mortality from infection and hemorrhage and can evolve into overt (polyblastic) AML. The smoldering or oligoblastic leukemias (refractory anemia with excess blasts) historically have been grouped along with the clonal cytopenias as composing MDS; and, the diagnosis and treatment of these variants are discussed in Chap. 87. Biologically and clinically, the disorders in this subset of the MDS with blast cell proportions in the marrow above normal are leukemias, not dysplasias, but they have a slower rate of progression than polyblastic myelogenous leukemia. Dysmorphogenesis of red cells, neutrophils, and platelets is more frequent and more striking than in the average case of polyblastic AML (Chap. 87), but such dysmorphogenesis also occurs in polyblastic leukemia, so-called AML with trilineage dysmorphia.²⁷⁵ A discussion of the spectrum of myelogenous leukemias, ranging from minimal to severe deviation neoplasms, can be found in Chap. 83.

Philadelphia Chromosome–Positive Acute Myelogenous Leukemia

Approximately 2 percent of patients with AML have the Philadelphia (Ph) chromosome t(9;22)(q34;q11) in a significant proportion (10 to 100 percent) of leukemic blast cells.^{356–358} The blast cells have surface antigens, such as CD13 and CD33, characteristic of myeloid leukemias.^{359,360} One interpretation of the concurrence of AML with t(9;22) is that it represents CML presenting in myeloid blast crisis.^{361–363} The arguments in favor of this proposal are as follows: (1) Blast crisis may occur within days after diagnosis of Ph chromosome–positive CML. (2) Cases can present with additional cytogenetic changes comparable to CML in blast crisis.^{361,363} (3) Marked hepatosplenomegaly, uncharacteristic of AML, may be present.^{362,363} (4) Platelet counts may be normal, and basophils can be increased.^{361,363} (5) A long prodromal period of weakness and weight loss may occur, and some features of CML, such as granulocytosis, can appear after treatment with chemotherapy.³⁶⁴ (6) Ph chromosome–positive AML has a poor prognosis, as in myeloid blast crisis of CML. (7) The breakpoint on chromosome 22 in the *M-bcr* may be typical of CML, and the product of the fusion *BCR-ABL* gene is a p210 tyrosine kinase identical to that of classic CML.^{360,363–368} (8) Occasional cases express p210 and p190 tyrosine kinases, now known to be features of CML.³⁶⁸ (9) Some patients enter a remission by converting to a phenotype analogous to chronic phase CML. An alternative view has been promulgated because (1) cases of Ph chromosome–positive AML can be a mosaic (normal and abnormal karyotypes)³⁶⁰, (2) the Ph chromosome may appear later in the course of the disease³⁶⁹; (3) additional chromosomal abnormalities often are different from those seen in the myeloblastic crisis of CML^{360,370,371}; and (4) in some cases, the *BCR-ABL* gene is not encoding a p210 but a p190 mutant tyrosine kinase,^{357,365,368,372} the former being most characteristic of CML. Moreover, Ph chromosome–positive AML has developed following Ph chromosome–negative oligoblastic myelogenous leukemia.^{357,373,374} Many cases of Ph chromosome–positive acute leukemia are myeloid-lymphoid hybrids.^{364,368,370,375} Thus, Ph chromosome–positive AML comes in two varieties: one with a break in *M-BCR* of chromosome 22 with a p210 product, which could be considered analogous to acute blast crisis of CML, and one with a molecular pathology resulting in the oncogene product being a p190 protein (*m-BCR*) that could be considered a *de novo* case.

Marrow Necrosis

Necrosis of the marrow is an uncommon event and can be seen in a wide variety of malignant and nonmalignant clinical disorders, but approximately two-thirds of cases are associated with lymphoid or myeloid

malignancies and about one-quarter of cases occur in patients with AML.³⁷⁶ Bone pain (approximately 80 percent of patients) and fever (approximately 70 percent of patients) are the two most common symptoms or signs. Anemia and thrombocytopenia, if not already present, results. White cell counts may be low or high. The blood may contain nucleated red cells and myeloid immaturity (approximately 50 percent of cases). Lactic dehydrogenase and alkaline phosphatase are elevated in approximately 50 percent of cases. The marrow aspirate is often watery and serosanguineous. An amorphous extracellular eosinophilic background with disintegrating cells that have lost their staining characteristics with indistinct margins and varying degrees of pyknosis and karyorrhexis is characteristic. Rare cases have been described in which the marrow contained Charcot-Leyden crystals without an increase in eosinophils or basophils.³⁷⁷ Bony spicules may also show evidence of necrosis. Destruction of spicule architecture with loss of osteocytes, osteoblasts, and osteocytes may be seen. It is important not to identify these changes as artifact. Usually more than 50 percent of the biopsy is involved. Careful search may identify the underlying hematologic disorder in small islands of intact cells. Technetium-99m sulfur colloid scans show little or no uptake. Magnetic resonance imaging (MRI) may not be diagnostic but can show the extent of the necrosis by changes in signal intensity signifying an increase in water content in relation to fat. Both technetium scanning and MRI can point to areas of intact marrow that may be used to make a diagnosis of the underlying disease, if it is unknown. The pathophysiology is uncertain but is thought to be related to marrow vascular injury and or thrombosis secondary to inflammatory or immune factors and cytokines. The prognosis of marrow necrosis is largely related to the underlying disease. Repair of marrow can occur, if the patient enters remission.

NEONATAL MYELOPROLIFERATION AND LEUKEMIA

Four myeloproliferative syndromes related to AML have been identified in the neonate: transient myeloproliferative disorder, transient leukemia, congenital leukemia, and neonatal leukemia. Transient myeloproliferative disorder and transient leukemia are considered to represent the same phenomenon.

Transient myeloproliferative disease (TMD) can be present at birth or occur shortly thereafter in approximately 10 percent of infants with Down syndrome.^{378–384} The leukocyte count is markedly elevated, blast cells are present in the blood and marrow, and anemia and thrombocytopenia may be present, but the latter are not constant findings. The liver and spleen may be enlarged. Results of cytogenetic studies and marrow cell culture studies are normal, except for trisomy 21, which is characteristic of Down syndrome. The blast cells usually have the immunophenotype of megakaryocytes. In contrast to congenital leukemia, the elevated white cell and blast cell counts disappear in most patients (approximately 80 percent) over a period of weeks to months. In approximately 20 percent of patients, severe and potentially lethal complications of hydrops fetalis, hepatic fibrosis, or cardiorespiratory failure may occur.

In some cases, an additional cytogenetic abnormality is present, which disappears after regression of the myeloproliferative syndrome, suggesting a reversible clonal disorder (transient leukemia) that is replaced by normal hematopoiesis. The presence of a trisomy of chromosome 21 is essential for the disease as judged by three observations: the trisomy occurs in (1) the TMD clone of patients with constitutional trisomy 21, (2) the TMD clone in patients with Down syndrome with a cell mosaic pattern of trisomy 21, and (3) in the TMD clone of phenotypically normal infants without a constitutional trisomy 21, but with TMD. In the last case, trisomy 21 disappears with resolution of

the myeloproliferation.³⁸⁵ Candidate oncogenes on chromosome 21 responsible for the phenomenon include *FPDMM*, *RUNX1* (*CBF-β*), and *IFNAR*, among others.³⁸⁵ *GATA-1* mutations have been found in nearly all patients with TMD and in acute megakaryocytic leukemia in Down patients.³⁸⁶ The TMD syndrome may disappear, only to be followed shortly thereafter by acute leukemia, predominantly AML, but occasionally acute lymphocytic leukemia (ALL).

One hypothesis for TMD is that the disorder originates in a primitive cell of fetal hepatic hematopoiesis. The cell involutes and is replaced with marrow stem cells. Approximately 25 percent of newborns with Down syndrome and transient leukemia develop acute megakaryocytic leukemia in the first 4 years of life.^{387–389}

Very-low-dose cytarabine has been suggested for those patients with severe hepatic fibrosis, very high white cell counts, or hydrops fetalis.³⁸⁵ TMD cells in these infants are very sensitive to cytarabine.^{390,391}

Children with Down syndrome have a 150-fold risk of AML and about a 40-fold risk of ALL by age 5 years. A slightly increased risk of acute leukemia persists into older age. Myelogenous leukemia in patients with Down syndrome often has a megakaryoblastic or erythroid phenotype and may have an interstitial deletion of chromosome 21.^{380,381,392–395} This requires mutation in the *GATA1* gene in addition to trisomy 21, and sequential epigenetic changes occur as well in the evolution of acute megakaryoblastic leukemia.^{395,396} The response rate of infants with Down syndrome and AML to chemotherapy is very high over prolonged followup and better than the response of patients without Down syndrome.^{387,391,397,398} The response to adjusted-dose anthracycline antibiotic and cytarabine in Down syndrome children with AML is approximately 90 percent and the event-free 5-year survival is approximately 80 percent.³⁹⁴ In those cases with relapsed or refractory disease, outcomes are poor even with allogeneic HSC transplantation.³⁹⁹ ALL may occur, and the response to therapy is similar to the response of patients without Down syndrome of the same age. Most solid tumors occur less frequently in Down syndrome patients.³⁹⁰

Congenital or neonatal leukemia, a rare syndrome, occurs 10 times more frequently in newborns with Down syndrome than in newborns without trisomy 21.^{392,393} Leukocytosis, blood and marrow blast cells, hepatosplenomegaly, thrombocytopenia, purpura, anemia, and skin infiltrates are usual. The disease has been diagnosed prenatally. Cytogenetic abnormalities can occur and mark the leukemic clone.^{393,400,401} Monocytic leukemia and t(4;11) are the most common phenotype and karyotype.^{401–403} A case of vertical (transplacental) transmission of acute monocytic leukemia from mother to son has been reported.⁴⁰⁴

Infants who are normal at birth but develop AML in the first few weeks of life (neonatal leukemia) often display pallor, inadequate food intake, insufficient weight gain, diarrhea, and lethargy. The presence of a cytogenetic abnormality on band q23 of chromosome 11 is a very poor prognostic sign. Most infants with congenital or neonatal leukemia do not survive for more than a few weeks or months. Because treatment has been largely ineffective, observation to ascertain if TMD or a transient leukemia is present has been recommended if the clinical picture is unclear.⁴⁰⁵

HYBRID AND MIXED LEUKEMIAS

Hybrid Leukemias

Although coincidental myeloid and lymphoid clonal diseases have been reported for more than 60 years, the availability of techniques to identify surface antigens with monoclonal antibodies, immunoglobulin gene, and T-lymphocyte receptor gene rearrangements with molecular methods, and chromosome translocations by chromosome banding cytogenetic techniques has led to the appreciation of several types of hybrid acute leukemia.^{406–411}

In bilineal (interlineal) acute leukemias, a proportion of cells (>10 percent) have lymphoid and myeloid markers; *interlineal* here refers to lymphopoietic and myeloid gene expression. Bilineal (biphenotypic) leukemias are heterogeneous. Some patients have cells with both lymphoid and myeloid markers (chimeric), whereas other patients have cells with either lymphoid or myeloid markers but evidence that all the cells are part of the same malignant clone (mosaic). The bilineal leukemias may be synchronous (lymphoid and myeloid cells are present simultaneously) or asynchronous (in which lymphoid cells are succeeded by myeloid cells or vice versa), but evidence exists for their origin from the same clone.

Cases of biphenotypic leukemia that are morphologically or cytogenetically indicative of myelogenous leukemia have been referred to as LY+AML; the cases that are more indicative of lymphocytic leukemia are referred to as MY+ALL. As a group, interlineal hybrid leukemias treated with current regimens respond to therapy at approximately the same rate as AML cases without lymphoid markers.⁴⁰⁶ Some observers suggest altering drug regimens, depending on the balance between lymphoid and myeloid biochemical (drug-response) patterns.⁴¹²

Acute leukemias may be intralinear hybrids in that the blast cells have markers for two or more myeloid lineages (e.g., erythroid, granulocytic, and megakaryocytic) or, in the case of lymphocytic leukemias, both immunoglobulin gene rearrangement (B-lymphocyte type) and T-cell receptor gene rearrangement (T-lymphocyte type).

Myeloid–Natural Killer Cell Hybrids and t(8;13) Myeloid–Lymphoid Leukemias

Although most hybrid leukemias share myeloid and either B- or T-lymphocyte markers, two notable syndromes are associated with hybrid leukemias: (1) the myeloid leukemia and natural killer cell hybrid (CD56+, CD7+, CD13+, CD33+)^{413–419} and (2) the lymphoma, eosinophilia, and t(8;13) myeloid leukemia hybrid.^{420,421} Signs of lymphoma, such as mediastinal or other lymphadenopathy and extranodal lymphoid tumor, are mixed with findings compatible with AML in both syndromes. The morphology of the myeloid–natural killer cell leukemia often simulates APL, with hypergranular cytoplasm present but abnormality of chromosome 17 absent. The hybrids can appear *de novo* or after relapse of a lymphoma, T-cell leukemia, or blast crisis of CML. The hybrid leukemias usually have a poor prognosis. Myeloid antigens may not be evident at diagnosis in the natural killer cell hybrid but appear later in the course.⁴²² Hematopoietic stem cell transplantation should be considered in an eligible patient.⁴²³

Hybrid leukemias may result from either lineage infidelity caused by genetic misprogramming⁴¹³ or promiscuous gene expression, which occurs transiently in the differentiation of normal pluripotential HSCs. In the case of promiscuity, persistence of the transient normal event is thought to be present because of the block in differentiation that occurs.⁴⁰⁸ Genetic misprogramming (infidelity) could result from rearrangements of the DNA sequences that control the transcription of genes designating differentiation antigens.⁴²⁴

Mixed Leukemias

In these cases, lymphoid and myeloid cells are present simultaneously but are derived from separate clones, or sequential myeloid and lymphoid leukemia are present but the two lineages are derived from separate clones.

MEDIASTINAL GERM CELL TUMORS AND ACUTE MYELOGENOUS LEUKEMIA

An unusual but significant concordance has been reported between nonseminomatous mediastinal germ cell tumors and AML, especially

the megakaryoblastic variant.^{425–430} Mediastinal tumors are rare variants of germ cell tumors. The latter ordinarily occur as testicular teratomas and seminomas in men or as ovarian teratomas in women. They are thought to be derived from yolk sac cells that failed to migrate.^{428,429} AML is a HSC tumor derived from a cell type that is present in the yolk sac. Cytogenetic studies are compatible with a clonal relationship (identity) of mediastinal germ cells and myelogenous leukemia cells.^{426,427} Apparently, hematopoietic lineage genes are predisposed to expression in extragonadal (mediastinal) germ cell tumors. Use of etoposide, platinum, and related cytotoxic drugs for treatment of mediastinal germ cell tumors may induce secondary AML in a predisposed cell population.⁴³¹

GASTROINTESTINAL TUMORS AND ACUTE MYELOGENOUS LEUKEMIA

A study of 1892 patients with KIT-positive mesenchymal gastrointestinal stromal tumors found a significant subsequent incidence of AML (nine patients). The standardized incidence ratio was approximately 3.0 (confidence interval: 1.1 to 5.8). The patients had not received prior chemotherapy or radiotherapy and the median duration of gastrointestinal stromal tumors before onset of AML was 6 years.⁴³²

MORPHOLOGIC VARIANTS OF ACUTE MYELOGENOUS LEUKEMIA

Morphologic variants of AML (Table 88–5) may occur *de novo* or may be the manifestation of clonal evolution from essential thrombocythemia, idiopathic myelofibrosis, CML, or other chronic clonal myeloid disorders. For example, every phenotypic variant of AML can occur as the blast crisis of CML (Chap. 89).

ACUTE MYELOBLASTIC LEUKEMIA

The designation *acute myeloblastic leukemia* came into existence in the second decade of the 20th century,⁴ following the specific description of the myeloblast.⁶ Approximately 25 percent of AML cases have the features of acute myeloblastic leukemia, a variant in which the leukemic myeloblast is the predominant cell in the marrow. Acute myeloblastic leukemia was divided into two forms, designated *M0* and *M1* in the French-American-British (FAB) Classification. In either type, little evidence of maturation of myeloblasts exists, and the marrow is replaced by a monotonous population of blasts. In acute myeloblastic leukemia (*M0*), the patient's age distribution, presenting white cell count, and cytogenetic abnormalities are not distinctive. The blasts are nonreactive when stained for myeloperoxidase activity, and Auer rods are not seen. The blasts react with antibodies to myeloperoxidase and antibodies to CD13, CD33, and CD34. Human leukocyte antigen (HLA)-DR is positive in most patients. Occasional cases require *in situ* hybridization to identify the myeloperoxidase gene⁴³³ or genomic profiling for early myeloid-associated genes.⁴³⁴ Abnormal and unfavorable karyotypes (e.g., 5q–,7q–) and expression of the multidrug resistance (MDR) glycoprotein (p170) are more frequent. This phenotypic variant has a poor prognosis.^{435–438} In the other type of myeloblastic leukemia, designated *M1*, myeloblasts are present in the blood and make up more than 70 percent of marrow cells. Less than 15 percent of marrow cells are promyelocytes and myelocytes. Auer rods may be present in occasional blasts, but azurophilic granules are not evident in the blasts by light microscopy. At least 3 percent, but usually a much higher percentage, of the blast cells, have a positive reaction when stained for peroxidase or with Sudan black or react with monoclonal antibodies specific to myeloblasts, such as CD33. This morphologic subtype is denoted as *M1* in

the FAB classification. The WHO has divided acute myeloblastic leukemia into three types: AML without differentiation, AML without maturation, and AML with maturation. There is no evidence of a clinical distinction in response to therapy or in prognosis within these rarified designations.

In many cases of myeloblastic leukemia, more prominent granulocytic maturation is evident (FAB type *M2* or WHO designation AML with maturation). This variant is present in approximately 15 percent of AML cases; thus, approximately 45 percent of cases of AML are myeloblastic leukemia with or without maturation. Blasts usually constitute at least 20 percent of the marrow cells. Auer rods may be present in blast cells. Promyelocytes, myelocytes, and segmented neutrophils, the latter often with the acquired Pelger-Huët anomaly, may constitute 20 to 60 percent of marrow granulocytes. The anomaly is reflected in bilobed or monolobed neutrophils. Histochemical and surface markers of blast cells are typical of myeloblastic leukemia, and monocytic markers are absent or infrequent. Monocytes represent less than 10 percent of cells. A translocation between chromosomes 8 and 21 t(8;21)(q22;q22), often accompanied by loss of the Y chromosome in men or loss of an X chromosome in women, is associated with the phenotype and occurs in younger patients (average age approximately 30 years).^{439–441} Patients whose cells contain t(8;21) are more prone to develop myeloid sarcoma.^{263,266}

ACUTE MYELOMONOCYTIC LEUKEMIA

The ability of AML to express cells of the monocytic and granulocytic lineages was first highlighted in the early 1900s by Naegeli. Later, Hal Downey, a leading hematologist of the day, proposed the eponym *Naegeli type* for myelomonocytic leukemia.⁴⁴² Approximately 15 percent of patients with AML present with this variant, and they are more likely to have extramedullary infiltrates in gingiva, skin, or CNS than are patients with acute myeloblastic leukemia (see “Myeloid [Granulocytic] Sarcoma” above).⁴⁴³ A mixture of myeloblasts and monoblasts is found in the blood and marrow. More than 30 percent of marrow cells are a mixed population of myeloblasts, which react with peroxidase or chloracetate esterase, and monoblasts or promonocytes, which react with fluoride-inhibitable nonspecific esterase (see Fig. 88–2F). More than 20 percent of cells are monoblasts or promonocytes in blood and marrow. In some cases, individual cells react with monocytic and granulocytic histochemical stains.⁴⁴⁴ Serum and urinary lysozyme levels are increased in most cases. This variant of AML is referred to as *M4* in the FAB classification and as acute myelomonocytic leukemia in the WHO classification. Translocations involving chromosome 3 are associated with this phenotype.⁴⁴⁵

The proportion of marrow eosinophils⁴⁴⁶ or basophils⁴⁴⁷ may be increased. A particular variant of myelomonocytic leukemia has increased numbers of marrow eosinophils (10 to 50 percent), Auer rods in blast cells, and inversion or rearrangement of chromosome 16 (see Fig. 88–2G).^{304–307} The eosinophils are abnormally large, and the eosinophilic myelocytes contain large basophilic granules. Macrophages with ingested Charcot-Leyden crystals may be present. This phenotypic variant of AML has been designated *M4Eo* in the FAB classification. Although this variant has an increased risk of CNS involvement, it carries a more favorable prognosis than the average case of AML. Fluorescence *in situ* hybridization (FISH) is a more accurate method for detection of cryptic 16q22 gene rearrangements and is useful in conjunction with conventional cytogenetics for patients with *M4Eo* AML. AML with t(6;9)(p23;q34) is an uncommon variant, occurring in approximately 1 percent of cases, and may express itself as acute myelomonocytic or acute myeloblastic leukemia. Anemia, thrombocytopenia, a variable white cell count, and increased myeloblasts are frequent.

TABLE 88-5. Morphologic Variants of Acute Myelogenous Leukemia

Variant	Cytologic Features	Special Clinical Features	Special Laboratory Features
Acute myeloblastic leukemia (M0, M1, M2)	<ol style="list-style-type: none"> 1. Myeloblasts range from 20–90% of marrow cells. Cytoplasm occasionally contains Auer bodies. Nucleus shows fine reticular pattern and distinct nucleolus (1 or 2 usually). 2. Blast cells are sudanophilic. They are positive for myeloperoxidase and chloroacetate esterase, negative for nonspecific esterase, and negative or diffusely positive for PAS (no clumps or blocks). 3. Electron microscopy shows cytoplasmic primary granules. 	<ol style="list-style-type: none"> 1. Most common in adults, and most frequent variety in infants. 2. Three morphologic-cytochemical types (M0, M1, M2) 	<ol style="list-style-type: none"> 1. Chromosomes +8, -5, -7, del(11q), and complex abnormalities common. <i>RUNX1(AML1)</i> and <i>FLT3</i> mutations occur in approximately 20–25% of cases. 2. M0 type blast cells positive with antibody to myeloperoxidase and CD34 and CD13 or CD33 coexpression. <i>AML1</i> mutations in ~25%. 3. M1 expresses CD13 and CD33. Positive for myeloperoxidase by cytochemistry. 4. M2 AML with maturation often associated with t(8;21) karyotype. 5. M2 AML with t(6;9)(p23;q34), an uncommon variant, is associated with marrow basophilia, a high blast count, a high frequency of <i>FLT3</i>-ITD, and a poor outcome.
Acute promyelocytic leukemia (M3, M3v)	<ol style="list-style-type: none"> 1. Leukemic cells resemble promyelocytes. They have large atypical primary granules and a kidney-shaped nucleus. Branched or adherent Auer rods are common. 2. Peroxidase stain intensely positive. 3. A variant has microgranules (M3v), otherwise the same course and prognosis. 	<ol style="list-style-type: none"> 1. Usually in adults. 2. Hypofibrinogenemia and hemorrhage common. 3. Leukemic cells mature in response to all-<i>trans</i>-retinoic acid. 	<ol style="list-style-type: none"> 1. Cells contain t(15;17) in >95% of cases or another rearrangement involving the <i>RAR-α</i> gene on chromosome 17. 2. Cells are HLA-DR–negative.
Acute myelomonocytic leukemia (M4, M4Eo)	<ol style="list-style-type: none"> 1. Both myeloblastic and monoblastic leukemic cells in blood and marrow. 2. Peroxidase-, Sudan-, chloroacetate esterase-, and nonspecific esterase-positive cells. 3. M4Eo variant has marrow eosinophilia. 	<ol style="list-style-type: none"> 1. Similar to myeloblastic leukemia but with more frequent extramedullary disease. 2. Mildly elevated serum and urine lysozyme. 	<ol style="list-style-type: none"> 1. Leukemic cells in eosinophilic variant (M4Eo) usually have inversion or translocation of chromosome 16.
Acute monocytic leukemia (M5)	<ol style="list-style-type: none"> 1. Leukemia cells are large; nuclear cytoplasmic ratio lower than myeloblast. Cytoplasm contains fine granules. Auer rods are rare. Nucleus is convoluted and cell simulates promonocytes (M5a) or may simulate monoblasts (M5b) and contain large nucleoli. 2. Nonspecific esterase-positive inhibited by NaF; Sudan-, peroxidase-, and chloroacetate esterase-negative. PAS occurs in granules, blocks. 	<ol style="list-style-type: none"> 1. Seen in children or young adults. 2. Gum, CNS, lymph node, and extramedullary infiltrations are common. 3. DIC occurs. 4. Plasma and urine lysozyme elevated. 5. Hyperleukocytosis common. 	<ol style="list-style-type: none"> 1. t(4;11) common in infants. 2. Rearrangement of q11;q23 very frequent.

(continued)

TABLE 88-5. Morphologic Variants of Acute Myelogenous Leukemia (Continued)

Variant	Cytologic Features	Special Clinical Features	Special Laboratory Features
Acute erythroid leukemia (M6)	1. Abnormal erythroblasts are in abundance initially in marrow and often in blood. Later the morphologic findings may be indistinguishable from those of AML.	1. Pancytopenia common at diagnosis.	1. Cells reactive with antihemoglobin antibody. Erythroblasts usually are strongly PAS and CD71-positive, express ABH blood group antigens, and react with antihemoglobin antibody. 2. Cells reactive with anti-Rc-84 (antihuman erythroleukemia cell-line antigen).
Acute megakaryocytic leukemia (M7)	1. Small blasts with pale agranular cytoplasm and cytoplasmic blebs. May mimic lymphoblasts of medium to larger size. 2. Leukemic cells with megakaryocytic morphology may coexist with megakaryoblasts.	1. Usually presents with pancytopenia. 2. Markedly elevated serum lactic dehydrogenase levels. 3. Marrow aspirates are usually "dry taps" because of the invariable presence of myelofibrosis. 4. Common phenotype in the AML of Down syndrome.	1. Antigens of von Willebrand factor, and glycoprotein Ib (CD42), IIb/IIIa (CD41), IIIa (CD61) on blast cells. 2. Platelet peroxidase positive.
Acute eosinophilic leukemia	1. Mixture of blasts and cells with dysmorphic eosinophilic granules (smaller and less refractile).	1. Hepatomegaly, splenomegaly, lymphadenopathy may be prominent. 2. Absence of neurologic, respiratory, or cardiac signs or symptoms characteristic of chronic eosinophilic leukemia (clonal hypereosinophilic syndrome).	1. Cyanide-resistant peroxidase stains eosinophilic granules. TEM shows eosinophilic granules to be smaller and missing central crystalloid. 2. Biopsy may show Charcot-Leyden crystals in skin, marrow, or other sites of eosinophil accumulation.
Acute basophilic leukemia	Mixture of blast cells and cells with basophilic granules in blood and marrow.	1. Often has hepatomegaly and or splenomegaly; symptoms often present. 2. Rash with urticaria, headaches, prominent gastrointestinal symptoms.	1. CD9-, CD11b-, CD25-, CD123-positive cells are usually present. 2. Toluidine blue-positive cells. 3. Hyperhistaminemia and hyperhistaminuria. 4. Cells negative for tryptase but positive for histidine decarboxylase.
Acute mast cell leukemia	1. Mast cells in blood and marrow. Most contain granules but some are agranular and may simulate monocytes.	1. Fever, headache, flushing of face and trunk, pruritus may be present. 2. Abdominal pain, peptic ulcer, bone pain, diarrhea more common than other AML subtypes. 3. Hepatomegaly, splenomegaly common. 4. Hemorrhagic diathesis may be evident.	1. CD13, CD33, CD68, CD117 often positive. 2. Cells positive for tryptase staining and serum tryptase elevated. 3. Hyperhistaminemia and hyperhistaminuria.

AML, acute myelogenous leukemia; DIC, disseminated intravascular coagulation; HLA-DR, human leukocyte antigen-D related; NaF, sodium fluoride; PAS, periodic acid-Schiff; RAR, retinoic acid receptor; TEM, transmission electron microscopy.

NOTE: Parentheses indicate French-American-British (FAB) classification designations M0 through M7.

The myeloblasts often contain Auer rods. Marrow basophilia is present in about half the cases.^{208,280,448} The variant occurs at a younger age, has a poor prognosis, and has a tendency to trilineage dysmorphism and ringed sideroblasts.⁴⁴⁹

ACUTE ERYTHROID LEUKEMIA

Prominence of erythroid cell proliferation in AML cases was noted by Copelli⁴⁵⁰ and DiGuglielmo⁴⁵¹ in the early 20th century. Moeschlin⁴⁵² used the term *erythroleukemia*. Dameshek⁴⁵³ suggested the name *DiGuglielmo syndrome* and dissected the disorder into three phases, depending on the decreasing prevalence of dysmorphic erythroblasts and the reciprocal increasing prevalence of myeloblasts. Erythroid leukemia makes up approximately 5 percent of AML cases and is referred to as *M6* in the FAB classification.⁴⁵⁴ Familial erythroleukemia has been described.^{455,456} Erythroid leukemia is arbitrarily divided into three degrees of severity: (1) *erythroleukemia* in which more than 50 percent of the marrow cells are dysmorphic; (2) erythroblasts admixed with myeloblasts, the latter composing approximately 20 percent of non-erythroid cells or approximately 5 to 10 percent of total marrow cells; and (3) a form in which dysmorphic erythroblasts dominate the marrow, *pure erythroid leukemia*, in which more than 80 percent of marrow cells are dysmorphic erythroblasts with a trivial granulocytic proportion of cells and very few if any myeloblasts. This last form of the disease may start in as a milder variant, formerly called *erythremic myelosis*, in which granulopoiesis, and thrombopoiesis may be only mildly abnormal. This phase, dominated morphologically by bizarre dysmorphism of erythroblasts, can be protracted but eventually evolves into a dimorphic phase in which myeloblasts are more prominent, severe neutropenia and thrombocytopenia develop, and the patient progresses to erythroid leukemia. The disease may evolve further into polyblastic AML.⁴⁵⁷⁻⁴⁶⁰ In the erythremic myelosis variant, erythropoiesis is ineffective. However, some normal regulation may remain because hypertransfusion decreases both erythropoietin levels and the amount of abnormal erythropoiesis.⁴⁶¹ Spontaneous growth of leukemic erythroid clonogenic cells is a feature of the disease.⁴⁶² Periodic acid-Schiff (PAS)-positive erythroblasts are evident in almost all cases.^{457,460}

The erythroid leukemias are characterized by a striking population of dysmorphic erythroblasts in marrow and red cells in blood (see Fig. 88-2I, J, and K). Anemia and thrombocytopenia are present in nearly all cases. Some patients may have elevated total leukocyte counts. The red cells show marked anisocytosis, poikilocytosis, anisochromia, and basophilic stippling. Nucleated red cells are present in the blood. The marrow erythroblasts are extremely abnormal, with giant multinucleate forms, nuclear budding, and nuclear fragmentation. Cytogenetic abnormalities are present in approximately 70 percent of patients and complex cytogenetic abnormalities are frequent. The frequency of erythroid leukemia is increased if methods for detecting erythroid differentiation more sensitive than light microscopy are used. These cell features include glycophorin A, spectrin, carbonic anhydrase I, ABH blood group antigens, and other antigens that occur on early erythroid progenitors, such as the transferrin receptor (CD71).⁴⁶³⁻⁴⁶⁵ Antihemoglobin antibody and antihuman erythroleukemic cell line antibody often are positive.⁴⁵⁸

Erythremic myelosis can have an indolent course and may be managed for a time without intensive chemotherapy. Treatment is warranted in patients with erythroleukemia and acute erythroid leukemia, and the results are approximately the same as with other phenotypes in patients of similar age.⁴⁶⁰ The more predominant the erythroid component and the lower the proportion of myeloblasts, the better the response to therapy.⁴⁰³

ACUTE PROMYELOCYTIC LEUKEMIA

The association of an exaggerated hemorrhagic syndrome with certain leukemias was described by French hematologists in 1949.⁴⁶⁶ In 1957, Hillstad⁴⁶⁷ bestowed the appellation *promyelocytic leukemia* upon this morphologic-clinical subtype of AML. This variant, which is called *M3* in the FAB classification and APL in the WHO classification, occurs at any age and constitutes approximately 7 percent of AML cases.^{290,291,468,469} APL occurs with greater frequency among Latinos from Europe and South and Central America.^{190,191} APL represents 19 percent of AML cases in the Chinese¹⁸⁹ as compared to 8 percent among persons of European descent. APL is also increased among persons with an increased body mass index.⁴⁷⁰⁻⁴⁷² Unlike all other major variants of AML, which increase in incidence logarithmically with age, the incidence of APL is constant over the human life span.¹⁸⁸ Hemorrhagic manifestations are prominent including hemoptysis, hematuria, vaginal bleeding, melena, hematemesis, and pulmonary and intracranial bleeding, as well as the more typical skin and mucous membrane bleeding. In severely leukopenic patients, blasts may not be evident in the blood. Moderately severe thrombocytopenia ($<50 \times 10^9/L$) is present in most cases. The marrow contains few agranular blast cells and some blast-like cells with scant granules. The dominant cells are promyelocytes, which comprise 30 to 90 percent of marrow cells (see Fig. 88-2D and E). Auer rods and cells with multiple Auer rods (1 to 10 percent) are present in nearly every case. Promyelocytes with multiple Auer rods have been referred to as *faggot cells*. Leukemic promyelocytes stain intensely with myeloperoxidase and Sudan black and express CD 9, CD13, and CD33, but not CD34 or HLA-DR.^{290,291,468,469}

A variant type of promyelocytic leukemia is referred to as *microgranular (M3v)* in the FAB nomenclature.⁴⁷³⁻⁴⁷⁶ Microgranular cases represent approximately 20 percent of patients with promyelocytic leukemia. The leukemic cells may mimic promonocytes with convoluted or lobulated nuclei. Auer rods may be present but are less evident. The majority of the leukemic cells contain azurophilic granules that are so small they are not visible by light microscopy, but the peroxidase stain usually is strongly positive. Typical hypergranulated promyelocytes usually are present on careful inspection. The total white cell count often is highly elevated, and severe coagulopathy is prominent in microgranular cases.⁴⁷⁴ Rarely, the cells contain eosinophilic or basophilic granules, but t(15;17) is present, and the response to all-*trans* retinoic acid (ATRA) persists,⁴⁷⁷⁻⁴⁷⁹ although the basophilic variant can be virulent.⁴⁸⁰

A translocation between chromosome 17(q21), which rearranges the *RAR- α* gene at band q21, and another chromosome is present in all cases of APL and in the acute promyelocytic transformation of CML; it is not found in other AML variants. The t(15;17)(q22;q21) is the most frequent cytogenetic abnormality (>95 percent), but variant translocations between chromosome 3, 5, or 11 and chromosome 17 or isochromosome 17, and other even less common variants have been described.^{290,468,481-483} In some cases, cytogenetic analysis is inadequate and Southern blot analysis is required to identify the rearrangement of the *RAR- α* gene. A functional distinction is that the t(15;17), *PML-RAR- α* fusion, the t(5;17), *NPM-RAR- α* fusion, and the t(3;17), *TBLR1-RAR- α* fusion confer retinoid therapy responsiveness, whereas t(11;17), *PLZF-RAR- α* fusion, usually is retinoid resistant. In cells with the t(11;17), Auer rods are absent and CD56 expression usually is present, offering some clinical variables to provoke special molecular investigations.⁴⁸⁴ The retinoid resistance may not always be present.⁴⁸⁵

The breakpoint on chromosome 17 is within the gene encoding the *RAR- α* , and the breakpoint on chromosome 15 is within the locus of a gene originally referred to as *MYL* and renamed *PML* (to indicate its relationship to promyelocytic leukemia).^{290,486} The gene encodes a unique transcription factor. The translocation results in two

new chimeric or fusion genes: *RAR- α -PML*, which is actively transcribed in APL, and *PML-RAR- α* , which also is transcribed and may account for the aberrancy in hematopoiesis. The *PML-RAR- α* gene has two isoforms that produce a short- and a long-type fusion messenger RNA, respectively.⁴⁸⁷ Patients with the short isoform may have a worse outcome than those with the longer form. Polymerase chain reaction (PCR) for the mRNA of the fusion gene can be used to identify residual cells during remission and may predict relapse. The *PML-RAR- α* transgene can reproduce the disease in mice,⁴⁸⁸ although in some models a superimposed *FLT3* mutation is required to express the disease. *FLT3* mutations are frequently found in human disease, especially in the hypogranular variant.¹⁵⁷

A propensity to hemorrhage is a striking feature of this subtype. The prothrombin and partial thromboplastin times are prolonged, and the plasma fibrinogen level is decreased in most cases. The disturbance in coagulation first was thought to principally result from intravascular coagulation initiated by procoagulant released from the granules of the leukemic promyelocytes. Elevated thrombin-antithrombin complexes, prothrombin fragment 1+2, and fibrinopeptide A plasma levels support that supposition. Increased levels of fibrinogen-fibrin degradation products, D-dimer, and evidence of plasminogen activation indicate fibrinolysis.⁴⁸⁹⁻⁴⁹¹ Furthermore, decreased levels of plasminogen, increased expression of annexin II on the leukemic cells,⁴⁹² and reports of responses to tranexamic acid support a role for fibrinolysis in the bleeding in APL.⁴⁹³ Release of nonspecific proteases may further contribute to fibrinogenolysis. Thus, the coagulopathy is now considered tripartite.⁴⁹⁴

Although APL responded to chemotherapy regimens for AML, especially those containing an anthracycline antibiotic,⁴⁹⁵ the cytologic pattern of response in the marrow often was paradoxical.⁴⁹⁶⁻⁴⁹⁹ Persistence of leukemic promyelocytes preceded remission in the absence of further therapy, whereas induction of marrow cell hypoplasia was classically considered a requirement for remission in patients with AML. Generally, if leukemic blast cells persist after therapy for AML, relapse ensues unless hypoplasia is induced by more cytotoxic therapy. The unusual pattern of response in APL was put into context by reports of successful treatment with isomers of retinoic acid, an agent that leads to maturation of leukemic promyelocytes *in vitro*.⁴⁹⁹ In 1988, the success of ATRA in remission induction was reported^{500,501} and confirmed.^{290,291} Relapse occurs invariably, however, so chemotherapy regimens or addition of arsenic trioxide also were required. Use of ATRA has decreased the risk of early hemorrhagic complications and death and has enhanced the long-term response to chemotherapy. Despite the improvement in therapy, approximately 5 to 10 percent of patients die during remission induction, most of hemorrhage, often into the brain. The prolonged remissions of patients with promyelocytic leukemia has been interrupted in approximately 3 percent of cases by the later appearance of oligoblastic myelogenous leukemia with deletions of all or part of chromosome 5 or 7 and no evidence of involvement of chromosome 17, compatible with a myelogenous leukemia secondary to cytotoxic chemotherapy.⁵⁰¹⁻⁵⁰³ The responsiveness to arsenic trioxide has provided additional treatment approaches that are discussed in the "Therapy" section below.

ACUTE MONOCYtic LEUKEMIA

Monocytic leukemia was first reported by Reschad and Schilling-Torgau⁵⁰⁴ in 1913. Approximately 8 percent of patients with AML present with monocytic leukemia, which is referred to as *M5* in the FAB classification. Patients with monocytic leukemia have a higher prevalence (50 percent) of extramedullary tumors in the skin, gingiva, eyes, larynx, lung, rectum and anal canal, bladder, lymph nodes, meninges, CNS, and other sites than do other phenotypes (<5 percent).

Hepatomegaly, splenomegaly, and lymphadenopathy are more frequent in monocytic leukemia.^{207,505-507}

The proportion of monocytic cells is usually greater than 75 percent. The total leukocyte count is higher in a larger proportion of patients, and hyperleukocytosis occurs more frequently (approximately 35 percent) than in other variants.⁵⁰⁸⁻⁵¹⁰ The marrow and blood cells may be largely monoblasts (acute monoblastic leukemia) or more mature-appearing promonocytes and monocytes (acute monocytic leukemia) (see Fig. 88-2H). When the blood contains more mature-appearing monocytic cells, the marrow contains a lower proportion of blast cells, approximately 15 to 50 percent. When the blood monocytes are largely blast cells, the marrow contains approximately 50 to 90 percent blasts. In nearly all cases, 10 to 90 percent of monocytic cells react for nonspecific esterase stains, α -naphthyl acetate esterase, and naphthol AS-D-chloroacetate esterase; in a cytochemical or chemoluminescence assay; or with monoclonal antibodies against monocyte surface antigens, especially CD14. Immunoreactivity of cells for lysozyme is characteristic. Serum and urine lysozyme levels are elevated in most patients. Serum lactic dehydrogenase and β_2 -microglobulin concentrations are increased in greater than 80 percent of patients.⁵¹¹ Plasminogen activator inhibitor-2 is present in the plasma and the cells of a high proportion of patients.⁵¹² Auer rods are absent when monoblasts dominate but may be present in cases where promonocytes and monocytes are prevalent in blood and marrow. Leukemic monocytes have Fc receptors and can ingest and kill microorganisms in some cases.^{513,514}

There is an association between translocations involving chromosome 11, especially region 11q23, and monocytic leukemia.²⁹²⁻²⁹⁴ In particular, t(9;11) is found in leukemic monocytes.^{295,296,507,508} In t(9;11) the β_1 -interferon gene is translocated to chromosome 11, and the protooncogene *ETS-1* is translocated to chromosome 9 adjacent to the α -interferon gene. The latter juxtaposition may be important in the pathogenesis of monocytic leukemia.⁵¹⁵

The expression of *FOS* is closely correlated with monocytic maturation of cells in myelomonocytic and monocytic leukemia and in normal monocytopenia.^{516,517} Absence or markedly decreased expression of the retinoblastoma gene growth-suppressor product (p105) is present in approximately half of patients with monocytic leukemia. Patients express a more dramatic phenotype.⁵¹⁸ A variant of acute monocytic leukemia in which the leukemic cells have monocytoïd features and are positive for early and late monocytic lineage antigens and for TdT activity often occurs after prior radiotherapy or chemotherapy and is relatively resistant to treatment.⁵¹⁹ A syndrome of acute monoblastic leukemia with t(8;16), resulting in *MOZ-CBP* fusion gene, is characterized by mildly granular promonocytes (simulating hypogranular promyelocytes), intense phagocytosis of red cells, erythroblasts, and sometimes neutrophils and platelets in blood and marrow, simulating macrophagic hemophagocytic syndrome, intravascular coagulation or primary fibrinolysis, and a high frequency of extramedullary disease.⁵²⁰

The management of monocytic leukemia is complicated by a greater incidence of CNS or meningeal disease either at the time of diagnosis or as a form of relapse during remission. Thus, examination of cerebrospinal fluid is often recommended, even in the absence of symptoms, when remission has been achieved.^{208,507,508} Some therapists recommend prophylactic intrathecal therapy with methotrexate or cytosine arabinoside for patients who enter remission after having presented with hyperleukocytic acute monocytic leukemia because of the risk of subclinical meningeal involvement. Others posit that high-dose cytarabine with CNS penetration potential used in consolidation chemotherapy suffices for this purpose. There are few data for guidance in this matter.

Rare cases of dendritic cell or Langerhans cell phenotype have been described (Chap. 71).^{521,522} Uncommon cases of histiocytic sarcoma are

the tissue or extramedullary variant of monocytic leukemia (Chap. 71).^{523,524} The outcome of treatment, once thought to be less favorable than with other forms of AML, is comparable to the outcome of other subtypes.⁵²⁵

ACUTE MEGAKARYOBLASTIC (MEGAKARYOCYTIC) LEUKEMIA

In 1963, Szur and Lewis⁵²⁶ reported patients with pancytopenia, low percentages of blast cells, and intense myelofibrosis but an absence of teardrop red cells, splenomegaly, leukocytosis, and thrombocytosis, the usual features of primary myelofibrosis. They designated the syndrome *malignant myelosclerosis*.⁵²⁶ Reports of similar cases ensued, with some investigators referring to the syndrome as *acute myelofibrosis*.⁵²⁷ The development of methods to phenotype megakaryoblasts indicated the cases were variants of AML rather than of primary myelofibrosis and have been designated *acute megakaryocytic* or *acute megakaryoblastic leukemia*.^{391,528,529} This leukemia is referred to as M7 in the FAB classification. The prevalence of this phenotype is approximately 5 percent of all AML cases if appropriate cell markers are used in the diagnosis, and is at least twice that frequency in childhood AML.^{530,531} The syndrome is an especially prevalent variant of AML that develops in patients with Down syndrome^{398,532} or in patients with mediastinal germ cell tumors and coincident AML.⁴²⁵⁻⁴²⁹

Leukemic megakaryoblasts and promegakaryocytes can be difficult to identify by light microscopy using polychrome staining. However, with experience, heightened suspicion can be engendered by blasts in the blood with abundant budding cytoplasm or blasts having a lymphoid appearance, especially if the marrow cannot be aspirated because of intense myelofibrosis, the latter evident on the marrow biopsy. Initially high-resolution histochemistry for platelet peroxidase and identification of the demarcation membrane system using transmission electron microscopy were required for diagnosis. Now antibodies to von Willebrand factor or to platelet glycoprotein Ib (CD42), IIb/IIIa (CD41), or IIIa (CD61) can be used to identify very primitive megakaryocytic cells.^{528,529} A small proportion of megakaryoblasts may be present in other cases of AML, but in megakaryocytic leukemia they are the prominent or the dominant leukemic cells (see Fig. 88-2L through O). Moreover, the other key features of the syndrome usually are present, especially severe myelofibrosis.⁵³⁰

Patients usually present with pallor, weakness, excessive bleeding and anemia, and leukopenia. Lymphadenopathy or hepatosplenomegaly is uncommon at the time of diagnosis. High leukocyte and blood blast cell counts may be present initially or may develop later. The platelet count may be normal or elevated in many patients at the time of presentation. Abnormal platelets or megakaryocytic cytoplasmic fragments may be found in the blood. Marrow aspiration often is unsuccessful ("dry tap") because of extensive marrow fibrosis in most cases, although not all. The marrow biopsy contains small blast cells, large blast cells, or a combination of both. The former have a high nuclear-to-cytoplasmic ratio, have dense chromatin with distinct nucleoli, and resemble lymphoblasts. Cases have been mistaken for ALL. The larger blasts may have some features of maturing megakaryocytes with agranular cytoplasm with cytoplasmic protrusions, clusters of platelet-like structures, or shedding of cytoplasmic blebs. The blast cells are peroxidase negative and tend to aggregate. Confirmation of their megakaryoblastic maturation requires immunocytologic studies for the presence of von Willebrand factor and the immunoreactivity to CD41, CD42, or CD61. The more mature megakaryocytes, which often coexist in the marrow, stain with PAS reagent, contain sodium fluoride-inhibitable nonspecific esterase, and fail to react for α -naphthylbutyrate

esterase or myeloperoxidase. The thrombopoietin receptor gene (*MPL*) is expressed in megakaryocytes (CD116) and exhibits the gain-of-function point mutation W515K/L in approximately 25 percent of cases of acute megakaryoblastic leukemia.⁵³³

The serum lactic acid dehydrogenase level frequently is strikingly increased and has an isomorphic pattern unlike that seen with other acute leukemias. Complex chromosome aberrations are common.⁵³⁴ An association of megakaryoblastic leukemia in infants with t(1;22) (p13;q13) has been reported.⁵³⁴⁻⁵³⁷ Abnormalities of chromosome 3 have been linked to clonal hemopathies expressing a prominent megakaryocytic phenotype.^{538,539} Progression of primary myelofibrosis or essential thrombocythemia to AML may have the phenotype of acute megakaryocytic leukemia. Paradoxically, in children with Down syndrome the disease can be treated with modified doses of chemotherapy, with a very high remission rate and long-term event-free survival.⁵⁴⁰⁻⁵⁴² The result is thought to be related to the exquisite sensitivity of the leukemic cells to drug-induced apoptosis,⁴⁷⁵ whereas the long-term remission rate as a result of chemotherapy in children without Down syndrome or in adults are not as good.^{543,544}

ACUTE EOSINOPHILIC LEUKEMIA

Acute eosinophilic leukemia is rare. Increased eosinophils in the marrow but not in the blood is a variant of acute myelomonocytic leukemia and inversion 16 or other abnormalities of chromosome 16 but is not considered an acute eosinophilic leukemia.³⁰³⁻³⁰⁶ First described in 1912,⁵⁴⁵ acute eosinophilic leukemia is a distinct entity that can arise *de novo* as AML, with 50 to 80 percent of eosinophilic cells in the blood and marrow.⁵⁴⁶⁻⁵⁴⁹ Anemia, thrombocytopenia, and blast cells in blood and marrow are present. There is apparent eosinophilic differentiation in striking proportions. The eosinophilic cells are dysmorphic and the cytoplasm hypogranulated with smaller than normal eosinophilic granules. The granules stain less intensely and are less refractile with polychrome stains. These findings are the result of the loss of the central crystalloid in the eosinophilic granules that can be identified with electron microscopic analysis. Biopsy of skin, marrow, or other sites of eosinophil accumulation often shows Charcot-Leyden crystals. A specific histochemical reaction, cyanide-resistant peroxidase, permits identification of leukemic cells with eosinophilic differentiation and diagnosis of acute eosinoblastic leukemia in some cases of AML with fewer identifiable eosinophils in blood or marrow.⁵⁵⁰ Eosinophilia, not part of the malignant clone, may be a feature of occasional patients with AML, an uncommon reactive phenomenon. In many cases, idiopathic eosinophilia (hypereosinophilic syndrome) is a monoclonal disorder representing a spectrum of more indolent chronic or subacute eosinophilic leukemia to more progressive acute leukemia (Chaps. 62 and 89).⁵⁵¹ Acute eosinophilic leukemia may develop in patients having the chronic form of a hypereosinophilic syndrome. Overexpression of *WT* gene expression has been proposed as a means of distinguishing acute eosinophilic leukemia from a polyclonal, reactive eosinophilia.⁵⁵²

Patients with acute eosinophilic leukemia do not usually develop bronchospastic signs, neurologic signs, and heart failure from endomyocardial fibrosis as is seen in chronic eosinophilic leukemia, probably because those tissue changes are the result of release of toxins in the granule crystalloid, absent in most eosinophils in acute eosinophilic leukemia and because of the shorter duration of survival in acute eosinophilic leukemia. Hepatomegaly, splenomegaly, and lymphadenopathy are more common than in other variants of AML. The treatment approach is similar to other types of AML. A combination of cytarabine and an anthracycline antibiotic is an appropriate choice for treatment. Response to treatment is approximately the same as in other types of AML.⁵⁵⁰

ACUTE BASOPHILIC AND MAST CELL LEUKEMIA

First described in 1906,⁵⁵³ basophilic differentiation as a feature of AML is an uncommon event, occurring in approximately one in 100 cases of AML.⁵⁴⁹ Most cases of acute basophilic leukemia evolve from the chronic phase of CML,⁵⁵⁴ but *de novo* acute basophilic leukemia, in which the cells do not contain the Ph chromosome, does occur.^{549,535-560} The cells stain with toluidine blue, and the basophilic granules can be most striking in myelocytes. In some cases of acute myelomonocytic leukemia associated with t(6;9)(p23;q34), basophils may be increased in the marrow but not in the blood. Because CML with t(9;22)(q34;q11) has the same breakpoint (q34) on chromosome 9 as AML with t(6;9) and both diseases are strongly associated with marrow basophilia, a gene(s) at the breakpoint on chromosome 9 may influence basophilopoiesis.⁴⁴⁸

Anemia, thrombocytopenia, and blast cells in the blood are present at the time of diagnosis. The blood leukocyte count usually is elevated, and proportions of the cells are basophils. The marrow is cellular with a high proportion of blasts and early and late basophilic myelocytes. Special staining with toluidine blue or Astra blue often is necessary to distinguish basophilic from neutrophilic promyelocytes and myelocytes. Immunophenotyping may show myeloid markers (CD33, CD13) that are not specific. Presence of CD9, CD25, or both is characteristic of basophilic differentiation. Cells may have granules with ultrastructural features of basophils and mast cells.⁵⁵⁸ Electron microscopy can be useful in identifying basophilic granules in cases where no granules are evident by light microscopy and the phenotype simulates M0.⁵⁵⁸ Basophilic leukemia can be confused with promyelocytic leukemia if the basophilic early myelocytes are mistaken for promyelocytes.⁵⁶¹ On the contrary, promyelocytic leukemia may have basophilic maturation and can be mistaken for basophilic leukemia. However, if the cells contain t(15;17), the disease should respond to ATRA and an anthracycline antibiotic.^{474,477,478} Prolonged clotting time, intravascular coagulation, and hemorrhage are uncommon presenting features in patients with basophilic leukemia, but are common in patients with promyelocytic leukemia. Coagulopathy can occur after chemotherapy. Cluster headaches, skin rashes, often with an urticarial component, and gastrointestinal symptoms may be present. Elevated blood and urine histamine and urinary methylhistamine levels are characteristic features. Rare cases of a chronic course in *BCR-ABL*-negative basophilic leukemia preceding the onset of rapid progression have occurred.⁵⁶² Treatment for acute (Ph-negative) basophilic leukemia is similar to that for other variants of AML.

Mast cell leukemia is a rare manifestation of systemic mast cell disease (Chap. 63).^{549,563} It can be related to a mutation of the *KIT* gene.⁵⁰⁷ The leukemic mast cells are KIT (CD117) positive, naphthol AS-D-chloracetate esterase positive, tryptase positive, myeloperoxidase negative, and CD25-negative.^{564,565} Plasma tryptase is elevated. In some cases, electron microscopy of the granule-containing cells, which demonstrates the characteristic scroll-like granules of mast cells, may aid in distinguishing basophils from mast cells (Chap. 63). Extensive, apparently reactive, mast cell tissue infiltrations may be provoked by cytokines during the course of AML.^{566,567}

The key laboratory distinctions between acute basophilic leukemia and acute mast cell leukemia are that the cells in the former are naphthol AS-D-chloracetate esterase negative, CD11b positive, CD117 negative or weakly positive, CD123 positive, have no increase in cell or plasma tryptase, and have basophilic-like granules on electron microscopy; whereas, the cells in mast cell leukemia are naphthol AS-D-chloracetate esterase positive, CD11b-negative, CD117-positive, CD123-negative, have an increase in cell and plasma tryptase, and have mast cell-like granules on electron microscopy.⁵⁴⁹

HISTIOCYTIC AND ACUTE MYELOID DENDRITIC CELL LEUKEMIA

Chapter 71 discusses histiocytic and myeloid dendritic cell leukemia.

