Integrin β_3 (GPIIIa) can also combine with the integrin α_V (CD51) subunit to form the integrin $\alpha_V\beta_3$ “vitronectin” receptor^{30,56,57} (see Fig. 120–2; Chap. 112). This receptor can bind many of the same adhesive glycoproteins as integrin $\alpha_{\text{IIb}}\beta_3$, although there are some differences in ligand preference and binding sequences.^{57–61} A small number of integrin $\alpha_V\beta_3$ receptors are present on platelets (50 to 100 per platelet)^{60,62,63}; osteoclasts, endothelial cells, macrophages, vascular smooth muscle, and uterine cells, among others, also have integrin $\alpha_V\beta_3$ receptors.^{64,65} In general, GT patients with defects in integrin β_3 also are deficient in integrin $\alpha_V\beta_3$, whereas patients with defects in integrin α_{IIb} have either normal or increased numbers of platelet integrin $\alpha_V\beta_3$ receptors.^{60,63,64,66–68} One exception to this rule is a patient with a defect in β_3 (H280P) that interferes with integrin $\alpha_{\text{IIb}}\beta_3$ biogenesis to a much greater extent than integrin $\alpha_V\beta_3$ biogenesis.⁶⁹ At present, there is no evidence that patients who lack integrin $\alpha_V\beta_3$ receptors in addition to lacking integrin $\alpha_{\text{IIb}}\beta_3$ receptors have a more-severe hemorrhagic diathesis or suffer from any other abnormalities, perhaps because alternative receptors containing integrin α_V associated with other β subunits can substitute for integrin $\alpha_V\beta_3$.⁶³ Upregulation of integrin $\alpha_2\beta_1$ on osteoclasts of Iraqi-Jewish patients with GT has been reported as a potential compensatory mechanism to explain the lack of bone changes despite the deficiency in osteoclast integrin $\alpha_V\beta_3$.⁷⁰

The molecular biologic abnormalities in more than 100 patients with GT have been identified and they are listed in an internet database that is updated continuously⁷¹ (<http://med.mssm.edu/glanzmandb>). Figure 120–3 contains information on mutations of particular interest.

Of note, many of the patients with identified mutations are compound heterozygotes rather than homozygotes, indicating that a sizable number of silent carriers are present in the population. Where consanguinity is common, the disorder is more likely to be caused by a homozygous mutation arising in a founder, but even under these circumstances, more than one mutation may be present. Thus, in the Iraqi-Jewish population, in which consanguinity has been present from 586 BCE to the present, two separate mutations have been identified in more than one family.³⁹ Most of the missense mutations result in decreased expression of integrin $\alpha_{\text{IIb}}\beta_3$ on the surface of platelets. This probably reflects the stringent structural requirements for proper folding and complex formation.

Mutations in Integrin $\alpha_{\text{IIb}}\beta_3$ Within the Metal Ion-Dependent Adhesion Site of Integrin β_3 and the Interface with the Integrin α_{IIb} β -Propeller A metal coordination site or MIDAS domain, which is highly conserved in six integrin receptor α -chain subunits and required for ligand-binding, is also present in the β -A (or I-like) domain of the integrin β_3 subunit.⁷² Mutagenesis and molecular modeling experiments suggested that a highly conserved DxSxS amino acid sequence⁷³ motif plus additional coordinating residues are brought together in the three-dimensional structure of the β_3 subunit to form a cation-binding sphere of the MIDAS domain,⁷⁴ and this was confirmed by the crystal structures of integrin $\alpha_V\beta_3$ and later integrin $\alpha_{\text{IIb}}\beta_3$ (see Chap. 112, Fig. 112–111, and Fig. 120–3).^{75,76} Thus, the β_3 MIDAS is composed of Asp¹¹⁹, Ser¹²¹, Ser¹²³, Glu²²⁰, and Asp²⁵¹. A region originally termed the ligand-associated metal binding site (LIMBS) in integrin $\alpha_V\beta_3$,⁷⁷ but now termed the synergy metal binding site (SyMBS) in integrin $\alpha_{\text{IIb}}\beta_3$,⁷⁸ binds a Ca²⁺ ion and is required for binding of ligands to the MIDAS. It is composed of atoms from D158, N215, D217, P219, and E220. Integrin β_3 residues 214 and 216 are in close proximity with both the SyMBS residues and the interface with the α_{IIb} subunit. Adjacent to the MIDAS domain is a metal ion site termed the ADMIDAS (adjacent to metal ion-dependent adhesion site), in which calcium is coordinated by

Figure 120–3. Diagram of $\alpha_{\text{IIb}}\beta_3$ structure and identification of select mutations causing Glanzmann thrombasthenia. The website <http://med.mssm.edu/glanzmandb> contains a full listing of reported Glanzmann thrombasthenia mutations. The $\alpha_{\text{IIb}}\beta_3$ structure depicted is a composite of data from crystal and NMR structures, as well as molecular modeling of missing regions. Among the missense mutations identified are ones that (1) interfere with inside-out and outside-in signaling (β_3 S752P); (2) interfere with ligand binding to either the metal ion-dependent adhesion site (MIDAS) in β_3 (β_3 D119Y and D119N) or the α_{IIb} component of the ligand binding site (Y143H, P145L/A, insert R160/T161); (3) result in receptors that are sensitive to dissociation by divalent cation chelation (β_3 R214W, R214Q, R216Q); (4) result in a constitutively active receptor (β_3 C560R); (5) alter the interface between α_{IIb} and β_3 and disrupt ligand binding (β_3 L262Y); (6) result in a β_3 protein that can complex more effectively with α_V than α_{IIb} (S162L, R216Q, H280P); or (7) alter the α_{IIb} propeller structure and prevent normal $\alpha_{\text{IIb}}\beta_3$ complex formation, processing, and/or transport. The mutations identified by number 8 in α_{IIb} (G991C and R995Q/W) and β_3 (L718P and D723H) are gain-of-function mutations associated with macro/anisothrombocytopenia. (Reproduced with permission from Dr. Ana Negri based on PDBids 3FCS, 3G9W, 2K9J, 2KNC, and 2KV9 and molecular modeling of the missing segments of the α_{IIb} calf domain, the β_3 hybrid domain, and the link between the β_3 EGF-1 and EGF-2 domains.)

Ser¹²³, Asp¹²⁶, Asp¹²⁷, and Met³³⁵ in unliganded integrin $\alpha_v\beta_3$ and integrin $\alpha_{IIb}\beta_3$, but Asp²⁵¹ substitutes for Met³³⁵ in the ligand-bound structures of both integrin $\alpha_v\beta_3$ and integrin $\alpha_{IIb}\beta_3$. The crystal structures also demonstrated that peptide ligands containing the Arg-Gly-Asp (RGD) cell adhesion sequence interact with integrin $\alpha_{IIb}\beta_3$ and integrin $\alpha_v\beta_3$ in part by coordination of the metal ion in the MIDAS by the aspartic acid in the RGD peptide.^{77,79} The low-molecular-weight drugs eptifibatid and tirofiban, which block ligand binding to the α_{IIb} subunit, have negatively charged regions that also interact with the MIDAS cation.⁷⁶ The fibrinogen γ -chain C-terminal dodecapeptide mediates binding to integrin $\alpha_{IIb}\beta_3$ and a crystal structure of the complex demonstrates that an aspartic acid carboxyl oxygen coordinates the MIDAS cation whereas the carboxy terminal valine interacts with the nearby cation in the ADMIDAS.^{76,79} A number of mutations in patients with GT have been identified within the cation-binding sphere of the MIDAS domain (see Fig. 120–3, and Chap. 112, Fig. 112–11). Two mutations D119Y (Cam variant)⁸⁰ and D119N (patient NR),⁸¹ are located within the conserved DxSxS amino acid motif and produce severe abnormalities of ligand binding to integrin $\alpha_{IIb}\beta_3$, but do not affect its surface expression. Mutations at residues R214 and R216 result in abnormal integrin $\alpha_{IIb}\beta_3$ receptors that cannot bind ligand and are very sensitive to dissociation by calcium chelation, perhaps because they are at the integrin $\alpha_{IIb}\beta_3$ interface.^{32,82–84} Disrupting the SyMBS with a D217V mutation also leads to GT despite the expression of normal amounts of the integrin protein.⁸⁵ Further support for the importance of the MIDAS domain, SyMBS, and adjacent residues comes from studies in which the mutations D119N, R214W, D217N, E220Q, and E220K were introduced into Chinese hamster ovary CHO cells *in vitro* and shown to result in functional abnormalities.⁸⁶

The interface between the α_{IIb} β -propeller and the β_3 subunit also involves, in part, the interaction between β_3 R261, contained in a four-amino-acid 3_{10} helix, with a number of hydrophobic residues in the α_{IIb} β -propeller arranged as inner and outer rings, making up a cage.⁷⁵ A β_3 subunit L262Y mutation, adjacent to R261 results in disruption of the helix and an unstable integrin $\alpha_{IIb}\beta_3$ complex that is expressed on the surface of platelets but is unable to bind fibrinogen.⁸⁷ The platelets of the patient with this mutation were able to bind fibrin and support clot retraction, suggesting different requirements for fibrinogen and fibrin binding.

Mutations in Integrin $\alpha_{IIb}\beta_3$ Within the α_{IIb} β -Propeller Sequence

Based on their homology to another integrin α subunit, the aminoterminal 450 amino acids of integrin α_{IIb} and the homologous region in integrin α_v , which contain the minimal ligand-binding sequence,⁸⁸ were predicted to fold into seven repeat (blade) β -propellers, containing four cation-binding sites,⁸⁹ and this prediction was confirmed by the crystal structures of both α_v and α_{IIb} integrin subunits.^{75,76} The upper surface of the propeller interacts with the β_3 subunit β -A (or I-like) domain to form the head of the integrin $\alpha_{IIb}\beta_3$ complex, which is the site of ligand binding. Each repeat (blade) contains four β strands that are connected by loops. The four calcium-binding sites in the α_{IIb} subunit, which are in β -hairpin structures, are located in loops on the undersurface of the propeller. Ligand binding in integrin α_{IIb} has been localized to a hydrophobic (F160, Y190, F231) and negatively charged (D224) pocket that lies adjacent to the MIDAS domain in the β_3 subunit, and is composed of contributions from the loops that link blade 2 to blade 3 (residues 144 to 171), β strand 2 to β strand 3 in blade 3 (residues 186 to 193), and blade 3 to blade 4 (residues 223 to 236). Integrin α_{IIb} contains a unique “cap” subdomain made up of four insertions in β propeller loops (residues 72 to 88, 111 to 126, 147 to 166, 200 to 217) that also plays a role in ligand binding.⁷⁶

GT missense mutations located within the integrin α_{IIb} β -propeller (see Fig. 120–3) primarily affect transport of the integrin $\alpha_{IIb}\beta_3$ complex to the cell surface,^{68,90–93} but several missense mutations and an insertion

result in functionally defective receptors. Thus, Y143H affects soluble ligand binding but not adhesion or clot retraction,⁹⁴ and P145A, which has been identified in several kindreds,^{32,95} and P145L, prevent ligand binding. A two-amino-acid insertion at residues 161 and 162, as well as a T176I missense mutation, also affect ligand binding.^{96–98} A L183P mutation, which is near to, but not in the loop containing Y190, affects both receptor expression and function.⁹⁹

Mutations in Integrin $\alpha_{IIb}\beta_3$ That Affect Receptor Activation

Several β_3 subunit missense mutations (C560R, V193M) result in the receptor adopting a high-affinity ligand binding state, which is paradoxical as it results in a bleeding diathesis.^{100,101} A β_3 subunit S527F mutation in the third I-EGF domain was also associated with a constitutively active receptor, presumably because it prevents the receptor from assuming a bent, inactive conformation.¹⁰² The cytoplasmic domain of the β_3 subunit plays a functional role in integrin activation and the regulation of ligand binding.^{103,104} Two GT mutations have been identified in this region. One is an R724X nonsense mutation (patient RM)¹⁰⁵ that results in the deletion of the carboxyterminal 39 residues of integrin β_3 and the other is a β_3 subunit S752P missense mutation (patient P or Paris I).^{106–108} This latter patient is unusual in that he had a generally mild history of excessive hemorrhage, but he did have a prolonged bleeding time and his platelets did not aggregate in response to ADP. These mutations do not severely affect surface expression of platelet integrin $\alpha_{IIb}\beta_3$ complexes, but both mutant receptors are unresponsive to agonist stimulation. Mammalian cell expression studies of these mutations show normal adhesion to immobilized fibrinogen, but abnormal cell spreading. Cells expressing the S752P mutant receptors have reduced focal adhesion plaque formation and cells expressing the R724X mutant receptors have undetectable tyrosine phosphorylation of focal adhesion kinase, pp125^{FAK}. These mutations provide evidence for the role of the β_3 subunit cytoplasmic tail in inside-out signaling (i.e., platelet signals that lead to integrin $\alpha_{IIb}\beta_3$ adopting a high-affinity ligand-binding conformation) and outside-in signaling (i.e., signaling to the interior of the platelet as a result of integrin $\alpha_{IIb}\beta_3$ binding ligand; see Chap. 112, Figs. 112–3, 112–4, and 112–12).

Variants of Integrin $\alpha_{IIb}\beta_3$ in the Population The application of missense variant whole-exome and whole-genome sequencing to large numbers of individuals has provided valuable information on the frequency of missense variants in the general population and the frequency of the genetic alterations leading to GT. For the most part, the frequency of a variant in a population is a reflection of its impact on reproductive fitness and when it entered the population, with lower frequencies for variants that entered the population more recently. Thus, variants with minor allele frequencies (MAFs) of approximately 0.5 percent or less probably entered the population fewer than 2500 years ago, when the recent explosive growth in human populations began.¹⁰⁹ Data from a study^{109A} involving approximately 33,000 alleles from approximately 16,500 people demonstrated the presence of 114 novel missense variant affecting approximately 10 percent of the integrin α_{IIb} amino acids and approximately 9 percent of the β_3 subunit amino acids. Thus, approximately 1.1 percent of the population studied carried at least one missense variant. None of the known GT mutations was observed in any of the alleles studied, indicating that they have MAFs of less than 0.01 percent and thus entered the population very recently. In fact, studies of two GT populations with high intragroup marriages, Palestinian Arabs and French Manouche gypsies, estimated that the GT mutations entered the population approximately 300 to 600 and approximately 300 to 400 years ago, respectively.^{110,111} Several novel missense variants identified in this study affected one of the amino acids mutated in patients with GT, and in two cases these variants were shown to profoundly affect expression of the receptor. In one case, a missense variant reduced expression by

approximately 50 percent but did not alter function. A series of prediction tools indicated that somewhere between 45 and 74 percent of the 114 novel missense mutations may be deleterious. Thus, perhaps approximately 0.6 percent of individuals in the general population is a silent carrier for a GT variant that profoundly affects structure and/or function. In addition, some of the rare individuals in the healthy population with levels of integrin $\alpha_{\text{IIb}}\beta_3$ receptor expression intermediate between those of obligate GT carriers and normal individuals may reflect heterozygosity for “hypomorphic” variants that partially affect receptor expression, but not function.¹¹²

Clinical Features

Table 120–2 summarizes the clinical manifestations of 177 patients with GT obtained from two reviews.^{22,33} Menorrhagia occurs in nearly all female patients. Purpura can be present immediately after birth but often is not dramatic. Petechiae of the face and subconjunctival hemorrhage associated with crying may be the first symptoms in neonates and babies. Spontaneous hemarthroses and central nervous system bleeding are very rare. The hemorrhagic diathesis in patients with GT is notable for its variability and the lack of correlation between the biochemical platelet abnormalities and clinical severity.²² Even within groups of patients such as the Iraqi Jews, most of whom share the same genetic α_{IIb} or β_3 subunit abnormalities, there is a wide spectrum of clinical severity.^{33,39} Moreover, the severity of bleeding symptoms can vary significantly during the lifetime of individual patients. GT does not appear to protect against the development of atherosclerosis as judged by the carotid artery intima-to-media ratio.¹¹³ Carriers of GT are usually asymptomatic or only mildly symptomatic and generally have normal results in platelet function tests.^{22,33,112,114,115}

TABLE 120–2. Bleeding in Patients with Glanzmann Thrombasthenia

	No. of Affected Patients	Frequency (%)
SYMPTOMS		
Menorrhagia	54/55	98
Easy bruising, purpura	152/177	86
Epistaxis	129/177	73
Gingival bleeding	97/177	55
Gastrointestinal hemorrhage	22/177	12
Hematuria	10/177	6
Hemarthrosis	5/177	3
Intracranial hemorrhage	3/177	2
Visceral hematoma	1/177	1
SEVERITY		
Requirement for red cell transfusions		
Patients from literature*	32/48	67
Paris patients	54/64	84

*Data are from 177 patients reviewed by George and colleagues²² of whom 113 were from the literature and 64 were studied in Paris.

Laboratory Features

Table 120–3 provides characteristic laboratory findings in GT. Patients have normal platelet counts and morphology, prolonged bleeding times, decreased or absent clot retraction, and abnormal platelet aggregation responses to physiologic stimuli. The initial slope of high-dose ristocetin-induced aggregation is normal (or near normal), reflecting the normal plasma VWF and the normal platelet GPIb/IX content; at lower doses of ristocetin, however, where GPIb/IX-mediated activation of integrin $\alpha_{\text{IIb}}\beta_3$ (Chap. 112) normally contributes to the aggregation response, patients have decreased second wave aggregation.¹¹⁶ GT platelets undergo normal shape change in response to ADP and thrombin, demonstrating their ability to undergo metabolic and cytoskeletal changes in response to these agents. Similarly, high doses of thrombin and collagen produce normal release of dense body and α -granule contents^{18,20,117}; the decreased secretion observed with lower doses of these agents reflect the lack of augmentation of the release reaction normally produced by platelet aggregation.^{18,116,118–120}

Platelets in whole blood or platelet-rich plasma adhere to glass because fibrinogen first becomes deposited on the glass and the platelets then adhere to the immobilized fibrinogen.^{121,122} Platelets from patients

TABLE 120–3. Laboratory Features of Glanzmann Thrombasthenia

- I. Platelet count: Normal
- II. Bleeding time: Markedly prolonged
- III. Tests of platelet function
 - A. Platelet aggregation
 1. Epinephrine—no observable response
 2. ADP and thrombin—shape change, but no aggregation
 3. Collagen—shape change followed by variable increase in light transmission most likely from progressive adhesion to collagen fibers (pseudoaggregation)
 4. Ristocetin—normal initial slope of aggregation; at low doses, inhibition of second wave; at high doses, cyclical aggregation–disaggregation
 - B. Aperture closure time (PFA-100): Prolonged
 - C. Clot retraction: Absent or reduced
 - D. Platelet release reaction: Decreased with epinephrine and low-dose adenosine diphosphate (ADP), thrombin, and collagen; normal with high-dose thrombin and collagen
 - E. Interaction with glass (platelet retention test): Absent or reduced
 - F. Platelet coagulant activity: Variably abnormal
 - G. Microparticle formation: Variably abnormal
 - H. *Ex vivo* interaction with deendothelialized blood vessels in flow chambers: Marked abnormality in platelet thrombus formation and defective platelet spreading; decreased platelet adhesion at high shear rates
- IV. Tests of $\alpha_{\text{IIb}}\beta_3$ and $\alpha_{\text{v}}\beta_3$ receptors: Number and functional integrity
 - A. $\alpha_{\text{IIb}}\beta_3$ content: Reduced or absent, except in variants
 - B. $\alpha_{\text{v}}\beta_3$ content: Reduced or absent in patients with β_3 defects; normal or increased in patients with α_{IIb} defects
 - C. Platelet binding of fibrinogen and other adhesive glycoproteins to $\alpha_{\text{IIb}}\beta_3$: Reduced or absent
 - D. Platelet fibrinogen content: Markedly reduced, except in some variants

with GT fail to adhere to glass,^{18,20,121} and this forms the basis of their abnormality in the glass bead retention assay.¹²³ Platelet coagulant activity has been variably reported as normal or abnormal.^{18–21,124–126} A defect in platelet microparticle formation and support of thrombin generation has been identified in some patients,^{125–128} but not in all patients.¹²⁹ Integrins $\alpha_{\text{IIb}}\beta_3$ and $\alpha_{\text{v}}\beta_3$ bind prothrombin, probably accounting for some of the abnormalities identified.^{130,131}

In flow-chamber studies, thrombasthenic platelets adhere normally to deendothelialized blood vessels at low and intermediate shear rates, but do not spread normally or form platelet thrombi.^{132–134} A defect in adhesion occurs at higher shear rates. A paradoxical increase in fibrin formation on these surfaces has been observed with thrombasthenic platelets, but the explanation for this phenomenon remains unknown.¹³⁵ In contrast to normal blood, blood from nearly all patients with GT fails to occlude a 150- μm PFA-100 aperture in collagen-coated membranes under high shear, either in the presence of ADP or epinephrine.^{136,137}

Platelet integrins $\alpha_{\text{IIb}}\beta_3$ and $\alpha_{\text{v}}\beta_3$ can be quantitated by several techniques, including, monoclonal antibody binding (using flow cytometry or radiolabeled binding), immunoblotting, and surface-labeling followed by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE). Based on such studies, GT patients are subcategorized by integrin $\alpha_{\text{IIb}}\beta_3$ content into those with less than 5 percent of normal (type I), 5 to 20 percent (type II), or 50 percent or more (variants).^{22,138} In one review of 64 patients, 78 percent were type I, 14 percent were type II, and 8 percent were variants.²² This subtyping predated the identification of integrin $\alpha_{\text{IIb}}\beta_3$ abnormalities as the cause of GT and was based on functional data; this categorization provides only limited information.

Measuring integrin $\alpha_{\text{v}}\beta_3$ content is technically more demanding than measuring that of integrin $\alpha_{\text{IIb}}\beta_3$ because there are only approximately 50 to 100 integrin $\alpha_{\text{v}}\beta_3$ receptors per platelet.⁶³ The integrin $\alpha_{\text{v}}\beta_3$ level is very useful, however, in making a preliminary assessment of whether the patient has a defect in the α_{IIb} or β_3 subunits, because, in general, patients who lack integrin $\alpha_{\text{v}}\beta_3$ receptors have a defect in the β_3 rather than α_{IIb} subunit.¹³⁹ A β_3 subunit missense mutation (H280P) that differentially affected integrin $\alpha_{\text{IIb}}\beta_3$ more than $\alpha_{\text{v}}\beta_3$ has, however, been described.⁶⁹

Fibrinogen-binding studies assess the function of the integrin $\alpha_{\text{IIb}}\beta_3$ complex.²⁵ Early studies used radiolabeled fibrinogen to the binding of fibrinogen when the platelets are stimulated with ADP²⁵ or a similar agonist. Fibrinogen can also be labeled with a fluorescent molecule and then flow cytometry can be used to measure fibrinogen binding. These techniques are most useful in detecting qualitative abnormalities of integrin $\alpha_{\text{IIb}}\beta_3$ in patients with variant GT. The binding of a monoclonal antibody (PAC1) to platelets gives similar information because the antibody only binds to the activated form of the integrin.¹⁴⁰

Carriers of GT have essentially normal platelet function.³⁴ Their platelets, however, only contain approximately 60 percent of the normal number of integrin $\alpha_{\text{IIb}}\beta_3$ receptors; the overlap in values between normal individuals and carriers, however, doesn't permit for unequivocal diagnosis of carriers by this technique.¹¹² Carrier detection is most accurately performed by DNA analysis.

Platelet fibrinogen is reduced to approximately 10 percent of normal in patients with marked reductions in integrin $\alpha_{\text{IIb}}\beta_3$ ^{18,21,43,44} but is variably reduced in patients with significant amounts of integrin $\alpha_{\text{IIb}}\beta_3$.^{138,141,142}

Therapy and Prognosis

Therapy of GT patients is discussed in the section entitled "Management of Inherited Platelet Function Disorders." Although GT is a severe disease, the prognosis for survival is generally good. In one series, two of 64 patients died of hemorrhage and in another series, three of 43 patients died of hemorrhage.^{22,33} A nationwide survey in Japan identified 98 GT

patients in 1976 and 192 in 1991.¹⁴³ The mortality rate decreased substantially during this time interval.

$\alpha_{\text{IIb}}\beta_3$: Select Macrothrombocytopenias Five heterozygous missense mutations in four different amino acids in integrin $\alpha_{\text{IIb}}\beta_3$ (α_{IIb} G991C, R995Q, and R995W, and β_3 L718P and D723H), as well as several different deletions, lead to variably mild reductions in both integrin $\alpha_{\text{IIb}}\beta_3$ expression and platelet aggregation, as well as constitutively active receptors, in patients with inherited aniso- and macrothrombocytopenia.^{144–150} The defects cluster on both sides of the transmembrane domains, and include both members of the α_{IIb} R995- β_3 D723 salt bridge proposed to maintain the receptor in a low affinity state.¹⁵¹ Proplatelet formation has been reported to be abnormal in several reported cases.

GLYCOPROTEIN Ib (CD42b,c)-IX (CD42a)-V: BERNARD-SOULIER SYNDROME

Definition and History

BSS is an inherited disorder of the platelet GPIb-IX-V complex characterized by thrombocytopenia, giant platelets, and a failure of the platelets to bind GPIb ligands, most importantly, VWF and thrombin.^{152–155}

In 1948 Bernard and Soulier described two children from a consanguineous family who had a severe bleeding disorder characterized by mucocutaneous hemorrhage, variable thrombocytopenia, and giant platelets.^{156,157} Beginning in the early 1970s, BSS platelets were shown to have a functional defect in VWF-dependent platelet adhesion and agglutination.^{158–160} In 1975, Nurden and Caen identified an abnormality in platelet GPIb as the cause of the functional defect.¹⁶¹ Later studies confirmed the defect in VWF-GPIb interactions^{162–164} and identified additional defects in platelet GPV and GPIX.^{165,166} Subsequent studies have identified additional ligands for the GPIb-IX complex, including thrombin,¹⁶⁷ P-selectin,¹⁶⁸ leukocyte integrin $\alpha_{\text{M}}\beta_2$,¹⁶⁹ high-molecular-weight kininogen,¹⁷⁰ thrombospondin-1,¹⁷¹ and coagulation factors XI¹⁷² and XII¹⁷³ (Chap. 112), but the precise contributions of these interactions to the disorder are not well defined. Molecular defects in the genes for GPIb α , GPIb β , and GPIX, but not GPV have been identified in BSS. Mouse models of BSS have been produced by gene targeting of *GPIb α* ¹⁷⁴ and *GPIb β* ,¹⁷⁵ and like humans, mice deficient in *GPV* do not demonstrate the typical features of human BSS.^{176,177}

Etiology and Pathogenesis

This rare disease, with a prevalence estimated as less than one in 1,000,000, has been reported from countries around the world.^{152,154,157,165} Both autosomal recessive ("biallelic") and autosomal dominant ("monoallelic") forms of the disorder have been described, with the biallelic producing the most severe symptoms and the monoallelic causing macrothrombocytopenia and a mild or no bleeding syndrome. Consanguinity is common in the biallelic form, with 85 percent of the reported cases being homozygous for the causative mutation.¹⁵⁴

Six different features of BSS may contribute to the hemorrhagic diathesis: thrombocytopenia, abnormal platelet adhesive interactions with VWF, abnormal platelet interactions with thrombin, abnormal platelet coagulant activity, abnormal platelet interactions with P-selectin, and abnormal platelet interactions with leukocyte integrin $\alpha_{\text{M}}\beta_2$.

The pathophysiology of the thrombocytopenia is uncertain. Early studies suggested a marked shortening of platelet survival, presumably from the decrease in platelet surface charge resulting from the GPIb defect.^{178,179} Later studies using ¹¹¹In-oxine to label platelets reported more modest or no shortening of platelet survival, indicating that ineffective thrombopoiesis and/or decreased thrombopoiesis may contribute to the thrombocytopenia.^{180,181} Morphologic abnormalities have been identified in BSS megakaryocytes and these may contribute to abnormal platelet production.¹⁸² Based on observations in other giant

platelet syndromes (Chap. 117), the large size of Bernard-Soulier platelets would tend to diminish the adverse hemostatic effects of the thrombocytopenia because the platelet mass is better preserved. With only rare exceptions,¹⁸³ however, the bleeding diathesis with BSS is more severe than expected from the thrombocytopenia, reinforcing the conclusion that a qualitative platelet defect is the predominant problem.^{157,184}

The platelet GPIb-IX complex functions as a receptor for VWF (Chaps. 112 and 126).^{152,185,186} This interaction is crucial in the adhesion of platelets to subendothelial surfaces, especially under high shear conditions, where VWF acts as a bridge between the subendothelial matrix and the platelet.^{133,134} The relative roles of subendothelial VWF, plasma VWF, and platelet VWF have not been completely defined, but they probably all contribute to platelet adhesion.¹⁸⁷ The interaction of VWF with GPIb/IX initiates activation of integrin $\alpha_{IIb}\beta_3$,^{188,189} which can also bind to VWF, but at a different site on the molecule.¹⁹⁰ The interaction of GPIb/IX with VWF also directly contributes to platelet-platelet interactions.¹⁹¹⁻¹⁹³

GPIb/IX-VWF interactions can also occur in platelet suspensions at high shear rates; this can lead to platelet activation, with subsequent aggregation mediated by integrin $\alpha_{IIb}\beta_3$.^{187,194-196} Whether sustained shear rates *in vivo* ever reach the levels required to initiate VWF binding, however, is not established.

Abnormalities of the GPIb-IX complex can be a result of genetic defects in *GPIb α* , *GPIb β* , or *GPIX*, all of which are required for surface expression. BSS is the most severe form of the disease and is caused by defects in both alleles of one of the proteins as a result of a homozygous mutation, compound heterozygosity, or a combination of hemizygoty of *GPIb β* because of a microdeletion and a mutation affecting the other *GPIb β* allele. These abnormalities have been termed the *biallelic forms*.¹⁵⁴ A macrothrombocytopenic syndrome associated with a mild bleeding syndrome has been reported with heterozygous defects in *GPIb α* and *GPIb β* .¹⁵⁴ Because obligate heterozygotes for the biallelic BSS mutations do not commonly demonstrate macrothrombocytopenia, the heterozygous defects associated with macrothrombocytopenia may exert a dominant negative effect.¹⁵⁴

The platelets of patients with BSS have a decreased response to platelet activation by thrombin, especially at limiting concentrations of thrombin.¹⁹⁷⁻¹⁹⁹ BSS platelets are deficient in two different proteins that interact with thrombin, namely GPIb α , which binds thrombin,¹⁶⁷ and GPV, which is a thrombin substrate (Chap. 112). The precise nature of the interactions of thrombin with GPIb α and its biologic consequences are still unclear, but binding of thrombin to GPIb α can initiate signaling within the platelet, perhaps directly through GPIb α crosslinking or indirectly by augmenting activation of other thrombin receptors (protease-activated receptors [PARs] 1 and 4) or other thrombin-dependent events at the platelet surface.¹⁶⁷ Paradoxically, mice deficient in GPV actually have increased sensitivity to thrombin activation and variably increased thrombus formation, perhaps because GPV limits access of thrombin to GPIb.^{200,201} Because thrombin is one of the major physiologic activators of platelets, the loss of thrombin binding to GPIb α may contribute to the hemorrhagic diathesis.

Platelets from patients with BSS are defective in supporting thrombin generation as judged by the serum PT,²⁰² a test performed with whole blood, but in other tests of platelet coagulant activity, BSS platelets support coagulation as well as, or better than, normal platelets.^{124,203} Defects in collagen-induced coagulant activity and the association of factors V, VIII, and XI with BSS platelets have been described,²⁰³ but their significance is unclear. Similarly, GPIb/IX has been identified as a binding site for other proteins involved in coagulation, including high-molecular-weight kininogen and factor XII, but the contributions of these interactions to the coagulant abnormality are also uncertain.^{170,172,173} Binding of VWF to GPIb/IX has been implicated

in fibrin-dependent, but not fibrin-independent, augmentation of platelet coagulant activity and thus fibrin-dependent coagulant activity is likely to be abnormal in BSS.¹²⁶ This finding may partially explain the variability in findings between the serum PT and some of the other assays as fibrin only forms in the serum PT. Abnormal membrane lipids have also been reported.²⁰⁴

The mechanism(s) producing the giant platelets in BSS has not been identified, but since giant platelets are found in BSS variants in which GPIb/IX is present, but unable to bind ligand, it has been postulated that the abnormality is a result of the inability of GPIb/IX to bind an unknown marrow ligand.¹⁵² It cannot be because of an inability to bind VWF as, with only rare exceptions,²⁰⁵ patients lacking VWF do not have large platelets. Moreover, in a mouse model of BSS, restoring a receptor with the GPIb transmembrane and cytoplasmic domains, but not the ligand-binding domain, partially corrected both the thrombocytopenia and large platelet size.²⁰⁶ A defect in GPIb/IX-mediated signaling has also been proposed to cause the large platelets as a deficiency of PLC has also been described in BSS.^{152,207} A mechanical alteration in the plasma membrane of BSS platelets has been identified by micropipette experiments, showing the plasma membrane to be more deformable than normal.²⁰⁸ Megakaryocytes in BSS have increased ploidy and volume, as well as alterations in the membrane demarcation system, granules, and microtubules.^{181,182} Both the increased size and deformability may reflect the loss of the normal interaction of GPIb/IX with the cytoskeleton via actin-binding protein (filamin-1; Chap. 112).

Platelets from patients with BSS are deficient not only in GPIb α , GPIb β , and GPIX, which are known to be associated as a complex, but also in GPV (Chap. 112).^{152,166} All of these proteins share highly conserved leucine-rich regions.^{152,187} One possible explanation for the loss of surface expression of all the proteins is that they need to form a complex during biosynthesis in order to be transported to the surface¹⁸⁷; evidence supports the need for GPIb α , GPIb β , and GPIX to all be present for optimal surface expression,²⁰⁹ but data from mice deficient in GPV indicate that this glycoprotein is not required for surface expression of the GPIb-IX complex.²⁰⁰ GPV may, however, improve the efficiency of expression of the other members of the complex.²¹⁰ Moreover, data from the BSS mouse expressing a chimeric GPIb α molecule in which the leucine-rich repeat domain was replaced with the external domain of another receptor indicate that complex formation does not require the GPIb α leucine-rich domain.²⁰⁶

At the molecular level, the platelets from different patients with BSS are heterogeneous, with many having no detectable GPIb and others having variable amounts, up to 50 percent of normal.^{152,207,211-214} There also is variability in the degree of concordance in the reduction of GPIb and the other deficient proteins.^{215,216}

Molecular Defects The molecular biologic basis of BSS has been determined in 161 patients from 132 unrelated families¹⁵⁴ and an online registry of defects is available at <http://www.bernardsoulier.org/>.²¹⁷ An international consortium reported on 211 families with the recessive form of BSS, which they termed "biallelic."¹⁵⁴ In total, 45 different mutations have been reported in *GPIb α* , 52 in *GPIb β* , and 28 in *GPIX*. No defects in *GPV* have been identified in patients with BSS. The association with consanguineous matings was reinforced as 85 percent of the families had homozygous mutations and 13 percent were compound heterozygotes for defects in one of the genes. None of the variants were identified in several gene variant databases,¹⁵⁴ suggesting that they are all rare and likely entered the population relatively recently. A number of likely founder mutations have been identified in each of the three genes in different populations.^{154,218} The ancestry of seven apparently unrelated families with a *GPIb β* W89D mutation was traced to a common ancestor in 1671 in India.²¹⁸ Five mutations in *GPIX* account for 137 of the 184 affected *GPIX* alleles and *GPIX* N61S is found in 64

Figure 120–4. Localization of select missense mutations causing platelet-type von Willebrand disease (VWD) and Bernard-Soulier syndrome (BSS) in the GPIIb N-terminal domain. Ribbon diagram of the topology of GPIIb N-terminal domain viewed from the side. The regulatory loop is colored *blue* with activating platelet-type VWD mutations G233V and M239V indicated as open *black* balls. Five BSS mutations, which cause loss of von Willebrand factor binding, are shown as *blue* balls. L57F and C65R localize to leucine-rich repeat (LRR) 2 with L129P, A156V, and L179del localized to the LRR5, LRR6, and LRR7 β -strands, respectively. The molecular structure of the sulfated tyrosine residues 276, 278, and 279 are shown. (Adapted with permission from Uff S, Clemetson JM, Harrison T, et al: Crystal structure of the platelet glycoprotein Ib(α) N-terminal domain reveals an unmasking mechanism for receptor activation. *J Biol Chem* 277(38):35657–35663, 2002.)

European families. A number of mutations have been identified to cause the heterozygous monoallelic form, including the GPIIb A172V mutation, which has been associated with biallelic and monoallelic forms of the disorder in 42 apparently unrelated families with macrothrombocytopenia in Italy.¹⁵⁴ Many of the defects affect the leucine-rich repeats or the conserved flanking sequences, supporting the importance of these structural elements in the biogenesis and surface expression of the GPIIb–IX–V complex (see Chap. 112, Fig. 112–14, and Fig. 120–4). Three patients have been described who are homozygous for a deletion in the last two bases of codon 492 of GPIIb, resulting in a frameshift that alters the membrane spanning region and results in premature termination, and another patient has been described who is heterozygous for this deletion and a missense mutation of GPIIb.^{219–222} These defects appear to result in a poorly anchored GPIIb with GPIIb antigen present in plasma. GPIIb mutations have affected the promoter region, at a binding site for the GATA-1 transcription factor,²²³ the signal peptide,²²⁴ and the transmembrane and intracellular domains.²²⁵ A homozygous Y88C defect in GPIIb has been reported to cause BSS in two Japanese families and heterozygotes with this mutation have a giant platelet syndrome.^{221,226} Similarly, a patient heterozygous for a GPIIb R17C mutation also had a giant platelet syndrome.²²⁷ An N45S mutation in GPIIb, affecting leucine rich repeat 1, has been reported in at least 12 different white patients, including four patients from a large Swiss family with variable clinical manifestations^{228–230} and one Turkish patient.²³¹

BSS has been reported in seven patients in association with hemizygous deletion of GPIIb and several neighboring genes on chromosome 22q11.2, leading to variable manifestations of the DiGeorge syndrome, including cardiac defects, dysmorphic facial features, thymic hypoplasia, and velopharyngeal insufficiency.^{154,232–239} Hemizygous mutations

in the remaining GPIIb allele have included P96S and P29L.^{236,237} In other studies of patients with the 22q11.2 deletion syndrome, modest reductions in platelet count and increases in platelet volume, as well as reduced platelet agglutination to ristocetin and decreased platelet GPIIb/IX expression, have been variably reported, consistent with hemizygosity for GPIIb.^{240–244}

A number of monoallelic, heterozygous mutations in the genes of the GPIIb–IX complex have been described as causing macrothrombocytopenia, some, but not all, of which have also been implicated in causing the biallelic form either because of homozygosity or compound heterozygosity.¹⁵⁴ These include a heterozygous mutation in the second leucine-rich repeat (L57F)²⁴⁵ in which the affected patients have moderate bleeding symptoms, moderate thrombocytopenia, and giant platelets. Additional monoallelic mutations of GPIIb that appear to produce dominant effects are N41H²⁴⁶ and Y54D.²⁴⁷

The “Bolzano” defect, which involves a mutation in the sixth leucine-rich repeat of GPIIb (A156V), results in a GPIIb molecule that has reduced ability to bind VWF, but can bind thrombin. It has been described in both biallelic and monoallelic forms. Two patients with biallelic forms have been described. In one patient, the Bolzano defect was homozygous, and the patient had a lifelong history of mucocutaneous hemorrhage in association with an approximately 50 percent reduction in GPIIb surface expression and total loss of ability to bind VWF.²⁴⁸ In the other, the Bolzano mutation coexisted with a 12-amino-acid deletion and an amino acid substitution (Q181K).²⁴⁹ The monoallelic form of the Bolzano defect has been reported in more than 100 patients from 48 pedigrees, primarily from southern Italy.²⁵⁰ Most patients have no bleeding symptoms, but some have mild to moderate bleeding symptoms. Mild thrombocytopenia, increased mean platelet volume, reduced expression of GPIIb/IX/V, and normal or borderline abnormal values for ristocetin-induced platelet aggregation are characteristic of this disorder.

Clinical Features

Epistaxis is the most common symptom of BSS (70 percent); also common are ecchymoses (58 percent), menometrorrhagia (44 percent), gingival hemorrhage (42 percent), and gastrointestinal bleeding (22 percent).¹⁵⁷ The combination of BSS with angiodysplasia can result in particularly severe recurrent hemorrhage.^{251–253} Hemorrhagic symptoms that occur with lower frequency include posttraumatic bleeding (13 percent), hematuria (7 percent), cerebral hemorrhage (4 percent), and retinal hemorrhage (2 percent). There is considerable variability in symptoms among patients, even among patients within a single family.^{152,254} A review that includes brief descriptions of the clinical features of 55 patients, reported through 1998, has been published.¹⁵²

Laboratory Features

Thrombocytopenia is present in nearly all patients, but is variable in its severity, ranging from approximately 20×10^9 platelets/L to near-normal levels. Platelets are large on smear, with more than one-third usually having diameters greater than $3.5 \mu\text{m}$, and some being as large or larger than lymphocytes. By electron microscopy, platelets display only minor variations in vesicular structures and the open canalicular system,¹⁵⁷ but megakaryocytes have more notable abnormalities in their demarcation membranes.¹⁸² The cell membranes of platelets from patients with BSS appear to be more deformable than normal,²⁰⁸ perhaps because GPIIb ordinarily interacts with the platelet cytoskeleton²⁵⁵ (Chap. 112).

Closure times of the apertures of collagen-coated membranes are markedly prolonged in the presence of ADP or epinephrine (PFA-100).¹³⁶ The hallmark findings in the BSS are the failure of platelets to aggregate in response to ristocetin¹⁵⁹ or botrocetin,^{162,256} agents that require VWF–GPIIb interactions. In VWD, but not BSS, this defect can be corrected by adding normal plasma (or VWF).

Although, the large size of the platelets in BSS and the thrombocytopenia make it technically difficult to perform platelet aggregation studies, in general, aggregation induced by ADP, epinephrine, or collagen is either normal or enhanced.^{160,257,258} The aggregation response to thrombin is usually dose-dependent, being essentially normal in response to high doses of thrombin but characterized by a prolonged lag phase and diminished aggregation in response to low doses of thrombin.^{197,259}

Platelet Coagulant Activity The coagulant activity of platelets from patients with BSS has been variably reported as reduced, normal, or increased.^{124,202,203} The variable presence of fibrin in the different assays used to assess platelet coagulant activity may account for these inconsistent results as GPIb-VWF interactions enhance platelet coagulant activity when fibrin is present, but not when it is absent.¹²⁶

Platelet-Thrombin Interactions Both GPIb and the seven-transmembrane domains PAR-1 and PAR-4 receptors are required for maximal response to thrombin.^{167,259} Two different crystal structures of the interactions between thrombin and GPIb α have been reported; in one, two molecules of thrombin bind to each GPIb α molecule, raising the possibility that free thrombin or thrombin adherent to fibrinogen can cluster GPIb-IX-V complexes.^{167,260,261} GPV, which is missing from the platelet surface in BSS, is cleaved by thrombin, but the cleavage is neither necessary nor sufficient for thrombin-induced platelet activation.^{262,263} In fact, platelets of mice lacking GPV have increased responsiveness to thrombin, perhaps because GPV ordinarily limits access of thrombin to GPIb α or inhibits GPIb α crosslinking.^{200,201}

Ex Vivo Interaction with Subendothelial Surfaces Platelets from patients with BSS demonstrate defective adhesion to subendothelial surfaces, especially at shear rates greater than 650 s⁻¹.^{133,134,158,264} The results are similar to those in patients with VWD.

Shear-Induced Platelet Aggregation Unlike normal platelets, platelets from patients with BSS are not aggregated by high shear rates.^{194,195} The initial interaction in this process appears to be binding of VWF to GPIb,¹⁸⁷ with subsequent activation of integrin $\alpha_{IIb}\beta_3$, perhaps through signaling via the protein 14-3-3 ζ associated with the cytoplasmic domain of GPIb α ,^{196,265} Fc γ receptor IIA, GPVI, and/or the Fc receptor γ chain (Chap. 112).²⁶⁶⁻²⁶⁸ Pathologic shear stress has been reported to increase binding of α -actin to GPIb/IX as part of the signaling process.²⁶⁸⁻²⁷⁰

Therapy

The therapy of BSS is described in the section "Management of Inherited Platelet Function Disorders" below. Splenectomy has been performed when the diagnosis of immune thrombocytopenia was mistakenly made, but this usually does not normalize the platelet count or improve the bleeding diathesis.²⁴⁹

GPIb α (CD42b,c): PLATELET-TYPE (PSEUDO-) VON WILLEBRAND DISEASE

Definition and History

A heterogeneous group of patients has been described with mild to moderate bleeding symptoms, variably enlarged platelets, variable thrombocytopenia, and diminished plasma high-molecular-weight VWF multimers.²⁷¹ The fundamental defect in these patients is thought to be an enhanced interaction between an abnormal platelet GPIb/IX receptor and normal plasma VWF.²⁷²⁻²⁸¹ Because these patients have some of the hallmarks of VWD, but the defect is in platelet GPIb/IX, it

has been termed both *pseudo-VWD* and *platelet-type VWD*. At present, 55 patients are listed in the database of patients with this disorder (www.pt-vwd.org).^{282,283}

Etiology and Pathogenesis

A qualitative abnormality in GPIb is responsible for this disorder, with ongoing *in vivo* binding of high-molecular-weight VWF multimers to platelets causing depletion of the plasma high-molecular-weight multimers. In addition, the binding of the VWF to platelets may lead to shortened platelet survival, perhaps accounting for the variable thrombocytopenia. Inheritance is autosomal dominant.

Abnormalities in the Mr of GPIb were identified in two families,²⁷⁷ but these may have resulted from a now-recognized polymorphism in GPIb (Chap. 112) rather than being related to the functional disorder. Heterozygous point mutations in the *GPIb α* gene causing a variety of missense alterations (G233V, G233S, M239V, D235Y, W230L) have been found in several different families.^{271,278,284-289} The G238V mutation is the most common among the patients in the database, affecting 31 of 35 patients. All of these mutations are in the R-loop (also termed β -switch) in the carboxyterminal flanking sequence of the leucine-rich repeats, a region implicated in ligand binding (see Fig. 120-4).^{152,187,290-293} Molecular modeling suggests that the M239V substitution produces a significant conformational change in the molecule,²⁹⁴ and this was confirmed by crystallographic analysis.²⁹⁵ It has been proposed that the platelet-type VWD mutations either destabilize the compact triangular structure of the R-loop by interfering with the D235-K237 salt bridge or stabilizing the extended β -hairpin form of the R-loop, which is better able to engage the VWF A1 domain.²⁸² A mouse model of the GPIb α G233V mutation recapitulated many of the human manifestations and had an unexpected increase in bone mass.²⁹⁶ Recombinant GPIb α fragments containing the G233V and M239V mutations demonstrated enhanced interactions with VWF in several different systems, including ones under shear stress.^{297,298} An increase in platelet GPIb/IX expression has also been reported.^{278,281} An in-frame 27-base-pair (bp) deletion in the macroglycopeptide region of GPIb α has also been reported to cause platelet-type VWD.²⁷⁹ Because the deletion may lead to the loss of up to four glycosylation sites, it has been proposed that the glycans play a negative regulatory role in ligand binding.²⁸²

Clinical Features

Patients have variable thrombocytopenia and mild to moderate mucocutaneous hemorrhage. A study of 13 patients with six different mutations using a standardized bleeding assessment tool found a wide range of clinical severity, with approximately 40 percent having a normal bleeding score and the remainder having a wide range of abnormal scores.²⁷¹ Bleeding scores did not correlate with age or sex, but did correlate with reductions in both platelet count and ristocetin cofactor activity. All patients had macrothrombocytopenia. Of note, pregnancy may exacerbate the thrombocytopenia and bleeding symptoms.²⁷⁸

Laboratory Features and Differential Diagnosis

Mild thrombocytopenia and somewhat enlarged platelets are present in some, but not all, patients. Plasma VWF levels are variably reduced, with a disproportionate reduction in plasma high-molecular-weight multimers. Platelet VWF multimers are normal.

The most characteristic laboratory finding in platelet-type VWD is enhanced platelet aggregation in response to low concentrations of ristocetin^{272-276,278,288} or botrocetin.²⁹⁹ This same abnormality is present in patients with type 2b VWD, as is selective depletion of plasma high-molecular-weight VWF multimers (Chap. 126). In platelet-type VWD, however, the defect is in platelet GPIb α , whereas in type 2b VWD, the

defect is in the VWF. In one study comparing platelet-type and type 2b VWD, patients with type 2b VWD had more severe bleeding, especially menorrhagia, and lower platelet counts.²⁷¹ Several assays can help differentiate between these abnormalities^{274,300–302}: (1) normal VWF (purified or in cryoprecipitate) will aggregate platelets from patients with platelet-type VWD, but not platelets from patients with type 2b VWD; (2) isolated platelets from patients with platelet-type VWD will bind normal VWF at lower concentrations of ristocetin than will normal platelets or platelets from patients with type 2b VWD; (3) plasma VWF from patients with type 2b VWD will bind to normal platelets at lower-than-normal concentrations of ristocetin, whereas higher-than-normal concentrations of ristocetin are required to promote the plasma VWF from patients with platelet-type VWF to bind to normal platelets³⁰¹; and (4) VWF lacking sialic acid residues (asialo-VWF) will agglutinate platelets from patients with platelet-type VWD in the presence of ethylenediaminetetraacetic acid (EDTA).³⁰³ A number of patients with platelet-type VWD were originally diagnosed as having type 2b VWD, leading to the conclusion that platelet-type VWD may be underdiagnosed, and an international registry based study supports this contention.^{278,280,304}

Therapy

Because normal VWF (especially the high-molecular-weight forms) can bind excessively to the platelets of patients with platelet-type VWD and potentially lead to rapid platelet clearance from the circulation, increasing the VWF level by any means (desmopressin infusion or VWF replacement with cryoprecipitate or VWF concentrates) poses a potential risk of inducing thrombocytopenia.^{300,305} It may be possible to estimate this risk by assessing whether the patient's platelets aggregate *ex vivo* in response to VWF (as in cryoprecipitate).²⁷³ Low-dose cryoprecipitate has successfully supported hemostasis, without inducing thrombocytopenia.^{275,305,306} Currently, cryoprecipitate is generally less favored for VWF replacement therapy than plasma-derived factor VIII concentrates such as Humate-P, which is approved in the United States for the therapy of VWD, because the plasma-derived factor VIII concentrates have a reduced risk of viral infection. Consideration should also be given to platelet transfusion in appropriate circumstances. Recombinant factor VIIa infusion may be beneficial and is licensed for this indication in Europe, but this therapy is not yet approved by the FDA; it has the theoretical advantage of avoiding excessive interactions between VWF and the abnormal GPIIb/IIIa receptor.^{307,308}

INTEGRIN $\alpha_2\beta_1$ DEFICIENCY (GLYCOPROTEIN Ia/IIa; VLA-2; CD49B/CD29)

Integrin $\alpha_2\beta_1$ (GPIIa/IIa) can mediate platelet adhesion to collagen and platelet activation under certain conditions (Chap. 112). A female patient with excessive posttraumatic bruising and menorrhagia but no epistaxis, gum bleeding, or excessive bleeding after tonsillectomy or appendectomy was described whose platelets selectively failed to aggregate or undergo shape change in response to collagen.^{309,310} The bleeding time was markedly prolonged, and the patient's platelets failed to adhere and spread normally on subendothelial surfaces. The patient's platelets only contained approximately 15 to 25 percent of the normal amount of integrin α_2 ,^{309,311} and a reduction in the β_1 subunit was also apparent.³⁰⁹ It is difficult to draw conclusions about the physiologic role of integrin $\alpha_2\beta_1$ in platelet function from this patient because her $\alpha_2\beta_1$ deficiency was incomplete, her bleeding symptoms were mild and variable, and some of the platelet function abnormalities (e.g., abnormal platelet-collagen interactions in the presence of the divalent chelating agent EDTA) are difficult to ascribe to the deficiency in $\alpha_2\beta_1$.^{309,312}

Another patient with integrin α_2 deficiency has been described.³¹³ She had a history of mucocutaneous and postoperative bleeding. Her bleeding time was prolonged and platelet aggregation in response to collagen was selectively reduced, but not absent. In addition to her α_2 subunit defect, she also had little or no intact thrombospondin, and exogenous thrombospondin corrected the defect in platelet aggregation. The patient's hemorrhagic symptoms and platelet defects disappeared when she entered menopause.

The variation in platelet integrin $\alpha_2\beta_1$ expression in healthy individuals is very wide (10-fold) and platelet levels have been correlated with allelic variants.³¹⁴ Reduced $\alpha_2\beta_1$ expression has been associated with alterations in megakaryocyte production and decreased mean platelet volume.³¹⁵

Mice with targeted deletion of integrin $\alpha_2\beta_1$ do not have a hemorrhagic phenotype or prolonged tail bleeding times but they do have reduced platelet adhesion to collagen and reduced thrombus formation after vascular injury³¹⁶; mice with a conditional loss of integrin $\alpha_2\beta_1$ in megakaryocytes and platelets have a decreased mean platelet volume.³¹⁵

CD36 (GPIV; FATTY ACYL TRANSLOCASE [FAT]; SCAVENGER RECEPTOR CLASS B, MEMBER 3 [SCARB3])

CD36 (GPIV) is a highly, but variably expressed platelet glycoprotein that is present on many cell types and documented to participate in long-chain fatty acid transport (Chap. 112). Approximately 3 percent of Japanese, 2 percent of African Americans, and 0.3 percent of whites in the United States have platelets that lack CD36 (GPIV).^{317,318} Although CD36 (GPIV) has been implicated in platelet interactions with collagen, thrombospondin, advanced glycation products,³¹⁹ and myeloid-related protein (MRP)-14,^{320–323} as well as in platelet-monocyte interactions,³²⁴ individuals lacking CD36 (GPIV) do not have a hemorrhagic diathesis. Platelets from these patients can bind thrombospondin via alternative receptors³²⁵ and there are differing data on its role in adhesion to collagen.^{326–328} A multiparameter analysis of platelet thrombus formation to different matrix proteins at differing shear rates identified a role for CD36 at low, but not high, shear rates.⁸ CD36 (GPIV) has also been implicated as a receptor for oxidized low-density lipoprotein (LDL), and the binding of very-low-density lipoprotein (VLDL) to CD36 (GPIV) has been reported to enhance collagen-induced platelet aggregation and thromboxane production.³²⁹ CD36 (GPIV) platelet expression varies widely among healthy individuals (200 to 14,000 molecules per platelet) and correlates with activation by oxidized LDL and genetic single-nucleotide variants.³³⁰

Two forms of CD36 (GPIV) deficiency have been described in Japan: type I in which both platelets and monocytes are deficient, and type II in which only platelets are deficient.^{331–333} A P90S substitution that also leads to abnormal posttranslational modification is a common abnormality contributing to both type I and type II deficiencies. In the type I form, patients are homozygous for the abnormality, whereas in type II deficiency, patients are doubly heterozygous for the P90S abnormality and an unidentified platelet-specific expression defect.^{331,334,335} Other abnormalities that have been associated with type I deficiency include a dinucleotide deletion (539–540) in exon 5, a 161-bp deletion^{331–491} corresponding to loss of exon 4, a nucleotide insertion at position 1159 in codon 317 leading to a frameshift and premature stop, and splice-site mutations.^{336–338} Other mutations have been identified in other populations.

CD36 (GPIV) deficiency can result in refractoriness to platelet transfusions because of isoimmunization and has been implicated in posttransfusion purpura (Chap. 117),³³⁹ as well as thrombocytopenia caused by the passive transfer of anti-CD36 antibodies.³⁴⁰

GLYCOPROTEIN VI DEFICIENCY

GPVI can mediate platelet adhesion to collagen and is important in collagen-induced signal transduction (Chap. 112). Twelve patients with mild to moderate bleeding disorders and variable deficiencies of platelet GPVI or signaling have been described; one had concomitant GPS (α -granule deficiency).^{341–350} The others had selective abnormalities in platelet–collagen interactions. Platelet GPVI deficiency associated with an autoantibody to GPVI has been described in several patients, one of whom also had systemic lupus erythematosus and another of whom had coexisting antibodies to integrin $\alpha_{IIb}\beta_3$.^{351–353} Antibody to GPVI may be detectable in eluates prepared from patient platelets even when it is not detectable in patient plasma.³⁵⁴ Acquired forms of GPVI-specific signal transduction have also been described in patients with myelodysplastic syndromes and chronic lymphocytic leukemia.³⁴⁷ Studies in mice and primates demonstrated that antibodies to GPVI can result in loss of GPVI from the platelet surface through either proteolytic shedding or a cyclic adenosine monophosphate (cAMP)-mediated internalization mechanism, even though the platelets continue to circulate.^{346,355} Thus, it is likely that the deficiency of GPVI most commonly results from the autoantibodies.³⁵³ It is unclear whether the patients reported earlier as having GPVI deficiency might also have had an immune basis for their GPVI deficiency.

Three different inherited forms of GPVI deficiency have been described. One patient with a lifelong history of “mild” mucocutaneous, posttraumatic, and postsurgery bleeding had a marked deficiency of platelet membrane GPVI resulting from both a 16-base out-of-frame deletion and a S175N missense mutation.³⁵⁰ The patient’s platelets failed to respond to collagen, convulxin, or collagen-related peptide. Of note, FcR γ expression was normal. Another patient with easy bruising, a prolonged bleeding time, abnormal PFA-100 closure time to collagen/epinephrine, and no platelet aggregation in response to collagen had a combination of a R38C mutation in one allele and a five-nucleotide duplication insertion in the other, leading to a nonsense codon.³⁵⁶ The R38C mutation led to misfolding of the protein, reduced surface expression, and a qualitative defect in collagen binding. Five subjects from four apparently unrelated families in Chile with variable histories of easy bruising, epistaxis, excessive bleeding after minor trauma, and gingival bleeding were found to have no platelet aggregation in response to collagen, convulxin, or collagen-related peptide.³⁵⁷ DNA analysis showed a homozygous adenine insertion between bases 711 and 712. Heterozygotes were asymptomatic and had nearly normal platelet function.

● ABNORMALITIES OF PLATELET GRANULES

Platelets contain at least three types of granules: dense or δ granules containing ADP, ATP, calcium, serotonin, and pyrophosphate; α granules containing a variety of proteins, some derived from plasma, others synthesized by the megakaryocyte; and lysosomes containing acid hydrolases. Following platelet activation, the contents of the α and dense granules are secreted. Inability to release these granule contents by virtue of a deficiency of the granules or their contents or in the cellular mechanisms governing the secretory process is associated with impaired platelet function. A heterogeneous group of disorders involving platelet granules has been described. They are broadly categorized into defects affecting dense granules (δ -storage pool deficiency [SPD]), α granules (α -SPD, or GPS), or both dense bodies and α granules ($\alpha\delta$ -SPD). Another disorder affecting granules is the Quebec platelet disorder, which affects the α -granules.

δ -STORAGE POOL DEFICIENCY

Definition and History

In 1969, a family with impaired platelet aggregation was described whose platelets displayed decreased levels of ADP.³⁵⁸ Holmsen and Weiss subsequently established that the defect was a deficiency in the nonmetabolic pool or “storage pool” of ADP present in the dense granules.³⁵⁹ δ -SPD is a heterogeneous disorder characterized by a bleeding tendency, abnormalities in the second wave of platelet aggregation, and variable deficiencies of platelet dense granule contents.

Etiology and Pathogenesis

Normal platelets contain two pools of adenine nucleotides that exchange very slowly.³⁶⁰ One pool is a metabolic nongranule pool in which the ratio of ATP to ADP content is 8 to 10:1. The second pool is the “storage pool” present in the dense granules and contains 65 percent of the platelet adenine nucleotides with an ATP-to-ADP ratio of 2:3. It is this storage pool that is deficient in δ -SPD. Dense granules also contain serotonin, which is taken up from plasma at a ratio of approximately 1000:1 via a pH-dependent amine trapping mechanism. Platelet serotonin levels are also decreased in δ -SPD.

δ -SPD can be a primary, inherited platelet disorder or a component of a multisystem (syndromic) disorder, such as the Hermansky-Pudlak syndrome (HPS)^{361–365} (variable oculocutaneous albinism, hemorrhagic disorder, and neurologic manifestations), the Chédiak-Higashi syndrome^{361,365,366} (partial oculocutaneous albinism, giant lysosomal granules, and frequent pyogenic infections), and the Wiskott-Aldrich syndrome^{361,367,368} (see below and Chap. 80). Other diseases associated with δ -SPD are Ehlers-Danlos syndrome,³⁶⁹ osteogenesis imperfecta,³⁷⁰ and TAR syndrome.^{361,371} The mode of inheritance in δ -SPD is not well defined, but an autosomal dominant pattern for the primary form has been identified in some patients.³⁷² The inheritance pattern of the syndromic forms follows the autosomal recessive and X-linked patterns characteristic of those disorders. Essential criteria for the diagnosis of HPS are the tyrosinase-positive oculocutaneous albinism and the δ -SPD in platelets.³⁷³ The hallmarks of albinism are diffuse hypopigmentation of skin, iris, hair and retina, although there is phenotypic heterogeneity.

Studies from animal models and, particularly, in patients with the syndromic variants indicate that defects in biogenesis of lysosome-related organelles form the basis of the disorders.^{361,374} These organelles share features with lysosomes but have distinct morphology, composition, and functions, and include melanosomes in melanocytes, platelet δ -granules, and Weibel-Palade bodies in endothelial cells.^{361,374} In δ -SPD associated with HPS, there may be a total failure of δ -granule formation as judged by electron microscopy of platelets and megakaryocytes³⁷⁵ and the absence of CD63 (granulophysin; ME491; LIMP-1; LAMP-3), a lysosomal and dense granule membrane protein of Mr 40,000 that is also found in melanosomes.^{361,363,376,377} The defect in melanosomes accounts for the oculocutaneous albinism. The defect in lysosomes results in accumulation of ceroid lipofuscin, a lipid-protein complex leading to granulomatous colitis and pulmonary fibrosis, which are variably manifest in these patients. Abnormalities of nine genes have been implicated in causing HPS (Fig. 120–5). Ultrastructural studies in patients with a variety of types of HPS indicate that α granules and other organelles are unaffected.³⁷⁸ Mutations in HPS-associated genes result in defects in intracellular protein trafficking and in the biogenesis of lysosomes and lysosome-related organelles.³⁶¹ The HPS gene products operate in distinct complexes termed *biogenesis of lysosome-related organelles complexes* (BLOCs), which consist of multiple proteins.³⁶¹ HPS is unusually common in patients from northwest Puerto Rico (frequency: 1:1800), and linkage analysis of these patients led to the identification of the abnormality in HPS gene (*HPS1*). The gene encodes a 700-amino-acid protein that participates in the complex of proteins called BLOC-3.^{361,363}

Figure 120-5. Hypothetical model of platelet granule formation and location of defects resulting in Hermansky-Pudlak syndrome (HPS). Early endosomes derive from invaginations from the plasma membrane whereas membrane-bound structures from the Golgi and endoplasmic reticulum contribute to the production of coated endosomes and late endosomes. Three multiprotein complexes termed *biogenesis of lysosome related organelles complexes* (BLOCs) are involved in the transport and interconversion of the different endosomal species. The gene products of HPS1 and HPS4 are involved in BLOC-3, whereas those of HPS3, HPS5, and HPS6 are involved in BLOC-2, and those of HPS7, HPS8, and HPS9 contribute to BLOC-1. HPS2 is a result of mutations in adaptor complex-3 (AP-3). It has not yet been determined which endosomal species contribute to α granules, lysosomes, and dense bodies, but all three organelles are affected in HPS. α Granules are in dynamic exchange with the plasma membrane, selectively taking up fibrinogen via integrin $\alpha_{IIb}\beta_3$ receptors. (Used with permission of Dr. Marjan Huizing and Dr. William Gahl, National Human Genome Research Institute, National Institutes of Health.)

The mutation in the Puerto Rican kindreds is a 16-bp duplication in HPS1 exon 15; other mutations of the same gene have been identified in patients from this region and in other ethnic groups.^{363,379,380} HPS2 is caused by mutations in the gene *AP3B1* (*HPS2*), which codes for the β_3A subunit of the heterotetrameric adaptor complex-3 (AP-3), which, in turn, facilitates the formation of vesicles of lysosomal lineage from membranes of the *trans*-Golgi network or late endosomes. Patients with mutations in this protein tend to also have neutropenia and childhood infections.^{373,381}

Defects in the *HPS3* gene cause a relatively mild form of HPS and pulmonary involvement is usually minimal.³⁸² *HPS4* encodes a protein that interacts with the *HPS1* protein in the BLOC-3 complex.³⁸³ Patients with mutations in this gene tend to have severe disease, and like patients with defects in *HPS1*, pulmonary involvement is common. The gene products of *HPS5* and *HPS6* interact with the *HPS3* gene product to form BLOC-2.^{384,385} Proteins implicated in HPS7 (encoded by *DTNBP1*) and HPS8 (encoded by *BLOC1S3*) are components of BLOC-1.^{386,387} Improper trafficking of melanocyte-specific proteins, including tyrosinase, has been found in the melanosomes of patients with *HPS5*.³⁸⁸ HPS is also associated with mutations in pallidin (*BLOC1S6/PLDN*), a protein of BLOC-1 and labeled as HPS9.³⁸⁹

Not all patients with δ -SPD have HPS. Some of the patients described to have δ -SPD have been subsequently shown to have mutations in *RUNX1*.^{358,372,390,391}

In other forms of δ -SPD, data obtained with uranaffin, a dye that specifically stains amine-containing granules, indicate that dense granule membranes are formed but are not properly filled.³⁹²⁻³⁹⁴ The defects in the different substances contained in dense granules are also heterogeneous, with some patients able to secrete significant amounts of calcium and pyrophosphate even when adenosine nucleotide secretion is nearly absent.³⁹²

Chédiak-Higashi syndrome results from mutation of the *LYST* gene, which encodes a protein of estimated molecular mass of 429 kDa,

predicted from domain analysis to participate in vesicle transport and to interact with microtubules; an *HPS1*-like region is also present.^{361,366}

Numerous animal models of human δ -SPD and HPS have been reported and several represent specific counterparts of the human disease. Thus, more than 20 separate inherited mouse defects have been reported to include dense granule deficiencies; of these, pale ear (*ep*) is linked to the mouse equivalent of the *HPS1* gene; pearl (*pe*) to the mouse equivalent of *HPS2* (β_3A subunit of AP-3 complex); cocoa to *HPS3*; light ear (*le*) to *HPS4*; ruby-eye-2 (*ru2*) to *HPS5*; ruby-eye (*ru*) to *HPS6*; sandy (*sd*) to *HPS7*; and pallid to *HPS9* (*PLDN*).^{361,395} The beige mouse and rat serve as models for Chédiak-Higashi syndrome.³⁶¹

Clinical Features

Patients with δ -SPD as part of the HPS may have severe, or even lethal, hemorrhage.³⁶³ For all other forms of the disorder, the bleeding tendency is variable, and mild to moderate.

Laboratory Features

When tested with the PFA-100 instrument, both prolonged and normal closure times have been reported, akin to prior findings with bleeding times.³⁹⁶⁻³⁹⁹ Interestingly, flow-dependent thrombus formation, assessed using a multisurface and multiparameter flow assay, is reported to be decreased.⁸ In platelet aggregation studies, ADP and epinephrine induce a normal primary wave of aggregation, but the secondary wave is variably abnormal. The abnormal platelet response is more easily discernible at low collagen doses than high doses. Secretion of ATP from platelets can be measured by luminescence simultaneously with platelet aggregation using a specially designed instrument.⁴⁰⁰ ATP release in response to activation is absent or decreased in δ -SPD patients. Thrombin at high doses causes maximal release of platelet dense body contents, even in patients with secretion abnormalities unrelated to granule deficiency,

and, therefore, this reagent may distinguish between δ -SPD (diminished release) and abnormalities of platelet secretory mechanisms, wherein the release may be normal or near-normal.

Measurement of platelet granule contents can establish further the platelet abnormality. The total platelet content of adenine nucleotides is reduced in δ -SPD, and the ratio of total platelet ATP to ADP is increased because it more closely reflects the ratio in the cytoplasmic, “metabolic” pool of adenine nucleotides (approximately 8:1) than in the “storage” pool in dense granules (approximately 2:3).^{360,401} Platelet serotonin is variably reduced.⁴⁰² Serotonin is taken up by platelets of patients with δ -SPD, but because it cannot be stored in dense granules, it is rapidly catabolized.⁴⁰² Abnormalities in platelet secretion and arachidonic acid metabolism have been identified, but are quite variable.⁴⁰³ Reduced plasma and platelet VWF activity in association with a decrease in plasma high-molecular-weight multimers has been reported in HPS,^{404,405} and may reflect abnormalities involving the endothelial Weibel-Palade bodies.

The decrease or absence of platelet dense bodies can be confirmed by electron microscopy, using either whole mounts or thin sections of platelets fixed in the presence of calcium, although it requires expertise to interpret the results.^{5,406} Some patients have abnormal granules. Uranaffin and osmium may help to identify dense granules. The fluorescent amine mepacrine can be used to quantify dense bodies by fluorescent microscopy or by flow cytometry.^{407,408} Immunoblot analysis of skin fibroblasts in HPS may facilitate identification of the protein responsible for the defect.⁴⁰⁹

Therapy, Course, and Prognosis

The general principles of patient management are similar to those described for all patients with platelet function defects. Patients with HPS suffer from a number of specific problems related to their albinism, colitis, and pulmonary fibrosis.³⁷³ In particular, they should avoid sun exposure. An antifibrotic agent, pirfenidone, demonstrated modest benefit in the initial study.⁴¹⁰ A second study⁴¹¹ failed to confirm this and was terminated because of futility.

GRAY PLATELET SYNDROME (α -STORAGE POOL DEFICIENCY)

Definition and History

The GPS is a markedly heterogeneous bleeding disorder characterized by selective deficiency of platelet α -granules and their contents, in combination with thrombocytopenia and large platelet size.^{412,413} The name derives from the initial observation by Raccuglia, in 1971,⁴¹⁴ of the gray appearance of platelets with paucity of granules on peripheral blood films from a patient with a life-long bleeding disorder.

Etiology and Pathogenesis

Normal platelets contain approximately 50 spherical or elongated α granules that contain a large number of proteins, some relatively specific for platelets (platelet factor 4 [PF4], β -thromboglobulin [β TG]), others that are also found in plasma, and yet others whose role in platelets is poorly understood.^{412,415,416} Plasma proteins present in α granules include fibrinogen, VWF, albumin, coagulation factor V, immunoglobulin (Ig) G, fibronectin, and several protease inhibitors. Some of these proteins, such as VWF are synthesized by megakaryocytes, whereas others, such as albumin and IgG, are incorporated into platelets by endocytosis. The α -granule membrane contains several proteins present in the platelet plasma membrane (integrin $\alpha_{IIb}\beta_3$, GPIb-IX-V) and some specific for α granules (P-selectin and osteonectin).

The molecular mechanisms leading to α -granule deficiency in GPS and the combined $\alpha\delta$ -SPD are also heterogeneous; thus, they have been

attributed to failure of α -granule maturation during MK differentiation, transport or targeting of proteins to α granules, and/or synthesis of granule membranes.^{412,415} Proteomic studies in a GPS patient suggested a failure to incorporate endogenously synthesized MK proteins into α granules.⁴¹⁵ Some GPS patients have elevated plasma PF4⁴¹² suggesting that PF4 synthesis was normal and the primary defect was impaired granule biogenesis with leakage of PF4. Some patients with decreased α -granule contents have a mutation in the gene for the transcription factor RUNX1^{372,390} and PF4 is a transcriptional target of RUNX1.⁴¹⁷ This suggests that decreased platelet PF4 levels in these patients represents a defect in transcriptional regulation and synthesis of PF4. GPS has been reported in association with a X-linked thrombocytopenia, thalassemia, and an R216N mutation in GATA-1, a major regulator of megakaryopoiesis.⁴¹⁸ Autosomal dominant GPS resulting from mutations in transcription factor gene *GFI1B* has been reported in two kindreds.^{419,420}

Three groups¹⁰⁻¹² have reported mutations in *NBEAL2* in patients with GPS, a gene that encodes for a protein linked to vesicle transport in neuronal cells. These studies implicate defective vesicle transport as a major mechanism in many forms of GPS. Studies in *Nbeal2*-deficient mice provide evidence^{421,422} that *Nbeal2* is required for α -granule biogenesis, platelet function, and MK survival, development and platelet production—key evidence linking GPS and *Nbeal2*. These mice were also found to have abnormalities in arterial thrombosis, inflammation, and wound repair. A mutation in the gene encoding the VPS33B protein (a member of the Sec1/Munc18 protein family) involved in vesicle trafficking has also been associated with human α -granule deficiency in the arthrogyrosis multiplex congenital, renal dysfunction, and cholestasis (ARC) syndrome.⁴²³ A mutation in *VPS16B* gene has also been linked to α -granule deficiency in the ARC syndrome, and it appears that VPS16B and VPS33B interact with each other.⁴²⁴ Thus, multiple mechanisms can lead to GPS. The inheritance of α -granule deficiency has been autosomal recessive in most reports, but autosomal dominant and sex-linked cases have also been described.^{372,390,412,418}

Clinical Features

GPS patients have a lifelong mild to moderate bleeding diathesis, which is variable in its manifestations.⁴¹²

Laboratory Features

Platelets appear as larger-than-normal, pale, ghost-like, oval forms on blood films and often difficult to identify (Fig. 120-6). Thrombocytopenia is variable but can be moderately severe, with counts below 50,000/ μ L. Platelet aggregation abnormalities vary considerably.^{343,412,413,425-427} ADP- and epinephrine-induced aggregation is normal or nearly normal. Collagen- and thrombin-induced aggregation tend to be more abnormal, but this is not a consistent finding. Concomitant GPVI deficiency was reported in one patient and if the association is more widespread, it may explain the variable abnormalities in collagen-induced aggregation.³⁴³ Studies in one patient showed flow-dependent thrombus formation to be decreased.⁸ Additional abnormalities in PI metabolism, protein phosphorylation, calcium mobilization, platelet factor Va, and platelet secretion have been described⁴²⁸⁻⁴³⁰ and may contribute to the platelet aggregation abnormalities and clinical symptoms. The failure of exogenous α -granule proteins to fully correct the aggregation defects suggests that these abnormalities may be important in the overall platelet dysfunction in GPS.⁴²⁵

Under the electron microscope platelets and megakaryocytes from GPS patients reveal absent or markedly decreased α granules (Fig. 120-6).⁴¹² The platelets are deficient in α -granule proteins: PF4,

Figure 120-6. Gray platelet syndrome (α -granule deficiency). **A.** Blood film. Note gray-staining of many, but not all, platelets with loss of internal granular structure. Two are megathrombocytes, one platelet being very large, almost the size of a red cell (giant platelet). **B.** Blood film. Treated with periodic acid–Schiff (PAS) stain for carbohydrate. Note large “gray platelet” stained with PAS (*arrow*) and typical PAS staining of neutrophil cytoplasm. **C.** Transmission electron microscopy of normal human platelets with abundant electron-dense α granules. **D.** Transmission electron microscopy of platelets from a patient with gray platelet syndrome. Note profound reduction in electron-dense α granules. (Reproduced with permission from Lichtman’s Atlas of Hematology, www.accessmedicine.com.)