DIFFERENTIAL DIAGNOSIS

Acute leukemia in infants with Down syndrome should be differentiated from TMD (see “Neonatal Myeloproliferation and Leukemia” above). In adults, the term *pseudoleukemia* has been applied to circumstances that mimic the marrow appearance of promyelocytic leukemia. Recovery from drug-induced or *Pseudomonas aeruginosa*-induced agranulocytosis is characterized by a striking cohort of promyelocytes in the marrow, which upon inspection of the marrow aspirate or biopsy mimics promyelocytic leukemia.⁵⁶⁸⁻⁵⁷⁰

In pseudoleukemia, the platelet count may be normal; the degree of leukopenia often is more profound ($<1.0 \times 10^9/L$) than usually seen in AML^{511,512}; promyelocytes contain a prominent paranuclear clear (Golgi) zone not covered with granules; and promyelocytes do not have Auer rods.⁵⁷⁰⁻⁵⁷² Similar reactions have been reported after granulocyte colony-stimulating factor (G-CSF) administration.⁵⁷³ In patients suspected of having pseudoleukemia, observation for a few days usually clarifies the significance of the marrow appearance, because progressive maturation to segmented neutrophils normalizes the marrow and leads to an increased blood neutrophil count.

In patients with hypoplastic marrows, careful examination of specimens is required to distinguish among aplastic anemia, hypoplastic acute leukemia,³⁵⁰⁻³⁵² and hypoplastic oligoblastic myelogenous leukemia (MDS).⁵⁷⁴ Leukemic blast cells are evident in the marrow in hypoplastic leukemia, and islands of dysmorphic cells, especially megakaryocytes, are present in hypoplastic oligoblastic leukemia.

Leukemoid reactions and nonleukemic pancytopenias can be distinguished from AML by the absence of leukemic blast cells in the blood or marrow.⁵⁷⁵ In older children and adults, myeloblasts usually do not constitute more than 2 percent of marrow cells except in patients with a myeloid neoplasm, and the proportion of blast cells usually decreases in the marrow as a result of exaggerated expansion of the myelocyte compartment with neutrophilic leukemoid reactions.

THERAPY

OVERVIEW OF TREATMENT PLAN

The usual treatment of AML includes an initial program termed the *induction* phase. Induction may involve the simultaneous use of multiple agents or a planned sequence of therapy called *timed sequential treatment*. Once a remission is obtained, further treatment is indicated to preserve the remission state. Remission is defined as elimination of the leukemic cell population in marrow as judged by microscopy and flow cytometry and the restitution of marrow hematopoiesis resulting in a normal or virtually normal white cell, hemoglobin, and platelet concentrations in the blood. The postinduction treatment can consist of cytotoxic chemotherapy, HSC transplantation, or low-dose maintenance chemotherapy, depending upon patient performance status and risk factors. If relapse occurs, treatment options may include different chemotherapy regimens, allogeneic HSC transplantation, or other investigational regimens, often as part of a clinical trial.

DECISION TO TREAT

Most patients with AML should be advised to undergo treatment promptly after diagnosis. Patients younger than 60 years of age have a

poorer outcome as the time from diagnosis to treatment lengthens.⁵⁷⁶ Although remission rates are lower in older patients, a significant proportion enter remission. Occasionally, very elderly patients refuse treatment or are so ill from unrelated illnesses that treatment may be unreasonable. Age per se is not a contraindication to treatment, and septuagenarians and octogenarians who are fit can enter remissions. Treatment can be tailored to the decreased tolerance of older patients, some of whom have a smoldering course (see “Treatment of Older Patients” below). Associated problems, such as hemorrhagic manifestations, severe anemia, or infections, should be treated in parallel.

PREPARATION OF THE PATIENT

Orientation of the patient and the family should provide them with an understanding of the disease, the treatment planned, and the adverse effects of treatment, as well as information about long-term prognosis to the extent this can be provided while awaiting cytogenetic and molecular markers. Socioeconomic status and distance from the treatment center have minimal effects on survival in AML,⁵⁷⁷ but impaired Karnofsky performance status and instrumental activities of daily living score do impact outcomes.⁵⁷⁸

Pretreatment laboratory examination should include blood cell counts, cytochemistry analysis and immunophenotyping of leukemic cells from blood or marrow, marrow examination including cytogenetic and molecular analyses to include *FLT3* ITD, *NPM-1*, *CEBPα*, and *KIT* mutation status in CBF leukemias, if available. If these are not available, they can be performed later as required based on AML subtype from a cryopreserved specimen. Blood chemistry studies, chest radiography, electrocardiogram, and determination of partial thromboplastin time, prothrombin time, and fibrinogen level should be obtained. More extensive evaluation of coagulation factors should be made if (1) clotting times are abnormal, (2) bleeding is exaggerated for the level of the platelet count, or (3) APL or acute monocytic leukemia is the phenotype. Early HLA typing is useful so that compatible platelet products can be provided if alloimmunization (Chap. 139) occurs and for patients who will become marrow transplantation candidates (Chap. 23). *Herpes simplex* virus and cytomegalovirus serotyping may be helpful, especially if transplantation is a consideration. HIV and hepatitis serology is indicated in patients with appropriate risk factors, and patients should have a baseline cardiac scan to determine ejection fraction prior to administration of an anthracycline antibiotic.

A peripherally inserted central catheter or a tunneled central venous catheter should be placed. This access to the circulation facilitates administration of chemotherapy, blood components, antibiotics, and other intravenous fluids and medications. It also permits sampling blood for analysis without patient discomfort or concern about venous access. Meticulous skin care at the catheter exit site is required to minimize tunnel infections. Central venous catheters have become a major source of infection during neutropenia, especially with Gram-positive organisms.⁵⁷⁹ In some patients with severe coagulopathy such as those with APL, a tunneled catheter may be best deferred to avoid significant bleeding or vessel activation during insertion. In those with neurologic symptoms, a head computed tomographic study or MRI followed by a lumbar puncture should be obtained. Before procedures, adequate platelet counts and control of coagulopathy should be achieved, if possible.

Therapy for hyperuricemia is required if (1) the pretreatment uric acid level is greater than 7 mg/dL (0.4 mmol/L), (2) the marrow is packed with blast cells, or (3) the blood blast cell count is moderately or markedly elevated. Allopurinol 300 mg/day orally should be given. Allopurinol can cause allergic dermatitis and should not be used if the uric acid level is less than 7 mg/dL and the total white cell count is less

than approximately $20 \times 10^9/L$, as long as hydration is adequate and urine flow is high (>150 mL/h). The dermatitis may appear when antibiotics are instituted. This concurrence may confound the decision to continue antibiotics. Thus, allopurinol should be discontinued after the risk of acute hyperuricosuria or tumor lysis has passed (usually 4 to 7 days). Recombinant urate oxidase (rasburicase) can be used to prevent urate-induced nephropathy. This preparation, although costly, can reduce plasma urate levels by approximately 80 percent within 4 hours of the first drug dose. It is well tolerated, and the recommended dose of rasburicase is 0.2 mg/kg daily for 5 to 7 days intravenously, although shorter courses are usually effective.⁵⁸⁰

Attention to decreasing pathogen exposure by assiduous hand washing and meticulous care of catheter and intravenous sites is important, especially when the total neutrophil count is less than $0.5 \times 10^9/L$. Care of the patient in a *single room* is advisable to provide privacy during periods of intensive care and to help decrease the risk of exogenously acquired infection until the neutrophil count recovers.

REMISSION-INDUCTION THERAPY

Principles

The cytotoxic therapy of AML rests on two tenets: (1) two competing populations of cells are present in marrow—a normal polyclonal and a leukemic monoclonal population; and (2) profound suppression of the leukemic cells to the point they are inapparent in the marrow aspirate and biopsy is required to permit restoration of polyclonal hematopoiesis.^{581,582} Although these two principles hold in most cases, two deviations from these guidelines are (1) the predisposition of patients with APL to enter remission despite cellular posttherapy marrow⁵⁸³ and (2) the rare presence of monoclonal hematopoiesis in some cases of AML during remission (see “Results of Treatment” below). AML is a heterogeneous disease, and subgroups with different prognosis can be identified. In the future, incorporation of knowledge about the biology of the particular AML subtype may be utilized for adapted therapies, but at present, all subtypes of AML classified by cytogenetics or molecular changes with the exception of APL are approached similarly during induction, and often induction therapy must be started before knowledge of cytogenetic and molecular factors is available.⁵⁸⁴

The goal of induction therapy in AML is achievement of complete remission (<2 percent blasts in the marrow), a neutrophil count greater than $1000/\mu L$, and a platelet count greater than $100,000/\mu L$. An International Working Group for Diagnosis, Standardization of Response Criteria, Treatment Outcomes, and Reporting Standards has redefined outcomes in an effort to standardize reporting and comparison of data (see “Course and Prognosis: Results of Treatment: Definition of Remission” below).⁵⁸⁵ Other treatment guidelines have been published.^{586,587} The majority of adults enter remission with standard induction therapy, but for patients with high-risk disease, consideration can be given to an experimental approach, and complete remission rates do not reach 100 percent, so clinical trial participation can be considered during induction chemotherapy. How durable a complete remission will be attained in an individual patient often is difficult to predict at diagnosis. Gene-expression profiling can separate some patients into prognostic groups that may indicate patients with a high risk of not responding to standard approaches.¹⁰⁵

Cytotoxic Regimens

Anthracycline Antibiotic or Anthraquinone and Cytarabine Current standard induction treatment for non-APL AML involves drug regimens with two or more agents that include an anthracycline antibiotic

TABLE 88-6. Remission Induction for Acute Myelogenous Leukemia: Examples of Cytosine Arabinoside and Anthracycline Antibiotic Combinations

Cytarabine	Anthracycline Antibiotic ± Another Agent	No. of Patients	Age Range in Years (Median)	Complete Remissions (%)	Year of Report	Reference
100 mg/m ² , days 1–7	DNR 50 mg/m ² days 1–5	407	15–64 (47)	77.5	2011	596
100 mg/m ² , days 1–7	IDA 12 mg/m ² days 1–3	525	15–64 (47)	78.2	2011	596
100 mg/m ² , days 1–7	DNR 45 mg/m ² , days 1–3	330	17–60 (47)	57	2009	593
100 mg/m ² , days 1–7	DNR 90 mg/m ² , days 1–3	327	18–60 (48)	71	2009	593
200 mg/m ² , days 1–7	DNR 60 mg/m ² , days 1–3	200	16–60 (45)	72	2004	611
200 mg/m ² , days 1–7	DNR 60 mg/m ² , days 1–3 Cladribine 5 mg/m ² , days 1–5	200	16–60 (45)	69	2004	611
200 mg/m ² twice per day for 10 days (some in this report received FLAG-IDA vs. H-DAT)	DNR 50 mg/m ² , days 1, 3, 5 Thioguanine 100 mg/m ² twice per day, days 10–20 Gemtuzumab ozogamicin 3 mg/m ² , day 1	64	18–59 (46.5)	91	2003	609
3 g/m ² every 12 h for 8 doses	60 mg/m ² DNR daily for 2 days	122	Adults	80	2000	603
100 mg/m ² daily for 7 days (2 courses always given)	IDA 12 mg/m ² daily for 3 days	153	NR	63	2000	589
500 mg/m ² by continuous infusion, days 1–3, 8–10	Mitoxantrone 12 mg/m ² for 3 days Etoposide 200 mg/m ² days 8–10	133	15–70 (43)	60	1996	606
100 mg/m ² daily for 7 days	DNR 45 mg/m ² for 3 days	113	NR (55)	59	1992	588
100 mg/m ² daily for 7 days	IDA 13 mg/m ² for 3 days	101	NR (56)	70	1992	588

DNR, daunorubicin; FLAG, fludarabine, cytarabine, and granulocyte colony-stimulating factor; H-DAT, hydroxydaunorubicin, cytarabine, and thioguanine; IDA, idarubicin; NR, not reported.

All drugs are administered intravenously, except for thioguanine, which is administered orally. The reader is advised to consult the original reports for details of induction, consolidation or continuation therapy, and ancillary therapy.

or an anthraquinone and cytarabine (see “Special Therapeutic Considerations: Acute Promyelocytic Leukemia” below for therapy of APL).^{588–617} Remission rates in the studies cited range from approximately 55 to 90 percent in adult subjects, depending on the composition of the population treated (Table 88-6). The two most important variables are the age of the patients and the proportion of patients with therapy-induced leukemia or an antecedent clonal myeloid disease. In the studies listed in Table 88-6, the median age of the patient populations was much younger (approximately 50 years) than the median age of the population of AML patients at large (approximately 70 years); thus the results cannot be generalized (see “Treatment of Older Patients” below). A combination of anthracycline and cytarabine has been the standard induction therapy since 1973.^{11,12} A now classic standard induction regimen is cytarabine 100 mg/m² daily by continuous infusion on days 1 through 7 and daunorubicin at 45 to 90 mg/m² on days 1 through 3, the “7 plus 3” regimen. Dose or schedule modulation of the anthracycline or cytarabine, addition of other agents such as etoposide, in various schedules of administration, represent attempts to improve upon results obtained with “7 plus 3” therapy.

Choice of Anthracycline Development of drug resistance is reduced with idarubicin relative to other anthracyclines. Idarubicin does not induce P-glycoprotein expression, but daunorubicin, doxorubicin, and epirubicin do.⁵⁹⁰ Idarubicin 12 mg/m² gives better complete remission rates in younger adults than does daunorubicin 45 mg/m², each given for 3 days. Amsacrine, aclarubicin, and mitoxantrone give improved results over standard-dose daunorubicin. In older adults, mitoxantrone may reduce cardiotoxicity, but this is controversial.⁵⁹¹ In two randomized studies, high-dose daunorubicin (90 mg/m²) for 3 days resulted in superior complete remission rates as compared to 45 mg/m² for 3 days when combined with cytarabine.^{592,593} When idarubicin 12 mg/m² was compared to daunorubicin 80 mg/m² for 3 days in patients 50 to 70 years of age, the remission rate with idarubicin was 83 percent compared to 40 percent with daunorubicin.⁵⁹⁴ Another analysis of idarubicin compared with high-dose daunorubicin in patients with AML showed idarubicin to result in a higher remission rate but not overall survival.⁵⁹⁵ In contrast, a randomized study showed no difference in remission and long-term efficacy between idarubicin 12 mg/m² daily for 3 days as compared to daunorubicin, 50 mg/m² daily for

5 days.⁵⁹⁶ In light of these studies, many therapists, when using daunorubicin, use the 90 mg/m² dose for 3 days in younger patients, and this is in keeping with the current National Comprehensive Cancer Network (NCCN) guidelines.⁵⁹⁷ This benefit of higher dose applies only to younger and favorable or intermediate-risk patients.⁵⁹³ Dexrazoxane may be given during induction to reduce the risk of cardiotoxicity in patients at higher than usual risk because of a history of coronary artery disease or congestive heart failure, but this is rarely used in adults.⁵⁹⁸ Other regimens that incorporate fludarabine with cytarabine can be used in those patients for which an anthracycline would not be ideal.

High-Dose versus Standard-Dose Cytarabine High-dose cytarabine does not increase complete remission rates and increases toxicity compared to conventional doses, especially in older patients (for doses of these regimens, see “Intensive Consolidation Therapy” below). Patients receiving high-dose cytarabine have more leukopenia, thrombocytopenia, gastrointestinal problems, and eye toxicity. Disease-free survival and overall survival may be better than that achieved with standard therapy, leading some investigators to suggest use of high-dose therapy for induction in patients younger than age 50 years, but this approach is not a standard one, and these studies do not take into account the role of high-dose cytarabine in postremission therapy.⁵⁹⁹ Some studies show that marrow blast clearance is higher after an induction with high-dose cytarabine and that there is an improvement in disease-free survival for patients 50 years of age or younger.⁶⁰⁰ When high-dose cytarabine was compared to intermediate doses in induction therapy, no improvement in outcome was noted, and higher incidences of grades 3 and 4 toxic effects were noted.⁶⁰⁰ A trial in younger patients with multiple arms; fludarabine, high-dose cytarabine, and G-CSF (FLAG regimen) with idarubicin resulted in a higher remission rate than did standard daunorubicin plus cytarabine with or without etoposide. Relapse rates were also less with the high-dose cytarabine induction (38 vs. 55 percent).⁶⁰¹ A superior remission rate and survival was achieved in younger patients (<46 years) induced with a regimen containing high-dose cytarabine, 82 versus 76 percent rate of remission and a 52 versus 43 percent rate of overall survival. These differences were also seen in secondary AML cases and in those with *FLT3-ITD* mutations.⁶⁰² Also, complete remission rates of greater than 60 percent have been noted with high-dose cytarabine in patients with poor-risk cytogenetics.^{603,604}

Timed Sequential Therapy and Other Drugs Timed sequential therapy, which uses agents in a scheduled sequence rather than concurrently, may prolong remission duration.^{605–607} Timed sequential chemotherapy combining mitoxantrone intravenously (IV) on days 1 to 3, etoposide IV on days 8 to 10, and cytarabine IV on days 1 to 3 and 8 to 10 resulted in a complete remission in 60 percent of patients, but treatment-related death in 9 percent of patients. Median disease-free survival was 9 months.⁶⁰⁵

Adding ATRA,⁶⁰⁸ gemtuzumab ozogamicin,⁶⁰⁹ fludarabine,⁶¹⁰ cladribine or topotecan^{611,612} to induction regimens has not improved results significantly. A recent randomized study showed that the addition of the purine analogue cladribine, but not fludarabine, to daunorubicin and cytarabine improved the remission rate and prolonged survival in patients younger than 60 years of age.⁶¹³ The addition of bortezomib to daunorubicin and cytarabine in those 60 to 75 years of age resulted in a remission rate of 65 percent. This was a single-arm trial with dose escalation of bortezomib.⁶¹⁴ There are preliminary reports suggesting that the addition of gemtuzumab ozogamicin to standard induction chemotherapy may increase disease-free survival in patients with low- and standard-risk cytogenetic abnormalities,⁶¹⁵ and inhibitors of *FLT3* ITD are now being examined, but no data are available regarding utility of this approach.⁶¹⁶ A recent prospective comparison of five different treatment strategies, adjusted for differences in prognostic

characteristics, did not show clinically relevant differences in outcome when compared to a standard cytarabine and anthracycline containing arm.⁶¹⁷ Thus, the standard practice guideline for AML, other than promyelocytic leukemia, recommends standard-dose cytarabine plus an anthracycline antibiotic as treatment.⁵⁸⁷

Hematopoietic Cytokines to Enhance Chemotherapy G-CSF and granulocyte-monocyte colony-stimulating factor (GM-CSF), when used in untreated leukemia, can increase the percentage of leukemic cells in the DNA synthetic phase, resulting in blast population expansion during short-term administration. This process could render the cells more sensitive to simultaneous chemotherapy, but clinical benefit from growth-factor priming has not been observed^{618,619} despite an increased ratio of intracellular cytosine arabinoside triphosphate to deoxycytidine-5'-triphosphate and enhanced cytarabine incorporation into the DNA of AML blasts.⁶¹⁹ Remission rates or overall survival did not differ among adult patients who received cytarabine plus idarubicin or cytarabine plus amsacrine with or without G-CSF given concurrently, but relapse rates decreased in patients who received G-CSF.⁶²⁰ GM-CSF priming in a younger patient group treated with timed-sequential therapy increased complete remission rates but did not impact overall survival.⁶²¹ Thus, these growth factors are not generally considered useful as enhancers of chemotherapy. A study did, however, suggest that an improved event-free survival and overall survival was noted in patients treated with high-dose cytarabine during remission induction,⁶²² and complete remissions have occurred in hypoplastic AML after G-CSF treatment without chemotherapy.⁶²³

Reinduction Therapy Patients who have persistent leukemia after the first course of induction chemotherapy generally are given the same regimen a second time. The effect is usually assessed by marrow aspirate and biopsy 7 to 10 days after completion of chemotherapy (the “14-day marrow” examination). For those with hypocellular marrow and no evidence of residual leukemic blasts, recovery of normal counts is awaited, and for those with a hypocellular marrow and a small number of residual blasts, additional therapy may be delayed until count recovery or until another marrow assessment. For those with significant amounts of leukemic cells remaining, repeating the original induction therapy or use of a high-dose cytarabine regimen can be considered. The patient's long-term outcome is worse if two courses of treatment are required, even if a complete remission is achieved. Approximately 40 percent of patients with persistent AML after one course of induction therapy have a complete remission after a second course,⁶²⁴ and disease-free survival at 5 years is approximately 10 percent. In some European centers, two courses of induction chemotherapy are given routinely, but the impact on remission rates or overall survival is uncertain.⁶²⁵ The longer the time to remission after the first induction therapy, the shorter the duration of disease-free survival.⁶²⁶ High-risk cytogenetic abnormalities, antecedent hematologic disorders, and other poor prognostic factors can be used to assign nonresponders to an experimental chemotherapy regimen designed to treat refractory disease, rather than repeating induction therapy. In one study, overall response to reinduction was 53 percent. Those patients with poor risk cytogenetics and those with a marrow blast percentage of 60 percent or greater following the 7-plus-3 regimen induction treatment were found to have a low probability of achieving a complete remission with reinduction.⁶²⁷ Mortality during induction therapy correlates with age⁶²⁸ and, perhaps, leukocyte count.⁶²⁹

Special Considerations during Induction Therapy

Hyperleukocytosis Patients with blast counts greater than 100 × 10⁹/L require prompt treatment to prevent the most serious complications of hyperleukocytosis: intracranial hemorrhage or pulmonary insufficiency. Hydration should be administered promptly to maintain urine flow

greater than 100 mL/h/m². Cytotherapy can be initiated with hydroxyurea 1.5 to 2.5 g orally every 6 hours (total dose 6 to 10 g/day) for approximately 36 hours. Appropriate remission-induction therapy should be initiated as soon as possible after the leukocyte count has been decreased significantly. Simultaneous leukapheresis can decrease blast cell concentration by approximately 30 percent within several hours^{331,630,631} without contributing to uric acid or cellular phosphate release. Leukapheresis may improve acute disturbances resulting from the vascular effects of blast cells, but the procedure may not alter the long-term outcome with current therapeutic programs.^{339,340,630} Inhaled nitric oxide may improve the hypoxemia related to hyperleukocytosis.⁶³¹

Antibiotic Therapy Pancytopenia is worsened or induced shortly after treatment is instituted. Absolute neutrophil counts less than 100/ μ L (0.1×10^9 /L) are expected and are a sign of effective drug action. The patient usually becomes febrile ($>38^\circ\text{C}$), often with associated rigors. Cultures of urine, blood, nasopharynx, and, if available, sputum should be obtained. Because the inflammatory response is blunted by severe neutropenia and monocytopenia, evidence of exudates on physical examination or imaging studies may be minimal or absent. Antibiotics should be started immediately after cultures are obtained.⁶³² Chapter 24 describes antibiotic usage in the setting of intensive chemotherapy. Infections remain a major cause of therapy-associated morbidity and mortality.^{633,634} Gram-positive bacterial isolates now outnumber Gram-negative organisms.⁶³⁴ Cultures are often negative, but if fever and other signs are present, antibiotic therapy should be continued until neutrophil recovery.

Some centers use prophylactic antibacterial, antifungal, and/or antiviral antibiotics, whereas other centers do not. Antifungal prophylaxis can consist of low-dose amphotericin or azoles such as fluconazole, itraconazole, posaconazole, or voriconazole.^{635,636} In a randomized study in patients undergoing induction therapy, posaconazole was more effective in preventing invasive fungal infections than fluconazole or itraconazole.⁶³⁷ Voriconazole was not included in the comparison. Acyclovir, valacyclovir, or famciclovir prophylaxis during remission-induction therapy of patients with AML does not affect the duration of fever or the need for antibiotics. The incidence of bacteremia is not reduced, but acute oral infections are less severe.⁶³⁸ Liposomal amphotericin, the caspofungins and azoles are available for treatment of established fungal infections.⁶³⁹ Some centers use outpatient supportive therapy, including oral antimicrobials, immediately after induction therapy administration in adult AML.⁶⁴⁰

Hematopoietic Growth Factors to Treat Cytopenias Cytokine therapy as an adjunctive treatment for AML remains controversial.⁶⁴¹ GM-CSF and G-CSF accelerate neutrophil recovery; neither GM-CSF nor G-CSF reproducibly decreases major morbidity or mortality. However, one study has shown decreased mortality from fungal infections in older patients.⁶⁴² Use of cytokines during periods of cytopenia following induction therapy is safe, and nearly all trials have shown a modestly reduced duration of severe neutropenia with a variable effect on the incidence of severe infections, antibiotic usage, and duration of hospital stays. Although no increase in relapse has been noted when growth factors are started after completion of chemotherapy, no consistent enhancement of remission, event-free survival, or overall survival has been noted.⁶⁴³ Therefore, the cost-effectiveness and clinical effectiveness of growth factor usage is doubtful. Also, growth factor usage can cloud marrow interpretation when used during induction.

Component Transfusion Therapy Red cell transfusions should be used to keep the hemoglobin level greater than 7.0 g/dL, or higher in special cases (e.g., symptomatic coronary artery disease; Chap. 138). Platelet transfusions should be used for hemorrhagic manifestations related to thrombocytopenia and prophylactically if necessary to maintain the platelet count between 5×10^9 /L and 10×10^9 /L.⁶⁴⁴ Patients

without coagulation abnormalities, anticoagulant use, sepsis, or other complications usually can maintain hemostasis with platelet counts of 5 to 10×10^9 /L. Initially, random donor platelets can be used, although single-donor platelets or HLA-matched platelets may be preferable products and should be tried if random-donor platelets do not raise the platelet count significantly. A no-prophylaxis platelet-transfusion strategy for blood cancers has been examined, but data support the need for prophylactic platelet transfusions.⁶⁴⁵ Family members may be effective donors, if allogeneic HSC transplantation is not being considered (Chap. 139). There are data that fever should result in increasing the platelet count used as a transfusion threshold, and there is some suggestion that higher hemoglobin values protect against bleeding related to thrombocytopenia.⁶⁴⁶

All red cell and platelet products should be depleted of leukocytes, and all products, including granulocytes for transfusions, should be irradiated to prevent transfusion-associated graft-versus-host disease (GVHD) in this immunosuppressed population (Chaps. 138 and 139).

Granulocyte transfusion should not be used prophylactically for neutropenia but may be used in patients with high fever, rigors, and bacteremia unresponsive to antibiotics, with blood fungal infections, or with septic shock. G-CSF administration to a volunteer donor increases neutrophil yield fourfold and results in posttransfusion blood neutrophil increments for more than 24 hours after transfusion.⁶⁴⁷ There is still ambiguity about the usefulness of this approach. GM-CSF administration may be warranted for treatment of major fungal infections (Chap. 24).

Jehovah's Witnesses and others who refuse blood product support can survive tailored chemotherapy.⁶⁴⁸ In general, phlebotomy is minimized, and antifibrinolytics, hematinics, and growth factors are used to support such patients during severe cytopenias.

Therapy for Hypofibrinogenemic Hemorrhage Patients with evidence of intravascular coagulation (Chap. 129) or exaggerated primary fibrinolysis (Chap. 135) should be considered for platelet and fresh-frozen plasma administration before antileukemic therapy is started. Infusion of cryoprecipitate can be used for fibrinogen levels under approximately 125 mg/dL. If the findings are equivocal, patients should be monitored closely with measurements of fibrinogen levels, fibrin(ogen) degradation products, D-dimer assay, and coagulation times. Intravascular coagulation or primary fibrinolysis may occur in patients with APL and acute monocytic leukemia, but also may occur in occasional patients with other AML subtypes.

Management of Central Nervous System Disease CNS disease occurs in approximately one in 50 cases at presentation.⁶⁴⁹ Prophylactic therapy usually is not indicated, but examination of the spinal fluid after remission should be considered in (1) monocytic subtypes,⁵⁰⁸ (2) cases with extramedullary disease, (3) cases with inversion 16²⁵⁴ and t(8;21)^{263,266} cytogenetics, (4) CD7- and CD56-positive (neural-cell adhesion molecule) immunophenotypes,⁶⁵⁰ and (5) patients who present with very high blood blast cell counts. In these situations, the risk of meningeal leukemia or a brain myeloid sarcoma is heightened, but prophylactic intrathecal chemotherapy is not recommended if high-dose cytarabine is used for consolidation. Patients who present with neurologic symptoms should have a head computed tomogram or MRI to rule out hemorrhage or mass effect. If negative, a lumbar puncture should be performed. Treatment of meningeal leukemia can include high-dose intravenous cytarabine (which penetrates the blood-brain barrier), intrathecal methotrexate, intrathecal cytarabine, cranial radiation, or chemotherapy and radiation in combination.⁶⁴⁹ If CNS leukemia is present, intrathecal therapy is often given twice per week until blasts are cleared, and then once per week for 4 to 6 weeks. This therapy can be accomplished via the lumbar puncture route or through placement of an Ommaya reservoir. If there is a mass present, radiation or high-dose

cytarabine with glucocorticoids can be considered.⁶⁵¹ Systemic relapse commonly follows relapse in the meninges, and concurrent systemic treatment usually is indicated. Long-term success is unusual unless allogeneic HSC transplantation is possible. Unless the patient has neurologic symptoms, lumbar puncture generally is deferred until blood blast cells have cleared. No consensus exists on a trigger for platelet transfusion in adults with AML undergoing lumbar puncture, but a platelet count less than $20 \times 10^9/L$ has been proposed as such a trigger,⁶⁵² but many therapists use a higher platelet count (e.g., $50 \times 10^9/L$) as a safety threshold for lumbar puncture.

Management of Nonleukemic Myeloid Sarcoma Some patients present with myeloid (granulocytic) sarcomas without evidence of leukemia in the blood or marrow (see “Myeloid [Granulocytic] Sarcoma” earlier). Myeloid sarcoma may be the presenting finding in approximately 1 percent of patients with AML. Such patients should receive intensive AML induction therapy.²⁶² Intensive therapy results in a longer nonleukemic period than patients who have undergone surgical resection or resection followed by local irradiation.²⁵⁰ Whether such patients should undergo allogeneic HSC transplantation in first remission irrespective of other factors has not been determined.^{653,654} Median relapse-free survival is approximately 12 months after AML-type chemotherapy.²⁶² Patients with trisomy 8 have poorer survival rates.²⁶⁰

POSTREMISSION THERAPY

Cytotoxic Therapy

General Considerations Postremission therapy is intended to prolong remission duration and overall survival, but no consensus exists regarding the best approach. Postremission chemotherapy that does not produce profound prolonged cytopenias, closely simulating intensive induction therapy, has produced on average only slight prolongation of remission or life. Regimens that fall between these intensities have been used, with equivocal results. Intensive consolidation therapy after remission results in a somewhat longer remission duration and, more significantly, a subset of patients who have a remission of more than 3 years. The issue of postremission therapy and its impact is complicated by the large proportion of patients with AML who are older than 60 years of age and have limited tolerance for intensive therapy. In addition, a very small pool of leukemic stem cells may sustain the process, and elimination of these cells may require approaches other than intensive chemotherapy, especially in adults.

Several randomized trials have studied whether AML patients in first remission should receive consolidation chemotherapy alone, autologous transplantation, or allogeneic HSC transplantation, without reaching a consensus. Allogeneic transplantation was compared to autologous transplantation using unpurged marrow and two courses of intensive chemotherapy in 623 patients who had a complete remission after induction chemotherapy.⁶⁵⁵ Disease-free survival was 53 percent at 4 years for those receiving allogeneic transplantation, 48 percent for those receiving autologous transplantation, and 30 percent for patients receiving intensive chemotherapy. Overall survival after complete remission was similar in all three groups because patients who relapsed after chemotherapy could be rescued with allogeneic HSC transplantation. No significant difference in the 4-year disease-free survival between allogeneic HSC transplantation (42 percent) and other types of intensive postremission therapy (40 percent) has been found.⁶⁵⁶ In another study, only patients younger than 35 years of age with poor-risk cytogenetics had improved disease-free survival if they had a sibling donor and underwent allogeneic transplantation (43.5 percent vs. 18.5 percent at 4 years).⁶⁵⁷ Thus, in several studies, the early mortality after allogeneic HSC transplantation and the chemotherapy-induced remissions in patients who relapse following autologous transplantation or

chemotherapy have led to comparable overall survival rates. However, leukemia-free survival was greater after allogeneic transplantation.⁶⁵⁸ In the last decade, treatment-related mortality from transplantation has declined and matched unrelated donor transplantations are as effective as those from a matched sibling donor, so currently, transplantation is recommended for all but good-prognosis patients (CBF leukemias or those with *NPM1* mutation without a *FLT3* mutation).⁶⁵⁹ A Markov decision analysis has shown that patients treated with allogeneic HSC transplantation have a longer life expectancy compared with those treated with chemotherapy among patients with an intermediate- or unfavorable-risk prognosis.⁶⁶⁰ A prospective matched-pairs analysis has also concluded that allogeneic HSC transplantation is the most effective postremission therapy for AML, especially for those 45 to 59 years of age and/or with high-risk cytogenetics.⁶⁶¹ When quality of life was measured for patients in complete remission for 1 to 7 years, those treated with chemotherapy had the highest quality of life, whereas those who underwent allogeneic HSC transplantation had the lowest.⁶⁶²

The decision to utilize autologous or allogeneic HSC transplantation or high-dose cytarabine alone for consolidation should be individualized, based on the patient's age and other prognostic factors, such as high-risk cytogenetic findings and antecedent hematologic disease. Patients with good-risk cytogenetics should receive up to four cycles of high-dose cytarabine. Patients with poor-risk cytogenetics should be considered for allogeneic HSC transplantation as soon as feasible. A meta-analysis has also shown that compared with nonallogeneic therapies, allogeneic HSC transplantation has superior relapse-free survival and overall survival for cases of AML classified intermediate and poor-risk, but not for cases considered good-risk AML in first remission.⁶⁶³

Intensive Consolidation Therapy For patients who do not receive high-dose chemotherapy with autologous or allogeneic transplantation in first remission, consolidation chemotherapy regimens containing high-dose cytarabine provide better results than intermediate-dose cytarabine,^{664,665} but these regimens are not universally accepted.⁶⁶⁶ Patients who are to have allogeneic HSC transplantation do not require four cycles of high-dose cytarabine, and may not benefit from even one, if a donor is readily available.⁶⁶⁷ *RAS* mutations are associated with benefit from high-dose cytarabine therapy.⁶⁶⁸ Patients with CBF leukemias such as t(8;21) also have particularly favorable responses to repetitive cycles of high-dose cytarabine. In patients who received three or more cycles, a relapse rate of 19 percent was reported.⁶⁶⁹

Other regimens, such as those containing gemtuzumab ozogamicin and fludarabine, have been used in postremission therapy, but whether they provide benefit over use of high-dose cytarabine has not been studied.⁶⁷⁰ Long-term disease-free survival at 5 years generally is approximately 30 percent when two to four cytarabine-containing regimens are administered.^{671,672} Adding mitoxantrone or amsacrine to high-doses cytarabine has not improved treatment outcomes in consolidation,⁶⁷³ and timed sequential chemotherapy used in consolidation did not improve outcome as compared with high-dose cytarabine.⁶⁷⁴ Most centers use four cycles of therapy. A cycle is 3 g/m^2 twice daily on days 1, 3, and 5, providing six doses per cycle, with cycle durations dependent on normal blood count recovery. The optimal number of cycles for this therapy is not known.⁶⁷⁵ High-dose cytarabine can be administered at a dose of 3 g/m^2 in a 1- to 3-hour intravenous infusion every 12 hours for up to 6 days (12 doses), but this schedule is almost never used because of its toxicity. There is some evidence that two cycles of intermediate-dose cytarabine (1 g/m^2 every 12 hours for 6 days) may be a viable alternative to the 3 g/m^2 for six doses schedules.⁶⁷⁶ When 36 g/m^2 total dosing was compared with 12 g/m^2 dosing in the first consolidation, there was no improvement in treatment outcomes.⁶⁷⁷ High-dose cytarabine frequently causes conjunctivitis and photophobia, and glucocorticoid eye drops are usually used every 6 hours until 24 hours after the last dose of

the drug.⁶⁷⁸ Cerebellar function abnormalities also may occur, and these require cessation of drug administration. A 1-hour duration infusion of high-dose or reduced-dose (e.g., 2 g/m²) cytarabine may decrease the likelihood of severe cerebellar toxicity.⁶⁷⁸ Older patients and patients with renal insufficiency require dose attenuation (i.e., to 1 to 2 g/m²).⁶⁷⁹

Additional Maintenance Therapy

Various forms of less-intensive maintenance chemotherapy have been attempted after completion of intensive consolidation chemotherapy. Many of the regimens consist of monthly chemotherapy, for example, low-dose 6-thioguanine or cytarabine. Although improved disease-free survival was noted in some studies, no improvement in overall survival has been demonstrated in most studies.⁶⁸⁰ Some groups are examining the role of demethylating agents (e.g., 5-azacytidine or decitabine) as maintenance therapy.⁶⁸¹

Autologous Stem Cell Infusion after Myeloablative Chemotherapy or Chemoradiotherapy for Consolidation Removal and cryopreservation of postremission marrow or collection of mobilized blood stem cells from patients with AML and reinfusion of these products following intensive chemotherapy and/or radiotherapy is a form of postremission therapy (Chap. 23).⁶⁸² This approach is loosely referred to as autologous transplantation but does not cross transplantation barriers. Autologous marrow or blood stem cell rescue can be used in patients with AML who achieve a remission, do not have a compatible stem cell donor, and are as old as 70 years. With the availability of high-resolution HLA-matched unrelated donors, cord blood and haploidentical donors, the number of autologous stem cell transplants used in AML has diminished.

Various treatment regimens for autologous transplantation in AML have been used,⁶⁸³ such as busulfan-cyclophosphamide, busulfan-etoposide-cytarabine, high-dose cytarabine-mitoxantrone plus total-body irradiation, melphalan plus total-body irradiation, and cyclophosphamide plus total-body irradiation. A disease-free survival rate of approximately 40 percent at 3 years is average after such regimens in the age-range treated.^{684,685} Long-term disease-free survival can occur in patients who undergo this treatment for AML in second remission.⁶⁸⁶ Patients older than age 50 years have inferior outcomes, but no strict upper-age limit for this procedure has been determined.⁶⁸⁷ Administration of two or more courses of consolidation chemotherapy prior to harvest and transplant is associated with decreased relapse rates and improved disease-free survival. A marrow nucleated cell dose greater than 2×10^8 /kg improves disease-free survival.⁶⁸⁸ Chemotherapy agents such as 4-hydroperoxycyclophosphamide have been used for purging residual leukemic cells in marrow before infusion,^{689,690} and antisense agents reportedly diminish leukemic cell contamination.⁶⁹¹ Use of marrow grafts purged of residual leukemia cells has not significantly improved the results obtained with unpurged marrow in many studies, suggesting that low proportions of leukemic stem cells may not transplant easily or that they do not survive the freeze-thaw cycle to which autologous marrow is subjected as well as do normal HSCs.⁶⁹² In addition, residual leukemia in the patient may contribute to relapse. For these reasons, marrow purging is rarely used in AML autografting (Chap. 23). In long-term cultures from patients newly diagnosed with AML, normal progenitors can be detected, and their numbers are increased by *in vitro* culture with cytokines.⁶⁹³ In oligoblastic myelogenous leukemia (high-risk myelodysplasia), secondary AML, and therapy-related AML, leukapheresis products obtained after chemotherapy and growth factor treatment contain normal progenitors,⁶⁹⁴ indicating mobilized stem cells may be relatively free of leukemic counterparts even in the absence of *ex vivo* purging.⁶⁹⁵ Early mortality may be decreased using blood stem cells because they engraft more rapidly, but relapse rates may be higher.⁶⁹⁶ Mobilized stem cells can be collected

after high-dose cytarabine plus G-CSF or after G-CSF alone.⁶⁹⁷ There is a plateau in the survival curve after autologous stem cell transplantation at about 2.2 years,⁶⁹⁸ and there is evidence that autologous transplantation improves disease-free survival but not overall survival.⁶⁹⁹ The total number of CD34+ cells infused influences early engraftment, but durable engraftment is associated more closely with the CD34+/CD38- subset of cells in the graft.⁷⁰⁰

Chemoradiotherapy Plus Allogeneic Hematopoietic Stem Cell Transplantation for Consolidation Therapy

General Considerations Utilization of allogeneic HSC transplantation for AML is increasing in Europe and the United States.⁷⁰¹ No strict upper-age limit for transplantation exists,⁷⁰² but many centers use age 60 or 65 years for transplantations following ablation of hematopoiesis and 70 to 75 years for transplantations not preceded by ablation of hematopoiesis (nonmyeloablative or reduced-intensity transplants). Decisions to proceed to allogeneic transplantation should be individualized, and feasibility depends on (1) the availability of a suitable donor, (2) the recipient's age and health status, and (3) whether AML is in remission.

For full-intensity transplantations, the patient is prepared with a regimen that includes total-body irradiation and/or high-dose chemotherapy, after which the donor stem cells are infused by vein. Patients given allogeneic blood stem cells have more rapid hematopoietic reconstitution than patients given marrow stem cells, but they may have more chronic GVHD and comparable risk of relapse.^{703,704} Chapter 23 describes the indications, procedure, and preparative regimens for allogeneic stem cell transplantation. In general, no single preparative regimen is superior for patients with AML in first remission.⁷⁰⁵ In one study, cyclophosphamide and total-body irradiation lowered relapse risk, but overall results were comparable to conditioning with chemotherapy alone.⁷⁰⁶ Another retrospective study showed outcomes with intravenous busulfan and cyclophosphamide were not different from those with cyclophosphamide and total-body irradiation in AML in remission.⁷⁰⁷ A retrospective registry analysis showed that leukemia-free and overall survivals were better with busulfan and cyclophosphamide, as compared with total body irradiation in AML in first remission.⁷⁰⁸ Postremission consolidation with cytarabine before allogeneic transplantation for AML in first remission does not improve outcome compared with immediate transplant after successful induction.⁷⁰⁹ It is unclear that this result will also hold in the setting of reduced-intensity transplants or for transplants performed beyond first remission.⁷¹⁰

Related Donors When matched-sibling transplantation is performed for AML in first remission, approximately half of patients have a disease-free survival of 4 years. Small series using T-cell depletion have reported 4-year disease-free survival of 65 percent.⁷¹¹ Leukemia relapses occur in approximately 20 percent of patients who receive an allogeneic transplant. Patients who are alive with good performance status 3 years after transplantation have excellent prospects of long-term survival.⁷¹¹ In the posttransplantation period, approximately one-third of patients die of severe GVHD, opportunistic infection, or interstitial pneumonitis. The outlook for long-term survival is improved if (1) the AML is in remission prior to transplantation, (2) grades III to IV acute GVHD does not occur, and (3) chronic GVHD is low grade.^{712,713} For patients with unfavorable cytogenetics, an allogeneic sibling transplantation in first remission is often recommended.⁷¹⁴ Patients with FLT3/ITD-positive AML may also benefit from allogeneic HSC transplantation in first remission.^{715,716} When AML patients in first remission were compared on a donor versus no donor basis, and more than 80 percent of patients with a donor went on to transplantation, patients with a donor had a significantly better disease-free survival, although treatment-related mortality was higher.⁷¹⁷ For patients with intermediate-risk cytogenetics, where the decision is made to delay transplantation until first

relapse and second remission, physicians should identify a source of a HSC graft and ensure that careful monitoring of the patient occurs so that transplantation can be instituted as quickly as possible.⁷¹⁸

In an attempt to decrease the relapse rate after stem cell transplantation for advanced acute leukemia,²⁰² I-labeled anti-CD45 antibody to deliver radiation to leukemic cells, followed by a standard transplant preparative regimen, has been used. With this regimen, more radiation can be delivered to hematopoietic tissues compared with liver, lung, or kidney, which may improve the efficacy of the transplant.⁷¹⁹

Unrelated Donors Approximately 70 percent of all patients with AML are older than 50 years of age, and the current mean family size in the United States is slightly more than two children per family. Thus, only approximately 10 to 15 percent of subjects with AML are within the age-range and have a sibling donor for marrow transplantation. The ability to extend the proportion of patients who can be transplanted has led to histocompatible, unrelated donors or HLA type-mismatched sibling or parent (haploidentical) donor transplants.⁷²⁰ More than 70 percent of patients of European descent can find a suitable unrelated-matched donor in the available donor registries,⁷²¹ and another study showed that the majority of patients with AML in first remission for whom transplantation is recommended are able to undergo the procedure; the main barriers to transplantation are relapse of disease while awaiting a donor and poor performance status.⁷²² Molecular matching of classes I and II HLA alleles adds to the clinical success of unrelated donor transplantations, but makes finding a donor more difficult.⁷²³ Using such typing, studies have demonstrated that use of matched-unrelated donors as compared with matched-related donors result in similar survival times in AML.⁷²⁴ Transplantation benefits younger adults in first remission, but no difference in outcome between matched-related donors and matched unrelated donors.⁷²⁵ HLA-matched or HLA-mismatched cord blood stem cells can be used in adults with acute leukemia but generally not for patients in first remission.^{726,727} In adults, the numbers of stem cells available in a single cord product may not result in engraftment, which has led to the use of two-cord blood units for grafting (Chap. 23).⁷²⁸

Reduced-Intensity and Nonmyeloablative Transplantation

Patients who, based upon comorbidities or performance status, are deemed too old or too ill to undergo a full-intensity (myeloablative) allogeneic stem cell transplantation may be offered a reduced-intensity transplantation procedure or a nonmyeloablative conditioning regimen, provided a suitable donor is available. Reduced-intensity transplant results in some degree of myeloablation but in non-ablative transplants, autologous stem cell recovery would occur in the case of graft failure.^{729,730} This type of transplantation for AML and closely related hematologic malignancies relies upon the graft-versus-leukemia effect as primary therapy.⁷³¹⁻⁷³³ These regimens have moderate hematologic and nonhematologic toxicity, and often can be performed on an outpatient basis. Engraftment and establishment of complete donor chimerism are successful in most patients. GVHD rates have been variable, and the ultimate risk of acute and chronic GVHD with these regimens is unclear. A variety of low-intensity regimens have been proposed.⁷³⁴ In AML in first remission, the 1-year progression-free survival is approximately 55 percent.^{735,736} The role of this approach in the treatment of AML remains to be defined, and comparative trials with longer followup are needed. Nonmyeloablative conditioning with unrelated donors has been used successfully.^{737,738} Although randomized trials of ablative versus reduced dose-intensity conditioning regimens for transplantation of AML patients in first remission have not been done, there is evidence that reduced dose intensity is an inferior option for disease control, but that disadvantage is offset by the decreased treatment-related mortality.⁷³⁹ One study found that reduced-intensity conditioning compared with myeloablative conditioning using unrelated

donors in AML gave similar rates of leukemia-free survival.⁷⁴⁰ In a multivariate analysis, active disease at transplant and development of grades II to IV GVHD after transplantation had a negative impact on survival in reduced-dose-intensity transplantations.⁷⁴¹ Reduced-intensity transplantations are feasible in elderly patients with both fludarabine and low-dose total-body irradiation⁷⁴² and with fludarabine and IV busulfan⁷⁴³ but donor availability and coexisting medical problems often limit its use.⁷⁴⁴

Use of Transplantation in Relapsed Patients Some form of allograft usually is recommended for patients in early first relapse or second remission, because long-term survival with chemotherapy alone is improbable, whereas histocompatible sibling transplants in these situations have a 25 percent survival rate. For patients who lack a sibling donor, matched-unrelated donor transplantations can be effective, but treatment-related mortality is high, suggesting that patients with unfavorable cytogenetics should undergo a matched-unrelated donor transplantation in first complete remission, if an acceptable donor can be found.⁷⁴⁵ However, when transplantation was compared to chemotherapy for AML in second remission, the 3-year probability of event-free survival was 17 percent with chemotherapy and 16 percent with transplantation. Patients younger than 30 years of age who were in remission for at least 1 year fared best.⁷⁴⁶ Development of chronic GVHD, an unrelated donor, a young age of donor, and blast cell count less than 30 percent at transplantation were found in another series to be favorable predictors of survival for transplantations performed in leukemia relapse.⁷⁴⁷ Another study found that those with a remission duration of less than 6 months, circulating blasts, donor other than an HLA-matched sibling, poor-performance status, and poor-risk cytogenetics were adverse pretransplantation variables for those in relapse or primary induction failure.⁷⁴⁸ Patients with extramedullary sites of leukemia are more likely to relapse after allogeneic transplantation.⁷⁴⁹

Patients with AML who relapse after allogeneic stem cell transplantation can have a long-term remission, if they undergo retransplantation.⁷⁵⁰ A second stem cell transplantation can induce 2-year overall survival in approximately 25 percent of patients and is effective after either related or unrelated donor transplantations. A clear advantage of changing the donor for the second transplantation has not been demonstrated.⁷⁵¹

The mechanism of benefit of allogeneic stem cell transplantation was thought to result from high-dose ablative chemoradiotherapy followed by marrow "rescue." The increased relapse rate of AML in patients transplanted with marrow from identical twins, compared to nonidentical siblings, or transplanted with T-lymphocyte-depleted marrow has indicated that an immunologic effect of donor lymphocytes may determine the results of transplantation. This immunologic response, referred to as *graft-versus-leukemia effect*, may play a role in preventing leukemia relapses.⁷⁵²

Donor Leukocyte Infusion In an attempt to enhance graft-versus-leukemia effects, adoptive immunotherapy with donor mononuclear cell infusions is sometimes used to treat relapse of leukemia after allografting.^{753,754} These infusions have been successful in only a minority of patients with AML, but given the high mortality associated with alternative procedures such as a second transplantation, the infusions are a reasonable approach for patients who relapse after allogeneic transplantation.⁷⁵⁵ GVHD and marrow aplasia are the major complications of this form of treatment.⁷⁵⁶ The graft-versus-leukemia reaction is thought to be directed against minor histocompatibility antigens on the cell surface of hematopoietic cells, but reactions against leukemia-specific antigens are possible. Relapses after donor leukocyte infusions for recurring acute leukemia have a higher probability of being extramedullary.⁷⁵⁷ Donor lymphocyte infusions are most effective in early relapses and in the absence of extensive or chronic GVHD.⁷⁵⁸ Some patients also enter a

new remission upon withdrawal of immune suppression. Patients who enter remission by donor lymphocyte infusion or cessation of immunosuppressive agents have a better survival than those who entered remission with chemotherapy alone or after a second transplantation.⁷⁵⁹ Unrelated donor-leukocyte infusions can be used to treat relapsed leukemia after unrelated donor stem cell transplantation.⁷⁶⁰ Approximately 40 percent of AML patients enter remission with this treatment. G-CSF has been used as an alternative to donor leukocyte infusions after AML relapse posttransplantation.⁷⁶¹ Donor blood stem cells can be combined with chemotherapy for early relapse of AML after allogeneic stem cell transplantation.⁷⁶² Strategies with donor leukocyte infusions are anticipated to become more effective once the effector cells are identified and the tumor target antigens better understood.⁷⁶³

Other Modalities to Decrease or Treat Relapse after Transplant. Killer-cell immunoglobulin-like receptor (KIR) genes among HLA-matched potential donors can point to donors with donor KIR genotype that are associated with enhanced disease-free survival.⁷⁶⁴ Early cytomegalovirus replication after transplantation is also associated with decreased relapse risk, possibly because of a virus-versus-leukemia effect in AML.⁷⁶⁵ Hypomethylating agents have been used for the treatment of relapse after allogeneic transplantation with some success and with induction of T-regulatory cells.^{766,767} Extramedullary sites of relapse are more common after transplant.⁷⁶⁷

Recurrent Leukemia in Donor Cells or New Leukemia in Recipient Cells Recurrence of AML in donor cells has been reported in patients who received transplants from healthy siblings. These recurrences in donor cells occurred in approximately one in 18 relapsed patients who received marrow from a donor of the opposite sex.⁷⁶⁸ A similar frequency of relapsed AML is observed in recipient cells but with a different clonal cytogenetic abnormality, suggesting a “new” leukemia.⁷⁶⁸ The frequencies are dependent on the sensitivity and specificity of cytogenetic techniques, which have been challenged. AML developing in a stem cell recipient but of donor cell origin long after transplantation has been documented in rare cases.^{768,769}

Summary of Postremission Therapy In younger patients with favorable cytogenetics (CBF with no mutation of *KIT*) or with *NPM1* or double *CEBPα* mutations in the absence of a *FLT3* mutation, there is no advantage to do an allograft in first remission and four cycles of high-dose cytarabine is appropriate treatment. Another option would be two cycles of high-dose cytarabine followed by autografting, an approach often favored in Europe. In those with intermediate-risk cytogenetics, an allograft should be considered as consolidation, and three to four cycles of high-dose cytarabine could be offered if a transplant donor cannot be found. Those with poor-risk cytogenetics or a *FLT3-ITD* mutation should be considered for an allograft in first complete remission. These recommendations may change as transplant mortality improves and subclasses of the “normal” cytogenetics group are better defined such that targeted agents might have an impact on relapse rates. After patients complete consolidation therapy, they are generally followed with blood counts every 3 months for 2 years, and then every 3 to 6 months for 5 years. Marrow examination is done to confirm continued remission after consolidation is completed but is rarely pursued regularly thereafter unless blood counts change.

TREATMENT OF RELAPSED OR REFRACTORY PATIENTS

Chemotherapy

Patients who relapse after remission-induction and postinduction therapy have a decreased probability of entering a subsequent remission, and the duration of any remission that occurs is usually shorter. In

patients who relapse more than 1 year after the first remission, the original remission-induction regimen can be readministered or a combination salvage chemotherapy regimen can be administered. At relapse, cell lineage trees suggest that the leukemic cell sustaining the relapse resembles the leukemic stem cell of origin.⁷⁷⁰ When primary tumor and relapse genomes are compared, two primary patterns of relapse are discerned: gain of mutations in a founding clone that evolved into the relapse clone or a subclone of the founding clone that survived induction, gained mutations, and gained ascendancy to become the dominant clone at relapse.⁷⁷¹

Refractory leukemia is defined as leukemia that does not respond to initial induction chemotherapy with cytarabine and an anthracycline antibiotic or anthraquinone. Patients with refractory disease are more likely to have disease with adverse cytogenetic findings, a history of antecedent clonal myeloid disease, adverse immunophenotypic features, and expression of MDR.⁷⁷²

Relapsed leukemia is leukemia that recurs following a remission. The duration of remission greatly affects the patient's prognosis and response to additional treatment. The wide range of response rates may not only reflect the regimen used but may also reflect variability in patient selection, age, and other prognostic factors.^{772,773}

Chemotherapy regimens can be divided into cytarabine-based, noncytarabine-based, and timed sequential therapy with growth factors and cytotoxic drugs. Table 88–6 lists regimens and their response rates; the duration of response usually is measured in months, and, therefore, clinical trials are also recommended for this patient group. The duration of response is difficult to define because many patients go on to other therapies, including allogeneic stem cell transplantation.