β TG, VWF, thrombospondin, fibronectin, factor V, high-molecular-weight kininogen, transforming growth factor (TGF)- β_1 , and platelet-derived growth factor (PDGF); albumin and IgG may also be decreased. There is increased reticulin in the marrow of some patients with GPS,^{431–433} which may be associated with splenomegaly and evidence of extramedullary hematopoiesis.^{431,434} The marrow fibrosis has been attributed to elevated marrow levels of PDGF and TGF- β_1 leaked from megakaryocytes.⁴¹² Megakaryocytes show emperipolesis and the capture of neutrophils. P-selectin is a protein present in the α -granule membranes and translocates to platelet surface on platelet activation. The content and surface expression of P-selectin has been reported as normal^{412,435} or decreased,⁴³⁶ which underscores the heterogeneity of the GPS.

α,δ -STORAGE POOL DEFICIENCY

This disorder is characterized by moderate to severe defects in both α and δ granules, with heterogeneous expression in the few patients in whom it has been reported.³⁷² Clinical and laboratory features are similar to those of δ -SPD. In general, the functional consequences of the defect in dense granules is more severe than the defect in α granules.

QUEBEC PLATELET DISORDER

Quebec platelet disorder (QPD) is an autosomal dominant bleeding disorder associated with reduced platelet counts and decreased α -granule proteins as a result of increased plasmin-mediated degradation of the α -granule proteins.^{437,438} Originally described as factor V Quebec,

the early description of this disorder included severe bleeding after trauma, mild thrombocytopenia, decreased functional platelet factor V, and normal plasma factor V.^{437,439} The bleeding time is normal to mildly prolonged and epinephrine-induced platelet aggregation is selectively decreased. Aggregation response to other agonists is variable. Platelets from patients with QPD display reduced levels of several α -granule proteins (factor V, fibrinogen, VWF, fibronectin, thrombospondin, multimerin, and osteonectin) as a consequence of enhanced proteolysis.^{437,440} The excessive plasmin generation inducing the degradation of α -granule proteins results from increased megakaryocyte expression of u-PA because of a tandem duplication mutation of the *cis* regulatory elements of the u-PA gene (*PLAU*).^{441,442} Plasma tests of systemic fibrinolysis (fibrinogen, D-dimer, plasminogen, plasmin- α_2 antiplasmin complexes, and u-PA), are normal in these patients. Genetic testing for the *PLAU* mutation provides a definitive diagnosis. Treatment with fibrinolytic inhibitors appears to be effective in controlling bleeding.⁴³⁷

● ABNORMALITIES OF PLATELET SIGNALING AND SECRETION

A sizable percentage of patients with variably severe mucocutaneous bleeding manifestations, mostly mild, have defects in platelet aggregation and secretion. In most of these patients the underlying platelet molecular mechanisms are unknown. The most common pattern on laboratory studies is blunted platelet aggregation and absence of the second wave of aggregation on exposure to ADP, epinephrine, collagen, or U46619, and decreased dense granule secretion. Such patients have been lumped together, more out of convenience than because of an understanding of the mechanisms, categorized as primary secretion defects, activation defects, or signal transduction defects.^{443–446} Simplistically, platelet activation is a complex process involving agonist binding to surface receptors; signal transduction through G-protein-coupled receptors and other types of receptors; phosphoinositol metabolism resulting in calcium mobilization and phosphorylation of target proteins; arachidonic acid metabolism leading to TXA₂ production; activation of the integrin $\alpha_{IIb}\beta_3$ receptor; and release of granule contents (Chap. 112). Defects involving these and other processes can result in impaired platelet function.

DEFECTS IN PLATELET AGONIST RECEPTORS OR AGONIST-SPECIFIC SIGNAL TRANSDUCTION

Thromboxane A₂ Receptor Defect

Platelets contain two different isoforms of the TXA₂ receptor. Both forms activate PLC, but they differ in their effects on adenylyl cyclase, with one stimulating and the other inhibiting this enzyme.⁴⁴⁷ A mutation in the first cytoplasmic loop of the TXA₂ receptor (R601L) has been described as causing an inherited bleeding disorder in several families from Japan.^{448,449} The platelets of these patients do not aggregate in response to TXA₂ mimetics. The aggregation defect also extends to other agonists, such as ADP, in which TXA₂ made by activated platelets and released into the surrounding medium, augments the response. The defect appears to be in signal initiation rather than ligand binding. TXA₂-induced activation of PLC (measured as Ca²⁺ mobilization, inositol trisphosphate, and phosphatidic acid formation) is impaired while PLA₂ activation and TXA₂ production is normal. Of note, the mutation appears to inhibit PLC activation by both receptor isoforms and impairs adenylyl cyclase stimulation by one of the isoforms; it does not, however, affect the inhibition of adenylyl cyclase produced by the

other isoform. Both dominant and recessive inheritance patterns have been reported. The abnormal aggregation responses in heterozygous family members suggests a dominant negative effect of the mutation.⁴⁴⁹ Another report⁴⁵⁰ describes a heterozygous D304N substitution in the seventh transmembrane region of the TXA₂ receptor associated with a bleeding history, a 50 percent reduction in ligand binding and loss of receptor function. A heterozygous TXA₂R mutation (V2416) in the third intracellular loop has been reported⁷ in a subject without any bleeding symptoms. This subject had impaired aggregation and Ca²⁺ mobilization in response to U46619, normal platelet receptor levels and had aspirin resistance in microfluidic experiments assessing platelet deposition under flow.

Adenosine Diphosphate Receptor Defects (P2Y₁₂ and P2X₁)

Multiple receptors (P2Y₁₂, P2Y₁, and P2X₁) mediate ADP interactions with platelets (Chap. 112).⁴⁵¹ P2Y₁ receptors induce PLC activation, intracellular Ca²⁺ mobilization, and shape change, while P2Y₁₂ receptors mediate inhibition of cAMP formation by adenylyl cyclase. ADP-induced platelet aggregation requires activation of both P2Y₁ and P2Y₁₂ receptors. P2X₁ receptors function as an ATP- and ADP-gated cation channel (Chap. 112). Patients with P2Y₁₂ receptor abnormalities have blunted ADP-induced platelet aggregation responses, impaired suppression of prostaglandin E₁ (PGE₁)-induced elevations in cAMP, and normal ADP-stimulated shape change.^{452–456} Bleeding symptoms have been variable, with some demonstrating moderately severe hemorrhage in association with surgery and trauma. Because ADP released from platelets potentiates the responses to other agonists, such as collagen and TXA₂, platelet aggregation in response to these agonists is also abnormal in these patients. Platelet binding of ADP or the ADP analogue 2-methylthio-ADP^{452–454,456} was decreased in all but one patient studied.⁴⁵⁷ Decreased platelet 2-methylthio-ADP binding has also been reported in other patients with impaired aggregation and secretion in response to several agonists, including ADP.⁴⁵⁹

The genetic defects have been defined in some of these patients. In three patients, homozygous deletions have been demonstrated in the P2Y₁₂ gene, resulting in premature termination and a lack of P2Y₁₂ protein.^{445,452,456} A homozygous missense mutation in the translation initiation codon was described in another patient,⁴⁵⁴ and another patient was reported to have a two-nucleotide deletion (at amino acid 240) in one P2Y₁₂ gene allele, resulting in a frameshift and a premature stop codon.^{453,460} Although this last patient had one P2Y₁₂ allele with a normal coding region, the patient's platelets lacked P2Y₁₂ receptors, suggesting repression of the normal allele or an unrelated abnormality in its transcriptional regulation. In contrast, platelets from the patient's daughter had an intermediate number of ADP-binding sites, a normal platelet response to ADP, and one frame-shifted allele and one normal allele, suggesting that the mutant allele does not act in a dominant negative manner.⁴⁵³ Studies in yet another patient with abnormal ADP-induced aggregation revealed a compound heterozygous state with one allele containing an R256N substitution in the sixth transmembrane domain, and the other allele containing an R265W substitution in the third extracellular loop of the receptor.⁴⁵⁷ Platelet binding of ³³P-2MeS ADP was normal; neither mutation affected the translocation of the P2Y₁₂ receptor to the cell surface, but ADP-induced inhibition of adenylyl cyclase was partially reduced, indicating a functionally abnormal receptor. A heterozygous mutation (K174E) in the second extracellular loop of P2Y₁₂ was identified in one patient⁴⁵⁵; this was associated with decreased 2-methylthio-ADP binding. Another heterozygous mutation, P258T in the third extracellular loop has been described in association with a bleeding diathesis.⁴⁶¹ Interestingly, a heterozygous mutation in P2Y₁₂ (P341A) has been shown to induce altered interaction with Rab guanosine triphosphatases (GTPases)

and endosomal trafficking of the receptor leading to its decreased surface expression.⁴⁶²

A defect in the P2X₁ purinergic receptor has been described in a 6-year-old patient with bleeding manifestations.⁴⁶³ The patient had isolated impairment of ADP-induced platelet aggregation and was heterozygous for a deletion of a single leucine in a stretch of four leucine residues^{351–354} in the second transmembrane domain of P2X₁. The mutant protein apparently caused a dominant negative effect on P2X₁-mediated calcium channel activity.

Epinephrine Receptor Defects

Abnormalities of α -adrenergic receptors or α -adrenergic-specific signal transduction have been described in several patients,^{464–466} but the relationship to bleeding manifestations remains unclear, particularly because responses to epinephrine are blunted even in some otherwise normal individuals. Responses to epinephrine are blunted in the QPD.⁴³⁷

Platelet-Activating Factor Receptor Defect

A defect in the platelet-activating factor receptor or platelet-activating factor-specific signal transduction has been reported.⁴⁶⁷

GUANOSINE TRIPHOSPHATE-BINDING PROTEIN DEFECTS

GTP-binding proteins are a heterotrimeric class of proteins (consisting of α , β , and γ subunits) that link surface receptors and intracellular enzymes (Chap. 112). Abnormalities involving G α _q, G α _{i1}, and G α _s proteins have been described.

G α _q Deficiency

G α _q plays a major role in mediating platelet responses to activation of G-protein-coupled receptors. One patient has been described with a selective platelet G α _q deficiency in association with a mild bleeding disorder, abnormal platelet aggregation and secretion in response to a number of agonists, and diminished GTPase activity (a reflection of G α -subunit dysfunction) in response to platelet activation.^{468,469} The downstream events from G α _q, including Ca²⁺ mobilization, release of arachidonic acid from phospholipids, and activation of integrin α _{IIb} β ₃ receptors, were impaired. The G α _q coding sequence in this patient was normal, but G α _q mRNA levels were decreased in platelets, suggesting a potential defect in transcriptional regulation of the gene. This abnormality appeared to be selective for platelets as the patient's neutrophils had normal G α _q protein.⁴⁷⁰

Gas Hyperfunction and Genetic Variation in Extra Large Gas

Two unrelated families have been described with inducible hyperactivity of G α _s.⁴⁷¹ These patients had a bleeding diathesis, prolonged bleeding times, variable mental retardation, and mild skeletal malformations. Platelet aggregation responses to physiologic agonists were normal, but the platelets showed increased sensitivity to inhibition by agents (PGE₁, prostacyclin [PGI₂]) that elevate cAMP. Platelet G α _s, which when activated increases platelet cAMP levels and inhibits platelet aggregation and secretion, was increased in these patients. The G α _s gene (GNAS1) has multiple alternative promoters and isoforms as a result of alternative splicing, including extralarge Gas (XLas). XLas is imprinted and thus normally only expressed from the paternal allele. A heterozygous 36-bp insertion and a 2-bp substitution were identified in exon 1 of the paternal XLas gene in these patients. Because XLas is not activated by the usual platelet G α _s-coupled receptors, the mechanisms leading to increased cAMP levels and enhanced expression of G α _s protein is unclear. Of note, 2.2 percent of control subjects also had

the same polymorphism, but only those individuals inheriting it from their father had inducible G α _s hyperfunction and increased platelet G α _s protein.

Platelet G α _s deficiency has also been described in a patient with pseudohypoparathyroidism Ib in association with disturbed imprinting and altered methylation in the GNAS1 gene cluster that encompasses the four GNAS1 splice variants, including the G α _s subunit.⁴⁷² The G α _s coding sequence was normal. As expected from the deficiency in G α _s protein, there was decreased platelet cAMP formation upon activation of receptors linked to G α _s. The authors did not indicate whether the patient had a bleeding diathesis.

G α _{i1} Deficiency

Platelet G α _{i1} deficiency has been reported in association with a bleeding disorder and abnormalities in integrin α _{IIb} β ₃ activation, platelet aggregation, and dense granule secretion upon activation with one or more agonists.⁴⁷³ In keeping with the known function of G α _i in inhibiting the activation of adenylyl cyclase and the subsequent increases in cAMP levels, the patient's platelets failed to inhibit forskolin-stimulated cAMP levels on activation. Platelet G α _{i1} protein was decreased by 75 percent, whereas other members of the G α _i family (G α _{i2}, G α _{i3}, G α _{iZ}) and G α _q were normal. Although a large subset of patients has been considered as having a defect in Gi signaling,⁴⁷⁴ this is based on abnormal responses on platelet aggregation and secretion studies to ADP and epinephrine, and direct evidence at the molecular level to support this conclusion has not been provided.

CalDAG-GEFI Deficiency

Three siblings from first cousin parents and severe mucocutaneous bleeding manifestations, had prolonged bleeding times and reduced platelet aggregation in response to ADP or epinephrine, and to low doses, but not high doses, of a thrombin receptor-activating peptide and collagen.⁴⁷⁵ Clot retraction was normal. Whole-exome analysis revealed a homozygous G248W mutation in RAS guanyl-releasing protein-2 (RASGRP2), the gene for the protein calcium- and diacylglycerol (DAG)-regulated guanine exchange factor-1 (CalDAG-GEFI), affecting the CDC25 catalytic domain critical for interacting with GTPases. The platelets demonstrated decreased Rap1 activation and fibrinogen binding and abnormal adhesion and spreading on immobilized fibrinogen and collagen. These results support a model of platelet activation in which CalDAG-GEFI stimulates GTP loading of Rap1 and Rac1 in response to an increase in intracellular Ca²⁺ and the activated Rap1 leads to integrin α _{IIb} β ₃ activation and the activated Rac1 enhances platelet spreading. The heterozygotes were asymptomatic but their platelets had a defective spreading.⁴⁷⁵

PHOSPHOLIPASE C- β DEFICIENCY AND DEFECTS IN PHOSPHOLIPASE C ACTIVATION

Several investigators have described patients with relatively mild bleeding diatheses and impaired platelet aggregation and dense granule secretion, despite normal granule stores and the ability to synthesize TXA₂.^{445,446,476–478} An early event after stimulating several platelet G-protein-coupled receptors is activation of PLC- β , leading to formation of the intracellular mediators IP₃ and DAG (Chap. 112); the former mediates Ca²⁺ mobilization and the latter for PKC-induced protein phosphorylation. Defects in one or more of these responses has been documented in several patients. In one study of eight patients with abnormal platelet aggregation and secretion in response to several different receptor-mediated agonists, Ca²⁺ mobilization and/or pleckstrin phosphorylation was abnormal in seven patients, suggesting that the impaired secretion and aggregation resulted from upstream abnormalities in early signaling events.⁴⁷⁸ Specific defects

at the level of PLC- β_2 ,^{479,480} G α_q ,⁴⁶⁸ and PKC- θ ⁴⁸¹ were identified in these eight patients. In another study, eight patients were described who had decreased initial rates and extents of platelet aggregation in response to ADP, epinephrine, and the TXA₂ mimetic U44069⁴⁷⁶; subsequent studies in one patient demonstrated impaired phosphatidylinositol hydrolysis, phosphatidic acid formation, and pleckstrin phosphorylation.^{482,483}

In two related patients described with PLC- β_2 deficiency, platelet aggregation and secretion were impaired in association with impaired IP₃ and DAG formation, calcium mobilization, and pleckstrin phosphorylation following activation with ADP, collagen, platelet-activating factor, or thrombin, indicating a defect in PLC activation.⁴⁷⁹ These patients had a mild bleeding disorder. Human platelets contain at least seven PLC isozymes and a selective decrease was observed in only the PLC- β_2 isozyme.⁴⁸⁰ The decreased platelet PLC- β_2 protein levels were associated with a normal gene coding sequence but with diminished PLC- β_2 mRNA levels in platelets, but not neutrophils, suggesting a hematopoietic lineage-specific defect in PLC- β_2 gene regulation.⁴⁸⁴ Defects in phosphatidylinositol metabolism and protein phosphorylation have been described in other such patients, although the primary protein abnormalities were not defined.^{482,483,485–488}

DEFECTS IN PROTEIN PHOSPHORYLATION: PROTEIN KINASE C- θ DEFICIENCY

PKC isozymes, a family of serine- and threonine-specific protein kinases, phosphorylate a wide array of proteins involved in signal transduction. PKC enzymes regulate several aspects of platelet function, including activation of integrin $\alpha_{IIb}\beta_3$ receptors, platelet aggregation and secretion, and platelet production (Chap. 112). Deficiency of a human platelet PKC isozyme (PKC- θ) has been described in a patient with lifelong mucocutaneous bleeding manifestations, mild thrombocytopenia, and markedly abnormal platelet aggregation (including primary wave) and dense granule secretion in response to multiple agonists.^{481,489} Agonist-induced phosphorylation of pleckstrin and myosin light chain were diminished in the patient's platelets. This subject was subsequently shown to have a heterozygous mutation in a transcription factor, RUNX1 (also termed core-binding factor A2, CBFA2, or *AML1*), which has been linked to a familial platelet function defect, associated with thrombocytopenia and predisposition to acute leukemia^{481,490} (see "Transcription Factor Mutations and Associated Platelet Dysfunction" below). Platelet expression of myosin light chain (*MYL9*) was also decreased in this patient.⁴⁹¹

DEFECTS IN ARACHIDONIC ACID METABOLISM AND THROMBOXANE PRODUCTION

Defects in Arachidonic Acid Release from Phospholipids

Release of free arachidonic acid from phospholipids, mediated by cytosolic PLA₂, is the initial and rate-limiting step in thromboxane synthesis upon platelet activation. Several patients have been described with abnormalities in the release of arachidonic acid.^{469,485,492–494} In general, their platelets aggregated normally in response to arachidonic acid but not to ADP, epinephrine, and/or collagen. In one of these patients this defect was related to an upstream abnormality in G α_q (see "G α_q Deficiency" above).⁴⁶⁸ Another patient had the HPS with δ -SPD and abnormal PLA₂ activity.⁴⁹² An inherited deficiency in cytosolic PLA₂ has been reported in a patient with recurrent small intestinal ulceration, markedly decreased eicosanoid synthesis (including in thromboxane, 12-hydroxyeicosatetraenoic acid [12-HETE], and leukotriene B₂) and impaired aggregation with ADP and collagen but normal with arachidonic acid.⁴⁹³ This patient had two heterozygous single-base-pair

mutations in the PLA₂ coding region, leading to S111P and R485H substitutions. Another report documents twins with a history of gastrointestinal ulcers, associated with similarly impaired platelet function associated with a homozygous D575H mutation in PLA₂ (*PLA2G4A*).⁴⁹⁴ These patients had mildly decreased plasma factor XI as well.

Cyclooxygenase (Prostaglandin H₂ Synthase-1) Deficiency

Deficient platelet cyclooxygenase (prostaglandin H₂ synthase-1) activity leading to impaired platelet function and a mild bleeding disorder has been identified in a number of patients.^{495–502} Platelets from such patients cannot make thromboxane from arachidonic acid but can make it from cyclic endoperoxides (prostaglandin G₂ and prostaglandin H₂). While some patients have had decreased platelet cyclooxygenase protein, others have had evidence of a dysfunctional molecule.^{501,502}

Thromboxane Synthase Deficiency

Presumed platelet thromboxane synthase deficiencies have been identified in two families based on the failure of cyclic endoperoxides to be converted into TXA₂.^{503,504}

● ABNORMALITIES OF PLATELET COAGULANT ACTIVITY (SCOTT SYNDROME)

DEFINITION AND HISTORY

Activated platelets play an essential role in providing the membrane surface on which specific blood coagulation reactions occur leading to thrombin generation.^{505,506} Patients whose platelets fail to facilitate thrombin generation are defined as having defects in platelet coagulant activity (PCA) (Chap. 112). Only a few patients have been described with isolated defects in PCA and normal aggregation and secretion responses.^{505,507–513} Defects in PCA may also be secondary to abnormalities in platelet aggregation, such as in patients with SPD and thrombasthenia.⁵⁰⁵ Patients with isolated abnormalities in PCA are referred to as having the Scott syndrome after the first patient described in 1979 by Weiss and colleagues.^{505,507–510}

ETIOLOGY AND PATHOGENESIS

The main functional abnormality in the Scott syndrome is the impaired ability of activated platelets to promote coagulation reactions; a second abnormality in these patients is a defect in release of microvesicles on cell activation.^{514,515} In resting platelets, membrane phospholipids are asymmetrically distributed, with the aminophospholipids phosphatidylserine (PS) and phosphatidylethanolamine (PE) concentrated in the inner membrane leaflet, and phosphatidylcholine (PC) and sphingomyelin concentrated in the outer leaflet. Cell activation induces phospholipid translocation, with PS moving to the outer leaflet. This process is regulated by several proteins that are descriptively identified by their functions. They include a "flippase" (i.e., an aminophospholipid translocase identified as a P4 adenosine triphosphatase [ATPase]), which promotes inward transport of lipids; a "floppase" that regulates outward phospholipid transport (encoded by gene *ABCC1*); and one or more "scramblase" that promotes bidirectional movement of lipids between the two layers.⁵⁰⁶ Surface expression of PS is essential for platelets to accelerate coagulation reactions, in particular, activation of the tenase complex leading to the activation of factor X to Xa and of the prothrombinase complex that converts prothrombin to thrombin (Chaps. 113 and 114). Scott syndrome platelets have a defect in PS translocation resulting in decreased binding of factors Va-Xa

and VIIIa-IXa,^{505,506} thus leading to impaired blood coagulation. Erythrocytes and lymphocytes also demonstrate similar defects in both microvesicle formation and coagulant activity.^{505,512} In a French family with Scott syndrome,⁵⁰⁸ the propositus' platelets were found to have a defect in protein tyrosine phosphorylation, suggesting an additional defect in signal transduction.⁵¹⁰

Apart from the above patients with the Scott syndrome, four patients from three unrelated families have been reported to have abnormal PCA, a bleeding disorder, impaired serum prothrombin consumption, and reduced microparticle formation.⁵¹⁶ However, in contrast to the Scott syndrome, the prothrombinase activity was normal.

The inheritance pattern in the Scott syndrome appears to be autosomal recessive.^{505,508} A heterozygous missense mutation has been reported in one patient in the gene *ABCA1*, which encodes the ATP-binding cassette transporter protein implicated in PS translocation; the significance of this remains unclear.⁵¹⁷ Mutations in *TMEM16F* have been identified in two patients with Scott syndrome. The patient Scott was found to have a homozygous mutation at the splice acceptor site for intron 12 of *TMEM16F*, resulting in a frameshift and premature termination of protein translation.⁵¹⁸ A second patient had compound heterozygosity for a mutation at the donor splice site of intron 6 and a single nucleotide insertion in exon 12, causing a frameshift and premature termination of translation.¹³ While these findings constitute strong evidence linking *TMEM16F* mutations to Scott syndrome, they leave open whether *TMEM16F* is itself the membrane scramblase or a protein that regulates the scramblase.

CLINICAL AND LABORATORY FEATURES

The bleeding symptoms in patients with the Scott syndrome are similar to those with other platelet defects. In contrast to other qualitative platelet abnormalities, the bleeding time in Scott syndrome patients is normal.^{508,509,514} The serum PT, which reflects the completeness of clotting of whole blood and consumption of prothrombin, is abnormally, indicating incomplete coagulation.⁵⁰⁷⁻⁵⁰⁹ More specific assays of "platelet factor 3," the phenomenologic designation of the platelet contribution to accelerating clot formation, are also abnormal.⁵¹⁹

Patients with the Scott syndrome have normal platelet aggregation and secretion in response to the usually used agonists.⁵⁰⁵ The patient Scott⁵⁰⁵ also had normal platelet phospholipid content, normal to enhanced platelet adhesion to subendothelium with diminished thrombus formation, diminished factor Va binding to platelets and platelet microparticles, and diminished platelet acceleration of both factor X activation and prothrombin activation. Abnormalities in exposure of negatively charged phospholipids and shedding of microparticles have been consistent findings in all patients described.^{506,508-512}

TREATMENT

Platelet or whole blood transfusions have been effective as prophylaxis and as therapy for bleeding episodes.^{505,507-509} Prothrombin complex concentrates were effective in the patient Scott,³⁹² but these preparations may be associated with thrombotic complications.

● ABNORMALITIES OF A CYTOSKELETAL STRUCTURAL PROTEIN: β_1 -TUBULIN AND FILAMIN A

Megakaryocytes and platelets express primarily and selectively the β_1 isoform of tubulin. A heterozygous β_1 -tubulin Q43P polymorphism was identified in a group of patients with a recessive form of

macrothrombocytopenia; the polymorphism could not account fully for the macrothrombocytopenia because of the difference in inheritance and its presence in approximately 11 percent of the normal population.⁵²⁰ Individuals heterozygous for the polymorphism had normal platelet counts, relatively high mean platelet volume values, abnormally rounded platelets with abnormal marginal bands of microtubules, and mild abnormalities of platelet aggregation, secretion, and adhesion to collagen. One study found the polymorphism was associated with decreased collagen-induced platelet aggregation and increased risk of intracerebral hemorrhage in men.⁵²¹

Subsequently, two patients with macrothrombocytopenia from a single kindred were reported to be heterozygous for a R318W β_1 tubulin mutation.⁵²² The mutation is strategically located at the α - β tubulin interface. Of note, the Q43P polymorphism and an R207H substitution were also found in this family, but neither was judged to be responsible for the macrothrombocytopenia.

Filamins are large dimeric actin-binding proteins that stabilize actin filament networks. Filamin A is the predominant platelet filamin. Several patients have been reported with dominant mutations of X-linked *Filamin A* (*FLNA*) gene associated with thrombocytopenia, and abnormalities in platelet aggregation, secretion, GPVI signaling and thrombus growth on collagen.^{522A}

● ABNORMALITIES OF CYTOSKELETAL LINKING PROTEINS

WISKOTT-ALDRICH SYNDROME PROTEIN

The Wiskott-Aldrich syndrome (WAS) is an X-chromosome-linked inherited disorder characterized by small platelets, thrombocytopenia, recurrent infections, eczema, and an increased incidence of autoimmunity and malignancies.^{523,524} In addition, a variety of immunologic abnormalities affecting T-lymphocyte function, Ig levels, cellular immunity, and responsiveness to polysaccharide antigens are commonly present. Death from infection, hemorrhage, or malignancy is common before adulthood. Some patients with WAS mutations may have only thrombocytopenia (X-linked thrombocytopenia [XLT]) without other features. WAS is caused by mutations in the WAS gene which encodes the WAS protein (WASP), a multidomain protein that relays signals from the cell surface to the actin skeleton and modulates the latter's reorganization. In platelets, WASP is localized to the cytoskeleton.^{524,525} It is phosphorylated on platelet activation by several different protein kinases, including Btk, Grb2, PLC- γ_2 , PKC- θ , and SGK1.⁵²⁴

Microthrombocytopenia is a consistent feature of WAS and XLT and the major contributor to the bleeding diathesis, which may be life-threatening in some patients because of gastrointestinal hemorrhage or intracranial hemorrhage. Marrow megakaryocytes are normal in number, but platelet formation is abnormal and platelet survival is decreased.^{523,524}

Abnormalities in platelet surface glycoprotein sialophorin (CD43, gp115, leukosialin), GPIb, platelet integrin α_2 , integrin $\alpha_{IIb}\beta_3$, and GPIV have been reported in some WAS patients.^{526,527} Platelets from patients with WAS also have qualitative defects, including SPD^{367,368,528} and impaired energy metabolism.^{528,529}

Platelet aggregation in WAS has been reported to be reduced, normal, or enhanced.^{524,530-533} Interpreting these studies is confounded by the low platelet count, methodological differences, and timing in relation to splenectomy.⁵²⁴ Despite the role of WASP in cytoskeletal reorganization, shape change and actin polymerization are normal in WAS platelets.^{531,534,535}

WASP has been implicated in regulating responses dependent on integrin $\alpha_{IIb}\beta_3$ outside-in signaling.⁵³⁶ Although Pac-1 binding is

normal in WAS platelets, there is decreased spreading on fibrinogen and decreased clot retraction associated with enhanced PS exposure.⁵³⁶

Splenectomy usually improves the thrombocytopenia.^{523,524} Hematopoietic stem cell transplantation is the accepted curative approach for WAS and can correct all aspects of the disease provided reconstitution is achieved.^{523,524} Autologous gene-modified hematopoietic stem cell transplantation is an emerging therapy for WAS patients.^{523,524}

● KINDLIN-3 (LEUKOCYTE ADHESION DEFECT-3; LEUKOCYTE ADHESION DEFECT—1 VARIANT; INTEGRIN ACTIVATION DEFICIENCY DISEASE)

DEFINITION AND HISTORY/ETIOLOGY AND PATHOGENESIS

A syndrome with the features of both mild LAD-1 and GT was first described in 1997⁵³⁷ and termed LAD-1 variant or LAD-3. Since then more than 10 families have been reported, with several from Turkey.^{538–541} The etiology is a deficiency or defect in the cytoskeletal linking protein kindlin-3 (*FERMTS3*). Kindlin-3 is a protein expressed exclusively in hematopoietic cells with homology to talin that also binds to the cytoplasmic domain of the β_3 subunit of integrin $\alpha_{IIb}\beta_3$ (Chap. 112). It has been implicated in the inside-out activation of integrin $\alpha_{IIb}\beta_3$ in mice.⁵⁴² It also participates in the activation of leukocyte integrins, which accounts for the defects in immune function. It may also affect red blood cell structure. Defects in *CALDAGGEF1*, the gene for another exchange factor, also cause abnormalities in platelet function and are discussed in the section on Guanosine Triphosphate-Binding Protein Defects.^{538,543}

The disorder is characterized by a hemorrhagic diathesis in combination with a variable predisposition to infections and inflammation without pus formation, poor wound healing, delayed umbilical cord stump detachment, and variable osteopetrosis. Intracerebral hemorrhage at birth or soon thereafter has been reported in several of the patients, as well as relatively severe mucosal and gastrointestinal bleeding. Thus, the bleeding diathesis is more severe than is found in patients with GT, perhaps because of additional abnormalities in blood vessels. The need for red blood cell transfusions in infancy has been reported in several patients as a result of blood loss from mucosal surfaces and perhaps red blood cell abnormalities. Leukocytosis, as is found in other LAD syndromes is a constant finding. Normal platelet counts are the usual finding, but thrombocytopenia has been reported. Platelet aggregation studies demonstrate defects similar to those observed in GT.^{541–543} Hematopoietic stem cell transplantation has been successful in restoring normal hematopoietic function in patients with life threatening hemorrhagic and infectious complications of the disease.⁵⁴¹

● TRANSCRIPTION FACTOR MUTATIONS AND ASSOCIATED PLATELET DYSFUNCTION

Transcription factors, and the *cis*-regulatory sequences to which they bind, regulate lineage-specific gene expression. Transcription factors RUNX1, FLI1 (a member of the ETS [E-twenty-six] family), GATA-1, and GFI1B (growth factor independent 1B) are important regulators of hematopoietic lineage differentiation, megakaryopoiesis, and platelet

production.^{419,420,544} They interact in a combinatorial manner in regulating megakaryocytic genes.⁵⁴⁴ A single transcription factor mutation may alter expression of numerous genes, affect diverse cellular mechanisms, and lead to defects in both platelet number and function. Until recently the pursuit of the molecular mechanisms in patients with platelet dysfunction has focused on delineating mutations in the genes encoding postulated candidate proteins. Therefore, the increasing spotlight on transcription factor mutations to explain platelet dysfunction is a paradigm shift.^{9,545,545A}

RUNX1 (FAMILIAL PLATELET DISORDER WITH PREDISPOSITION TO ACUTE MYELOGENOUS LEUKEMIA)

An association between inherited platelet dysfunction, thrombocytopenia, and a predisposition to acute myeloid leukemia has been reported in several families in which the platelet abnormalities antedated the leukemia.^{390,490,546–551} Inherited mutations in RUNX1 (AML1, CBFA2) is the basis for this constellation, which is inherited as an autosomal dominant trait, because of haploinsufficiency.⁴⁹⁰ Patients generally display mild thrombocytopenia from birth and a bleeding disorder disproportionate to the thrombocytopenia. Approximately one-third of patients develop leukemia, with a median age of onset of 33 years.⁵⁵²

Platelet abnormalities reported in patients with *RUNX1* mutations include decreased aggregation, secretion, protein phosphorylation (myosin light chain and pleckstrin), production of 12-hydroxyeicosapentaenoic acid; decreased integrin $\alpha_{IIb}\beta_3$ activation upon platelet activation; δ and/or α -granule SPD; and a selective decrease in one PKC isoform (PKC- θ).^{372,390,553–555} Of note, several patients described earlier as having SPD (δ or α granules) have been subsequently shown to harbor *RUNX1* mutations.^{358,372,390,391} In one patient, platelet albumin and IgG were diminished, suggesting a defect in the uptake and packaging of these proteins into α granules.^{481,489}

Most mutations of *RUNX1* have been in the conserved Runt domain,³⁹⁰ although a mutation in the transactivating domain (Y260X) has been reported.³⁹⁰ Platelet transcript expression profiling in a patient with *RUNX1* haploinsufficiency revealed downregulation of numerous genes involved in platelet structure and function, including *MYL9* (myosin light chain), *ALOX12* (12-lipoxygenase), *PF4*, and *PRKCQ* (PKC- θ).^{491,554–556} *ALOX12*, *PRKCQ*, *PF4*, and *MYL9*^{554–556} are direct transcriptional targets of RUNX1. Patients with *RUNX1* haploinsufficiency also have impaired megakaryopoiesis⁴⁹⁰ and decreased platelet thrombopoietin receptors (Mpl).⁵⁵¹ Targeted correction of *RUNX1* mutation in induced pluripotent stem cells (iPSCs) developed from skin fibroblasts from two patients resulted in normalization of the defect in megakaryopoiesis.³⁹¹ These studies raise the potential for targeted gene therapy for this disorder. Using next-generation sequencing, Stockley and colleagues⁹ identified mutations in *RUNX1* and *FLI1*, in six of 13 patients with excessive bleeding, and impaired aggregation and platelet dense granule secretion in response to multiple agonists. Thus, transcription factor mutations are an important mechanism for inherited platelet dysfunction.^{545,545A}

GATA-1

GATA-1 is a critical regulator of both megakaryocyte and erythroid development. GATA-1 mutations have been associated with an X-linked syndrome consisting of dyserythropoiesis, anemia, thrombocytopenia, and large platelets²; selectively impaired responses to collagen and ristocetin related to abnormalities in GPIIb β ^{557,558}; diminished platelet Gas protein and mRNA⁵⁵⁷; and a form of GPS (with R216N mutation).⁴¹⁸

FLI-1 (DIMORPHIC DYSMORPHIC PLATELETS WITH GIANT α -GRANULES AND THROMBOCYTOPENIA (PARIS-TROUSSEAU/JACOBSEN SYNDROME])

The Paris-Trousseau syndrome, a variant of Jacobsen syndrome, is a rare autosomal dominant disorder^{559–562} characterized by mental retardation, congenital macrothrombocytopenia, giant α granules (1 to 2 μm in diameter) in a subpopulation (1 to 5 percent) of circulating platelets, and marrow dysmegakaryopoiesis in association with deletion of the distal part of either the maternally or paternally derived chromosome 11 (11q23.3–24). Among the genes deleted is the transcription factor FLI1, which is important in megakaryocyte development via its effects on expression of several genes, including *ITGA2*, *GPIX*, *GPIb α* , and *c-MPL*.² Although platelet survival is normal, there is dramatic expansion of marrow megakaryocytes resulting from arrested megakaryocyte development. Thrombin-induced platelet release of α -granule contents is impaired.⁵⁵⁹ Both the inheritance pattern and the dimorphic population of normal and dysmorphic giant α granules are explained by the observation that during a period in early megakaryocyte development, only one of the two FLI1 alleles appears to be expressed in any single megakaryocyte precursor.^{561,562}

GFI1B

Two studies^{419,420} implicate autosomal dominant mutations in GFI1B with a bleeding disorder and multiple alterations in platelet number and function, and red cell anisopoikilocytosis. In one study,⁴²⁰ the affected family members had a single nucleotide insertion in exon 7 of GFI1B leading to a frameshift mutation associated with macrothrombocytopenia, impaired platelet aggregation responses, α -granule deficiency, and decreased platelet P-selectin, fibrinogen, GPIb α , and integrin β_3 . The second study identified⁴¹⁹ a dominant-negative truncating mutation (c.859C to T) in the zinc finger 5 region of GFI1B in a family originally reported in 1968 with macrothrombocytopenia and platelet dysfunction.⁵⁶³ The family members had decreased platelet α granules, PF4, βTG , and GP1b α , and deficiency of platelet factor 3. There was myelofibrosis and emperipoiesis in the marrow.

MISCELLANEOUS INHERITED DISORDERS ASSOCIATED WITH PLATELET FUNCTION DEFECTS

The TAR syndrome is characterized by a reduction in platelet counts, absence of the radius bone in the forearm, skeletal abnormalities, and decreased marrow megakaryocytes. Dense granule SPD and impaired platelet aggregation and secretion have also been reported in TAR syndrome.³⁷¹ Early studies reported that majority of these patients have a deletion on chromosome 1q21.1,¹⁵ and later studies showed that these patients have both a rare null allele of *RBM8A* along with one of two low-frequency single nucleotide polymorphisms (SNPs) in the gene's regulatory regions.¹⁴ *RBM8A* encodes for the Y14 subunit of the exon-junction complex (EJC), which plays an essential in RNA processing.