In a large patient cohort treated on successive Medical Research Council trials, of those patients who relapsed after first remission, 55 percent entered a second remission. For those with favorable cytogenetics, 5-year survival was 32 percent; for those with intermediate cytogenetics, 5-year survival was 17 percent; and for those with adverse cytogenetic patterns, 5-year survival was 7 percent. In those in a second remission who underwent transplant, 42 as compared to 16 percent survived 5 years.⁷⁷⁴ Results from therapy were better in younger patients, and in those with longer first remissions, longer durations since last chemotherapy, and better general health. The probability of a second remission is approximately 40 percent in younger (ages 15 to 60 years) and approximately 25 percent in older (ages 60 to 80 years) patients, but the duration of remission is nearly always much shorter than the first remission. An eventual fatal outcome is nearly certain unless allogeneic HSC transplantation can be performed. Rare patients may have a third (or more) relapse followed by a remission when treated with cytotoxic drugs, but each remission is shorter than the preceding one and usually is measured in weeks. For those who have favorable or normal karyotype, long second remission, and no previous stem cell transplantation, intensive chemotherapy can be useful.⁷⁷⁵ In one study, 21 (approximately 17 percent) of 124 patients had a second remission duration at least 2 months longer than the first remission.⁷⁷⁶ In patients in relapse treated with the sequential high-dose cytosine arabinoside and mitoxantrone (S-HAM) regimen, the duration of the first remission was the only factor associated with a successful outcome, and unfavorable karyotype was the only factor related to duration of survival.⁷⁷⁷ Patients who relapse less than 1 year from remission should be treated with investigational agents, whereas patients who relapse more than 1 year later may benefit from standard reinduction therapy.⁷⁷⁸ No standard chemotherapy regimen provides a durable remission of AML patients who relapse (Table 88–7),^{779–789} and all such patients should be considered for clinical trials if available. For patients not fit for intensive salvage regimens, low-dose cytarabine, hypomethylating agents, or supportive or palliative care can be offered.

TABLE 88-7. Examples of Chemotherapy Regimens Used for Relapsed or Refractory Patients

Regimen	No. of Patients	Percent of Patients Entering a Complete Remission (Median Duration)	Year	Reference
Clofarabine 40 mg/m ² , IV, days 1–5	163	35.2 (6.6 months)	2012	789
Cytarabine 1 g/m ² , IV, days 1–5	163	17.8 (6.3 months)	2012	789
Clofarabine 25 mg/m ² , IV, daily for 5 days Cytarabine 2 g/m ² , IV, daily for 5 days G-CSF 5 mcg/kg per day subcutaneously daily until ANC ≥2,000/μL	50	46 (9 months)	2011	787
Gemtuzumab ozogamicin 6 mg/m ² , IV, days 1 and 13 Idarubicin 12 mg/m ² , IV, days 2–4 Cytarabine 1.5 g/m ² , IV, days 2–5	15	21 (27 weeks)	2003	780
Mitoxantrone 12 mg/m ² , IV, days 1–3 Cytarabine 500 mg/m ² , IV, days 1–3 Followed (at blood count recovery) by: Etoposide 200 mg/m ² , IV, days 1–3 Cytarabine 500 mg/m ² , IV, days 1–3	66	36 (5 months)	2003	781
Cladribine 5 mg/m ² , IV, days 1–5 Cytarabine 2 g/m ² , IV, days 1–5, 2 h after cladribine G-CSF 10 mcg/kg subcutaneously, each day, days 1–5	58	50 (29% disease-free at 1 year)	2003	782
Fludarabine 30 mg/m ² , IV, days 1–5 Cytarabine 2 g/m ² , IV, days 1–5 Idarubicin 10/m ² , IV, days 1–3 G-CSF 5 mcg/kg subcutaneously each day, up to 6 doses until neutrophil recovery	46	52 (13 months)	2003	783
Gemtuzumab ozogamicin 9 mg/m ² , IV, days 1 and 15	43	9	2002	784
Mitoxantrone 4 mg/m ² , IV, days 1–3 Etoposide 40 mg/m ² , IV, days 1–3 Cytarabine 1 g/m ² , IV, days 1–3, ± valspodar (PSC-833)	37	32	1999	785
Fludarabine 30 mg/m ² , IV, days 1–5 Cytarabine 2 g/m ² , IV, days 1–5± Idarubicin 12 mg/m ² , IV, days 1–3 G-CSF 400 mcg/m ² , subcutaneously, daily until complete remission	85	66	1995	786

ANC, absolute neutrophil count; G-CSF, granulocyte-colony-stimulating factor.

NOTE: The reader is advised to consult the original reference for details of chemotherapy regimen administration.

Allogeneic Hematopoietic Stem Cell Transplantation

Allogeneic stem cell transplantation may be the only means to induce a sustained remission in patients with AML who do not enter remission with cytotoxic drug therapy or who relapse after a first remission. Approximately 25 percent of patients with refractory or relapsed AML have a sustained remission of at least 3 years.⁷⁹⁰ Transplant-related mortality at 3 years is approximately 50 percent. Relapse rates are higher after sibling than matched-unrelated transplantation.^{791,792} If a histocompatible donor is available and the patient is younger than age 50 years, allogeneic stem cell transplantation can be as successful, if it is performed when the patient is in early relapse compared with in second remission, but this is often done in the context of a clinical trial.⁷⁹³

Relapse after Stem Cell Transplantation For patients who relapse after allogeneic stem cell transplantation, the prognosis is extremely poor and available chemotherapy, donor leukocyte infusions,

or second transplants do not result in consistent durable remissions.⁷⁹⁴ For patients who relapse after reduced-intensity allogeneic transplantations, median overall survival after relapse was found to be 6 months, and no advantage was found for donor leukocyte infusions or second transplantations as compared with chemotherapy.⁷⁹⁵ Patients who relapse after autologous stem cell transplantation can sometimes be salvaged with reduced-intensity allogeneic transplantation or with full-intensity allogeneic transplantations with high treatment-related mortality rates even in younger patients.

OTHER TREATMENT MODALITIES

Chemotherapy

Several newer chemotherapeutic agents are being examined for treatment of AML. For example, liposomal preparations of fixed ratios of

daunorubicin and cytarabine have entered trials.⁷⁹⁶ This has shown some responses in older adults with secondary leukemia.

Epigenetic Modulation

Methylation of DNA at critical sites can cause transcriptional inactivation of genes or chromosomal instability. In AML, aberrant methylation, especially preferential methylation of chromosome 11, has been described.⁷⁹⁷ Epigenetic gene silencing caused by DNA methylation is a target for presumptive demethylating agents such as 5-azacytidine or decitabine, and silencing mediated by histone deacetylation is a target for histone deacetylases.⁷⁹⁸ Decitabine, a potent agent, can cause maturation and growth arrest of AML cells.^{799–801} 5-Azacytidine also has activity in AML, and it is being studied in an oral formulation.⁸⁰² These agents, singly or in combination, have resulted in response rates of 25 to 60 percent.⁸⁰³ Methylome analysis may be useful as a pharmacodynamic end point in those treated with decitabine,⁸⁰⁴ and higher levels of *miR-29b* are associated with responses to decitabine.⁸⁰⁵ Histone deacetylase inhibitors can restore retinoic acid-dependent transcriptional activation and maturation in AML blasts.⁸⁰⁶ Depsipeptide can promote histone acetylation and gene transcription in RUNX1/ETO-positive leukemic cells.⁸⁰⁷ Depsipeptide (romidepsin),⁸⁰⁸ LBH589,⁸⁰⁹ vorinostat (suberoylanilide hydroxamic acid [SAHA]),⁸¹⁰ and MGCD0103⁸¹¹ have each been studied in early phase trials in leukemia. Combination therapy of these agents with other targeted therapies is being explored,⁸¹² and combination therapy with hypomethylating agents and histone deacetylase inhibitors has been reported.⁸¹³

Inhibitors of DOT1L, Isocitric Dehydrogenase, and MDM2

The histone methyltransferase DOT1L is necessary for sustaining *MLL*-rearranged, AML. EPZ-5676, an aminonucleoside inhibitor of DOT1L histone methyltransferase activity is under clinical investigation in *MLL*-rearranged leukemias.⁸¹⁴ Other DOT1L inhibitors are being explored in IDH1/2 mutated AML.⁸¹⁵ AGI-6780 has been identified as an IDH2 R140Q inhibitor with potential for differentiation.⁸¹⁶ Inhibitors of MDM2, a regulator of p53 and p53-specific E3 ubiquitin ligase have also entered trials.⁸¹⁷

Antibodies to CD33

The CD33 antigen is expressed on approximately 90 percent of AML blasts and is a target for antibody-mediated destruction. Gemtuzumab ozogamicin is a recombinant humanized anti-CD33 monoclonal immunoglobulin G₄ antibody conjugated to the cytotoxin calicheamicin.⁸¹⁸ The conjugated antibody is rapidly internalized and causes subsequent cell apoptosis.⁸¹⁹ Hyperbilirubinemia and transaminase elevations can occur. Although it results in similar survival rates as standard chemotherapy reinduction, its use was associated with fewer days of hospitalization.⁸²⁰ In patients who relapsed between 3 and 11 months, gemtuzumab ozogamicin resulted in higher remission rates compared to regimens containing high-dose cytarabine in different trials. However, in patients who had prolonged first remissions of greater than 19 months, cytarabine resulted in superior remission rates.⁸²¹ Prior gemtuzumab ozogamicin exposure may increase the risk of venoocclusive disease in patients who later undergo myeloablative allogeneic HSC transplantation procedures.⁸²² Gemtuzumab ozogamicin was approved by the FDA in 2000, but withdrawn from the market in 2010. Studies in Europe are examining its role in induction treatment coupled with standard chemotherapy, in postremission therapy, and in the treatment of APL.^{823–825} In those studies, it did not alter remission rates but appeared to decrease relapse rate or improve relapse-free survival.

Therapies Targeted to Signal Transduction Mediators

Tyrosine Kinase Inhibitors: FLT3 Inhibitors Constitutively activating FLT3 receptor mutations have been found in approximately 30 percent

of patients with AML. Several small-molecule *FLT3* tyrosine kinase inhibitors have been formulated, but none have yet received regulatory approval.^{826–831} Myeloblast differentiation may occur, including a syndrome with neutrophilic dermatosis wherein the neutrophils are *FLT3*-positive.⁸³² *FLT3*-mutant allelic burden may predict response to such inhibitors.⁸³³ These agents are in phase I and phase II trials, in which they have induced a decline in blood blast cells, but rarely result in complete remissions.^{834,835} Newer-generation *FLT3* inhibitors have been developed in an attempt to improve their effects.⁸³⁶ Crenolanib may inhibit both ITD and TKD mutations.⁸³⁷ Quizartinib (previously AC220) showed activity in a phase I study in relapsed/refractory AML, especially in patients with *FLT3-ITD* mutations.⁸³⁸ Trials are now under way to examine inhibitors such as midostaurin (PKC412)⁸³⁹ and sorafenib⁸⁴⁰ in combination with cytostatic drugs for AML.

Kit Tyrosine Kinase Inhibitors: Imatinib Mesylate Activation of the KIT tyrosine kinase by somatic mutation has been documented in a small minority of AML cases. Paracrine or autocrine activation of *KIT* may occur in AML cells.⁸⁴¹ Imatinib mesylate has induced a complete remission in refractory secondary AML,⁸⁴² but this is a very uncommon result of its use.⁸⁴³ Dasatinib has been studied in CBF leukemias with a *KIT* mutation in conjunction with chemotherapy, but final results of studies are awaited.⁸⁴⁴

Nuclear Factor-Kappa B Inhibitors AML leukemia stem cells have activated NF- κ B, unlike normal HSCs.⁸⁴⁵ Proteasome inhibitors such as bortezomib inhibit NF- κ B and have been examined in AML. They have been found to increase sensitivity to chemotherapy agents in *NPM1*-mutated AML.⁸⁴⁶ Bortezomib is also being combined with chemotherapy agents in AML patients.⁸⁴⁷ Other inhibitors more specific to the NF- κ B family have been proposed for study in AML.⁸⁴⁸

Other Signal Transduction and Tyrosine Kinase Inhibitors Numerous inhibitors of activated tyrosine kinases have been examined for AML therapy.^{849,850} These include mammalian target of rapamycin (mTOR) inhibitors,^{851,852} phosphoinositol 3'-kinase inhibitors,^{853,854} AKT inhibitors, such as perifosine,⁸⁵⁵ small-molecule mitogen-activated protein kinase (MEK) kinase inhibitors,⁸⁵⁶ Aurora kinase inhibitors,⁸⁵⁷ and heat-shock protein inhibitors.⁸⁵⁸ None of these agents have had an impact on AML survival as single agents, but using a combination of agents that target multiple pathways or using multitargeted tyrosine kinase inhibitors may hold promise for incremental improvements in AML therapy.⁸⁵⁹ There is some indication that extramedullary disease may increase in incidence in cases treated with signal transduction agents alone.⁸⁶⁰

Other Inhibitors of Signal Transduction and Apoptosis Pathways Many malignancies overexpress antiapoptotic proteins, such as BCL-2 and BCL-x_L.⁸⁶¹ Small-molecule BCL-2 homology domain-3 (BH3) mimetics such as ABT-737⁸⁶² and GX15-070 (obatoclax)⁸⁶³ inhibit BCL-2. CDDO-Me, a triterpenoid, studied *in vitro* induces apoptosis and differentiation in AML cells through activation of caspase-8 and caspase-3 and induction of mitochondrial cytochrome *c* release.⁸⁶⁴

Prenylation Inhibitors: Farnesyltransferase inhibitors (FTIs)^{865–868} and geranylgeranyltransferase-1 inhibitors (GTIs), such as statins, have been examined as therapy in AML. Examples of responses of AML to lovastatin have been reported.⁸⁶⁹ Simvastatin adds to the effect of cytarabine's inhibition of AML cell lines.⁸⁷⁰ Other studies suggest that the statins may mediate antileukemic effects independent of Ras/Rho prenylation through blockade of cholesterol responses to cellular injury.⁸⁷¹ Effectiveness of either FTIs or GTIs as single agents has been minimal in untreated AML patients.^{865–868}

Maturation Therapies Several analogues of vitamin D inhibit AML cells by inducing inhibition of cyclin-dependent kinases.⁸⁷² In general, AML cells have not responded to retinoids. Single-strand conformational polymorphism analysis and DNA sequencing of leukemic

cells from AML, other than APL, have not found mutations of *RAR- α* .⁸⁷³ Nevertheless, combinations of retinoids, growth factors, and chemotherapeutic agents are being examined for therapeutic potential in AML.⁸⁷⁴ Leukemias with 11q, -5, and -7 chromosome abnormalities have high telomerase activity, which can be inhibited by maturation-inducing agents.⁸⁷⁵ In one study, addition of ATRA to chemotherapy did not improve patient outcome but did result in a 25 percent increase in apoptosis in AML marrow cells *in vitro*.⁸⁷⁶ ATRA has induced a complete remission in a patient with acute myelomonocytic leukemia.^{877,878} Arsenic trioxide induces apoptosis and cytotoxic effects in blasts from patients with AML other than APL, and it is not influenced by permeability glycoprotein (P-gp) expression.^{879,880}

Antiangiogenesis Agents and Agents That Inhibit Microenvironmental Interactions

Targeting the increased vascular density of marrow noted in AML or cytokines secreted by marrow endothelium has been examined as means to inhibit AML cell growth. Amifostine,⁸⁸¹ thalidomide,⁸⁸⁰ sunitinib,⁸⁸¹ and other agents that target VEGF and interleukin (IL)-8,⁸⁸² as well as of the angiopoietin signaling pathway,⁸⁸³ are potential antiangiogenic agents in the treatment of AML. Lenalidomide, which also has antiangiogenic properties, is used to treat deletion 5q- AML.⁸⁸⁴ Antagonists of the chemokine receptor CXCR4, which plays a role in retention of hematopoietic cells in marrow and of integrins or selectins, have been proposed as therapeutic agents to overcome stromal-mediated resistance and to enhance chemotherapy-induced cell death.^{885,886}

Modulation of Drug Resistance

Numerous mechanisms of drug resistance occur in AML,⁸⁸⁷ and several attempts to overcome this resistance have been instituted, but none of the agents used, such as cyclosporine or PSC-833, have had a significant impact on AML outcomes to date. P-gp, MDR protein-1 (MRP-1), and breast cancer resistance protein (BCRP) expression all have been found in AML.⁸⁸⁸

Other Immunotherapy and Antisense DNA Approaches

Culture of AML blasts upregulates costimulatory molecules, and the role of dendritic cells in antileukemia therapy is being examined.⁸⁸⁹⁻⁸⁹¹ Other approaches to generating autologous T-cell antileukemic activity include vaccination with AML-specific peptides, immunization with AML blasts exhibiting dendritic cell phenotype and function,^{892,893} and pulsing normal dendritic cells with AML-specific peptide sequences.⁸⁹⁴ Natural killer cells may mediate antileukemia effects.⁸⁹⁵ Low doses of IL-2 have been used in the maintenance phase of AML, and some patients have remained on this regimen for 10 or more years without significant side effects.⁸⁹⁶ However, low-dose IL-2 does not improve outcomes when used as maintenance treatment in older AML patients.⁸⁹⁷ The WT gene *WT1* is expressed on AML blasts, and a *WT1* vaccine may elicit cytotoxic T-cell responses against this protein.⁸⁹⁸ Peptides derived from the mutated nucleophosmin I gene can elicit *in vitro* CD4 and CD8 T-cell responses.¹²⁹ Other proteins against which such humoral responses have been elicited include minor HLA antigens and proteinase-3.⁸⁹⁹ Coinhibitory molecule signaling can hamper benefit of immune therapies, so efforts to modulate coinhibitory networks are underway in leukemias.⁹⁰⁰ Small interfering RNA (siRNA) targeting of transcription factors⁹⁰¹ and GTI-2040, an antisense to ribonucleotide reductase, have been used in AML therapy.⁹⁰² In addition to CD33, CD45, CD66, and CD38 have been examined as targets for immunotherapy of AML.^{903,904} Immunotoxin conjugates are being examined in AML as well to increase potency of naked monoclonal antibodies.⁹⁰⁵ Alloreactive haploidentical KIR ligand-mismatched natural killer cells are also being examined in high-risk elderly AML cases.⁹⁰⁶

The immunomodulatory drug lenalidomide has also been examined in AML and has some activity in high doses in relapsed or refractory AML.^{907,908}

The IL-3 receptor α (CD123) is overexpressed in AML as compared with normal HSCs, so it has been proposed as a target for chimeric antigen receptors (CARs) as a bridge to allogeneic HSC transplantation.^{909,910}

SPECIAL THERAPEUTIC CONSIDERATIONS

Acute Promyelocytic Leukemia

General Consideration in Therapy Because of the early induction mortality in APL, patients who are suspected based on morphology and presence of coagulopathy should begin ATRA without waiting for definitive FISH or molecular confirmation. There is now an International Consortium on APL, the goal is to improve outcomes through education and guidelines formulation.⁹¹¹ While many trials with variations in the induction, consolidation, and maintenance phases are published, the clinician is urged to consider clinical trials and to follow one protocol plan through all the phases of therapy.

Induction Treatment ATRA has become a standard component of induction therapy for APL. Used alone, ATRA can induce a short-term remission in at least 80 percent of patients.⁹¹² However, ATRA should be combined with an anthracycline such as idarubicin or with arsenic trioxide during induction treatment for most benefit and to prevent drug resistance.⁹¹³ Idarubicin by itself can induce remission in approximately 75 percent of patients.⁹¹⁴ A typical induction regimen for APL is ATRA 45 mg/m² daily in divided doses with idarubicin at standard induction doses (e.g., 12 mg/m² on days 1 to 3).^{915,916} Although cytarabine has been largely abandoned as part of induction, some studies show a high degree of efficacy of high-dose cytarabine combined with ATRA.⁹¹⁷ There is evidence that in patients who present with a white cell count of $10 \times 10^9/L$ or greater, the complete remission rate and overall survival may be superior when cytarabine is added to induction or consolidation regimens, especially if arsenic trioxide is not part of the induction regimen.^{918,919} The addition of arsenic trioxide to ATRA and idarubicin in induction regimens results in approximately 95 percent complete remission rates. This approach allows reduction in anthracycline usage and excellent overall survival (93 percent).⁹²⁰ In low- to intermediate-risk APL (WBC $<10 \times 10^9/L$), the combination of ATRA and arsenic trioxide was found equal to, or possibly superior to, an ATRA plus chemotherapy regimen.^{921,922} Also, there was less hematologic toxicity and fewer infections with that combination of drugs. Older patients generally tolerate a combination of ATRA and an anthracycline.⁹²³ Combinations that include gemtuzumab ozogamicin are being examined for their effectiveness in APL induction therapy, but this antibody is no longer marketed in the United States.⁹²⁴ The combination of ATRA and arsenic trioxide results in more rapid remissions and lower PML-*RAR- α* transcript levels than either agent alone.⁹²⁵ Despite the high remission rates and frequency of long-term event-free survival achieved in this disease, controversies remain regarding therapy because of the 5 to 10 percent of patients who die as a result of fatal intracranial hemorrhage.⁹²⁶ This relatively high early death rate (17.3 percent) persisted despite use of ATRA in induction therapy.⁹²⁷ Thus, there are several induction regimens that can be chosen to treat APL based on WBC at diagnosis and, to a lesser extent, patient age and ability to tolerate anthracyclines. For those with low-risk disease, a combination of ATRA plus arsenic trioxide, ATRA plus idarubicin alone, or ATRA plus daunorubicin plus cytarabine can be used. In high-risk patients, ATRA plus daunorubicin and cytarabine, ATRA plus idarubicin, or ATRA and arsenic trioxide with idarubicin (dose-adjusted based on age) can be used.⁹²⁸ Table 88-8 lists APL induction regimens.

All-Trans Retinoic Acid: Dose and Mechanism of Action ATRA, an analogue of vitamin A, has been used to initiate the therapy of APL

TABLE 88-8. Examples of Treatment Protocols for Acute Promyelocytic Leukemia

Induction	Consolidation	Reference
HIGH-RISK PATIENT		
ATRA 45 mg/m ² PO in divided doses Daunorubicin 60 mg/m ² IV for 3 days Cytarabine 200 mg/m ² IV for 7 days	1st Cycle: Daunorubicin 60 mg/m ² IV for 3 days; Cytarabine 200 mg/m ² IV for 7 days 2nd Cycle: Cytarabine 2 g/m ² (or 1.5 g/m ² in older patients) IV, every 12 hours for 5 days plus daunorubicin 45 mg/m ² IV for 3 days	922
ATRA 45 mg/m ² PO (days 1–36 in divided doses) Idarubicin (6–12 mg/m ² based on age) IV on days 2, 4, 6, and 8 Arsenic trioxide 0.15 mg/kg IV (days 9–26)	1st Cycle: ATRA 45 mg/m ² PO in divided doses for 28 days; arsenic trioxide 0.15 mg/kg IV per day for 28 days 2nd Cycle: ATRA 45 mg/m ² PO for 7 days every 2 weeks × 3. Arsenic trioxide 0.15 mg/kg per day × 5 days IV for 5 weeks	928
LOW-RISK PATIENT		
ATRA 45 mg/m ² PO in divided doses daily until remission; arsenic trioxide 0.15 mg/kg IV daily until remission	Arsenic trioxide 0.15 mg/kg IV per day, 5 days per week for 4 weeks every 8 weeks for 4 cycles ATRA 45 mg/m ² PO per day for 2 weeks every 4 weeks for 7 cycles	921
ATRA 45 mg/m ² PO in divided doses until clinical remission; Idarubicin 12 mg/m ² IV on days 2, 4, 6, and 8	1st Cycle: ATRA 45 mg/m ² PO for 15 days; idarubicin 5 mg/m ² IV for 4 days 2nd Cycle: ATRA 45 mg/m ² PO for 15 days; mitoxantrone 10 mg/m ² IV for 5 days 3rd Cycle: ATRA 45 mg/m ² PO for 15 days; idarubicin 12 mg/m ² IV for 1 dose	919

NOTE: The reader is advised to consult the original reference for details of the administration of the chemotherapy regimens. "High risk" is defined as a white cell count at diagnosis $\geq 10 \times 10^9/L$. "Low risk" is defined as a white cell count at diagnosis $< 10 \times 10^9/L$.

since 1987 in the United States. ATRA induces complete remissions in approximately 80 percent of previously untreated patients.⁹²⁹ *In vitro*, ATRA is 10 times more potent in inducing maturation of leukemic promyelocytes to neutrophils than 13-*cis* retinoic acid, the other naturally occurring isomer.⁹³⁰ ATRA induces maturation of the leukemic cells and their apoptosis results in the reappearance of normal polyclonal hematopoiesis and a remission in most cases.⁹³¹ ATRA may induce synthesis of a protein that selectively degrades PML-RAR- α . ATRA can overcome the recruitment of histone deacetylase activity by the PML-RAR- α fusion gene through interference with a nuclear corepressor.⁹³² STAT1 is induced and activated by ATRA. Promyelocytic leukemia cells with PML-RAR- α break-fusion sites in PML exon 6 have decreased *in*

vitro responsiveness to ATRA.⁹³³ The t(11;17) variant of APL, in which the promyelocytic leukemia zinc finger (PLZF) gene is fused to RAR- α , does not respond to ATRA.⁹³⁴ Other nonpromyelocytic leukemia subtypes of AML have not responded to ATRA therapy. ATRA is beneficial in APL during the induction and maintenance phases of disease,⁹³⁵ and improved outcome with ATRA is reflected in the 5-year survival rates of 75 to 80 percent.⁹³⁶ Additional cytogenetic changes do not influence treatment outcomes with ATRA plus an anthracycline.⁹³⁷ ATRA induction therapy can result in favorable results without blood product support.⁹³⁸

Toxic Effects of All-Trans Retinoic Acid ATRA therapy is associated with dryness of the skin and lips, occasionally leading to mild exfoliation, nausea, headache, arthralgia, and bone pain. The white cell count may rise dramatically in the first week or two of therapy. Serum glutamic-pyruvate transaminase and triglyceride concentrations often increase. Leukemic promyelocytes disappear from the blood in 2 to 4 weeks, and a normal marrow aspirate may be obtained in 4 to 10 weeks. Anemia improves gradually. The majority of patients become PML-RAR- α -negative by PCR after the second consolidation therapy in conjunction with ATRA.⁹³⁹ ATRA has been used successfully to treat APL diagnosed during pregnancy.⁹⁴⁰ ATRA has been used from week 3 of gestation, but may result in fetal malformations when it is used during the first trimester.⁹⁴¹

Differentiation Syndrome A rapid increase in the total blood leukocyte count to as high as $80 \times 10^9/L$ in the first several weeks of therapy, referred to as the *differentiation syndrome* (previously called the *retinoic acid syndrome*), is a potential cause of early death during therapy.⁹⁴²⁻⁹⁴⁴ The median time of onset is 11 days, but the syndrome has occurred up to 47 days after therapy starts.⁹⁴⁴ Two approaches to treatment of this phenomenon have been suggested: early use of cytotoxic chemotherapy^{945,946} and glucocorticoid administration.^{947,948} The syndrome consists of fever, weight gain, dependent edema, pleural or pericardial effusion, and bouts of hypotension. Respiratory distress is the key feature. In fatal cases, pulmonary interstitial infiltration with maturing granulocytes is prominent. Once respiratory distress is evident, the patient should receive dexamethasone 10 mg IV every 12 hours for several days. Because the syndrome may occur at relatively low total white cell counts and its onset is unpredictable, high-dose glucocorticoid therapy should be instituted if respiratory symptoms develop even in the absence of pulmonary infiltrates or an elevated white cell count.^{942,946} ATRA can be continued or resumed with glucocorticoids or with concurrent cytotoxic chemotherapy, but the syndrome may recur.⁹⁴² This syndrome is not observed during maintenance therapy. It may also occur with arsenic trioxide therapy, and some recommend prophylactic glucocorticoids in those with a WBC greater than $10 \times 10^9/L$ or in those receiving both ATRA and arsenic trioxide.⁹⁴³

Treatment of Coagulopathy Reducing the risk of early death from hemorrhage as a result of the coagulopathy accompanying APL requires use of fresh-frozen plasma, platelet replacement, and fibrinogen replacement.^{489,490,949} Targeted levels for platelet counts are usually 30 to $50 \times 10^9/L$ ⁹²⁸ and for fibrinogen levels 1.5 g/L or higher, but these levels are often difficult to achieve in patients with active hemorrhage.⁹⁵⁰ Heparin treatment was used during induction chemotherapy in the past to prevent onset of disseminated intravascular coagulopathy during treatment, but rarely is used now.⁹⁵¹ ATRA may have some corrective effect on coagulation disorders in APL.⁹⁵² However, a reduction of 5 to 10 percent of fatal hemorrhages has not been significant with ATRA used early during treatment. Paradoxically, hypercoagulable clotting tendency may occur in patients during the first months of ATRA therapy.⁹³¹ In the coagulopathy of APL, the blasts overexpress annexin II, and there is evidence that the effects of annexin II can be reversed by L-methionine administration.⁹⁵³

Chemotherapy Induction of remission with ATRA alone is followed by relapse in weeks to months unless intensive chemotherapy is used concomitantly.⁹⁵⁴ At relapse, cells show high levels of a cytosolic retinoic-acid-binding protein not detected prior to ATRA therapy.⁹³² The mechanism of retinoid resistance in leukemic cells may involve cytochrome P450 and P-gp because of induction of various enzymes that may alter ATRA metabolism.⁹⁵⁵ ATRA, whether administered as part of induction therapy or as maintenance therapy, confers a disease-free survival advantage. More than 70 percent of patients receiving ATRA at any point were in continuous remission at 2.5 years versus less than 20 percent of patients who never received ATRA.⁹⁵⁶ The acquired *in vivo* resistance that occurs rapidly to ATRA as a single agent requires consolidation of ATRA-induced complete remission with intensive chemotherapy using an anthracycline antibiotic. Customary treatment today involves simultaneous administration of ATRA and an anthracycline and/or arsenic trioxide. Some therapists have returned to combining an anthracycline antibiotic with cytarabine in an effort to decrease CNS relapse, especially in patients younger than 60 years of age with white counts greater than $10 \times 10^9/L$ at presentation.⁹⁵⁶ Maintenance therapy with ATRA alone or in combination with mercaptopurine or methotrexate has been recommended. This additional therapy has not been examined in a randomized trial of ATRA dosing and scheduling, but ATRA usually is given in an interrupted fashion. Intensified maintenance therapy may have a negative impact on those patients who have become negative for the PML-RAR- α fusion transcript after induction plus consolidation therapy.⁹⁵⁷ Some therapists have proposed that elderly patients can be treated with ATRA and arsenic trioxide without chemotherapy and with addition of gemtuzumab ozogamicin in the event of an elevated white count at the time of diagnosis.⁹⁵⁸

Arsenic Trioxide Arsenic trioxide can trigger apoptosis of APL cells at high concentrations and maturation at low concentrations. The presence of PML-RAR- α is important for the response. Apoptosis may occur through induction of activation of caspase-1 and caspase-3 after changes in the mitochondrial membrane potential with increase in H_2O_2 .^{959,960} It also may function through NF- κ B inhibition.⁹⁶¹ Death-associated protein 5 also contributes to arsenic trioxide-induced apoptosis in APL.⁹⁶² Arsenic trioxide given at 0.06 to 0.12 mg/kg body weight per day until leukemic cells were eliminated from the marrow induced remission within 12 to 89 days in 11 of 12 patients.⁹⁶³ Suppression of hematopoiesis did not occur. Rash, light-headedness, fatigue, and musculoskeletal pain were the main side effects. Arsenic trioxide can be combined with idarubicin in relapsed patients; it also has been used with ATRA.^{921,964,965} A retinoic acid-like syndrome (see “All-Trans-Retinoic Acid: Dose and Mechanism of Action” above) has been described in patients with APL treated with arsenic trioxide.⁹⁶⁶ Torsade de pointes, an uncommon variant of ventricular tachycardia in which the underlying etiology and management are different from those of the usual variety of ventricular tachycardia, has been described with arsenic trioxide use,⁹⁶⁷ and monitoring of electrocardiographic QTc intervals and electrolyte levels during therapy is recommended.⁹⁶⁸

Consolidation Therapy Consolidation therapy is required in APL to achieve a durable molecular remission. Consolidation typically consists of anthracycline plus ATRA, but in high-risk patients, the addition of cytarabine or use of arsenic trioxide can be used to diminish the rate of relapse. Almost every induction regimen described in APL has a distinct consolidation regimen attached to it, dependent on disease stratification. To achieve uniformly good responses, it is recommended that one follow a given protocol's induction, consolidation, and maintenance regimen. Table 88-8 provides examples of paired induction and consolidation regimens. Excellent results can be achieved with all of these regimens, if treatment plans are executed faithfully.

Maintenance Therapy After consolidation phases of therapy are complete, patients should be in a molecular remission, that is, PCR-negative for PML-RAR- α . ATRA maintenance with chemotherapy is recommended based on the APL 93 trial, which showed that relapse-free survival was superior with ATRA versus no ATRA, and that the best results were achieved when ATRA was combined with 6-mercaptopurine and methotrexate.⁹⁶⁹ The 10-year cumulative relapse rates were 43 percent with no maintenance, 33 percent with ATRA alone, 23 percent with chemotherapy alone, and 13 percent with ATRA and chemotherapy.⁹⁷⁰ Maintenance is usually recommended for 2 years, and studies to examine whether maintenance is beneficial in low-risk disease are ongoing.⁹²⁸ During maintenance, PCR monitoring on blood samples is recommended.⁹²⁸ If the PCR is positive in blood, a marrow examination should be done.

Treatment for Relapsed Acute Promyelocytic Leukemia Conventional chemotherapy can be effective after relapse. Arsenic trioxide has been used in those who do not achieve molecular remission at completion of consolidation or who subsequently demonstrate molecular relapse and can generate high molecular remission rates in more than 80 percent of patients alone or when combined with chemotherapy.⁹⁷¹ It is still uncertain whether ATRA has benefit in patients previously exposed to ATRA. Patients younger than age 70 years should be considered for allogeneic or autologous HSC transplantation after they have achieved a second remission or for allogeneic transplantation if a second remission cannot be induced.⁹⁷² Other treatments for patients in relapse include the combination of ATRA, arsenic trioxide, and gemtuzumab ozogamicin. This combination has resulted in durable remissions.⁹⁷³ Transplantation generally is not recommended for patients with APL in first remission given the prolonged remissions after standard treatments. Allogeneic stem cell transplant is best used in advanced APL, especially in patients with persistent disease by PCR.⁹⁷⁴ The outcome of autologous stem cell transplantation in second complete remission is excellent if the stem cells used are negative for PML-RAR- α .⁹⁴¹ High-dose cytarabine can be used for stem cell mobilization which will also treat CNS relapse, and when a second molecular remission is followed by an autograft, the 5-year disease-free survival is approximately 75 percent. This result is superior to survival after allografting, but a direct comparison of autologous transplantation, allogeneic transplantation, and arsenic trioxide or ATRA with standard chemotherapy has not been made in patients with APL in a second remission after relapse.⁹⁷⁵ For patients in a second remission who are not candidates for allogeneic stem cell transplant, up to six cycles of arsenic can be used.

Many cases of extramedullary relapse in APL have been reported.⁹⁷⁶ Many of the relapses occur in patients who received ATRA and who initially were diagnosed with hyperleukocytosis,⁹⁷⁷ and many of the patients are in marrow remission. Relapses occurring more than 5 years after diagnosis have been reported, some at extramedullary sites such as in the mastoid bone.⁹⁷⁸ Early detection of relapse is important as those with molecular relapse before hematologic relapse has occurred fare best.⁹⁷⁹ Patients should be monitored with PCR every 3 months for 2 years after remission induction, especially those with intermediate- or high-risk disease.⁹²⁸

MDS can occur in patients in remission with APL, usually 24 months or more after diagnosis. The complication results from a second (drug-induced) clonal disease in long-term responders.⁹⁸⁰⁻⁹⁹² Cases of therapy-related APL have been described.⁹⁸³ Patients with APL who are FLT3-ITD-positive generally have worse overall outcomes than do those persons who present with elevated white cell counts and older age.⁹⁸⁴ There is also evidence that mutations in the ATRA-targeted ligand binding domain of PML-RAR- α and additional chromosome abnormalities may be associated with reduced postrelapse survival in those on

ATRA.⁹⁸⁵ Oral arsenic trioxide and tamibarotene, a synthetic retinoid, are being examined in relapsed APL.^{986,987} Children older than 4 years and adolescents have outcomes with ATRA-treated APL equivalent to that of adults, but younger children have more frequent relapses.⁹⁸⁸

SECONDARY ACUTE MYELOGENOUS LEUKEMIA

Secondary leukemias arise after treatment of another malignancy or an autoimmune disease with cytotoxic chemotherapy or radiation. Secondary AML responds more poorly to chemotherapy and allogeneic stem cell transplantation than does *de novo* AML. Secondary AML accounts for approximately 5 to 10 percent of all AML cases, although this percentage is increasing.^{980,990} The leukemogenic risk of treatment regimens depends on the agents used. Future development of agents with lower risk of inducing AML is an important goal.⁹⁹¹

Effect of Topoisomerase II Inhibitors

Exposure to topoisomerase II inhibitors (e.g., etoposide, mitoxantrone, amsacrine) can lead to AML with *MLL* gene rearrangements on chromosome 11q32.⁹⁹² Inversion 16 is an uncommon aberration in secondary AML and, like balanced translocations of chromosome bands 11q32, 21q22, and t(15;17), is associated with prior chemotherapy with topoisomerase II inhibitors when seen in the setting of treatment-induced leukemias. The site of breakpoints within the *MYH11* gene involved in inversion 16 may vary between therapy-induced AML and AML occurring *de novo*.⁹⁹³ The latency period for development of AML after topoisomerase II inhibitors is approximately 2 years. No relationship with higher cumulative dose has been identified. Studies of single nucleotide polymorphisms to ascertain genetic predisposition are ongoing.⁹⁹⁴ Polymorphisms in detoxification genes and in genes involved in DNA repair pathways might be involved.⁹⁹⁵ Even the use of low-dose or oral etoposide can be associated with development of secondary AML.

Effect of Alkylating Agents and Cisplatin

Alkylating agents cause secondary AML, often preceded by myelodysplasia. The mean latency period after onset of treatment is approximately 6 years. Deletions of all or part of chromosome 5 or 7 are the most common cytogenetic changes. The risk is related to cumulative alkylating agent dose. Germline aberrancies of *NFI* and *p53* may increase the risk of AML. Cisplatin used for treatment of ovarian cancer also increases the risk of secondary leukemia.⁹⁹⁶

Other Cytotoxic Agents

Other drugs that may increase the risk of secondary leukemias include low-dose weekly methotrexate for rheumatoid arthritis,⁹⁹⁷ etanercept therapy,⁹⁹⁸ temozolamide,⁹⁹⁹ growth hormone administration,¹⁰⁰⁰ and G-CSF given to patients with congenital, but not idiopathic or cyclic neutropenia.¹⁰⁰¹ In the latter cases, a cause-and-effect relationship between MDS/AML and G-CSF therapy has not been established. Improved survival duration with G-CSF may allow expression of an underlying leukemic predisposition.

Other Settings for Secondary Leukemia

Patients with APL in remission may develop a new MDS (oligoblastic leukemia), presumably secondary to therapy.¹⁰⁰² Series of children with treatment-related myelodysplasia or AML have the same latency period as do adults treated with alkylating agents or topoisomerase II inhibitors for AML.¹⁰⁰³ Breast cancer patients receiving doxorubicin and cyclophosphamide regimens of such intensity that they required G-CSF support had increased rates of posttherapy AML. Breast and prostate radiotherapy

are associated with an increased risk of AML.^{1004,1005} In patients with non-Hodgkin lymphoma, up to 10 percent of patients treated with either conventional chemotherapy or high-dose therapy developed secondary AML within 10 years.¹⁰⁰⁶ Secondary leukemia is seen after autologous marrow or blood stem cell transplants involving high-dose chemotherapy and/or radiotherapy. In a study of 83 patients after autografting, 12 had nonclonal cytogenetic abnormalities and 10 had clonal abnormalities, five of whom developed secondary AML. Onset occurred 12 to 48 months after autografting. The relative contribution of the underlying disease and the conditioning therapy is uncertain.¹⁰⁰⁷ Clonality analysis using an X chromosome gene, based on methylation of the human androgen receptor locus in cell samples in patients with lymphoma, found a clonal marrow cell population 6 months after autologous transplantation at a time when no morphologic or clinical evidence of AML was present. AML appeared later in some patients.¹⁰⁰⁸ More than 10 percent of patients with non-Hodgkin lymphoma who underwent stem cell rescue after total body irradiation and cyclophosphamide developed AML at a median followup of 6 years.¹⁰⁰⁹ Using a triple FISH assay to detect loss of chromosomal material from 5q31, 7q22, or 13q14, abnormal cells were detected before high-dose therapy was given to non-Hodgkin lymphoma patients.¹⁰¹⁰ Thus, some patients are at increased risk for developing secondary AML based on pretreatment chromosome studies.

Treatment of Secondary Leukemia

Secondary leukemia generally is treated similarly to *de novo* leukemia. However, given the lower response rates and remission durations of secondary leukemia, patients can be treated in clinical trials examining new therapies or treated initially with chemotherapy regimens used for refractory disease.¹⁰¹¹ Some patients may benefit from early allogeneic HSC transplantation.¹⁰¹² Autologous transplant can be successful if stem cells are harvested prior to the development of secondary AML.¹⁰¹³ In those who have low blood blast counts, allogeneic stem cell transplantation as initial therapy may be superior to induction chemotherapy followed by transplantation, but this remains an area of controversy.¹⁰¹⁴ Although patients may have a response rate of approximately 50 percent to standard induction chemotherapy, most soon relapse, and long-term survival is approximately 10 percent.¹⁰¹⁵ Secondary AML more often has unfavorable cytogenetic features compared to *de novo* leukemia.¹⁰¹⁶

TREATMENT OF Ph CHROMOSOME-POSITIVE AML

This cytogenetic variant of acute leukemia is characterized by extraordinary drug resistance. Imatinib mesylate in doses of 600 to 800 mg/day may produce a hematologic remission in a small proportion of patients with Ph chromosome-positive AML, based on the response in patients with CML who go on to a myeloid blast crisis. No formal studies of the response to imatinib mesylate of *de novo* Ph chromosome-positive AML have been performed. In myeloid blast crisis of CML, the uncommon full hematologic response (blood and marrow) usually is short lived, measured in weeks or a few months. This outcome also seems to be the case when therapy with other drugs (e.g., cytarabine, etoposide, anthracycline antibiotics) is included. Occasional cases in which chemotherapy has induced remission in Ph chromosome-positive AML and imatinib mesylate has appeared to help induce and sustain the remission have been reported.¹⁰¹⁷ Thus, in Ph chromosome-positive AML, a matched-related or matched-unrelated donor stem cell transplant should be considered if the patient is younger than age 50 years. This approach may have the highest probability of a long-term remission. There is little information about the use of second generation *BCR-ABL* inhibitors in this setting.

TREATMENT OF OLDER PATIENTS

Biologic Features

Approximately 65 percent of patients with AML are older than age 60 years at the time of diagnosis.¹⁰¹⁸ The disease in this age group is less responsive to therapy, and this age group has a higher proportion of patients who have oligoblastic myelogenous leukemia (MDS); an antecedent clonal myeloid disease; prior chemotherapy for cancer of another site; and comorbid conditions that decrease the tolerance to intensive chemotherapy programs.^{1019–1022} The AML cells of elderly patients often have more CD34 expression, suggesting origin from a more primitive multipotential (? stem) cell. This finding is thought to contribute to longer duration of postchemotherapy aplasia and to the increased risk of induction deaths in this age group.¹⁰²³ Patients older than age 60 years also have a high frequency of unfavorable cytogenetic findings (32 percent) and higher *MDR1* expression (71 percent) and functional drug efflux (58 percent).^{1024,1025}

Chemotherapy

The therapist and patient determine whether a standard regimen, a standard regimen with dose reductions, or a special regimen is used.^{1026,1027} Decisions based on chronologic age should be supplanted by measurements of cognitive, neurologic, and physical fitness used by geriatricians to evaluate the wisdom of considering intensive treatment.¹⁰²⁸ These are often not well-validated in geriatric AML populations, but there is evidence that assessments focused on cognition and objective measures of physical function may predict for overall survival in those older than age 60 years who undergo standard induction chemotherapy.¹⁰²⁹ In patients older than age 60 years who are fit and otherwise are considered good candidates, standard two-drug therapy can be used: cytarabine and an anthracycline antibiotic, and on some occasions the addition of a third drug, etoposide. Remission rates of approximately 35 to 45 percent can be achieved. Based on case studies, those who are able to receive induction chemotherapy may have a median survival slightly better than those who receive supportive care alone,^{1030,1031} but there are no randomized trials that address this issue.¹⁰³² Patients older than 70 years (median: 74; range: 70 to 88) may not have much benefit from intensive chemotherapy with an 8-week mortality of greater than 30 percent and a median survival of less than 6 months.¹⁰³³ Some investigators have proposed waiting for cytogenetic information before therapy decisions are made in older patients. Those with unfavorable cytogenetics and two or more other criteria including age older than 75 years, poor performance status, and WBC greater than $50 \times 10^9/L$ were found not to benefit from chemotherapy.¹⁰³⁴ Chemotherapy has been combined with growth factor support to accelerate neutrophil recovery in older patients.¹⁰³⁵ In a study in which patients older than age 55 years were randomized to receive either placebo or G-CSF after induction therapy, no reduction in the duration of hospitalization, survival prolongation, or cost of supportive care was noted.¹⁰³⁶ In previously untreated elderly patients with AML, mitoxantrone induction therapy produces a slightly higher remission rate than did daunorubicin, but had no significant effect on remission duration and survival.¹⁰³⁷ Oral idarubicin alone has been used with success.¹⁰³⁸

Attenuated standard regimens can be used in older patients. An example of an attenuated regimen is cytarabine 100 mg/m² subcutaneously every 12 hours for 10 doses on days 1 through 5 and daunorubicin 30 mg/m² IV on days 1 through 3 of treatment. One induction regimen is not superior to another in older patients. Outcomes achieved with cytarabine and daunorubicin are comparable to results with mitoxantrone and etoposide.¹⁰³⁹ Other regimens for older patients include lower total doses of idarubicin, etoposide, and cytarabine (DIVA regimen)¹⁰⁴⁰ and a combination of continuous infusion low-dose

cytarabine with etoposide and G-CSF.¹⁰⁴¹ Temozolomide has been used in this age group,¹⁰⁴² and clofarabine is also being tested in patients age 60 years and older.¹⁰⁴³ In one study of clofarabine in older patients who were deemed unfit for 7-plus-3 chemotherapy, a 5-day clofarabine regimen resulted in a 48 percent response rate, and 18 percent died within 30 days.¹⁰⁴⁴ Another study in those older than 60 years showed a response rate of 46 percent and an overall median survival of 41 weeks and a 30-day all-cause mortality of approximately 10 percent.¹⁰⁴⁵ Several investigational therapies, including 5-azacytidine, decitabine, cloretazine, and depsiptide, are also being studied. There are also several reports concerning addition of other agents to standard chemotherapy to improve responses. These include bevacizumab,¹⁰⁴⁶ sorafenib,¹⁰⁴⁷ and gemtuzumab ozogamicin.^{1048,1049} Thus far, none of these drugs have resulted in improvement in overall survival.

Autologous Stem Cell Infusion or Nonmyeloablative Allogeneic Transplantation

Autologous stem cell transplantation has been used in fit patients older than age 60 years.¹⁰⁵⁰ The incidence of relapse is lower when marrow stem cells are used compared to blood stem cells. Some patients older than age 60 years may be eligible for reduced-intensity allogeneic stem cell transplantation from related or unrelated donors, but more data regarding outcomes are needed.¹⁰⁵¹ In a large registry study, examining reduced-intensity allogeneic HSC transplantation for older patients with AML and MDS in first remission, older age was not found to affect 2-year nonrelapse mortality, disease-free or overall survival.¹⁰⁵²

Postremission Therapy in Older Patients

No consensus exists regarding the best regimen or the number of treatment cycles for postremission therapy in older adults. Regardless of the consolidation regimen, the duration of the leukemia-free survival is longer with high-dose cytarabine and autologous stem cell transplantation, just as it is in younger patients,¹⁰⁴² but fewer older patients can tolerate this degree of therapeutic intensity. Higher-dose cytarabine can be used in older adults with AML, but usually at a reduced dose.¹⁰⁵³ Older patients treated with attenuated high-dose cytarabine at 750 mg/m² intravenously for 12 doses and then consolidated with four to six doses had an approximately 50 percent remission rate with a median duration of remission of 326 days.¹⁰⁵⁴ Fifty-one percent of 110 patients older than 60 years of age had a 9-month median remission duration when consolidated with high-dose cytarabine.¹⁰⁵⁵ Older patients are at higher risk for relapse despite successfully completing intensive consolidation therapy, regardless of whether other adverse prognostic features are present. Cytarabine as maintenance therapy may prolong disease-free survival but does not improve overall survival.¹⁰⁵⁶ Decitabine and 5-azacytidine are also being examined for maintenance therapy. In one randomized study, those receiving consolidation therapies had more hospitalizations and more transfusion requirements.¹⁰⁵⁷

Patients older than 80 years of age do not tolerate treatments well. Remission rates are approximately 30 percent, but the median survival of treated patients is approximately 1 month. Less than 10 percent of patients survive for 1 year.¹⁰⁵⁸

Unlike the case in younger patients, the treatment outcomes for older patients have not improved over the last two decades.¹⁰⁵⁹ Treatment options in older patients include (1) no treatment, (2) supportive care, (3) palliative low-dose chemotherapy, (4) attenuated induction chemotherapy, or (5) high-dose chemotherapy regimens. Investigative agents should also be given strong consideration in this population.¹⁰⁶⁰ Comorbidities are independent predictors of complete remission and should be taken into account during decision making,¹⁰⁶¹ as should performance status.¹⁰⁶² Some argue that the approximately 15 percent rate of death in those older than 60 years of age in the first month after

standard induction chemotherapy is unacceptable given the less than 1 year median survival expected.¹⁰⁶³ Lower-dose regimens can also be toxic and can lead to severe cytopenias. Use of colony-stimulating factor permits older patients to tolerate full-dose induction therapy. The Medical Research Council of the United Kingdom observed remission rates of 80 percent in children, 70 percent in adults younger than 50 years of age, 68 percent in adults 50 to 59 years old, 53 percent in adults 60 to 69 years old, 39 percent in adults 70 to 75 years old, and 22 percent in adults older than 75 years of age.¹⁰⁶⁴ In one study of patients older than 60 years of age, the 2-, 5-, and 10-year survivals were 22, 11, and 8 percent, respectively.^{1065,1066} The older patients who remain free of leukemia beyond 1 year have a reasonable quality of life.^{1067,1068} The National Cancer Institute 5-year relative survival rates for patients with AML are 11 percent for adults ages 65 to 74 years and 1.8 percent for adults ages 75 years and older.¹⁰⁶⁹

Even though t(8;21) and inversion 16 are rare in older AML patients, remission rates are high with these favorable prognostic chromosome changes, so induction chemotherapy is often recommended, although rates of relapse remain high.¹⁰⁷⁰ In parallel, elderly patients with unfavorable cytogenetics have a dismal prognosis, and those who have a monosomal karyotype have low complete remission and overall survival rates; 37 versus 64 percent and 8 versus 28 percent, respectively, in those with and without monosomal karyotype.¹⁰⁷¹

TREATMENT OF PREGNANT PATIENTS

Leukemia (AML, ALL, CML) is the second most common malignancy of women in the childbearing age group and is expected to occur in approximately 1 in 75,000 to 100,000 pregnancies.^{1072,1073} No systematic studies of the (1) effects of leukemia on pregnancy or delivery, (2) effects of the leukemia or its treatment on the fetus, or (3) postnatal development of the offspring exposed to maternal chemotherapy *in utero* have been performed. A recent literature review led to the conclusion that treatment during the second and third trimesters resulted in fewer complications to the fetus, but delaying treatment adversely affected the outcome of mothers. Remission rates were comparable to that of non-pregnant patients.¹⁰⁷⁴ Folic acid inhibitors, purine, pyrimidine, or retinoid analogues given during the first trimester of pregnancy increase the probability of major congenital malformations. In a French study of 37 patients with acute leukemia during pregnancy, 34 patients achieved remission, and disease-free survival appeared equivalent to that of patients who were not treated during pregnancy.¹⁰⁷⁵ In another study from Saudi Arabia, of 21 pregnant patients with acute leukemia, 10 were given chemotherapy with seven livebirths and three spontaneous abortions without any teratogenic or congenital malformations. In the 11 not given chemotherapy until after 34 weeks of gestation, three had normal births and eight had an abortion before starting chemotherapy.¹⁰⁷⁶

If the pregnancy is not terminated, leukapheresis might be useful in the first trimester, when chemotherapy poses a high risk to the embryo. Intensive chemotherapy given to women in the second and third trimesters of pregnancy does not present an inordinate risk to fetal or neonatal development,^{1077,1078} although an increased frequency of premature delivery, higher perinatal mortality, and lower birthweight for gestational age are observed, especially if the fetus is exposed to chemotherapy.

Cytarabine is highly teratogenic in animal models and malformations have been described in women who were treated in the first trimester of pregnancy. Doxorubicin is the preferred anthracycline antibiotic to treat pregnant women as it has lower transplacental transfer. Doxorubicin is considered relatively safe when used in pregnant women.¹⁰⁷⁹ Newborn infants may be transiently cytopenic if the mother receives chemotherapy near the time of delivery. Development of the

newborn usually is normal after intensive chemotherapy for AML during pregnancy, if therapy is started after the first trimester.^{1072,1077,1078} Vaginal delivery should be used whenever possible. Pregnant women with AML who enter remission have little difficulty with childbirth or postparturition. The remission rates of AML are approximately the rates expected for the age group, and long-term remissions can occur with current therapy. Leukemic infiltrates can be found on the maternal side of the placenta, but usually not in the villi. One case of maternal-to-fetal transmission of AML has been documented.¹⁰⁸⁰ Transmission of AML from one identical twin to another through a shared placental circulation accounts for the dual occurrence in twins in the first several years of life.¹⁷⁷ There are reports of the use of ATRA for APL treatment during pregnancy, but use during the first trimester is discouraged, and data are sparse.^{941,1081,1082}

TREATMENT OF CHILDREN

AML represents approximately 15 percent of the acute leukemias in children (younger than 20 years of age) in the United States. APL is treated as in adults, with ATRA and an anthracycline antibiotic. In other phenotypes of AML, intensive treatment—including initial therapy with cytarabine and daunomycin or doxorubicin and a third drug such as mitoxantrone or 6-thioguanine, followed by intensive multidrug consolidation therapy including additional agents such as etoposide, and intrathecal cytarabine—has resulted in remission in approximately 80 percent of children and 5-year relapse-free remissions in approximately 50 percent of treated children.^{1083–1086} Most of the children in long-term remission are considered cured.