Platelet function abnormalities have also been reported in inherited connective tissue disorders such as osteogenesis imperfecta, the Ehlers-Danlos syndrome, and the Marfan syndrome^{369,370,564,565}; bleeding manifestations are more likely caused by the underlying connective tissue defect than by the platelet dysfunction. Abnormalities in platelet responses and α granules have been reported in patients with

hexokinase deficiency,⁵⁶⁶ glucose-6 phosphatase deficiency (glycogen storage disease, type I),^{567,568} and the Down syndrome.^{569–573} In glucose-6 phosphatase deficiency the platelet abnormalities were reversed following total parenteral nutrition for 10 to 12 days^{567,568} indicating that the platelets may be intrinsically normal. The *MYH9*-related disorders (May-Hegglin anomaly) are characterized by giant platelets, thrombocytopenia, and basophilic granulocyte inclusions; some patients with this anomaly have platelet function and ultrastructural abnormalities.^{8,574,575} Despite the large platelet size, the surface membrane glycoproteins appear to be normal.⁵⁷⁶ Markedly impaired platelet responses to multiple agonists have been reported with partial trisomy 18p associated with three copies of the *PACAP* (pituitary adenylate cyclase-activating polypeptide) gene and elevated plasma levels of *PACAP*, which induces increased platelet cAMP levels via stimulation of *G α* .⁵⁷⁷

Familial hemophagocytic lymphohistiocytosis (FHLH) is a genetic disorder of lymphocyte cytotoxicity associated with mutations in the gene encoding perforin or proteins important for vesicular trafficking and exocytosis. Flow cytometric analyses of the platelets of FHLH type 5 patients, who have *MUNC18–2* (*STXBP2*) mutations, revealed that thrombin-induced secretion from both α and δ granules is impaired.^{578,579} Platelets from an FHLH type 4 patient with a mutation in syntaxin-11 (*STX11*) also had a defect in agonist-induced secretion associated with normal cargo levels.⁵⁸⁰

MANAGEMENT OF INHERITED PLATELET FUNCTION DISORDERS

Management of patients with inherited platelet function disorders needs to be individualized because of the wide variation in clinical manifestations, even in patients with the same defect. A general approach is described here; additional features specific to some individual entities are provided in their respective descriptions. Management of these patients involves preventive measures and treatment of specific bleeding episodes.^{581–583} Dental hygiene is important in minimizing gingival hemorrhage. Antiplatelet agents should be avoided as they increase the bleeding manifestations. Iron and folate supplementation may be needed in patients with chronic hemorrhage. Hepatitis B vaccine should be administered early in life.

PLATELET TRANSFUSIONS AND GENERAL APPROACHES

Transfusion of platelets (Chap. 139) is a time-tested therapy for serious bleeding and as prophylaxis prior to surgery or invasive procedures. In addition to the usual risks associated with transfusions (transmission of infections, allergic reactions, Rh-immunization in Rh-negative individuals, and rarely hemolytic reactions) patients with GT and the BSS may develop specific antibodies against the missing glycoproteins, which may seriously compromise efficacy of future platelet transfusions.^{581,582} This occurs particularly in patients whose platelets have no detectable integrin $\alpha_{\text{IIb}}\beta_3$.⁵⁸⁴ Therefore, platelet transfusions should be kept to a minimum. Transfusions of both platelets and red blood cells should be given with leukocyte depletion filters to decrease the risk of alloimmunization and cytomegalovirus transmission. It is reasonable to use human leukocyte antigen (HLA)-matched and ABO-matched platelets to minimize the risk of alloimmunization and side effects.^{581–583}

Treatment with 1-deamino-8-D-arginine vasopressin (DDAVP; desmopressin) may shorten the bleeding time and/or improve hemostasis in some, but not all, patients with platelet function defects.^{585–588} Responses to DDAVP appear dependent on the cause of the platelet

dysfunction.^{585,587,588} Most patients with thrombasthenia do not respond to DDAVP with a shortening of the bleeding time^{585,587-589} with exceptions,⁵⁹⁰ but it is unknown whether DDAVP improves hemostasis in these patients despite a lack of shortening of the bleeding time. Responses to DDAVP in SPD patients have been variable with a shortening of the bleeding time in some patients^{588,591} but not others.^{585,587} In uncontrolled studies it has been feasible to manage selected patients with inherited platelet defects undergoing surgical procedures with DDAVP alone.^{585,587} However, this approach needs to be individualized based on the nature and location of the surgery and the intensity of the patient's bleeding symptoms, and platelet need to be readily available for transfusion in the event of excess hemorrhage. The abnormal *in vitro* platelet aggregation or secretion responses in patients with platelet defects are usually not corrected by DDAVP.^{587,592} It has been proposed that one mechanism by which DDAVP improves platelet function is via increased formation of procoagulant "COAT" platelets induced by combined activation by collagen and thrombin.⁵⁹²

Investigators have reported the successful use of recombinant factor VIIa (rFVIIa) in the management of bleeding events in patients with inherited platelet defects, including GT (including patients with antibodies to integrin $\alpha_{IIb}\beta_3$), the BSS and SPD.^{581,583,593-596} rFVIIa is thought to increase thrombin generation through both tissue factor dependent and independent mechanisms.

The antifibrinolytic agents epsilon-aminocaproic acid (EACA) and tranexamic acid,⁵⁸¹⁻⁵⁸³ which may be given orally, intravenously, or topically have been successfully used in patients with coagulation disorders and platelet function abnormalities.^{586,597} Antifibrinolytic agents are useful in patients with gingival bleeding, epistaxis, and menorrhagia, and those undergoing dental extractions. A tranexamic acid mouthwash (10 mL of a 5 percent solution used four times daily) has been found effective in controlling gum bleeding and bleeding after tooth extractions.⁵⁸² A short 3- to 4-day course of prednisone (20 to 50 mg)⁵⁹⁸ has also been used.

Topical agents can also help arrest bleeding and have been used in GT patients. Gelfoam (a form of resolvable, oxidized, regenerated cellulose) soaked in either tranexamic acid or topical thrombin may be effective.⁵⁹⁹ Fibrin sealants prepared from a source of fibrinogen and a source of thrombin (exogenous or from the patient's own plasma), with or without antifibrinolytic agents or other components⁵⁹⁹ have been used successfully in patients with GT.⁶⁰⁰ Some preparations of bovine thrombin induced antibody formation to itself and contaminated factor V and factor XI and have been associated with serious hemorrhage; recombinant human thrombin is now available and appears to have low immunogenicity.⁶⁰¹

Allogeneic marrow transplantation has successfully in treated patients with GT, BSS,⁵⁸¹ LAD-3,⁵⁴¹ and WAS.^{523,524} Progress has been made in gene therapy approaches to correcting the genetic defect in GT in megakaryocytes.⁶⁰²⁻⁶⁰⁴ Several GT animal models are available, including the integrin subunits α_{IIb} and β_3 -null mouse models,⁶⁰⁵ and dog models involving mutations in the α_{IIb} subunit.^{604,606,607} With respect to BSS, in mouse models, lentiviral transduction of hematopoietic stem cells with human GPIIb under the control of the integrin α_{IIb} promoter has been effective in improving hemostasis when transplanted into animals.²⁸⁹ Thus, as methods of marrow transplantation and gene transfer therapy improve, it will be important to reassess the risk-to-benefit ratios of these therapies for individual patients with GT.

BLEEDING AT SPECIFIC SITES

Control of epistaxis can be particularly difficult in some patients.⁶⁰⁸ When topical measures fail, platelet transfusions or factor VIIa should be considered. Nosebleeds occur primarily along the anterior nasal septum at the Kiesselbach area,⁶⁰⁸ posterior nosebleeds can occur either

along the septum or the lateral nasal wall. Self-administered home therapy for anterior hemorrhage consists of pinching the outer aspect of the nose against the septum for 15 minutes to tamponade the septal vessels.⁶⁰⁸ If this fails, topical application by medical personnel of an anesthetic such as lidocaine in combination with a vasoconstrictor such as phenylephrine or oxymetazoline is commonly effective. Electrical cautery sometimes is effective when chemical cauterization fails. In many cases anterior or posterior packing may be needed for persistent severe epistaxis.

Menarche may be associated with the severe bleeding manifestations and require transfusions in some patients. Antifibrinolytics have been used for menorrhagia; hormonal therapy with progesterone alone or combined progesterone-estrogen is effective in those with persistent hemorrhage.^{581,583}

PREGNANCY

Management during pregnancy and delivery requires close interaction between the hematologist and the obstetrician. Most patients with severe bleeding symptoms, particularly those with GT and the BSS, will need platelet transfusions during childbirth and this need may continue for several days after delivery.⁵⁸¹⁻⁵⁸³ Postpartum bleeding may occur 2 to 4 weeks after delivery in some patients. rFVIIa has been used successfully in women with GT with persistent bleeding despite platelet transfusions, and those with integrin $\alpha_{IIb}\beta_3$ antibodies.^{581-583,609,610} Of note, fetal thrombocytopenia and intracranial hemorrhage may occur because of transplacental passage of the antibodies.

SURGERY

Management during surgical procedures needs to be individualized and depends on the bleeding history of the patient, the nature of the surgery, and on information such as alloimmunization and refractoriness to prior transfusions. Therapeutic options include DDAVP, platelet transfusions, rFVIIa and ancillary measures, such as antifibrinolytics, which may be continued for several days postsurgery.⁵⁸¹⁻⁵⁸³

CHAPTER 121

ACQUIRED QUALITATIVE PLATELET DISORDERS

Charles S. Abrams, Sanford J. Shattil, and Joel S. Bennett

SUMMARY

Acquired qualitative platelet disorders are frequent causes of abnormal platelet function measured *in vitro*, although by themselves are usually associated with little or no clinical bleeding. However, there are important exceptions. Nevertheless, their major clinical impact becomes apparent in the additional presence of thrombocytopenia, or additional acquired or congenital disorders of hemostasis. Acquired disorders of platelet function can be conveniently classified into those that result from drugs, hematologic diseases, and systemic disorders. Drugs are the most frequent cause of acquired qualitative platelet dysfunction. Aspirin is the most notable drug in this regard because of its frequent use, its irreversible effect on platelet prostaglandin synthesis, and its documented effect on hemostatic competency, although this effect is minimal in normal individuals. Other nonsteroidal antiinflammatory drugs reversibly inhibit platelet prostaglandin synthesis and usually have little effect on hemostasis. The antiplatelet effects of a number of drugs have proven useful in preventing arterial thrombosis, but as would be anticipated, excessive bleeding can be a complication of their use. In addition to aspirin, these drugs include the P2Y₁₂ adenosine diphosphate receptor antagonists, clopidogrel, prasugrel and ticagrelor, vorapaxar, an inhibitor of the PAR1 thrombin receptor, and drugs that specifically inhibit adhesive ligand binding to platelet integrin $\alpha_{IIb}\beta_3$ (GPIIb/IIIa). Other drugs used to treat thrombosis, such as heparin and fibrinolytic agents, may also impair platelet function *in vitro* and *ex vivo*, but the clinical significance of these observations is uncertain. High doses of the β -lactam antibiotics can impair platelet function *in vitro*, whereas clinically significant bleeding is unusual in the absence of a coexisting hemostatic defect. Similarly, a number of miscellaneous drugs, including a variety of psychotropic, chemotherapeutic and anesthetic agents, as well as a number of foods and food additives, can affect platelet function *in vitro*, but do not appear to be of clinical significance by themselves. Hematologic diseases associated with abnormal platelet function include marrow processes in which platelets may

Acronyms and Abbreviations: ADP, adenosine diphosphate; BCNU, bis-chloroethylnitrosourea; BTK, Bruton tyrosine kinase; cAMP, cyclin adenosine monophosphate; cGMP, cyclic guanosine monophosphate; COX, cyclooxygenase; coxibs, COX inhibitors; CYP, cytochrome P; DDAVP, desmopressin or 1-desamino-8-D-arginine vasopressin; DIC, disseminated intravascular coagulation; EPO, erythropoietin; GP, glycoprotein; Ig, immunoglobulin; ITP, immune thrombocytopenia; KGD, lysine-glycine-aspartic acid tripeptide; NO, nitric oxide; NSAID, nonsteroidal antiinflammatory drug; PAR, protease-activated receptor; PCI, percutaneous coronary interventions; PG, prostaglandin; PGI₂, prostacyclin; PKC, protein kinase C; RGD, arginine-glycine-aspartic acid tripeptide; SLE, systemic lupus erythematosus; TXA₂, thromboxane A₂; t-PA, tissue plasminogen activator; TTP, thrombotic thrombocytopenic purpura; VWF, von Willebrand factor.

be intrinsically abnormal such as the myeloproliferative neoplasms, leukemias, and myelodysplastic syndromes; dysproteinemias in which monoclonal immunoglobulins can impair platelet function; and acquired forms of von Willebrand disease. Of the systemic diseases, renal failure is most prominently associated with abnormal platelet function because of the retention in the circulation of platelet inhibitory compounds. Platelet function may also be abnormal in the presence of antiplatelet antibodies, following cardiopulmonary bypass, and in association with liver disease or disseminated intravascular coagulation.

Platelet function may be adversely affected by drugs and by hematologic and nonhematologic diseases. Because the use of aspirin and other nonsteroidal antiinflammatory agents is pervasive, acquired platelet dysfunction is much more frequent than inherited platelet dysfunction. Acquired disorders of platelet function can be classified according to the underlying clinical conditions with which they are associated (Table 121-1).

It is important to have a balanced view of the clinical significance of acquired disorders of platelet function. On the one hand, their severity is usually mild. On the other hand, there are important exceptions to this rule, particularly when platelet dysfunction is associated with other hemostatic defects. If a patient does not present with a history of bleeding, it may be difficult to predict the risk of future bleeding. This is not surprising since even patients with thrombocytopenia may experience little or no spontaneous bleeding until their platelet count is less than $10 \times 10^9/L$. Furthermore, clinical assessment of these disorders is made problematic by difficulties in standardization and interpretation of laboratory tests of platelet function, including platelet aggregometry. These tests are more useful in diagnosing platelet dysfunction than in predicting the risk of bleeding.^{1,2}

● DRUGS THAT AFFECT PLATELET FUNCTION

Drugs are the most common cause of platelet dysfunction (Table 121-2). For example, in an analysis of 72 hospitalized patients with a prolonged bleeding time (a test no longer considered reliable), 54 percent were receiving large doses of antibiotics known to prolong the bleeding time and 10 percent were taking aspirin or other nonsteroidal antiinflammatory drugs.³ Some drugs can prolong the bleeding time and either cause or exacerbate a bleeding diathesis. Other drugs may prolong the bleeding time but not cause bleeding, while many only affect platelet function *ex vivo* or when added to platelets *in vitro*. It is important for the hematologist to understand the clinical significance of these distinctions.

ASPIRIN AND OTHER NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Aspirin

Aspirin irreversibly inactivates the enzyme cyclooxygenase (COX), also known as prostaglandin endoperoxide H synthase, by acetylating a serine residue at position 529.⁴ Two isoforms of COX have been identified (COX-1 and COX-2),⁵ as well as a splice variant of COX-1, COX-1b (COX-3), whose functional significance is uncertain.⁶ COX-1 is constitutively expressed by many tissues, including platelets, the gastric mucosa, and endothelial cells (Chap. 134 discusses the use of aspirin as an antithrombotic agent).⁵ COX-2 is undetectable in most tissues, but its synthesis is rapidly induced in cells such as endothelial cells,

TABLE 121-1. Acquired Qualitative Platelet Disorders

Drugs that affect platelet function
Aspirin and other nonsteroidal antiinflammatory drugs
P2Y ₁₂ antagonists (clopidogrel, prasugrel, ticagrelor)
PAR1 thrombin receptor antagonist (vorapaxar)
Integrin $\alpha_{IIb}\beta_3$ receptor antagonists (abciximab, eptifibatide, tirofiban)
Drugs that increase platelet cyclic adenosine monophosphate
Antibiotics
Anticoagulants and fibrinolytic agents
Cardiovascular drugs
Volume expanders
Psychotropic agents and anesthetics
Oncologic drugs
Foods and food additives
Hematologic disorders associated with abnormal platelet function
Chronic myeloproliferative neoplasms
Leukemias and myelodysplastic syndromes
Dysproteinemias
Acquired von Willebrand syndrome
Systemic disorders associated with abnormal platelet function
Uremia
Antiplatelet antibodies
Cardiopulmonary bypass
Liver disease
Disseminated intravascular coagulation
Infection with HIV

fibroblasts, and monocytes by growth factors, cytokines, endotoxin, and hormones.⁵ Platelets express only COX-1, whereas endothelial cells can express both COX-1 and COX-2.^{7,8} In the cardiovascular system, COX products regulate complex interactions between platelets and the vessel wall. The platelet product of COX-1 mediated prostaglandin synthesis, thromboxane A₂ (TXA₂), produces vasoconstriction and is a receptor-mediated agonist for platelet aggregation and secretion.⁴ Thus, inactivation of COX-1 by aspirin prevents platelet synthesis of TXA₂, thereby inhibiting platelet responses that depend on this substance. Accordingly, platelet responses to adenosine diphosphate (ADP), epinephrine, low doses of collagen and thrombin, and arachidonic acid are affected (arachidonic acid completely), but there is almost no effect on the responses to higher doses of collagen or thrombin.^{9,10} On the other hand, the endothelial cell prostaglandin (PG) product, prostacyclin (PGI₂), produces smooth muscle cell relaxation and vasodilation and increases the platelet content of cyclic adenosine monophosphate (AMP), thereby decreasing overall platelet reactivity.¹¹

Platelet PG synthesis in an adult is nearly completely inhibited by a single 100-mg dose of aspirin or by 30 mg taken daily for 7 to 10 days.⁴ Although single doses of aspirin irreversibly inhibit platelet and endothelial cell COX,¹² they have no lasting effect on PG synthesis by endothelial cells because of the ability of these cells to synthesize additional COX unaffected by aspirin.¹³ *In vitro* studies also suggest that the presence of erythrocytes contributes to agonist-stimulated platelet reactivity,¹⁴ an effect that can be inhibited by aspirin at doses greater than those required to inhibit platelet COX-1.¹⁵ A meta-analysis of clinical trials indicates that aspirin doses varying from 50 to 1500 mg daily are equally

TABLE 121-2. Drugs That Affect Platelet Function

Nonsteroidal antiinflammatory drugs
Aspirin, ibuprofen, sulindac, naproxen, meclufenamic acid, mefenamic acid, diflunisal, piroxicam, tolmetin, zomepirac, sulfapyrazone, indomethacin, phenylbutazone, celecoxib
P2Y ₁₂ antagonists
Clopidogrel, prasugrel, ticagrelor
PAR1 receptor antagonist
Vorapaxar
Integrin $\alpha_{IIb}\beta_3$ antagonists
Abciximab, eptifibatide, tirofiban
Drugs that affect platelet cyclic adenosine monophosphate levels or function
Prostacyclin, iloprost, dipyridamole, cilostazol
Antibiotics
Penicillins
Penicillin G, carbenicillin, ticarcillin, methicillin, ampicillin, piperacillin, azlocillin, mezlocillin, sulbenicillin, temocillin
Cephalosporins
Cephalothin, moxalactam, cefoxitin, cefotaxime, ceftazidime
Nitrofurantoin
Miconazole
Anticoagulants, fibrinolytic agents, and antifibrinolytic agents
Heparin
Streptokinase, tissue plasminogen activator, urokinase
ϵ -aminocaproic acid
Cardiovascular drugs
Nitroglycerin, isosorbide dinitrate, propranolol, nitroprusside, nifedipine, verapamil, diltiazem, quinidine
Volume expanders
Dextran, hydroxyethyl starch
Psychotropic drugs and anesthetics
Psychotropic drugs
Imipramine, amitriptyline, nortriptyline, chlorpromazine, promethazine, fluphenazine, trifluoperazine, haloperidol
Anesthetics
Local
Dibucaine, tetracaine, Cyclaine, butacaine, nupercaine, procaine, cocaine
General
Halothane
Oncologic drugs
Mithramycin, daunorubicin, BCNU, ibrutinib
Miscellaneous drugs
Ketanserin
Antihistamines
Diphenhydramine, chlorpheniramine, mepyramine
Radiographic contrast agent
Iopamidol, iothalamate, ioxaglate, meglumine diatrizoate, sodium diatrizoate
Foods and food additives
ω -3 Fatty acids, ethanol, Chinese black tree fungus, onion extract ajoene, cumin, turmeric

efficacious in preventing adverse cardiovascular and cerebrovascular events.¹⁶ This has led many to suggest that the lowest effective doses should be prescribed to minimize gastrointestinal toxicity. Nonetheless, even low doses of aspirin can be associated with significant gastrointestinal hemorrhage.¹⁷⁻¹⁹

Aspirin is one of the relatively few drugs that prolongs the bleeding time in humans and appears to do so by blocking aggregation rather than adhesion. In normal individuals, the effect on the bleeding time is slight (generally no more than 1.2 to 2.0 times the preaspirin bleeding time),^{20,21} observed in both males and females, and requires that almost all the COX in the circulating platelets be inhibited.¹¹ The sensitivity of the bleeding time to aspirin is dependent on such technical variables as the direction of the incision on the forearm and the degree of hydrostatic pressure applied to the arm,²² and hence the current view that the test is unreliable. The bleeding time may remain prolonged for 1 to 4 days after aspirin has been discontinued, and platelet aggregation tests may remain abnormal for up to a week until platelets affected by aspirin are replaced as the result of thrombopoiesis.²³

The significance of aspirin ingestion on the hemostatic competency of normal individuals appears to be minimal. Nevertheless, patients taking aspirin chronically report significant increases in bruising, epistaxis, and gastrointestinal blood loss.¹⁷⁻¹⁹ Gastrointestinal blood loss appears to be the result of a direct effect of aspirin on the gastric mucosa.^{24,25} Furthermore, there is an increase in the incidence of hemorrhagic stroke when aspirin is used in the primary and secondary prevention of vascular disease, as well as an increase in major gastrointestinal and other extracranial bleeding.²⁶ Aspirin may also increase bleeding in the mother and the neonate during parturition.²⁷ In addition, some studies show that aspirin taken preoperatively increases the amount of blood loss following cardiothoracic surgery.^{28,29} In contrast, a retrospective analysis has documented the safety of performing epidural and spinal anesthesia in patients who had ingested aspirin.³⁰ Aspirin may increase the amount of blood loss following general surgery.³¹ The significance of aspirin ingestion in this setting was tested in the POISE-2 study³² in which patients at risk for vascular complications were randomized to aspirin or placebo prior to their noncardiac surgery. Although taking aspirin did not reduce the incidence of cardiovascular events, there was a small increase in hemorrhagic complications. This suggests that discontinuing aspirin prior to surgery is a useful practice, particularly prior to plastic or neurosurgical procedures in which the limits of tolerable bleeding are narrow.³³ On the other hand, patients taking aspirin and other antiplatelet agents for severe cardiovascular disease may be at risk for thrombosis if these medications are discontinued. Thus, the clinician must thoroughly weigh the potential risks and benefits of discontinuing aspirin prior to noncardiac surgery. This is especially true in patients with other hemostatic disorders; for example, aspirin precipitates hemorrhage in individuals with von Willebrand disease, hemophilia A, warfarin ingestion, uremia, and disorders of platelet function.³⁴⁻³⁶ Infusion of desmopressin (DDAVP) has been effective in correcting a prolonged bleeding time caused by aspirin.^{37,38}

Resistance to the antiplatelet effects of aspirin (“aspirin-resistance”) is a controversial topic and whether it exists depends to large extent on whether resistance is considered from a biochemical or clinical perspective.³⁹ Biochemical resistance to the platelet inhibitory effects of aspirin, that is, the failure to achieve pharmacologic inhibition of TXA₂ production, is uncommon.³⁹ For example, when healthy subjects were given either standard or enteric-coated aspirin, 49 percent given a single dose of enteric-coated aspirin failed to inhibit TXA₂ synthesis, whereas the failure to inhibit TXA₂ synthesis was never seen in subjects given standard aspirin.⁴⁰ Nevertheless, subjects given enteric-coated aspirin eventually responded when taking it daily, implying that although some patients absorb enteric-coated aspirin preparations poorly, they will

ultimately absorb sufficient amounts of aspirin to prevent platelet TXA₂ synthesis. Most commonly, aspirin-resistance occurs because patients are non-adherent with aspirin therapy, often because of gastrointestinal toxicity.⁴¹ Clinically, the term aspirin-resistance has been applied to patients who develop cardiovascular events despite taking aspirin. Given that aspirin treatment selectively inhibits platelet synthesis of only one endogenous platelet agonist, TXA₂, it is not surprising that aspirin does not completely abolish platelet-mediated vascular events.

Traditional Nonsteroidal Antiinflammatory Drugs

Unlike aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), such as ibuprofen, naproxen, diclofenac, sulindac, piroxicam, indomethacin, and sulfapyrazone, reversibly inhibit COX enzymes.⁴² Although these drugs can cause a transient prolongation of the bleeding time when given in therapeutic doses, this is usually not clinically significant.⁴³ Population studies have suggested that concurrent treatment with NSAIDs and anticoagulants increases the risk of bleeding complication, but many bleeding events were limited to the gastrointestinal tract where NSAIDs are known to induce gastritis and peptic ulcerations.⁴⁴ As evidence of the modest effect of NSAIDs on platelet function, ibuprofen has been given safely to patients with hemophilia A.^{45,46} Nonetheless, care must be taken when ibuprofen is given to patients with hemophilia and HIV infection receiving zidovudine because increased bleeding has been reported in this circumstance.⁴⁷ Because ibuprofen, and probably other NSAIDs, binds to COX-1, blocking its acetylation by aspirin,⁴² coadministration of NSAIDs and aspirin may impair the irreversible, antithrombotic effects of aspirin on platelets.⁴⁸ For this reason, patients who require both medications should ingest aspirin at least 2 hours prior to the ingestion of traditional NSAIDs.

Coxibs (COX-2 Inhibitors)

COX-1 is present in the gastric mucosa where its products protect the integrity of the gastric lining cells. In inflammatory cells, COX-2 products such as PGE₂ and PGI₂ elicit an increased sense of pain and perpetuate the inflammatory process.⁴⁰ Thus, the coxibs (COX inhibitors), designed to be relatively more specific for COX-2 versus COX-1, were intended to reduce pain and inflammation with fewer gastric side effects than traditional NSAIDs.^{40,42} However, clinical trials revealed that coxib administration was associated with cardiovascular toxicity (myocardial infarction, stroke, edema, exacerbation of hypertension), partly because of inhibiting PGI₂ synthesis.^{11,49-52} On the basis of these results, rofecoxib and valdecoxib were withdrawn from the market (valdecoxib was also associated with cases of Stevens-Johnson syndrome) and a black box warning regarding serious cardiovascular events was added to prescribing information for celecoxib, the only coxib now available in the United States.⁵⁰ Nonetheless, clinical evidence suggests there is no excess cardiovascular risk from daily doses of celecoxib of 200 mg or less.⁵¹ Traditional NSAIDs also inhibit COX-2 to a variable extent and several observational trials have revealed excess cardiovascular events associated with use of these drugs.^{50,53-55} Thus, a warning has also been added to their prescribing information. If indicated, analgesics such as acetaminophen, sodium or choline salicylate and narcotics may be substituted for aspirin and NSAIDs for treating musculoskeletal pain.⁵⁰ One report suggests that acetaminophen can selectively inhibit COX-2,⁵⁶ but the clinical significance of this observation is not clear.

THIENOPYRIDINES

Ticlopidine, clopidogrel, and prasugrel are thienopyridines that are used as antiplatelet agents in arterial diseases (Chap. 134) with results at least comparable to aspirin in the secondary prevention of cerebrovascular and cardiovascular events.^{16,57}

Thienopyridines differ from aspirin in their mechanism of antiplatelet activity and their toxicity profile. All three thienopyridines are prodrugs that depend on oxidation by cytochrome P450 (CYP) enzymes in the liver (ticlopidine and clopidogrel) or in liver and intestine (prasugrel) to form the active metabolites that irreversibly inhibit the platelet P2Y₁₂ ADP receptor.⁵⁸⁻⁶¹ Ticlopidine at 250 mg twice a day, clopidogrel at 75 mg once per day, and prasugrel at 10 mg once a day inhibit platelet aggregation *ex vivo* in humans. The extent of this effect is equivalent to or greater than that of aspirin and the effect of thienopyridines and aspirin appears additive.^{62,63} When given at their usual oral doses, the effect of thienopyridines on platelet aggregation and the bleeding time can be seen within hours of the first dose, but are not maximal for 4 to 6 days. A 300-mg loading dose of clopidogrel or 60 mg of prasugrel, followed by their usual daily doses, shortens the time required for their maximal antiplatelet effect to a few hours.^{64,65} The common CYP polymorphism CYP2C19 results in lower levels of active clopidogrel and ticlopidine metabolites and has been reported to be associated with decreased platelet inhibition and an elevated risk for major adverse cardiovascular events.^{55,66,67} Because the enzyme CYP3A is present in the intestine and can oxidize prasugrel to its pharmacologically active metabolite, intestinal metabolism may account for the rapid appearance and higher levels of the active metabolite in plasma after an oral dose.^{61,68-70} Furthermore, prasugrel metabolism and inhibition of platelet function are not affected by CYP2C19 polymorphisms.^{61,68-70}

The clinical efficacy of prasugrel has been compared to clopidogrel in patients with acute coronary syndrome scheduled for percutaneous coronary intervention in the Triton-TIMI 38 trial. Patients who received prasugrel had a significantly decreased incidence of ischemic events compared to patients who received clopidogrel (9.9 percent vs. 12.1 percent, $p < 0.001$).⁶⁹ However, major bleeding was also significantly increased in patients receiving prasugrel compared to clopidogrel (2.4 percent vs. 1.8 percent, $p < 0.03$). Thus, although prasugrel appeared to be more efficacious than clopidogrel, this benefit was partially offset by a higher rate of hemorrhage.⁶⁹

The platelet inhibitory effects of thienopyridines persist for 4 to 10 days after the drugs have been discontinued, either because of their extended half-life after multiple dosing or their irreversible effect on platelets.⁵⁸ Ticlopidine administration is associated with potentially serious hematologic complications, including neutropenia (neutrophils $< 1200 \times 10^9/L$ in 2.4 percent of individuals)^{58,71,72} and, less commonly, aplastic anemia, and thrombocytopenia.^{73,74} In addition, at least one in 5000 patients develop a thrombotic thrombocytopenic purpura (TTP)-like syndrome.⁷⁵⁻⁷⁷ Results from a large clinical trial suggest that hematologic complications may be less common with clopidogrel or prasugrel.⁵⁷ Clopidogrel may also be rarely associated with a TTP-like syndrome (one in 270,000),⁷⁸ although this rate is close to the TTP incidence in the general population. Because of its toxicity profile, ticlopidine has been replaced by the other thienopyridines in the United States.

Because aspirin and the thienopyridines inhibit platelet function by different mechanisms, their antithrombotic effects may be additive. In theory, this would be beneficial in the treatment of diseases associated with platelet activation such as ischemic heart disease, peripheral vascular disease, and ischemic strokes.^{62,79,80} This hypothesis was tested in the CURE trial of patients with acute coronary syndromes.⁶² Although clopidogrel plus aspirin decreased the combined incidence of cardiovascular deaths, myocardial infarctions, and strokes from 11.4 percent to 9.3 percent, the benefit was partially offset by an increase in severe bleeding from 2.7 to 3.7 percent. Similarly, in the CHARISMA trial of a broad population of patients at risk for cardiovascular events, there were 94 fewer ischemic events in patients treated with both clopidogrel and aspirin, but this occurred at the expense of 93 more

moderate or severe bleeding events.⁸¹ Furthermore, a meta-analysis of seven randomized controlled trials involving more than 39,000 patients confirmed that intracranial hemorrhage was more frequent in patients who received both clopidogrel plus aspirin compared to clopidogrel alone.⁸² Thus, except for special circumstances such as coronary artery stenting, it appears that the added benefit of dual antiplatelet therapy is small and has the added risk of increased bleeding.⁸³

OTHER ADENOSINE DIPHOSPHATE RECEPTOR ANTAGONISTS

Ticagrelor, cangrelor, and elinogrel are oral, reversible, nonthienopyridine P2Y₁₂ receptor antagonists. Because they are not prodrugs and do not require metabolic activation, the onset of their inhibitory activity is more rapid than that of the thienopyridines. A novel, and as yet unexplained, side effect of treatment with this class of the P2Y₁₂ antagonists is the occurrence of dyspnea which can complicate the management of patients with coronary artery disease.⁸⁴

Ticagrelor, the first drug of the class, has been approved for use in acute coronary syndromes. Its efficacy versus clopidogrel was tested in the PLATO trial in which patients with an acute coronary syndrome were randomized to treatment with either ticagrelor or clopidogrel.⁸⁵⁻⁸⁷ At 1 year, the combined end point of death, myocardial infarction, and stroke was 9.8 percent in patients treated with ticagrelor compared to 11.7 percent in patients treated with clopidogrel.⁸⁸ Although stent thrombosis was also decreased in the ticagrelor-treated group, major bleeding not associated with coronary artery bypass surgery was increased in this group. The incidence of fatal intracranial hemorrhage was also greater in the ticagrelor-treated patients, but it was a rare event (0.1 percent of treated patients). In the ATLANTIC trial, patients suffering from an ST-segment elevation myocardial infarction were randomized to receive ticagrelor in the ambulance or in the catheterization laboratory.⁸⁹ Although initiating therapy before hospitalization was safe and lowered the incidence of stent thrombosis, there was no overall improvement in preventing major cardiovascular adverse events. Thus, ticagrelor, like prasugrel appears to be more efficacious than clopidogrel at preventing adverse cardiovascular events, but with more hemorrhagic complications.

THROMBIN RECEPTOR ANTAGONISTS

Thrombin is the most potent physiologic platelet agonist. Three G-protein-coupled thrombin receptors have been identified in humans (protease-activated receptors [PARs] 1, 3, and 4).⁹⁰ Although human platelets express both PAR-1 and PAR-4, the major platelet thrombin receptor is PAR-1 and can be activated by nanomolar concentrations of thrombin. PAR-4 signaling appears to be unnecessary for platelet activation if PAR-1 signaling is intact.⁹⁰ Vorapaxar is a potent, selective, long-acting, oral PAR-1 inhibitor generated from the naturally occurring muscarinic receptor antagonist himbacine.⁹¹ A high-resolution crystal structure of vorapaxar bound to PAR-1 revealed that the binding pocket for the drug is unusual for a peptide-activated G-protein-coupled receptor in that it consists of a superficial tunnel with little of the bound drug surface exposed to aqueous solvent, perhaps accounting for the very slow dissociation rate of vorapaxar from PAR-1.⁹²

The efficacy of vorapaxar for the secondary prevention of arterial thrombosis was examined in the phase III TRA 2P-TIMI 50 trial in which patients with a history of myocardial infarction, stroke, or peripheral arterial disease were randomized between vorapaxar and placebo.⁹³ Most patients were also taking either aspirin or a thienopyridine. Because of a high incidence of intracranial bleeding in the first years of

the study, entry criteria were modified to eliminate patients with a history of a stroke. At 3 years, the incidence of the primary end point (cardiovascular death, myocardial infarction, and stroke) was significantly reduced in vorapaxar-treated patients (9.3 percent vs. 11.2 percent, $p < 0.001$). However, moderate to severe bleeding, including intracranial bleeding, was significantly increased in the vorapaxar-treated patients (4.2 percent vs. 2.5 percent, $p < 0.001$). Nonetheless, based on efficacy, vorapaxar received FDA approval in 2014. Atopaxar, a second PAR-1 antagonist, is currently being evaluated in clinical trials.⁹⁴ Atopaxar has a shorter half-life than vorapaxar, suggesting that potential bleeding complications might be easier to manage.

INTEGRIN $\alpha_{IIb}\beta_3$ RECEPTOR ANTAGONISTS

Drugs that specifically impair the function of the major platelet integrin $\alpha_{IIb}\beta_3$ (GPIIb/IIIa) have been developed for short-term use as antithrombotic agents in the setting of ischemic coronary artery disease.^{95,96} Integrin $\alpha_{IIb}\beta_3$ mediates platelet–platelet cohesion by binding the divalent ligand fibrinogen, thereby crosslinking the integrin on adjacent platelets, causing the formation of platelet aggregates.⁹⁷ Thus, integrin $\alpha_{IIb}\beta_3$ is a viable therapeutic target to prevent arterial thrombosis. Abciximab, eptifibatide, and tirofiban are three FDA-approved structurally dissimilar integrin $\alpha_{IIb}\beta_3$ inhibitors that rapidly impair platelet aggregation. Abciximab is a human–murine chimeric Fab fragment, eptifibatide is a cyclic heptapeptide based on the sequence Lys–Gly–Asp (KGD), and tirofiban is an Arg–Gly–Asp (RGD)-based peptidomimetic. All three drugs have demonstrated efficacy in the management of patients with acute coronary syndromes, particularly in the setting of percutaneous coronary interventions (PCI) where iatrogenic artery wall injury occurs.⁹⁷

Inherited integrin $\alpha_{IIb}\beta_3$ abnormalities cause the bleeding disorder Glanzmann thrombasthenia (Chap. 120).^{98,99} Thus, it is not surprising that integrin $\alpha_{IIb}\beta_3$ antagonists can predispose to bleeding. In EPIC, a clinical trial of abciximab in patients undergoing PCI, 14 percent of patients given abciximab experienced major bleeding compared to 7 percent of patients given placebo.¹⁰⁰ However, patients were also given aspirin and heparin. When the heparin dose was decreased in the subsequent EPILOG trial, the incidence of major bleeding in patients receiving abciximab decreased to 2.0 percent compared to 3.1 percent in the control group receiving heparin and aspirin alone.¹⁰¹ Nonetheless, in both EPIC and EPILOG, minor bleeding was significantly more frequent in patients given abciximab and standard-dose heparin compared to patients given standard-dose heparin alone, attesting to the ability of an integrin $\alpha_{IIb}\beta_3$ antagonist to impair normal hemostasis. In the PRISM-PLUS trial of tirofiban and the PURSUIT trial of eptifibatide, major and minor bleeding were slightly more frequent in patients receiving the study drug compared to controls.^{102,103} Similarly, patients receiving the oral integrin $\alpha_{IIb}\beta_3$ inhibitors xemilofiban and sibrafiban for 30 and 28 days, respectively, frequently experienced mucocutaneous bleeding similar to that experienced by patients with congenital thrombasthenia.^{104,105} Although short-term use of the parenteral integrin $\alpha_{IIb}\beta_3$ antagonists is often beneficial in patients with acute coronary syndrome of following PCI, paradoxically the long-term use of oral integrin $\alpha_{IIb}\beta_3$ inhibitors was associated with an increase in mortality.¹⁰⁶ The cause of this paradoxical effect is not clear, but has been attributed by some to an antagonist-induced conformational change in integrin $\alpha_{IIb}\beta_3$, simulating the effect of physiologic platelet agonists.¹⁰⁷

The risk of bleeding in patients undergoing PCI in the presence of integrin $\alpha_{IIb}\beta_3$ antagonists can be minimized by using heparin on a weight basis,¹⁰¹ by avoiding treatment of patients who are receiving warfarin at therapeutic doses, by early vascular sheath removal, and by meticulous care of vascular puncture sites.¹⁰⁸ Platelet transfusions can

rapidly reverse the platelet function defect in patients receiving abciximab, presumably by decreasing the overall extent of integrin blockade. The ability of platelet transfusion to reverse the effects of the other integrin $\alpha_{IIb}\beta_3$ antagonists is less clear, but these drugs have very short half-lives if renal and hepatic function are normal.