Monocytic leukemia and hyperleukocytic ($>100 \times 10^9/L$) myelogenous leukemia are unfavorable phenotypes. In children, *FLT3-ITD* mutations are approximately half as common (15 percent) as in adults (30 percent), but are a very poor prognostic indicator.¹⁰⁸⁷ Therapy can be adjusted for children based on the presence of poor prognostic variables, which include age younger than 2 years or older than 10 years; abnormalities of chromosome 3, 5, or 7, complex karyotypes, *FLT3* mutations, elevated white cell count of $50 \times 10^9/L$ or greater, male gender; and, perhaps, most importantly, because it reflects the effect of all factors, the presence of greater than 15 percent blast cells in the marrow examined 14 days after onset of treatment.^{1088,1089} The presence of residual blast cells detected by flow cytometry after induction therapy is a very poor prognostic finding.¹⁰⁹⁰ The duration of first remission predicts the subsequent remission rate and long-term survival in children with relapse.

Translocations 8;21, 15;17, or inv16 are good prognostic markers. Loss of a sex chromosome in the t(8;21) group is especially favorable. Monosomy 7 and abnormalities of chromosomes 3 or 5 are poor prognostic features.¹⁰⁹¹ Pediatric AML with t(8;16)(p11;p13) has been found to be a distinct clinical entity, and in a subset of neonatal cases, spontaneous remissions can occur.¹⁰⁹² In childhood 11p23/*MLL* AML, there are large differences in outcome based on translocation partners that are independent prognostic markers as assessed in a large international study.¹⁰⁹³ When gene mutations were examined in childhood leukemia, *FLT3-ITD* was most frequent, and 29 percent had more than one gene mutation. Mutated epigenetic regulators were less than in adults, but were often seen with other mutations.¹⁰⁹⁴

In the United Kingdom Medical Research Council Trial 12, completed in 2002, using daunorubicin, mitoxantrone cytarabine, etoposide, and asparaginase in different combinations, approximately 90 percent of children with AML had a remission, 60 percent of children had a 5-year disease-free survival, and most were considered cured.¹⁰⁹¹ Approximately 4 percent of children are drug resistant with this program and approximately 4 percent die during induction and

intensification therapy. Studies are under way to examine the effects of using fludarabine in the regimen (Medical Research Council 15 Trial).

Autologous stem cell transplantation has not improved outcome compared to current intensive chemotherapy treatment regimens.¹⁰⁹⁵ Allogeneic stem cell transplantation from a histocompatible sibling should be considered in children in first remission with a donor and poor prognostic indicators or in children who relapse.¹⁰⁹⁵ Trials have shown good results of allogeneic transplantation in first remission; event-free survival was better in childhood AML with those allografted than with those who underwent autografting.¹⁰⁹⁶ Children younger than age 2 years previously had a very poor prognosis. They tend to present with myelomonocytic or monocytic leukemia with high blast counts and CNS involvement. The t(9;11) abnormality has a more favorable prognosis. Intensive multidrug regimens have resulted in 3-year survivals approaching 70 percent of all infants treated. Thus, most infants can be successfully treated with intensive chemotherapy or allogeneic stem cell transplantation.^{1097,1098} Cord blood may be a suitable allograft option for children with AML who lack an acceptably matched unrelated marrow donor.¹⁰⁹⁹

Growth failure, neurocognitive abnormalities, endocrine deficiencies, and cardiac abnormalities are found in children treated at a young age.¹¹⁰⁰ The occurrence of a second malignancy in cured children is approximately 10-fold greater than expected in a matched population by age.¹¹⁰¹ Indefinite followup of children in remission or believed to be cured is important to assess developmental and intellectual progress and to evaluate long-term adverse events.

NONHEMATOPOIETIC ADVERSE EFFECTS OF TREATMENT

Skin Rashes

More than 50 percent of patients with AML develop skin lesions during remission-induction or remission-consolidation therapy. The rash may be on the trunk and extremities. The rash usually is maculopapular initially but can become hemorrhagic in patients who have thrombocytopenia. Allopurinol, trimethoprim-sulfamethoxazole, and other β -lactam antibiotics are commonly implicated causes. Use of multiple drugs enhances the probability of skin reactivity of patients.¹¹⁰² Cytostatic therapy coupled with the effects of leukemia predisposes patients to an increased frequency of allergic dermatitis.

Cardiac Toxicity

Alterations in cardiac function, especially left ventricular and intraventricular septal diastolic wall motion abnormalities, occur frequently in patients after they are exposed to the anthracycline antibiotics, daunorubicin, or doxorubicin.¹¹⁰³ The risk of serious cardiac effects is correlated with increasing dose of anthracycline antibiotic, increasing patient age, and presence of underlying heart disease. Adverse effects include electrocardiographic changes, such as prolonged QT interval, myocarditis, pericarditis, myocardial infarction, and congestive heart failure. The incidence of congestive heart failure is dose related and ranges from approximately 5 percent at doses of 550 mg/m² to greater than 30 percent at doses of 600 mg/m².¹¹⁰⁴ The frequency and long-term sequelae increase as anthracycline dose increases. However, even lower doses of these agents exert negative effects on cardiac myocytes. Measurement of heart wall behavior, valvular competence, and ejection fraction by ultrasonography can assist in assessing the risk of proceeding with anthracycline treatment in patients with or without pretreatment heart disease.^{1105,1106} In younger patients, transient abnormalities, although frequent, often improve after therapy is completed. Increased long-term remissions in children and younger adults have led to an increase

in serious ventricular and valvular disturbances years after therapy in some patients. Periodic evaluation of cardiac status by ultrasonography should be undertaken in long-term survivors.¹¹⁰⁶ Cardiomyopathy and heart failure can occur 10 to 15 years after therapy. Two approaches that may ameliorate the cardiomyopathic effect of anthracycline antibiotics are the use of these agents in liposome encapsulated preparations¹¹⁰⁷ and the use of dexrazoxane. Either approach may reduce the cardiotoxicity of anthracycline antibiotics.¹¹⁰⁸

Hepatitis

Hepatitis may occur in multiply transfused patients and usually is mild, but persistent hepatitis can develop, although hepatitis viruses A and B infection are not increased above the expected incidence in the general population. Hepatitis caused by type A virus is nearly nonexistent early in the course of AML. Cases of type B hepatitis can occur infrequently in patients who are carriers of the B virus and in whom chemotherapy and transient immunosuppression reactivate the virus.¹¹⁰⁹⁻¹¹¹¹ These rare cases of fibrosing cholestatic hepatitis can be fulminant. Screening blood products for hepatitis virus C has markedly decreased the risk of hepatitis C.¹¹¹² Reactivation of carriers of the C virus after chemotherapy is unusual.¹¹¹³ Medication induced chemical hepatitis or cholestasis can occur but is usually reversible. Iron overload in the multiply transfused survival may lead to later liver abnormalities.

Systemic Candidiasis Syndrome

The syndrome is manifested by fever, abdominal pain, and hepatomegaly. Increased serum alkaline phosphatase activity often is noted. Blood cultures are often negative. Abdominal ultrasonography, computed tomography, and MRI show characteristic hepatic lesions: circular areas of decreased attenuation of liver and often spleen, kidney, lung, or paraspinal muscles by imaging.¹¹¹⁴ Ultrasonography reveals multiple hypoechoic areas with a bull's-eye appearance. Laparoscopic-guided liver biopsy reveals yellow nodules on the liver surface, which on microscopic examination are large granulomas with *Candida* and pseudohyphae. Cure of this infection is possible with long-term (2 to 10 months) antifungals. Hepatosplenic candidiasis is seen much less frequently when azoles are used for fungal prophylaxis.

Neutropenic Enterocolitis

Necrotizing inflammation of the cecum with secondary infection can occur in patients with acute leukemia on intensive chemotherapy.²³³ Bacteremia may occur. Right lower abdominal pain and fever can simulate appendicitis. The diagnosis can be confirmed by sonography or computerized tomographic scanning in which a characteristic mucosal thickening and polypoid appearance are evident.^{1115,1116} Management includes bowel rest, nasogastric suction, fluids, and antibiotics. Parenteral alimentation is sometimes used but is generally not helpful.¹¹¹⁷ Restoration of the neutrophil count after chemotherapy is an important feature of resolution. In the absence of resolution, right hemicolectomy should be considered but is a last resort in neutropenic patients, usually imposed if hemodynamic stability is lost.²³³

Thromboembolic Disease

Although bleeding is associated with AML, thrombotic complications can also occur; up to 10 percent in APL and up to 3 percent in other AML subtypes.¹¹¹⁸ Management can be difficult because of thrombocytopenia. Central lines may contribute to this incidence.¹¹¹⁹ Thrombotic thrombocytopenic purpura has also been reported in patients in remission of AML during consolidation chemotherapy.¹¹²⁰ Patients with AML undergoing allogeneic stem cell transplantation also may develop post-transplantation thrombotic thrombocytopenic purpura, which rarely responds to plasmapheresis.

Fertility and Gonadal Function

Patients treated for AML, especially patients undergoing conditioning for allogeneic stem cell transplantation, have decreased gonadal function.^{1121–1123} Men may develop oligospermia. Women may develop ovarian dysfunction and very high gonadotropin levels.¹¹²⁴ Men recover gonadal function more often and sooner than do women. Recovery of ovarian function in women is partly dependent on a younger age at the time of treatment. In survivors of childhood AML treated only with chemotherapy and not transplantation, normal pubertal development and fertility are found, but antimüllerian hormone was low in some women.¹¹²⁵ Women in remission following treatment for AML with allogeneic transplantation can become pregnant and deliver healthy infants^{1126,1127}; however, this preservation of fertility is rare.¹¹²⁸ Histologic studies of the testes show marked suppression of spermatogenesis as a function of duration of treatment for AML and not of the specific agents used or the patient's age. Residual spermatogenesis in intensively treated patients enables recovery of reproductive function in males.¹¹²⁹ Males receiving intensive daunorubicin, cytosine arabinoside, or 6-thioguanine treatment for AML have conceived children during therapy.¹¹³⁰ Banking of sperm should be offered, and cryopreservation of ova can be attempted prior to institution of cytotoxic therapy, but often neither is logistically possible or successful in patients with AML who are acutely ill at presentation and require urgent chemotherapy.¹¹²¹ Banking of sperm or ova-ovarian tissue should be considered before myeloablative conditioning regimens for transplantation are administered. Many AML survivors report they were not, or not fully, informed about fertility-related issues.¹¹³¹

COURSE AND PROGNOSIS

RESULTS OF TREATMENT

Definition of Remission

Complete remission (CR) after AML therapy is defined as neutrophil count greater than 1000/ μL and platelet count greater than 100,000/ μL ¹¹³² with less than 5 percent blasts morphologically in marrow and the absence of extramedullary AML, although this definition has been called into question.¹¹³³ Remission with incomplete platelet recovery CR_{platelets} (CRp) has all these requirements but the platelet count does not reach $100 \times 10^9/\text{L}$. In a large cooperative group study, at least 94 percent of patients receiving cytarabine-based therapy who survived more than 3 or 5 years achieved a remission. Three- and 5-year survivals with CRp were less frequent.¹¹³⁴ With residual leukemic cell detection now possible by flow cytometry, cytogenetic, and molecular methodologies, definitions of remission may change. Persistence of

cytogenetic abnormalities at morphologic remission after induction therapy predicts for a significantly shorter relapse-free survival and overall survival, for example.¹¹³⁵

Rates of Remission

Remission rates have improved dramatically in the last 60 years, but remission, relative 5-year survival, and cure rates are most dependent on the patient's age when AML occurs.^{1136,1137} Initial remission rates now approach 90 percent in children, 70 percent in young adults, 60 percent in middle-aged patients, and 40 percent in older patients. Within age groups, remission is related to other variables such as cytogenetic risk category and expression of *MDR* genes in leukemic cells, but these variables also are correlated with age at onset. For example, the more favorable cytogenetic patterns t(8;21), t(15;17), inv16, or t(16;16) are present in approximately 30 percent of patients between 10 and 39 years old, 15 percent of patients between 40 and 59 years old, and 5 percent of patients 60 to 90 years old (Table 88–9).¹¹³⁷ Other factors, such as AML evolving from a prior clonal myeloid disease or developing as a result of cytotoxic treatment for another cancer or immune disorder, can decrease the expected remission and survival rates for the age group. In one study, treatment-related AML was an adverse prognostic factor for death in remission for younger patients and for relapse in remission in older patients.¹¹³⁸ Age-related comorbid conditions may limit the appropriateness or tolerance of intensive therapy, decreasing the opportunity for remission. The expected increase in the proportion of old and old-old individuals in the population may decrease remission rates and their duration unless counteracting improvements in treatment approaches are developed. In one study of 1069 consecutive AML patients in first CR treated between 1991 and 2003, the yearly risk of treatment failure was 69.1 in the first year, 37.7 in the second year, 17 in the third year, 7.6 in the fourth year, and 6.6 in the fifth year. The effects of cytogenetics remained constant during the first 3 years, but the effect of age increased with time. The probability of relapse-free survival at 6 years was 84 percent for those in remission at 3 years, but for the group older than 60 years old, it was only 56 percent, suggesting that different variables contribute differently over time to overall outcomes.¹¹³⁹

Early death can occur during induction chemotherapy, and performance status and age are the most important predictors of treatment related mortality. Age may be primarily a surrogate for other factors which also predict treatment related mortality.¹¹⁴⁰

Clonal Remissions

A small proportion of patients who enter remission have apparently normal hematopoiesis supported by a single clone rather than the expected polyclonal hematopoiesis. Evidence points to this clone being

TABLE 88–9. Frequency of Cytogenetic Findings with a More Favorable Prognosis by Age Group

Age (Years)	No. of Cases Studied	t(8;21) (No. of Cases)	t(15;17) (No. of Cases)	Inv16/t(16;16) (No. of Cases)	Total (No. of Cases)	Favorable Karyotypes (% of All Cases)
10–39	307	27	38	33	98	32
40–59	584	36	28	28	92	16
60–69	579	18	24	21	63	11
70–79	381	5	7	5	17	4.5
>80	45	1	2	0	3	6.6
Total	1896	87	99	87	273	22

These observations were made in Germany by Claudia Schoch and colleagues and kindly provided to the authors. (See also Schoch C, Kern W, Krawitz P, et al: Dependence of age-specific incidence of acute myeloid leukemia on karyotype. *Blood* 98:3500, 2001.)

a preleukemic cell rather than a normal stem cell.^{1141–1144} This finding is in keeping with previous hypotheses about the possible patterns of remission and relapse in AML^{1145–1148} and has implications for minimal residual disease detection.

Spontaneous Remissions

Spontaneous disappearance of AML has been reported for more than 100 years; however, most cases reported before 1960 had poor documentation of the diagnosis. Bona fide cases of AML patients who entered CR, usually after or concurrent with an infection, occur but are very rare.^{1148–1151} The occurrence of spontaneous remission with infection is consistent with the observation that the antibody response to *Pseudomonas* vaccine¹¹⁵² correlates with improved probability of chemotherapy-induced remission. Spontaneous remissions often are short lived but have lasted up to 3 years in adults and more than 9 years in children.¹¹⁵³ A particularly notable case of remission for more than 60 years has been documented following “treatment” prior to the introduction of chemotherapeutic drugs. The regimen included arsenic.¹¹⁵⁴

LONG-TERM SURVIVAL

Prior to the introduction of chemotherapy for AML 60 years ago, the median survival of patients was approximately 6 weeks,¹¹⁵⁵ the 1-year survival was approximately 3 percent, and longer survival occurred in less than 1 percent of patients. Five-year relative survival rates of patients in the United States from 2004 to 2010, based on the Surveillance, Epidemiology, and End Results Program of the National Cancer Institute, are 56 percent for patients younger than age 45 years, 39 percent for patients 45 to 54 years old, 27 percent for patients 55 to 64 years old, 11 percent for patients 65 to 74 years old, and 1.8 percent for patients older than age 75 years at the time of diagnosis (Table 88–10).¹⁰⁶⁹ Considering that the median age at disease onset is approximately 70 years and that 75 percent of patients are older than 45 years, the overall median survival is approximately 12 months. A study of the cost of care of older AML patients using Medicare data found that in adults older than age 65 years who were diagnosed between 1991 and 1996, the median survival was 2 months and the 2-year survival was 6 percent.¹¹⁵⁶ Very similar results were found in a study of nearly 10,000 patients in Sweden.¹¹⁵⁷ Better survival has been reported for younger patients who have received allogeneic stem cell transplantation in first remission, but the confidence limits for remission duration and survival are overlapping for drug-treated and drug- and transplantation-treated

groups, and the proportion of AML patients receiving transplantation is very small.^{1136,1158–1161} Abnormalities of chromosomes 17p and –5/5q– have negative impact on outcomes after allogeneic transplant.^{1162,1163}

In contrast to other AML subtypes, APL has had an increased incidence as well as improved survival since the introduction of ATRA. In one large study, relative survival rates were 0.18 for the period 1975 to 1990, with increase to 0.64 from 2000 to 2008. Age did remain an important predictor of survival; 0.38 in those older than age 60 years and 0.73 for those 20 to 29 years old.¹¹⁶⁴

Relapse (or a new leukemic event) in long-term survivors occurring as late as 8 years after remission has been reported in adults^{1153,1154} and after more than 16 years in children.^{1153,1154} Relapse in long-term survivors nearly always occurs in the marrow in adults and usually in the marrow in children, with occasional childhood cases of CNS or gonadal relapses occurring initially, followed by relapse in the marrow.¹¹⁵⁹ Studies of long-term survivors of AML show that most can return to work and that, at a median followup of 9 years, no increased risk of secondary invasive cancer or secondary AML had occurred.^{1160,1161} An exception to this finding is the occasional report of myelodysplasia or presumably secondary AML in long-term survivors of APL. Health-related quality of life in long-term survivors appears to recover completely as related to physical, psychological, and emotional well-being, but continued sexual dysfunction has been reported.¹¹⁶⁵ The quality of life at the time of diagnosis and during the course of therapy usually is poor.^{1165,1166}

FEATURES INFLUENCING OUTCOME OF THERAPY IN ACUTE MYELOGENOUS LEUKEMIA

Numerous features are related to outcome of AML treatment. Older age and less-favorable cytogenetic risk group are the two most compelling determinants of a poor outcome. Even with multivariate analysis, dissecting which other features are themselves important or are associations that segregate with another prognostic factor is difficult (Table 88–11).^{1167–1264} As noted previously, prognostic models of AML that rely solely on molecular mutations have been proposed.¹⁰⁵

Determining useful prognostic variables in patients with AML is imprecise because negative prognostic factors may be eliminated by better treatment protocols. Moreover, several prognostic factors are significant only when AML is stratified by age or by morphologic phenotype. Conflicting findings are common among studies. In addition, although a prognostic variable may be correlated significantly with a favorable outcome, the lack of a very strong statistical correlation with the outcome of treatment makes the variable's presence or absence of little prognostic value in an individual patient. If a stem cell donor is available, unfavorable prognostic factors could influence the therapist to use allogeneic stem cell transplantation as a means of remission maintenance in patients entering remission. The impact of prognostic factors may change in patients treated with allogeneic stem cell transplantation compared with conventional cytotoxic treatment.^{1265,1266}

DETECTION OF MINIMAL RESIDUAL DISEASE

General Considerations

The tumor cell burden in acute leukemia at presentation is approximately one trillion (10^{12}) cells. Apparent marrow aplasia followed by restitution of normal hematopoiesis can occur with at least a three-log reduction in leukemic cell numbers, which represents a residual tumor cell burden of approximately one billion cells. Intensification therapy is intended to decrease further the residual cell numbers. With the advent of specific monoclonal antibodies for leukemic cell antigens and FISH coupled with flow cytometry and DNA amplification by PCR, residual leukemic cell populations at or below the level of one billion cells,

TABLE 88–10. Acute Myelogenous Leukemia: Five-Year Percent Relative Survival Rates (2004–2010)

Age (Years)	Acute Myelogenous Leukemia*
<45	56
45–54	39
55–64	27
65–74	11
>75	1.8
<65	43
>65	6.0

*Percent rounded to nearest integer.

Data from SEER Cancer Statistics. Table 13.6. National Cancer Institute, Washington, DC. Available at: http://seer.cancer.gov/csr/1975_2011/browse_csr.php?sectionSEL=13&pageSEL=sect_13_table.16.html

TABLE 88-11. Prognostic Factors in Acute Myelogenous Leukemia**Better prognosis than average of all patients**

Early blast clearance during remission induction therapy^{1167,1168}
 Leukemic cells contain t(8;21), t(15;17), inv(16) t(16;16), trisomy 21^{282,284,1169}
CEBPA mutations in cytogenetically normal AML¹¹⁷⁰
 Absence of exaggerated dysmyelopoiesis¹¹⁷⁰
 Residual normal metaphases admixed with clonal cytogenetic abnormalities¹¹⁷²
 High telomerase activity levels¹¹⁷³
 Low levels of TdT expression by flow cytometry (<5%)¹¹⁷²
 High BAX expression¹¹⁷⁵ and high BAX/BCL-2 ratios¹¹⁷⁶
 High expression of integrin CD11b¹¹⁷⁷
 Absence of VLA-4 expression on AML blast cells¹¹⁷⁸
 High levels of soluble VCAM-1 binding to AML blast cells¹¹⁷⁹
 High levels of caspase-3¹¹⁸⁰
 Mutant *CEBPA* expression¹¹⁸¹
NPM1 gene expression in adults or children (usually present in cytogenetically normal cases)¹¹⁸²
 Higher neutrophil and higher platelet counts at time of complete remission¹¹⁸³
 <5% blasts on day 14 marrow predicts for complete remission but not for overall survival¹¹⁸⁴
MIR-181a expression in NK AML¹¹⁸⁵
 High methylation levels of polycomb group genes¹¹⁸⁶

Poorer prognosis than average of all patients

Older age: Age at the time of diagnosis has the greatest impact on the probability of remission and on duration of survival. Children in the first 15 years of life, exclusive of the neonatal period, have the highest rate of remission and longest relapse-free remission; patients older than age 60 years have only half the chance of a young adult to enter remission and less likelihood of a long relapse-free remission.¹¹³⁷ There is a gradient of poor response to treatment through adulthood, with the largest decrease after the sixth decade of life

Unfavorable karyotypes: The cytogenetic pattern of leukemic blast cells influences outcome, but the relationship is complex.²¹²⁻²⁸⁴ The presence of -5, -7, 5q-, 7q-, or of exaggerated hyperdiploidy (>47 chromosomes), trisomy 8, t(6;9), trisomy 11, and multiple chromosomal abnormalities in leukemic cells are poor prognostic signs.

Multidrug resistance phenotype: Leukemic cells expressing P-glycoprotein, a unidirectional drug efflux pump, encoded by the *MDR1*.¹¹⁸⁷ Expression of this gene product can result in decreased accumulation of anthracyclines, amsacrine, mitoxantrone, and etoposide. Expression of P-glycoprotein does not influence outcome of treatment, but if rhodamine-123 efflux also is increased, relapse is more common.¹¹⁸⁸⁻¹¹⁹¹ Frequently observed in AML cells after relapse. Associated with CD34 expression and chromosome 7 abnormalities.¹¹⁹⁰ Alternative non-*MDR1*-mediated drug efflux mechanisms are important also.¹¹⁹¹⁻¹¹⁹⁴ *MDR1* expression is low in favorable prognosis subtypes of AML¹¹⁹⁵

Presence of mutated *KIT* with t(8;21): Associated with higher relapse risk and poorer overall survival¹¹⁹⁶

Prior clonal hemopathy: Chemotherapy or radiotherapy remission rates are one-third to one-half that of *de novo* AML in the same age group. Remission duration is shorter with remissions >3 years very uncommon.¹¹⁹⁷⁻¹¹⁹⁸ AML developing from the clonal

hemopathy may relapse as a smoldering leukemia. It then reverts to AML but can be treated with remissions lasting several years¹¹⁹⁹⁻¹²⁰³

Higher white cell count: Count >30 × 10⁹/L or a blast cell count >15 × 10⁹/L¹²⁰⁴⁻¹²⁰⁶

Very low platelet count (<30 × 10⁹/L)¹²⁰⁵

High serum lactic dehydrogenase¹²⁰⁷

High stem cell mobilizing capacity during complete remission predicts for relapse risk¹²⁰⁸

Another medical disorder: extreme obesity, diabetes mellitus, chronic renal disease.

Low serum albumin or prealbumin

Need for intubation or ventilator support during induction therapy¹²⁰⁹

Autonomous clonal growth of leukemic blast cells¹²¹⁰

High BCL-2 expression^{1211,1212}

High MCL-1 expression: Elevated at the time of leukemic relapse. Suggests prognostic importance or that chemotherapeutic regimen selects for leukemia cells with elevated levels of apoptosis inhibitors¹²¹³

Low expression of retinoblastoma gene¹²¹⁴

High levels of WAF/Cip1 protein: This is a regulator at the G₁ checkpoint of cell cycle¹²¹⁵

High CD34 expression: High CD34 antigen expression often in AML subtypes M0, M1, and M4.¹²¹⁶ Remission rate of 61% vs. to 88% in AML not expressing CD34. Correlation is stronger between high-intensity expression of CD34 and lower remission rate.¹²¹⁶⁻¹²¹⁷ CD34 expression in APL¹²¹⁸

GATA-1 expression¹²¹⁹

Neural cell adhesion molecule (CD56) expression¹²²⁰

Elevated soluble L-selectin: Seen especially in extramedullary disease¹²²¹

Higher expression of interleukin (IL)-1β gene¹²²²

Low *FMS* expression¹²²²

Expression of the thrombopoietin receptor (c-*MPL*) mRNA¹²²³

FLT3 mutations^{1224,1225}

Increased angiogenesis/vascular endothelial growth factor levels¹²²⁶

High β₂-microglobulin levels in adults younger than 60 years old¹²²⁷

MN1 (meningioma 1) gene overexpression in AML patients with normal cytogenetics¹²²⁸

Young adults with the genotype *WT1*(mutation)/*FLT3*-ITD(positive) have a lower complete remission rate and an inferior relapse-free and overall survival compared to those with the genotype *WT1*(mutation)/*FLT3*-ITD(negative)¹²²⁹

WT1 gene mutations in patients with AML and a normal karyotype^{1230,1231}

Patients with AML with a large number of AML stem cells

Elevated expression of IL-3Rα¹²³²

MLL tandem duplications¹²³³ and 11p23/MLL abnormalities¹²³⁴

CD56 expression in APL.¹²³⁵ High incidence of CNS involvement, especially with CD7 expression.¹²³⁶ Also contributes to poorer outcomes in t(8;21) cases¹²³⁷

P15 methylation¹²³⁸

(continued)

TABLE 88–11. Prognostic Factors in Acute Myelogenous Leukemia (Continued)

Microsatellite instability ¹²³⁹ (may not be independent of age and t-AML)	High Nrf2 and high ROS expression ^{1254,1255}
AC133 expression (shorter remissions and disease-free survival) ¹²⁴⁰	Overexpression of IL-1 receptor accessory protein ¹²⁵⁶
Constitutive activity of signal transducer and activator of transcription 3 protein (shorter disease-free survival) ¹²⁴¹	Survivin expression in CD34+CD38– cells ¹²⁵⁷
<i>BAALC</i> gene expression ¹²⁴²	High TRAIL-R3 (tumor necrosis factor [TNF]-related apoptosis-inducing ligand) expression ¹²⁵⁸
High S-phase activity in cells surviving after 7 days of induction ¹²⁴³	<i>PICALM-MLLT10</i> fusion gene expression ³⁰²
High EVI1 expression ^{1244,1245}	Factors with no or uncertain prognostic findings
Overexpression of CXCR4 ¹²⁴⁶	Complex karyotype or secondary aberrations in patients with t(8;21), inv(16) t(16;16), or t(9;11) ¹²⁵⁹
Increased marrow angiogenesis as measured by magnetic resonance imaging ¹²⁴⁷	Myeloid antigens: CD11b expression may be predictive of shorter survival ¹²⁶⁰
The presence of the CTLA4 CT60 A/G genotype adult patients with AML ¹²⁴⁸	Detection of the WT1 (Wilms tumor) transcript ¹²⁶¹
<i>miR 155</i> upregulation ¹²⁴⁹	<i>FLT3</i> -ITD or <i>Asp835</i> mutations in APL ¹²⁶²
<i>ERG</i> expression ¹²⁵⁰	Levels of initiator caspase ¹²⁶³
<i>EVI1</i> expression in <i>MLL</i> -rearranged AML ¹²⁵¹	Persistent thrombocytopenia after remission induction ¹²⁶⁴
Clonal heterogeneity by metaphase karyotyping ¹²⁵²	Lung resistance protein: Functional test is needed to assess activity. ¹²⁶⁵ Expression may predict poor outcome in <i>de novo</i> AML ^{1193,1266}
Abnormal expression of FLI1 protein ¹²⁵³	

which are undetectable by light microscopy of stained marrow films, can be quantified.¹²⁶⁷ When real-time PCR is used to quantify PML-RAR- α , RUNX1/ETO, or CBF- β /MYH11, risk for treatment failure can be determined by the levels of the fusion gene at diagnosis and after the first 3 to 4 months of therapy.¹²⁶⁸ Sampling remains an important problem because marrow aspiration contains approximately 1/10,000 of the marrow cell population, and variation among sites of aspiration is well documented. In addition, the markers of the leukemic cell used for detection can change during the course of the disease. For example, persistence of circulating cells containing t(8;21) in patients with AML despite long-term remission has been established using PCR.¹²⁶⁹

There are many other pitfalls when interpreting these studies, including timing of sampling in relationship to therapy, sensitivity of the PCR reaction for target genes, interlaboratory standardization, selection of patients, and retrospective or prospective design of the study.¹²⁷⁰ There is emerging evidence, however, that detection of minimal residual disease (MRD) by multiparameter flow cytometry has prognostic relevance in older patients,¹²⁷¹ in children with *de novo* AML,¹²⁷² and in adults younger than age 60 years.¹²⁷³ Pretransplantation, detection of MRD by flow cytometry has negative impact on outcome in patients with AML in either first or second remission. Even MRD levels less than 0.1 percent have an adverse correlation with outcome.¹²⁷⁴ Detection of MRD in the after allogeneic stem cell transplantation is also important. Sensitive chimerism assays have been developed using PCR-based technology to detect short tandem-repeat polymorphisms. Whether these will have impact on management of posttransplantation relapses is still undetermined.^{1275,1276}

Marrow examinations are not needed in the majority of AML patients in first CR.¹²⁷⁷ Because of increased myeloid precursors in regenerating marrow, detection of residual disease may be difficult early after a given therapeutic modality.¹²⁷⁸ Cytogenetic followup usually is not helpful. Emergence of a karyotypically unrelated clone of AML cells, especially containing chromosome 7, can occur. Studies using multiparameter flow cytometry to identify leukemic cells by aberrant antigen expression have a high positive predictive value in identifying relapse.¹²⁷⁹ Detection of residual disease in AML patients using double immunologic marker analysis for TdT and myeloid CD antigens can

be useful because these two markers are expressed on leukemic cells in the majority of AML patients and these markers are rare in normal marrow cells.^{1280,1281} In other cases, aberrant combinations of surface antigens^{1280,1282} or increased expression of various surface antigens, such as CD34, are seen.¹²⁸³ Immunophenotype may change at relapse and has implications for MRD detection.¹²⁸⁴ Five-color staining has been reported to improve the percentage of AML cases in which a leukemia-associated aberrant immunophenotype can be identified.¹²⁸⁵ Various markers, such as CLL-1 (C-type lectin-like molecule-1) and other lineage markers and marker combinations, have been found aberrantly expressed on leukemic CD34+CD38–, cells allowing residual disease detection at the stem cell level.¹²⁸⁶ Other methods for detecting MRD include MRI; fluorescence DNA in FISH^{1287,1288}; reverse transcriptase (RT)-PCR to detect amplification of abnormal fusion genes, such as t(15;17), t(8;21), inversion 16, and 11q23; and DNA PCR for mutations in the *RAS* coding regions.¹²⁶⁷ Quantitative assessment of WT1 expression¹²⁸⁹ or presence of a *FLT3* mutation¹²⁹⁰ can also be evaluated for MDR monitoring. Real-time quantitative PCR can be used to quantitate MDR more precisely than other methods, but this test requires standardized criteria and is not widely available clinically.¹²⁹¹

Multiparameter flow cytometry is applicable to most AML cases, whereas real-time quantitative PCR is applicable in just above half the cases when *NPM1* and *FLT3* mutations are examined in addition to fusion oncogenes.¹²⁹² Gene profiling of CD34+CD38– cells, a fraction that contains both normal and leukemic stem cells, might be important in MRD measurement, but 34 percent of genes modulated in AML stem cells are shared with normal stem cells.¹²⁹³

Detecting Inversion 16

Minimal residual disease in acute myelomonocytic leukemia with inversion 16 can be detected by nested PCR with allele-specific amplifications (*CBF- β* on 16q and *MYH11* on 16p).^{1294,1295} This fusion transcript occurs not only in the majority of cases of acute myelomonocytic leukemia with marrow eosinophilia (M4Eo), but also in 10 percent of acute myelomonocytic leukemia M4 without eosinophilic abnormalities, a much higher incidence than suggested by the sporadic reports of

chromosome 16 abnormalities in AML. Following completion of chemotherapy (induction and consolidation), patients who had a CBF- β /MYH11 fusion transcript copy number greater than 10 had a shorter remission duration and higher risk for relapse than did patients with a copy number less than 10.¹²⁹⁵ Evidence indicates transcript ratios of samples may have utility in establishing thresholds for curability and for relapse risk in standard clinical CR states in the future.¹²⁹⁶

Detecting t(8;21)

Translocation 8;21 is one of the most common translocations in AML, especially in younger patients (see Table 88–9). This translocation fuses the *RUNX1* gene on chromosome 21p to *RUNXIT1* (ETO) on chromosome 8p to produce the fusion gene.^{1297,1298} The fusion has been detected in the majority of patients in remission. One study found its persistence in all patients with t(8;21) after chemotherapy or autologous marrow transplantation.^{1299–1301} Quantitation of the amount of the fusion transcript during remission may be more predictive of cure or relapse than a simple qualitative assessment.^{1302,1303} Real-time quantitative RT-PCR can be used for this purpose.

In general, CBF leukemias lend themselves to MRD monitoring by quantitative RT-PCR. In a trial from the Medical Research Council, in 163 patients with t(8;21) and 115 with inv(16), quantitative PCR transcripts at end of induction and end of consolidation course three were informative for relapse. Rising MRD levels in blood also predicted relapse.¹³⁰⁴ Another study showed that a three-log reduction in MRD after one consolidation had prognostic value whereas expression of *KIT* and *FLT3* mutations did not.¹³⁰⁵

Detecting t(15;17)

Unlike AML with the fusion transcript t(8;21), in APL the t(15;17) fusion transcript usually disappears after intensive therapy.¹³⁰⁶ At least one in 100,000 cells with the *PML-RAR- α* transcript can be detected by RT-PCR.¹³⁰⁶ FISH also can be used.¹³⁰⁷ Molecular monitoring has shown treatment is capable of achieving a molecular remission (negative RT-PCR).¹³⁰⁸ Nested PCR can be used to determine the need for additional treatment at the end of consolidation, to determine the advisability of autologous stem cell transplantation in second remission, and to predict relapse after transplantation.¹³⁰⁹ Real-time quantitative RT-PCR may improve the predictive value of MDR assessment and aid in laboratory standardization.¹³¹⁰

Detecting *NPM-1* and *FLT3* Mutations

In AML patients who have normal cytogenetics, mutational status of *NPM1*, *FLT3*, *CEPBA*, *MLL*, and *RAS* have implications for treatment outcomes and prognosis.¹³¹¹ Whether detection of these mutations as a reflection of MRD will have implications for relapse and therapy remains undetermined. Cumulative incidence of relapse is higher in those who remain positive using real-time quantitative PCR consolidation.¹³¹² There is evidence in *NPM1*-mutated cases, relapse was accompanied by an increase of mutant gene copy numbers; it has been concluded that quantitative PCR monitoring may have prognostic impact in such patients.¹³¹³

The technology to detect MRD has increased in sensitivity and availability. Detection of MRD to determine a patient's treatment or prognosis remains an evolving area of investigation. The role that proteomic^{1314,1315} and microRNA profiles^{1316–1319} will play in MRD detection is under study.

Marshall A. Lichtman has been an expert witness on behalf of defendants in toxic tort cases involving occupational exposure to chemicals, including benzene.

CHAPTER 89

CHRONIC MYELOGENOUS LEUKEMIA AND RELATED DISORDERS

Jane L. Liesveld and Marshall A. Lichtman

SUMMARY

The chronic myelogenous leukemias (CMLs) include *BCR* rearrangement-positive CML, chronic myelomonocytic leukemia, juvenile myelomonocytic leukemia, chronic neutrophilic leukemia, chronic eosinophilic leukemia, and chronic basophilic leukemia. The term *chronic*, in contrast to *acute*, once had prognostic implications. However, although the terms remain useful for nosology, they no longer reflect an invariable difference in prognosis. For example, acute myelogenous leukemia in children and young adults has higher remission and cure rates than juvenile or chronic myelomonocytic leukemia in children or adults, respectively. *BCR* rearrangement-positive CML presents with anemia, exaggerated granulocytosis, a large proportion of myelocytes and mature neutrophils, absolute basophilia, normal or elevated platelet counts, and, frequently, splenomegaly. The marrow is intensely hypercellular, and marrow cells contain the Philadelphia (Ph) chromosome in approximately 90 percent of cases by cytogenetic analysis. A rearrangement of the *BCR* gene on chromosome 22 is present by molecular diagnostic analysis in approximately 96 percent of cases that have a classic morphologic appearance. The *BCR*-rearranged form of the

Acronyms and Abbreviations: ALL, acute lymphocytic leukemia; BCR, breakpoint cluster region; CCyR, complete cytogenetic response; CFU-GM, colony-forming unit–granulocyte–monocyte; CHR, complete hematologic response; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CMML, chronic myelomonocytic leukemia; CMR, complete molecular response; DLI, donor lymphocyte infusion; FISH, fluorescence *in situ* hybridization; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–monocyte colony-stimulating factor; GRB2, growth factor receptor–bound protein-2; GTP, guanosine triphosphate; GTPase, guanosine triphosphatase; GVHD, graft-versus-host disease; HLA, human leukocyte antigen; HPRT, hypoxanthine phosphoribosyltransferase; hsp, heat shock protein; HUMARA, human androgen receptor assay; IFN, interferon; IL, interleukin; IRIS, International Randomized Study of Interferon; JAK, Janus-associated kinase; LTC-IC, long-term culture–initiating cell; MCP, monocyte chemotactic protein; MCyR, major cytogenetic response; MDS, myelodysplastic syndrome; MIP, macrophage inflammatory protein; MMR, major molecular response; NF- κ B, nuclear factor- κ B; *NF1*, neurofibromatosis tumor-suppressor gene; NK, natural killer; NOD, nonobese diabetic; OCT-1, organic cation transporter 1; PCR, polymerase chain reaction; PCyR, partial cytogenetic response; PDGFR, platelet-derived growth factor receptor; Ph, Philadelphia chromosome; PI3K, phosphatidylinositol 3'-kinase; Rb, retinoblastoma; RT-PCR, reverse transcriptase polymerase chain reaction; SCID, severe combined immunodeficiency; STAT, signal transducer and activator of transcription; TBI, total-body irradiation; TdT, terminal deoxynucleotidyl transferase; TGF, transforming growth factor; TKI, tyrosine kinase inhibitor; VEGF, vascular endothelial growth factor; WT, Wilms tumor.

disease usually responds to a tyrosine kinase inhibitor, and median survival has been extended significantly. Allogeneic hematopoietic stem cell transplantation can cure the disease, especially if the transplantation is applied early in the chronic phase, although this approach is now uncommon as a result of the effect of tyrosine kinase inhibitor therapy. The effect of stem cell transplantation is related in part to a robust graft-versus-leukemia effect, engendered by donor T lymphocytes. The natural history of the chronic phase is to evolve into an accelerated phase that often terminates in acute leukemia (blast crisis), but the frequency of this progression has been markedly decreased by the advent of tyrosine kinase inhibitors. Blast crisis results in a myelogenous leukemic phenotype in 75 percent of cases and a lymphoblastic leukemic phenotype in approximately 25 percent of cases. Ph chromosome–positive acute myeloblastic leukemia (AML) may appear *de novo* in approximately 1 percent of cases of AML, and Ph chromosome–positive acute lymphocytic leukemia (ALL) may occur *de novo* in approximately 20 percent of cases of adult ALL and approximately 5 percent of childhood ALL cases. In Ph chromosome–positive ALL, the translocation between chromosomes 9 and 22 results in the fusion gene encoding a mutant tyrosine kinase oncoprotein that may be identical in size to that in classic CML (210 kDa) in approximately one-third of cases. A smaller mutant tyrosine kinase (190 kDa) is encoded in approximately two-thirds of cases. In children, the cells in approximately 90 percent of cases contain a 190-kDa mutant tyrosine kinase. These acute leukemias may reflect (1) the presentation of CML in acute blastic transformation without a preceding chronic phase or (2) *de novo* cases resulting from a *BCR-ABL1* mutation occurring in a different early hematopoietic cell from the event in CML or with as yet unidentified modifying gene alterations. Chronic myelomonocytic leukemia has variable presenting features. Anemia may be accompanied by mildly or moderately elevated leukocyte counts; an elevated total monocyte count; a low, normal, or elevated platelet count; and sometimes splenomegaly. Although cytogenetic abnormalities may be present, there is no specific genetic marker of the disease. In a very small proportion of cases, a translocation involving the platelet-derived growth factor receptor (PDGFR)- β gene is associated with eosinophilia and is responsive to a tyrosine kinase inhibitor. Juvenile myelomonocytic leukemia occurs in infancy or very early childhood. Anemia, thrombocytopenia, and leukocytosis with monocytosis are usual. The disease is refractory to treatment and, even with current maximal therapy and stem cell rescue, cures are uncommon. Chronic neutrophilic leukemia presents with mild anemia and exaggerated neutrophilia, with very few immature cells in the blood. Splenomegaly is common. The disease usually occurs after age 60 years. Chronic and juvenile myelomonocytic leukemia and chronic neutrophilic leukemia have a propensity to evolve into acute myelogenous leukemia. Prior to that evolution, morbidity and mortality are related to infection, hemorrhage, and complicating medical conditions. Chronic eosinophilic leukemia represents the major subset of the hypereosinophilic syndrome. It is a clonal disorder with a striking absolute eosinophilia, often neurologic and cardiac manifestations secondary to toxic effects of eosinophil granules, and sometimes a translocation involving the PDGFR- α gene that encodes a mutant tyrosine kinase, imparting sensitivity to a tyrosine kinase inhibitor.

DEFINITION AND HISTORY

Chronic myelogenous leukemia (CML) is a multipotential hematopoietic stem cell disease characterized by anemia, extreme blood granulocytosis and granulocytic immaturity, basophilia, often thrombocytosis, and splenomegaly. The hematopoietic cells contain a reciprocal translocation between chromosomes 9 and 22 in more than

95 percent of patients with classic morphologic findings, which leads to an overtly foreshortened long arm of one of the pair of chromosome 22 (i.e., 22,22q-), referred to as the *Philadelphia (Ph) chromosome*. A rearrangement of the breakpoint cluster region gene (*BCR*) on the long arm of chromosome 22 defines this form of CML and is present even in the 10 percent of patients without an overt 22q abnormality by Giemsa chromosome banding. The natural history of the disease is to undergo clonal evolution into an accelerated phase and/or a rapidly progressive blast phase, an acute leukemia, highly refractory to therapy, which had been a frequent event prior to the introduction of tyrosine kinase inhibitors (TKIs) in 2001.

In 1845, Bennett¹ in Scotland and Virchow² in Germany described patients with splenic enlargement, severe anemia, and enormous concentrations of leukocytes in their blood at autopsy. Bennett initially favored an extreme pyemia as the explanation, but Virchow argued against suppurative as a cause. Additional cases were reported by Craige³ and others, and in 1847 Virchow⁴ introduced the designation *weisses Blut* and *leukämie* (leukemia). In 1878, Neumann⁵ proposed that the marrow not only was the site of normal blood cell production, but also was the site from which leukemia originated and used the term *myelogene* (myelogenous) leukemia. Subsequent observations amplified the clinical and laboratory features of the disease, but few fundamental insights were gained until the discovery by Nowell and Hungerford,⁶ who reported in 1960 that two patients with the disease had an apparent loss of the long arm of chromosome 21 or 22, an abnormality that was quickly confirmed⁷⁻⁹ and designated the Ph chromosome.⁷ Advanced cytogenetic techniques confirmed that it was chromosome 22. This observation led to a new approach to diagnosis, a marker to study the pathogenesis of the disease, and a focus for future studies of the molecular pathology of the disease. The availability of banding techniques to define the fine structure of chromosomes^{10,11} led to the discovery by Rowley¹² that the apparent lost chromosomal material on chromosome 22 was part of a reciprocal translocation between chromosomes 9 and 22. The discovery that the cellular oncogene *ABL1* on chromosome 9 and a segment of chromosome 22, the *BCR*, fuse as a result of the translocation provided a basis for the study of the molecular cause of the disease.^{13,14} The appreciation that the fusion gene encoded a constitutively active tyrosine kinase (*BCR-ABL1*) that was capable of inducing the disease in mice established the fusion gene product as the proximate cause of the malignant transformation. The search for, identification of, and clinical development of a small molecule inhibitor of the mutant tyrosine kinase provided a specific agent, imatinib mesylate, with which to inhibit the molecule that incites the disease.¹⁵ Several more potent congeners have also been synthesized (see “Etiology and Pathogenesis” below). Thomas and colleagues established that allogeneic hematopoietic stem cell transplantation could cure the disease.¹⁶ An engaging monograph on the discoveries and the scientists involved from the identification of the Ph chromosome to the development of imatinib has been published.¹⁷

● EPIDEMIOLOGY

CML accounts for approximately 15 percent of all cases of leukemia, or approximately 6500 new cases in the United States in 2015. The age-adjusted incidence rate in the United States is approximately 2.3 per 100,000 persons for men and approximately 1.2 per 100,000 persons for women. The incidence around the world varies by a factor of approximately twofold. The lowest incidence is in Sweden and China (approximately 0.7 per 100,000 persons), and the highest incidence is in Switzerland and the United States (approximately 1.5 per 100,000 persons).¹⁸ The age-specific incidence rate for CML in the United States increases logarithmically with age, from approximately 0.2 per 100,000

per year in persons younger than 20 years to a rate of approximately 10.0 per 100,000 in octogenarians (Fig. 89-1). Although CML occurs in children and adolescents, less than 10 percent of all cases occur in persons between 1 and 20 years old. CML represents approximately 3 percent of all childhood leukemias. Multiple occurrences of CML in families are rare. There is no concordance of the disease between identical twins. There is no analytical epidemiologic evidence for a familial predisposition to CML in Swedish databases.¹⁹ There is some evidence that overweightness and obesity can increase the incidence of CML.²⁰

● ETIOLOGY AND PATHOGENESIS

ENVIRONMENTAL LEUKEMOGENS

Exposure to very high doses of ionizing radiation can increase the occurrence of CML above the expected frequency in comparable populations. Three major populations—the Japanese exposed to the radiation released by the atomic bomb detonations at Nagasaki and Hiroshima,²¹ British patients with ankylosing spondylitis treated with spine irradiation,²² and women with uterine cervical carcinoma who received radiation therapy²³—had a frequency of CML (as well as acute leukemia) significantly above the frequency expected in comparable unexposed groups. The median latent period was approximately 4 years in irradiated spondylitics, among whom approximately 20 percent of the leukemia cases were CML; 9 years in the uterine cervical cancer patients, of whom approximately 30 percent had CML; and 11 years in the Japanese survivors of the atomic bombs, of whom approximately 30 percent of the leukemia patients had CML.²⁴ Chemical leukemogens, such as benzene and alkylating agents, are not causative agents of CML, presumably because of their inability to induce the specific chromosome translocation required to cause the disease.²⁵⁻²⁷

ORIGIN FROM A MUTANT HEMATOPOIETIC STEM CELL

CML results from the malignant transformation of a single hematopoietic stem cell. The disease is acquired (somatic mutation), given that the identical twin of patients with CML and the offspring of mothers with the disease neither carry the Ph chromosome nor develop the disease.²⁸ The origin of CML from a single hematopoietic stem cell is supported by the following lines of evidence:

1. Involvement of erythropoiesis, neutrophilopoiesis, eosinophilopoiesis, basophilopoiesis, monocytopoiesis, and thrombopoiesis in chronic phase CML.²⁹
2. Presence of the Ph chromosome (22q-) in erythroblasts; neutrophilic, eosinophilic, and basophilic granulocytes; macrophages; and megakaryocytes.³⁰
3. Presence of a single glucose-6-phosphate dehydrogenase isoenzyme in red cells, neutrophils, eosinophils, basophils, monocytes, and platelets, but not in fibroblasts or other somatic cells in women with CML who are heterozygotes for isoenzymes A and B.³¹⁻³³
4. Presence of the Ph translocation only on a structurally anomalous chromosome 9 or 22 of each chromosome pair in every cell analyzed in occasional patients with a structurally dissimilar 9 or 22 chromosome within the pair.³⁴⁻³⁶
5. Presence of the Ph chromosome in one, but not the other, cell lineage of patients who are a mosaic for sex chromosomes, as in Turner syndrome (45X/46XX)³⁷ and Klinefelter syndrome (46XY/47XXY).³⁸
6. Molecular studies showing variation in the breakpoint of chromosome 22 among different patients with CML but precisely the same breakpoint among cells within a single patient with CML.^{39,40}

Figure 89-1. Incidence of chronic myelogenous leukemia by age. Note the exponential increase in incidence with age from about teenagers to octogenarians. Rare cases occur in younger children but too few to generate an incidence rate.

7. Combined DNA hybridization-methylation analysis of women who have restriction fragment length polymorphisms at the X-linked locus for hypoxanthine phosphoribosyltransferase (HPRT), which enables distinction of the two alleles of the HPRT gene in heterozygous females, coupled with methylation-sensitive restriction-enzyme cleavage patterns, which permits delineation of whether cells contain either the maternally derived or the paternally derived copy of the gene.⁴¹

The foregoing observations place the parent cell of the clone at least at the level of the hematopoietic multipotential cell.

THE CHRONIC MYELOGENOUS LEUKEMIA STEM CELL

Acquisition of the *BCR-ABL1* fusion gene as a result of the t(9;22) (q34;q11.2) in a single primitive multipotential hematopoietic cell (possibly the pluripotential stem cell) results in the CML stem cell, necessary for the initiation and maintenance of the chronic phase of CML.^{42,43} The phenotype of the CML stem cell is not fully defined but they are among the CD34+CD33-Lin-Thy1+ KIT- fraction of CML cells.⁴³ A proportion of CML stem cells is in the G₀ phase of the cell cycle and is resistant to therapy with *BCR-ABL1* inhibitors. These cells represent a pool for the regrowth of the tumor in most patients, if suppressive therapy is interrupted. The leukemia stem cell is resistant to TKI therapy, but a pan-BCL2 inhibitor has been found to sensitize marrow leukemia stem cells to tyrosine kinase inhibition.⁴⁴ N-cadherin and WNT- β -catenin signaling are also thought to mediate microenvironmental protection of CML stem cells from TKIs.⁴⁵ The acquisition of genetic and epigenetic

events in a derivative *BCR-ABL1*-positive cell can result in evolution to accelerated phase and blastic transformation⁴⁶ (see “Accelerated Phase and Blast Crisis of Chronic Myelogenous Leukemia” below).

PLURIPOTENTIAL STEM CELL LESION

Some patients in chronic phase CML have lymphocytes that are derived from the primordial malignant cell. Evidence for this finding includes the following: A single isoenzyme for glucose-6-phosphate dehydrogenase has been found in some T and B lymphocytes in women with CML who are heterozygous for isoenzymes A and B⁴⁷; blood cells from patients with CML induced to proliferate with Epstein-Barr virus (presumptive B lymphocytes) are of the same glucose-6-phosphate dehydrogenase isoenzyme type, have cytoplasmic immunoglobulin heavy and light chains, and contain the Ph chromosome⁴⁸; blood lymphocytes stimulated with B lymphocyte mitogens contain the Ph chromosome^{49,50}; purified B lymphocytes from the blood in chronic phase CML contain an abnormal, elongated phosphoprotein coded for by the chimeric gene resulting from the t(9;22)⁵¹; and fluorescence *in situ* hybridization (FISH) has detected the *BCR-ABL1* fusion gene in approximately 25 percent of B lymphocytes in some, but not all, patients in chronic phase.^{52,53} These findings suggest that B lymphocytes are derived from the malignant clone, placing the lesion closer to, if not in, the pluripotential lymphohematopoietic stem cell.⁴⁷⁻⁵¹ Previous studies have found that the B lymphocyte pool is a mosaic, containing both Ph chromosome- and *BCR-ABL1*-positive cells and Ph chromosome- or *BCR-ABL1*-negative cells. Results of studies examining the derivation of T lymphocytes from the malignant clone are more ambiguous but indicate that T lymphocytes are derived from the malignant clone in

some patients.^{47,49,54–63} Natural killer (NK) cells isolated from patients with chronic phase CML do not contain the *BCR-ABL1* fusion gene.⁶⁴ It is possible that myelopoiesis is invariably clonal and lymphopoiesis is an unpredictable mosaic derived largely from normal residual stem cells. This conclusion is supported by the finding that progenitors of T, B, and NK lymphocytes contain the Ph chromosome and *BCR-ABL1*, but most B-cell and all T-cell progenitors derived from the leukemic clone undergo apoptosis, leaving unaffected cells in the blood.^{65–68}

The cell in which the mutation occurs may be even more primitive in that some endothelial cells generated *in vitro* express the *BCR-ABL1* fusion gene, as do some cells in the patient's vascular endothelium.⁶⁹

ETIOLOGIC ROLE OF THE Ph CHROMOSOME

Early studies indicated that the Ph chromosome may appear after the initial leukemogenic event.^{70–73} Patients with CML have developed the Ph chromosome during the course of the disease, have experienced periods of the disease when the Ph chromosome disappeared,⁷⁴ or have had Ph chromosome–positive and Ph chromosome–negative cells concurrently.^{75–79}

Nearly all, if not all, patients with CML have an abnormality of chromosome 22 at a molecular level (*BCR* rearrangement). Thus, earlier studies indicating an absence of a Ph chromosome was not a valid measure of the normality of chromosome 22. The molecular abnormality in CML involving the *ABL1* gene on chromosome 9 and the *BCR* gene on chromosome 22 has been established as being the proximate cause of the chronic phase of the disease (see “Molecular Pathology” below).