Thrombocytopenia occurring within 24 hours of initiating therapy has been observed in small numbers of patients following the administration of all integrin $\alpha_{IIb}\beta_3$ antagonists.^{102,105,108,109} In EPIC, the incidence of platelet counts of less than $100 \times 10^9/L$ and of less than $50 \times 10^9/L$ in patients receiving abciximab for the first time was 3.9 percent and 0.9 percent, respectively.¹⁰⁹ Thrombocytopenia has also been reported in patients receiving eptifibatide, tirofiban, and a variety of small molecule RGD- and non-RGD-based integrin $\alpha_{IIb}\beta_3$ inhibitors with an incidence of up to 13 percent.^{102,105,109–113}

The mechanism responsible for thrombocytopenia following the administration of these drugs is uncertain, but may be related to the presence of preexisting antiintegrin $\alpha_{IIb}\beta_3$ antibodies that recognize epitopes exposed by the antagonist, or, in the case of abciximab, to murine sequences incorporated into the abciximab Fab fragment.¹¹⁴ The thrombocytopenia usually reverses readily when the drug is stopped, but it may also be reversed by platelet transfusion if clinically indicated.¹⁰⁸ Thrombocytopenia in patients receiving integrin $\alpha_{IIb}\beta_3$ antagonists must be differentiated from pseudothrombocytopenia as a result of drug-induced platelet clumping, from heparin-induced thrombocytopenia in patients receiving heparin concurrently, and from other causes of thrombocytopenia, depending on the clinical circumstances.^{115,116} It is important to identify thrombocytopenia early because integrin $\alpha_{IIb}\beta_3$ antagonists are administered as long infusions and the drug should be stopped as soon as true thrombocytopenia has been confirmed. In most cases of profound thrombocytopenia, a platelet count obtained 2 to 4 hours after initiating therapy will provide evidence of a significant decrease in platelet count, although cases of delayed thrombocytopenia have been observed after treatment with abciximab.¹¹⁴

DRUGS THAT AFFECT PLATELET CYCLIC NUCLEOTIDE LEVELS OR FUNCTION

The pyrimidopyrimidine derivative, dipyridamole, inhibits platelet cyclic nucleotide phosphodiesterase, resulting in the intraplatelet accumulation of the inhibitory cyclic nucleotide cyclic AMP (cAMP). Dipyridamole may also inhibit the breakdown of cyclic guanosine monophosphate (cGMP), resulting in potentiation of the platelet inhibitory effect of nitric oxide.¹¹⁷ Although the platelet inhibitory effects of dipyridamole are seen *in vitro*, the clinical utility of dipyridamole has been controversial.^{118,119} A meta-analysis failed to demonstrate the clinical benefit of adding dipyridamole to aspirin.¹⁶ However, many older dipyridamole trials used formulations with limited dipyridamole bioavailability.¹²⁰ In the European Stroke Prevention Study 2 (ESPS 2), dipyridamole was beneficial in preventing stroke and transient ischemic attack, but there was no difference in mortality between patients taking dipyridamole and placebo or among patients taking dipyridamole plus aspirin compared to either dipyridamole or aspirin alone.¹²¹ The basis for the benefit of dipyridamole in the ESPS 2 trial is unclear, but could be from a higher dipyridamole dosage or to the sustained-release dipyridamole preparation used in the trial.

Intravenous infusions of PGE₁, PGI₂, or stable PGI₂ analogues stimulate platelet adenylyl cyclase, causing an increase in platelet cAMP and a decrease in platelet responsiveness.¹²² These agents cause a transient inhibition of platelet shape change, aggregation, and secretion. However, their clinical utility is limited by their short half-life and side effects that include peripheral vasodilation.¹²³ Cilostazol, a phosphodiesterase III

inhibitor has been approved in the United States for the treatment of peripheral vascular disease¹²⁴ and may have utility in the prevention of cardiac stent occlusion.¹²⁵ Nitric oxide (NO) and organic nitrates such as nitroglycerin inhibit platelet function *in vitro*, probably by activating guanylyl cyclase, thereby increasing cGMP.¹²⁶ Their effect on *in vivo* platelet function is uncertain. High concentrations of caffeine and theophylline also inhibit platelet phosphodiesterases *in vitro*.

ANTIBIOTICS

Penicillins contain a β -lactam ring and a unique side chain. Most cause a dose-dependent prolongation of the bleeding time in normal volunteers.¹²⁷ Because they reduce platelet aggregation and secretion, as well as ristocetin-induced platelet agglutination, they may affect both platelet adhesion and platelet activation. Tests of platelet aggregation are abnormal in 50 to 75 percent of individuals receiving large doses (at least several grams per day) of carbenicillin, penicillin G, ticarcillin, ampicillin, nafcillin, and azlocillin and in 25 to 50 percent of patients taking piperacillin, azlocillin, or mezlocillin.¹²⁷⁻¹²⁹ Differences in the antiplatelet effects of these antibiotics probably relate to differences in blood levels and drug potency. Their effect on platelets is maximal after 1 to 3 days of administration and may remain for several days after the antibiotic has been stopped, suggesting that the effect of these antibiotics on platelets *in vivo* is irreversible.

Penicillins can impair the interaction of agonists and von Willebrand factor (VWF) with the platelet membrane.¹³⁰ Indeed, when many penicillins are incubated with washed platelets, albeit at concentrations higher than those attained *in vivo*, they inhibit the interaction of VWF and agonists, such as ADP and epinephrine, with their platelet receptors.¹³¹ The relative *in vitro* antiplatelet potency of the penicillins correlates well with their lipid solubility and with the inhibitory potency of the isolated side chains.¹³² Moreover, the inhibitory effect of penicillin G on platelet function *in vitro* is potentiated by the presence of probenecid.¹³³ When platelet function was tested after intravenous administration of penicillin, oxacillin or mezlocillin for 3 to 17 days to patients or normal volunteers, irreversible inhibition of agonist-induced aggregation was noted, along with a 40 percent reduction in low-affinity TXA₂ receptors.¹³⁴ Thus, penicillins probably inhibit platelet function by binding to one or more membrane components necessary for adhesive interactions with the vessel wall or for stimulus-response coupling.

Although clinically significant bleeding is associated with the use of carbenicillin, penicillin G, ticarcillin, and nafcillin, it is far less common than prolongation of the bleeding time.^{127,135} Patients with coexisting hemostatic defects (e.g., thrombocytopenia, vitamin K deficiency, uremia) may be particularly prone to this complication. On the other hand, high doses of penicillin G did not increase gastrointestinal blood loss in a thrombocytopenic rabbit model.¹³⁶ In our experience, bleeding attributable to antibiotic-induced platelet dysfunction is uncommon and unpredictable. Because β -lactam-induced platelet dysfunction resolves with time following cessation of the drug, this class of drugs should only be considered as a cause of bleeding in the appropriate clinical setting. A similar pattern of platelet dysfunction has been reported with some cephalosporins or related antibiotics, but not with others.^{127,137,138} Broad-spectrum antibiotics can also cause a bleeding diathesis attributable to killing of gut flora, resulting in vitamin K deficiency. Nitrofurantoin, a structurally unrelated antibiotic, may cause a mild prolongation of the bleeding time and impair platelet aggregation when blood levels of the drug are higher than 20 μ M, as may occur in patients with renal insufficiency.¹³⁹ Miconazole, an antifungal agent, inhibits human and rabbit platelet COX *in vitro* and rabbit platelet COX after intravenous infusion.¹⁴⁰

ANTICOAGULANTS, FIBRINOLYTIC AGENTS, ANTIFIBRINOLYTIC AGENTS

Heparin predisposes to bleeding primarily through its anticoagulant effect, but it may also impair platelet function. For example, a bolus injection of heparin (100 U/kg) can cause a significant prolongation of the bleeding time in normal subjects and in patients prior to cardiopulmonary bypass, suggesting that therapeutic doses of heparin may impair platelet function.¹²⁶ Heparin likely impairs platelet function by inhibiting the generation and action of the potent platelet agonist thrombin. On the other hand, *in vitro* studies suggest that heparin can enhance platelet aggregation induced by other platelet agonists.¹⁴¹ Heparin binds to a single class of high-affinity binding sites on resting platelets and to an additional class of lower-affinity binding sites on fully activated platelets.¹⁴² High heparin doses also impair VWF-dependent platelet function, possibly by binding to the heparin-binding domain of VWF.¹⁴³ The contributions of these effects on platelet function to the bleeding complications of heparin therapy are uncertain.

Bleeding during fibrinolytic therapy is predominantly a result of the combined effects of structural lesions in blood vessels and the fibrin(ogen)olytic activity of the agent used. However, pharmacologic doses of streptokinase, urokinase, and tissue plasminogen activator (t-PA) can affect platelet function.¹⁴⁴ High concentrations of plasmin *ex vivo* cause platelet aggregation.¹⁴⁵ Moreover, marked increases in the urinary excretion of the TXA₂ metabolite 2,3-dinor-TXB₂ have been detected in patients receiving streptokinase or t-PA for coronary thrombolysis, suggesting that *in vivo* platelet activation had occurred during infusion of the drug.^{146,147} Nevertheless, several *in vitro* studies indicate that plasmin generation has an inhibitory effect on platelet function. First, very high levels of fibrin(ogen) degradation products, coupled with very low levels of fibrinogen, may impair platelet aggregation.¹⁴⁸ Second, plasminogen can bind to platelets¹⁴⁹ and after its conversion to plasmin, enzymatically degrade platelet glycoprotein (GP) Ib, impairing the interaction of platelets with VWF.^{150,151} Third, plasmin can inhibit platelet arachidonic acid metabolism.¹⁵² Fourth, t-PA promotes the disaggregation of platelet aggregates, presumably by inducing lysis of the fibrinogen that mediates aggregate formation.¹⁵³ Finally, after initial activation, platelets incubated with plasmin and recombinant t-PA *in vitro* become refractory to activation by other agonists.¹⁵⁴ Whether any of these *in vitro* and *ex vivo* observations apply to the *in vivo* situation and are clinically significant remains uncertain.¹⁵⁵ The antifibrinolytic drug, ϵ -aminocaproic acid, can increase the bleeding time when administered for several days at doses 24 g/day or greater.¹⁵⁰

CARDIOVASCULAR DRUGS

Administration of nitroprusside, which increases platelet cGMP,¹⁵⁶⁻¹⁶⁰ nitroglycerine,¹⁶¹ and propranolol,^{162,163} can decrease platelet aggregation and secretion *ex vivo*. Nitroprusside can increase the bleeding time twofold when administered at infusion rates of 6 to 8 mcg/kg/min.^{156,164} Inhalation of NO advocated for the treatment of pulmonary hypertension and the adult respiratory distress syndrome, can impair agonist-induced platelet aggregation *ex vivo*, although the clinical significance of these observations is unclear.¹⁶⁵⁻¹⁶⁷ Calcium channel blockers such as verapamil, nifedipine, and diltiazem inhibit platelet aggregation when added at very high concentrations to washed platelets.¹²³ This effect is seen primarily with epinephrine-induced aggregation and does not appear to be related to calcium channel blockade.¹⁶⁸ At therapeutic doses, calcium channel blockers do not prolong the bleeding time, although one agent, nisoldipine, has been reported to inhibit agonist-induced calcium transients and platelet aggregation after ten days of oral administration.¹⁶⁹ At high concentrations, the antiarrhythmic drug

quinidine has been reported to cause a mild prolongation of the bleeding time and to potentiate the effect of aspirin.¹⁷⁰

VOLUME EXPANDERS

Dextran is a neutral polysaccharide that is heterogeneous in molecular size. Two preparations with average molecular weights of 40,000 and 70,000 are in clinical use. Although dextran infusions may prolong the bleeding time of normal subjects and patients with von Willebrand disease, this phenomenon has not been observed in most normal subjects.^{9,171,172} Infused dextran adsorbs to the platelet surface and can impair platelet aggregation, secretion, and procoagulant activity. The maximal effect of dextran may require several hours, suggesting that larger molecules with a slower rate of clearance are responsible.⁹ Curiously, the drug has no effect when added to platelet-rich plasma.⁹ Dextran infusion produces a modest reduction in plasma VWF antigen levels and ristocetin cofactor activity.¹⁷¹ Despite these effects on primary hemostasis, prospective studies indicate that dextran is not associated with significant postoperative bleeding, unless it is administered together with low-dose heparin.^{173,174} Hydroxyethyl starch, another volume expander, while generally safe, may prolong the bleeding time and predispose to hemorrhage, particularly if it is administered in doses exceeding 20 mL/kg of a 6-percent solution. Lower doses of hydroxyethyl starch may contribute to bleeding if administered simultaneously with low-dose heparin or if given to patients with preexistent hemostatic defects or after major cardiothoracic surgery.^{175–178} Different hydroxyethyl starch preparations vary in the average number of hydroxymethyl groups per glucose unit, and this may affect both intravascular survival and effects on hemostasis.^{179,180}

PSYCHOTROPIC DRUGS, ANESTHETICS, AND COCAINE

Platelets from patients taking antidepressants or phenothiazines may exhibit impaired aggregation, but this is not associated with bleeding.^{181,182} The effect on aggregation has been attributed to inhibition of intracellular signaling molecules such as protein kinase C (PKC).¹⁸³ Selective serotonin reuptake inhibitors such as paroxetine, have been shown to decrease platelet serotonin storage.¹⁸⁴ Fluoxetine does not appear to impair platelet aggregation *in vitro* and has only rarely been associated with clinical bleeding.^{185,186} General anesthesia with halothane or propofol may cause a slight prolongation of the bleeding time, most likely the result of an effect on calcium signaling, but this has no adverse effect on surgical hemostasis.^{187,188} In addition to an association with thrombocytopenia, cocaine has been reported to either inhibit^{189,190} or stimulate platelet activation.¹⁹¹ It has been suggested that heroin decreases platelet NO production.¹⁹² The clinical relevance of these observations is unknown.

ONCOLOGIC DRUGS

Administering mithramycin to a total dose of 6 to 21 mg decreases platelet aggregation and is associated with mucocutaneous bleeding.¹⁹³ An *ex vivo* defect in platelet secretion and secondary aggregation has been reported in patients with solid tumors within 48 hours of receiving infusions of autologous marrow and high-dose chemotherapy consisting of cisplatin, cyclophosphamide, and either *bis*-chloroethylnitrosourea (BCNU) or melphalan.¹⁹⁴ Both daunorubicin and BCNU can inhibit platelet aggregation and secretion when added to platelet-rich plasma, but they have not been shown to cause clinically significant platelet dysfunction.^{195–197} Administration of recombinant forms of thrombopoietin to thrombocytopenic patients with cancer results in the production of normally functioning platelets.^{198,199} Dasatinib, the broad-spectrum

protein tyrosine kinase inhibitor, impairs collagen-induced platelet activation *in vitro* and increases tail bleeding times in mice, perhaps explaining some bleeding episodes in patients with chronic myelogenous leukemia who have been treated with the drug.²⁰⁰ Ibrutinib, a Bruton tyrosine kinase (BTK) inhibitor efficacious in a wide variety of lymphoid malignancies,^{201,202} is associated with hemorrhagic complications in up to half of patients, with significant hemorrhagic toxicity in 5 percent.^{201–203} Exposing platelets to ibrutinib *ex vivo* can produce defective platelet adhesion.²⁰⁴ Furthermore, humans or mice lacking BTK have impaired *ex vivo* platelet function, although the impairment is quite mild.^{205,206} Whether the hemorrhagic toxicity of ibrutinib is caused by platelet BTK inhibition or by an off-target effect remains to be determined.

MISCELLANEOUS AGENTS

The immunosuppressive drug cyclosporine has been reported to enhance ADP-stimulated platelet aggregation *in vitro*.²⁰⁷ It is unclear whether this contributes to the TTP-like syndrome associated with this drug. Antihistamines,²⁰⁸ the serotonin antagonist ketanserin,²⁰⁹ and certain radiographic contrast agents^{210,211} can impair platelet aggregation responses *ex vivo* by unknown mechanisms.

FOODS AND FOOD ADDITIVES

Certain foods and food additives affect platelet function *in vitro*, and it is conceivable that some may affect hemostasis, particularly in association with other hemostatic defects. For example, diets rich in fish oils containing ω -3 fatty acids (eicosapentaenoic acid; docosahexaenoic acid) cause a slight prolongation of the bleeding time.²¹² These fatty acids act by reducing the platelet content of arachidonic acid and by competing with arachidonic acid for COX.^{213,214} Easy bruising noted after eating Chinese food has been attributed to an antiplatelet effect of the black tree fungus.²¹⁵ A component of extract of onion can inhibit platelet arachidonic acid metabolism.²¹⁶ Ajoene, a component of garlic, is an inhibitor of fibrinogen binding and platelet aggregation.²¹⁷ Extracts of two commonly used spices, cumin and turmeric, also inhibit platelet aggregation and eicosanoid biosynthesis.²¹⁸

HEMATOLOGIC DISORDERS ASSOCIATED WITH ABNORMAL PLATELET FUNCTION

CHRONIC MYELOPROLIFERATIVE NEOPLASMS

Definition and History

Bleeding and thrombosis are significant causes of morbidity and mortality in the chronic myeloproliferative neoplasms, particularly in essential thrombocythemia, polycythemia vera, and primary myelofibrosis.^{219–221} Thrombocytosis is a constant finding in essential thrombocythemia, but the differential diagnosis includes these other myeloproliferative neoplasms, including chronic myelogenous leukemia, as well as other diseases associated with reactive thrombosis (Chap. 119).^{222,223} Most of the information about platelets, bleeding and thrombosis in the myeloproliferative neoplasms comes from studies of essential thrombocythemia and polycythemia vera.

Etiology and Pathogenesis

Several factors contribute to the hemostatic abnormalities in the myeloproliferative neoplasms: (1) Increased whole-blood viscosity in polycythemia vera: The engorgement of blood vessels associated with

polycythemia is a risk factor for thrombosis and bleeding, particularly in postoperative situations.^{224–226} (2) Intrinsic defects in platelet function: Many intrinsic platelet function defects have been reported in the myeloproliferative neoplasms, although their precise relationships to clinical bleeding are generally unclear.^{227,228} (3) Elevated platelet counts: The contribution of an elevated platelet count, per se, to the risk of hemorrhage and thrombosis in myeloproliferative neoplasms is controversial, as the risk does not extend to patients with reactive thrombocytosis.^{229,230} A number of retrospective studies indicate that the risk of abnormal hemostasis cannot be confidently predicted from the degree of thrombocytosis.²²⁷ On the other hand, acquired von Willebrand syndrome, which represents a potential major cause of bleeding in the chronic myeloproliferative neoplasms, is most frequently associated with extreme elevations of the platelet count (e.g., ≥ 1000 to $1500 \times 10^9/L$)^{231–233}; in some, the VWF abnormality can be corrected, albeit transiently, by infusion of DDAVP or factor VIII/VWF concentrates, while in others it can be partially or completely corrected by cytoreductive therapy.²³⁴ (4) Leukocytosis may represent a risk factor for thrombosis in the myeloproliferative neoplasms.^{221,235} In this context, leukocyte and/or endothelial dysfunction may contribute to the thrombotic phenotype in some individuals with polycythemia vera^{236,237} or essential thrombocythemia²³² through leukocyte–platelet and leukocyte–endothelial cell interactions.^{232,238,239}

Under the light or electron microscope, platelets in these disorders may be larger or smaller than normal, may be abnormally shaped, and may exhibit a reduction in the number of storage granules.²⁴⁰ In essential thrombocythemia, platelet survival may be modestly reduced.²⁴¹ A number of functional and biochemical abnormalities have been described in platelets from patients with myeloproliferative neoplasms. The most frequently encountered functional abnormality is a decrease in platelet aggregation and granule secretion in response to epinephrine, ADP, or collagen.²²⁷ The defect in epinephrine-induced aggregation often includes absence of the primary wave of aggregation, which is unusual in other conditions. This is not simply the result of an elevated platelet count, because it is not encountered in reactive thrombocytosis.^{222,242} Thus, loss of platelet responsiveness to epinephrine may help to support the presence of a myeloproliferative neoplasm in otherwise ambiguous cases, although the discovery of genetic abnormalities (e.g., JAK2, thrombopoietin receptor [MPL], calreticulin) is beginning to eliminate all ambiguity in the diagnosis of a myeloproliferative neoplasm (Chaps. 84 to 86).

Reduced platelet aggregation and secretion in the myeloproliferative neoplasms is associated with one or more of the following: decreased agonist-induced release of arachidonic acid from membrane phospholipids^{243,244}; reduced conversion of arachidonic acid to PG endoperoxides or lipoxigenase products²⁴⁵; reduced platelet responsiveness to TXA₂²⁴⁶; decreased numbers of α_2 -adrenergic receptors associated with reduced or absent platelet responses to epinephrine^{247,248}; deficiency of integrin $\alpha_2\beta_1$, resulting in variable changes in platelet responsiveness to collagen²⁴⁹; diminished stimulus–response coupling downstream of several agonists associated with reduced activation of phosphatidylinositol 3′-kinase, Rap1 and integrin $\alpha_{IIb}\beta_3$ ²⁵⁰; and deficiency of dense or α granules.^{251,252} Reduction in platelet procoagulant activity has been reported in some patients with myeloproliferative neoplasms and thrombocytosis,²⁵³ as have specific platelet membrane abnormalities, including decreased expression and activation of integrin $\alpha_{IIb}\beta_3$,²⁵⁴ decreased amounts of the GPIb–V–IX complex, resulting in an acquired form of Bernard-Soulier syndrome²⁵⁵; decreased numbers of receptors for PGD₂²⁵⁶; increased numbers of Fc γ RIIA receptors²⁵⁷; an increase in GPIV (CD36) with^{258,259} or without²⁶⁰ a corresponding decrease in GPIb; and impaired expression of MPL in polycythemia vera²⁶¹ and essential thrombocythemia.¹¹¹

On the other hand, evidence for *in vitro* platelet or coagulation hyperactivity has been reported in the myeloproliferative neoplasms. This includes spontaneous platelet aggregation in a patient with essential thrombocythemia and thrombosis,²⁶² increased thromboxane biosynthesis by platelets from patients with essential thrombocythemia²⁶³ or polycythemia vera,²⁶⁴ and increased “procoagulant imbalance” in patients manifested by increased endogenous thrombin potential²⁶⁵ and increased procoagulant activity in circulating microparticles.²⁶⁶

Several features of these protean *in vitro* platelet functional defects require emphasis relative to the clinical setting. First, none are unique to a particular myeloproliferative neoplasm. Second, their relative frequencies have varied widely in reported series. Third, none has been prospectively shown to be predictive of bleeding or thrombosis. Fourth, although the chronic myeloproliferative neoplasms comprise several distinct clinicopathologic entities, they represent clonal abnormalities of hematopoiesis.²⁶⁷ Consequently, megakaryocytes and their platelet progeny may acquire genetic, biochemical, and structural abnormalities as they develop from clones of abnormal progenitors. Examples of clonal defects in the chronic myeloproliferative neoplasms are acquisition of activating mutations in JAK2 (e.g., V617F in polycythemia vera, essential thrombocythemia, and myelofibrosis; or in exon 12 in polycythemia vera)^{268–272} or MPL (W515L/K in essential thrombocythemia and myelofibrosis).^{273,274} Mutations in the calreticulin gene have been found in most of the essential thrombocythemia and myelofibrosis patients who lack activating mutations in JAK2 or MPL.^{275,276} It is biologically plausible that mutations in these or other leukocyte and platelet proteins might influence hemostatic mechanisms, including the activation state of platelets.^{277–279} However, the precise impact of their presence or allele burden on human platelet function and on thrombotic risk is only now beginning to be understood.^{232,280} For example, most,^{232,268} but not all,^{237,281} studies have concluded that the presence of the JAK2 (V617F) mutation or a high JAK2 (V617F) allele burden confers increased thrombotic risk in essential thrombocythemia, the latter in part a result of higher hemoglobin values. On the other hand, essential thrombocythemia or myelofibrosis patients with calreticulin mutations tend to have higher platelet counts, lower hemoglobin and leukocyte values, and fewer thromboses compared to patients with JAK2 mutations.^{275,282–285} The same may hold true for rare patients with familial essential thrombocythemia or myelofibrosis and somatically-acquired calreticulin mutations.²⁸²

Clinical and Laboratory Features

Pathologic bleeding occurs in approximately one-third of patients with myeloproliferative neoplasms and contributes to mortality in 10 percent of those affected patients. Thrombosis also occurs in one-third of patients with myeloproliferative disorders, contributing to mortality in 15 to 40 percent of affected patients.^{228,232} Most symptomatic patients experience either bleeding or thrombosis; however, some develop both complications during the course of their disease. Bleeding usually involves the skin or mucous membranes, but may also occur after surgery or trauma. Thrombosis can involve arteries or veins and may occur in unusual locations such as abdominal wall vessels or the hepatic, portal, and mesenteric circulations.^{286–291} Indeed, full-blown or latent chronic myeloproliferative neoplasms account for a substantial proportion of patients with splanchnic vein thrombosis.^{286,291–294} Individuals with essential thrombocythemia may experience ischemia and necrosis of the fingers and toes from digital artery thrombosis, microvascular occlusion in the coronary circulation, or transient neurologic symptoms, including headaches,²⁹⁵ because of cerebrovascular occlusion.²⁹⁶ A syndrome of redness and burning pain in the extremities, termed *erythromelalgia*, is strongly associated with essential thrombocythemia and polycythemia vera and is thought to be partly caused by arteriolar platelet thrombi, although it may also have vasculopathic and

neuropathic components.^{297,298} It has been difficult to predict the risk of bleeding or thrombosis in an asymptomatic patient,²²⁹ but an increase in leukocyte count^{221,232,235} or the number of reticulated platelets in patients with thrombocytosis, thought to reflect an increase in platelet turnover, has been associated with an increased risk for thrombosis.²⁹⁹ Vascular complications are also more likely to occur in patients older than 60 years of age and, most importantly, in patients with other cardiovascular risk factors, such as diabetes, hypertension, hyperlipidemia and obesity.^{221,300-303}

Therapy

Therapy should be risk-adapted and considered for symptomatic patients, for patients with a history of thrombosis or bleeding, for those with standard cardiovascular risk factors, for patients older than 60 years of age, and for individuals about to undergo surgery. Readers are referred to expert recommendations for a summary of the treatment of essential thrombocythemia and polycythemia vera, with particular relevance to risk factors for hemostasis and thrombosis (Chaps. 84 and 85).^{221,232,301,303-306} Treatment includes phlebotomy to correct the polycythemia and maintenance of a normal red cell mass, with the goal to achieve a hematocrit of less than 45 percent,^{235,307,308} as well as therapy of the underlying disorder.^{228,232,309,310} Platelet count reduction to less than $400 \times 10^9/L$ in patients with thrombocytosis, either by plateletpheresis or cytoreductive agents, has been considered to be a target value associated with clinical improvement in patients with essential thrombocythemia.^{228,302,311}

Effective cytoreductive agents include the ribonuclease reductase inhibitor hydroxyurea,³¹² interferon- α (most recently the pegylated form of interferon alfa-2a), and anagrelide.^{301,311,313,314} In a prospective, randomized trial of 114 “high-risk” individuals with essential thrombocythemia who were either older than 60 years of age or had a previous history of thrombosis, hydroxyurea significantly reduced the incidence of new thrombosis from 24.0 to 3.6 percent.³¹² Anagrelide, an imidazoquinazoline derivative, is thought to decrease platelet counts by impairing megakaryocyte maturation.³¹⁵ Anagrelide has essentially no effect on red and white cell counts and is not known to be leukemogenic. Nevertheless, 10 to 20 percent of patients experience neurologic, gastrointestinal, and cardiac side effects, in particular fluid retention, often necessitating discontinuation of the drug.^{314,316,317} When hydroxyurea and anagrelide were compared head-to-head in a randomized trial of 809 patients with essential thrombocythemia (all of whom were taking aspirin), subjects in the anagrelide group showed an increased rate of arterial thrombosis, major bleeding, and transformation to myelofibrosis relative to the group treated with hydroxyurea; however, the anagrelide group showed a relative decreased rate of venous thrombosis.³¹⁸ Progression to myelofibrosis despite treatment with anagrelide has also been observed in a phase II study.³¹⁹ However, in a newer, although relatively small, randomized, phase III study of 259 previously untreated high-risk patients with essential thrombocythemia, anagrelide was found to be noninferior to hydroxyurea in the prevention of arterial or venous thrombotic complications.³²⁰ It should be noted that this study used a long-lasting anagrelide drug that is not currently available in the United States. During an episode of acute bleeding in the chronic myeloproliferative neoplasms, DDAVP infusion may temporarily improve hemostasis if the patient has an acquired storage pool defect or acquired von Willebrand syndrome.^{252,321} In the case of acquired von Willebrand syndrome, cytoreduction to reduce the platelet count may also ameliorate the process, although this may take time and require more temporizing interventions including DDAVP or factor VIII/VWF concentrates.²³⁴

Low-dose aspirin (~80 to 100 mg/day) may be useful in patients with essential thrombocythemia and thrombosis, particularly those with

erythromelalgia or with digital or cerebrovascular ischemia.^{231,232,298,322} However, the evidence to date remains largely anecdotal, and aspirin can exacerbate a bleeding tendency in patients with myeloproliferative neoplasms, particularly in those individuals with acquired von Willebrand syndrome or with World Health Organization (WHO)-defined prefibrotic myelofibrosis masquerading as essential thrombocythemia.^{221,301,303,323} Consequently, even though a single, daily, low-dose aspirin is recommended for thromboprophylaxis in essential thrombocythemia, a risk-adapted approach is advised.^{221,305} In addition, because platelet volume and turnover may be enhanced in essential thrombocythemia and polycythemia vera, the platelets of some individuals may not achieve total COX-1 inhibition with a single daily dose of aspirin. In such circumstances, 12-hour dosing may be considered, although this protocol has not been formally evaluated in a prospective clinical trial.^{324,325}

In a double-blind, placebo-controlled study of 518 patients with polycythemia vera who were judged to have no contraindications to daily low-dose (100 mg) aspirin, subjects in the aspirin arm exhibited a reduced risk of nonfatal arterial and venous cardiovascular end points. Although aspirin was well-tolerated, there was no effect of aspirin on overall and cardiovascular mortality.³²⁶ As has been noted,³⁰⁷ this study population was heavily pretreated to normalize the platelet count, although some individuals may have had residual elevations in red cell mass. Consequently, the safety and efficacy of aspirin as observed in this study may not be relevant to all patients with polycythemia vera.

Pregnant women with essential thrombocythemia or polycythemia vera pose special challenges because of an apparent increased risk of unsuccessful pregnancy, thrombotic or bleeding complications, and potential teratogenicity of hydroxyurea.^{305,327} In essential thrombocythemia, the risk of first trimester miscarriages may be higher among women with the JAK2 (V617F) mutation.³²⁸ Although evidence-based recommendations are not available, Barbu and Finazzi recommend a risk-adapted approach to management in pregnancy. High-risk women are defined as those with previous major bleeding or thrombotic episodes, previous pregnancy complications, or a platelet count greater than $1500 \times 10^9/L$.³²⁹ Low-risk individuals are recommended to be maintained at a hematocrit of less than 45 percent and to receive aspirin, 100 mg/day during pregnancy and low-molecular-weight heparin, 4000 U/day for 6 weeks after delivery. Interferon- α , rather than aspirin, is considered if there has been previous major bleeding or if platelets are greater than $1500 \times 10^9/L$. High-risk patients are recommended to receive low-molecular-weight heparin throughout pregnancy.

LEUKEMIAS AND MYELODYSPLASTIC SYNDROMES

Clinical and Laboratory Features

The most frequent cause of bleeding in patients with leukemia or a myelodysplastic syndrome is thrombocytopenia. However, abnormal platelet function *in vitro* has been described in acute myelogenous leukemia, and in some patients this may be clinically significant. In acute myelogenous leukemia and its variants, platelets may be larger than normal, abnormally shaped, and exhibit a marked variation in the number of granules. There may be decreased aggregation and serotonin release in response to ADP, epinephrine, or collagen, decreased surface P-selectin expression in response to platelet activation via the PAR-1 thrombin receptor, and decreased platelet procoagulant activity. These functional abnormalities may be caused by either acquired storage pool deficiency or a defect in the process of platelet activation through one or more signaling pathways.³³⁰⁻³³⁴ These defects are intrinsic to the platelet and probably relate to the fact that the megakaryocytes from which platelets were derived originated from a leukemic stem cell. Indeed, in a familial

platelet disorder with a predisposition to acute leukemia, platelet dysfunction prior to the development of leukemia occurs, at least in part, because of downregulation of genes such as *NF-E2* or *ALOX12*, themselves target genes of RUNX1, a transcription factor that is germline-mutated in these individuals.^{335,336}

As discussed in the section on oncology drugs, drugs used to treat acute leukemias may affect platelet function, at least *in vitro*.^{200,337,338} Bleeding in the acute leukemias usually responds to platelet transfusions and to treatment of the underlying disease. Similar *in vitro* platelet abnormalities may be seen in the myelodysplastic syndromes, sometimes accompanied by clinical bleeding disproportionate to that expected for the degree of thrombocytopenia.^{330,339–344} In these syndromes, platelets may be less uniformly affected; perhaps because there is a residual population of normal platelets admixed with those from the malignant clone.

Reduced platelet aggregation has been reported in children with acute lymphocytic leukemia.³³¹ Unless the leukemia is biphenotypic, it is difficult to ascribe the platelet defect to the leukemic process itself. Platelets are normal in children with acute lymphoblastic leukemia in complete remission.³⁴⁵ Single cases have been reported of patients with acute B-lymphoblastic leukemia³⁴⁶ or Hodgkin lymphoma³⁴⁷ whose severe bleeding was attributed, in part, to acquired Glanzmann thrombasthenia associated with antiintegrin $\alpha_{IIb}\beta_3$ antibodies. Hairy cell leukemia is a lymphoproliferative disease in which platelet dysfunction may rarely complicate the clinical picture; bleeding is usually due to thrombocytopenia rather than platelet dysfunction.³⁴⁸ Some patients may exhibit storage pool deficiency or a defect in the process of platelet activation. These abnormalities have been reported to disappear following splenectomy,³⁴⁹ which usually corrects the thrombocytopenia as well. Acquired von Willebrand syndrome has been reported in association with hairy cell leukemia.³⁵⁰

DYSPROTEINEMIAS

Definition and History

Platelet dysfunction is observed in approximately one-third of patients with Immunoglobulin (Ig) A multiple myeloma or Waldenström macroglobulinemia, 15 percent of patients with IgG myeloma, and in occasional patients with monoclonal gammopathy of undetermined significance (Chap. 106).^{351,352} In addition to platelet dysfunction, other causes of bleeding should be considered in these patients, including the hyperviscosity syndrome,³⁵³ thrombocytopenia, complications of amyloidosis such as amyloid angiopathy³⁵⁴ or acquired factor X deficiency^{355,356}, and rarely, a circulating heparin-like anticoagulant^{357–359} or systemic fibrinolytic activity.^{360,361} The monoclonal immunoglobulin may also affect *in vitro* coagulation tests by interfering with fibrin polymerization and with the function of other coagulation proteins. On occasion, paraproteins can impair *in vivo* hemostasis as well.