COEXISTENCE OF NORMAL STEM CELLS

Most, if not all, patients with CML have hematopoietic stem cells that, after treatment^{80–82} or culture *in vitro*,^{83–85} use of special cell isolation techniques,^{81,82} or use of cell transfer to nonobese diabetic (NOD)/severe combined immunodeficiency (SCID) mice⁸⁸ do not have the Ph chromosome^{89,90} or the *BCR-ABL1* fusion gene.^{91–95} The switch to Ph chromosome–negative cells *in vitro* is associated with a loss of monoclonal glucose-6-phosphate dehydrogenase isoenzyme patterns, indicating the persistence and reemergence of normal polyclonal hematopoiesis rather than reversion to a Ph chromosome–negative clone.⁹⁶ In confirmation, *BCR-ABL1*+, CD34+, human leukocyte antigen (HLA)–DR– cells isolated from women with early phase CML are polyclonal using the human androgen receptor assay (HUMARA) to assess X chromosome inactivation patterns.⁹⁷ Very primitive hematopoietic cells, the long-term culture–initiating cells (LTC-ICs), are present in Ph chromosome–negative cytopheresis samples collected during early recovery after chemotherapy for CML.⁹⁸ These LTC-ICs are most commonly present when samples are collected within 3 months of diagnosis.⁹⁹ Variable levels of *BCR-ABL1*–negative progenitors are found in the CD34+DR– population, but low levels are found in the CD34+CD38– population.^{95,100} Preprogenitors for the CD34+DR– cells are predominantly *BCR-ABL1*–negative in both marrow and blood at diagnosis.¹⁰¹ However, some cells with surface marker characteristics of very primitive normal hematopoietic cells do express the *BCR-ABL1* gene.¹⁰² Both normal and leukemic SCID-repopulating cells coexist in the marrow and blood from CML patients in chronic phase, whereas only leukemic SCID-repopulating cells are detected in blast crisis.^{103,104}

PROGENITOR CELL CHARACTERISTICS

Progenitor Cell Dysfunction

The leukemic transformation resulting from the *BCR-ABL1* fusion oncogene is maintained by a relatively small number of *BCR-ABL1* stem cells that favor differentiation over self-renewal.¹⁰⁵ This predisposition

to differentiation and progenitor cell expansion is mediated by an autocrine interleukin (IL)-3–granulocyte colony-stimulating factor (G-CSF) loop.¹⁰⁵ The earliest progenitors have the capacity to undergo marked expansion of erythroid, granulocytic, and megakaryocytic cell populations, and have a decreased sensitivity to regulation.^{105–107} This expansion is especially dramatic in the more mature progenitor cell compartment.^{105,108} The proliferative capacity of individual granulocytic progenitors is decreased compared to normal cells. Thus, the progenitor cell population in marrow and blood expands proportionately more than the increase in granulopoiesis.¹⁰⁹ *BCR-ABL1* reduces growth factor dependence of progenitor cells.

Erythroid progenitors are expanded, erythroid precursor maturation is blocked at the basophilic erythroblast stage, and the extent of erythropoiesis is inversely proportional to the total white cell count.¹¹⁰

Progenitor Cell Characterization

Phenotypic differences of stem and progenitor cells in CML patients compared to normal subjects have been identified.¹¹¹ For example, a greater proportion of the circulating leukemic colony-forming unit–granulocyte-monocytes (CFU-GMs) express high levels of the adhesion receptor CD44¹¹² and low levels of L-selectin¹¹³ in contrast to normal cells. Leukemic CD34+ cells overexpress the P glycoprotein that determines the multidrug resistance phenotype.¹¹⁴

BCR-ABL1–positive progenitors survive less well in long-term culture than do their normal counterparts. Leukemic CFU-GM colonies, unlike normal colonies, decrease in long-term cultures that are deficient in KIT ligand,¹¹⁵ whereas their proliferation is favored in the presence of KIT ligand.¹¹⁶ Macrophage inflammatory protein (MIP)-1 α , renamed CCL3, does not inhibit growth factor-mediated proliferation of CD34+ cells from CML patients, as it does CD34+ cells from normal subjects, even though the CCL3 receptor is expressed.¹¹⁷ Another chemokine, monocyte chemoattractant protein (MCP)-1 or CCL2, unlike CCL3, is an endogenous chemokine that cooperates with transforming growth factor beta (TGF- β) to inhibit the cycling of primitive normal, but not CML, progenitors in long-term human marrow cultures.¹¹⁸ Leukemic progenitors are less sensitive than normal progenitors to the antiproliferative effects of TGF- β .¹¹⁹

Effects of *BCR-ABL1* on Cell Adhesion

Primitive progenitors and blast colony-forming cells from patients with CML have decreased adherence to marrow stromal cells.¹²⁰ This defect is normalized if stromal cells are treated with interferon (IFN)- α .¹²¹ As a result, *BCR-ABL1*–negative progenitors are enriched in the adherent fraction of circulating CD34+ cells in chronic phase CML patients. The most primitive *BCR-ABL1*–positive cells in the blood of patients with CML differ from their normal counterparts. They are increased in frequency and are activated, such that signals that block cell mitosis are bypassed.¹²²

Ph chromosome–positive colony-forming cells adhere less to fibronectin (and to marrow stroma) than do their normal counterparts. Adhesion is fostered as a result of restoration of cooperation between activated β_1 integrins and the altered epitopes of CD44.^{123,124} CML granulocytes have reduced and altered binding to P-selectin because of modification in the CD15 antigens.¹²⁵ *BCR-ABL1*–induced defects in integrin function may underlie the abnormal circulation and proliferation of progenitors^{126,127} because growth signaling can occur through the fibronectin receptor.¹²⁸ IFN- α restores normal integrin-mediated inhibition of hematopoietic progenitor proliferation by the marrow microenvironment.¹²⁹ There are conflicting data regarding the effects of TKI effects on adhesion of CML cells to stroma.^{130,131}

BCR-ABL1–encoded fusion protein p210^{BCR-ABL} binds to actin, and several cytoskeletal proteins are thereby phosphorylated. The

p210^{BCR-ABL} interacts with actin filaments through an actin-binding domain. *BCR-ABL1* transfection is associated with increased spontaneous motility, membrane ruffling, formation of long actin extensions (filopodia), and accelerated rate of protrusion and retraction of pseudopodia on fibronectin-coated surfaces. IFN- α treatment slowly converts the abnormal motility phenotype of *BCR-ABL1*-transformed cells toward normal.¹³² Integrins regulate the *c-ABL*-encoded tyrosine kinase activity and its cytoplasmic nuclear transport.¹³³ The p210^{BCR-ABL1} abrogates the anchorage requirement but not the growth factor requirement for proliferation.¹³⁴

In normal cells exposed to IL-3, paxillin tyrosine residues are phosphorylated. In cells transformed by p210^{BCR-ABL1}, the tyrosines of paxillin, vinculin, p125^{FAK}, talin, and tensin are constitutively phosphorylated. Pseudopodia enriched in focal adhesion proteins^{134,135} are present in cells expressing p210^{BCR-ABL1}.

The sum of evidence suggests that defects in adhesion (contact and anchoring) of CML primitive cells remove them from their controlling signals normally received from microenvironmental cells via cytokine messages. These signals retain the balance among cell survival, cell death, cell proliferation, and cell differentiation. Inappropriate phosphorylation of cytoskeletal proteins, possibly independent of the mutant tyrosine kinase, is thought to be the key factor in disturbed integrin function of CML cells.

MOLECULAR PATHOLOGY

Ph Chromosome

The genetic disturbance became evident with the knowledge that CML was derived from a primitive cell containing a 22q⁻ abnormality.^{6,11} The abnormal chromosome contained only 60 percent of the DNA in other G-group chromosomes.¹³⁶ Cytogenetic analysis indicated the G-group chromosome involved was different from the extra G-group chromosome in Down syndrome, which had been assigned number 21. Thus, the former was assigned number 22—even though it proved to be slightly longer than the chromosome involved in Down syndrome.^{11,137} The Paris Conference on Nomenclature decided not to undo the concept that Down syndrome is trisomy 21 and assigned the Ph

chromosome and its normal counterpart, 22.¹³⁸ Using quinacrine (Q) and Giemsa (G) banding, Rowley¹² reported in 1973 that the material missing from chromosome 22 was not lost (deleted) from the cell, but was translocated to the distal portion of the long arm of chromosome 9. The amount of material translocated to chromosome 9 was approximately equivalent to that lost from chromosome 22, and the translocation was predicted to be balanced.¹² Moreover, the breaks were localized to band 34 on the long arm of chromosome 9 and band 11 on the long arm of chromosome 22. Therefore, the classic Ph chromosome is t(9;22)(q34;q11), abbreviated t(Ph) (Fig. 89–2). The Ph chromosome can develop on either the maternal or the paternal member of the pair.¹³⁹

Mutation of *ABL1* and *BCR* Genes

Mutations of the *ABL1* gene on chromosome 9 and of the *BCR* gene on chromosome 22 are central to the development of CML (Fig. 89–3).^{140–142}

In 1982, the human cellular homologue *ABL1* of the transforming sequence of the Abelson murine leukemia virus was localized to human chromosome 9.¹⁴³ In 1983, *ABL1* was shown to be on the segment of chromosome 9 that is translocated to chromosome 22¹⁴⁴ by demonstrating reaction to hybridization probes for *ABL1* only in somatic cell hybrids of human CML cells containing 22q⁻ but not those containing 9q⁺. *v-abl* is the viral oncogenic homologue of the normal cellular *ABL1* gene. This gene (*v-abl*) can induce malignant transformation of cells in culture and can induce leukemia in susceptible mice.¹⁴⁵

The *ABL1* gene is rearranged and amplified in cell lines from patients with CML.¹⁴⁶ Cell lines and fresh isolates of CML cells contain an abnormal, elongated 8-kb RNA transcript,^{147–150} which is transcribed from the new chimeric gene produced by the fusion of the 5' portion of the *BCR* gene left on chromosome 22 with the 3' portion of the *ABL1* gene translocated from chromosome 9 (Fig. 89–4).¹⁴⁴ The fusion mRNA leads to the translation of a unique tyrosine phosphoprotein kinase of 210 kDa (p210^{BCR-ABL}), which can phosphorylate tyrosine residues on cellular proteins similar to the action of the *v-abl* protein product.^{151–155} The *ABL1* locus contains at least two alleles, one having a 500-bp deletion.¹⁵⁷ In normal cells, the *ABL1* protooncogene codes for a tyrosine kinase of molecular weight 145,000, which is translated only in trace quantities and lacks any *in vitro* kinase activity.¹⁵² The fusion product

Figure 89–2. Schematic of normal chromosome 9 showing the *ABL* gene between bands q34 and qter of chromosome 22, which has the *BCR* and *SIS* genes between bands q11 and qter. The t(9;22) is shown on the right. The *ABL* from chromosome 9 is transposed to the chromosome 22 *M-bcr* sequences, and the terminal portion of chromosome 22 is transposed to the long arm of chromosome 9. The 22q⁻ is the Ph chromosome. *bcr*, breakpoint cluster region; *c-Sis*, cellular homologue of the viral simian sarcoma virus-transforming gene; *IGL*, gene for immunoglobulin light chains. Figure 89-3. Schematic of the normal *ABL* and *BCR* genes and of the *BCR-ABL* fusion transcripts. In the upper panel of the diagram, the possible breakpoint positions in *ABL* are marked by vertical arrows. Note the position immediately upstream of the *ABL* locus of the *8604Met* gene. The *BCR* gene contains 25 exons, including first (*e1*) and second (*e2*) exons. The positions of the three breakpoint cluster regions, *m-bcr*, *M-bcr*, and *μ-bcr*, are shown. The lower panel of the figure shows the structure of the *BCR-ABL* messenger RNA fusion transcripts. Breakpoints in *μ-bcr* result in *BCR-ABL* transcripts with an *e19a2* junction. The associated number designates the exon (location) at which the break occurs in each gene.

expressed by the *BCR-ABL1* gene is hypothesized to lead to malignant transformation because of the abnormally regulated enzymatic activity of the chimeric tyrosine protein kinase.^{153,154,158,159} Construction of *BCR-ABL1* fusion genes indicated that *BCR* sequences could also activate a microfilament-binding function, but the tyrosine kinase and microfilament-binding functions were not linked. Nevertheless, tyrosine kinase modification of actin filament function has been proposed as a step in leukemogenesis.¹⁶⁰

Figure 89-4. Molecular effects of the Ph chromosome translocation t(9;22)(q34;q11). The upper panel shows the physically joined 5' *BCR* and the 3' *ABL* regions on chromosome 22. The exons are solid (from chromosome 22, *BCR*) and hatched (from chromosome 9, *ABL*). The middle panel depicts transcription of chimeric messenger RNA. The lower panel shows the translated fusion protein with the aminotermis derived from the *BCR* of chromosome 22 and the carboxy-terminus from the *ABL* of chromosome 9. (Reproduced with permission from De Klein A: *Oncogene activation by chromosomal rearrangement in chronic myelocytic leukemia*. *Mutat Res* 1987 Sep;186(2):161–172.)

p210^{BCR-ABL} Fusion Protein

The breakpoints on chromosome 9 are not narrowly clustered, ranging from approximately 15 to more than 40 kb upstream from the most proximate region (first exon) of the *ABL1* gene.^{143,144,161} The breakpoints on chromosome 22 occur over a very short, approximately 5 to 6 kb, stretch of DNA referred to as the breakpoint cluster region (*M-bcr*),^{162,163} which is part of a much longer *BCR*^{164,165} gene (see Fig. 89-4). Three main *BCRs* have been characterized on chromosome 22: major (*M-bcr*), minor (*m-bcr*), and micro (*μ-bcr*). The three different breakpoints result in a p210, p190, and p230 fusion protein, respectively (see Fig. 89-3). The overwhelming majority of CML patients have a *BCR-ABL1* fusion gene that encodes a fusion protein of 210 kDa (p210^{BCR-ABL1}), for which mRNA transcripts have *e14a2* or a *e13a2* fusion junction (see Fig. 89-3).¹⁶⁶ The “e” represents the *BCR* exon and “a” the *ABL1* exon sites involved in the translocation. A *BCR-ABL1* with an *e1a2* type of junction has been identified in approximately 50 percent of the Ph chromosome-positive acute lymphoblastic leukemia cases and results in the production of a *BCR-ABL1* protein of 190 kDa (p190^{BCR-ABL}). Almost all CML cases at diagnosis that encode a p210^{BCR-ABL} also express *BCR-ABL* transcripts for p190.¹⁶⁷ The biologic or clinical significance of these dual transcripts is not known. Transgenic mice expressing p210^{BCR-ABL} develop acute lymphoblastic leukemia in the founder mice, but all transgenic progeny have a myeloproliferative disorder resembling CML.¹⁶⁸

The *BCR* gene encodes a 160-kDa serine-threonine kinase, which, when it oligomerizes, autophosphorylates and transphosphorylates several protein substrates.¹⁶⁹ Aberrant methylation of the *M-bcr* in CML occurs.¹⁶⁶ The first exon sequences of the *BCR* gene potentiate the tyrosine kinase of *ABL* when they fuse as a result of the translocation.¹⁷⁰ The central portion of *BCR* has homology to *DBL*, a gene involved in the control of cell division after the S phase of the cell cycle. The C-terminus of *BCR* has a guanosine triphosphatase (GTPase)-activating protein for p21^{rac}, a member of the *RAS* family of guanosine triphosphate (GTP)-binding proteins.¹⁷¹ A reciprocal hybrid gene *ABL-BCR1* is formed on chromosome 9q+ when *BCR-ABL1* fuses on chromosome 22. The *ABL-BCR1* fusion gene actively transcribes in most patients with CML.¹⁷²

Variations in breakpoints involving smaller stretches of chromosome 9 and rearrangements outside the *M-bcr* of chromosome 22 can occur.³⁷ In a few cases of CML with no evident elongation of chromosome 9, molecular probes have shown that *ABL1* still is translocated to chromosome 22.¹⁷³ In occasional patients with Ph chromosome-positive CML, the break in chromosome 22 is outside the *M-bcr*, and transcription of a fusion RNA of the usual type fails or a fusion RNA is transcribed that does not hybridize with the classic *M-bcr* complementary DNA (cDNA) probe.¹⁷⁴

In cases in which the Ph chromosome is not found, *BCR-ABL1* still may be located on chromosome 9 (a masked Ph chromosome).¹⁷⁵ The *BCR* gene can recombine with genomically distinct sites on band 11q13 in complex translocations in a region rich in Alu repeat elements.¹⁷⁶ *ETV6/ABL1* fusion genes have also been found in *BCR-ABL1*-negative CML.¹⁷⁷

The *BCR* breakpoint site has been examined as a factor in disease prognosis. Some studies have shown no correlation between CML chronicity and breakpoint site, although thrombocytosis may be more common with 3' breakpoint sites and basophilia with 5' breakpoint sites.¹⁷⁸ No difference in response to IFN- α therapy was noted, and survival was not significantly different, although patients with 3' deletions tended to have shorter survival.¹⁷⁹ Others have observed a better response to IFN- α in patients with a 3' rearrangement, which is being examined with imatinib mesylate therapy.¹⁸⁰

CML patients with *m-bcr* breakpoints develop a blast crisis with monocytosis and an absence of splenomegaly and basophilia.¹⁸¹ The p230 (e19a2 RNA junction) encoded by μ -*bcr* is rarely expressed but has been associated with neutrophilic CML or thrombocytosis (see "Special Clinical Features" below). Other rare breakpoints have been described.¹⁸² For example, a case with a 12-bp insert between *BCR* and *ABL1* resulted in a *BCR-ABL1*-negative (false-negative), Ph chromosome-positive CML with thrombocytopenia.¹⁸³ Another novel *BCR-ABL1* fusion gene (e6a2) in a patient with Ph chromosome-negative CML encoded an oncoprotein of 185 kDa.¹⁸⁴ Typical CML also has been associated with an e19a2 junction *BCR-ABL1* transcript.¹⁸⁵

Experimental support for the hypothesis that p210^{BCR-ABL1} tyrosine phosphoprotein kinase is transforming is provided by a retroviral gene transfer system that permits expression of the protein. Mouse marrow cells transfected with *BCR-ABL1* develop clonal outgrowths of immature cells expressing the p210^{BCR-ABL1} tyrosine kinase. Some clones progress to a malignant phenotype, can be transplanted, and can induce tumors in syngeneic mice.¹⁸⁶ Similar studies suggest that the p210^{BCR-ABL} can transform 3T3 murine fibroblasts if the *gag* gene sequence from a helper virus cooperates.¹⁸⁷ The *BCR-ABL1* gene from a retroviral vector has been expressed in an IL-3-dependent cell line. Clones derived from the infected line transform over months to IL-3 independency, are capable of increased proliferation, and develop chromosomal abnormalities.¹⁸⁸

A series of mouse models in which the *BCR-ABL1* was used to induce leukemogenesis have been described.¹⁸⁹⁻¹⁹⁷ Lethally irradiated mice have been reconstituted with marrow enriched for cycling stem cells infected with a *BCR-ABL1*-bearing retrovirus. Fatal diseases with abnormal accumulations of macrophagic, erythroid, mast, and lymphoid cells develop.¹⁸⁸ Classic CML did not occur, and complete transformation was not documented. The cell lines from spleen and marrow from mice with a *BCR-ABL1* retrovirus infection were predominantly mast cells; however, in some cases these cell lines spontaneously switched to either erythroid and megakaryocytic, erythroid, or granulocytic lineages displaying maturation. They were transplantable (transformed) and contained the same proviral inserts as the original mast cell line.¹⁹⁸ Murine marrow also has been infected with a retrovirus encoding p210^{BCR-ABL} and transplanted into irradiated syngeneic recipients.¹⁸⁹ Although several types of hematologic malignancies developed,

a syndrome mimicking human CML also occurred. Mice transgenic for a p190^{BCR-ABL} develop an acute lymphocytic leukemia (ALL) lymphoma syndrome¹⁹⁰ that resembles human Ph chromosome-positive ALL. When a p210^{BCR-ABL} transcript is introduced into a mouse germ-line (one-cell fertilized eggs), the p210 founder and progeny transgenic animals developed leukemia of B or T lymphoid or of myeloid origin after a relatively long latency period. In contrast, p190 transgenic mice exclusively developed leukemia of B-cell origin, with a relatively short period of latency. This finding was believed to be consistent with the apparent indolent nature of human CML during the chronic phase.¹⁹¹ When transgenic mice express p210^{BCR-ABL}, the transgenes develop ALL, whereas the progeny develop a myeloproliferative disorder.¹⁹²

Mouse models remain important for exploring the pathogenesis of the acute and chronic *BCR-ABL1*-mediated leukemias *in vivo* and in examining the potential effects of new drugs targeted at *BCR-ABL1*.¹⁹⁹

BCR-ABL IN HEALTHY SUBJECTS

BCR-ABL1 fusion genes can be found in the leukocytes of some normal individuals using a two-step reverse transcriptase polymerase chain reaction assay. Thus, although *BCR-ABL1* may be expressed relatively frequently at very low levels in hematopoietic cells, only infrequently do the cells acquire the additional changes necessary to produce leukemia. This may be a dosage effect.²⁰⁰

BCR-ABL1 AND SIGNAL TRANSDUCTION

The tyrosine phosphoprotein kinase activity of p210^{BCR-ABL1} has been causally linked to the development of Ph chromosome-positive leukemia in man.²⁰¹⁻²¹² p210^{BCR-ABL1} is, unlike the *ABL1* protein that is located principally in the nucleus, located in the cytoplasm making it accessible to a large number of interactions, especially components of signal transduction pathways.^{205,206,213} It binds and/or phosphorylates more than 20 cellular proteins in its role as an oncoprotein.²⁰⁶ A subunit of phosphatidylinositol 3'-kinase (PI3K) associates with p210^{BCR-ABL}; this interaction is required for the proliferation of *BCR-ABL1*-dependent cell lines and primary CML cells. Wortmannin, a nonspecific inhibitor of the p110 subunit of the kinase, inhibits growth of these cells.²⁰⁷

The pathways and interactions invoked by *BCR-ABL1* acting on mitogen-activated protein kinases are multiple and complex.^{214,215} A RAF-encoded serine-threonine kinase activity is regulated by p210^{BCR-ABL}. Downregulation of RAF expression inhibits both *BCR-ABL1*-dependent growth of CML cells and growth factor-dependent proliferation of normal hematopoietic progenitors.²⁰⁸ The efficiency of cell transformation by *BCR-ABL1* is affected by an adaptor protein that can relate tyrosine kinase signals to RAS. This involves growth factor receptor-bound protein-2 (GRB2). p210^{BCR-ABL} also activates multiple alternative pathways of RAS.²⁰⁹ PI3K is constitutively activated by *BCR-ABL1*, generates inositol lipids, and is dysregulated through the downregulation by *BCR-ABL1* of polyinositol phosphate tumor suppressors, such as PTEN and SHP1.²¹³ Figure 89-5 demonstrates interaction of p210^{BCR-ABL} with various mediators of signal transduction.

Reactive oxygen species are increased in *BCR-ABL1*-transformed cells and may act as a second messenger to modulate enzymes regulated by the reduction-oxidation (redox) equilibrium. An increase in these reactive oxygen products is postulated to play a role in the acquisition of additional mutations as a result of production of reactive oxygen species through the chronic phase, contributing to the progression to accelerated phase.^{213,216}

The adaptor molecule CRKL is a major *in vivo* substrate for p210^{BCR-ABL}, and it acts to relate p210^{BCR-ABL} to downstream effectors. CRKL is a linker protein that has homology to the *v-crk* oncogene

Figure 89-5. Major intracellular signaling events associated with *BCR/ABL*. Constitutive activation of ABL protein tyrosine kinase (PTK) induces phosphorylation of the tyrosine moiety of various substrates, including the autophosphorylation of *BCR/ABL* and complex formation of *BCR/ABL* with adaptor proteins. This process subsequently activates multiple intracellular signaling pathways, including RAS activation and phosphatidylinositol 3'-kinase (PI3K) activation pathways. *BCR/ABL* also activates the c-MYC pathway, which involves *ABL*-SH2 domain. *BCR/ABL* inhibits apoptosis, possibly in part through upregulation of Bcl-2, and alters cellular adhesive properties, possibly by interacting with focal adhesion proteins and the actin cytomatrix. Broken lines indicate hypothetical pathways. FAK, focal adhesion kinase; JNK, Jun N-terminal kinase; MEKK, MEK kinase; Sos, Son-of-sevenless; STAT, signal transducer and activator of transcription. (Reproduced with permission from Gotoh A, Broxmeyer HE: The function of *BCR/ABL* and related proto-oncogenes. *Curr Opin Hematol* 4(1):3-11, 1997.)

product. Antibodies to CRKL can immunoprecipitate paxillin. Paxillin is a focal adhesion protein²¹⁰ that is phosphorylated by p210^{BCR-ABL}. The p210^{BCR-ABL} may be physically linked to paxillin by CRKL. CRKL binds to CBL, an oncogene product that induces B cell and myeloid leukemias in mice.²¹¹ The Src homology 3 domains of CRKL do not bind to CBL, but they do bind *BCR-ABL*. Therefore, CRKL mediates the oncogenic signal of *BCR-ABL* to CBL. The p120^{CBL} and the adaptor proteins CRKL and c-CRK also link c-abl, p190^{BCR-ABL}, and p210^{BCR-ABL} to the PI3K pathway.²¹² The p120^{CBL} also coprecipitates with the p85 subunit of PI3K, CRKL, and c-CRK. The p210^{BCR-ABL} may, therefore, induce the formation of multimeric complexes of signaling proteins.²¹⁷ These complexes contain paxillin and talin and may explain some of the adhesive defects of CML cells.²¹⁸

Hef2 also binds to CRKL in leukemic tissues of p190^{BCR-ABL} transgenic mice. Hef2 is involved in the integrin signaling pathway²¹⁹ and encodes a protein that accelerates GTP hydrolysis of RAS-encoded proteins and neurofibromin. The latter negatively regulates granulocyte-monocyte colony-stimulating factor (GM-CSF) signaling through RAS in hematopoietic cells.²²⁰ p62^{DOK}, a constitutively tyrosine-phosphorylated, p120^{RAS} GAP-associated protein, which is rapidly tyrosine phosphorylated upon activation of the *c-kit* receptor,²²¹ is also associated with ABL1.²²²

Nuclear factor (NF)- κ B activation is also required for p210^{BCR-ABL}-mediated transformation.²²³ Expression of p210^{BCR-ABL} leads to activation of NF- κ B-dependent transcription via nuclear translocation.²²⁴

Cell lines that express p210^{BCR-ABL} also demonstrate constitutive activation of Janus kinases (JAKs) and signal transducers and activators of transcription (STATs), usually STAT5.²²⁵ STAT5 is also activated in primary mouse marrow cells acutely transformed by the *BCR-ABL1*²²⁶; p210^{BCR-ABL1} coimmunoprecipitates with and constitutively phosphorylates the common β subunit of the IL-3 and GM-CSF receptors and JAK2.²²⁷ Both ABL1 and BCR are also multifunctional regulators of the GTP-binding protein family Rho^{228,229} and the growth factor-binding protein GRB2, which links tyrosine kinases to RAS and forms a complex with *BCR-ABL1* and the nucleotide exchange factor Sos that leads to activation of RAS.²³⁰

The p210^{BCR-ABL1} also activates Jun kinase and requires Jun for transformation.²³¹ In some CML cell lines, p210^{BCR-ABL1} is associated with the retinoblastoma (Rb) protein.²³² Loss of the neurofibromatosis (*NF1*) tumor-suppressor gene, a RAS GTPase-activating protein, also is sufficient to produce a myeloproliferative neoplasm in mice akin to human CML resulting from RAS-mediated hypersensitivity to GM-CSF.²³³

EFFECTS OF BCR-ABL ON APOPTOSIS

Whether p210^{BCR-ABL1} influences the expansion of the malignant clone in CML by inhibiting apoptosis is uncertain. In one study, the survival of normal and CML progenitors was the same after *in vitro* incubation in serum-deprived conditions and after treatment with X-irradiation or glucocorticoids.²³⁴ p210^{BCR-ABL1} inhibits apoptosis by delaying the G₂/M transition of the cell cycle after DNA damage.²³⁵ The p210^{BCR-ABL1} also may exert an antiapoptotic effect in factor-dependent hematopoietic cells.^{236,237}

p210^{BCR-ABL1} does not prevent apoptotic death induced by human NK or lymphokine-activated killer cells directed against CML or normal cells.²³⁸ In accelerated and blast phases, apoptosis rates were lower in CML neutrophils. G-CSF and GM-CSF considerably decreased the rate of apoptosis in CML neutrophils.²³⁹

TELOMERE LENGTH

Patients with CML present with a somewhat shortened mean telomere length in granulocytic cells but not blood T lymphocytes at diagnosis, but considerable overlap exists in the distribution of telomere length with healthy individuals.²⁴⁰⁻²⁴² The rate of shortening of telomere length during the chronic phase is correlated with a more rapid onset of accelerated phase.^{240,242} Telomerase reverse transcriptase (TERT) is the catalytic subunit, expression of which is closely correlated with telomerase activity. In CML CD34+ cells containing BCR-ABL1, the expression of TERT is significantly lower than in normal CD34+ cells, consistent with accelerated shortening of telomeres in CML cells.²⁴³ A further significant decrease in telomere length occurs in the accelerated phase of

CML. Telomerase activity is increased in the accelerated phase.²⁴⁴ When therapy permits restoration of Ph chromosome–negative cells in the blood, these cells have telomere length comparable to that in matched healthy controls.²⁴⁵

CLINICAL FEATURES

SIGNS AND SYMPTOMS

In the 70 percent of patients who are symptomatic at diagnosis, the most frequent complaints include easy fatigability, loss of sense of well-being, decreased tolerance to exertion, anorexia, abdominal discomfort, early satiety (related to splenic enlargement), weight loss, and excessive sweating.^{246–248} The symptoms are vague, nonspecific, and gradual in onset (weeks to months). A physical examination may detect pallor and splenomegaly. The latter was present in approximately 90 percent of patients at diagnosis, but with medical care being sought earlier, the presence of splenomegaly at the time of diagnosis is decreasing in frequency.²⁴⁷ Sternal tenderness, especially the lower portion, is common; occasionally, patients notice it themselves.

Uncommon presenting symptoms include those of dramatic hypermetabolism (night sweats, heat intolerance, weight loss) simulating thyrotoxicosis; acute gouty arthritis, presumably related in part to hyperuricemia; priapism, tinnitus, or stupor from the leukostasis associated with greatly exaggerated blood leukocyte count elevations.^{249–251}; left upper quadrant and left shoulder pain as a consequence of splenic infarction and perisplenitis; vasopressin-responsive diabetes insipidus^{252,253}; and acne urticata associated with hyperhistaminemia.²⁵⁴ Acute febrile neutrophilic dermatosis (Sweet syndrome), a perivascular infiltrate of neutrophils in the dermis, can occur. In the latter situation, fever accompanied by painful maculonodular violaceous lesions on the trunk, arms, legs, and face are characteristic.^{255,256} Spontaneous rupture of the spleen is a rare event.^{257,258} Digital necrosis has been reported as a rare paraneoplastic event.^{259,260}

In an increasing proportion of patients, the disease is discovered, coincidentally, when blood cell counts are measured at a periodic medical examination.

CHILDHOOD PRESENTATION

Hyperleukocytosis and symptoms or signs therefrom are a more common feature in patients who present with CML before the age of 20 years. The white cell counts at diagnosis are on average more than twice that in adults, the fraction of blood blasts, promyelocytes, and myelocytes is significantly higher, and clinical manifestations of hyperleukocytosis are far more frequent in children than adults.²⁵⁰

LABORATORY FINDINGS

Blood

The presumptive diagnosis of CML can be made from the results of the blood cell counts and examination of the blood film.^{26,246,247} The blood hemoglobin concentration is decreased in most patients at the time of diagnosis. Red cells usually are only slightly altered, with an increase in variation from small to large size and only occasional misshapen (elliptical or irregular) erythrocytes. Small numbers of nucleated red cells are commonly present. The reticulocyte count is normal or slightly elevated, but clinically significant hemolysis is rare.^{246,261,262} Rare cases of mild erythrocytosis^{263,264} or erythroid aplasia^{265,266} have been documented.

The total leukocyte count is always elevated at the time of diagnosis and is nearly always greater than $25 \times 10^9/L$; at least half the patients have total white counts greater than $100 \times 10^9/L$ (Fig. 89–6).^{26,246,247} The total leukocyte count rises progressively in untreated patients. Rare patients

Figure 89–6. Total white cell count and platelet count of 90 patients with CML at the time of diagnosis. The cumulative percent of patients is on the *ordinate*, and the cell count is on the *abscissa*. Fifty percent of patients had a white cell count greater than $100 \times 10^9/L$ and a platelet count greater than approximately $300 \times 10^9/L$ at the time of diagnosis.

may have dramatic cyclic variations in white cell counts as much as an order of magnitude with cycle intervals of approximately 60 days.^{267,268} Granulocytes at all stages of development are present in the blood and are generally normal in appearance (Fig. 89–7). In this series, the mean blast cell prevalence was approximately 3 percent but can range from 0 to 10 percent; progranulocyte prevalence was approximately 4 percent; myelocytes, metamyelocytes, and bands accounted for approximately 40 percent; and segmented neutrophils accounted for approximately 35 percent of total leukocytes (Table 89–1). Often, there is a “myelocyte bulge” in which the differential count shows an exaggerated proportion of myelocytes compared to the proportion observed in normal persons. Hypersegmented neutrophils are commonly present.

Neutrophil alkaline phosphatase activity is low or absent in more than 90 percent of patients with CML.^{269–271} The mRNA for alkaline phosphatase is undetectable in neutrophils of patients with CML.²⁷² The activity increases toward or to normal in the presence of intense inflammation or infection and when the total leukocytic count is decreased to or near normal with treatment.^{271,273} CML neutrophils regain alkaline phosphatase activity after infusion into leukopenic recipients, suggesting the effect of regulators or factors extrinsic to the neutrophils. With the availability of specific markers, *BCR-ABL1* in CML and *JAK2* mutations in polycythemia, leukocyte alkaline phosphatase is no longer used for diagnostic purposes.

The proportion of eosinophils usually is not increased, but the absolute eosinophil count nearly always is increased. Rarely, eosinophils are so prominent that they dominate the granulocytic cells and lead to the designation *Ph chromosome–positive eosinophilic CML*. An absolute increase in the basophil concentration is present in almost all patients, and this finding can be useful in preliminary consideration of the differential diagnosis.^{26,278} Basophilic progenitor cells are increased in the blood.²⁷⁹ The proportion of basophils usually is not greater than 10 to 15 percent during the chronic phase but may, in rare patients, represent 30 to 80 percent of the total leukocyte count during chronic phase and lead to the designation of *Ph chromosome–positive basophilic CML*.²⁸⁰ Flow cytometry using anti-CD203c provides very accurate assessment of the basophil frequency. Basophils may be hypogranulated or have an immature phenotype and may be left uncounted in an optical differential white cell count. Anti-CD203c recognizes these cells as basophils.²⁸¹ Granules of basophils in patients with CML, unlike normal basophils, contain mast cell α -tryptase.^{281,282} Granulocytes containing both eosinophilic and basophilic granules (mixed granulation) are commonly present.²⁸³

Figure 89-7. Blood and marrow cells characteristic of chronic myelogenous leukemia. **A.** Blood film. Elevated leukocyte count. Elevated platelet count (aggregates). Characteristic array of immature (myelocytes, metamyelocytes, band forms) and mature neutrophils. **B.** Blood film. Elevated leukocyte count. Characteristic array of immature (myelocytes, metamyelocytes, band forms) and mature neutrophils. Two basophils in the field. Absolute basophilia is a constant finding in CML. **C.** Blood film. Elevated leukocyte count. Characteristic array of immature (promyelocytes, myelocytes, metamyelocytes, band forms) and mature neutrophils. Basophil in the field. Two myeloblasts in upper center. Note multiple nucleoli (abnormal) and agranular cytoplasm. **D.** Marrow section. Hypercellular. Replacement of fatty tissue (normally approximately 60 percent of marrow volume in adults of this patient's age) with hematopoietic cells. Intense granulopoiesis and evident megakaryocytopoiesis. Decreased erythropoiesis. (Reproduced with permission Lichtman's Atlas of Hematology, www.accessmedicine.com.)

The total absolute lymphocyte count is increased (mean: approximately $15 \times 10^9/L$) in patients with CML at the time of diagnosis²⁸⁴ as a result of the balanced increase in T-helper and T-suppressor cells.²⁸⁵ B lymphocytes are not increased.²⁸⁸ T lymphocytes also are increased in the spleen.²⁸⁶ NK cell activity is defective in CML patients as a result of decreased maturation of these cells *in vivo*^{287,288} and a decrease in the absolute number of circulating NK cells in patients with CML. The latter change can perhaps be related to increased apoptosis.²⁸⁹ The CD56 bright subset of NK cells is particularly decreased. These cells are reduced more as CML progresses, and they respond less to stimuli that recruit clonogenic NK cells compared to NK cells from normal subjects.²⁹⁰

The platelet count is elevated in approximately 50 percent of patients at the time of diagnosis and is normal in most of the rest.²⁹¹ The median value in patients at diagnosis is approximately 400×10^9 cells/L. The platelet count may increase during the course of the chronic phase. Platelet counts greater than $1000 \times 10^9/L$ are not unusual, and platelet counts as high as 5000 to $7000 \times 10^9/L$ have occurred. Thrombohemorrhagic complications of thrombocytosis are infrequent. Occasionally, the platelet count may be below normal at the time of diagnosis, but this finding usually signals an impending progression to the accelerated phase of the disease (see "Accelerated Phase and Blast Crisis of Chronic

Myelogenous Leukemia" below) and may also occur in with massive splenomegaly.

Functional abnormalities of neutrophils (adhesion, emigration, phagocytosis) are mild; are compensated for by high neutrophil concentrations; and do not predispose patients in chronic phase to infections by either usual or opportunistic organisms.²⁹²⁻²⁹⁴ Platelet dysfunction can occur but is not associated with spontaneous or exaggerated bleeding. A decrease in the second wave of epinephrine-induced platelet aggregation is the most common abnormality and is associated with a deficiency of adenine nucleotides in the storage pool.^{295,296}

Marrow

Morphology The marrow is markedly hypercellular, and hematopoietic tissue takes up 75 to 90 percent of the marrow volume, with fat markedly reduced (see Fig. 89-7).^{297,298} Granulopoiesis is dominant, with a granulocytic-to-erythroid ratio between 10:1 and 30:1, rather than the normal 2:1 to 4:1. Erythropoiesis usually is decreased, and megakaryocytes are normal or increased in number. Eosinophils and basophils may be increased, usually in proportion to their increase in the blood. Mitotic figures are increased in number. Mast cells are often seen, and uncommonly a juxtamembrane domain mutant of *KIT* coincides with *BCR-ABL1* in CML.²⁹⁹ Rare reports of marrow mastocytosis

TABLE 89-1. White Blood Cell Differential Count at the Time of Diagnosis in 90 Cases of Ph Chromosome–Positive Chronic Myelogenous Leukemia

	Percent of Total Leukocytes (Mean Values)
Myeloblasts	3
Promyelocytes	4
Myelocytes	12
Metamyelocytes	7
Band forms	14
Segmented forms	38
Basophils	3
Eosinophils	2
Nucleated red cells	0.5
Monocytes	8
Lymphocytes	8

In these 90 patients, the mean hematocrit was 31 mL/dL, mean total white cell count was $160 \times 10^9/L$, and mean platelet count was $442 \times 10^9/L$ at the time of diagnosis.

Data from Hematology Unit, University of Rochester Medical Center.

have been explained by a *KIT* mutation as an additional genetic abnormality or by dual clones in the marrow.^{300,301} Macrophages that mimic Gaucher cells in appearance are sometimes seen. This finding is a result of the inability of normal cellular glucocerebrosidase activity to degrade the increased glucocerebroside load associated with markedly increased cell turnover.³⁰² Macrophages also can become engorged with lipids, which, when oxidized and polymerized, yield ceroid pigment. This pigment imparts a granular and bluish cast to the cells after polychrome staining; such cells have been referred to as *sea-blue histiocytes*.³⁰²

Collagen type III (reticulin fibrosis), which takes the silver impregnation stain, is commonly increased at the time of diagnosis in nearly half the patients,³⁰³ and is correlated with the proportion of megakaryocytes in the marrow.^{304,305} Increased fibrosis also is correlated with larger spleen size, more severe anemia, and a higher proportion of marrow and blood blast cells.

The marrows of CML patients have a mean doubling of microvesel density compared to healthy controls and have more angiogenesis in marrow than other forms of leukemia.³⁰⁶⁻³⁰⁸ This increased marrow vascularity decreases to normal after treatment.³⁰⁹

Progenitor Cell Growth Cells that form colonies of neutrophils and macrophages or eosinophils (CFUs) are increased in the marrow and blood. The increase in CFUs in marrow is approximately 20-fold normal and in blood approximately 500-fold normal. The CFUs are of lighter buoyant density than those in normal marrow.¹⁰⁰ More primitive progenitors that can initiate long-term cultures of hematopoiesis also are markedly increased.³¹¹ Spontaneous blood-derived granulocyte-macrophage colony growth is common, although CFUs also respond to growth factor stimulation.

Cytogenetics The marrow and nucleated blood cells of more than 90 percent of patients with clinical and laboratory signs that fall within the criteria for the diagnosis of CML contain the Ph chromosome (22q–) as measured by G-banding, and virtually all patients have the t(9;22)(q34;q11)(*BCR-ABL1*) by FISH. The Ph chromosome is present in all blood cell lineages (erythroblasts, granulocytes, monocytes,

megakaryocytes, T- and B-cell progenitors) but is not present in the majority of blood B lymphocytes or in most T lymphocytes.^{54,56} Approximately 70 percent of patients in the chronic phase have the classic Ph chromosome in their cells.³¹² The remaining 20 percent also have a missing Y chromosome [t(Ph),–Y]; an additional C-group chromosome, usually number 8 [t(Ph),+8]; an additional chromosome 22q– but without the 9q+ [t(Ph), 22q–]; or t(Ph) plus either another stable translocation or another minor clone. These variations have not been shown to affect the duration of the chronic phase. Deletion of the Y chromosome occurs in approximately 10 percent of healthy men older than 60 years.^{313,314}

Variant Ph chromosome translocations occur in approximately 5 percent of subjects with CML and involve complex rearrangements (three chromosomes), and every chromosome except the Y chromosome can be involved.³¹⁵⁻³¹⁹ The Ph chromosome, that is, 22q–, is present, but the gross exchange of chromosomal material involves a chromosome other than 9 (simple variant) or involves exchange of material among chromosomes 9 and 22 and a third or more chromosomes (complex variant; Fig. 89-8). High-resolution techniques have indicated that 9q34-qter is transposed to 22q11 in simple and in complex translocations.^{320,321} Thus, the fusion of 9q34 with 22q11 seems to occur in the cells of most patients with CML.³²³ Complex translocations involving chromosome 3 have been notable.³²²⁻³²⁴ In rare cases, a reciprocal translocation with a chromosome other than 9 to chromosome 22 is larger than usual, and the posttranslocation shortening of the long arms of 22 is not apparent. This circumstance has been referred to as a *masked Ph chromosome* or *masked translocation* because the 22q– is not evident by microscopic examination,^{325,326} although t(9;22) may occur as judged by banding techniques or molecular probes.³²⁷

Approximately 10 percent of patients have a deletion of the derivative 9 chromosome adjacent to the chromosome breakpoint. Although this deletion is thought to be an important factor in resistance to drug effects with IFN therapy, it does not appear to be significant with the use of imatinib.²¹⁴

Molecular Probes In a small proportion of patients with a clinical disease analogous to CML, cytogenetic studies do not disclose a classic, variant, or masked Ph chromosome. In these cases, use of a panel of restriction enzymes and Southern blot analyses with a molecular probe for the breakpoint cluster region on chromosome 22 nearly always detects rearrangement of fragments. This finding has led to the conclusion that almost all cases of CML have an abnormality of the long arm of chromosome number 22 (*BCR* rearrangement).³²⁸⁻³³² Ph chromosome-negative CML cells with *BCR* rearrangement can express p210^{*BCR-ABL1*}, and such patients have a clinical course similar to Ph chromosome-positive CML.^{328,333-336}

The ability to identify the molecular consequences of the t(9;22), that is, *BCR* rearrangement, mRNA transcripts of the mutant fusion gene, and p210^{*BCR-ABL1*}, has resulted in diagnostic tests supplementary to cytogenetic analysis.³³² These tests include Southern blot analysis of *BCR* rearrangement,³³⁴⁻³³⁸ polymerase chain reaction (PCR) amplification of the abnormal mRNA,³³⁹ and a less complex variation on the latter, a hybridization protection assay.³⁴⁰

PCR can achieve a sensitivity of one positive cell in approximately 500,000 to one million cells. This extreme sensitivity requires special care in analysis and the inclusion of negative controls.³⁴¹⁻³⁴⁴ Fusions e13a3, e14a3, and e19a2 are not detectable with standard PCR primers.^{344A}

A multicolor FISH method to detect the *BCR-ABL1* fusion in patients with CML is a rapid and sensitive alternative to Southern blot and PCR-dependent methods.³⁴⁵ For diagnostic purposes, FISH is simple, accurate, and sensitive, and can detect the various molecular fusions (e.g., e13a2, e14a2, e1a2).³⁴⁶⁻³⁵⁰ Interphase FISH is faster and more sensitive than cytogenetics in identifying the Ph chromosome. If

Figure 89–8. Translocations involved in chronic myelogenous leukemia. The positions of the *ABL* gene in each of the chromosomes before and after the translocation are noted. The origin of the chromosomal segments in each of the translocated chromosomes is indicated by a bracket on the side of the chromosome. (Reproduced with permission from Rosson D, Reddy EP: Activation of the *abl* oncogene and its involvement in chromosomal translocations in human leukemia. *Mutat Res* 1988 May;195(3):231–243.)

the concentration of CML cells is very low, interphase FISH may not detect *BCR-ABL1*, so it has limited use for detecting minimal residual disease.³⁵¹ Hypermetaphase FISH allows analysis of up to 500 metaphases per sample in 1 day. Several factors influence the false-positive and false-negative rates of FISH identification of *BCR-ABL1*, including definition of a fusion signal, nuclear size, and the genomic position of the *ABL1* breakpoint.³⁵² Double *BCR-ABL* fusion signals (double-fusion [D]-FISH) have been proposed as being more accurate than the fusion signal used in dual color (single-fusion) S-FISH, because in the latter case a small percentage of the normal *BCR* and *ABL1* signals overlap.³⁵³

The frequency of cytogenetic analysis can be reduced if patients are monitored by molecular methods such as competitive reverse transcriptase (RT)-PCR. Molecular analyses can be performed on blood samples and therefore are much easier to use than cytogenetic analysis of marrow cell metaphases. Quantitative RT-PCR is the method of choice for monitoring patients for residual disease or reappearance of disease after marrow transplantation and for following response to TKIs once routine cytogenetics and FISH are negative for the Ph chromosome. Competitive PCR can detect reappearance of or increasing levels of *BCR-ABL1* RNA transcripts prior to clinical relapse in patients after transplantation.^{354–356}

Chemical Abnormalities

Uric Acid An increased production of uric acid with hyperuricemia and hyperuricosuria occurs in untreated CML.³⁵⁷ Uric acid excretion often is two to three times normal in patients with CML. If aggressive therapy leads to rapid cell lysis, excretion of the additional purine load may produce urinary tract blockage from uric acid precipitates. Formation of urinary urate stones is common in patients with CML, and some patients with latent gout may develop acute gouty arthritis or uric acid nephropathy.³⁵⁸ The likelihood of complications from urate overproduction is greatly increased by starvation, acidosis, renal disease, or diuretic drug therapy.

Serum Vitamin B₁₂-Binding Proteins and Vitamin B₁₂ Neutrophils contain vitamin B₁₂-binding proteins, including transcobalamins I and III (synonym: R-type B₁₂-binding protein or cobalophilin).^{359–362} Patients with myeloproliferative neoplasms have an increased serum level of vitamin B₁₂-binding capacity, and the source of the protein is principally mature neutrophilic granulocytes.^{359,360} The increase in transcobalamin level and the resultant increase in vitamin B₁₂ concentration are particularly notable in CML, although any increase in the number of neutrophilic granulocytes, as in leukemoid reactions, can be accompanied by an increase in serum vitamin B₁₂-binding protein levels and vitamin B₁₂ concentration.³⁶² The serum vitamin B₁₂ level in CML patients is increased on average to more than 10 times normal.³⁶³ The increase is proportional to the total leukocyte count in untreated patients and falls toward normal levels with treatment, although increased vitamin B₁₂ levels commonly persist even after the white cell count is lowered to near normal with therapy.

Pernicious anemia and CML may rarely coexist. In this situation, the tissues are vitamin B₁₂ deficient, but the serum vitamin B₁₂ level may be normal because of the elevated level of transcobalamin I, a binder with a very high affinity for vitamin B₁₂.³⁶³

Whole Blood Histamine Mean histamine levels are markedly increased in patients in chronic phase (median: approximately 5000 ng/mL) compared to healthy individuals (median: approximately 50 ng/mL); and, this elevation is correlated with the blood basophil count.³⁶⁴ Cases of exaggerated basophilia and disabling pruritus, urticaria, and gastric hyperacidity have occurred, associated with enormous increases (several hundredfold) of blood histamine concentration.^{365,366}

Serum Lactic Dehydrogenase, Potassium, Calcium, and Cholesterol The level of serum lactic acid dehydrogenase (LDH) is elevated in CML.³⁶⁷ Pseudohyperkalemia resulting from the release of potassium from white cells during clotting³⁶⁸ and spurious hypoxemia or pseudohypoglycemia from *in vitro* utilization of oxygen or glucose by granulocytes can occur. Hypercalcemia³⁶⁹ or hypokalemia³⁷⁰ has

occurred during the chronic phase of the disease, but such complications are very rare until the disorder transforms to acute leukemia. Elevated serum and urinary lysozyme levels are features of leukemia with greater monocytic components and are not features of CML.³⁷¹ Serum cholesterol is decreased in patients with CML.^{372,373}

Serum Angiogenic Factors Angiogenin, endoglin (CD105), vascular endothelial growth factor (VEGF), β -fibroblast growth factor, and hepatocyte growth factor are increased strikingly in the serum of CML patients.^{307,308,374,375}

● SPECIAL CLINICAL FEATURES

BCR-ABL1-POSITIVE THROMBOCYTHEMIA

Either of two syndromes—thrombocytopenia with the Ph chromosome and *BCR-ABL1* rearrangement or thrombocytopenia without a Ph chromosome but with the *BCR-ABL1* rearrangement—may precede the overt signs of CML or its accelerated phase.^{376–379} In general, the disease closely mimics classic essential thrombocytopenia initially: marked platelet elevation, extreme megakaryocytic hyperplasia, normal or mildly elevated white cell count, no or very slight myeloid immaturity in the blood, and minimal anemia. Minor bleeding, such as epistaxis, erythromelalgia, or signs of thrombosis, such as cerebral or limb ischemia, are occasionally present. In some cases, the absolute basophil count is mildly elevated. Approximately 5 percent of patients with apparent essential thrombocytopenia have a Ph chromosome.³⁷⁶ In another study, two of 121 patients with essential thrombocytopenia had *BCR-ABL1* transcripts, and one of these patients also had a Ph chromosome in the marrow cells, whereas in a different study, four of 32 patients with thrombocytopenia had low levels of *BCR-ABL1* transcripts in blood cells. Approximately one in 20 patients with CML present with the features of essential thrombocytopenia.^{377,378} Evolution to blast crisis may occur.^{380,381}

NEUTROPHILIC CHRONIC MYELOGENOUS LEUKEMIA

A rare variant of *BCR-ABL1*-positive CML has been described in which the elevated white cell count is composed principally of mature neutrophils.^{382,383} The white cell count is lower (on average: 30 to 50 $\times 10^9/L$) at the time of diagnosis than is the case with classic CML (median: 100 to 150 $\times 10^9/L$). Moreover, patients with neutrophilic CML usually do not have basophilia, notable myeloid immaturity in the blood, prominent splenomegaly, or low leukocyte alkaline phosphatase scores. The cells of these patients have the Ph chromosome but have an unusual *BCR-ABL1* fusion gene in that the breakpoint in the *BCR* gene is between exons 19 and 20. This breakpoint location results in fusion of most of the *BCR* gene with *ABL1* (e19a2 type *BCR-ABL1*), which leads to a larger fusion protein (230 kDa) compared to the fusion protein in classic CML (210 kDa; see Fig. 89–3). This correlation between genotype and phenotype has not been observed in all cases.³⁸⁴ This variant usually has an indolent course, which may be the result of very low levels of mRNA for p230 and the undetectable or barely detectable p230 protein in cells.³⁸⁵

MINOR-BCR BREAKPOINT-POSITIVE CHRONIC MYELOGENOUS LEUKEMIA

A small portion of patients with *BCR-ABL1*-positive CML have the breakpoint on the *BCR* gene in the first intron (*m-bcr*), resulting in a 190-kDa fusion protein instead of the classic 210-kDa protein observed in most patients with CML (see Fig. 89–3). The *m-bcr* molecular lesion is similar to that observed in approximately 60 percent of patients

with *BCR* rearrangement-positive ALL. In patients with *m-bcr* CML, monocytes are more prominent, the white cell count is lower on average, and basophilia and splenomegaly are less prominent than in disease with classic *BCR* breakpoint (*M-bcr*). The few reported cases had a short interval before either myeloid or lymphoid blast transformation developed.^{386,387}

HYPERLEUKOCYTOSIS

Approximately 15 percent of patients present with symptoms or signs referable to leukostasis as a result of the intravascular flow-impeding effects of white cell counts greater than 300 $\times 10^9/L$.²⁴⁹ Hyperleukocytosis is more prevalent in children with Ph chromosome-positive CML.²⁵⁰ The effects of total leukocyte counts from 300 to 800 $\times 10^9/L$ include impaired circulation of the lung, central nervous system, special sensory organs, and penis, resulting in some combination of tachypnea, dyspnea, cyanosis, dizziness, slurred speech, delirium, stupor, visual blurring, diplopia, retinal vein distention, retinal hemorrhages, pilledema, tinnitus, impaired hearing, and priapism.²⁵¹ In asymptomatic patients with hyperleukocytosis, initial treatment with hydration and hydroxyurea usually can be used to decrease the white cell count. Hydroxyurea treatment should be designed to accomplish a gradual decrease in white cell count over a few days so as to avoid the tumor lysis syndrome. If signs of hyperleukocytosis are present, hydration, leukapheresis, and hydroxyurea can be used simultaneously; hydroxyurea dose should be selected to avoid exaggerated tumor lysis.