Etiology and Pathogenesis

The bleeding time may be prolonged in patients with dysproteinemias, even in the absence of clinical bleeding. The platelet defect is caused by the monoclonal protein. It has been suggested that some monoclonal immunoglobulins interact with the platelet surface to interfere nonspecifically with platelet adhesion or stimulus–response coupling. This concept is supported by the observations that platelet dysfunction is more common when the concentration of the paraprotein in plasma or on the platelet membrane is very high³⁶²; that platelet aggregation, secretion, clot retraction, and platelet procoagulant activity may all be affected; and that normal platelets can acquire these defects when incubated with the purified monoclonal immunoglobulin.³⁶³

In some cases, specific interactions of the monoclonal protein with platelets or with components of the extracellular matrix have been

described. One reported IgA myeloma protein inhibited the ability of a suspension of aortic connective tissue to aggregate normal platelets.³⁶⁴ The bleeding time and bleeding diathesis of the patient from whom this myeloma protein was obtained were corrected by removal of the protein by plasmapheresis. In another patient with IgD λ myeloma, λ dimers were found to bind to the A1 domain of VWF, inhibiting shear-induced platelet aggregation.³⁶⁵ In still another patient, an IgG myeloma protein bound specifically to the platelet integrin β_3 subunit. Both the intact immunoglobulin and its F(ab')₂ fragment inhibited the binding of fibrinogen to activated integrin $\alpha_{IIb}\beta_3$, thus inducing a thrombasthenic-like state.³⁶⁶ A number of patients with myeloma, monoclonal gammopathy of undetermined significance, lymphoma, or chronic lymphocytic leukemia have been reported to have an acquired form of von Willebrand disease in which the level of plasma VWF is reduced or the high-molecular-weight multimers of VWF are selectively reduced.^{321,352,367–374}

Therapy

When clinically significant platelet dysfunction occurs in a patient with a dysproteinemia, cytoreductive therapy should be considered as a means to reduce the production and plasma level of the monoclonal immunoglobulin.^{351,352} Plasmapheresis can also control bleeding by reducing the level of the abnormal protein and can be lifesaving during acute bleeds.^{352,375,376} Cryoprecipitate, DDAVP and/or plasmapheresis may be transiently effective in patients with acquired von Willebrand syndrome.^{321,368,377,378} However, high-dose intravenous gamma globulin (IVIG) appears to be particularly effective in individuals with acquired von Willebrand syndrome associated with an IgG monoclonal gammopathy of undetermined significance, although intermittent infusions may be required at approximately 3-week intervals (Chap. 126).^{352,369–371,379–381} The reported experience with rituximab for the latter condition is extremely limited, but so far disappointing.³⁸²

ACQUIRED VON WILLEBRAND SYNDROME

Acquired von Willebrand syndrome is a relatively rare disorder that typically occurs in the setting of an autoimmune or clonal hematologic disease.^{231,381,383–385} It is being increasingly recognized in conditions associated with high shear and turbulence in the circulation, such as severe aortic stenosis, hypertrophic obstructive cardiomyopathy and circulatory assist devices.^{381,386–390} It also can occur in association with a number of other unrelated medical conditions,³⁸¹ including Gaucher disease,³⁹¹ hypothyroidism^{392,393} and Noonan syndrome.³⁹⁴ As discussed above, it can represent one cause of bleeding in multiple myeloma,^{321,377} Waldenström macroglobulinemia,³⁹⁵ monoclonal gammopathy of undetermined significance,³⁷⁰ low grade non-Hodgkin lymphoma,^{396,397} chronic lymphocytic leukemia,³⁹⁸ and chronic myeloproliferative neoplasms, the latter particularly in association with very high platelet counts.²³³

The pathophysiology of acquired von Willebrand syndrome involves a reduction in circulating VWF (and its associated factor VIII molecule), generally because of rapid VWF turnover in the circulation.³⁸¹ VWF levels and multimer patterns may simulate type I, II or III von Willebrand disease. In lymphoproliferative disorders, a specific, often nonneutralizing anti-VWF antibody is present,^{321,352,377,399} whereas in autoimmune disorders, anti-VWF antibodies are part of a generalized autoimmune response.⁴⁰⁰ In other situations, the syndrome may result from increased adsorption of VWF by tumor cells (e.g., Wilms tumor, osteosarcoma⁴⁰¹) or platelets (myeloproliferative neoplasms),^{315,350,402–404} increased VWF proteolysis (e.g., aortic stenosis, ventricular assist devices), or decreased VWF production (hypothyroidism).^{381,405,406}

Mucocutaneous bleeding should raise the suspicion of acquired von Willebrand syndrome in patients without a prior personal or

family history of bleeding. This is especially important in patients with a known autoimmune, lymphoproliferative, or myeloproliferative disorder.^{315,381} Diagnostic evaluation includes measurements of factor VIII activity, VWF antigen, ristocetin cofactor activity, and VWF multimer analysis.⁴⁰⁷ The presence of an *in vitro* inhibitor may, or may not, be detected depending on whether the antibody binds to VWF and neutralizes its function or merely leads to accelerated VWF clearance by the reticuloendothelial system.³¹⁵ An abnormally high ratio of VWF propeptide to von Willebrand antigen may be present as a result of the rapid clearance of von Willebrand antigen but not VWF.⁴⁴

Given the uncommon prevalence of this syndrome, reports of patient management have been retrospective and largely anecdotal. Treatment should be reserved for patients with active bleeding or those who are likely to bleed if left untreated.^{352,381} Infusions of DDAVP^{321,398,400} or factor VIII/VWF concentrates^{408,409} may be useful, although the rapid clearance of VWF may limit efficacy. Treatment has included glucocorticoids or rituximab in patients with lupus,^{231,385,410} and recombinant factor VIIa,⁴¹¹ or high-dose IVIG.^{190,384,412} High-dose IVIG is particularly effective when acquired von Willebrand syndrome is associated with a lymphoproliferative disorder or, as discussed in the section “Dysproteinemias,” with an IgG monoclonal gammopathy of undetermined significance. IVIG likely acts by delaying VWF clearance via reticuloendothelial cell blockade, although other mechanisms have been postulated.^{297,369,370,379,380,397,413} Treatment of the underlying disease can be effective in some situations^{381,414,415} (e.g., hypothyroidism with thyroid replacement,^{416,417} Gaucher disease with enzyme replacement therapy,³⁹¹ and extreme thrombocytosis with cytoreduction^{233,315,323,418}). As with inherited von Willebrand disease, longstanding acquired von Willebrand syndrome can be associated with and complicated by gastrointestinal tract arteriovenous malformations, resulting in severe bleeding.⁴¹⁹ An example of such gastrointestinal bleeding is found in patients with severe aortic stenosis and referred to as Heyde syndrome. In this situation, valve replacement can correct the hemostatic defect.^{387,420}

● SYSTEMIC DISORDERS ASSOCIATED WITH ABNORMAL PLATELET FUNCTION

UREMIA

Definition and History

In the predialysis era, hemorrhage occurred in approximately 50 percent of uremic patients and was a cause of death in approximately 30 percent.^{421,422} With the advent of dialysis, the frequency of spontaneous hemorrhage in patients with renal failure has decreased.⁴²² Experience with percutaneous renal biopsy in several thousand patients with renal disease supports the notion that the hemostatic defect in patients with renal disease is usually mild. Although the incidence of small perirenal hematomas following biopsy may be as high as 85 percent when patients are examined by computerized tomography, gross hematuria is observed in only 5 to 10 percent of cases and is usually transient.^{423,424} Severe bleeding following biopsy requiring surgical intervention is even less common and usually can be attributed to factors other than a uremic hemostatic defect, such as needle lacerations of the kidney or spleen, anomalous vessels, heparin anticoagulation, or the presence of amyloid in the kidney.

Etiology and Pathogenesis

The hemostatic defect in uremia has been attributed to defects in platelet function and appears to be multifactorial.⁴²⁵ One prominent factor is renal failure-associated anemia.⁴²⁶ A lowered hematocrit *ex vivo*

induces a defect in platelet adhesion that can be corrected by increasing the hematocrit to 30 percent or more.⁴²⁷ In uremic patients, successful treatment of anemia with red blood cell transfusion or recombinant human erythropoietin (EPO) results in partial or complete correction of prolonged bleeding times when the hematocrit is increased to 27 to 32 percent.^{428–431} The effect of anemia on primary hemostasis is not unique to uremia. In normal individuals, the bleeding time correlates with the hematocrit and bleeding times can be prolonged in patients with severe anemia of any etiology.⁴²⁶ Red cells may have a beneficial effect on hemostasis both because they displace platelets toward the periphery of the column of circulating blood⁴³² and they may enhance platelet reactivity.¹⁴

Because correction of anemia does not always return the bleeding time to normal, other factors present in renal failure may perturb platelet function.⁴²⁷ Ristocetin-induced platelet aggregation, a surrogate for VWF binding to the platelet GPIb-IX-V complex, may be decreased in uremia. However, plasma VWF concentrations are normal or elevated in renal failure⁴³³ and qualitative VWF abnormalities have not been uniformly observed.^{434,435} Mixing studies using uremic platelets and normal plasma, and vice versa, do not demonstrate consistent quantitative or qualitative abnormalities in GPIb-IX-V.^{434–436} Nonetheless, uremic plasma can inhibit the adhesion of normal platelets to denuded human umbilical artery segments, whereas uremic platelets adhere normally in the presence of normal plasma.⁴³⁴ Because the defective adhesion appears independent of VWF, an unidentified component of uremic plasma may be responsible for the adhesion defect.⁴³⁴ Uremic platelets also exhibit markedly reduced spreading on the sub-endothelium of rabbit vessels, a defect attributed to impaired VWF binding to platelet integrin $\alpha_{IIb}\beta_3$.⁴³⁷ Because VWF binding to integrin $\alpha_{IIb}\beta_3$ requires platelet stimulation, this observation suggests a uremia-induced defect in platelet signal transduction.

There are a number of reports describing defective agonist-induced platelet activation in uremic patients, including reduced fibrinogen binding, aggregation, and secretion. These abnormalities may be retained after platelets are separated from uremic plasma and in some cases, uremic plasma imparts the defect to normal platelets.⁴³⁸ Furthermore, the ability of activated platelets to express procoagulant activity is reduced in uremia.⁴³⁹ These functional defects likely result from uremia-induced abnormalities in platelet biochemistry, including reduced agonist-induced increases in cytoplasmic free calcium,⁴⁴⁰ reduced release of arachidonic acid from platelet phospholipids,⁴²¹ and reduced conversion of released arachidonic acid to PG endoperoxides and TXA₂.^{138,441,442}

A number of dialyzable and nondialyzable substances have been reported to be responsible for the platelet function defects in uremia,⁴⁴³ but urea itself is not responsible. *Ex vivo* platelet aggregation can be inhibited by small dialyzable substances, such as guanidinosuccinic acid and phenolic acids, as well as by poorly characterized “middle molecules” at concentrations found in uremic plasma.^{444,445} Venous and arterial segments from uremic patients have been reported to produce more PGI₂ than segments from normal individuals, an abnormality not corrected by dialysis.⁴⁴⁶ Altered NO metabolism has been observed in uremia.^{447,448} In a uremic rat model, defective platelet adhesion was normalized by an inhibitor of NO formation,⁴⁴⁹ suggesting that increased NO synthesis by endothelial cells or platelets is at least partially responsible for the defective platelet function.⁴⁵⁰ Why renal failure increases NO synthesis is not entirely clear, although exposing endothelial cells to guanidinosuccinic acid can mimic the effects of NO, suggesting that retained guanidinosuccinic acid may be the relevant substrate.⁴⁵¹ Uremia has been reported to upregulate the γ^L system for L-arginine transport into platelets, enabling platelets to maintain or enhance NO synthesis, even in the face of low circulating L-arginine concentrations.^{452,453}

By contrast, some substances found in high concentrations in uremic plasma, such as urea and parathyroid hormone, appear to play no role in platelet dysfunction.⁴⁵⁴

Concurrent medications and thrombocytopenia must always be considered when a patient with renal failure exhibits a bleeding tendency. Aspirin can prolong the bleeding time inordinately in uremia. Unlike aspirin's effect on COX, this effect is transient and correlates with blood levels of aspirin.^{34,35} Bleeding may be potentiated by the administration of heparin during hemodialysis; in this situation, the use of an ethylene-vinyl alcohol copolymer hollow fiber dialyzer or intermittent saline infusion and high blood flow rates may eliminate the need for heparin.⁴⁵⁵ β -Lactam antibiotics that prolong the bleeding time may have a greater effect in uremic patients and increase the occurrence of bleeding.⁴⁵⁶

Mild thrombocytopenia has been reported in chronic renal failure, particularly in patients on dialysis,⁴⁵⁷ as a result of diminished marrow production and decreased platelet survival.⁴⁵⁸ Serum thrombopoietin levels in hemodialysis patients are increased,^{457,459} perhaps reflecting increased platelet turnover or a decrease in megakaryocyte mass. But when platelet counts are greater than $100 \times 10^9/L$, it is necessary to consider whether a systemic disease or medication, such as multiple myeloma, systemic vasculitis, hemolytic uremic syndrome, eclampsia, renal allograft rejection, or heparin, could be responsible for bleeding in a uremic patient.

Clinical and Laboratory Features

Despite dialysis, abnormal platelet function in uremia remains a clinical issue because it may contribute to bleeding following surgery or trauma or in conjunction with anatomic lesions of the gastrointestinal tract.^{441,455} The bleeding time has often been used as an indication of hemorrhagic risk in uremia, but critical reviews of the literature indicate that it is not appropriate to use for this purpose.^{460,461}

Therapy

Abnormal platelet aggregation is common in uremic patients, but by itself is not an indication for therapeutic intervention.⁴²⁵ The frequency of excessive bleeding after biopsies or other surgical procedures in uremic patients who have not received specific treatment is not known, but may be uncommon. Thus, if bleeding does complicate a procedure, a thorough search for causes of bleeding other than uremia should be initiated without assuming that uremia is the etiology. However, when therapy for a uremic bleeding diathesis is necessary, the uremic platelet defect can usually be successfully treated.

There are several therapeutic maneuvers that can either partially or completely correct an abnormal bleeding time in uremic patients and anecdotal observations indicate that they may also improve hemostasis. Because prospective studies comparing various treatment regimens have not been performed, the choice of therapy should be based on the severity of the bleeding, the anticipated severity of the hemostatic stress imposed by surgery or trauma, the predicted duration of the therapeutic effect, and the risks of therapy.

The mainstay of therapy is *dialysis*. Intensive dialysis can correct the bleeding diathesis in many patients, but is only partially effective in others.⁴⁶² Peritoneal dialysis and hemodialysis are equally effective.^{462,463} If a patient undergoing dialysis bleeds, it may be worthwhile to increase the intensity of the dialysis.

In uremic individuals, increasing the hematocrit by transfusion or treatment with recombinant human EPO to 27 to 32 percent is often associated with diminished clinical bleeding.^{428-430,464,465} A number of reports suggest that EPO has an effect on platelets independent of an increase in hematocrit,⁴³¹ perhaps the result of an increase in the number of young platelets in the circulation.⁴⁶⁶

DDAVP, a vasopressin analogue whose pressor effects are substantially less than its antidiuretic effects, causes the release of VWF from tissue stores, has been reported to shorten the bleeding time in 50 to 75 percent of patients with uremia. In many cases, surgery has been carried out safely after administration of this drug, although no controlled trials have been performed.⁴⁶⁷ DDAVP is usually administered intravenously in a dose of 0.3 mcg/kg over 15 to 30 minutes (maximum dose: 20 mcg) but it is also effective at this dose when given subcutaneously.⁴⁶⁷ Alternatively, the drug can be given intranasally.⁴⁶⁸ Improvement in the bleeding time is seen within 30 to 60 minutes of administration, lasts for approximately 4 hours, and roughly correlates with the rise in the plasma levels of VWF and the appearance in the circulation of high-molecular-weight VWF multimers.⁴⁶⁷ In some patients, the drug has been given repeatedly at 12- to 24-hour intervals, although tachypylaxis can occur.⁴⁶⁹

Side effects of DDAVP have been mild and uncommon and have included a 10 to 15 percent decrease in mean arterial pressure, a 20 to 30 percent increase in pulse rate, facial flushing, water retention, and hyponatremia leading to seizures; the latter is more common after repeated administration and when fluids are given freely.⁴⁶⁷ Water retention and hyponatremia have not been observed in patients whose kidneys cannot respond to the hormone. Several uremic and nonuremic individuals with atherosclerosis have been reported to develop stroke or myocardial infarction after DDAVP administration, although such complications appear to be rare.^{470,471} If dialysis is not effective, DDAVP is the treatment of choice for uremic bleeding, particularly if only a short-term effect is required.⁴⁶⁷

Conjugated estrogens at a dose of 0.6 mg/kg intravenously for 5 days have also been reported to shorten the bleeding time in most, but not all, uremic individuals, both in uncontrolled studies and in randomized, double-blind studies.^{34,472-474} They may also be useful in some patients with uremia who bleed from gastrointestinal telangiectasia.⁴⁷⁵ No changes in the plasma levels or multimer distribution of VWF have been noted with this treatment and it has been postulated that the active component in conjugated estrogens, 17β -estradiol, acts through an estrogen receptor mechanism.⁴⁷⁶

Lastly, uncontrolled studies suggest that infusions of cryoprecipitate can shorten the bleeding time in uremic patients and ameliorate bleeding.²⁴³ However, others have reported inconsistent results,⁴⁷⁷ and because of concerns of viral contamination, cryoprecipitate is very rarely used for this indication.

ANTIPLATELET ANTIBODIES

Definition and History

Antibody binding to platelets in several pathologic conditions, including immune thrombocytopenia (ITP), systemic lupus erythematosus (SLE), and platelet alloimmunization can cause thrombocytopenia as a result of decreased platelet survival. Less commonly, bleeding times may be shorter than expected for the degree of thrombocytopenia, suggesting enhanced platelet function.⁴⁷⁸ On occasion, platelet function is impaired in ITP.⁴⁷⁹⁻⁴⁸³

Etiology and Pathogenesis

The mechanism by which autoantibodies or alloantibodies impair platelet function is likely antibody binding to specific platelet GPs. Most antiplatelet antibodies are directed against integrin $\alpha_{IIb}\beta_3$,⁴⁷⁹⁻⁴⁸² but antibodies directed against GPIb-IX-V, integrin $\alpha_2\beta_1$, and GPIV have been detected as well.^{484,485} In most instances, the functional consequences of antibody binding are obscured by the presence of thrombocytopenia. However, patients have been reported with normal platelet counts, absent platelet aggregation, autoantibodies against integrin $\alpha_{III}\beta_3$,

and a bleeding diathesis reminiscent of Glanzmann thrombasthenia.^{479–482,486–489} Similarly, autoantibodies against GPIb and integrin $\alpha_{IIb}\beta_3$ have been detected that selectively inhibit ristocetin-induced platelet aggregation^{490,491} and collagen-induced platelet aggregation,^{492,493} respectively. A patient with ITP has also been identified whose anti-GPVI autoantibody produced GPVI shedding from the platelet surface and platelets unresponsive to stimulation by collagen.⁴⁹⁴

Besides interfering with platelet function, some autoantibodies can activate platelets and induce aggregation and secretion *in vitro*. Such antibodies can activate platelets through immune complex binding to platelet Fc receptors, by depositing sublytic quantities of the membrane attack complex of complement (C5b-9) on the cell surface,⁴⁹⁵ or by binding to a specific membrane antigen.²⁴⁶ The prototypic example of this phenomenon is heparin-induced thrombocytopenia in which antibodies bound to neopeptides exposed on the platelet factor 4 molecule by heparin activate platelets after binding to platelet Fc receptors (Chap. 118).⁴⁹⁶

Clinical Laboratory Features and Therapy

Platelet dysfunction should be suspected in any patient with ITP or SLE who has mucocutaneous bleeding with a platelet count that is not ordinarily associated with bleeding (e.g., equal to or greater than approximately $30 \times 10^9/L$). Likewise, this scenario has been described occasionally in patients with Hodgkin disease,^{347,480} non-Hodgkin lymphoma and myeloma,^{497,498} and hairy cell leukemia.⁴⁹⁹ The clinical spectrum of autoimmune platelet dysfunction may also include some individuals with “easy bruising” and a normal platelet count. These patients may have ITP with “compensated thrombocytolysis,” as a substantial proportion have circulating antiplatelet antibodies and large platelets.⁵⁰⁰

Patients with antiplatelet antibodies may exhibit defective platelet function *in vitro*, even if they do not manifest a prolonged bleeding time or excessive bleeding. These deficits include impaired platelet aggregation to ADP, epinephrine, and collagen,^{501–504} as well as impaired adhesion to the subendothelial matrix.²⁰ The most frequently reported abnormalities are absence of platelet aggregation in response to low concentrations of collagen and absence of the second wave of aggregation in response to ADP or epinephrine. This pattern is identical to that seen in individuals with inherited storage pool disease. In fact, both ITP and SLE may be associated with an acquired form of storage pool disease manifested by a reduced platelet content of dense- and α -granule components.^{432,505} In one report, platelets in ITP also exhibited an activation defect manifested by impaired conversion of arachidonic acid to TXA_2 .⁵⁰⁶

Because antibody-mediated platelet dysfunction and bleeding almost always occur in the setting of ITP, therapeutic efforts should be directed to the treatment of these disorders.

CARDIOPULMONARY BYPASS

Definition and History

Circulating blood through an extracorporeal bypass circuit during cardiac surgery induces a variety of hemostatic defects. The most significant of these are thrombocytopenia, platelet dysfunction, and hyperfibrinolysis.^{507–509} At their extreme, these defects can result in substantial postoperative bleeding that may last hours to days after bypass. Approximately 5 percent of patients experience excessive postoperative bleeding after extracorporeal bypass; roughly half of the bleeding is from surgical causes; much of the remainder is caused by qualitative platelet defects and hyperfibrinolysis.

Etiology and Pathogenesis

Thrombocytopenia is a consistent feature of bypass surgery.^{126,508} Typically, platelet counts begin to decrease to approximately 50 percent of presurgical levels within the first half hour after the initiation of

bypass, but thrombocytopenia can occur within 5 minutes and often does not nadir for the first few days.^{507,509,510} The major factor responsible for thrombocytopenia is hemodilution from priming the pump with colloid or crystalloid solutions, but it is often more profound than can be accounted for by hemodilution alone.^{509–511} Platelet adhesion to artificial surfaces in the circuit has been demonstrated by scanning electron microscopy.⁵¹² The mechanism of this interaction is uncertain, but it may be a result of the deposition of fibrinogen on the bypass circuit and platelet adhesion mediated by integrin $\alpha_{IIb}\beta_3$.⁵¹³ Less-common causes of thrombocytopenia during bypass are disseminated intravascular coagulation, sequestration of damaged platelets in the liver, and heparin-induced thrombocytopenia.⁵¹⁴ Like antibodies against the complex of platelet factor 4 and heparin that are commonly detected after bypass surgery and can be responsible for heparin-induced thrombocytopenia,⁴⁹⁶ antibodies against protamine and protamine/heparin complexes are commonly detected as well.^{82,515,516} Such antibodies may contribute to the thrombocytopenia and possibly to thromboembolic events following cardiopulmonary bypass.⁵¹⁷

Qualitative platelet defects are the primary nonstructural hemostatic defects induced by the bypass circuit^{508,518} and are manifest as abnormal *ex vivo* platelet aggregation, decreased ristocetin-induced platelet agglutination, deficiency of platelet α and δ granules, release of soluble CD40 ligand, and the generation of platelet microparticles.^{507,509,510,519–522} The severity of these abnormalities correlates with the duration of extracorporeal bypass⁵²³ and they generally resolve within 2 to 24 hours.⁵⁰⁸

Bypass-induced defects in platelet function are likely caused by platelet activation and fragmentation,^{521,524} hypothermia, contact with fibrinogen-coated synthetic surfaces, contact with the blood-air interface, cardiomy suction and retransfusion of cardiomy suction blood, and platelet exposure thrombin, plasmin, ADP, or complement.^{513,519,525–528} Drugs such as heparin, protamine, integrin $\alpha_{IIb}\beta_3$ antagonists, and aspirin, as well as the production of fibrin degradation products, can also impair platelet function.^{126,529–531} Controversy exists about the significance of these defects *in vivo*. Some investigators suggest that the entire qualitative platelet defect is a result of the use of heparin during bypass and its inhibitory effect on thrombin activity⁵²⁹; however, this would not account for the bleeding diathesis that can exist hours after heparin reversal.

Hyperfibrinolysis may also contribute to the bleeding diathesis associated with cardiopulmonary bypass.^{532,533} This is likely from thrombus formation in the pericardial cavity followed by local, and subsequently systemic, fibrinolysis.⁵³² The relevance of hyperfibrinolysis to postbypass bleeding is bolstered by the efficacy of antifibrinolytic therapy in minimizing cardiopulmonary bypass surgery blood loss.

Therapy

A preoperative evaluation of cardiac surgical candidates should include a history of bleeding in either the patient or family member. Some authors recommend a screening prothrombin time, partial prothrombin time, and bleeding time even in individuals with no history of bleeding.⁵³⁴ However, the validity of this approach is controversial.⁵³⁵ Regardless, prophylactic transfusion of allogeneic blood components is not indicated.^{508,536,537} Preoperative administration of recombinant human EPO has been reported to reduce the need for allogeneic blood transfusion in undergoing elective open-heart surgery.^{538–541} Cell washes are now often used during bypass surgery and the collected washed autologous red blood cells are reinfused after completion of cardiopulmonary bypass. In addition, blood collected from chest tube drainage has been reinfused to minimize allogeneic transfusions.⁵⁴¹ The safety of transfusing large quantities of blood by this technique has not fully been established.^{528,542}

A number of maneuvers have been taken to reduce the hemostatic abnormalities associated with cardiac surgery. These include coating the artificial surfaces of cardiopulmonary bypass devices with heparin,⁵⁴³⁻⁵⁴⁷ using centrifugal rather than roller pumps,⁵⁴⁸ use of a number of pharmacologic agents,⁵⁴⁹ and performing coronary artery surgery without bypass.^{301,550} Off-pump coronary artery bypass surgery appears to preserve platelet function, but concerns have been raised about adverse thromboembolic events postsurgery because of the concurrence of normal platelet function, late thrombin generation, and reduced fibrinolysis.⁵⁵¹⁻⁵⁵³ Several pharmacologic maneuvers have been tried to assist in the management of postoperative bleeding. Postoperative patients with a prolonged bleeding time and excessive blood loss may respond to DDAVP, as evidenced by a shortening of the bleeding time. However, results of trials using this agent have been contradictory, some studies showing a reduced blood loss and most showing no benefit.⁵⁵⁴⁻⁵⁵⁶ Based on the assumption that platelet activation during bypass could be a major cause of postoperative platelet dysfunction, infusion of platelet activation inhibitors such as PGE₁, PGI₂, or stable PGI₂ analogues have been carried out in animal models and in humans. By increasing platelet cAMP and reducing platelet responsiveness, these agents prevent bypass-induced thrombocytopenia and platelet dysfunction. However, randomized trials using PGI₂ and its analogue, iloprost, have not shown a clear overall benefit, in part because of significant toxicity, including hypotension.^{123,557} Recombinant factor VIIa has been recommended to treat uncontrolled postoperative bleeding that has not responded to routine hemostatic therapy.⁵⁵⁸ However, the off-label use of recombinant factor VIIa is associated with an increased risk for arterial and venous thromboembolism⁵⁵⁹ and a retrospective case-matched review of patients who had received recombinant factor VIIa perioperatively during major cardiac surgery indicated that it was associated with worse survival.²²³ Nonetheless, it remains a potentially useful therapeutic consideration in view of the prognosis of uncontrolled postoperative hemorrhage.⁵⁶⁰ Based primarily on the cardiovascular complications encountered by patients in two randomized studies of the use of parecoxib/valdecoxib to treat pain after cardiac surgery, the use of coxibs as well as traditional NSAIDs appears contraindicated in this setting.^{561,562}

Inhibiting fibrinolysis using ϵ -aminocaproic acid or tranexamic acid during cardiopulmonary bypass can reduce mediastinal blood loss and transfusion requirements.⁵⁴⁹ Aprotinin (Trasylol), a broad-spectrum protease inhibitor, was also used for this purpose, but observational studies,⁵⁶³⁻⁵⁶⁵ as well as a blinded clinical trial,⁵⁶⁶ revealed that its use is associated with serious end-organ damage and a higher mortality than the use of ϵ -aminocaproic acid or no antifibrinolytic agent.

The most important determinant of blood loss following cardiopulmonary surgery is the surgical procedure itself. If excessive nonsurgical postoperative bleeding occurs, one should verify that the patient is no longer hypothermic and that heparin has been fully reversed. At this point, the administration of pharmacologic agents, along with judicious transfusions of platelets, cryoprecipitate, fresh frozen plasma and red blood cells is appropriate.

MISCELLANEOUS DISORDERS

Measurements of hemostatic function are frequently abnormal in patients with end-stage and fulminant liver disease and result from decreased coagulation factor production, fibrinolysis, dysfibrinogenemia, thrombocytopenia as a result of hypersplenism and thrombopoietin deficiency, as well as disseminated intravascular coagulation (DIC).^{425,567} However, the clinical consequences of these laboratory abnormalities have been reassessed because they do not take into account that both anti- and prohemostatic pathways are perturbed in liver disease.^{568,569} Thus, hemostasis in liver disease is considered to be

“rebalanced,” although it remains unstable, with patients prone to both bleeding and thrombosis. Chronic liver disease can be associated with a prolonged bleeding time and reduced platelet aggregation and procoagulant activity,^{567,570,571} but there is no evidence for a platelet function defect specific to liver disease.⁵⁷² Rather, they are the result of multiple factors, including thrombocytopenia, hypofibrinogenemia, and anemia, none of which imply an intrinsic defect in platelet function.⁵⁷³ Regardless, the prolonged bleeding in these patients may respond to infusion of DDAVP,⁵⁷⁴ but clinical relevance of this observation is uncertain.⁵⁷⁵

Patients with DIC may exhibit reduced platelet aggregation and acquired storage pool deficiency.^{576,577} These result from platelet activation *in vivo* by thrombin or other agonists. Alternatively, elevated levels of fibrin(ogen) degradation products and the low fibrinogen levels that accompany DIC may contribute to the platelet defect. Although purified low-molecular-weight fibrinogen-degradation products can impair platelet aggregation, this effect requires concentrations of degradation products unlikely to occur *in vivo*.⁵⁷⁸ Moreover, it is difficult to assess the significance of platelet dysfunction in most patients with DIC because of the simultaneous presence of thrombocytopenia and other hemostatic defects.

Decreased platelet aggregation and secretion in response to ADP and epinephrine has been reported in Bartter syndrome, a group of rare inherited disorders characterized by severe restrictions of salt reabsorption by the thick ascending limb of Henle, perhaps caused by excessive PGE₂ synthesis.⁵⁷⁹⁻⁵⁸² However, reviews of series of patients with Bartter syndrome make no mention of hemostatic problems⁵⁸⁰ so that the clinical significance of the platelet aggregation abnormalities is doubtful.

In addition to thrombocytopenia, platelet dysfunction has been observed in some patients with hemorrhagic fevers caused by Dengue, Hanta, Lassa, Junin, and Ebola viruses.⁵⁸³ There are also isolated reports of a slight prolongation of the bleeding time and/or *ex vivo* platelet function defects in a number of other clinical conditions. These include non-thrombocytopenic purpura with eosinophilia,⁵⁸⁴⁻⁵⁸⁶ atopic asthma and hay fever,⁵⁸⁷ acute respiratory failure,⁵⁸⁸ and Wilms tumor elaborating hyaluronic acid.⁵⁸⁹ The clinical significance of these associations is not clear.

CHAPTER 122

THE VASCULAR PURPURAS

Doru T. Alexandrescu and Marcel Levi

SUMMARY

Purpura, the clinical manifestation of blood extravasation into mucosa or skin, results from various conditions, including rheumatologic, infectious, dermatologic, traumatic, and hematologic disorders. This chapter does not detail purpura resulting from quantitative or functional defects in hemostasis and coagulation, such as deficiencies of platelets or coagulation factors; these causes are discussed in other chapters (e.g., thrombocytopenia in Chap. 117; coagulation factor deficiencies in Chaps. 123 and 124).

The differential diagnosis of the disparate causes of noncoagulopathic purpura is best approached by stratifying purpura into three types of lesions: (1) palpable or retiform and noninflammatory, such as hyperglobulinemic purpura of Waldenström; (2) palpable or nonpalpable but inflammatory, such as Henoch-Schönlein purpura; and (3) nonpalpable and noninflammatory, such as senile purpura. By accounting for palpability, presence of inflammation, size, and shape, the differential diagnosis of a particular lesion can be significantly reduced.

DEFINITION AND DIAGNOSTIC APPROACH

Purpura refers to visible hemorrhage into mucous membranes or skin, which corresponds to extravasation of red blood cells around small dermal vessels and chronic hemosiderin deposition.¹ Purpuric lesions, by definition, do not blanch completely upon compression, as opposed to erythema. Blanching is commonly tested by compression of skin lesions with a glass slide, referred to as diascopy (Fig. 122-1). Certain conditions give rise to lesions that mimic purpura with incomplete blanching upon diascopy, but are not purpura because no hemorrhage has occurred. Examples include disorders that impede on the red cell flow, such as tortuous veins.¹

Assessing lesion palpability is the first step in evaluating purpuric lesions (Fig. 122-2). The causes for palpability are varied and include fibrin deposition, localized edema, significant cellular infiltration, and subcutaneous extravasation of red blood cells.

Inspecting the lesion for inflammatory changes is the next step in evaluating purpuric lesions. The presence of pain, erythema, and palpation for warmth and localized swelling are signs of inflammation and suggest a vasculitis or immune complex disorder.

Acronyms and Abbreviations: ANCA, antineutrophil cytoplasmic antibody; APS, antiphospholipid syndrome; CSS, Churg-Strauss syndrome; DIC, disseminated intravascular coagulation; HCV, hepatitis C virus; HHT, hereditary hemorrhagic telangiectasia; HP, hypergammaglobulinemic purpura; HSP, Henoch-Schönlein purpura; MELAS, mitochondrial encephalopathy, lactic acidosis, stroke-like; SLE, systemic lupus erythematosus; WG, Wegener granulomatosis.

The shape of a purpuric lesion, either round or retiform (branching), is important in assessing the lesion. In the absence of accompanying inflammation, retiform purpuric lesions suggest small vessel occlusion. A retiform, inflammatory purpuric lesion supports the diagnosis of vasculitis as a result of immunoglobulin (Ig) complex formation.² Small, focal areas of hemorrhage are referred to as *petechiae* (≤ 4 mm). Larger lesions are referred to as *intermediate* or *midsize purpura* (>4 mm, <1 cm) or *ecchymosis* (≥ 1 cm).³

Purpuric lesions frequently appear purple; however, they can take on a variety of colors, according to the age of the lesion and the oxygen saturation of the hemoglobin in the extravasated blood. Ecchymosis usually starts as blue or purple, evolves to a greenish brown (a mixture of blue and yellow), and ultimately changes with variable speed to yellow as hemoglobin degrades to bilirubin.⁴ These examples of hemorrhage into the dermis must be distinguished from telangiectasia, which are vascular anomalies that blanch with pressure (see Fig. 122-1). Tables 122-1 through 122-3 classify the etiologies for purpura discussed in this chapter.

PALPABLE NONINFLAMMATORY PURPURIC LESIONS

See Table 122-1.

DYSPROTEINEMIAS

Cryoglobulinemia

Cryoglobulinemia refers to the presence in plasma of cold-insoluble immunoglobulins,⁵ and is a secondary finding associated with several disease states. Cryoglobulins are commonly present in low concentrations, therefore approximately 90 percent of patients are asymptomatic or have minimal symptoms.⁶ Symptoms occur when the abnormal protein precipitates at the temperatures present in superficial venules in the skin and acral parts of the body. Cryoglobulinemia syndromes are divided into three main types based on the immunoglobulin composition of the precipitate. Type I cryoglobulinemia results from the accumulation of monoclonal IgG, IgM, or IgA. It is most commonly seen in association with lymphoproliferative disorders, such as myeloma, Waldenström macroglobulinemia, or lymphoma. Type II, or mixed cryoglobulinemia involves formation of complexes composed of polyclonal IgG with monoclonal immunoglobulins, typically IgM with anti-IgG specificity. Exposure to various exogenous antigens appears to cause polyclonal immunoglobulin production, with activity against bacteria, viruses, and fungi. Mixed cryoglobulinemia is commonly seen secondary to hepatitis C virus (HCV) infection,⁷ HIV, collagen vascular disorders, and hematologic neoplasias.^{8,9} In mixed cryoglobulinemia secondary to HCV infection, the presence of active cutaneous vasculitis correlates with increased levels of the B-cell-attracting chemokine 1 (CXCL13).¹⁰ This process manifests with petechiae of the legs, palpable purpura, and necrotic skin ulcerations. First-line treatment includes use of interferon- α or other antiviral agents, often with adjunct glucocorticoids or plasmapheresis.¹¹ Direct treatment of the HCV infection with ribavirin, interferon, or other antiviral therapy, such as the protease inhibitors, ameliorates this associated lymphoproliferative disorder.¹² Deposition of immune complexes on vessel walls leads to tissue damage in the vasculature, nerves, joints, and skin leading to the hallmark findings of mixed cryoglobulinemia: weakness, arthralgia, and purpura. This purpura often is palpable and is accompanied by areas of hemorrhagic necrosis (Fig. 122-3) and occasionally follicular pustular purpura. Other cutaneous manifestations include lower-extremity ulcerations, urticaria, Raynaud phenomena, and subungual purpura (Fig. 122-4). Type III

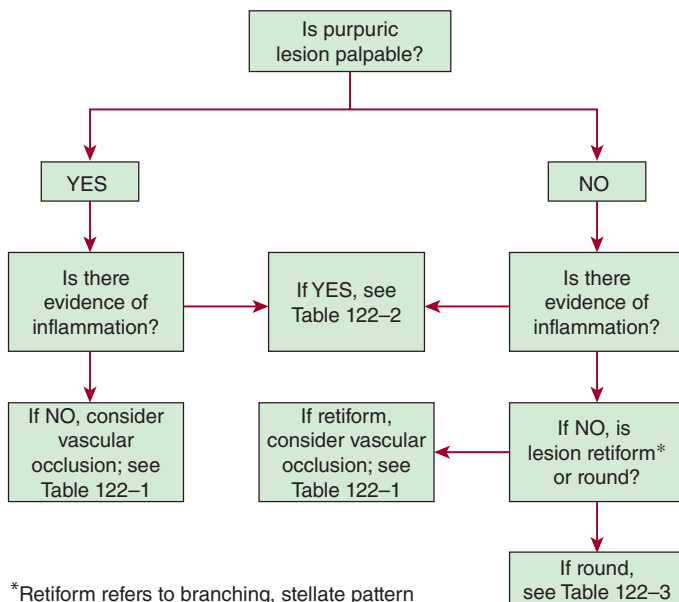

A

B

Figure 122-1. A. Spider telangiectasia. B. Blanching of spider telangiectasia. Note that spider telangiectasia blanches with diascopy.

*Retiform refers to branching, stellate pattern

Figure 122-2. Bedside approach to purpuric lesion diagnosis.

TABLE 122-1. Palpable Noninflammatory Purpuric Lesions

- A. Dysproteinemias
 1. Cryoglobulinemia (see Figs. 122-3 and 122-4)
 2. Waldenström hyperglobulinemic purpura (see Fig. 122-5)
 3. Light-chain vasculopathy
 4. Cryofibrinogenemia
- B. Thrombotic
 1. Heparin necrosis
 2. Warfarin necrosis (see Fig. 122-6)
 3. Protein C and protein S deficiencies
 4. Paroxysmal nocturnal hemoglobinuria
 5. Antiphospholipid syndrome (see Fig. 122-8)
 6. Livedoid vasculitis
- C. Embolic
 1. Cholesterol emboli (see Fig. 122-9)
 2. Cutaneous calciphylaxis
 3. Emboli from intracardiac thrombi
- D. Arthropod bites

TABLE 122-2. Palpable and Nonpalpable Inflammatory Purpuric Lesions

- A. Pyoderma gangrenosum (see Fig. 122-7)
- B. Sweet syndrome (see Fig. 122-10)
- C. Behçet disease

Figure 122-3. Cryoglobulinemia: peripheral purpura.

cryoglobulinemia associates polyclonal IgG and IgM complexes, also resulting in symptoms of mixed cryoglobulinemia.⁶ It is associated with a variety of infections, systemic lupus erythematosus (SLE), and poststreptococcal glomerulonephritis.

Waldenström Hyperglobulinemic Purpura

A polyclonal increase of immunoglobulins, most commonly IgG₁, appears to be responsible for the varied cutaneous findings seen in this hypergammaglobulinemic purpura (HP). Waldenström first described a hyperproteinemic syndrome characterized by hypergammaglobulinemia, recurrent purpura, elevated erythrocyte sedimentation rate, and anemia.¹³ Most commonly seen in young women, this syndrome is associated with a large number of autoimmune disorders, including rheumatoid arthritis, Sjögren syndrome, SLE, hepatitis C, polymyositis, and sarcoidosis. Discrete to confluent collections of lower limb petechiae are its most common skin findings (Fig. 122-5), but lesions can occur in various body locations.¹⁴ Although lesions are usually self-limited and resolve in 7 to 10 days, recurrence of purpura is common and is associated with exposure to cold temperatures or increases in hydrostatic pressure, such as with the use of tight stockings or prolonged standing.¹⁵ Clinical manifestations consist of palpable purpura or diminutive macular erythematous lesions occurring on the lower legs. A reticulate pattern of purpura has been described.¹⁶ Development of edema and arthralgia has also been described.¹⁷

Figure 122-4. Cryoglobulinemia: subungual purpura.

Figure 122-5. Waldenström hyperglobulinemic purpura. Note discrete and coalescing petechiae on lower limb.

Common histologic findings include perivascular infiltrates, hemorrhage, and vascular necrosis. In addition to a polyclonal increase in either IgA, IgM, or IgG, serology may reveal cryoglobulinemia, rheumatoid factor, or antinuclear antibodies.¹⁸ Imbalances in IgG subclass expression, usually because of a decrease in IgG₂, appear to be associated with recurrent infections.¹⁷ Development of antilymphocyte antibodies results in lymphopenia. Anti-Ro/SSA antibodies occur in up to 78 percent of HP patients, suggesting that screening for anti-Ro/SSA should be considered in cases suspicious for Waldenström.¹⁹

Light-Chain Vasculopathy

Precipitates of immunoglobulin light chains that form crystalline deposits in the skin cause hemorrhagic palpable purpura. A nonamyloid monoclonal light chain of predominant κ type is involved in two-thirds of the cases.^{20,21} Crystalline deposits are present in the skin and other tissues. Although the clinical presentation may mimic a systemic vasculitis, no histologic signs of inflammation are seen. Light-chain vasculopathy with cutaneous findings has also been described in association with multiple myeloma. Intravascular deposition of crystals containing IgG and λ light chains were found on immunohistochemical analysis and manifested with gangrene of the feet and intestinal perforation.²²

Cryofibrinogenemia

First described by Korst and Kratochvil in 1955, cryofibrinogenemia is a form of serum dysproteinemia characterized by formation of an abnormal cold-precipitable fibrinogen. Cutaneous manifestations include cyanosis, erythema, Raynaud phenomenon, and palpable purpura of the nose, ears, and distal extremities.²³ Tissue ischemia and gangrene may result. Pathogenesis of cryofibrinogenemia may involve an inhibition of normal fibrinolysis produced by a high plasma level of α_1 -antitrypsin and α_2 -macroglobulin proteases.²⁴ Cryofibrinogenemia is commonly secondary to thromboembolic disorders, metastatic malignancies, infections, and collagen vascular disease.²⁵ Treatment modalities include avoidance of cold, plasmapheresis, and danazol, an anabolic glucocorticoid, or immunosuppression with glucocorticoids or cytotoxic agents.

THROMBOTIC PURPURA

Heparin Necrosis

Cutaneous reactions to heparin administration vary greatly from a type I urticarial rash to purpuric plaques with cutaneous ulceration or necrosis.²⁶ The syndrome occurs after both subcutaneous and intravenous

Figure 122-6. Coumadin necrosis. Develops in acral areas and areas of fat deposition such as buttocks or breast. Typically, lesions develop 3 to 10 days after initiation of anticoagulant treatment and are caused by rapid clearing of protein C. The lesions are characterized microscopically by small-vessel thrombosis.

administration of unfractionated heparin, but it has also been rarely described after low-molecular-weight heparin.²⁷ A delayed-type hypersensitivity reaction to the medication is involved. Skin lesions appear within 1 to 2 weeks after treatment initiation and include necrotic purpuric lesions.²⁸ Development of cutaneous lesions is closely related to heparin-induced thrombocytopenia (Chap. 118), which involves antiplatelet factor 4 antibody-mediated platelet aggregation with development of thrombosis and microvascular occlusion.²⁷

Warfarin Necrosis

The development of painful erythematous plaques and nodules is a potential complication of warfarin therapy (Fig. 122-6). These lesions can rapidly become hemorrhagic and necrotic, leading to large areas of infarct with black eschar formation and subsequent skin sloughing. Purpura, vesicular, maculopapular, or urticarial eruptions can be encountered.¹ Warfarin-induced necrosis has a prevalence between 0.01 and 0.1 percent and presents typically 3 to 10 days after initiation of anticoagulant treatment.^{29,30} However, an atypical presentation can occur much later, for example, in a patient with protein S deficiency.^{31,32} Although warfarin necrosis tends to develop in areas of greatest fat deposition, such as breasts, thighs, and buttocks, acral areas, including penis, fingers, and toes, can also be involved.³³ Warfarin necrosis results from the rapid decrease of vitamin K-dependent coagulation factors of relatively short half-life, such as proteins C and S, while longer-lasting coagulation factors, such as factor II and factor X, are not yet decreased, resulting in a net procoagulant state. Microvascular occlusion of small dermal and subcutaneous vessels by fibrin deposits is seen on histologic analysis, but true vasculitis is infrequent.²⁹ Treatment involves prompt cessation of the vitamin K antagonist, along with administration of heparin and vitamin K, and occasionally surgical debridement. Because patients with protein C or S deficiency are at increased susceptibility to warfarin necrosis, heparin should always be administered in these patients prior to initiation of Coumadin.³⁴

Proteins C and S Deficiencies

Clinical manifestations of proteins C and S deficiencies include venous thromboembolism, warfarin-induced skin necrosis, and neonatal purpura fulminans (Chap. 129). Congenital and acquired deficiencies in these proteins can lead to palpable necrotic purpura and ecchymosis.^{35,36}

Erythematous purpuric lesions associated with homozygous protein C deficiency can develop within hours of birth and can rapidly progress to hemorrhagic necrosis.³⁷ Acquired deficiencies of protein C are associated with autoantibodies to protein C, antibiotics administration, septic shock, HIV, and liver disease (Chap. 127).³⁸ Acquired protein S deficiency may occur after varicella infection, when it is associated with the generation of antiprotein S immunoglobulins.³⁹ Protein repletion with fresh-frozen plasma or protein C concentrate is effective as initial treatment for protein C deficiency to help clear both cutaneous lesions and venous occlusion, while lifelong anticoagulant treatment is used to prevent recurrence.^{34,40}

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (Chap. 40) is a hematopoietic clonal disorder resulting in defective production of cell surface-binding proteins.⁴¹ Cutaneous manifestations are secondary to a hypercoagulable state and include palpable purpura, petechiae, ecchymosis, leg ulcers, plaques, necrosis, and hemorrhagic bullae.⁴² Parvovirus B19 may play an etiologic role in the development of cutaneous necrosis.⁴³ An association with pyoderma gangrenosum (Fig. 122-7)⁴⁴ and occurrence of purpura fulminans⁴⁵ have been described. Histology reveals formation of microvascular fibrin thrombi.⁴²

Antiphospholipid Syndrome

Antiphospholipid syndrome (APS) is a disease characterized by hypercoagulability associated with the presence of antibodies against phospholipids, such as anticardiolipin and lupus anticoagulant (Chap. 131).⁴⁶ Approximately 40 percent of patients with APS present with cutaneous lesions secondary to both large-vessel and microvascular thrombosis.⁴⁷ Skin manifestations include ecchymosis, livedo reticularis and racemosa, leg ulcerations, bullae, splinter hemorrhages, livedoid vasculopathy, superficial venous thrombosis, atrophie blanche, and extensive necrosis (Fig. 122-8).^{47,48} Presence of livedo reticularis is frequently the presenting symptom of APS, most commonly when the syndrome is secondary to SLE, and its presence commonly precedes vascular events.⁴⁹ Development of acute bullous purpura has been described.⁵⁰ Treatment includes anticoagulant agents with immunosuppressant administration for associated thrombocytopenia. Prevention of thromboembolic events with aspirin is of uncertain value.⁵¹

Figure 122-7. Pyoderma gangrenosum. A large number of systemic diseases are associated with pyoderma gangrenosum, including inflammatory bowel diseases, hematologic and solid malignancies, and rheumatologic disorders. Microscopically, the lesions are characterized by central necrotizing, neutrophilic infiltration, and a surrounding perivascular and intramural lymphocytic infiltration.

Figure 122-8. **A.** Antiphospholipid antibody syndrome. A number of skin lesions can be seen, including ecchymosis, livedo reticularis and racemosa, leg ulcerations, bullae, splinter hemorrhages, superficial venous thrombosis, atrophie blanche, and, as shown here, extensive necrosis. **B.** Anticardiolipin antibody. **C.** Lupus anticoagulant.

Livedoid Vasculitis

Livedoid vasculitis (segmental hyalinizing vasculitis) is a chronic recurrent thrombo-occlusive disorder characterized by the initial development of erythematous purpuric lesions with telangiectasis and peripheral petechiae, and lower-extremity ulcerations. Subsequent healing leads to atrophie blanche, a term that refers to the appearance of ivory-white stellate scars commonly surrounded by hyperpigmented areas and telangiectasia. These lesions appear to be caused by small-vessel fibrin thrombi in the middle and lower dermis as a result of a procoagulant tendency.⁵² Although most commonly arising without associated cause, livedoid vasculitis is associated with polyarteritis nodosa, APS, and SLE.^{53,54} Although not consistently beneficial, common therapies include discontinuation of oral contraceptives, anticoagulation and antiplatelet medications, glucocorticoids, and dapsone. Ketanserin, an S_2 serotonergic receptor blocker, psoralen plus ultraviolet A therapy, and intravenous immunoglobulins also have been used successfully.⁵⁵

EMBOLIC PURPURA

Cholesterol Crystal Emboli

Also known as atheroemboli, cholesterol crystal emboli are responsible for a syndrome characterized by lower extremity pain and livedo reticularis with preservation of peripheral pulses. Other common cutaneous findings include gangrene, purpura, ulcerations, cyanosis, and

nodules (Fig. 122-9).⁵⁶ Clinical symptoms include fever, myalgia, and altered mental status. Laboratory features include an elevated erythrocyte sedimentation rate, eosinophilia, and acute renal failure. Onset of symptoms varies from immediate after physical dislodgement of plaque, up to months later when caused by anticoagulant therapy.¹ A blue toe syndrome is, in fact, rare, and most atheroemboli are clinically silent.⁵⁷ Atherosclerotic lesions in the descending aorta are the most common source of cholesterol emboli. This explains the propensity for lower-extremity findings during intravascular procedures or initiation of thrombolytic or anticoagulant therapy.⁵⁶ Histologic evaluation can offer a definitive diagnosis with findings of intraluminal birefringent cholesterol crystals within blood vessel lumen, in the absence of vasculitis.⁵⁸ No effective treatment is available. Nevertheless, supportive care with proper hydration and dialysis may lessen the potential for end-organ damage.

Cutaneous Calciphylaxis

Calciphylaxis (calcific uremic arteriopathy)⁵⁹ is a thrombo-occlusive disorder involving formation of cutaneous, subcutaneous, and vascular calcifications. It is most commonly seen in patients with end-stage renal disease, classically caused by the development of secondary hyperparathyroidism.⁶⁰ Approximately 4 percent of hemodialysis-dependent patients suffer from calciphylaxis. Survival is less than 50 percent at 5 years after diagnosis.⁶¹ Other etiologies include primary hyperparathyroidism, malignancy, alcoholic liver disease, and collagen

Figure 122-9. A. Cholesterol emboli. B. Rupture of an atherosclerotic plaque can result in showers of microemboli that lodge in distal arterioles, causing splinter hemorrhages.

tissue disorders.⁶² Cutaneous lesions present initially as reddish-purple plaques, evolving to tender, gangrenous ulcers or reticular hemorrhagic necrosis. Treatment involves a combination of medical and surgical interventions, such as parathyroidectomy, renal transplantation, wound debridement, and amputation.⁶¹

Emboli from Intracardiac Thrombi

Acral purpuric lesions secondary to emboli arise from left atrial myxomas or right atrial clots through paradoxical embolization.⁶³ These purpuric lesions include palpable purpura, livedo reticularis, erythematous macules and papules, cyanosis, petechiae, splinter hemorrhages, ulcerations, and cutaneous necrosis. Cyanosis, livedo reticularis, and lower-extremity ulcerations can also be seen.⁶⁴

ARTHROPOD BITES

Purpuric lesions are not uncommon after arthropod bites. Bites from bed bugs, *Cimex lectularius*, can give rise to localized purpuric macules or papules, while bites from kissing bugs, *Reduviidae*, often manifest as urticaria with hemorrhagic bulla.⁶⁵ Cutaneous findings after envenomation from a brown recluse spider, *Loxosceles reclusa*, include purpuric necrosis with surrounding erythema evolving to ulcer formation.

● PALPABLE AND NONPALPABLE INFLAMMATORY PURPURIC LESIONS

See Table 122-2.

PYODERMA GANGRENOSUM

Pyoderma gangrenosum is an idiopathic inflammatory skin condition characterized by early follicular erythematous papules and pustules or tender, fluctuant nodules with surrounding erythema that spread peripherally and ulcerate, surrounded by a violaceous rim (see Fig. 122-7).⁶⁶ In 50 percent of cases of pyoderma gangrenosum, there is an associated disorder, such as inflammatory bowel disorders (classically ulcerative colitis), arthritis, hematologic disorders,

and solid tumors.⁶⁷ All four main clinical variants (ulcerative, pustular, bullous, and vegetative) share the histopathologic finding of a sterile abscess with central necrotizing neutrophilic infiltration, and a surrounding perivascular and intramural lymphocytic infiltration. First-line treatment involves wound care and immunosuppressants, such as glucocorticoids, cyclosporine, dapsone, azathioprine, and infliximab.⁶⁸

SWEET SYNDROME

Also referred to as acute, febrile neutrophilic dermatosis, Sweet syndrome is characterized by the acute manifestation of painful erythematous and violaceous papules, nodules, and plaques accompanied by fever and elevated neutrophil count (Fig. 122-10).⁶⁹ These papules, which most commonly appear on face, neck, and upper extremities, present a central yellowish discoloration and tend to coalesce, forming well-circumscribed, irregularly bordered plaques. Other organs can be involved, including the central nervous system, kidneys, lungs,

Figure 122-10. Sweet syndrome. The lesions are characterized by nonvasculitic neutrophilic infiltration, commonly on the face.

and bones.⁷⁰ Classically more prominent in middle-aged women, this syndrome associates a complex cytokine dysregulation. Other manifestations include respiratory and urinary infections and autoimmune disorders (including rheumatoid arthritis), SLE, inflammatory bowel disease). Histologic analysis shows a distinct nonvasculitic neutrophilic infiltrate in the superficial dermis with dermal edema. Systemic glucocorticoid treatment is the standard treatment, while clofazimine, dapsone, colchicine, indomethacin, and cyclosporine have also been used successfully.⁷¹

BEHÇET DISEASE

Besides its classification as a neutrophilic dermatosis, Behçet disease is also an inflammatory disorder that affects multiple organ systems. Clinical features include chronic and relapsing cutaneous manifestations, such as palpable purpura, infiltrative erythema, and papulopustular lesions, as well as oral mucosal and genital ulcers, arthralgias, and gastrointestinal and central nervous system involvement.⁷² Genetic studies show an association between Behçet disease and human leukocyte antigen B51.⁷³ Histologic features include leukocytoclastic or lymphocytic vasculitis, hence its previous classification as a vasculitis. Antitumor necrosis factor- α directed therapies (infliximab, etanercept), interferon- α , immunosuppressive and immunomodulatory agents such as thalidomide, intravenous immunoglobulin, and even stem cell transplantation are used in Behçet disease.^{74,75}

SERUM SICKNESS

Serum sickness reflects the clinical manifestations of immune complex formation and deposition. Cutaneous lesions such as urticarial and morbilliform eruptions predominate, though palpable purpura and erythema multiforme can also be encountered. Serum sickness associated with infection or medical therapy can result in specific characteristic lesions. The use of antithymocyte globulin for marrow failure, for instance, results in 75 percent of patients developing seriginous bands of erythema and purpura on the sides of their hands and feet (Fig. 122-11).⁷⁶ These characteristic lesions consistently appear 1 to 2 days prior to the onset of systemic symptoms of serum sickness, which include fever and malaise. Analysis of biopsies by direct immunofluorescence reveals deposition of IgM, IgE, IgA, and C3. This deposition appears to activate neutrophils leading to release of lysosomal enzymes and the development of dermal vasculitis.⁷⁷

Figure 122-11. Serum sickness caused by antithymocyte globulin. The lesions consist of immunoglobulins and neutrophils.

HENOCH-SCHÖNLEIN PURPURA

Henoch-Schönlein purpura (HSP), is a predominantly pediatric vasculitic syndrome characterized by the acute onset of abdominal pain and lower-extremity eruption of diffuse urticarial plaques and palpable purpura. It was first described in 1801 by Dr. William Heberden.⁷⁸ HSP predominantly affects patients 2 to 20 years of age, 90 percent of patients being younger than 10 years old.⁷⁹ Several environmental triggers precede HSP onset, such as viral (upper respiratory infections, hepatitis B virus, HCV, parvovirus B19, and HIV) and bacterial (*Streptococcus* spp., *Staphylococcus aureus*, and *Salmonella* spp.) infections in children. Adult disease may be precipitated by medications (nonsteroidal antiinflammatory drugs [NSAIDs], angiotensin-converting enzyme inhibitors, and antibiotics), food allergies, vaccinations, and insect bites.⁸⁰ The pathogenesis of HSP leukocytoclastic vasculitis is complex. It appears to involve IgA₁ immune complex and complement deposition on vessel walls. Elevated values of thrombomodulin, tissue plasminogen activator, and plasminogen activator inhibitor-1 appear to correlate with endothelial injury and fibrinolytic activity in the acute phase of HSP.⁸¹

Cutaneous eruptions often begin acutely as urticarial papules and plaques evolving to petechiae, ecchymoses, and palpable and nonpalpable purpura over the lower extremities and buttocks (Fig. 122-12). Palpable purpura is a universal finding, being present in one series in 98.6 percent of patients.⁸² Clinically, lesions may take the form of retiform or patterned purpura, presence of a retiform edge of various inflammatory lesions, or skin necrosis.⁸³ Other common manifestations include localized subcutaneous edema, glomerulonephritis, arthritis, and (severe) abdominal pain.

In spite of its chronic relapsing pattern, the long-term evolution is benign in the majority of patients.⁸² The self-limited course of HSP may be contributed by an enhanced apoptosis of immune cells, which diminishes the severity of the acute inflammatory response.⁸⁴ Consequently, treatment is frequently supportive. Immunosuppressive drugs, including glucocorticoids, are typically reserved for cases with renal involvement.⁷⁸

Figure 122-12. Henoch-Schönlein purpura. Urticarial papules and plaques can evolve into palpable purpura. The lesions are characterized by leukocytoclastic vasculitis.

Persistent purpura, severe abdominal symptoms, and diminished plasma coagulation factor XIII activity are predictive of renal involvement, requiring initiation of glucocorticoids.⁸⁵

INFECTIONS

Careful analysis of skin lesions of infectious etiology can provide important hints toward identifying the responsible pathogen. Purpura can arise through a variety of pathophysiologic mechanisms associated with infection: (1) vascular effects of toxins, (2) septic emboli, (3) direct invasion of vessels with subsequent vascular occlusion, and (4) immune complex formation.⁸⁶ Although the morphology of such purpuric lesions may be nonspecific, many pathogens lead to characteristic findings.

Bacterial

Gram-positive and Gram-negative infections may give rise to a large array of purpuric patterns depending on organism virulence and patient immune status. Skin lesions range from simple macules and papules to bullae, ulcers, and necrosis.

Purpura fulminans, a hemorrhagic infarction syndrome consisting of disseminated intravascular coagulation (DIC), acral purpura, and shock may manifest in the setting of bacterial sepsis with encapsulated organisms (Chap. 129).⁸⁷ Most commonly seen in immunocompromised hosts, purpura fulminans can also be produced by bacterial pathogens in immunocompetent patients.⁸⁸ This syndrome can be associated with asplenic or functional hyposplenism.⁸⁹ Although most patients are younger than the age of 10 years, adults can also be affected.⁹⁰ Retiform purpuric lesions result from fibrin-induced microvascular occlusion, and commonly have a rapid evolution toward necrosis and eschar formation. Adult patients with purpura fulminans as a result of meningococemia have significantly depressed proteins C and S levels, which may explain the tendency toward fibrin deposition and development of cutaneous ischemic lesions, such as symmetrical peripheral gangrene.⁹¹ Facial purpura and livedo reticularis may be seen during fulminant pneumococcal infection in asplenic patients.⁹² Postinfectious purpura fulminans may also occur after infections with streptococci or varicella zoster,³⁹ and was associated with development of anti-protein S antibodies. Another characteristic lesion is the development of ecthyma gangrenosum in immunocompromised hosts (Fig. 122-13).

Figure 122-13. Ecthyma gangrenosum. Associated with Gram-negative sepsis, disseminated fungal infection, or other serious infectious diseases, these hemorrhagic bullae evolve from erythematous plaques, both of which are shown here.

Figure 122-14. Lyme disease. Erythema migrans with a central hemorrhagic bulla is the characteristic lesion.

In children, more than 20 percent of cases admitted to the hospital with petechiae and fever were found to have invasive bacterial infections (*Neisseria meningitidis*, *Haemophilus influenzae* type B, and *Streptococcus pneumoniae*), and approximately 7 percent of cases were diagnosed with meningococemia.⁹³ Sepsis secondary to *N. meningitidis* can produce a characteristic pattern of purpuric lesions. Erythematous papules can quickly progress to numerous petechiae combined with violaceous reticular purpuric lesions.⁹⁴ A retiform aspect can be seen during progression of the infection to purpura fulminans. The finding of petechiae on a patient with symptoms and signs of bacterial meningitis is predictive of meningococcal meningitis.⁹⁵

Borrelia burgdorferi infection gives rise to erythema migrans, the characteristic lesion of Lyme disease. Skin lesion is classically a nonpruritic annular erythematous expanding plaque, occasionally including a central hemorrhagic bullae (Fig. 122-14). Other reported cutaneous findings associated with this infection include papular urticaria, Henoch-Schönlein-like purpura, and morphea.⁹⁶

Viral

Purpuric lesions can also be a manifestation of a viral infection. For example, the adenoviruses and enteroviruses have been associated with fever and petechiae in children.⁹⁷ Similarly, parvovirus B19 can produce a syndrome of petechiae or purpuric papules progressing to confluent purpuric papules or plaques in a sharply demarcated glove-and-sock distribution.⁹⁸ In addition to the cutaneous findings, the “gloves-and-socks syndrome” is characterized by fever and occasionally leukopenia, and can also be produced by the measles virus.⁹⁹ Purpura in the axilla and chest also has been described during parvovirus B19 infection (Fig. 122-15).¹⁰⁰ Histopathologic analysis of these purpuric lesions show an evolution from superficial perivascular lymphocytic infiltrate to a dermatitis accompanied by necrotic keratinocytes and hemorrhage.¹⁰¹ *Hantavirus* causes a syndrome of hemorrhagic fever and renal failure accompanied by headache, cutaneous and mucosal petechiae, and purpuric lesions.¹⁰²

Fungal

Fungal infections in the immunocompromised population are a growing medical issue, given the increasing number of patients receiving immunosuppressants for organ transplantation or malignancy. Disseminated or locally invasive infections can give rise to petechiae and hemorrhagic necrosis. Common fungal pathogens in disseminated disease includes *Candida* (Fig. 122-16), *Aspergillus* (Fig. 122-17), *Histoplasma*, and *Fusarium*.¹⁰³ Disseminated candidiasis can manifest as ecthyma

Figure 122-15. Parvovirus B19 erythema and petechiae. The classic slapped-cheek rash on the face can appear on other areas of the body, sometimes punctuated with petechiae of unclear etiology.

Figure 122-17. Aspergillosis: primary cutaneous inoculation from contaminated armboard.

gangrenosum in immunocompromised patients, suggesting consideration for a skin biopsy.¹⁰⁴ Cutaneous aspergillosis can also occur in immunocompetent individuals, and manifest as eruptive maculopapules, necrotizing plaques, or subcutaneous granulomas.¹⁰⁵

Parasitic

Immunocompromised patients are at risk of developing purpuric lesions secondary to parasitic infections, such as *Pneumocystis jiroveci*. Disseminated strongyloidiasis is characterized by larva currens, a serpiginous urticarial eruption caused by the migration of filiform larvae through the dermis.¹⁰⁶ Other cutaneous lesions include generalized petechiae and widespread reticular purpura of the arms, legs, and abdomen (Fig. 122-18), with a characteristic thumbprint periumbilical distribution.¹⁰⁷

Figure 122-18. Disseminated strongyloidiasis.

Rickettsial

Infections caused by *Rickettsia* species can also lead to purpuric lesions as a result of their direct invasion of endothelial cells. This is followed by medial and intimal necrosis with subsequent thrombosis and hemorrhage.⁸⁶ Cutaneous lesions in Rocky Mountain spotted fever range from petechiae to acral purpuric lesions and hemorrhagic necrosis (Fig. 122-19). Maculopapular and vesicular rashes along with

Figure 122-16. Disseminated candidiasis. Purpuric nodules in a patient with acute myelogenous leukemia. Ecthyma gangrenosum can also occur in this disease.

Figure 122-19. Rocky Mountain spotted fever. This rickettsial disorder can present with petechiae on the dorsum of the hand.

Figure 122-20. Erythema multiforme. This hypersensitivity reaction, usually to one of various drugs, characteristically presents with targetoid lesions.

lower-extremity eschars produced by *Rickettsia africae* may also occur in travelers to sub-Saharan Africa.¹⁰⁸

ERYTHEMA MULTIFORME

Erythema multiforme (EM) is a cutaneous disorder characterized by the development of crops of well-demarcated, erythematous target lesions with central clearing,¹⁰⁹ most commonly representing a hypersensitivity reaction triggered by infection or drug exposure (Fig. 122-20). The severity of this disorder ranges from mild (EM minor), to severe (EM major or Stevens-Johnson syndrome). EM has been reported to be triggered by a number of viruses (most commonly herpes simplex, but also adenovirus, cytomegalovirus, and HIV),^{110,111} and medications (sulfonamides, penicillins, bupropion, phenylbutazone, phenytoin, NSAIDs, adalimumab).¹¹² A cellular allergic reaction coupled with impaired histamine metabolism because of a decrease in histamine-*N*-methyltransferase activity may be causative.¹¹³ Treatment for mild cases is supportive, while the use of glucocorticoids is warranted in severe cases.

CUTANEOUS POLYARTERITIS NODOSA

Classic polyarteritis nodosa represents a systemic small- and medium-size vessel vasculitis most commonly involving the skin, heart, liver, and kidneys. A relatively benign cutaneous form exists that lacks significant systemic involvement¹¹⁴ and consistently involves the deep dermis and panniculus.¹¹⁵ Lesions develop as tender erythematous nodules¹¹⁶ with occasional retiform purpura and livedo reticularis localized to the upper and lower extremities, but the trunk, neck, and face can also be involved (Fig. 122-21). The duration of lesions varies from days to a few months.¹¹⁵ Histologic analysis of involved skin shows deep dermal artery necrosis with infiltration of neutrophils and eosinophils, and fibrin deposition. Treatment typically involves the use of NSAIDs and glucocorticoids, alone or in combination. Some cases of cutaneous polyarteritis nodosa are reported to have progressed on long-term followup,¹¹⁷ hence the need for close monitoring of patients diagnosed with an apparently benign, cutaneous form of disease.¹¹⁸

PARANEOPLASTIC VASCULITIS

Most common vasculitis associated with neoplasia are cutaneous leukocytoclastic vasculitis, paraneoplastic vasculitis, and HSP.^{119,120}

Figure 122-21. Polyarteritis nodosa. Acral purpura accompanying tender erythematous nodules.

Paraneoplastic vasculitis is most commonly associated with hematologic neoplasia,¹²¹ and is commonly a result of paraproteinemia. However, an association with carcinomas of the lung, colon, breast, and cervix has been observed.¹²²⁻¹²⁴ Solid tumors predominate in certain types of paraneoplastic vasculitis, such as the HSP.¹²⁵ Cutaneous manifestations include petechiae, urticaria, and palpable purpura, and are often intensely pruritic. In hematologic disorders, these lesions often precede the development of malignancy by an average of 10 months.¹²⁶ Histologic examination shows necrotizing leukocytoclastic vasculitis with neutrophilic infiltration.

DRUG-INDUCED VASCULITIS

A long list of drugs are reported to cause a vasculitis resulting in erythematous purpuric lesions. One-fifth of all cutaneous vasculitis are produced by drugs, including allopurinol, cefaclor, colony-stimulating factors, D-penicillamine, furosemide (Fig. 122-22), hydralazine, isotretinoin, methotrexate, phenytoin, minocycline, and propylthiouracil.¹²⁷

Figure 122-22. Leukocytoclastic vasculitis secondary to furosemide.

Figure 122-23. Wegener granulomatosis.

ANTINEUTROPHIL CYTOPLASMIC ANTIBODY-ASSOCIATED VASCULITIS

Wegener Granulomatosis

This small- to medium-vessel vasculitis most commonly affects upper and lower respiratory tracts and kidneys and is strongly associated with the development of circulating antineutrophil cytoplasmic antibodies (ANCA).¹²⁸ Skin involvement has been reported in 35 to 50 percent of cases.¹²⁹ Cutaneous manifestations include a combination of palpable purpura, oral ulcers, and erythematous cutaneous and subcutaneous nodules (Fig. 122-23).¹³⁰ Necrotizing vasculitis, palisading granulomas, and granulomatous vasculitis are characteristic histologic findings.¹³¹

Churg-Strauss Syndrome

Churg-Strauss syndrome (CSS) is characterized by granulomatous inflammation in the lungs associated with asthma and eosinophilia.¹³² Cutaneous findings such as ulcers, papules, palpable purpura, cutaneous nodules, and infarcts of fingers and toes are encountered in 50 to 80 percent of cases.¹³⁰ CSS limited to the skin was described.¹³³ Eosinophilia accompanies elevated IgE levels and a positive perinuclear ANCA. Granulomatous inflammation and necrotizing vasculitis of small- to medium-size blood vessels are present histologically.¹³¹

● NONPALPABLE, NONINFLAMMATORY, ROUND PURPURIC LESIONS

See Table 122-3.

INCREASED TRANSMURAL PRESSURE GRADIENT AND TRAUMA

Acute increases in vascular transmural pressure gradients lead to extravasation of red blood cells resulting in nonpalpable, noninflammatory petechial and larger purpuric lesions. Examples include postictal purpura,¹³⁴ weightlifting,¹³⁵ postemesis facial purpura,¹³⁶ prolonged Valsalva, and childbirth. Acute decreases in extravascular negative pressure, referred to as suction purpura from gas mask, kissing, or cupping, can also increase this gradient, resulting in well-circumscribed lesions in the shape of the causative device.¹³⁷ The development of petechiae in mountain climbers, is presumably caused by significantly reduced atmospheric pressures at high elevations.¹³⁸ Lower-extremity venous incompetence, predominantly at the medial ankle, can result in macules or patches of yellowish-brown purpura.

Focal ecchymosis and other purpuric lesions can manifest as a result of trauma. Characteristic patterns of purpuric lesions are commonly used in forensic science. Traumatic asphyxia, for instance, is characterized by cervicofacial cyanosis and swelling, petechiae, and subconjunctival hemorrhage.¹³⁹ Factitious purpura, often related to deliberate suction purpura, should be considered in the differential for purpura.¹⁴⁰ Other physical causes of purpura consist of physical remedies, such as spooning (Quat Sha) or coin rubbing (Cao Gio). Exercise-induced purpura results in purpuric, erythematous, or urticarial lesions distributed on the lower legs.¹⁴¹

THROMBOCYTOPENIAS

Disseminated Intravascular Coagulation

DIC is defined as widespread, amplified and uncontrolled intravascular coagulation with a range of causes including sepsis, trauma, and malignancy.¹⁴² Petechiae and purpuric plaques result from thrombocytopenia, and are common manifestations of DIC (Chap. 129).

Immune Thrombocytopenia Purpura

Immune (or idiopathic) thrombocytopenia purpura is an acquired disease characterized by autoantibody-mediated platelet destruction commonly resulting in purpuric lesions of the skin and mucosa as well as other sites of abnormal bleeding (Chap 117).¹⁴³

Thrombotic Thrombocytopenia Purpura

Thrombotic thrombocytopenia purpura is characterized by nonimmune platelet consumption, microvascular hemolysis, and organ damage. It is associated with a deficiency in the von Willebrand factor cleaving protease, ADAMTS-13 (a disintegrin and metalloproteinase with thrombospondin domain 13; Chap. 132).¹⁴⁴ Petechiae and purpuric plaques may occur.

DRUG REACTIONS

A large number of medications are reported to result in vasculitic and nonvasculitic purpuric eruptions.¹⁴⁵ Nevertheless, *any* drug on the medication list of a patient with a purpuric lesion (within 2 weeks of starting a new drug or a few days if prior sensitization is suspected) may be involved.¹⁴⁶

COAGULATION DISORDERS

A large number of disorders manifest with thrombocytopenia or impaired thrombocyte function, that result in increased bruising. Also, impaired fibrin formation, resulting from coagulation factor deficiencies, the use of anticoagulants, vitamin K deficiency, or poor hepatic function may cause bruising and hematomas.

DECREASED VESSEL INTEGRITY WITHOUT TRAUMA

Senile Purpura

Synonymous with actinic purpura, senile purpura refers to the easy bruising seen in the aged and sun-damaged skin, commonly appearing on the dorsal aspect of the hands and forearms (Fig. 122-24). One proposed etiology is the degeneration of skin extracellular matrix components that leaves dermal capillaries unsupported and vulnerable to shearing injuries,¹⁴⁷ but zinc deficiency is also suspected.¹⁴⁸

Excess Glucocorticoid

The presence of excess endogenous (Cushing syndrome) or exogenous (iatrogenic) glucocorticoid use can result in dermal thinning and

A

B

Figure 122-24. Senile purpura. Note accompanying skin atrophy.

vessel fragility. Consequently, bright red, nonpalpable purpuric lesions tend to arise after slight or even undetected trauma and manifest in a linear or geometric pattern.¹⁴⁹

Scurvy—Vitamin C Deficiency

Vitamin C (ascorbic acid) deficiency occurs because of reduced dietary intake or absorption. A consequent disruption in normal collagen production results in blood vessel fragility leading to petechiae, perifollicular hemorrhage, and larger purpuric plaques, most commonly on the lower extremities (Fig. 122-25).¹⁵⁰ Thus, scurvy is usually a clinical diagnosis. Cutaneous features can also include follicular hyperkeratotic papules, poor wound healing, and bent or corkscrew-shaped body hairs.¹⁵¹ Vitamin C supplementation is rapidly effective.

Systemic Amyloidosis

Systemic amyloidosis is characterized by a clonal proliferation of plasma cells with consequent immunoglobulin light-chain deposition in vital organs. Microscopic 8 to 10 nm protofilaments aggregate to form fibrils.¹⁵² It can present as a primary disorder or secondarily to multiple myeloma (Chaps. 107 and 108). Characteristic features are periorbital “pinch purpura,” “raccoon eyes,” and macroglossia.¹⁵³

Waxy, purpuric cutaneous and mucocutaneous lesions manifest when light-chain aggregates deposit in dermal blood vessels. Although rare, palmodigital purpura has been reported as the sole cutaneous finding in a case of myeloma-associated systemic amyloidosis.¹⁵⁴ A distinct

Figure 122-25. Parafollicular purpura characteristic of scurvy.

localized form, primary cutaneous amyloidosis, is caused by local dermal infiltration of plasma cells.¹⁵⁵

CONNECTIVE TISSUE DISORDERS

Ehlers-Danlos Syndrome

A rare autosomal dominant syndrome, Ehlers-Danlos syndrome is a consequence of a mutation in collagen synthesis, tenascin X, or lysyl hydroxylase, and others. This leads to loss of skin elasticity, delayed wound healing, easy bruising, joint hypermobility, and systemic organ and tissue fragility.¹⁵⁶ Cutaneous findings include thin skin and a tendency to develop nonpalpable purpuric lesions.¹⁵⁷

Pseudoxanthoma Elasticum

Pseudoxanthoma elasticum is genetic disorder characterized by mineralization and fragmentation of elastin in the skin, retina, and blood vessels.¹⁵⁸ This autosomally inherited disease is associated with a mutation in the *ABCC6* gene, an ATP-binding cassette transporter, which may play an important role in connective tissue turnover.¹⁵⁹ Cutaneous lesions include small white or yellow papules classically appearing on the neck in a “gooseflesh” aspect,¹⁶⁰ but systemic hemorrhagic events are also encountered.