CONCURRENCE OF LYMPHOID MALIGNANCIES

CML may emerge in patients with established chronic lymphocytic leukemia (CLL).^{388–390} A few patients have presented with simultaneous occurrence of the two diseases.^{391,392} A single case of lymphocytic leukemia reaction simulating CLL that regressed as CML emerged has been reported.³⁹³ In some cases, the CLL lymphocytes did not contain the Ph chromosome, whereas the CML cells did, suggesting the presence of two independent clonal disorders.^{388,389,393,394} In other cases, the Ph chromosome was present in the myeloid and lymphoid cells, indicating a common origin.³⁹² Patients may present with Ph chromosome-positive acute lymphoblastic leukemia and, following chemotherapy-induced remission, develop the features of typical CML.³⁹⁵

● DIFFERENTIAL DIAGNOSIS

DISEASES MIMICKING CHRONIC MYELOGENOUS LEUKEMIA

The diagnosis of CML is made based on the characteristic granulocytosis, white cell differential count, increased absolute basophil count, and splenomegaly coupled with the presence of the Ph chromosome or its variants (90 percent of patients) or a *BCR* rearrangement on chromosome 22 (>95 percent of patients).

Patients with other chronic hematopoietic stem cell diseases, such as polycythemia vera, essential thrombocytopenia, or primary myelofibrosis, only occasionally have closely overlapping features. For example, the total white cell count is greater than 30 $\times 10^9/L$ in more than 90 percent of patients with CML and increases inexorably over weeks or months of observation, whereas the total white cell count is less than 30 $\times 10^9/L$ in more than 90 percent of patients with the three other classic chronic clonal myeloid diseases and usually does not change significantly over months to years. Polycythemia vera is associated with increased red cell mass and hemoglobin concentration and displays clinical signs of plethora; CML does not have these features. Patients

with primary myelofibrosis invariably have marked teardrop poikilocytes and other severe red cell shape, size, and chromicity changes, as well as prominent nucleated red cells in the blood; CML rarely has these features. Patients with essential thrombocythemia have a platelet count greater than $450 \times 10^9/L$ and usually only mild neutrophilia ($<20 \times 10^9/L$); the slight neutrophilia distinguishes it from the proportion (approximately 25 percent) of CML patients with platelet counts greater than $450 \times 10^9/L$, who at the time of diagnosis have white cell counts above $25 \times 10^9/L$. In addition, patients with the clinical features of polycythemia vera or primary myelofibrosis do not have the Ph chromosome or *BCR* rearrangement in their blood and marrow cells, except in extremely rare cases. A very small proportion of patients with apparent essential thrombocythemia has *BCR-ABL1* transcripts in their marrow and blood cells, and occasionally a Ph chromosome and may represent an atypical initial phase of CML (see “*BCR-ABL1*-Positive Thrombocythemia” above). The presence of a mutation in the *JAK2* gene in more than 95 percent of patients with polycythemia vera is an important distinguishing feature (Chap. 84). The blood cells of approximately 50 percent of patients with primary myelofibrosis or essential thrombocythemia carry the *JAK2* gene mutation and in those with primary myelofibrosis who do not, a significant proportion have a mutation in the calreticulin or the *c-MPL* gene (Chap. 86).

Increased awareness of the features of related disorders, such as chronic myelomonocytic leukemia (CMML) and chronic neutrophilic leukemia, and an appreciation that older patients are prone to atypical clonal myeloid diseases, have minimized the inappropriate diagnosis of Ph chromosome–negative CML, which should be avoided unless the clinical features are characteristic of classic CML and a masked Ph chromosome or *BCR* rearrangement is not found.

Reactive leukocytosis can occur with absolute neutrophil counts of 30 to $100 \times 10^9/L$. Usually these leukemoid reactions occur in the setting of an overt inflammatory disease (e.g., pancreatitis), cancer (e.g., lung), or infection (e.g., pneumococcal pneumonia). If the incitant is not apparent, the absence of granulocytic immaturity, basophilia, or splenomegaly, and the absence of *BCR/ABL1* in blood cells virtually eliminates classic CML as a consideration.

The precise diagnosis of CML is helpful in estimating the patient's prognosis, identifying the utility of TKIs, and assessing the timing of special therapies, such as allogeneic hematopoietic stem cell transplantation.

Ph CHROMOSOME-POSITIVE CLONAL MYELOID DISEASES AND APLASTIC ANEMIA

The Ph chromosome has been found rarely in patients with apparent polycythemia vera,³⁹⁶ polycythemia vera that later evolves into Ph chromosome–positive CML,^{397–399} primary myelofibrosis,^{400,401} and myelodysplastic syndrome (MDS).^{402,403} Molecular studies to determine the presence of the *BCR-ABL1* were not performed in cases reported before 1985. Essential thrombocythemia with a Ph chromosome and/or *BCR-ABL1* rearrangement in blood cells was discussed earlier (see “Special Clinical Features” above). Rare cases of aplastic anemia have presented with *BCR-ABL1*-positive cells or have evolved into *BCR-ABL1* CML.^{404,405}

THERAPY

HYPERURICEMIA

Hyperuricemia and hyperuricosuria are frequent features of CML at diagnosis or in relapse.⁴⁰⁶ The need for treatment of hyperuricemia is a function of the elevated pretreatment serum uric acid concentration,

blood white cell concentration, spleen size, and dose of cytolytic therapy planned. If these variables suggest a high risk for a significant amount of cell lysis, allopurinol 300 mg/day orally and adequate hydration to maintain a good urine flow should be instituted prior to therapy. Allopurinol is associated with a high frequency of allergic skin reactions and should be discontinued after the blood leukocyte count and spleen size have decreased and the risk of exaggerated cell lysis has passed. If hyperuricemia is extreme, usually over 9 mg/dL, rasburicase can be administered.⁴⁰⁷ Rasburicase is a recombinant urate oxidase that converts uric acid to allantoin. Rasburicase, unlike allopurinol, reduces the uric acid pool very rapidly, does not result in the accumulation of xanthine or hypoxanthine, and does not require alkalinization of urine facilitating phosphate excretion.⁴⁰⁸ Although the manufacturer recommends a dose every day for 5 days, several reports have indicated that one injection will produce a rapid and sustained decrease in serum uric acid, significantly decreasing the cost of therapy.⁴⁰⁹ Another alternative is to use allopurinol for a few days after one injection of rasburicase. A dose of 0.2 mg/kg of ideal body weight of rasburicase intravenously has been used.⁴¹⁰

INITIAL CYTOREDUCTION THERAPY

A TKI is now used as initial therapy in patients with CML. In cases where the white cell count is markedly elevated, hydroxyurea can be used prior to or in conjunction with a TKI. If rapid cytoreduction is required because of signs of the hyperleukocytic syndrome, leukapheresis and hydroxyurea often are combined.

Leukapheresis

Leukapheresis can control CML only temporarily. For this reason, it is rarely used in chronic phase CML and is useful in only two types of patients: the hyperleukocytic patient in whom rapid cytoreduction can reverse symptoms and signs of leukostasis (e.g., stupor, hypoxia, tinnitus, papilledema, priapism),^{249–251} and in the pregnant patient with CML who can be controlled by leukapheresis treatment without other therapy either during the early months of pregnancy when therapy poses a higher risk to the fetus or, in some cases, throughout the pregnancy.^{411,412} Because of the large body burden of leukocytes in marrow, blood, and spleen, and the high proliferative rate in CML, leukocyte reduction by apheresis is less efficient than in other types of leukemia.^{249,251} Leukapheresis reduces the burden of tumor cells subject to chemotherapeutically induced cytotoxicity and thus the production and the excretion of uric acid. In hyperleukocytic nonpregnant patients, leukapheresis is best used in conjunction with hydroxyurea to ensure rapid and optimal reduction in white cell count.

Hydroxyurea

Hydroxyurea 1 to 6 g/day orally, depending on the height of the white cell count, can be used to initiate elective therapy.⁴¹³ Urgent treatment of extraordinary total white cell counts may require higher doses. The dose of hydroxyurea should be decreased as the total white cell count decreases and usually is given at 1 to 2 g/day when the total white cell count reaches $20 \times 10^9/L$. The drug should be temporarily discontinued if the white cell count drops below $5 \times 10^9/L$. If hydroxyurea is being used in combination with a TKI, it is usually tapered and discontinued once a hematologic response to the TKI is observed.

Anagrelide

Anagrelide can be used for platelet reduction in patients who present with elevated platelet counts. This agent acts directly to decrease megakaryocyte mass, and it can lead to a precipitous fall in platelet counts. In occasional patients who still have significant thrombocythemia after a

TKI is initiated, combination with anagrelide is associated with a normalization of platelet counts.⁴¹⁴

INITIAL THERAPY WITH A TYROSINE KINASE INHIBITOR

Imatinib mesylate (imatinib) was the first TKI developed, and it was approved by the FDA for initial therapy of CML in 2002. Subsequently, two second-generation TKIs, nilotinib and dasatinib, were approved for initial therapy in 2010. This approval was based upon superior cytogenetic and molecular response rates with nilotinib and dasatinib at benchmark time points and lower rates of conversion to accelerated

or blast phase as compared with imatinib. Thus far, an overall survival advantage of dasatinib or nilotinib compared with imatinib has not been shown.⁴¹⁵ Third-generation TKIs, bosutinib and ponatinib, are under study. Table 89–2 compares these inhibitors.

Imatinib Patients with newly diagnosed, chronic phase CML can be started on imatinib, 400 mg/day by mouth. The goal of imatinib therapy is to decrease the cells bearing the t(9;22) translocation (leukemic cells) to the lowest levels possible, during which process normal (polyclonal) hematopoiesis is restored. The efficacy of imatinib is judged by measuring three benchmarks: hematologic response, cytogenetic response, and molecular response as defined in Table 89–3.^{416,417} These benchmarks are used to determine its maximal therapeutic effect. The time to achieve

TABLE 89–2. Comparison of Tyrosine Kinase Inhibitors

	Imatinib (Gleevec)	Nilotinib (Tasigna)	Dasatinib (Sprycel)	Bosutinib (Bosulif)	Ponatinib (Iclusig)
Indications	First-line therapy (CP, AP, BP); relapsed/refractory Ph+ ALL	First-line therapy (CP), resistance or intolerance to imatinib (CP and AP)	First-line therapy (CP), resistance or intolerance to other TKIs (CP, AP, or BP); Ph+ ALL with resistance or intolerance to prior therapy	Second-line therapy (CP, AP, BP with resistance or intolerance)	Resistance or intolerance to prior TKI or Ph+ ALL resistant or intolerant to all other TKIs; all T3151 + cases ¹
Usual dosing	CP 400 mg/day AP/BP/progression 600–800 mg/day	CP 300 mg BID AP/BP 400 mg BID	CP 100 mg/day AP/BP 140 mg/day	500 mg/day	45 mg/day
Common toxicities (nonhematologic)	GI disturbance, edema (including periorbital), muscle cramps, arthralgias, Hypophosphatemia, rash	Rash, GI disturbances, elevated lipase, hyperglycemia, low phosphorus, increased LFTs	Edema, pleural effusions, GI symptoms, rash, low phosphorus	GI (diarrhea), rash, edema, fatigue, low phosphorus, elevated LFTs	HBP, rash, GI, fatigue, headache
Other significant toxicities	Elevated LFTs (usually appear in first month); rare cardiac toxicity reported	Peripheral vascular disease, PT prolongation, pancreatitis	Pulmonary arterial hypertension, QTc prolongation		Arterial and venous thrombosis, pancreatitis, liver failure, ocular toxicity, cardiac failure
Drug–drug interactions	CYP3A4 inducers decrease levels CYP3A4 inhibitors may increase levels It is an inhibitor of CYP3A4 and CYP2D6 Pgp substrate	CYP3A4 inhibitors increase levels CYP3A4 inducers may decrease levels Inhibitor of CYP3A4, CYP2C8, CYP2C9, CYP2D6 Induces CYP2B6, CYP2C8, and CYP2C9	CYP3A4 inhibitors increase levels CYP3A4 inducer decrease levels Antacids decrease levels H ₂ antagonists/proton pump inhibitors decrease levels	CYP3A inhibitors and inducers may alter levels Acid-reducing medication may lower levels	Strong CYP3A inhibitors increased serum levels
Administration considerations	Taken with food	Taken on empty stomach; avoid food 2 hours before and 2 hours after dose	Can be taken with or without a meal	Taken with food	Taken with and without food
Black box warnings	None	QT prolongation and sudden death	None	None	Arterial thrombosis; hepatotoxicity
Other considerations	Approved in pediatric patients (340 mg/m ² /day) in CP	Keep potassium, Mg, calcium, phosphorus repleted	Ascites and pericardial effusion can also occur; has CSF penetration		Has activity with T3151 mutations; Available in U.S. through ARIAD PASS program

ALL, acute lymphocytic leukemia; AP, accelerated phase; BP, blast phase; CP, chronic phase; CSF, cerebrospinal fluid; CYP, cytochrome P450; GI, gastrointestinal; HBP, high blood pressure; LFT, liver function tests; Pgp, P-glycoprotein; PT, prothrombin time; TKI, tyrosine kinase inhibitor. All information is from the commercial package insert of the TKIs as listed.

TABLE 89-3. Definition of a Treatment Response to a Tyrosine Kinase Inhibitor

Complete hematologic response (CHR)	White cell count $<10 \times 10^9/L$, platelet count $<450 \times 10^9/L$, no immature myeloid cells in the blood, and disappearance of all signs and symptoms related to leukemia (including palpable splenomegaly) lasting for at least 4 weeks.
Minor cytogenetic response (mCyR)	$>35\%$ of cell metaphases are Philadelphia (Ph) chromosome-positive by cytogenetic analysis of marrow cells.
Partial cytogenetic response (pCyR)	1–35% of cell metaphases are Ph chromosome-positive by cytogenetic analysis of marrow cells.
Major cytogenetic response (MCyR)	$<35\%$ of cell metaphases contain the Ph chromosome by cytogenetic analysis of marrow cells.
Complete cytogenetic response (CCyR)	No cells containing the Ph chromosome by cytogenetic analysis of marrow cells.
Major molecular response (MMR)	<i>BCR-ABL1/ABL1</i> ratio $<0.1\%$ or a 3-log reduction in quantitative polymerase chain reaction (qPCR) signal from mean pretreatment baseline value, if International Standard (IS)-based PCR not available.
Complete molecular response (CMR)	<i>BCR-ABL1</i> mRNA levels undetectable by qPCR with assay sensitivity at least 4.5 logs below baseline (IS).

a maximal effect is variable, but as long as a patient is having a continued reduction in the size of the leukemic clone as judged by cytogenetic or PCR measurements, and has met response benchmarks, the drug is continued at 400 mg/day. If the patient stops responding before a complete cytogenetic remission or complete molecular remission is achieved, the dose can be increased to 600 mg/day or to 800 mg/day (400 mg every 12 hours), if tolerated. Alternatively, another TKI can be used. About two-thirds of patients who do not have a significant hematologic response or who relapse while receiving imatinib at a dose of 400 mg/day achieve a complete or partial hematologic response with higher doses, but few cytogenetic responses occur.⁴¹⁸ Some patients without a cytogenetic response can enter a partial or complete cytogenetic response (CCyR) with higher doses of imatinib. Unfortunately, the responses to higher doses of imatinib in patients lacking a hematologic or cytogenetic response at 400 mg/day usually are transient.^{419,420}

Several studies have examined use of imatinib at doses higher than 400 mg/day. Patients with newly diagnosed chronic phase CML treated with imatinib, 800 mg/day, administered in two 400-mg doses, every 12 hours, had a frequency of 90 percent CCyR, and 96 percent had at least a major cytogenetic response (MCyR). At a median of 15 months, no patients had progressed and 63 percent showed blood *BCR-ABL1/ABL1* percentage ratios of less than 0.05 percent. Twenty-eight percent

of patients had undetectable *BCR-ABL1* blood levels.⁴²¹ In one trial, major molecular remission (MMR) at 12 and 24 months was higher in those receiving doses of imatinib greater than 600 mg/day.⁴²² In another trial, patients receiving 400 mg twice per day had a MCyR of 90 and 96 percent at 12 and 18 months, respectively. MMR rates were 48 percent and 54 percent at 6 and 12 months, respectively. These results compared favorably to historical data in the IRIS (International Randomized Study of Interferon) trial studying 400 mg/day of imatinib, but myelosuppression, rash, fatigue, and musculoskeletal symptoms were greater with these higher doses. Responses were, also, more rapid with the higher doses. More edema, gastrointestinal symptoms, rash, and myelosuppression occurred at the higher doses.⁴²³ Despite these reports the current starting dose is customarily 400 mg/day, balancing both effectiveness and tolerability in newly diagnosed patients. Moreover, the more rapid response with higher doses of imatinib may not translate into better long-term results.^{424,425} For example, in another trial, MMR and CCyR at 12 months were not significantly different between standard and high-dose patients, although patients in higher-risk categories based on Sokal scores, fared better with high-dose imatinib.⁴²⁴ (See “Course and Prognosis” below for an explanation of the Sokal Score.)

Doses of imatinib lower than 400 mg/day result in fewer CCyR and a shorter duration of that response. Patients who are older and who have lower body weight may only tolerate a lower dose, but they are less likely to achieve a CCyR.⁴²⁶ If however, a patient is on a lower dose (e.g., 300 mg/day) for a special reason (body size or tolerance level) and achieves a complete hematologic response (CHR) and CCyR within 12 months of onset of therapy, acceptable outcomes without excess toxicity can result.⁴²⁷

Some patients have been followed for up to 8 years on imatinib in the IRIS trial (IFN vs. STI571).⁴²⁸ With median followup of 60 months, the best observed MCyR and CCyR rates were 89 percent and 82 percent, respectively. Only 7 percent had progressed to accelerated or blast phase, and overall survival rate was 89 percent. The best MMR rate was 86 percent during the 8-year followup. No patient with an MMR at 12 months progressed to accelerated or blast phase. By 8 years of follow up on the IRIS trial, 22 percent of patients had discontinued imatinib treatment because of an unsatisfactory response or toxicity, and only 55 percent remained on study. The 5-year probability of remaining in MCyR while receiving imatinib was approximately 60 percent. Achieving a CCyR correlated with progression-free survival, but achieving a MMR conferred no further survival benefit.⁴²⁹

Use of Imatinib in Patients with Variant Chromosomal Translocations or Breakpoints

Patients with variant Ph chromosome translocations have a similar prognosis to that of patients with classic Ph chromosome translocations who are treated with imatinib.⁴³⁰ (See Fig. 89-3 for a diagram of breakpoints.) Patients with the e13a2, p210*BCR-ABL* translocation respond well to imatinib, with similar rates of complete cytogenetic remission.⁴³¹ The e13a2 transcript may be more sensitive to imatinib than the e14a2 transcript.⁴³² In a patient with both e1a2 and e14a2 fusion transcripts, only the p210 e14a2 transcript disappeared, whereas the e1a2 transcript persisted during progression to blast phase. No mutation in the kinase domain of *ABL1* was found.⁴³³ Thus, different clones in a patient may have a different sensitivity to imatinib. Deletions of the derivative chromosome 9 do not influence the response and outcomes in CML chronic phase when using imatinib.⁴³⁴

Response to Imatinib in Children and Older Patients

More than 80 percent of children with chronic phase CML who are treated with imatinib, 260 to 570 mg/m², enter a complete cytogenetic remission. Imatinib is now approved for use in pediatric patients.

Weight gain is the most common side effect of imatinib.⁴³⁵ In patients who were older than age 60 years, similar cytogenetic response rates and survival rates were noted as in younger patients in the late chronic phase who were treated concurrently, suggesting that age is not usually a factor in response.^{436,437}

Side Effects and Special Treatment Considerations

Imatinib is usually tolerated. Most adverse effects are manageable and seldom require permanent cessation of therapy. Reduction to subtherapeutic doses is not recommended; it is better to interrupt therapy for a time.⁴³⁸

Myelosuppression is common, especially at treatment onset when the CML clone accounts for most of the blood cells. Dose reduction to less than 300 mg/day is not advisable for myelosuppression. The drug should be stopped until blood counts recover. G-CSF or GM-CSF can prevent or treat neutropenia.^{439,440} Platelet transfusion may be used for severe thrombocytopenia. Patients with imatinib-induced chronic cytopenias have inferior responses.⁴⁴¹ Myelosuppression is an independent adverse factor for achieving cytogenetic responses with imatinib.⁴⁴² Erythropoiesis-stimulating agents may be used to raise hemoglobin levels, and their use does not appear to affect CML outcomes, but may increase the risk of thrombosis.⁴⁴³ Severe irreversible marrow aplasias after imatinib exposure can occur.⁴⁴⁴

The main side effects noted with imatinib include fatigue, edema, nausea, diarrhea, muscle cramps, and rash.⁴⁴⁵ Elevated hepatic transaminases can occur. Mild transaminase elevations often respond to glucocorticoid use.⁴⁴⁶ Hepatotoxicity is uncommon, occurring in approximately 3 percent of patients, usually within 6 months of onset of imatinib use. Acute liver failure has been described.⁴⁴⁷ The severe periorbital edema occasionally observed is postulated to be a drug effect on the function of platelet-derived growth factor receptor (PDGFR) and KIT expressed by dermal dendrocytes. Surgical decompression of severe edema rarely has been required.⁴⁴⁸ Although no effects on spermatogenesis have been reported, women of childbearing age are at risk of teratogenic effects on their fetus.⁴⁴⁸

Weight gain is associated with imatinib use.⁴⁴⁹ Patients with renal impairment require lower doses of imatinib.⁴⁵⁰ Hypophosphatemia⁴⁵¹ and altered bone and mineral metabolism have occurred.^{452,453} Cutaneous reactions with imatinib therapy occur in approximately 15 percent of patients.⁴⁵⁴ Except for severe reactions (approximately 5 percent of patients), such as Stevens-Johnson syndrome, exfoliative dermatitis, and erythema multiforme, cutaneous reactions rarely require permanent discontinuation of therapy. With milder reactions, concomitant glucocorticoid therapy or brief discontinuation of imatinib with gradual reintroduction at a lower dose and then a gradual increase in dose can be accomplished.^{456,457} With very mild cases, concurrent treatment with antihistamine or other symptomatic therapy may be successful. Oral desensitization regimens have been described that allow some patients to continue imatinib therapy. Hair depigmentation⁴⁵⁸ and hypopigmentation of the skin,⁴⁵⁹ probably related to the inhibition of the KIT receptor tyrosine kinase by imatinib, have been reported.

Other Effects of Imatinib

Imatinib has been found to cause regression of marrow fibrosis.⁴⁶⁰ One study found that the extent of marrow fibrosis in CML is not a prognostic factor with imatinib therapy,⁴⁶¹ whereas another study observed that although imatinib reverses marrow fibrosis in patients with CML, it does not change the unfavorable prognosis associated with fibrosis.⁴⁶²

Imatinib reverses exaggerated VEGF secretion in patients with CML,⁴⁶³ and it may reverse exaggerated marrow angiogenesis.⁴⁶⁴ It can reduce marrow cellularity and normalize morphologic features regardless of cytogenetic response. *BCR-ABL1*-positive cells persist in patients despite prolonged treatment responses with imatinib.⁴⁶⁵

Pharmacokinetic Considerations During Imatinib Therapy

Mean plasma trough concentration of imatinib and its metabolite, CGP74588, obtained at about 1 month (presumptive steady-state) was 979 ± 530 ng/mL. The rate of CCyR and MMR was higher within the highest quartiles of imatinib trough levels.⁴⁶⁶ Some therapists suggest that imatinib plasma levels be checked in cases of suboptimal response in order to adjust the dose, but access to this monitoring is not routinely available.⁴⁶⁷ Comedications and population covariates, such as body weight and white cell count, had no, or minimal, effect on imatinib clearance.⁴⁶⁸ Patients with CML on hemodialysis have been successfully treated with imatinib.⁴⁶⁹ Therapy interruptions and nonadherence with oral imatinib usage are common, and patient education and close monitoring are important to ensure compliance.⁴⁷⁰

Initiation of Therapy with Newer Tyrosine Kinase Inhibitors

Dasatinib Dasatinib is a second-generation oral BCR-ABL1 inhibitor with dual inhibition of ABL1 and SRC.⁴⁷¹ It can bind to both the active and inactive conformation of the *ABL1* kinase domain, so it may be affected by mutations resulting in resistance.⁴⁷¹

Dasatinib was first studied for use in initial therapy in a phase II trial that accrued 62 patients. Ninety-eight percent achieved a CCyR, and the median time to CCyR was 3 months. The MMR rate was 82 percent. Responses were durable, and the recommended treatment schedule based on a safety profile was 100 mg, once daily.⁴⁷² A randomized, phase III trial compared the efficacy of dasatinib to imatinib.⁴⁷³ In this study, 259 patients received dasatinib, 100 mg/day, and 260 received imatinib, 400 mg/day. After 12 months of followup, the rates of CCyR by 3, 6, and 9 months were 54, 73, and 78 percent, respectively, for patients on dasatinib as compared to 31, 59, and 67 percent, respectively, for those on imatinib. The 24-month CCyR was 80 percent for patients using dasatinib, as compared to 74 percent for those on imatinib. The MMR showed a similar trend, and the median time to MMR was 15 months for those using dasatinib, compared to 36 months for those using imatinib.

Long-term followup data have confirmed faster and deeper responses to dasatinib as compared to imatinib.⁴⁷⁴ At 4 years, 76 percent of dasatinib-treated patients had attained a MMR (*BCR/ABL1* <0.1 percent) as compared to 63 percent using imatinib. At 3, 6, and 12 months, more patients achieved molecular responses using dasatinib than those using imatinib. There were fewer patients who progressed to accelerated or blast phase using dasatinib as compared to imatinib. To date, there is no difference in progression-free survival or overall survival between the two groups.⁴⁷⁴ In a randomized study, with a minimal followup of 3 years, the proportion of patients with *BCR-ABL1* transcript levels less than 10 percent was higher in those using dasatinib as compared to those using imatinib.⁴⁷⁵ Better responses were observed at 3, 6, and 12 months in the patients using dasatinib. The achievement of an early molecular response was predictive of improved progression-free and overall survival.⁴⁷⁶

Toxicity of Dasatinib Most grade 3 or 4 adverse events with dasatinib are hematologic and all cell lines can be affected. Some patients may have bleeding from inhibition of platelet aggregation.⁴⁷⁷ Adverse events noted less frequently with dasatinib than imatinib include nausea, vomiting, myalgia, rash, and fluid retention, including superficial edema. Pleural effusions can be seen with dasatinib use. In one trial, 14 percent of patients had grade 1 or 2 pleural effusions at 24 months, but grade 3 or 4 effusions occurred in only 2 patients. This toxicity did not affect drug efficacy. Dasatinib may also increase the risk of pulmonary arterial hypertension at any time, and this is an indication to discontinue dasatinib.⁴⁷⁸ Dasatinib may prolong the QTc interval, and it should be used with caution in those who have long QT syndrome or those taking drugs that may lengthen the QT interval.⁴⁷⁴ Hypophosphatemia was found in 7 percent of cases.⁴⁷⁴

Dasatinib is metabolized primarily by hepatic cytochrome P450 (CYP) 3A4 enzymes, so inducers of this enzyme may decrease the effective dose, and inhibitors may increase the effective dose. Increases or decreases in administered dose may be needed to compensate for these effects. Antacids can also reduce dasatinib effects.⁴⁷⁹ Lymphocytosis from the clonal expansion of NK/T cells has occurred during dasatinib treatment.⁴⁸⁰ In a population of dasatinib-treated patients with large granular lymphocyte expansion, 90 percent had T-cell receptor delta rearrangements, the functional significance of which is unknown.⁴⁸¹ Lymph node follicular hyperplasia has been noted on dasatinib therapy.⁴⁸² Unlike the case with imatinib, dasatinib cellular uptake is not affected by octamer-binding protein-1 (OCT-1) activity, which is a substrate of the efflux proteins, ABCB1 and ABCG2. Resistance to dasatinib is often found with point mutations in *ABL1* at residue 315 or 317.

Nilotinib Unlike dasatinib, nilotinib is a selective, orally bioavailable, ATP-competitive inhibitor of BCR-ABL1 which is 20 to 50 times more potent than imatinib *in vitro*.⁴⁸³ Like imatinib, it does not induce apoptosis in CD34+ CML cells.⁴⁸⁴ As with dasatinib, nilotinib was first tested as initial therapy in phase II trials,⁴⁸⁵ which were followed by a randomized phase III trial. In one phase II trial, 51 patients received nilotinib 400 mg, twice a day, and 98 percent entered CCyR and 76 percent had a MMR by 6 months.⁴⁸⁶ The phase III trial compared nilotinib, 300 mg twice daily, 400 mg twice daily, and imatinib 400 mg daily.⁴⁸⁷ At 12 months, the MMR which had been chosen as the primary end point, was 44 percent (nilotinib 300 mg dose), 43 percent (nilotinib 400 mg dose), and 22 percent (imatinib 400 mg daily). The CCyR rates were 15 percent higher with nilotinib than imatinib. The rate of progression to accelerated or blast phase was 4 percent at 1 year with imatinib and less than 1 percent with nilotinib. These improvements were observed in each prognostic group based on Sokal risk groups. The patients using either 300 or 400 mg doses had minimal differences, so in 2010, nilotinib was approved at a dose of 300 mg twice daily for initial CML therapy. At 4 years of followup, more patients using either dose of nilotinib achieved a MMR than those using imatinib (73 and 70 percent vs. 53 percent).⁴⁸⁸ The rates of progression to accelerated and blast phase were also lower for nilotinib than imatinib. The 4-year freedom-from-progression and overall-survival rates were not different between the two groups. MMR rates at 3 years were higher for those patients using nilotinib, 300 mg, twice per day, in the three risk groups of Sokal (low risk, 79 percent; intermediate risk, 76 percent; and high risk, 52 percent progression as compared to those using imatinib (65, 55, and 30 percent progression, respectively).⁴⁸⁸ There was a reduced incidence of *BCR-ABL1* mutations in in patients using nilotinib compared to those using imatinib. Nilotinib use led to fewer (less than half as many) treatment-emergent *BCR-ABL1* mutations than did imatinib treatment, and to reduced rates of progression to accelerated phase and blast crisis in patients with these mutations.⁴⁸⁹

Toxicity of Nilotinib Nilotinib is rarely associated with edema or muscle cramps. Grades 3 and 4 cytopenias were seen in 29 percent of cases in one trial.⁴⁸⁷ Grade 3 or 4 elevations in lipase, bilirubin, and hyperglycemia were observed in 17, 8, and 12 percent of patients, and hypophosphatemia was seen in 16 percent. QTc prolongation can occur, so one should monitor the electrocardiogram (EKG) readings for 7 days after starting therapy and with dose changes.⁴⁸³ Electrolyte abnormalities should be corrected at outset of treatment. Nilotinib may be associated with an increased risk of peripheral vascular disease, which may be arterial or venous.⁴⁹⁰ If thrombosis occurs, it should no longer be used for therapy.

Bosutinib and Ponatinib These TKIs are not approved for use in initial therapy. In the one trial, which compared efficacy for bosutinib, 500 mg once daily, with imatinib, 400 mg daily in newly diagnosed chronic phase patients, the primary end point of CCyR at 12 months

was 70 percent for bosutinib and 63 percent for imatinib.^{491,492} Results from followup of MMR rates, transformation rates, and durability of remission are not yet available.

Summary of Tyrosine Kinase Inhibitor Selection for Initial Therapy of Chronic Phase Chronic Myelogenous Leukemia

The goal of initial TKI therapy is to achieve a CCyR within 12 months or no later than 18 months of therapy, and to prevent progression to the accelerated or blast phase. How best to achieve these goals remains controversial. Hence, the National Comprehensive Cancer Network (NCCN) guidelines list imatinib, nilotinib, and dasatinib as all being acceptable TKIs for initial treatment of CML.⁴⁹² Many clinicians would choose a second-generation TKI, given the rapidity and depth of response and the lower rates of transformation to advanced phases of the disease, but others use imatinib because of the lack of proof of prolongation of survival with nilotinib or dasatinib. In those with intermediate- or high-risk disease as assessed by the Sokal and Hasford models (see "Course and Prognosis" below for details of these scores), nilotinib or dasatinib may be preferred over imatinib to achieve rapid, better responses—the "hit hard, hit early" approach.⁴⁹³ Thus, until survival data are available, any one of the three approved TKIs may be used for initial therapy. Choice of agent may be dependent upon cost considerations, ease of administration, patient risk scores or perceived risk,⁴⁹⁴ and the drug's side-effect profile (see Table 89–2).

Defining a Response to Tyrosine Kinase Inhibitors

Table 89–3 contains definitions of hematologic, cytogenetic, and molecular responses. The guidelines for periodic monitoring patients who are in chronic phase and receiving TKI therapy are shown in Table 89–4. The median *BCR-ABL1* levels for imatinib-treated patients can decrease over at least 5 years. Table 89–5⁴⁹⁵ lists the milestones at 3, 6, 12, and 18 months expected of patients as indicators of an appropriate response in patients treated initially with a TKI.⁴³⁴ There is variation in an individual patient's time to maximal response. Consequently, if a patient has not met those precise milestones but shows a continued decrease in the proportion of Ph chromosome–positive cells on cytogenetic examination of marrow, or if in a CCyR, a continued decrease in the level of the PCR signal for *BCR-ABL1* and is near the benchmark, the treatment can be continued. Only (1) failure to meet the benchmarks at 3, 6, or 12 months or (2) loss of response as defined as loss of a CHR or CCyR, (3) development of new cytogenetic abnormalities, (4) acquisition of a *BCR-ABL1* mutation, or (5) an increase in the *BCR-ABL1/ABL1* ratio of 1-log or more on serial RT-PCR testing or into the range associated with reappearance of the Ph chromosome on G-banding should generate a change in treatment to limit the risk of progression of the disease. Because of the variability in PCR testing, those changes should be confirmed within 1 month. Patients who have 100 percent Ph chromosome–positive cells after 6 months of therapy have a minimal chance of achieving a MCyR or CCyR and may be offered allogeneic stem cell transplantation, if applicable.^{417,496}

Achieving a cytogenetic response is associated with progression-free survival in patients treated with imatinib and is an important goal of therapy (97 percent in those with a CCyR vs. 81 percent in those without a MCyR).⁴⁹⁷ At 5 years of followup, of those patients who achieved CCyR on imatinib in the IRIS study, only 3 percent had progressed to accelerated or blast phase during treatment.⁴²⁸ A CCyR at 1 year may be the major predictor for overall survival and progression-free survival.⁴⁹⁸ In patients in chronic phase treated with imatinib, nilotinib, or dasatinib, early responses (at 3 months) in *BCR-ABL1* transcript reduction or decrease of Ph chromosome frequency predicted for better outcomes as measured by event-free or overall survival. For example, patients with less than 10 percent *BCR-ABL1*

TABLE 89-4. Guidelines for Monitoring of Patients in Chronic Phase Who are Undergoing Tyrosine Kinase Inhibitor Therapy

1. At diagnosis, before starting therapy, obtain Giemsa-banding cytogenetics and measure *BCR-ABL1* transcript numbers by qPCR using marrow cells. If marrow cannot be obtained, use FISH on a blood specimen to confirm the diagnosis.
2. At 3, 6, 9, and 12 months after initiating therapy, measure qPCR for *BCR-ABL1* transcripts. (If qPCR using the International Standard is not available, perform marrow cytogenetics.) If there is a rising level of *BCR-ABL1* transcript or 1 log increase after MMR achieved, qPCR should be repeated in 1 to 3 months.
3. At 12 months obtain marrow cytogenetics for cells with Ph chromosome if no CCyR or MMR.
4. Once CCyR is obtained, monitor qPCR on blood cells every 3 months for 3 years and then every 4 to 6 months, thereafter. If there is a rising level of *BCR/ABL1* transcripts (1 log increase after MMR achieved), repeat quantitative PCR in 1 to 2 months for confirmation.
5. These guidelines presume continued response to a TKI until CCyR achieved. If this does not occur see text for approach.
6. Mutation analysis should be performed with loss of chronic phase, loss of any previous level of response, inadequate initial response (*BCR/ABL1* transcripts >10%) at 3 or 6 months or no CCyR at 12 or 18 months, and a 1-log increase in *BCR/ABL* after MMR once achieved.

CCyR, complete cytogenetic response; CP, chronic phase; FISH, fluorescence *in situ* hybridization; MMR, major molecular response; Ph, Philadelphia; qPCR, quantitative polymerase chain reaction; TKI, tyrosine kinase inhibitor.

Data from http://www.nccn.org/professionals/physicians_gls/PDF/cml.pdf.

transcripts at 3 months had a 3-year event-free survival of 95 percent or greater, whereas those with greater than 10 percent transcript level at 3 months had a 61 percent event-free survival.⁴⁹⁹

Molecular response is determined by the decrease in *BCR-ABL1* mRNA by PCR. This is the only means to measure the depth of the response once a CCyR is attained. The achievement of MMR after treatment with imatinib is associated with durable long-term CCyR and a lower rate of disease progression. Only 5 percent of patients achieving a MMR with imatinib lost a CCyR compared to 37 percent who did not achieve that degree of response.⁵⁰⁰ Also, the 5-year followup of the IRIS trial showed that no patient with a CCyR and MMR at 12 months had progressed to a more advanced phase of the disease.⁴⁹⁷ The IRIS study 7-year followup also showed that in those with a MMR at that point in time, progression was rare. The estimated event-free survival was 95 percent for those with MMR at 18 months compared with 86 percent in those without a MMR.⁵⁰¹ To date, there is no evidence that a change of therapy would improve survival in those with CCyR but not a MMR. In those with stable CCyR after treatment with a second-generation TKI, achievement of MMR may not have significance as a predictor of survival.⁴⁹⁹

The time taken to achieve MMR is also thought to have prognostic significance. In the IRIS study, the chance of disease progression was higher in those who failed to achieve a 1-log reduction in *BCR/ABL1* transcripts by 3 months or a 2-log reduction by 6 months.⁵⁰² A *BCR-ABL1* transcript level greater than 10 percent after 3 months is a significant predictor for long-term outcomes.⁵⁰³ In another analysis, chronic phase patients treated with imatinib 400 mg/day who had

TABLE 89-5. Milestones for Assessing Response to Tyrosine Kinase Inhibitors^{417,495}

Time of Observation (months)	Disease Response		
	Unsatisfactory	Suboptimal Response/Warning	Optimal Response
3	No CHR and/or Ph+ >95%	<i>BCR/ABL1</i> >10% and/or Ph+ 36–95%	<i>BCR/ABL1</i> ≤10% and/or MCyR
6	<i>BCR/ABL1</i> >10% and/or no MCyR	<i>BCR-ABL1</i> 1–10% and/or MCyR	<i>BCR/ABL1</i> <1% and/or CCyR
12	<i>BCR/ABL1</i> >1% and/or no CCyR	<i>BCR-ABL1</i> <0.1–1%	<i>BCR/ABL1</i> <0.1%
18	No CCyR	CCyR if no MMR	CCyR or MMR

CHR, complete hematologic response; CCyR, complete cytogenetic response; MCyR, major cytogenetic response; MMR, major molecular response.

Response is defined in Table 89-3. These data were derived from studies with imatinib but are applicable to therapy with any tyrosine kinase inhibitor (TKI) as initial therapy in chronic phase. “Unsatisfactory” implies the need to consider change in treatment approach, as appropriate for that patient. Usually this change is an increase in the dose of imatinib, a shift to an alternative TKI, or allogeneic hematopoietic stem cell transplantation, if eligible. These guidelines are approximate in that a patient showing continued response to a TKI can be continued on that therapy until a response plateau has been reached, at which time the response can be evaluated using the milestones described. The suboptimal category indicates at least closer monitoring is recommended. See text for further details.

BCR-ABL1 transcripts of 9.84 percent or less at 3 months had better overall, progression-free, and event-free survival at 8 years than did those with values of 9.84 percent or greater.⁵⁰³ Also, there is evidence that early molecular response to initial therapy with dasatinib or nilotinib in patients with CML is a predictor of overall response. In one trial with dasatinib, patients with *BCR-ABL1* transcripts of 10 percent or less at 3 months had significantly better 5-year progression-free (92 vs. 67 percent) and 4-year overall survival than did those with greater than 10 percent transcripts (95 vs. 83 percent).⁵⁰⁴ In another study with nilotinib, patients with *BCR-ABL1* of 10 percent or less at 3 months also had improved 4-year progression-free survival compared to those with *BCR-ABL1* greater than 10 percent at 3 months (95 vs. 85 percent).⁵⁰⁵ Progression was defined as transformation to accelerated or blast phase.

Rising *BCR-ABL1* Transcript Levels Rising *BCR-ABL1* transcripts can indicate a new mutation or cytogenetic relapse. A significant change has been defined as either a twofold increase, serially increasing levels, or a 1-log increase.^{492,495} There are no current recommendations for therapy changes based on an increase in *BCR-ABL1* transcripts. Serial increases or increases of 1-log or more should trigger *ABL* mutational analysis and frequent monitoring of *BCR-ABL1* transcripts.

Suboptimal Therapeutic Responses The initial European Leukemia Network guidelines defined suboptimal response as no cytogenetic response at 3 months, less than a partial cytogenetic response (PCyR) at 6 months, a PCyR at 12 months, and less than a MMR at 18 months.^{495,506} The significance of a suboptimal response is dependent on the cause; for example, this may be insignificant if the result of drug intolerance or noncompliance as opposed to drug resistance (see

“Acquired Resistance” below). The significance also depends on time of suboptimal response with earlier time points indicating a worse prognosis. Currently, CCyR and PCyR at 3 months are considered optimal and suboptimal responses. Suboptimal responses are labeled as a “warning” response in the Network guidelines.⁴⁹⁵ These response levels may trigger *ABL* mutation analysis or closer monitoring.

Secondary Chromosomal Changes with Tyrosine Kinase Inhibitors

Because of its earlier development, most of these data are obtained with imatinib treatment. Clonal abnormalities in cells lacking a detectable Ph chromosome or *BCR-ABL1* rearrangements have been detected in patients undergoing imatinib therapy who previously were treated with IFN- α .^{507,508} These cytogenetic changes were noted in seven patients at a median of 13 months of imatinib therapy, and trisomy 8 was the most frequent abnormality. All of these patients had MCyRs to imatinib.⁵⁰⁷ The presence of additional chromosomal abnormalities is considered to be a feature of the accelerated phase of CML. In some patients, clonal evolution may be related to imatinib resistance.⁵⁰⁹ Clonal abnormalities may be present in up to 10 percent of patients taking imatinib.⁵¹⁰ Some of these cases may be associated with a MDS, especially in those patients with previous exposure to cytarabine and idarubicin. The antiproliferative effect of imatinib allows restoration of polyclonal hematopoiesis in CCyR, which could permit the manifestation of a Ph chromosome-negative disorder.⁵¹¹ Some investigators have found that, with the possible exception of +8, +Ph, and i(17), additional chromosomal abnormalities at diagnosis are not associated with an inferior outcome to imatinib therapy.^{512,513} In contrast, another group found that development of trisomy 8 in patients taking imatinib, while associated with pancytopenia, did not result in signs of disease progression. In a series of 34 CML patients who developed Ph chromosome-negative clones while taking imatinib, the most common abnormalities were trisomy 8 and monosomy 7. In 11 of these patients, no archival evidence of these clones was present before imatinib therapy was initiated, and none of the patients developed myelodysplasia.⁵¹⁴ In patients treated at diagnosis with imatinib, 9 percent developed chromosomal abnormalities in Ph chromosome-negative metaphases. These appeared at a median of 18 months, and the most common abnormalities were -Y and +8. Most were temporary and disappeared within 5 months. Only one patient with -7 progressed to acute myelogenous leukemia (AML).⁵¹⁵ Cytogenetic clonal evolution may not be an important impediment to achieving a MCyR or CCyR with imatinib, but it is an independent poor prognostic factor for survival of patients in chronic and accelerated phases of CML.⁵¹⁶ Imatinib therapy may overcome the poor prognostic significance of derivative chromosome 9 in CML.⁵¹⁷

Adherence to Tyrosine Kinase Inhibitor Therapy

Noncompliance with therapy is associated with poorer outcomes. In one trial, patients with a suboptimal response had higher nonadherence (23 percent) than did those with optimal responses (7 percent).⁵¹⁸ In another study, adherence was the only independent predictor for achieving a complete molecular response (CMR) on imatinib. Patients with an adherence rate of 85 percent or less had a greater chance of losing their CCyR at 2 years (27 percent) than did those with better adherence (1.5 percent). They, also, had a lower chance of remaining on imatinib.⁵¹⁹ Adherence has also been correlated with level of molecular response. In patients using a TKI for about 5 years, median adherence was 98 percent (range: 24 to 100 percent). If adherence was greater than 90 percent, there was a higher probability for a 3-log reduction in *BCR/ABL1* transcripts and a CMR. If adherence was less than 80 percent, no MMRs occurred.⁵²⁰ The poor adherence to second-generation TKIs has not been studied for a sufficient duration to determine its impact.

Management of side effects is of importance in maintaining a high rate of adherence.

Development of Tyrosine Kinase Inhibitor Resistance

The development of resistance to imatinib is not surprising.^{521,522} Its specificity and “snug fit” into the *ABL1*-kinase pocket provide the ideal circumstance for resistance.⁵²³ Some cases demonstrate primary resistance to imatinib, and gene profiling has demonstrated differential expression of about 46 genes in responders compared to nonresponders.⁵²⁴ Even in patients with CCyR, malignant progenitors at the LTC-IC stage persist. Chronic phase CML stem cells are resistant to imatinib and are genetically unstable.⁵²⁵ These cells have a high level of *BCR-ABL1* transcription, and they are thought to express transporter proteins that result in abnormal imatinib flux.⁵²⁶ Mathematical models suggest that imatinib rapidly eliminates leukemic progenitors, but does not deplete CML stem cells. Such models predict the probability of developing resistant mutations and can estimate the time that resistance will emerge.⁵²⁷ Several potential mechanisms of resistance include *BCR-ABL1* amplification in the presence of imatinib, P-glycoprotein-mediated drug efflux, altered drug metabolism, acquisition of *BCR-ABL1*-independent signaling characteristics, and point mutations in the *ABL1* kinase domain that decrease imatinib binding. Each of these mechanisms of resistance may have clinical relevance.

Primary Resistance Primary resistance to imatinib is defined as lack of CHR at 6 months or failure to achieve any level of cytogenetic response at 6 months, a MCyR at 12 months, or a CCyR at 18 months. This may occur in 15 to 25 percent of patients. Primary resistance may often be the result of inadequate plasma concentration because of binding of the drug to proteins, such as albumin or α_1 -acid glycoprotein. In an analysis of the IRIS study, plasma levels of imatinib following the first month of treatment proved to be a significant predictor for clinical response. Plasma levels are not available for clinical use, however, so these have minimal influence on treatment decisions when responses are not as expected. Only one gene, prostaglandin-endoperoxide synthase 1/cyclooxygenase 1 (*PTGS1/COX1*) was found to differentiate primary imatinib resistance. Eleven genes were associated with secondary resistance after imatinib therapy in those without an *ABL1* kinase domain mutation.⁵²⁸ Expression of the OCT-1, which mediates drug influx, is thought to be important for imatinib but not dasatinib effectiveness.^{529,530} Many CML patients who have a suboptimal response to imatinib have low OCT-1 activity, but this can be overcome with higher doses of imatinib or use of dasatinib, which uptake is not dependent on OCT-1 expression.⁵³⁰ OCT-1 expression is associated with MMR at 12 and 24 months, and it is a predictor of the long-term risk of resistance and of transformation in patients treated with imatinib.⁵³¹ CML CD34+ cells overexpress the drug transporter ABCG2, and imatinib, dasatinib, and nilotinib are substrates for ABCB1 and ABCG2. Overexpression of MDR1 has been associated with decreased intracellular concentration of imatinib.⁵³²

Acquired Resistance Acquired resistance is that which occurs after exposure to TKIs or other treatments. Amplified gene expression and increased *BCR-ABL1* protein expression are often reported in resistant patients. Duplication of the Ph chromosome and isodicentric chromosomes are a possible mechanism of resistance to imatinib.^{533,534}

Mutations in the *ABL1* kinase domain are a frequent mechanism of resistance. Kinase domain mutations were the only independent predictor for the loss of CCyR and progression when compared to those without a mutation.⁵³⁵ Mutations in the *ABL1* kinase domain may predate imatinib treatment,⁵³⁶ and several *BCR-ABL1* kinase domain mutants associated with imatinib resistance remain sensitive to the drug, suggesting a need for characterization before a resistant phenotype can be attributed to the given mutation.⁵³⁷ The mutant clone does not always

have a proliferative advantage.⁵³⁸ Some of these mutations may lie outside the kinase domain, and more than 40 such mutations have been described. Screening early phase CML patients for mutations before the start of imatinib therapy is not cost-effective because of their low incidence, but in patients with evidence of an increase in CML cells while on imatinib, mutation searches are indicated.⁵³⁹ *BCR-ABL1* kinase domain point mutations are rare in those who have had good cytogenetic responses to imatinib, and when detected in that setting, their presence does not always predict relapse.⁵⁴⁰ Mutations in the *ABL1* portion of the *BCR-ABL1* oncogene are present in approximately 40 percent of patients who do not achieve a CHR or CCyR to imatinib. *ABL1* mutations were found in those patients with both primary and acquired resistance. Amino acid substitutions in seven residues accounted for 85 percent of all mutations associated with resistance.⁵⁴¹ The mutations most associated with resistance are Thr315Ile, Gly250Glu, Glu255Lys, and Thr253His substitutions. Few of the described mutations directly affect imatinib binding.⁵⁴² Mutations in the *ABL1*-ATP phosphate-binding loop (P-loop) are most closely associated with a poor prognosis,⁵⁴³ and these P-loop mutations predict for disease progression. Overall survival is worse for P-loop and for T315I mutations, but not significantly different when other mutations are present.⁵⁴⁴

Ultra-deep sequencing approaches have shown that routine Sanger sequencing underestimates *BCR-ABL1* mutation in 55 percent of samples where the missed mutations had low abundance.⁵⁴⁵ Mass spectrometry can detect a 0.05 to 0.5 percent level of mutations, as well.⁵⁴⁶ For many mutations, the concentration that inhibits 50 percent (IC_{50}) of various TKIs and response have not been documented.⁵⁴⁷

Second-generation BCR-ABL1 inhibitors (see “Dasatinib and Nilotinib” below) are able to overcome imatinib-resistant mutants, with the exception of the T315I mutations (Table 89–6). Mutations F317L and V299L are resistant to dasatinib and mutations Y253H, E255K, and F359I are resistant to nilotinib. Ponatinib was active against T315I and against other BCR-ABL1 mutations resistant to dasatinib or nilotinib.⁵⁴⁸ Ponatinib may be effective against individual *ABL1* point mutations but may not overcome some compound mutations, which are two or more mutations in the same BCR/ABL1 molecule. Some mutations may be polyclonal as well.⁵⁴⁹ The T315I mutation results in steric hindrance, which precludes access of some TKIs to the ATP-binding pocket of the *ABL1* kinase domain.⁵⁵⁰ In a series of 27 patients with T315I mutation, survival was dependent on stage of disease, with many of the chronic phase patients described as having an indolent course.⁵⁵¹ In addition to ponatinib, agents such as IFN- α and homoharringtonine have also been proposed as therapy for those with the T315I mutation.⁵⁵²

In some cases of resistance associated with imatinib, other signal pathways independent of BCR-ABL1 may become important in cell

proliferation.⁵⁵³ These include heat shock protein (hsp) 70,⁵⁵⁴ survivin,⁵⁵⁵ LYN kinase,⁵⁵⁶ SRC,⁵⁵⁷ and GRB2, among others.⁵⁵⁸

Dose escalation, combination therapy, and treatment interruption have been proposed as means to overcome drug resistance.⁵⁵⁹ Combination therapy from the outset⁵⁶⁰ also has been proposed to prevent development of resistance. Treatment interruption to stop clonal selection of resistant cells has been proposed.⁵⁵⁷ Gene-expression profiles may be useful to predict the clinical effectiveness of imatinib for CML treatment, thereby allowing individualized therapy from the outset.⁵⁶⁰ In patients with relapse or resistance, alternative approaches include increasing the dose of imatinib or switching to dasatinib or nilotinib.⁵⁶¹ Allogeneic hematopoietic stem cell transplantation is not recommended unless patients have inadequate response or intolerance to multiple TKIs or have the T315I mutation. Mutational analysis is not recommended at diagnosis but is of help in selecting TKI therapy for patients with an inadequate initial response or loss of response to TKI therapy. Mutation type may dictate choice of the next TKI.⁵⁶²

Management of Resistance

Dose Escalation If the patient is on imatinib, 400 mg/day, dose escalation to 800 mg/day can be tried. This may be most efficacious in patients with cytogenetic relapse who had achieved a cytogenetic response with the initial dose of imatinib, but is not likely to benefit those who have not had a cytogenetic response with imatinib at 400 mg/day.

Second-Generation Tyrosine Kinase Inhibitor Therapy Several TKIs are approved for use in the case of imatinib resistance or intolerance. In general, outcome with each is comparable, so the choice of agent often depends on its side-effect profile or in some cases on mutation type (see Tables 89–2 and 89–6).⁵⁶²

The 3-month molecular response after initiation of a second TKI is also a predictor of overall and event-free survival for those patients in chronic phase when switched from imatinib to another TKI.⁵⁰⁵ A *BCR-ABL1* level of 10 percent or less at 3 months is desirable. In patients treated with nilotinib after imatinib resistance or intolerance, the 4-year progression-free and overall survival was 85 and 95 percent, respectively, if *BCR-ABL1* transcripts were 10 percent or less as compared to 42 and 71 percent for those with *BCR-ABL1* transcripts greater than 10 percent at 3 months.⁵⁶³

Either dasatinib or nilotinib can be used in cases of imatinib resistance or intolerance. Dasatinib is 325-fold more potent than imatinib; and, as a dual inhibitor of SRC and ABL1 kinases, dasatinib is able to bind to *BCR-ABL1* with less-stringent conformational requirements.⁵⁶⁴ In patients resistant to imatinib, dasatinib, 140 mg/day (70 mg q12h), resulted in a higher proportion of MCyR, CCyR, and MMR than did 800 mg/day (400 mg q12h) of imatinib. Treatment failure was decreased and progression-free survival was improved with dasatinib.⁵⁶⁵ Unlike imatinib, dasatinib penetrates the blood–brain barrier.⁵⁶⁶ In long-term followup of 670 patients with imatinib-resistant or intolerant CML, treated with various doses of dasatinib, 28 percent of patients remained on study treatment at 6 years. Survival was in the range of 76 to 83 percent and a MMR was achieved in 45 percent on a dose of 100 mg daily. Molecular and cytogenetic responses at 3 and 6 months were predictive of survival. For those with *BCR-ABL1* transcripts less than 10 percent at 3 months, progression-free survival was 68 percent, whereas it was only 26 percent for those with *BCR-ABL1* transcripts greater than 10 percent.⁵⁶⁷ Nilotinib in a dose of 400 mg every 12 hours induced approximately 40 percent of patients who were resistant to or intolerant of imatinib into a MCyR, and approximately 30 percent into a CCyR. Nilotinib, 400 mg BID, is the recommended dose for those intolerant or resistant to imatinib.

Bosutinib and Ponatinib In addition to dasatinib and nilotinib, bosutinib and ponatinib, third-generation TKIs, are active against many of the imatinib-resistant *BCR-ABL1* kinase domain mutations and are

TABLE 89–6. Prevalent *ABL1* Mutations Conferring Resistance to a Tyrosine Kinase Inhibitor

Mutation	Treatment Recommendation
T315I	Ponatinib or stem cell transplant
V299L, T315A, F317L/V/I/C	Consider nilotinib over dasatinib; bosutinib and ponatinib may be effective
F359V/C/I	Consider dasatinib rather than imatinib; bosutinib and ponatinib may be effective
Others	Any tyrosine kinase inhibitor not previously used or high-dose imatinib

The reader is referred to the text, which includes references describing listings of known sensitivities of reported mutations.

effective treatment options for CML resistant to standard-dose imatinib. Both were FDA approved for this indication in 2012. Bosutinib is active with F317L, Y253H, and F359C/I/V mutations. Ponatinib is also effective against many mutations resistant to nilotinib or dasatinib and has activity in cases with a T315I mutation (see Table 89–6).

Bosutinib is a dual SRC-ABL1 TKI that resulted in a CCyR in 24 percent and CHR in 73 percent of patients who had used two prior TKIs.⁵⁶⁸ All mutations except T315I were responsive. It is approved for chronic phase, accelerated phase, or blast phase in those resistant or intolerant to prior TKI therapy. The dose is 500 mg/day, orally, with food. Diarrhea, nausea, decreased platelet count, other gastrointestinal complaints, rash, and anemia were the most common adverse events, and most of these were of low-grade. Bosutinib is not yet approved for use as an initial agent in CML, as it did not demonstrate significant improvement in CCyR rates at 1 year compared to imatinib. It was, however, associated with higher 1-year MMR rates, faster time to response, and less disease progression.⁴⁹¹

Ponatinib blocks native and mutated *BCR-ABL1* including the gatekeeper mutation T315I. In a phase I dose escalation study, pancreatitis, rash, and myelosuppression were major toxicities. In 12 patients with T315I mutations, 92 percent had a MCyR. In those with accelerated or blast phase, or Ph chromosome–positive ALL, 36 percent had a major hematologic response and 32 percent had a MCyRs. Arterial thrombotic events occurred, however.⁵⁴⁸ Retrospective analyses of these incidents led to temporary withdrawal of this medication, which is now used primarily in cases of T315I mutation or failure of several other TKIs. If vascular occlusion occurs, therapy should be halted immediately.⁵⁶⁹ Ponatinib has a black box warning for vascular occlusion, heart failure, and hepatotoxicity.

A third-line TKI should be considered in patients who have failed two prior generations of TKI therapy, but responses tend to be infrequent and are usually not durable, so clinical trials, other agents, or allogeneic hematopoietic stem cell transplantation should be considered. A prior CCyR on either imatinib or subsequent nilotinib or dasatinib therapy was the only predictor of a cytogenetic remission on a third-line therapy.⁵⁷⁰

Non-Tyrosine Kinase Inhibitor Therapies

Omacetaxine Omacetaxine (homoharringtonine) is a *Cephalotaxus* alkaloid that has activity against the T315I mutation. Omacetaxine was approved on the basis of a study that recruited patients who had already been on two or more TKIs. In those enrolled in chronic phase, 67 percent had a CHR; a MCyR or a CCyR was achieved in 22 and 4 percent, respectively. Median overall survival was 30 months.⁵⁷⁰ In those with T315I mutations enrolled on a separate study, MMR was achieved in 17 percent of patients and the T315I clone was reduced in 61 percent of patients.⁵⁷¹ The most common side effects with this medication are cytopenias. This agent also has activity in accelerated phase CML, but little in blast phase. It was approved by the FDA in October 2012 for chronic and accelerated phase patients intolerant of other therapy or in cases not responding to two or more TKIs.

Several inhibitors of signal transduction mediators involved in the downstream effects of BCR-ABL have been proposed for use in imatinib-resistant CML. These inhibitors include the JAK2 inhibitor AG490,⁵⁷² SRC kinase inhibitors, mTOR (mammalian target of rapamycin) inhibitors, such as rapamycin,⁵⁷³ the proteasome inhibitor bortezomib,^{574,575} histone deacetylators,^{576,577} PI3K or MEK (mitogen-activated kinase) inhibitors and inhibitors of the WNT/ β -catenin pathway thought to be active in CML stem cells. Imatinib resistance often is associated with restored activation of the BCR-ABL1 signal transduction pathway, suggesting that BCR-ABL1 remains a valid target to overcome resistance in these cases.⁵⁷⁸ *BCR-ABL1* point mutations isolated from patients with

imatinib-resistant CML are sensitive to inhibitors of the BCR-ABL1 chaperone hsp90, such as geldanamycin.⁵⁷⁹ Many of these agents have not yet entered clinical trials, but some are in early phase trials, such as inhibitors of the hedgehog pathway, which is activated in CML but not normal hematopoietic stem cells.⁵⁸⁰ Some are being used in conjunction with imatinib in resistant cases.

Combined Therapy Agents that have been proposed for use in combination to improve response rates or to overcome resistance to imatinib have included IFN- α , cytarabine, omacetaxine multiagent chemotherapy, arsenic trioxide, and decitabine, with some supporting *in vitro* data.^{581–586} Combining imatinib with chemotherapeutic agents is more myelosuppressive, and final effects on response rates and survival have yet to be determined. This approach is rarely used in chronic phase CML, but is used in accelerated or blast phase or in Ph chromosome–positive acute lymphoblastic leukemia.⁵⁸⁷

Disease Prognosis and Monitoring During Tyrosine Kinase Inhibitor Therapy

Treatment failure should lead to alterations in therapeutic strategy.⁵⁸⁸ For patients treated initially with imatinib, BCR-ABL1 expression in cytogenetic responders and nonresponders was similar. BCR-ABL1 expression became significantly different 3 months after treatment and became increasingly different between responders and nonresponders with continued therapy at 6, 9, and 12 months.⁵⁸⁹

One mode of monitoring patients undergoing TKI therapy is to measure blood counts at least once per month and to obtain marrow samples every 6 months until a complete cytogenetic remission is obtained.⁵⁹⁰ Thereafter, marrow samples are obtained no more often than yearly to monitor for other clonal abnormalities. Quantitative RT-PCR is performed every 3 months on blood or marrow. A 1-log increase in the level of *BCR-ABL1* reactivity, confirmed on a repeat sample at least 1 month later, suggests a loss of response to treatment. In patients who do not have a CHR at 3 months, or a MCyR after 6 to 12 months, other therapeutic options are considered.⁵⁹¹ The molecular response after 2 to 3 months of therapy is a strong predictor of clinical and cytogenetic response.⁵⁹² Sequencing the *BCR-ABL1* kinase domain can reveal emergence of resistant clones and is useful if there is an insufficient initial response to imatinib or a second-generation TKI (see Table 89–5) or any sign of loss of response, such as relapse to Ph chromosome–positive status, a 1-log increase in BCR/ABL1 transcript ratio, or loss of a MMR.⁴¹⁷

In patients receiving second-generation TKIs as second-line therapy, those who have no cytogenetic response at 3 to 6 months should be considered for allogeneic transplantation or switched to an alternative therapy in a clinical trial. After CCyR is attained, molecular monitoring is recommended every 3 months for 3 years and every 4 to 6 months thereafter.⁴⁹² After 12 months, those with a MCyR had a significant survival advantage over those with lesser responses.⁵⁹³ Those with *BCR-ABL1* transcripts greater than 10 percent following initial imatinib treatment should be switched to dasatinib, nilotinib, or bosutinib. If this is not an option because of cost or availability, high-dose imatinib can be considered, but it also unlikely to have benefit for more than a few months. For those already on a second-generation TKI, a clinical trial or alternative TKI could be tried or patients may continue on the same TKI with very careful followup, as the impact of this benchmark on overall survival is not yet known.⁴⁹² The 6-month evaluation should identify patients with a poor outcome. For those who have MCyR or *BCR-ABL1* of less than 10 percent at 6 months, overall survival was 100 percent as compared to 79 percent for those with no response.⁵⁹⁴ At 12 and 18 months, CCyR is the optimal response.⁴¹⁷ In those who have achieved CCyR, MMR may not be of prognostic significance.⁵⁹⁵

Rising BCR-ABL1 levels may be associated with an *ABL1* mutation or relapse of disease. Those with more than a twofold rise in BCR-ABL1 are more likely to have a mutation.⁵⁹⁶ A serial rise in the BCR-ABL1 level may also indicate loss of response to therapy.⁴¹⁵

OTHER AGENTS USED IN TREATMENT OF CHRONIC PHASE

Interferon- α

IFN- α , formerly the most effective agent, is rarely used in the treatment of CML. A CCyR with IFN- α was uncommon (13 percent), but 10-year survival rates in responders were approximately 70 percent.⁵⁹⁷ CCyRs to IFN- α were stable and durable.⁵⁹⁸ Approximately 50 percent of complete responders become long-term survivors. Common toxicities of IFN- α use include fatigue, low-grade fever, weight loss, liver function test abnormalities, hematologic changes, and neuropsychiatric symptoms. Overall survival is improved in imatinib-treated patients compared with patients treated with IFN- α or IFN- α plus cytarabine.⁵⁹⁹ Nevertheless, among all patients who attained a major or CCyR at 12 months, the survival rate was comparable in either case. IFN- α has also been proposed as an immune stimulant to consolidate imatinib remissions because additive effects have been noted.^{600,601} Conversely, those treated initially with IFN- α who achieve a CCyR have an improved molecular response with imatinib.^{602,603} Some patients intolerant to a TKI may be treated successfully with IFN- α .

Use of Other Chemotherapeutic Agents in Chronic Phase

Hydroxyurea The major side effect of hydroxyurea is an extension of its pharmacologic effect, that is, reversible suppression of hematopoiesis, often with megaloblastic erythropoiesis. The median survival of patients with CML treated with hydroxyurea alone is approximately 5 years. Studies with high-dose hydroxyurea indicate that marrow metaphase cells in some patients lose the Ph chromosome either partially or completely after such therapy.⁶⁰⁴ Hydroxyurea often is used for initial cytoreduction, but it has few other indications in the TKI era of CML therapeutics. Chronic use of hydroxyurea is associated with leg ulcers.⁶⁰⁵

Cytarabine IFN- α_{2b} combined with cytarabine (20 mg/m² per day for 10 days per month) in the chronic phase was associated with a greater proportion of MCyRs at 12 months and with greater survival prolongation than was IFN alone.⁶⁰⁶ Toxicities with these drug combinations were greater, and this combination has been replaced by TKI therapy and is rarely used.

Busulfan Once the mainstay of treatment for the chronic phase, busulfan usage now is rare.⁶⁰⁷ It is used primarily as part of the preparative regimen for allografting or autografting. It may be used occasionally in older patients who do not tolerate TKIs.

Other Cytotoxic Agents Intensive multidrug regimens have been used in an attempt to eradicate the Ph chromosome–positive clone and, occasionally, have led to prolongation of remission or cure of the disease. This approach did not significantly increase population survival.⁶⁰⁸

Other Potential Therapeutic Agents in Chronic Phase Chronic Myelogenous Leukemia The farnesyltransferase inhibitors lonafarnib and tipifarnib have been combined with imatinib and have activity after imatinib failure.^{609,610} The hypomethylation agent decitabine has activity in imatinib refractory CML. INNO-406, a dual BCR-ABL/LYN inhibitor, suppresses the growth of CML cells in the central nervous system.⁶¹¹ MicroRNA approaches may eventually play a role in CML treatment,⁶¹² and synthetic *BCR-ABL1* small interfering ribonucleic acid (siRNA) has been used in a patient with resistant CML, postallografting with inhibition of *BCR-ABL1* noted.⁶¹³ Ribozymes targeting *BCR-ABL1* mRNA have been used as CML treatment,^{614,615} and these approaches probably

will have the most utility for *in vitro* purging of CML marrow cells before autotransplantation.^{616,617}

RADIOTHERAPY

Palliative splenic irradiation may be useful occasionally in subjects who have entered the accelerated or advanced chronic phase and are troubled with extreme splenomegaly with splenic pain, perisplenitis, and encroachment of the spleen on the gastrointestinal tract.⁶¹⁸ Splenic irradiation may palliate symptoms for a short time.⁶¹⁹ Spleen size associated with chronic phase disease usually is decreased with TKI therapy.

Palliative radiotherapy may be useful for extramedullary myeloid sarcomas, which may occur occasionally in bone or soft tissue during the late chronic or accelerated phase.

SPLENECTOMY

Splenectomy does not prolong the chronic phase of CML, delay the onset of the accelerated phase, enhance sensitivity to TKIs or chemotherapy, or prolong survival of patients.⁶²⁰ In carefully selected patients with symptomatic thrombocytopenia unresponsive to therapy, mechanical discomfort, hypercatabolic symptoms, and portal hypertension, splenectomy may be useful. Postoperative morbidity from infection, thrombosis, or hemorrhage has been high, with mortality rates up to 10 percent reported.⁶²¹ Splenectomy performed before allografting has not been found to influence the severity of graft-versus-host disease (GVHD) or survival after allogeneic hematopoietic stem cell transplantation.⁶²²

TREATMENT OF CHRONIC PHASE CHRONIC MYELOGENOUS LEUKEMIA DURING PREGNANCY

Treatment of chronic phase CML during pregnancy is sometimes needed to prevent placental insufficiency from hyperleukocytosis. Imatinib may be teratogenic. Normal newborns have been delivered by patients who conceived and ingested imatinib during early pregnancy.^{623–626} In 125 women exposed to imatinib during pregnancy, 50 percent delivered normal infants, and 25 percent underwent elective terminations, three of the latter following the identification of fetal abnormalities. Twelve other infants had abnormalities.⁶²⁷ The majority of patients who discontinue imatinib during pregnancy lose their complete hematologic remission and their cytogenetic responses.⁶²⁸ One fetal fatality during pregnancy as a result of a meningocele has been reported. Males treated with imatinib have fathered healthy infants.⁶²⁹ Current recommendations are to practice contraception during treatment with any TKI, or, if pregnant, at the onset of the disease, to consider IFN treatment until delivery.^{626,630} Imatinib does appear in breast milk.⁶³¹

IFN can be used during pregnancy with minimum risk of teratogenicity. Eight patients treated with IFN from the first trimester have been described, and each of these pregnancies resulted in normal infants, except for one with mild neonatal thrombocytopenia. All infants had normal growth patterns.⁶³² Hydroxyurea may be useful during the second and third trimester but should be avoided in the first trimester.^{626,633} Leukapheresis in the first trimester (or longer) also can be used to avoid fetal drug exposure early in pregnancy (see “Leukapheresis” above). It is important to use a TKI after delivery to achieve the best outcome. Further observation may show it to be safe later in pregnancy. Although controversial, stopping and later restarting TKI therapy may not result in as favorable an outcome of therapy as use of IFN or other approaches, initially.⁶²⁶ If conception is desired, attaining a MMR before the TKI therapy is discontinued and a 3-month washout period are

recommended.⁴¹⁵ The patient should be made aware of the risk for CML progression during the pregnancy.

DISCONTINUATION OF TYROSINE KINASE INHIBITOR THERAPY

Patients responding to TKI therapy are likely to maintain their response. TKIs are associated with a significant symptom burden, however,⁶³⁴ and one-third have persistent moderate to severe symptoms. Persistent CMR is seen in only a minority of patients, and the vast majority of patients on TKIs have minimal residual disease even if their *BCR-ABL1* transcripts are undetectable, and this may lead to relapse if the drug is stopped. Thus, in the absence of a clinical trial, life-long therapy with a TKI is recommended.

Some patients in a CMR for 2 years or more have been able to discontinue imatinib without relapse.^{635,636} Discontinuation of imatinib in 12 patients who had undetectable disease for at least 2 years resulted in six patients having a molecular relapse within 1 to 5 months (imatinib was reintroduced with a response) and six others remaining in CMR for a median of 18 months.⁶³⁷ There are numerous anecdotes of patients relapsing when imatinib was stopped. In patients with intolerable side effects on imatinib, the dose may be reduced in some cases without the loss of a CMR.⁶³⁸ In occasional patients in whom imatinib is stopped, a cytogenetic response of up to 15 months has persisted.⁶³⁹⁻⁶⁴² In a study of 100 patients with a CMR (>5-log reduction in *BCR/ABL1* transcripts) for at least 2 years who stopped imatinib, 69 patients had at least 12 months of followup. Of these, 39 percent were stable and 61 percent relapsed, most within the first 6 months. The outcome of stopping was better for those with a lower Sokal risk score at diagnosis.⁶³⁶ In another study, 40 patients were evaluated, and treatment-free remission at 24 months was 47.1 percent for all patients and was higher if patients had prior IFN treatment.⁶³⁵ Female sex and early molecular response predict stable undetectable *BCR-ABL1* transcripts in chronic phase CML, the criteria for early stopping.⁶⁴³ In a series of 423 CML patients treated with imatinib, the rate of undetectable *BCR/ABL1* transcripts and stable MMR (4.5-log decrease) was 36.5 percent.⁶⁴³ A model to analyze the risk of molecular relapse after cessation of TKIs has been developed.⁶⁴⁴ Reports of discontinuations, reappearance of the clone, treatment with a second prolonged course of imatinib, discontinuation with retention of MMR at 32 months followup, and retention of CMR in 12.5 percent have been described.⁶⁴⁵

Discontinuation of nilotinib or dasatinib has not been reported in a significant series, and larger prospective studies will be needed to determine in which patients stopping treatment can be safely attempted. Because early, quiescent Ph chromosome-positive cells (CD34+Lin-) are insensitive to imatinib *in vitro*,⁵⁴⁶ at present it is advisable to maintain treatment indefinitely until the criteria for cessation, if any, can be established in clinical trials. Intermittent imatinib dosing has been explored in selected elderly patients with CML without adverse impact on overall and progression-free survival.⁶⁴⁷

HIGH-DOSE CHEMOTHERAPY WITH AUTOLOGOUS STEM CELL INFUSION

Since the availability of imatinib, autografting in CML is rarely used.⁶⁴⁸ Ph chromosome-negative stem cells are present in most patients with CML at the time of diagnosis. Techniques that use these cells to reconstitute hematopoiesis after high-dose therapy have been developed.⁶⁴⁹ Ph chromosome-negative progenitors can be mobilized with G-CSF and collected from the blood of patients who have responded to prior treatment with a TKI.⁶⁵⁰ Such cells also can be collected after recovery from chemotherapy regimens, such as after idarubicin and cytarabine,

followed by G-CSF stimulation.⁶⁴⁹ G-CSF was used for at least 4 days while imatinib treatment was continued for stem cell mobilization in 58 patients with a CCyR. The cells were collected in two cytapheresis procedures in 74 percent of patients, and the cells of 84 percent of those cytapheresis products were negative for the Ph chromosome.⁶⁵¹

In another series, stem cells were mobilized in 32 patients in complete cytogenetic remission after imatinib, with uninterrupted imatinib therapy in 50 percent of patients and with imatinib temporarily withheld in approximately 50 percent. Blood levels of *BCR-ABL1* transcripts were not changed by the use of G-CSF.⁶⁵² In yet another series, 13 of 15 patients were successfully mobilized with G-CSF while receiving imatinib, and 28 percent of stem cell harvests were negative for *BCR-ABL1* mRNA. No change in blood *BCR-ABL1* transcript level was noted after stem cell mobilization as assessed by RT-PCR.⁶⁵³ No series of patients autografted with cells mobilized while they were receiving imatinib have been reported.⁶⁵⁴ Autografting might find a role in cases of imatinib resistance,⁶⁵⁵ or to reduce the level of residual disease in cases without a molecular response.⁶⁵⁶ Imatinib can be effective and safe in chronic phase CML patients who have previously undergone autografting,⁶⁵⁷ although there is an increased frequency of hematologic toxicity.

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Until imatinib became available in 2001, allogeneic transplantation was used in most new patients with CML who were younger than 65 years of age and who had a suitable donor. The advent of imatinib treatment and the projected survival of patients with a complete cytogenetic remission has changed the indications for transplantation in CML.^{658,659} There has been a marked reduction in number of transplants performed for CML worldwide and a decline in the proportion performed in first chronic phase.^{660,661} Although no randomized trials of imatinib versus transplantation have been or are likely to be conducted, there is circumstantial evidence that survival is superior for populations of patients treated with drugs who have a CCyR as compared to transplantation.⁶⁶² Allografting continues to play a role in the treatment of patients, who are refractory or intolerant to serial TKIs, and remains the optimal therapy in those who progress to accelerated or blast crisis in the face of treatment with a series of TKIs.

Patients in the chronic phase of CML who are younger than approximately 70 years and who have an identical twin,⁶⁶³ or a histocompatible sibling,^{664,665} or access to a histocompatible unrelated donor,⁶⁶⁶ can be transplanted after intensive therapy, usually with cyclophosphamide and fractionated total-body irradiation (TBI) or a combination of busulfan and cyclophosphamide. Busulfan can be administered as an intravenous preparation and as a single daily dose.⁶⁶⁷ When targeted steady-state busulfan levels are used, a 3-year survival rate of 86 percent and a disease-free survival rate of 78 percent with no age effect is achieved.⁶⁶⁸ With nonmyeloablative or "reduced-intensity" conditioning regimens, older patients and those with comorbidities can undergo successful allografting.⁶⁶⁹ With the success of TKI therapy, allogeneic stem cell transplantation is no longer recommended as a treatment option in chronic phase CML responding to any sequence of TKIs.⁶⁷⁰ Allogeneic transplant should be considered for patients with disease progression to accelerated or blast phase on TKI therapy. In these cases, TKIs to which the patient has not been previously exposed and for which they do not possess a resistant mutation can be used to bridge or prepare for the transplant.⁶⁷¹ Allogeneic transplant can be used in those rare patients who present with blast crisis and in those with T315I mutations who do not respond to ponatinib.^{672,673} In those who do not respond to their first TKI exposure and are switched to a second TKI, transplantation in chronic phase would be indicated for those patients

with *BCR-ABL1* transcripts greater than 10 percent or less than a PCyR at 3 and 6 months, minor or no cytogenetic response at 12 months, and only a PCyR at 18 months or cytogenetic relapse at 12 or 18 months.⁴¹⁷

Myeloablative Allogeneic Transplants

Stem cell transplantation from HLA-compatible siblings results in engraftment and an actual or projected long-term survival in 45 to 85 percent of recipients.^{674–676} In patients older than age 50 years, survival rates are slightly less at 5 years. The risk of CML relapse is approximately 20 percent, with a plateau of relapse at 5 to 7 years. Transplanted T lymphocytes, especially if activated by a (mild) GVHD, may be an important factor in preventing leukemic relapse. This phenomenon, referred to as *graft-versus-leukemia reaction*, is thought to suppress the leukemic process through T-cell-mediated cytotoxicity.⁶³⁴ The relative benefit of marrow compared to mobilized blood stem cells as the source of the allograft has not been established.^{677,678} Mobilized blood stem cells engraft more rapidly but may be associated with more chronic GVHD. The majority of survivors have no evidence of residual leukemia.⁶⁷⁹

For younger patients who do not have a histocompatible sibling, an unrelated donor or a mismatched family member as a source of stem cells is feasible. When class I HLA genes are typed with molecular methods, an improvement in matching and better outcomes using unrelated donors have been demonstrated and are comparable to those transplanted with a matched-sibling donor. When matched-unrelated donor and sibling donor transplants were compared, unrelated donor transplants had increased risk of graft failure and acute GVHD, but only a slightly poorer survival and disease-free survival. For patients who survived to 1 year, only a slightly inferior disease-free survival was observed.⁶⁸⁰ The rate of extensive chronic GVHD is up to 60 percent with unrelated donor transplants, but 63 percent disease-free survival in younger CML chronic phase patients has been reported. Cord blood stem cell transplantation from an unrelated donor has also been used in adults with CML.⁶⁸¹

Pretransplantation imatinib is not associated with increased transplant-related morbidity or decreased survival, but those who are transplanted with suboptimal response to imatinib or loss of response to imatinib fare worse, probably related to a higher disease burden at the time of transplantation and more aggressive disease.^{682,683} Second-generation TKIs do not increase transplant-related toxicity.⁶⁸⁴ Disease status after allografting can be monitored with cytogenetic studies, PCR, or FISH analysis. A positive PCR assay 3 months after allogeneic transplantation has not been found to correlate with an increased risk of relapse compared with PCR-negative patients. A positive assay at 6 months and beyond is associated with subsequent relapse. In one series, 42 percent of patients with a positive PCR assay at 6 to 12 months relapsed versus 3 percent with a negative assay.⁶⁸⁵ Paradoxically, patients who remain *BCR-ABL1* positive more than 36 months after transplantation have little propensity for relapse.⁶⁸⁵ Serial quantitative RT-PCR analysis of blood specimens has been proposed to distinguish patients destined to relapse.⁶⁸⁶ Patients who remain in remission have undetectable, low, or falling *BCR-ABL1* levels on sequential analysis. After 6 to 9 months, these levels are undetectable in most cases. Recognition of relapse at the molecular level may allow for early therapeutic intervention.

Killer immunoglobulin-like receptors (KIRs) are expressed by NK cells and subpopulations of T cells. NK clones from a single individual can vary substantially in the type of KIR molecules they express. The ligands for several of the inhibitory KIR have been shown to be subsets of HLA class I molecules. Missing KIR ligands in recipients lead to less relapse and increased GVHD based on NK alloreactivity.⁶⁸⁷ KIR ligand mismatch has also been found to be an important prognostic factor in achieving molecular responses after transplantation for CML.⁶⁸⁸ Increased frequency of regulatory T cells characterized as CD4+,

CD25-high are associated with higher rates of relapse after allografting in CML.⁶⁸⁹

Nonmyeloablative Allogeneic Transplants

Nonablative regimens have been developed in an attempt to expand the indication for allogeneic transplantation to older patients. These regimens rely on immunosuppressive therapy to allow engraftment of cells that potentially will generate a graft-versus-leukemia effect. These procedures in general are associated with acceptable degrees of engraftment, less mortality, similar rates of GVHD, and possible durable effects on persistent or recurrent disease.⁶⁹⁰ Approximately 60 percent of patients, mostly in initial chronic phase (median age: 50 years) and transplanted with reduced-intensity conditioning regimens, had a 3-year survival and about one-third had a 3-year progression-free survival.⁶⁹¹ Patients no longer in first chronic phase do not fare as well.⁷¹² Conditioning regimens include fludarabine and busulfan,^{693,694} low-dose TBI and fludarabine, and low-dose TBI and cyclophosphamide, but no prospective randomized trials comparing regimens or comparing ablative and nonmyeloablative transplant approaches have been conducted.^{693,695,696} In one case, imatinib given concurrently with nonmyeloablative stem cell transplantation did not compromise engraftment and resulted in a cytogenetic remission in a patient with CML in blast crisis.⁶⁹⁷ Whereas nonmyeloablative or reduced intensity regimens are still considered investigational, they can achieve molecular remissions.

USE OF TYROSINE KINASE INHIBITORS AFTER STEM CELL TRANSPLANT

In patients treated with stem cell transplantation before the wide availability of imatinib, complete cytogenetic remissions with imatinib treatment can occur if treated at relapse after allografting and after donor lymphocyte infusion (DLI) fails to give a response. Such remissions may include a molecular response.⁶⁹⁸ Complete responses after imatinib therapy have been noted in accelerated or blast phase CML persisting after stem cell transplantation.⁶⁹⁹ In another series, 45 percent of relapsed patients had a CCyR of up to 28 months and without significant GVHD.⁷⁰⁰ In a series of 28 adults with relapse after allogeneic stem cell transplantation who then received imatinib, the response rate was 74 percent, and the complete cytogenetic remission rate was 35 percent. Five patients had recurrence of GVHD, and 13 had received previous DLI infusions.⁶⁹⁸ In one series, imatinib was able to generate complete molecular remissions in 26 percent of chronic phase patients after allografting, with full donor chimerism usually observed.⁷⁰¹ One study found that more relapsed patients had a molecular remission with DLI at 5 years than with imatinib alone. Most of these patients had cytogenetic relapses only.⁷⁰² In a retrospective comparison of 37 patients with hematologic or molecular relapse of CML who received imatinib, DLI, or a combination of both in concurrent or sequential regimens, the overall survival was 100, 89, and 54 percent for both modalities, imatinib, alone, and DLI alone, respectively.⁷⁰³ There are few studies examining use of nilotinib or dasatinib for posttransplantation relapses.⁷⁰⁴

Prophylactic administration of imatinib after transplantation has been used for patients at high risk of relapse.⁷⁰⁵ Posttransplantation imatinib may also postpone the requirement for DLI with its attendant risks of GVHD and marrow aplasia.⁷⁰⁶ Some have found that DLI are superior to imatinib therapy in preventing relapse and increasing leukemia-free survival. Posttransplantation imatinib is usually well-tolerated; pancytopenia is the principal toxicity. The cytopenias resolve with doses adjustments or temporary drug discontinuation. Many questions remain regarding the use of posttransplantation TKIs. When should they be started? Which drug is superior? For how long should

the drugs be used? Should they only be started in cases of molecular relapse? How can they be best combined with DLI in cases of relapse?

IMMUNOTHERAPY: ADOPTIVE CELL THERAPY FOR POSTTRANSPLANTATION RELAPSE

Substantial evidence indicates that the effectiveness of allografting in CML does not result solely from the eradication of the leukemic clone with high-dose chemoradiotherapy conditioning regimens, but also from adoptive immunotherapy provided by lymphocytes in the allograft, the graft-versus-leukemia effect (see “Myeloablative Allogeneic Transplants” above).⁷⁰⁷ This phenomenon has been recreated to produce a therapeutic response by infusing the lymphocytes from the stem cell donor after a relapse following allogeneic stem cell transplantation.^{708,709} The overall response rate to DLI is approximately 75 percent. The response rate is higher when this approach is used early after detecting a relapse by PCR,⁷¹⁰ compared to use after a hematologic or cytogenetic relapse. Patients with a short interval between transplantation and DLI have a higher probability of response than patients with longer intervals. Responses are the same with related versus unrelated donors.⁷¹¹ Some patients show a very rapid decline of *BCR-ABL1* transcript levels (<6 months after DLI), whereas other patients demonstrate PCR negativity only over a longer period.⁷¹² The responses to DLI can be durable.⁷¹³ Molecular responses can occur in up to two-thirds of patients.⁷¹⁴

The main toxicities of DLI have been the induction of GVHD and myelosuppression. Chronic GVHD can occur in up to 60 percent of cases.⁷¹⁵ Attempts to diminish these toxicities have included use of CD8-depleted DLIs and infusion of smaller numbers of T cells.^{716,717} Lower initial cell dose is associated with less myelosuppression, the same response rate, better survival, and less DLI-related mortality, leading to suggestions that the initial dose should not exceed 0.2×10^8 mononuclear cells/kg.⁷¹⁸ The initial doses should be lower when matched unrelated donors are used. Immune suppression should first be tapered before DLIs are administered. As noted above, imatinib may synergize with DLI to foster rapid molecular responses after relapse.⁷¹⁹

COURSE AND PROGNOSIS

Imatinib was first used experimentally for CML treatment in June 1998. Although it has completely altered the treatment approach to CML, its use has raised several questions. Studies require long-term followup of survival, but the degree of cytogenetic response, and degree of molecular response can be used as surrogate end points. The durability of cytogenetic and molecular responses in the face of persistent minimal residual disease during imatinib therapy require longer followup of larger numbers of patients, as more than 95 percent of cases have molecular evidence of disease at 2 years.

With the advent of TKI treatment, median survival in chronic phase CML is estimated to be 25 to 30 years. The prevalence of CML in the TKI era is estimated to reach a plateau 35 times the annual incidence with plateau estimated to occur in 2050. Therefore, the prevalence of CML is predicted to increase by a factor of 10.⁷²⁰ Using the Swedish Cancer Registry over a 36-year period, relative survival rates compared with the total population for CML improved from 0.21 in 1973 to 1979 to 0.80 for 2001 to 2008; imatinib was introduced in Sweden in 2001.⁷²¹ Another study from the Swedish CML registry of 779 patients showed that the mean survival ratio at 5 years was close to 1.0 for those younger than 60 years old and 0.9 for those 60 to 80 years old. Only 3 percent had progressed to accelerated or blast phase at 12 months.⁷²² Resistance rates decline with each passing year, and adverse effects have not emerged over time.⁷²³ Those who require 1 year or more of imatinib therapy to attain a complete cytogenetic remission have comparable rates of

TABLE 89-7. Chronic Myelogenous Leukemia: 5-Year Period Relative Survival Rates (2004–2012) by Age at Diagnosis

Age (years)	Percent of Patients*
<45	86
45–54	82
55–64	70
65–74	51
<75	27

molecular response, progression-free, and overall survival to those who achieve a cytogenetic remission sooner.⁷²⁴ In patients with failure to respond or intolerance to imatinib the estimated 3-year survival rate was approximately 70 percent for patients in chronic phase. Survival in chronic phase was better when subsequent therapy was nilotinib or dasatinib as compared to allogeneic hematopoietic stem cell transplantation or to others agents. This result was at a median followup of 2 years.⁷²⁵ Older patients have lower response rates when treated in late chronic phase, but if they attain a CCyR, no difference was found in the level of molecular response.⁷²⁴ Table 89-7 shows the most recent 5-year relative survival data by age at diagnosis in the United States.

The introduction of imatinib has minimized the impact of prognostic factors at diagnosis of chronic phase CML.⁷²⁶ Several prognostic scales have been proposed in CML, including the Sokal and Hasford systems for patients at the time of diagnosis (Table 89-8). The European Bone Marrow Transplantation Consortium Risk Score was introduced

TABLE 89-8. The Variables Used to Calculate the Risk Group (High, Intermediate, Low) at Diagnosis in Patients with Chronic Phase Chronic Myelogenous Leukemia to Estimate Prognosis

The Sokal score, which is a hazard ratio, is calculated using the following formula based on age, spleen size, platelet count, and blood percent blast cells: $\exp(0.0116 \times (\text{age} [\text{years}] - 43.4)) + (0.0345 \times (\text{spleen size} [\text{cm}] - 7.51) + (0.188 \times ((\text{platelets} [10^9/\text{L}]/700)^2 - 0.563)) + (0.0887 \times (\text{blasts} [\%] - 2.10))$. There are three risk groups: low-risk (Sokal score <0.8), intermediate-risk (Sokal score 0.8–1.2), and high-risk (Sokal score >1.2).

The Hasford score (or Euro score) is calculated using the following formula based on the four Sokal variables plus percent eosinophils and basophils in the blood: $(0.6666 \times \text{age} [0 \text{ when age} < 50 \text{ years}; 1 \text{ otherwise}]) + (0.0420 \times \text{spleen size} [\text{cm}]) + (0.0584 \times \text{blasts} [\%]) + (0.0413 \times \text{eosinophils} [\%]) + (0.2039 \times \text{basophils} [0 \text{ when basophils} < 3\%; 1 \text{ otherwise}]) + (1.0956 \times \text{platelet count} [0 \text{ when platelets} < 1500 \times 10^9/\text{L}; 1 \text{ otherwise}]) \times 1000$. Three risk groups are: low-risk (score ≤ 780 , 40.6% of patients), intermediate-risk (score 781–1480, 44.7% of patients), and high-risk (score ≥ 1481 , 14.6% of patients).

These scores may be calculated electronically by insertion of the individual variables, such as age, spleen size, blood blast percentage, etc. at the following website. <http://bloodref.com/myeloid/cml/sokal-hasford>.

for patients undergoing allogeneic hematopoietic stem cell transplantation,⁷²⁷ in which performance status is added to five variables (age, spleen size, blood blast cell count, basophil and eosinophil count, and platelet count [Hasford score]), and has been validated with good discrimination for survival.⁷²⁸ The Sokal score based on age, spleen size, platelet count, and percent blasts was developed much earlier during the busulfan era of treatment and was less accurate in patients treated with IFN. The European Treatment and Outcome Study (EUTOS) score uses basophils and spleen size but has not been well-validated. A simple prognostic scale that includes donor type, stage of disease at time of transplantation, age of recipient, sex of donor and recipient, and interval between diagnosis and transplantation has been proposed to predict outcome of allogeneic hematopoietic stem cell transplantation.⁷²⁹ These prognostic scales require revalidation given the dramatic impact of conversion to TKI therapy. There is evidence that a patient with chronic phase CML and a favorable Sokal Score at the time of diagnosis has a higher proportion of CHR and CCyR than other patients.⁷³⁰ Cytogenetic response and molecular response as a surrogate marker for survival is useful in patients undergoing TKI therapy.⁷³¹ The score of a patient may be calculated, easily, using an online website (Table 89–8). Studies suggest that in certain healthcare systems, healthcare setting may influence survival time, especially for those in advanced phases of the disease.⁷³²

Outcomes after allogeneic hematopoietic stem cell transplantation have also improved in the imatinib era, but those in chronic phase have better 3-year survival rates than those in advanced phases (91 percent vs. 59 percent, respectively).⁷³³ There is favorable long-term survival after 5 years free of relapse after allogeneic hematopoietic stem cell transplantation.⁷³⁴ Prognostic factors in the TKI era for allogeneic transplantation are also being defined, and in addition to disease phase, donor-match, age, sex, and calculated comorbidity indices are of importance.⁷³⁵

DETECTION OF MINIMAL RESIDUAL DISEASE

Detection of minimal residual disease by molecular probes makes possible the identification of approximately one cell in 1,000,000 that is derived from the CML clone.⁷³⁶ Techniques used to monitor residual disease have been reviewed.^{737,738} PCR permits observation of regression or persistence of subclinical disease following therapy and of progression of subclinical disease prior to the disease becoming overt, and it is therefore critical for monitoring responses to CML treatment.^{739,740} The stable persistence of subclinical disease does not invariably predict early relapse.^{741,742}

Efforts are underway to standardize the technique for measuring and reporting real-time RT-PCR,⁷⁴³ and serial measurements are required for treatment decisions based on increases in transcript numbers.⁷⁴⁴ Some studies show that marrow values tend to be higher than blood in real-time RT-PCR assays, but both follow a similar trend during treatment.⁷⁴⁵ Interchanging these may lead to misinterpretation of disease status.⁷⁴⁵ In patients on imatinib, who have MMR, confirmed by real-time quantitative PCR, no marrow cell cytogenetic abnormalities were found, indicating that patients with MMR do not require regular marrow examinations for cytogenetics. The International Standard uses baseline diagnosis levels in the IRIS study as 100 percent and fixes a 3-log reduction from a standardized baseline (MMR) at 0.1 percent. Widespread use of the International Standard will require laboratories to send in specimens for analysis,^{743,746} but is a priority in order to ascertain response to therapy accurately and to be able to analyze responses among treatment centers.

Patients who achieve a MMR (expressed as a 3-log reduction from median baseline value) at the time of achieving a CCyR have been found to have longer cytogenetic remissions than those without this magnitude of molecular response.⁷⁴⁹ The achievement of a 2-log molecular

response at the time of a CCyR or a 3-log response anytime thereafter is an independent prognostic marker of progression-free survival.⁷⁴⁸ Other studies, however, show that patients who achieve CCyR do not derive additional benefit from a CMR.⁷⁴⁹ The treatment response, to imatinib, nilotinib, or dasatinib showed the 3-year event-free survival was 95 percent for those with *BCR-ABL1* transcripts of 1 percent or less at 3 months, 98 percent for greater than 1 percent to 10 percent, and 61 percent for greater than 10 percent. These 3-month responses translated into overall survival of 98, 96, and 92 percent, respectively.⁷⁵⁰

Interphase FISH is not standardized, but a large number of cells can be rapidly analyzed (100 to 500). Fixation, specimen preparation, and hybridization conditions may account for differing false-positive ranges and scoring criteria.⁷⁵¹ In CML patients treated with imatinib, FISH for *BCR-ABL1* on interphase blood neutrophils, but not unselected white cells, correlates with marrow cytogenetics.⁷⁵² FISH and RT-PCR can be useful complementary techniques,⁷⁵³ but FISH is generally not suitable for monitoring minimal residual disease.⁷⁵⁴

For patients who are undergoing allogeneic hematopoietic stem cell transplantation, the kinetics of minimal residual disease in either standard or nonmyeloablative transplants differ. *BCR-ABL1/ABL1* ratios were 0.2 percent with reduced-intensity transplants versus 0.01 percent in transplantation patients with traditional conditioning regimens in the first 3 months. By 12 months, however, 20 percent of patients who received standard transplants and 50 percent of patients who received reduced-intensity transplants had reached a level less than 0.01 percent, supporting the concept of different kinetics of disease eradication between the two transplantation modalities.⁷⁵⁵ Patients who relapse after allografting have reappearance and/or rising levels of *BCR-ABL1* transcripts.⁷⁵⁶ Use of quantitative RT-PCR early (3 to 5 months) after stem cell transplantation can project long-term outcomes.⁷⁵⁷ When RT-PCR was negative, the 3-year risk of relapse was 16.7 percent; when RT-PCR was positive at a ratio of less than 0.02 percent, the relapse rate was 42.9 percent; and when RT-PCR was positive at a level greater than 0.02 percent, the relapse rate was 86.5 percent. Another group found that detection of blood *BCR-ABL1* at 18 or more months after transplantation was associated with a highly significant risk of relapse and that patients who had a positive test result but failed to relapse generally had only one positive test result at a low copy number.⁷⁵⁸ Performance of quantitative PCR (qPCR) at regular intervals after allogeneic transplant (every 2 to 4 months in the first year and every 6 months thereafter) is appropriate. If the PCR results are persistently positive or become positive, qPCR should be performed at monthly or shorter intervals. Molecular relapse is defined as a 10-fold increase of PCR positivity without any signs of cytogenetic relapse.⁷⁵⁹ Detection of increasing recipient chimerism by FISH for the male chromosome in sex-mismatched donor-recipient pairs or variable number of tandem repeats after allogeneic transplantation or after DLI infusion also is usually associated with a relapse.⁷⁶⁰

In an imatinib-treated patient, the absence of *BCR-ABL1* transcripts should not be interpreted as an absence of the leukemic clone.⁷⁶¹ In terms of response to second-generation TKIs, there was no difference in event-free survival and CCyR duration between patients with CCyR with and without MMR up to 18 months with followup at 3-month intervals.⁷⁶² One study examined 116 patients with durable cytogenetic responses on imatinib who had increased PCR levels on at least two occasions. Only 9 percent of those had CML progression. Ten patients had lost MMR or had never had it, and all of these had more than 1-log increase in qPCR.⁷⁶³ With second-generation TKI, the *BCR-ABL1* transcript levels at 3 months are also correlated with CCyR and MMR by 24 months, with levels less than 10 percent at 3 months being optimal.⁷⁶⁴ The European Leukemia Net criteria for failure or suboptimal response may also identify CML in early chronic phase treated with imatinib

where the eventual outcome will be poor. These landmarks at 3, 6, 12, and 18 months are associated with poorer overall survival and cytogenetic responses.⁵⁰⁵ Only 60 percent of patients on the IRIS trial were in CCyR on imatinib after 6 years of therapy, indicating the need for close monitoring and for alternative therapies.⁷⁶⁵ There is also evidence that the *BCR-ABL1* transcript doubling-time more reliably assesses CML relapse as compared to the fold rise in *BCR-ABL1* transcripts. A short doubling-time for a patient in chronic phase should raise suspicion of nonadherence.⁷⁶⁶

● ACCELERATED PHASE AND BLAST CRISIS OF CHRONIC MYELOGENOUS LEUKEMIA

DEFINITION

In all patients with chronic phase CML, the disease has the potential to evolve into a more aggressive, more symptomatic, and troublesome phase, which is poorly responsive to the therapy that formerly controlled the chronic phase. The failure of therapy to restore or maintain near-normal red cell and white cell counts, increased spleen size, increased numbers of marrow blasts and blood basophils, loss of the sense of well-being, and appearance of extramedullary tumors are the most consistent clinical hallmarks of the metamorphosis of the chronic to the accelerated phase of CML. The most objective findings are a blood blast percentage greater than 10, a platelet count less than $100 \times 10^9/L$, blood basophils greater than 20 percent, and new clonal cytogenetic abnormalities accompanying the Ph chromosome.⁷⁶⁷

Several criteria have been published to define accelerated phase and blast crisis.⁷⁶⁸⁻⁷⁷⁰ The terminology used has included *accelerated phase*, *acute phase*, *acute transformation*, or, in its most dramatic expression, *blast crisis*, but the metamorphosis, which can be acute, often is more gradual, hence the preference for *transformation* or *accelerated phase* to describe this transition from a controllable to a poorly controlled malignancy. Blast phase is the most severe manifestation of the accelerated phase and can occur abruptly or after a period of worsening disease. Blast crisis is in effect the evolution to overt acute leukemia, either myeloid or lymphoid.

PATHOGENESIS

Effect of Tyrosine Kinase Inhibitors in Rate of Progression

The advent of TKI therapy for CML has resulted in a marked increase in the duration of a subclinical chronic phase, with normal blood counts and spleen size, often with the loss of identifiable Ph chromosome-bearing cells in blood and marrow, and sometimes with the loss of laboratory evidence of the *BCR-ABL1* oncogene as judged by PCR. This therapeutic advance has greatly delayed the evolution to accelerated phase and blast crisis, but the risk for such a conversion exists since under experimental conditions CML stem cells do not undergo apoptosis when exposed to *BCR-ABL1* TKIs and *BCR-ABL1*-positive cells return in virtually all patients if tyrosine kinase therapy is interrupted. There is evidence that genomic instability may derive from an imatinib-refractory CML stem cell.⁷⁷¹

Blast Crisis Stem Cells

The onset of accelerated phase is thought to occur in a *BCR-ABL1*-bearing granulocyte-monocyte progenitor. Experimental^{772,773} and theoretical⁷⁷⁴ evidence supports this concept. This progenitor for clonal evolution also could explain the reversion to chronic phase in some patients in whom the suppression of the advanced phase of the disease is achieved.

Molecular and Genetic Alterations

The transformation of chronic phase CML to accelerated and then blast crisis or directly to blast crisis is thought to be the result of seven molecular processes: (1) maturation arrest, (2) failure of genome surveillance, (3) failure of adequate DNA repair, (4) development of a mutator phenotype, (5) telomere shortening, (6) loss of tumor-suppressor function, and (7) unknown factors.^{775,776}

Progression of chronic phase to accelerated phase is marked by an increase in *BCR-ABL1* expression.^{777,778} Superimposed on the increased transcription of mRNA^{*BCR-ABL1*} are additional cytogenetic abnormalities that are added to the persistent Ph chromosome in approximately 50 to 65 percent of patients.⁷⁷⁹⁻⁷⁸¹ In lymphoid blast crisis, in which the blast cells have a lymphocytic phenotype, acquisition of mutations in tumor suppressor genes, such as p16/*ARF*, occurs in approximately 50 percent of cases, and *RB* gene mutations occurs in approximately 20 percent of cases. In myeloid blast crisis, in which blast cells have a myeloid phenotype, approximately 25 percent of cases have cells containing a p53 mutation.⁷⁸² The possible role of loss of p53 function in fostering transformation of a human chronic phase CML clone has been demonstrated in transgenic mice in which p53 function was abrogated.^{783,784} Progression of the clone to a more malignant clone is reflected in a more disordered growth and maturation pattern of progenitor cells in culture, ultimately mimicking the growth failure of acute leukemia,⁷⁷⁹ and in increased morphologic and functional abnormalities of blood cells,^{785,786} eventuating in a block in maturation and replacement of blood and marrow by blast cells.

Approximately 65 percent of patients have cytogenetic abnormalities in addition to the Ph chromosome. A double Ph chromosome, trisomy 8, and isochromosome 17p are the secondary changes most commonly seen.^{782,787} Because the frequency of trisomy 8 was greater after treatment with busulfan compared to hydroxyurea, the frequency of secondary chromosomal changes may be quite different after imatinib therapy.⁷⁸² Clonal instability has also been found in cases of lymphoid blast crisis. Clones distinct from those identified later may be detected before overt lymphoid transformation. Identification of these abortive clones suggests clonal instability before the onset of transformation, which might have prognostic value.⁷⁸⁸ FISH has been used to determine which cells have secondary cytogenetic abnormalities, and these cells often are not the blast cells. This finding suggests that some chromosomal abnormalities merely denote genomic instability.⁷⁸⁹ The abnormal mRNA and protein product p210^{*BCR-ABL1*} are present in the marrow and blood cells of patients who have transformed to acute leukemia.⁷⁹⁰⁻⁷⁹²

Although the breakpoint site on *M-bcr* was thought to be correlated with the time of the onset of the accelerated phase,⁷⁹³ subsequent studies have not indicated a correlation between length of chronic phase and the specific site of the *BCR-ABL1* fusion.⁷⁹⁴ Rare cases have displayed deletion of the *BCR-ABL1* fusion gene, loss of transcription of the message, and loss of expression of the p210 tyrosine kinase after transformation, the latter finding indicating the abnormal protein kinase may not always play a unique role in sustaining the acute state.⁷⁹⁵ In contrast, the frequent response, albeit temporary, to imatinib suggests that the *mutant BCR-ABL1* product usually plays a role at this stage of the disease.

Numerous molecular changes identified in the cells of patients with acute transformation that might contribute to the increased malignant behavior of the CML clone, include activation of the *N-RAS* gene,^{796,797} rearrangement of the p53 gene,⁷⁹⁷⁻⁸⁰⁰ hypermethylation of the calcitonin gene,⁸⁰¹ and methylation of the *ABL1* gene.⁸⁰² One report described p53 mutations in 17 percent of blast crisis patients. An association between the failure of CML cells to express the *RB1* gene product and acute blast crisis with a megakaryoblastic phenotype has been reported.⁸⁰² Homozygous deletions of the *p16* gene are associated with lymphoid

transformation of CML,⁸⁰⁴ but such deletions are not seen in the chronic phase and in myeloid blast crisis. p16 is also known as the *cyclin-dependent kinase 4 inhibitor gene* and is located on chromosome 9p21.^{805,806} This gene inhibits the kinase CDK-4, which regulates a cell-cycle checkpoint prior to commitment to DNA synthesis. The Wilms tumor (*WT*) gene on chromosome 11p13 encodes a zinc finger motif-containing transcription factor found in CML patients only after progression to blast crisis.⁸⁰⁷ Overexpression of the *EVI-1* gene has also been found in CML blast crisis.^{808,809} Microsatellite instability has not been found to be involved with progression to blast crisis.⁸¹⁰ *BCL-2*, *c-MYC*, *RUNX1*, *IKZF1*, *ASXL1*, *WT1*, *TET2*, *IDH1*, *NRAS*, *KRAS*, *CBL*, and various other genes have also been implicated in the evolution of CML.^{811–815}

Approximately 50 genes have been identified that could play a role in the progression to accelerated phase or blast crisis,⁷⁷⁵ including genes identified by expression profiling that are dysregulated in accelerated phase compared to chronic phase.^{816,817} These include the WNT- β -catenin and JunB pathways.

CLINICAL FEATURES

Signs and Symptoms

The features that might signal the conversion of the chronic to the accelerated phase include unexplained fever, bone pain, weakness, night sweats, weight loss, loss of sense of well-being, arthralgia, and left upper quadrant pain related to splenic enlargement or infarcts. These features may occur weeks in advance of laboratory evidence of the accelerated phase. Localized or diffuse lymphadenopathy or enlarging masses in extralymphatic and extramedullary sites containing *BCR-ABL1*-positive myeloblasts or lymphoblasts may develop. A poor response of blood cell counts and splenic enlargement despite previously effective therapy may be evident.^{767,782,818–820} Symptoms caused by histamine excess in basophilic crisis can be present.⁸²¹

Several of these changes may occur in series or in parallel. The time of onset of transformation and the appearance of a blast crisis and its clinical expression are unpredictable.

LABORATORY FEATURES

Blood Findings^{782,818–820}

Anemia may worsen and be associated with increasing poikilocytosis, anisocytosis, and anisochromia. The number of nucleated red cells in the blood may increase. These red cell changes may be accentuated further if advancing marrow fibrosis is a feature of the disease.

The total leukocyte count may fall without treatment. The proportion of blasts increases to greater than 10 percent in blood and marrow in the accelerated phase and when blast crisis ensues represents 20 to 90 percent of the cells. The morphology of the blast cells may be lymphoid or myeloid. Myelocytes decrease in number. Hyposegmented neutrophils (Pelger-Huët cells) and other dysmorphic changes may become evident. Basophils increase and often represent 20 to 80 percent of the total blood leukocytes. A decrease of the platelet count to less than $100 \times 10^9/L$ develops. Giant platelets, micromegakaryocytes, and megakaryocyte fragments may enter the blood. Decreased progenitor cell growth in culture is present, akin to that in acute leukemia.

Marrow Findings^{782,818–820}

The marrow findings are widely variable. Marked dysmorphic changes in one, two, or three of the major cell lineages; an increase in blast count to greater than 10 percent; marrow morphology simulating subacute myelomonocytic leukemia; or, in the extreme, florid blastic transformation with blast counts greater than 30 percent can occur. Reticulin fibers may increase in prominence, and occasionally severe reticulin

and collagen fibrosis develop. Additional clonal cytogenetic abnormalities develop in as many as half the patients in accelerated phase (see “Cytogenetic Studies” below).

EXTRAMEDULLARY BLAST CRISIS

A variety of symptoms or signs may occur as a result of the specific effects of new extramedullary blastic tumors, referred to as *extramedullary blast crisis*.^{821–824} Extramedullary blast crisis is the first manifestation of accelerated phase in approximately 10 percent of patients with CML. Lymph nodes,^{822–824} serosal surfaces,^{825,826} skin and soft tissue,^{821–824} breast,^{824,827} gastrointestinal or genitourinary tract,^{822,824} bone,^{822,824,824–831} and central nervous system^{822,832–836} are among the principal areas involved. Isolated or diffuse lymphadenopathy may occur. Bone involvement may lead to severe pain, tenderness, and pathologic fracture, and may be evident on imaging of the involved area. Central nervous system involvement usually is meningeal and may be preceded by headache, vomiting, stupor, cranial nerve palsies, and papilledema and is associated with an increase in cells, protein, and the presence of blasts in the spinal fluid.^{824,832–834}

Appropriate histochemical and immunologic tests are required to determine if the extramedullary disease is composed of phenotypic myeloblasts or lymphoblasts. Because the tumor cells may have features of lymphoma cells, the terms *myeloid* or *granulocytic sarcoma*, *chloroma*, and *myeloblastoma* can be misnomers, and the term *extramedullary blast crisis* is used for this circumstance in CML.^{833,835–837} The lymphoblasts, like the myeloblasts, are Ph chromosome–positive. A combination of morphology, histochemistry (e.g., peroxidase, lysozyme), terminal deoxynucleotidyl transferase assay, and monoclonal antibodies specific for lymphoid or myeloid cells can be used to classify the extramedullary blast cells.

MARROW BLAST CRISIS

Approximately half of patients with CML enter the accelerated phase by developing acute leukemia. The onset of blast crisis can develop from days^{838–840} to decades after diagnosis of CML. The signs and symptoms may include fever, hemorrhage, bone pain, and lymphadenopathy.^{776,838–840} The morphology of the acute leukemia usually is myeloblastic or myelomonocytic.^{776,841} A substantial proportion of myeloid leukemia in this setting may not have myeloperoxidase demonstrable by cytochemistry.⁸⁴² The proportion of cases classified as erythroblastic leukemia is approximately 10 percent, based on morphologic features,⁸⁴³ but may be as high as 20 percent if expression of glycophorin-A is used as the determinant.⁸⁴⁴ Occasional cases have megakaryoblastic transformation.^{803,845} These cases may be difficult to identify by light microscopy because the megakaryoblasts may be mistaken for lymphoid cells or undifferentiated blasts. Myelofibrosis is a feature of this variant. Antiplatelet glycoprotein antibodies and other monoclonal antiplatelet antibodies now are available as reagents to identify megakaryoblasts without the need for ultrastructural studies.⁸⁴⁵ Promyelocytic^{846–848} and eosinophilic⁸⁴⁹ blast crises also can occur. Basophilic leukemia is a known variant of CML.⁸⁵⁰ Patients with promyelocytic crisis often have t(15;17) in addition to the Ph chromosome, and some have presented with disseminated intravascular coagulation.⁸⁵¹

CML may transform into acute lymphoblastic leukemia in approximately 30 percent of blastic crisis cases.^{767,852–856} The lymphoid cells generally express terminal deoxynucleotidyl transferase (TdT)^{852,853} and are of the B-cell lineage,^{856–878} as judged by antiimmunoglobulin staining. TdT is a DNA polymerase that adds deoxynucleoside monophosphates from triphosphate substrates to single-stranded DNA by end addition, differing in the latter respect from replicative polymerases.⁸⁵⁹

The enzyme is present in normal immature thymocytes and in the blast cells of nearly all patients with acute lymphoblastic leukemia. Rare patients have blasts with a T-lymphocyte phenotype.^{835,836,860–862} Some cases are biphenotypic; the blasts have both lymphoid and myeloid markers.^{841,863–865} Some cases may have myeloperoxidase activity in blast cells and express CD33 or CD13. Myeloid to lymphoid clonal succession following autologous transplantation in the second chronic phase has been described.⁸⁶⁶ Patients with lymphoid blast crisis seldom have an intermediate accelerated phase, have less splenomegaly and basophilia, and usually have a higher degree of marrow blast infiltration. With non-TKI therapy, remission rate and survival were somewhat longer in cases of lymphoid than in myeloid blast crisis.⁸⁶⁷

CYTOGENETIC STUDIES

Most large studies have shown seven recurrent changes in patients' cells prior to, or during, the accelerated phase: trisomy 8 (33 percent of cases), additional 22q- (30 percent of cases), isochromosome 17 (20 percent of cases), trisomy 19 (12 percent of cases), loss of Y chromosome (8 percent of males), trisomy 21 (7 percent of cases), and monosomy 7 (5 percent of cases).^{867–870} In addition, a large number of other chromosome abnormalities have been described.^{871–875} In one study, 46 (63 percent) of 73 blast crisis patients had secondary cytogenetic abnormalities. These abnormalities were more common in myeloid blast crisis and were associated with shorter remission.⁷⁸⁸ The changes may be features of myeloid blast crisis compared to lymphoid crisis.^{869,874} Some abnormalities, such as inv16, are associated with early transformation to AML.^{870,874–877} A significant proportion (50 percent) of patients in the accelerated phase or blast crisis have no additional cytogenetic abnormalities beyond t(9;22)(q34;q11) after banding and multicolor FISH analysis.⁸⁷⁶ In cases where the blastic transformation is in extramedullary sites, such as lymph nodes or spleen, the additional cytogenetic abnormalities may be in the cells at those sites but not in cells in the blood or marrow.⁸⁷⁸

TREATMENT

Optimal treatment is allogeneic stem cell transplantation if the patient is eligible based upon patient's age and donor availability. The role of stem cell transplantation is also evolving as TKI use in these phases of diseases becomes better defined. Thus far, treatment with TKIs has improved survival only modestly in blast crisis, and most long-term survivors have been transplanted. At present, it is recommended that patients in blast crisis be treated with TKIs with or without chemotherapy to a second chronic phase and proceed to stem cell transplant as soon as possible once a donor is identified. One of the major goals of treatment of chronic phase CML is the prevention of evolution to accelerated or blast phases of the disease.

Tyrosine Kinase Inhibitors in Accelerated and Blast Crisis

The initial dose of imatinib in accelerated phase is 600 mg/day.⁸⁷⁹ Imatinib, dasatinib 140 mg/day, and nilotinib 400 mg BID, bosutinib 500 mg daily, and ponatinib 45 mg/day have been used as bridging therapies to permit allogeneic stem cell transplantation in accelerated phase.⁸⁸⁰ Dasatinib and nilotinib can achieve a better molecular response, and thus the role for and timing of transplantation in accelerated phase CML is being redefined. Imatinib can be combined with an anthracycline plus cytarabine for patients in myeloid blast crisis.⁸⁸¹ Imatinib has produced complete hematologic remissions in approximately 20 percent of patients.^{882,883} However, CCyRs are uncommon. Central nervous system and other extramedullary blast crisis can occur during imatinib therapy for accelerated phase disease,^{884,885} and all types of blast crisis,

including promyelocytic blast crisis,⁸⁸⁶ can occur during imatinib therapy. Compared to historical controls in which various combinations of chemotherapy were utilized, imatinib used alone results in comparable outcomes (6-month median survival of patients in blast crisis).⁸⁸⁷ Although dasatinib therapy can result in CCyRs in 29 percent of blast crisis CML, and nilotinib can result in CCyRs in 27 percent of myeloid blast crisis and in 43 percent of lymphoid blast crisis, these responses are rarely durable, so in a patient of appropriate age with an acceptable donor, transplantation options should be considered with the second-line TKIs used as a bridge to transplantation therapy.^{888,889} The choice of TKI in accelerated phase is based on prior therapy and/or mutational status. If response to TKI therapy is inadequate in accelerated phase, allogeneic hematopoietic stem cell transplantation should be considered. In lymphoid or myeloid blast phase, allogeneic hematopoietic stem cell transplantation is recommended if there is a suitable donor.⁴¹⁷ Omacetaxine has shown activity in patients with disease progression to accelerated phase CML after prior TKI use.⁸⁹⁰

Chemotherapy

The treatment approach is predicated on the phenotype of the blast cells in CML patients with blast crisis and is rarely used in accelerated phase. In patients with myeloid phenotypes, the approach has been similar to that used for AML: combinations of an anthracycline antibiotic, such as idarubicin or daunorubicin, with cytosine arabinoside and sometimes etoposide.⁸⁹¹ Because this approach produces few remissions that are of short duration (median survival approximately 6 months), a variety of other drug combinations have been used, but with no significant improvement in outcome.⁸⁸⁷ Complete hematologic response is observed in only a quarter to a third of patients with this approach.

In patients with lymphoid phenotypes, vincristine sulfate 1.4 mg/m² (not to exceed 2 mg/dose) given intravenously once per week and prednisone 60 mg/m² per day given orally are the mainstay of treatment. A minimum of two cycles of treatment (2 weeks) should be given to judge responsiveness. Other more intense ALL-type regimens, such as HyperCVAD (cyclophosphamide, vincristine, doxorubicin, and dexamethasone),⁸⁹² have also been used. Approximately one-third of patients with lymphoid blast transformation reenter the chronic phase after such treatment. However, because only about one-third of patients have lymphoid blasts, this number represents a remission rate of only approximately 10 percent of patients who enter blast crisis using this approach. The benefit of intensive chemotherapy has been small because remission durations have been modest. TdT-positive, CD10 (CALLA)-positive lymphoblasts may be the lymphoblast phenotype most responsive to vincristine and prednisone.⁸⁵⁵ mTOR inhibitors may be useful in lymphoid blast crisis.⁸⁹⁷

Use of Chemotherapy with Tyrosine Kinase Inhibitors in Accelerated Phase or Blast Crisis

Imatinib has been successfully combined with decitabine, low-dose cytarabine, and standard anthracycline plus cytarabine ("7 + 3") where complete remission can be as high as 75 percent. Median time to relapse and overall survival are brief, however.⁸¹⁵ Imatinib and dasatinib have been combined with HyperCVAD in lymphoid blast crisis.^{892,893}

Allogeneic Hematopoietic Stem Cell Transplantation

Stem cell transplantation from an appropriately HLA-matched donor has been used in some patients after entry into the blastic crisis. Occasional patients have had long-term survival. The 3-year survival rate is approximately 15 to 20 percent,^{894–896} unlike transplantation in the chronic phase, in which the 3-year survival rate is 50 to 60 percent. However, for patients who present in blast crisis, who develop blast

crisis in the first year of the chronic phase, or who delay transplantation for other reasons, transplantation remains the best hope for long-term survival if a histocompatible donor is available.^{832,833} Relapse of accelerated phase after allogeneic stem cell transplantation has responded to infusion of donor cytotoxic T lymphocytes.⁸⁹⁷ The use of TKIs before allogeneic stem cell transplantation for patients in advanced phases of disease may favorably improve transplantation outcomes, especially when MCyR occurs before transplantation.⁸⁹⁸

Autologous Hematopoietic Stem Cell Transplantation

Autografting in the accelerated phase or blast crisis, either with stem cells collected during chronic phase or with mobilized Ph chromosome-negative progenitor cells collected upon cell rebound after intensive chemotherapy, has resulted in apparent prolonged remission in some patients, but this procedure is rarely used in advanced disease because of the high rate of relapse.⁸⁹⁹ Whether Ph chromosome-negative cells collected during imatinib therapy have the same potential is unknown.

Splenectomy

Splenectomy may be performed for palliation of painful splenic infarctions or hemorrhage. However, the complication rates are high, and the procedure performed in this setting should be avoided if possible.⁹⁰⁰

COURSE AND PROGNOSIS

The accelerated phase of CML generally is very poorly responsive or refractory to treatment and is a morbid state that can be fatal in weeks to months in all but a few patients who undergo a successful stem cell transplant from a histocompatible donor. Patients with myeloid blast crisis have a median survival of approximately 6 months, whereas patients with lymphoid blast crisis have a median survival of approximately 12 months.⁸⁸⁷⁻⁹⁰¹ In the earliest study of imatinib in blast crisis, patients with myeloblastic crisis had a slightly longer median survival (approximately 5 months) than patients with lymphoid blast crisis plus Ph chromosome-positive ALL (3 months). The results are poor in either case. A worse survival was seen with abnormalities of chromosome 17, other superimposed translocations, or a high percentage of abnormal metaphases.⁹⁰² Severe cytopenias from repeated courses of cytotoxic therapy contribute to infections, hemorrhage, and organ dysfunction, especially liver and kidney dysfunction. Opportunistic infections with herpes viruses, cytomegalovirus, or fungi often supervene. The addition of imatinib or other TKI therapies has made only a small difference in long-term outcome, although formal studies of combinations of chemotherapy and imatinib at a higher dose (600 mg/day) have not been completed, and the results of trials with second-generation TKIs are anticipated.

RELATED CLONAL MYELOID DISEASES WITHOUT THE BCR REARRANGEMENT

In addition to classic CML with the *BCR-ABL1* fusion gene, there are several other chronic myeloid leukemias which are listed in [Table 89-9](#).

CHRONIC MYELOMONOCYTIC LEUKEMIA

This leukemia is part of the spectrum of clonal myeloid diseases that may have findings that simulate CML. In the past, when rigorous criteria for the diagnosis of CML were not applied, CMML was among a heterogeneous group of related diseases that sometimes were referred to as *Ph chromosome-negative CML*. These diseases share the feature of originating in the clonal expansion of a primitive multipotential hematopoietic cell.⁹⁰³

Epidemiology

Most patients with CMML are older than age 50 years, the median age is approximately 72 years, and approximately 90 percent of patients are older than age 60 years at the time of diagnosis.⁹⁰⁴ Occasional cases have been reported in older children and younger adults. Men are affected more frequently than women (approximately 2:1).⁹⁰⁴⁻⁹⁰⁶ An evaluation of exogenous factors that might increase the incidence of CMML, did not find an association with benzene or other occupational or non-occupational risk factors.⁹⁰⁷

The disease may occur following therapy for an unrelated malignancy, most commonly lymphoma, breast, or prostate cancer. The prior therapy was radiation, combined radiation and chemotherapy, or chemotherapy, alone. The median time of onset of CMML was 6 years.⁹⁰⁸

Clinical Findings

Signs and Symptoms The onset usually is insidious, and weakness, infection, or exaggerated bleeding may bring patients to medical attention.^{905,906} Hepatomegaly and splenomegaly occur in approximately 50 percent of patients. Leukemia cutis occurs in a small proportion of patients and the skin cellular infiltrate is usually has a monocytic phenotype: CD45, CD68, and lysozyme positive by immunostaining. Immune manifestations, such as vasculitis, pyoderma gangrenosum, immune cytopenias, and connective tissue diseases, may occur in coincidence with CMML.⁹⁰⁹

Blood and Marrow Findings The disease is characterized by anemia and blood monocytosis greater than $1 \times 10^9/L$.⁹¹⁰ The white cell count may be decreased, normal, or moderately elevated. In one study of 275 patients, the range in 247 informative patients was 0.9 to $160 \times 10^9/L$.⁹⁰⁴ Occasional patients, however, may have hyperleukocytosis with total white cell counts of 250 to $300 \times 10^9/L$ associated with respiratory insufficiency resulting from pulmonary leukostasis.⁹¹¹ Promonocytes and monocytes are present in blood and may have dysmorphic features. Immature granulocytes (promyelocytes and myelocytes) may be present in the blood. Blood myeloblasts are absent in approximately 75 percent of patients or, when present, usually do not exceed 10 percent of total white cells. Most patients have thrombocytopenia, but normal or elevated platelet counts may occur (range: 3.0 to $1385 \times 10^9/L$ among 227 patients in one series).⁹⁰⁴ Eosinophilia may be so prominent in occasional cases that the designation *chronic eosinophilic leukemia* may be appropriate.^{905,906,912}

The marrow is hypercellular as a result of granulomonocytic hyperplasia; the dominant cells are early myelocytes. Blasts cells are 1 to 4 percent in about two-thirds of patients and are from 5 to 19 percent in one-third of cases.⁹⁰⁴ The proportion of promyelocytes is increased. Promonocytes and monocytes also are increased in number. Distinction between poorly granulated myelocytes and promonocytes with primary granules can be difficult. Macronormoblasts and hypersegmented or hyposegmented, often bilobed (acquired Pelger-Huët anomaly), neutrophils may be evident but are more frequent in cases with lower white cell counts. Despite thrombocytopenia, megakaryocytes usually are present in the marrow. Microvessel density is increased in the marrow, and myelomonocytic cells contain cytoplasmic mRNA for VEGF and membrane VEGF receptors.^{912,913} *In vitro* colony studies suggest that autocrine stimulation of cell growth by VEGF may occur. "Spontaneous" cluster/colony growth of granulocyte-monocyte colony-forming cells occurs *in vitro*. The spontaneous growth may result from autocrine or paracrine production of GM-CSF, based on anti-GM-CSF inhibition of colony growth.⁹¹⁴

Cytogenetic and Genetic Findings Patients with CMML have an approximately 35 percent frequency of chromosomal abnormalities. Trisomy 8 and, to a lesser extent, monosomy 7 and -Y are the most prevalent findings. A low-risk karyotype is either a normal pattern or

TABLE 89–9. Types of Chronic Myelogenous Leukemia

Type of Chronic Myelogenous Leukemia	Molecular Genetics	Major Clinical Features	Further Details
<i>BCR</i> rearrangement-positive chronic myelogenous leukemia	>95% p210 ^{BCR-ABL} ; <5% p190 or p230	Splenomegaly in 80% of cases; WBC >25 × 10 ⁹ /L; blood blasts <5%; absolute basophilia in virtually all cases. Ph chromosome in 90% of cases; <i>BCR</i> gene rearrangement in 100% of cases	Pages 1437–1467
Chronic myelomonocytic leukemia	>40% mutation in <i>SRSF2</i> gene and 90% have a mutation in 1 of 9 genes. ¹⁰³² Various cytogenetic abnormalities	Anemia, monocytosis >1.0 × 10 ⁹ /L; blood blasts <10%; increased plasma and urine lysozyme; <i>BCR</i> rearrangement absent; rare cases with <i>PDGFR-β</i> mutation respond to imatinib	Page 1467
Chronic eosinophilic leukemia	Various cytogenetic abnormalities; <i>PDGFR-α</i> mutations in some cases.	Blood eosinophil count >1.5 × 10 ⁹ /L; cardiac and neurologic manifestations common; a proportion of cases have <i>PDGFR-α</i> mutations and are responsive to imatinib mesylate	Page 1469
Chronic basophilic leukemia	Various cytogenetic abnormalities	Only 5 cases reported; hemoglobin 6–13 g/dL; basophilia of 3.4–41 × 10 ⁹ /L; 2 of 5 cases with splenomegaly; very cellular marrow (>90%) in each case with mild increase in type III collagen, and megakaryocytic dysmorphia; increase in marrow mast cells in 3 of 5 cases	Page 1470
Juvenile myelomonocytic leukemia	<i>RAS</i> pathway mutations (<i>PTPN11</i> , <i>NF1</i> , <i>NRAS</i> , <i>KRAS</i> and <i>CBL</i>) in 89% of cases. ¹⁰³³ Various cytogenetic changes	Infants and children <4 years; eczematoid or maculopapular rash; anemia and thrombocytopenia; increased Hgb F in 70% of cases; neurofibromatosis in 10% of cases; abnormality of chromosome 7 (e.g., del 7, del 7q, etc.) in approximately 20% of patients; <i>BCR</i> rearrangement absent	Page 1470
Chronic neutrophilic leukemia	Colony-stimulating factor 3 receptor gene (<i>CSF3R</i>) alone (~30% of cases); a combination of mutated <i>CSF3R</i> and a SET binding protein gene (<i>SETBP1</i>) mutation (~60% of cases); the <i>JAK2</i> ^{V617F} mutation alone (~10% of cases) ^{990–992}	Segmented neutrophilia >20,000/μL; splenomegaly >90% of cases; no blood blasts; platelets >100 × 10 ⁹ /L; 75% of cases have normal cytogenetics; <i>BCR</i> rearrangement absent	Page 1471
<i>BCR</i> rearrangement-negative chronic myelogenous leukemia	Various cytogenetic changes	Clinical findings indistinguishable from <i>BCR</i> rearrangement-positive CML; Ph chromosome and <i>BCR-ABL</i> fusion gene absent	Page 1472
Atypical myeloproliferative disease	Various cytogenetic changes	Usually older patient (>65 years); variable blood cell changes: anemia, granulocytosis, normal or decreased platelet counts; hypercellular marrow, marrow blasts <10%; dysmorphia of blood and marrow cells common (e.g., Pelger-Huët neutrophils, dyserythropoiesis, and megakaryopoiesis; often splenomegaly)	Page 1473

Hgb, hemoglobin; PDGFR, platelet-derived growth factor receptor; Ph, Philadelphia; WBC, white blood cells.

isolated -Y, an intermediate-risk is any other abnormality, and high-risk is trisomy 8 or complex karyotypes (more than three abnormalities). Approximately 35 percent of patients have point mutations of the *K-RAS* or *N-RAS* gene.⁹⁰⁴ The *RAS* gene also may be involved in the transforming events. Abnormal methylation of p15^{INK4B} is a common finding in CMML.⁹¹⁵ Translocation between the gene *PDGFR-β* on chromosome 5(q33) and four partner genes—*TEL* at 12(p13), *HIP-1* at 7(q11.2), *H4* at 10(q22), and *Rabaptin-5* at 17(p13)—occur in a very small proportion of patients (approximately 3 to 4 percent).^{905,916–919} This mutation juxtaposes the gene encoding the *PDGFR-β* with a partner gene, which results in the encoding of a mutant tyrosine kinase that is constitutively activated and sensitive to inhibition by imatinib or a congener⁹²⁰ (see “Treatment” below). The cases with *PDGFR-β* translocations are more likely to be accompanied by eosinophilia than are cases with other cytogenetic abnormalities. Other gene mutations identified

in the leukemic cells of patients with CMML include *RUNX1*, *IDH1/2*, *CBL*, *JAK2*, *TET2*, *DNMT3A*, *ASXL1*, *UTX*, *EZH2*. The gene *SRSF2* (serine/arginine-rich splicing factor 2), was found to be the most frequently mutated gene in patients with CMML, 28 percent of patients studied. In an effort to determine the frequency of the mutation in a large sample of patients and to look for coincident mutations with *SRSF2* in CMML patient’s cells, eight other genes known to be mutated in some patients with CMML were studied among 275 patients with the disease.⁹⁰⁴ *SRSF2* was mutated in 47 percent of patients in this large series, and had a significantly increased coincidence with *EZH2* and *TET2*. Ninety-three percent of patients had at least one mutated gene.

Serum and Urine Findings Plasma and urine lysozyme concentrations nearly always are elevated. Plasma levels of VEGF, hepatocyte growth factor, and tumor necrosis factor alpha are elevated. Serum vitamin B₁₂, β₂-microglobulin, and LDH levels often are elevated.^{905,906}

Treatment

Treatment of most patients with CMML has been unsatisfactory, and remissions of any duration are uncommon. The age and performance status of the patient are considered in determining the intensity of treatment. Cytarabine, either standard or low-dose, etoposide, hydroxyurea, and other approaches used for the oligoblastic myelogenous leukemias have been attempted, but with little success (Chap. 88). Decitabine and 5-azacytidine have been useful in a small proportion of patients.^{905,906} One study of azacytidine treatment reported a complete response in 11 percent, a partial response in 3 percent, and hematologic improvement in 25 percent. The median survival of responders was 15 months compared to 12 months among nonresponders, a modest result.⁹²¹ Unfortunately, although a particular approach may confer significant benefit in a small proportion of cases, determining which patients will respond is not possible, except by trial and error. An exception is the patient with a translocation involving *PDGFR-β*, which itself occurs in only a small percentage of patients. In the case of *PDGFR-β* fusion genes with several of the partner genes, imatinib 400 mg/day has resulted in normal blood counts, cytogenetic remissions, and, occasionally, molecular remission.^{915-917,922,923} These fortunate patients probably will benefit from this treatment, as evidenced by prolonged remissions and survival, compared to other drug options, but the number of patients and duration of followup do not permit quantitative estimates at this point. Allogeneic stem cell transplantation is an option for the small proportion of younger patients with an appropriate matched-related or unrelated donor.⁹²⁴

Course and Prognosis

Median survival in CMML is approximately 12 months, with a range from approximately 1 to more than 60 months. Approximately 20 percent of patients progress to frank AML. Arbitrary stratification of CMML into types 1 (<5 percent blood myeloblasts) and 2 (5 to 20 percent blood myeloblasts) based on the height of the blast count has been proposed, but distinguishing patients by whether, for example, they have 4 (type 1) or 8 percent blasts (type 2) on a marrow examination is of little use for care of an individual patient. Blast percentage may be a significant correlate with outcome in any large group of patients with a clonal myeloid disease, and this factor among several others should guide therapy. Clusters of prognostic variables have been used to stratify patients into risk groups for survival duration. In general, the severity of the anemia, the cytogenetic risk category, and the height of the blast percentage are the most important. Other variables that may confer a shorter life expectancy are height of the absolute lymphocyte count, high spontaneous rates of myelomonocytic colony growth, higher total leukocyte counts, higher LDH level, and larger spleen size.⁹²⁵⁻⁹²⁷ These risk factors for progression are validated in large groups of patients but the confidence intervals are not shown. In an individual patient the variability in outcome is great based on such variables; careful clinical observation for progression is most important. Unfortunately, at this time, unless the patient is a candidate for imatinib therapy or allogeneic stem cell transplantation, long-term salutary therapeutic effects are uncommon.

CHRONIC EOSINOPHILIC LEUKEMIA

History and Definition

The recognition of eosinophilic lineage prominence in myelogenous leukemia dates to a case published in 1912.⁹²⁸ In 1968, the term *hypereosinophilic syndrome* was introduced to encompass a group of disorders with (1) prolonged exaggerated eosinophilia without an apparent cause, (2) frequent cardiac and neurologic tissue damage, (3) a poor or transient response to therapy, and (4) a progressive course and a high fatality rate. Shortly thereafter, Benvenisti and Ultmann⁹²⁹ presented five cases

of eosinophilic leukemia and reviewed the literature regarding that phenotypic designation. In 1975, Chusid and colleagues⁹³⁰ described 14 cases of hypereosinophilic syndrome, highlighted the frequency of secondary cardiac and neurologic disorders, and suggested the existence of a continuum of manifestations. Because some cases had clonal cytogenetic abnormalities and hematologic findings compatible with a clonal myeloid disease, the presence of eosinophilic leukemia was suspected in this apparently heterogeneous group of patients.

The relationship of blood eosinophilia to clonal myeloid diseases is complex because the former can be reactive or represent acute eosinophilic leukemia, chronic eosinophilic leukemia, or eosinophilia associated with a different category of disease, such as *BCR-ABL1*-positive CML, primary myelofibrosis, oligoblastic leukemia (MDS), or mastocytosis.⁹³¹ Chronic eosinophilic leukemia is a *BCR-ABL1*-negative, clonal myeloid disease with a striking eosinophilia in the blood and marrow, often with clonal cytogenetic abnormalities that have features including, when present, cytogenetic findings that usually distinguish chronic eosinophilic leukemia from other clonal myeloid diseases that may have an associated eosinophilia, such as CMML. The phenotype of the eosinophilic variant of CMML overlaps somewhat with that of chronic eosinophilic leukemia. However, the fusion gene associated with CMML involves the *PDGFR-β* (see “Chronic Myelomonocytic Leukemia” above), whereas in chronic eosinophilic leukemia the cytogenetic findings are different and in some cases involve *PDGFR-α*. This definition of chronic eosinophilic leukemia recognizes that, at the margins, classification may be arbitrary. Studies in cases with the *FIP1L1-PDGFR-α* translocation were consistent with multilineage involvement, consistent with an origin in a pluripotential lymphohematopoietic cell.⁹³² Another report found multilineage involvement but with a presumptive lesion in a multipotential, not pluripotential, hematopoietic cell.⁹³³

Signs and Symptoms

Fever, cough, weakness, easy fatigability, dyspnea, abdominal pain, maculopapular rash, cardiac symptoms and signs of heart failure, and a variety of neurologic manifestations ranging from peripheral neuropathy to cerebral encephalomalacia may occur, ranging from mild to severe in expression. Splenomegaly often is evident.

Laboratory Findings

Eosinophilia is a constant finding (see Chap. 62, Fig. 62-3). Anemia usually but not always is present at the time of presentation. The leukocyte count may be high-normal or more often elevated. Platelet counts often are normal or mildly decreased. The marrow shows myelocytic and eosinophilic hyperplasia and, occasionally, Charcot-Leyden crystals. Mast cells, often spindle-shaped, may be increased. In the *FIP1L1-PDGFR-α* type of chronic eosinophilic leukemia, which may make up approximately 14 percent of cases of primary eosinophilia not found to be reactive to another disease, marrow aggregates of spindle-shaped mast cells are invariably found (see “Cytogenetic Findings” below).^{933,934} Megakaryocytes usually are present but may appear dysmorphic. Reticulin fibrosis is common. Immunophenotyping and PCR do not show evidence of either a clonal T-cell population or T-cell-receptor rearrangement. Pulmonary function studies may provide evidence of fibrotic (restrictive) lung disease. Echocardiography may detect mural thrombi, thickening (fibrosis) of the ventricular wall, valvular dysfunction from papillary muscle, and chordae fibrosis. Magnetic resonance imaging can detect subendocardial fibrosis, thickening of ventricles, and markedly reduced ventricular lumen volume. Serum immunoglobulin (Ig) E, vitamin B₁₂, and tryptase levels usually are elevated. Skin biopsy of lesions uncovers intense eosinophilic infiltrates. Neural or brain biopsy may disclose eosinophilic infiltrates, often perivascular, with microthrombi, axonal degeneration, and gliosis.

Cytogenetic Findings A wide array of cytogenetic findings have been reported in cases of chronic eosinophilic leukemia.⁹³⁵ Notable translocations include a high frequency of translocations involving chromosome 5, t(1;5), t(2;5), t(5;12), t(6;11), 8p11, trisomy 8, and numerous others, infrequently. Chromosome 5 often is translocated at the site of the *PDGFR-β* gene, and the phenotype usually is more compatible with CMML with eosinophilia. Chromosome 5 from band q31–35 contains several genes relevant to eosinophilopoiesis, including those encoding IL-5, IL-3, GM-CSF, and *PDGFR-β*. A cryptic interstitial *CHIC2* deletion on chromosome 4 (q12;q12) results in the fusion gene *FIL11-PDGFR-α*, normally separated by the *CHIC2* gene, and in a phenotype that can be considered a form of chronic eosinophilic leukemia, virtually always associated with marrow mastocytosis, which is of particular note because, like the *PDGFR-β* mutations in CMML with eosinophilia, of a near-universal response to treatment with imatinib.^{935–937}

Serum Tryptase Level Elevation Versus Normal Levels

The elevation of serum tryptase level (>11.5 ng/mL) has been used to distinguish a subset of patients who (1) are male, (2) have marrows that are intensely hypercellular with a higher proportion of immature eosinophils and with dysmorphic mast cells with a CD117–CD25+CD2– genotype and phenotype (distinguishing these cells from classic mastocytosis, which are CD117+CD25+CD2+), (3) have dramatically higher serum vitamin B₁₂ and IgE levels, (4) are more prone to restrictive pulmonary disease and endomyocardial fibrosis, (5) have the *FIP11-PDGFR-α* fusion gene, and (6) are responsive to imatinib.⁸⁶⁹ Patients with normal serum tryptase levels are more prone to obstructive pulmonary restrictive disease, eosinophilic dermatitis, and gastrointestinal complaints.

Differential Diagnosis

Eosinophilia can occur for many reasons (Chap. 62). The first step is to identify signs that may point to a clonal myeloid disease. These signs include anemia, thrombocytopenia, splenomegaly, immature eosinophils in the marrow examination, evidence of dysmorphic cells in blood or marrow, for example, atypical megakaryocytes or dysmorphic mast cells, cardiac or pulmonary manifestations, which may occur secondary to chronic eosinophilic leukemia, and markedly elevated serum tryptase or vitamin B₁₂ level. The former signs, especially in the aggregate, are highly suggestive, but the presence of a cytogenetic abnormality in myeloid cells is diagnostic of a clonal myeloid disease (leukemia). If the latter is not evident, PCR and/or flow cytometry to search for a clonal T lymphocyte abnormality should be performed. Whether the eosinophilic leukemia is typical or represents an eosinophilia with idiopathic myelofibrosis, CMML, or MDS is less important than if it has a mutation that is imatinib sensitive (e.g., *PDGFR* mutation).

Therapy

Patients (nearly always men) whose cells display a *FIP11-PDGFR-α* have a very high probability of responding to imatinib at a dose of 100 to 400 mg/day.^{936–940} The tyrosine kinase activity of this fusion protein is two orders of magnitude more sensitive to imatinib than that of BCR-ABL1. However, because not all patients taking 400 mg/day achieve a molecular remission, and that goal may be more likely to result in long-term remission, initial therapy remains at 400 mg/day or an equivalent dose of another TKI, such as dasatinib or nilotinib, and PCR monitoring is appropriate. Dose adjustment upward if molecular remission is not achieved can be considered. Unlike the case in CML, patients with chronic eosinophilic leukemia with significant side effects when taking imatinib, 400 mg/day, have a reasonable probability of having a good response at lower doses.⁹⁵⁰ Dasatinib and nilotinib are also active.⁹⁴¹

In patients with eosinophilic leukemia without an imatinib-sensitive mutation or in patients who become resistant to imatinib and unresponsive to a second-generation TKI (e.g., dasatinib or nilotinib) and who are progressing, ablative or nonablative allogeneic stem cell transplantation can be considered if they are in an acceptable age range and have access to a matched-related or matched-unrelated donor.^{942,943}

In TKI-insensitive patients without the option of transplantation, empirical treatment with glucocorticoids, hydroxyurea, or anti-IL-5^{944,945} to decrease eosinophil counts and mute the progress of eosinophil-mediated cutaneous, cardiac, pulmonary, and neurologic tissue damage should be considered. These approaches may relieve symptoms for a time, but are temporizing if therapy with drugs that might be effective in inhibiting clonal expansion or evolution is not effective (e.g., cytarabine, anthracycline antibiotic, etoposide).

Course and Prognosis

If chronic eosinophilic leukemia is not TKI-sensitive, the long-term outlook is one of probable progressive cardiac and neurologic disability. Transformation to acute eosinophilic or myelogenous leukemia can occur. Allogeneic stem cell transplantation is potentially curative. In tyrosine kinase sensitive cases, hematologic normalization, reversal of marrow fibrosis and mastocytosis, resolution of skin lesions, normalization of spleen size, and restoration of well-being occurs in the great preponderance of cases. Cardiac, neurologic, and pulmonary changes usually cannot be reversed but should be stabilized. The long-term outlook with tyrosine kinase therapy is uncertain. However, it likely will decisively and dramatically improve survival compared to other prior therapy and should greatly improve the prognosis of patients with a molecular target for the drug.

CHRONIC BASOPHILIC LEUKEMIA

This type of clinical disorder, in which the patient has marrow and blood basophilia and other findings compatible with a clonal myeloid disease without evidence of the *BCR-ABL1* translocation, is rare. Two reports of such a syndrome occurring in five patients have been published.^{946,947} The marrow was intensely hypercellular in the three major lineages. Dysmorphic megakaryocytes were evident. Basophilia in marrow and blood was striking, although eosinophilia also was evident in two patients and increased mast cells in three patients. The clinical effects of basophilic mediator release were evident in two patients. One patient evolved to AML; another recovered after allogeneic transplantation. The cases had similar findings, leading to the suggestion they represented Ph chromosome–negative chronic basophilic leukemia. In one case, a *PRKG2-PDGFR-β* fusion gene was evident and the patient responded to imatinib.

JUVENILE MYELOMONOCYTIC LEUKEMIA

Epidemiology

Ph chromosome–positive, adult-type CML occurring in children younger than age 15 years makes up approximately 3 percent of childhood leukemias and approximately 10 percent of all cases of CML.⁹⁴⁸ Although CML occurs in children of all ages, it is rare in children younger than age 5 years. With the exception of a propensity to present with higher total leukocyte counts and with leukostatic signs or symptoms, CML in children has the typical manifestations and course of the disorder seen in adults.

A disorder different from adult-type CML, designated *juvenile myelomonocytic leukemia*, represents approximately 1.5 percent of childhood leukemias. It occurs most often in infants and children younger than age 4 years and is similar in some respects to adult subacute or

CMML because the two diseases share a prominent monocytic component in the leukemic cell population.⁹⁴⁹⁻⁹⁵²

Pathogenesis

This disorder is a clonal myeloid disease that originates in an early hematopoietic multipotential cell. Evidence indicates this cell may be pluripotential (myeloid-lymphoid) in some cases and myeloid in others.⁹⁵³⁻⁹⁵⁶ Patient-derived induced pluripotential stem cells recapitulated the growth patterns *in vitro* of the human disease and drug inhibition of MEK kinase reduced their GM-CSF growth potential.⁹⁵⁷ RAS mutations in hematopoietic cells are present in approximately 20 percent of patients.⁹⁵⁸ Approximately one in 10 patients with juvenile myelomonocytic leukemia have mutations of *NF1* and manifest type 1 neurofibromatosis. This frequency is approximately 400 times the expected occurrence in a comparable pediatric population.⁹⁵⁹⁻⁹⁶¹ The linkage between neurofibromin, the protein encoded by the *NF1* gene, GTPase activity proteins, and the activation state of RAS-encoded proteins has led to a postulated sequence of events that may be triggered by the extraordinarily heightened sensitivity of the colony-forming cells in the marrow and blood of infants with the disease to the proliferative effects of GM-CSF. The latter initiates signal transduction from the cell membrane to the nucleus via RAS protein activation.^{961,962} Mutations in the *PTPN11* gene have been found in approximately one-third of children with juvenile myelomonocytic leukemia, and the mutations in *NF1*, RAS, and *PTPN11* usually do not coincide.^{1025,1026} However, they each may act through a common pathway. *PTPN11* encodes SHP-2, a phosphatase, which is an upstream regulator of RAS; thus, all three mutations can contribute to deregulation of RAS signaling. As an aside, children with Noonan syndrome, which is characterized by short stature, dysmorphic facies, skeletal abnormalities, and cardiac defects, have a germ-cell mutation of *PTPN11*. These children may have a transient disorder that closely mimics juvenile myelomonocytic leukemia.⁹⁶³

Clinical Findings

Symptoms and Signs Infants present with failure to thrive, and children present with malaise, fever, persistent infections, and exaggerated skin, oral, or nasal bleeding. Hepatomegaly can occur. Splenomegaly, sometimes massive, is present in almost all cases. Lymphadenopathy is frequent.⁹⁴⁹⁻⁹⁵² More than half of the patients have eczematoid or maculopapular skin lesions⁹⁶⁴ and xanthomatous lesions, and multiple *café-au-lait* spots (neurofibromatosis type 1) may occur.⁹⁵⁰ The xanthomas may be the earliest signs of neurofibromatosis.^{950,951} Noonan syndrome (dysmorphic facies, short stature, heart disease, mental retardation, cryptorchidism, webbed neck, chest deformities, and bleeding diathesis) may coexist.⁹⁵¹

Laboratory Findings Anemia, thrombocytopenia, and mild to moderate leukocytosis are common. The leukocyte count usually is greater than $10 \times 10^9/L$ with a median leukocyte count at diagnosis of approximately $35 \times 10^9/L$. The blood has an increased monocyte concentration of 1 to $100 \times 10^9/L$, immature granulocytes including a small percentage of blast cells, and nucleated red cells. Fetal hemoglobin concentration is increased in approximately two-thirds of the patients. The marrow aspirate is hypercellular as a result of granulocytic hyperplasia; the number of erythroblasts and megakaryocytes usually are decreased. Monocytic cells are increased but may not be as striking as in the blood. Leukemic blast cells are present in modest proportions (<20 percent).

Cell culture of blood and marrow shows a striking preponderance of monocytic progenitors, even in the absence of overt monocytosis in the marrow.^{965,966} Granulocyte-monocyte colony-forming cells show a marked tendency to spontaneous growth if adherent (monocytic) cells are not depleted from culture.⁹⁶⁶ The effect is mediated by a release of large quantities of GM-CSF by monocytes in culture.⁹⁶⁷

Although clonal chromosome abnormalities have been found in some cases,⁹⁶⁸ the cytogenetic abnormalities have no consistent pattern, and more than half of the patients have normal karyotypes. The *BCR-ABL1* fusion gene is not present.⁹⁶⁸⁻⁹⁷⁰ The phenotype of monosomy 7 syndrome overlaps with juvenile myelomonocytic leukemia, and an abnormality of chromosome 7 (del 7, del 7q, others) is present in approximately one-fifth of patients.⁹⁴⁹

Course, Prognosis, and Treatment

The median survival of patients with juvenile myelomonocytic leukemia has been less than 2 years.^{949,950} Children younger than 2 years are more likely to have a protracted course.⁸⁸² The disease has been refractory to most chemotherapy. In a study of nine patients, four of whom were treated with a five- or six-drug intensive regimen, remissions were 11 months to more than 27 months, compared with untreated or lightly treated patients, four of whom died within 7 months.⁹⁷¹ Even in the treated patients, complete suppression of the disease did not occur, and treatment protocols to induce and sustain remissions were lacking.⁹⁶⁶ A program of cytosine arabinoside, etoposide, vincristine, and isotretinoin resulted in a highly favorable response in five children treated. Three patients relapsed and were treated with cytarabine by infusion and subcutaneously and with etoposide. All patients were alive, and the range of survival at the time of publication was 8 to 89 months, with a median survival of 27 months. The resistance of these cells to currently available therapy is distressingly highlighted by the sense of success in prolonging the life of infants and young children by a few years. Intensive therapy can control disease, but curative chemotherapy has been elusive.⁹⁷² The inclusion of isotretinoin was based on a prior report of responsiveness to the drug used alone; however, this observation has not been confirmed.⁹⁷³ The GM-CSF antagonist E21R, inhibitors of *RAF-1* gene expression, blockers of RAS protein farnesylation, and angiogenesis inhibitors are among other drug approaches to the disease being studied.^{952,974}

Allogeneic stem cell transplantation is an important approach to therapy and may provide the best chance of long-term survival in selected children.⁹⁷⁵⁻⁹⁷⁷ Hence, a rapid search for a matched-unrelated donor, including cord blood sources, is important in patients without matched sibling donors. Transplantation from a histocompatible sibling or matched-unrelated donor resulted in an event-free survival at 5 years of approximately 50 percent, and from matched-cord blood stem cells of approximately 45 percent, unless monosomy 7 was present, which lowers 5-year survival to approximately 25 percent.⁹⁷⁷ Children transplanted before age 1 year had better results (approximately 50 percent) than did older children (approximately 30 percent).⁹⁷⁷ DLI has placed a posttransplantation patient in relapse into remission,⁹⁷⁸ but, in general, this procedure is ineffective in patients who relapse after transplantation.

A minority of patients have a smoldering course for 2 to 4 years. Thereafter, the disease usually rapidly progresses, and patients die of infection or hemorrhage. Occasional patients have a very long survival (>10 years) despite persistence of abnormal blood counts and splenomegaly, independent of the type or intensity of therapy. Some children convert to a full-blown AML with a rapidly fatal outcome. Cases of juvenile myelomonocytic leukemia may be associated with transformation to acute lymphoblastic leukemia.⁹⁷⁹

CHRONIC NEUTROPHILIC LEUKEMIA

History, Pathogenesis, and Epidemiology

In 1920, Tuohey⁹⁸⁰ described the first recorded case of an unusual sustained neutrophilia with splenomegaly without fever, inflammation, cancer, or other cause of a leukemoid reaction. Use of X-chromosome-linked polymorphic genes in blood cells and FISH of chromosome abnormalities

have been indicative of a clonal myeloid disorder.^{981–983} Some cases may arise in the hematopoietic multipotential cell, others in a neutrophil progenitor cell (Chap. 85).^{981–985} Evidence points to defective apoptotic signals accounting, in part, for the striking accumulation of segmented neutrophils in the blood.⁹⁸⁶ The median age at onset is approximately age 65 years. Younger patients may be affected.⁹⁸⁷ As in most clonal myeloid diseases, men are affected more frequently than are women.

Clinical Features

Symptoms and Signs Patients may complain of weakness, anorexia, weight loss, abdominal pain, and easy bruising. Symptoms and signs of gouty arthritis occur in approximately one-third of cases. The spleen is enlarged in almost all cases, and the liver frequently is enlarged. Lymphadenopathy is very infrequent.⁹⁸⁵ A hemorrhagic tendency is present in some patients.

Laboratory Findings Although some patients have a normal hemoglobin concentration at the time of presentation, most have mild to moderate anemia on presentation. The reticulocyte count usually is between 0.5 and 3.0 percent. The platelet count rarely is less than $125 \times 10^9/L$ and usually is normal. Coagulation times are normal. The total leukocyte count usually is between 25 and $100 \times 10^9/L$ in most cases, and only rarely is less than $20 \times 10^9/L$ or exceeds $100 \times 10^9/L$. Neutrophils compose 85 to 95 percent of the white cells. Although segmented cells usually dominate, occasional cases have a high proportion of band forms. Very infrequently, metamyelocytes, myelocytes, and nucleated red cells may be present in patients. Basophil and eosinophil counts are not increased. Blasts nearly always are absent from the blood. Neutrophil alkaline phosphatase activity is increased in almost all cases.

The marrow invariably shows granulocytic hyperplasia with myeloid-to-erythroid ratios as high as 10:1. Myeloblasts are not overtly increased in number (0.5 to 3.0 percent). Megakaryocytes are either normal or slightly increased in number and have normal distribution and morphology. Erythropoiesis usually is mildly decreased. Unlike CML, reticulin fibrosis is unusual. A few cases with dysmorphic features in the marrow (acquired Pelger-Huet anomaly, erythroid, dysplasia, micromegakaryocytes) have been reported. Serum vitamin B₁₂-binding protein and vitamin B₁₂ levels both are markedly increased above normal. Serum uric acid concentration is increased, and serum LDH activity may be increased.

Almost every case examined postmortem had liver and splenic enlargement. Portal hepatic and splenic red pulp infiltrates of neutrophils or islands of extramedullary hematopoiesis with immature myeloid cells and megakaryocytes are characteristic.

Cytogenetic and Genetic Findings By definition, the Ph chromosome, *BCR* gene rearrangements, and *BCR-ABL1* transcripts are absent.^{987–990} Most patients have normal karyotypes, but approximately 25 percent of patients have nonrandom abnormalities of chromosomes.⁹⁹⁰ Deletions of chromosome 20q and trisomy 21 or 9 are the most common abnormalities. The disease has been shown to be associated with a mutation in the colony-stimulating factor 3 receptor gene (*CSF3R*) alone (approximately 30 percent of cases), or a combination of mutated *CSF3R* and a SET binding protein gene (*SETBP1*) mutation (approximately 60 percent of cases) or the *JAK2*^{V617F} mutation alone (approximately 10 percent of cases).^{991,992} Two principal mutations were observed in *CSF3R*: membrane proximal *CSF3R*^{S783fs} mutation and truncated *CSF3R*^{T6181} mutation. The former results in deregulation of the JAK family kinases and may respond to JAK inhibitors, whereas the later deregulates SRC family-TNK2 kinases and confers sensitivity to dasatinib.⁹⁹¹ Four of five prior reports of *JAK2* mutations in a single patient with chronic neutrophilic leukemia were cited. In the fifth report, six patients with the disease were studied and one had a *JAK2*^{V617F} mutation.

Differential Diagnosis

Most leukemoid reactions are associated with an obvious underlying cause, such as pancreatitis, carcinoma, connective tissue disease, smoker's neutrophilia, and chronic bacterial or fungal infection. The leukocyte alkaline phosphatase level usually is markedly elevated in chronic neutrophilic leukemia and markedly decreased in CML. More to the point, molecular studies identifying *BCR* gene rearrangement or the presence of *BCR-ABL1* transcripts should distinguish chronic neutrophilic leukemia (*BCR-ABL1*-negative) from neutrophilic CML (*BCR-ABL1*-positive; see "Special Clinical Features" above). In the latter case, more than half of the patients have thrombocytosis and megakaryocytic hyperplasia, which are uncharacteristic of chronic neutrophilic leukemia. The presence of a *CSF3R* or *JAK2* mutation with a classical clinical picture would be strong diagnostic evidence for the disease.

Treatment

No systematic studies of treatment have been reported. Although hydroxyurea, IFN- α , or cytarabine may decrease the white count and spleen size, long-term benefit is unusual.^{987–990} Intensive therapy has led to early posttreatment deaths. With identification of a specific genetic mutation, either a JAK2 inhibitor (e.g., ruxolitinib) (for the *CSF3R*^{T6181} mutation) or dasatinib (for the *CSF3R*^{S783fs} mutation) should be considered. The disease is rare and clinical trials would be difficult. *In vitro* studies of cell sensitivity and reports of individual responses may have to be relied upon.^{991–993} Allogeneic stem cell transplantation in eligible patients may be curative.⁹⁹⁴

Course and Prognosis

The disease is fatal, with a median survival of approximately 2.5 years and a range of 0.5 to 6 years.^{987–990} A case of spontaneous remission has been reported. The prognosis is considerably worse than the prognosis for CML despite the prevalence of mature neutrophils and the paucity of blasts. Newer approaches with dasatinib or ruxolitinib for the appropriate genetic mutations (see "Treatment" above) may provide better outcomes. Causes of death have included (1) intracranial hemorrhage, sometimes in the presence of adequate platelet counts and coagulation times, suggesting a vascular infiltrative process; (2) severe infection; (3) transformation to AML; and (4) the toxic effects of intensive therapy. The disease usually afflicts older persons, and cardiac, pulmonary, and vascular diseases contribute to a fatal outcome.

A remarkable frequency of concordant essential monoclonal gammopathy or myeloma has been described.^{983,995–1003} In two cases, the extreme neutrophilia proved to be a polyclonal response to a plasma cell disorder.^{983,1004} Chronic neutrophilic leukemia has evolved from polycythemia vera or oligoblastic leukemia,^{1005–1009} supporting its relationship to the clonal hemopathies.^{983,1010,1011}

BCR REARRANGEMENT-NEGATIVE PHENOTYPICALLY TYPICAL CHRONIC MYELOGENOUS LEUKEMIA

A very small proportion of patients (approximately 4 percent) with clinical manifestations within the limits usually applied to the diagnosis of CML have neither a Ph chromosome (classic, variant, or masked) nor evidence of rearrangement of *BCR* on chromosome 22. This circumstance represents *BCR*-negative CML. The literature describing Ph chromosome-negative CML prior to 1987 is difficult to evaluate because many cases were not studied carefully for masked or variant translocations and for the *BCR* gene rearrangement. Ph chromosome-negative CML is a clonal disease⁹⁰³ that has the propensity for lymphoid and myeloid transformation.^{1012,1013} Although most cases of *BCR* rearrangement-negative CML are closer in manifestations to

CMML,^{903,927,1014–1016} some cases are indistinguishable from classic CML but without the *BCR-ABL1* after exhaustive molecular diagnostic evaluation.^{1017–1021} In a report of 76 such patients, the median age was 66 years (range: 24 to 88), splenomegaly was present in 50 percent of cases, the median white cell count was 38,000 cells/ μ L (38×10^9 cells/L; range: 11 to 296), and the median hemoglobin was 11 g/dL (range: 7 to 16), with classical morphologic features in blood and marrow.¹⁰²¹ As the disease progressed, patients developed severe cytopenias.¹⁰¹⁸ Median survival was 24 months and only 7 percent survived for more than 5 years. Myeloid blast phase occurred in one-third of those followed until their death. Occasional patients had extended complete remissions with IFN- γ therapy.¹⁰²⁰ Hydroxyurea can be useful as palliative therapy.

Some patients have transposition of *ABL1* to chromosome 22 but not the classic translocation. In such cases, including *TEL-ABL1* translocations, transient responses to imatinib have been observed.¹⁰²²

Uncommon cases of coexisting BCR-negative and BCR-positive clones have been described, and the basis for such cases is in dispute.¹⁰²³ One proposed explanation is that this case is an example of “field carcinogenesis” in which multiple clones coexist.¹⁰²³ An alternative explanation is that these cases represent the dual progeny of a single unstable clone.¹⁰²⁴ The long-term survival of patients with CML may permit the emergence of a drug-induced or spontaneous second malignancy, and in the former it may be notably associated with imatinib (see “Secondary Chromosomal Changes with Tyrosine Kinase Inhibitors above”).^{1025–1027}

ATYPICAL MYELOPROLIFERATIVE DISEASE

Definition

There is a small but measurable frequency of patients who do not fit the diagnostic criteria of the other chronic myeloproliferative diseases, yet their findings represent the manifestations of a clonal myeloid neoplasm.^{1028–1031} A neoplasm of a hematopoietic stem cell has many variations in expression (Chap. 83), and it is surprising that nearly all can be pigeonholed into a generally agreed upon phenotype. These cases are among those that do not fit a standard diagnostic pattern. These cases have been classified by the WHO as atypical CML (aCML) or alternatively myelodysplastic-myeloproliferative syndrome, which category excludes BCR-rearrangement-positive CML, CMML, chronic neutrophilic leukemia, refractory sideroblastic anemia with thrombocytosis, and other classical syndromes, as judged phenotypically and genotypically. An attempt at teasing apart these syndromes into specific classifications proved how difficult that was, even when very arbitrary criteria were applied.¹⁰³¹ Until a genetic basis is more clearly defined and specific therapy becomes available, we prefer to use the term atypical myeloproliferative disease for this category of hematopoietic multipotential (stem) cell disorder because, when starting with a single patient, the clinical features do not allow clear distinctions among patients and therapy is based on the manifestations in a given case, the consensus between patient and physician about the desirability and likely utility of therapy, and the rate of progression of the disease in that patient.

Clinical Features These patients are principally in the 60 to 90 year-old age range, but atypical expression of a multipotential hematopoietic cell neoplasm can occur at any age. Hepatomegaly and (or) splenomegaly are present in a minority of patients. Anemia and nearly always granulocytosis (granulocytes, notably neutrophils, and granulocytic precursors), sometimes with neutrophilic dysmorphia (e.g., acquired Pelger-Huët neutrophils) are characteristic. Neutrophilic precursors represent less than 15 percent of blood cells. The blast cell count in blood and marrow is low, usually less than 10 percent. Monocytes are not increased and eosinophils or basophils are usually not increased but may be as high as 10 percent of total leukocytes.

Laboratory Features The LDH is often elevated. The marrow is hypercellular with variable evidence of dysmorphic granulopoiesis and dysmorphic megakaryocytopoiesis. Mild marrow reticular fibrosis may be evident. Clonal cytogenetic abnormalities may occur but do not include translocations characteristic of classical chronic myeloid neoplasms, such as a *BCR-ABL1* or translocations involving *PDGFR- α* , *PDGFR- β* , or *FGFR1* seen in chronic eosinophilic leukemia with or without mastocytosis. Common myeloid-related cytogenetic abnormalities may occur, such as trisomy 8, del(20q), and others.

Therapy This type of neoplasm has no specific treatment and is usually treated “symptomatically” with red cell or platelet transfusion and an agent to reduce the white cell count, if that is a problem (e.g., hydroxyurea, 5-azacytidine, low-dose cytarabine, numerous others).¹⁰³¹ Appropriate patients may be considered for allogeneic hematopoietic stem cell transplantation, if a suitable donor is available, but this approach is problematic in an older population because they would be transplanted during active disease and with a higher-risk of GVHD. Nonmyeloablative allogeneic stem cell transplantation has also been used.

Course and Prognosis This patient population has a median survival of approximately 18 months, but the upper range is approximately 5 years. The disease may undergo clonal evolution to AML.