Melas Syndrome

Nonpalpable purpuric lesions can occur on the palms and soles in mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS) syndrome.¹⁶¹ MELAS syndrome, one of a family of mitochondrial encephalomyopathies, has been associated with a mutation in a mitochondrial transfer RNA (tRNA) or the reduced form of nicotinamide adenine dinucleotide (NADH) dehydrogenase complex I.¹⁶² Skin manifestations can also include hypertrichosis, ichthyosis, and vitiligo.¹⁶³

RENDU-OSLER-WEBER DISEASE (HEREDITARY HEMORRHAGIC TELANGIECTASIA)

Rendu-Osler-Weber disease is an autosomal dominant hereditary disorder characterized by local angiodysplasia, mostly present in the skin, mucous membranes, and often in organs such as the lungs, liver, and brain.¹⁶⁴ It may lead to nose bleeding, acute and chronic digestive tract bleeding, and various problems resulting from the involvement of other organs. Vascular malformations may present as telangiectasias

Figure 122-26. Rendu-Osler-Weber disease (hereditary hemorrhagic telangiectasia).

(small vascular malformations) in the skin (Fig. 122-26). Subcutaneous bleeding may occur as well, presenting as non-palpable purpuric lesions. Angiodysplasia in Rendu-Osler-Weber disease is caused by a defect in angiogenesis. Five genetic types of hereditary hemorrhagic telangiectasia (HHT) are recognized. More than 80 percent of all cases of HHT are caused by mutations in either *ENG* (*endoglin*, *HHT1*) or *ALK1* (*ACVRL1*, *HHT2*).¹⁶⁵ Treatment of the disease is symptomatic, for example, by iron administration when iron-deficiency anemia occurs, or by laser treatment of small (bleeding) malformations in mucous membranes or embolization of larger arteriovenous malformations.

CHAPTER 123

HEMOPHILIA A AND HEMOPHILIA B

Miguel A. Escobar and Nigel S. Key

SUMMARY

Hemophilias A and B are the only two bleeding disorders inherited in a sex-linked fashion. The gene for both disorders is on the long arm of the X-chromosome. Both disorders appear as otherwise clinically indistinguishable hemorrhagic diseases of mild, moderate, or life-threatening severity. In the most-severe form, both hemophilias A and B are characterized by multiple bleeding episodes into joints and other tissues leading to chronic crippling hemarthropathy and internal organ hemorrhage unless treated early or prophylactically with factor VIII or IX concentrates, respectively. Even though phenotypically similar, both diseases are genetically heterogeneous with more than 1000 mutations leading to the absence of or dysfunctional factor VIII or IX molecules that do not support normal thrombin generation nor adequate fibrin clot formation.

Despite similarities in hemorrhagic symptoms, there are major differences between hemophilias A and B. Hemophilia A is about five times more common than hemophilia B, and is caused by defects in the factor VIII gene, a large 186-kb gene with 26 exons. A common mutation results from inversion and crossing over of intron 22 during meiosis. This mutation leads to severe hemophilia, and because no factor VIII protein is made, these patients are prone to developing antibody inhibitors to therapeutically administered factor VIII that neutralize its coagulant function, making adequate therapy problematic. Approximately 20 percent of severely affected hemophilia A patients develop such inhibitors, whereas only 3 percent or fewer of severely affected hemophilia B patients develop inhibitors against factor IX. About one-third of the mutations in hemophilias A and B arise *de novo* at CpG “hotspots.” These mutations are apt to occur in the germ cells of a maternal grandfather whose daughters will be carriers and whose grandsons will have a 50 percent chance of having hemophilia.

Replacement therapy is available for both hemophilia A and hemophilia B patients. Safe, effective, and highly purified factor VIII and factor IX concentrates derived from plasma or made by recombinant technology are available for prophylactic therapy to prevent bleeding episodes or prompt treatment of

Acronyms and Abbreviations: AAV, adeno-associated virus; aPTT, activated partial thromboplastin time; BT, bleeding time; BU, Bethesda unit; CGA, cytosine, guanine, adenine; CJD, Creutzfeldt-Jakob disease; COX, cyclooxygenase; CRM, cross-reacting material; CT, computerized tomography; DDAVP, 1-desamino-8-D-arginine vasopressin, desmopressin; DVT, deep vein thrombosis; EACA, ϵ -aminocaproic acid; FEIBA, factor VIII inhibitor bypassing activity; GLA, γ -carboxyglutamic acid; Ig, immunoglobulin; PT, prothrombin time; PTC, plasma thromboplastin component (factor IX); RFLP, restriction fragment length polymorphism; TCT, thrombin clotting time; VWD, von Willebrand disease; VWF, von Willebrand factor.

hemorrhagic events. Prophylaxis is the treatment of choice and can prevent disabling joint disease and other hemorrhagic events such that patients can expect a relatively normal life span provided that adequate replacement therapy is available. For patients with inhibitors, factor VIIa and factor VIII inhibitor bypassing activity can be used to “bypass” the factor VIII or factor IX deficiency. Both disorders are good candidates for gene therapy that may eventually lead to their cure.

● HEMOPHILIA A (CLASSIC HEMOPHILIA, FACTOR VIII DEFICIENCY)

DEFINITION AND HISTORY

Hemophilia A is an X-linked hereditary disorder caused by defective synthesis of factor VIII. Hemophilia A is less common than von Willebrand disease (VWD; Chap. 126), but it is more common than other inherited clotting factor abnormalities. The estimated incidence of hemophilia A is one in every 5000 to 7000 live male births. It occurs in all ethnic groups in all parts of the world.¹

Sex-linked hemophilia was recognized at least as early as the 2nd century, when a rabbi correctly deduced that sons of hemophilic carriers were at risk for bleeding following circumcision.² In the 19th century, several authors noted the sex-linked inheritance pattern of the disease and ascribed the hemorrhagic episodes to delayed blood coagulation. Morawitz³ developed the classic theory of blood coagulation, which recognized two major reactions: (1) conversion of prothrombin to thrombin by a tissue substance that Morawitz termed *thrombokinese*, and (2) conversion of fibrinogen to fibrin by thrombin. In 1911, Addis⁴ demonstrated that thrombin formed more slowly in hemophilic blood than in normal blood and that the defect could be corrected by small amounts of normal plasma. However, he incorrectly theorized that hemophilia resulted from prothrombin deficiency. As protein purification techniques improved throughout the 1930s and 1940s, thrombokinese was resolved into several distinct components. Brinkhous⁵ demonstrated that the prothrombin content of hemophilic plasma was normal and that the basic defect in hemophilia was the delayed conversion of prothrombin to thrombin. The defect could be corrected by a fraction of normal plasma containing the antihemophilic factor, later named *factor VIII*. In 1947, Pavlovsky⁶ observed that when blood from one patient with hemophilia was transfused into another patient with a similar clinical phenotype, the prolonged clotting time in the recipient was corrected. At the time, Pavlovsky did not recognize that he was dealing with two different types of hemophilia. This fact was recognized by Aggeler and coworkers⁷ in 1952, when they described a patient deficient in “plasma thromboplastin component,” a blood clotting factor different from factor VIII. A deficiency of “plasma thromboplastin component,” later termed *factor IX*, was identified as the cause of hemophilia B. A month later, Biggs and colleagues described a similar patient whose surname was Christmas, thus the synonym “Christmas disease.”⁸ Hemophilias A and B are the only two hereditary clotting factor defects inherited in a sex-linked pattern, and they are clinically indistinguishable, although data suggest that on the whole, hemophilia B may be less severe than hemophilia A.⁹ However, in an individual patient, the disorders cannot be distinguished without a specific assay for factor VIII or IX.

In 1964, a proposal to organize the growing number of coagulation factors into a cascade or waterfall mechanism was put forth by Davie and Ratnoff and by Macfarlane.^{10,11} In this scheme, each zymogen clotting factor was sequentially activated to a protease that subsequently

activated the next zymogen until thrombin ultimately was produced. In this scheme, factors VIII and IX were considered to be proenzymes. Later, however, factor VIII, when activated by thrombin, was shown not to be a proenzyme but rather an essential cofactor for factor IXa. The waterfall hypothesis has been modified so that the primary role of the tissue factor–factor VII complex in the initiation of coagulation is emphasized (Chap. 113).¹²

ETIOLOGY AND PATHOGENESIS

Hemophilia A is a heterogeneous disorder resulting from defects in the factor VIII gene that leads to absent or reduced circulating levels of functional factor VIII. The reduced activity can result from a decreased amount of factor VIII protein, the presence of a functionally abnormal protein, or a combination of both. For factor VIII to be an effective cofactor for factor IXa, it must first be activated by thrombin, a reaction that results in the formation of a heterotrimer composed of the A₁, A₂, A₃, C₁, and C₂ domains of factor VIII in a complex with calcium (Chap. 113).¹³ Activated factor VIII (factor VIIIa) and activated factor IX (factor IXa) associate on the surface of activated platelets, forming a functional factor X-activating complex (“tenase” or “Xase”).¹⁴ In the presence of factor VIIIa, the rate of factor X activation by factor IXa is dramatically enhanced. That hemophilia A and hemophilia B have similar clinical manifestations is not surprising, because both factor VIIIa and factor IXa are required to form the Xase complex. The lack of either activated protein leads to a similar lack of platelet surface Xase activity with subsequent decreased thrombin generation. In patients with hemophilia, clot formation is delayed because of the decreased thrombin generation. The clot that is formed is friable, easily dislodged, and highly susceptible to fibrinolysis, all of which lead to excessive bleeding and poor wound healing.¹⁵

GENETICS

Hemophilia A results when mutations occur in the factor VIII gene located on the long arm of the X-chromosome (X-q28). The disease occurs almost exclusively in males. Figure 123–1 shows the inheritance pattern of hemophilia A and hemophilia B. All the sons of affected

hemophilic males are normal, whereas all the daughters are obligatory carriers of the factor VIII defect. Sons of carriers have a 50 percent chance of being affected, whereas daughters of carriers have a 50 percent chance of being carriers themselves.

The factor VIII gene is very large, approximately 186 kb, with approximately 9 kb of exons. The gene contains 26 exons and 25 introns.¹⁶ Based on the sequence of the factor VIII gene in normal individuals and patients with hemophilia A, numerous specific mutations have been described^{16,17}; as of 2015, more than 2000 specific variants in the factor VIII gene resulting in classic hemophilia have been described.¹⁷

Hemophilia A can result from multiple alterations in the factor VIII gene. These include gene rearrangements; missense mutations, in which a single base substitution leads to an amino acid change in the molecule; nonsense mutations, which result in a stop codon; abnormal splicing of the gene; deletions of all or portions of the gene; and insertions of genetic elements.¹⁸ The genetic defects leading to hemophilia have been reviewed.¹⁷

One of the most common mutations, accounting for 40 to 50 percent of severe hemophilia A patients, is a unique “combined gene inversion and crossing over” that disrupts the factor VIII gene.^{19,20} Figures 123–2 and 123–3 schematically depict the factor VIII gene and the mechanism of the “inversion–crossing over.”²¹ Within intron 22 are two other genes: (1) *F8A(a₁)*, which is transcribed in the 5′ direction, and (2) *F8B*, which is transcribed in the 3′ direction of the factor VIII gene. The hatched boxes in Figure 123–3 show two other extragenic homologous sequences (*a₂*, *a₃*) 5′ to the *F8A* gene that lies within intron 22 (*a₁*). The presence of extragenic *F8A* sequences 5′ to the *F8A* gene within intron 22 is central to the inversion and translocation of part of the factor VIII gene from exon 1 to exon 22. The mechanism is homologous recombination between the *F8A* sequence that lies within intron 22 and one of the homologous extragenic sequences of the *F8A* gene 5′ to the factor VIII gene. During meiosis, crossing over of homologous sequences occurs between the *F8A* gene lying within intron 22 and one of the extragenic homologous *F8A* sequences 5′ to intron 22. Thus, the transcription of the complete factor VIII sequence is interrupted (Fig. 123–3). Figure 123–3 shows a common inversion and crossing over, but homologous recombinations can occur with either of the extragenic genes. Approximately 2 to 5 percent of the severe cases of hemophilia A carry the intron 1 inversion resulting in the separation of the F8 promoter–exon 1 sequence from the remainder of the *F8* gene.²² The “inversion–crossing over” mutations result in severe hemophilia, and approximately 20 percent of these patients are susceptible to developing antibody inhibitors that neutralize factor VIII coagulant function.

Of the different insertions in the factor VIII gene that have been reported, a few are long interspersed elements (LINEs) that are transposon sequences; that is, sequences that have been inserted frequently throughout the genome.²³ Most of these insertions result in severe hemophilia.

In many cases of hemophilia, there is no family history of the disease, and at least 30 percent of the cases of hemophilia are a result of spontaneous (*de novo*) mutations. Most of these occur at CpG dinucleotides in the factor VIII gene.²³ *De novo* occurrences of hemophilia usually result from a mutation in the gamete of a normal male; for example, a mutation in the germ cell of a maternal grandfather will give rise to the hemophilia gene in his daughters such that his grandsons may have hemophilia.¹⁸ Codons for the amino acid arginine (CGA [cytosine, guanine, adenine]) are frequently affected by mutations at CG doublets. A C→T transition often results in a stop codon with synthesis of a truncated factor VIII molecule and usually is associated with severe hemophilia A. However, a G→A transition results in a missense mutation, which often leads to a dysfunctional factor VIII molecule that may be associated with mild, moderate, or severe hemophilia. Some missense

		Hemophilic male $X^{h}Y$	
Normal female	X	XX^{h} (Carrier female)	XY (Normal male)
	X	XX^{h} (Carrier female)	XY (Normal male)
		Normal male XY	
Carrier female	X^{h}	XX^{h} (Carrier female)	$X^{h}Y$ (Hemophilic male)
	X	XX (Normal female)	XY (Normal male)

Figure 123–1. Inheritance pattern of hemophilia. All daughters of a hemophilic male are carriers of hemophilia, whereas all sons are normal. Daughters of carriers have a 50 percent chance of being a carrier, whereas sons of carriers have a 50 percent chance of having hemophilia. X, normal; X^{h} , abnormal X chromosome with the hemophilic gene; $X^{h}Y$, hemophilic male; XX, normal female; XX^{h} , carrier female; XY, normal male; Y, normal.

Figure 123-2. Schematic of the factor VIII gene (*FVIII*). The *FVIII* gene is located at q28 on the long arm of the X chromosome. The region of the *FVIII* gene is enlarged on the *second line*. Note that two genes, designated a_2 and a_3 , are 5' to the *FVIII* gene. The *hatched area* indicated on *FVIII* corresponds to intron 22 shown on the *third line*. Within intron 22 (*fourth line*) are two nested genes, one designated *F8A*, which is transcribed in a direction opposite to that of the whole *FVIII* and is homologous to the a_2 and a_3 genes shown on *line 2*. G6PD, glucose-6-phosphate dehydrogenase. (Reproduced with permission from Scriver CR, Beaudet AL, Sly WS et al: *Metabolic and Molecular Basis of Inherited Diseases*, 8th ed. McGraw-Hill, New York, 1995.)

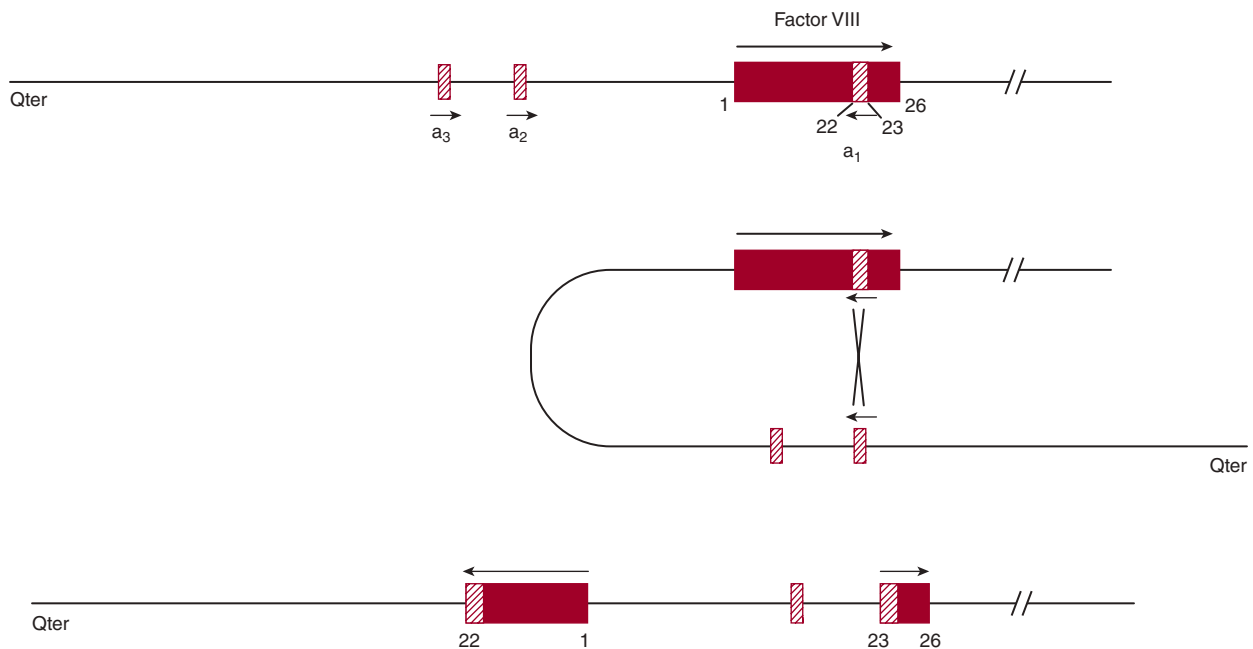

Figure 123-3. Schematic of inversion and crossing over at intron 22. Inversion and crossing-over of the a_3 gene with its homologous sequence a_1 nested within intron 22 are shown. *Middle panel:* When crossing over of the a_1 gene nested within intron 22 and the a_3 gene extragenic to *FVIII* occurs, a portion of *FVIII* is transcribed in a reverse manner from exon 1 through exon 22. Homologous recombination with the extragenic a_2 gene is also possible. In some individuals there are two a_2 or a_3 extragenic sequences giving rise to four possible types of the “inversion–crossing over” mechanism. (Reproduced with permission from Antonarakis SE, Kazazian HH, Tuddenham EG: *Molecular etiology of factor VIII deficiency in hemophilia A*. Hum Mutat 1995;5(1):1–22.)

mutations result in the production of normal or near-normal amounts of factor VIII antigen, while the coagulant activity may be dramatically or only slightly reduced. Many other single-base substitutions have been described, resulting in hemophilia of varying degrees of severity.

Large deletions in the factor VIII gene almost always are associated with severe hemophilia. On the other hand, a small deletion that does not change the reading frame of the gene may result in milder disease. Patients with large deletions who have no detectable factor VIII antigen are more susceptible to the development of anti-factor VIII antibodies, although antibodies clearly also occur in patients without deletions.^{16,23}

Hemophilia A in females is extremely rare, although an affected female offspring from a hemophilic father and carrier mother have been reported. Hemophilia A may occur in females with X chromosomal abnormalities such as Turner syndrome, X chromosomal mosaicism, and other X chromosomal defects.^{23,24} If the normal X chromosome is inactivated disproportionately (“imbalanced X inactivation”) in a carrier female, factor VIII levels may be sufficiently low to cause bleeding manifestations. Usually these manifestations are mild, but they may be serious during surgical procedures or following significant trauma.

PRENATAL DIAGNOSIS AND CARRIER DETECTION

A careful and complete family history is important for carrier detection.²⁵ All daughters of a hemophilic father are obligatory carriers of the hemophilic defect. If a known carrier has a daughter, that daughter has a 50 percent chance of being a carrier.

Carrier detection is important when a daughter of a known carrier or a female offspring of a hemophilic patient wishes to become pregnant. At times, the history of hemophilia in the family is in a distant blood relative, and the gene for hemophilia may skip several generations. The current standard for identifying carrier status is through direct gene sequencing. Carriers who harbor the intron 22 inversion or intron 1 inversion can be identified using the Southern blot technique and polymerase chain reaction, respectively.^{22,25} If these mutations are found to be absent, sequencing of the complete coding region is performed.²⁶

Use of markers for restriction fragment length polymorphism (RFLP) is simpler than direct sequencing of the coding region of the factor VIII gene, but use of the RFLP technique requires that the pedigree analyses include at least one hemophilic male whose mother is heterozygous for one or more RFLP markers.^{27,28} This technique is no longer considered to be the optimal approach in genotyping of affected males or carrier females.

Prenatal diagnosis of hemophilia now can be performed almost routinely.²⁹ If a carrier female has a fetus that can be identified as a female by chromosomal analysis of cells obtained by amniocentesis (at approximately 16 weeks of gestation), analysis of free fetal DNA, ultrasound or by chorionic villus sampling at week 10 of gestation, little concern exists regarding whether the female fetus is a carrier because carriers usually have no bleeding tendency. If the fetus is a male, sufficient cells can be obtained to perform DNA analysis using the methods described above. The decision on whether to carry an affected male fetus to term should be decided by the parents after they are appropriately counseled and provided with all the necessary genetic, clinical, and therapeutic information about hemophilia. As the treatment for hemophilia A improves, the decision to continue an affected pregnancy should become far easier.

CLINICAL FEATURES

Hemophilia A is characterized by excessive bleeding into various tissues of the body, including soft-tissue hematomas and hemarthroses that can lead to severe crippling hemarthropathy. Recurrent hemarthroses are characteristic of the disease. The disease has been broadly classified

TABLE 123–1. Clinical Classification of Hemophilia

Classification	Factor VIII Level	Clinical Features
Severe	≤1% of normal (≤0.01 U/mL)	1. Spontaneous hemorrhage from early infancy 2. Frequent spontaneous hemarthroses and other hemorrhages, requiring clotting factor replacement
Moderate	1–5% of normal (0.01–0.05 U/mL)	1. Hemorrhage secondary to trauma or surgery 2. Occasional spontaneous hemarthroses
Mild	6–40% of normal (0.06–0.40 U/mL)	1. Hemorrhage secondary to trauma or surgery 2. Rare spontaneous hemorrhage

as mild, moderate, and severe, although overlap exists between these categories. Table 123–1 shows a classification based on the severity of clinical manifestations. A range of plasma factor VIII concentrations in percentages of normal and in units per milliliter is given for each category. Approximately 10 percent of individuals with factor VIII levels compatible with severe hemophilia may exhibit milder symptoms.³⁰ Among other explanations, this phenotypic heterogeneity could be a result of coinheritance of thrombophilic mutations, such as the factor V Leiden mutation (R506Q).³¹ Severely affected patients (<1 percent factor VIII) frequently experience “spontaneous” bleeding without known trauma other than that associated with the usual day-to-day activities. Without effective treatment, recurrent hemarthroses, resulting in chronic hemophilic arthropathy, occur by young adulthood and are highly characteristic of the severe form of the disorder. However, bleeding episodes are intermittent, and some patients do not bleed for weeks or months. Except for intracranial bleeding, sudden death because of hemorrhage is rare in societies where clotting factor concentrates are freely available.

Moderately affected patients with hemophilia may have occasional hematomas. Hemarthroses, usually associated with a known trauma, may occur as well. These patients have greater than 1 percent but less than 5 percent of normal factor VIII activity.

Mildly affected patients with hemophilia, who have factor VIII levels between 6 to 40 percent, have infrequent bleeding episodes. The disease may go undiagnosed and be discovered only because of excessive hemorrhage postoperatively, following trauma, or after the toss and tumble of contact sports.

Most carriers have approximately 50 percent factor VIII activity and experience no bleeding symptoms, even with surgical procedures. Carriers with factor VIII levels significantly less than 50 percent, as a result of imbalanced X chromosome inactivation, may experience excessive bleeding after trauma (e.g., childbirth or surgery). Therefore, measurement of factor VIII level is recommended in all carriers.

Hemarthroses

Bleeding into joints accounts for approximately 75 percent of bleeding episodes in severely affected patients with hemophilia A.^{32,33} The normal synovium has few cells, but numerous capillaries beneath the synovial layer can be damaged by the mechanical trauma associated with daily use of joints. The joints most frequently involved, in decreasing order of frequency are knees, elbows, ankles, shoulders, wrists, and hips.

Figure 123-4. Hemophilic arthropathy. The chronic effects of repeated hemorrhage into the knees of a severely affected hemophilic patient are seen. Note contractures, and deformity with atrophy of muscle tissue.

Hinge joints are much more likely to be involved than are ball-and-socket joints. Hemarthroses usually occur when an affected child begins to walk.

Hemarthroses are heralded by an aura of mild discomfort that, over a period of minutes to hours, becomes progressively painful. The joint usually swells, becomes warm, and exhibits limited motion. Occasionally, the patient experiences a mild fever. Significant and sustained fever, however, suggests an infected joint. When joint bleeding does not respond to replacement therapy, one should suspect the presence of an inhibitor of factor VIII or an infected joint. Bleeding into the knee joint is more easily detected by physical findings than is bleeding into either the elbow or shoulder. When bleeding stops, the blood resorbs, and the symptoms gradually subside over a period of several days. If hemarthroses are treated early, pain usually subsides in 6 to 8 hours and disappears in 12 to 24 hours. However, repeated hemorrhage into the joints eventually results in extensive destruction of articular cartilage, synovial hyperplasia, and other reactive changes in the adjacent bone and tissues. Iron deposits from residual blood is a major factor in the pathogenesis of hemophilic arthropathy.³³ Acute bleeding into a chronically affected joint may be difficult to distinguish from the pain of degenerative arthritis.

A major complication of repeated hemarthroses is joint deformity complicated by muscle atrophy and soft-tissue contractures (Fig. 123-4). Figure 123-5 shows the various radiologic stages of progressive destruction of joint cartilage and adjacent bone. Osteoporosis and cystic areas in the subchondral bone may develop, and progressive loss of joint space occurs. Figure 123-6 shows a magnetic resonance image (MRI) of a normal knee in comparison to a knee from an individual with severe hemophilia with arthropathy. Figure 123-7 depicts bleeding into a hemophilic ankle.

Repeated bleeding into a joint results in synovial hypertrophy and inflammation. The synovium is thickened and folded, leading to limited joint motion. The result is a tendency for repeated hemorrhages leading to a so-called target joint.³² Indeed, a target joint is defined by the occurrence of three or more spontaneous bleeds within a 6-month period. The joints most often involved are the knees, ankles, and elbows, which become chronically swollen. Chronic synovitis may persist for months or years unless the condition is adequately treated.

Infection of hemophilic joints is not common but must be suspected in all patients with fever, leukocytosis, or other systemic manifestations. Rapid diagnosis is mandatory, because infection of such joints leads to rapid loss of joint architecture and function. A painful and swollen joint may require aspiration, which should be performed by experienced personnel using meticulous aseptic techniques and appropriate factor replacement therapy prior to aspiration.

Hematomas

Soft-tissue hematomas are also characteristic of hemophilia A. Hemorrhage into subcutaneous connective tissues or into muscles may occur with or without a known trauma. Hematomas, once formed, may stabilize and slowly resorb. However, in moderately and severely affected patients, hematomas have a tendency to enlarge progressively and to dissect in all directions, unless appropriately treated. Rarely, retroperitoneal hematomas, after beginning in the iliopsoas muscle, can dissect superiorly through the diaphragm, into the chest, and sometimes even into the soft tissues of the neck, compromising the airway. A retroperitoneal hematoma is more likely to compromise renal function by causing ureteral obstruction. Figure 123-8 shows the computed tomography (CT) scan of a patient with a retroperitoneal hemorrhage. Other hematomas expand locally and may compress adjacent organs, blood

Figure 123-5. Various radiologic stages of hemophilic arthropathy. Stages 0 (normal joint) and 1 (fluid in the joint) are not shown. **A.** Stage 2. Some osteoporosis and epiphyseal overgrowth are present in knee 2. Epiphysis is wider in knee 2 than in knee 1 (arrows). **B.** Stage 3. Subchondral bone cysts (arrowheads). Joint spaces exhibit irregularities. **C.** Stage 4. Prominent bone cysts with marked narrowing of joint space (arrow). **D.** Stage 5. Obliteration of joint space with epiphyseal overgrowth (arrow).

vessels, and nerves. A rare, and often fatal, complication of an abdominal hematoma is perforation and drainage into the colon. Subcutaneous hematomas may dissect into muscle. Pharyngeal and retropharyngeal hematomas, sometimes complicating simple colds, may enlarge and obstruct the airway. Hemorrhage in or around the airway is a potentially life-threatening situation that requires prompt administration of factor VIII.

Hemorrhages occur into muscle in the following order of frequency: calf, thigh, buttocks, and forearm. Recurrent or unresolved hematomas may lead to muscle contractures, nerve palsies, and muscle

atrophy. Bleeding into the tongue (Fig. 123-9) or frenulum is particularly frequent in young children and usually is caused by trauma.

Bleeding into fascia and muscle can result in a so-called compartment syndrome. This results when hemorrhage in a confined space compresses the arterial vasculature resulting in ischemic muscle injury. Compartment syndrome tends to occur in the distal part of the extremities, particularly in the flexor muscles, and sometimes requires urgent fasciotomy under cover of clotting factor replacement therapy. Bleeding into the myocardium or erect penis is very unusual, perhaps explained by the high concentration of tissue factor in these tissues.

Figure 123-6. Magnetic resonance imaging (MRI) of normal and hemophilic knees. **A.** MRI of normal knee. **B.** A transverse T2-weighted spin-echo image of the knee shows an effusion (*) and multiple foci of hemosiderin deposition (arrows) along the synovium lining the suprapatellar bursa. **C.** A sagittal T2-weighted spin-echo image of the knee shows dark foci of synovial hemosiderin deposition (white arrows) accompanied by narrowing of the femorotibial joint (black arrow). **D.** A sagittal STIR (short tau inversion recovery) image of the knee (in the same patient as **B**) demonstrates an effusion in the suprapatellar bursa (asterisks). The irregular, lumpy surface of the bursa represents thickened, hemosiderin-laden synovium. Femorotibial joint narrowing (black arrow) is associated with edema in the subchondral bone of the femoral condyle (white arrow). (Used with permission of Dr. Jordan Renner, University of North Carolina.)

Figure 123-7. **A.** A sagittal STIR (short tau inversion recovery) image of an ankle shows an effusion (*white arrow*). Edema in the distal tibia (*asterisks*) surrounds a debris-filled defect in the subchondral bone of the distal tibia (*black arrows*). **B.** A coronal proton density of the ankle in the same patient as in **A** shows the defect in the subchondral bone of the distal tibia (*white arrow*). Mild narrowing of the tibiotalar joint (*black arrows*) is more apparent laterally.

Figure 123-8. Computed tomography scan of a retroperitoneal hematoma in a patient with severe hemophilia A. Extent of the hematoma is indicated by the *arrows*.

Figure 123-9. Photograph of a tongue hematoma caused by trauma.

Pseudotumors (Blood Cysts)

Pseudotumors are blood cysts that occur in soft tissues or bone. They are rare but dangerous complications of hemophilia (*Fig. 123-10*).³⁴ They are classified into three types. One type is a simple cyst that is confined by tendinous attachments within the fascial envelope of a muscle. The second type initially develops as a simple cyst in soft tissues such as a tendon, but it interferes with the vascular supply to the adjacent bone and periosteum, resulting in cyst formation and resorption of bone. The third type is thought to result from subperiosteal bleeding that separates the periosteum from the bony cortex. Most pseudotumors are not associated with pain unless rapid growth or nerve compression occurs. As the volume of the cyst increases, the cyst compresses and destroys the adjacent muscle, nerve, and/or bone or expands around structures like ureters causing renal failure. Pseudotumors usually contain either serosanguineous fluid or a viscous brownish material surrounded by a fibrous membrane (*Fig. 123-10*). Pseudotumors have a tendency to expand over several years and eventually become multiloculated. Some reach enormous size and involve so many structures that make them inoperable. Erosion through surrounding tissues and penetration into viscera or through the skin can occur, usually as a late event. Sinus tracts from the pseudotumor predispose to infection and septicemia. Pseudotumors often develop in the lower half of the body, usually in the thigh, buttock, or pelvis, but they can occur anywhere, including the temporal bone. CT or MRI is useful for diagnosis. Needle biopsies of pseudotumors should be avoided because of the risk of infection and hemorrhage. A reliable treatment is operative removal of the entire mass because the pseudotumor likely will reform if it is not completely removed. Embolization, percutaneous drainage, and radiotherapy of a pseudotumor have been reported and may be of value in hemophiliacs with inhibitors when surgery is not possible.³⁵ Surgical treatment of patients with large pseudotumors should be done in a hemophilia treatment center with a specialized multidisciplinary team of experts.³⁶

Hematuria

Many severely affected patients with hemophilia experience episodes of spontaneous and asymptomatic hematuria. The urine may be brown or red, depending upon the rate of bleeding. Most bleeding arises from the renal pelvis, usually from one kidney but occasionally from both. Appropriate studies to exclude a structural lesion in the kidneys should be performed. Administration of factor replacement and hydration is usually sufficient to arrest the bleeding. Antifibrinolytic agents, such as aminocaproic acid and tranexamic acid should be avoided in individuals with hematuria because of the risk of forming clots and producing obstructing clots in the ureter.

Neurologic Complications

Intracranial bleeding is one of the most dangerous hemorrhagic events in hemophilic patients.³⁷ Currently, bleeding into the brain is a leading cause of death in hemophilic patients. Hemorrhage into the central nervous system may be “spontaneous” but usually follows trauma, which may be trivial. Symptoms often occur soon after trauma, but sometimes are delayed. For example, symptoms of a subdural hematoma may be delayed for days or several weeks. Hemorrhage into the brain parenchyma or a subdural or epidural hematoma should always be suspected in hemophilic patients with unusual headaches. When intracranial bleeding is suspected, the patient should be treated immediately with factor VIII and diagnostic procedures, such as CT scans or MRI studies should be delayed until after treatment is initiated. Although lumbar puncture has been performed safely in severe hemophilic patients without replacement therapy, replacing factor VIII to a level of approximately 50 percent of normal prior to the procedure is advisable.

Figure 123-10. Retroperitoneal pseudotumor. **A** and **B.** Magnetic resonance imaging and computed tomography scan of pseudotumor arising from the iliopsoas muscle compressing the kidney and other adjacent structures. Loculations and calcifications can be seen. **C.** Gross specimen after surgical removal, weighting approximately 6 pounds. **D.** Cross-section of pseudotumor shows peripheral red hemorrhage, centrally caseified blood and necrosis. Note the thick capsule that surrounds the tumor.

Hemorrhage into the spinal canal is an uncommon neurologic complication in hemophilia, mostly related to trauma that can result in paraplegia. Bleeding may occur within the spinal cord itself, but epidural bleeding compressing the cord is more common.

Peripheral nerve compression is a frequent complication of muscle hematomas, particularly in the extremities. Compression of the femoral nerve by a hematoma in the iliopsoas muscle can result in sensory loss over the lateral and anterior thigh, weakness and atrophy of the quadriceps, and loss of the patellar reflex. The ulnar nerve is the next most frequently involved peripheral nerve. Bleeding may occur in any muscle and may compress local neural blood supply. This situation can be followed by permanent neuromuscular defects and multiple contractures.

Mucous Membrane Hemorrhage

Mucous membrane bleeding is common in hemophilia. Epistaxis and hemoptysis, often resulting from allergic reactions or trauma, can be associated with local structural lesions involving the upper and/or lower respiratory tract. Treatment of epistaxis by cautery or nasal packing sometimes is followed by recurrent bleeding because of sloughing of the cauterized area or dislodging of a poorly formed clot when the packing is removed. Gastrointestinal hemorrhage has a 1.3 percent annual incidence and is mostly associated to older age and complications of advanced liver disease. Ingestion of antiinflammatory drugs for relief of pain of hemophilic arthropathy is a frequent cause of upper gastrointestinal hemorrhage, and a history of ingestion of aspirin and other antiinflammatory drugs should be specifically addressed (and proscribed) when assessing the etiology of such bleeding.³⁸

Dental and Surgical Bleeding

Hemophilic patients are treated with clotting factor preoperatively and postoperatively to prevent bleeding. Mildly or sometimes moderately affected patients may go unrecognized until surgery results in excessive

bleeding at the surgical site. Bleeding may be delayed for several hours or, occasionally, for several days. Surgery in such patients is characterized by delayed wound healing because of poor clot formation.¹⁵ Prolonged bleeding and subsequent infection of the wound hematoma may further complicate healing. Appropriate factor VIII replacement therapy, sometimes supplemented by anti-fibrinolytic agents, can prevent intraoperative and postoperative hemorrhages.

Dental extraction is the most frequent surgical procedure performed on hemophilic patients. Loss of deciduous teeth seldom causes excessive bleeding, but extraction of permanent teeth may result in excessive hemorrhage that can persist intermittently for several days to weeks unless appropriate treatment is administered. In the untreated patient with severe hemophilia, life-threatening, dissecting pharyngeal and/or sublingual hematomas may result from dental procedures or from administration of regional block anesthesia.

LABORATORY FEATURES

Patients with severe hemophilia A have a prolonged activated partial thromboplastin time (aPTT). The prothrombin time (PT) and thrombin clotting time (TCT) are normal. Different combinations of aPTT reagents and instrumentation exhibit varying sensitivities to factor VIII levels. In mild hemophilia, the aPTT may be only slightly prolonged or at the upper limit of normal, especially if factor VIII activity is 20 percent or greater. The aPTT is corrected when hemophilic plasma is mixed with an equal volume of normal plasma. If the hemophilic plasma contains an anti-factor VIII inhibitor antibody, the aPTT on a similar mixture is prolonged, but incubation of the mixture for 1 or 2 hours at 37°C is sometimes required to detect the prolongation. A definitive diagnosis of hemophilia A should be based on a specific assay for factor VIII activity.

Functional factor VIII coagulant activity is measured by one-stage clotting assays based on the aPTT. Chromogenic assays for factor VIII activity also are used widely, but do not always agree with one-stage assays.³⁹ Although infrequently measured in practice, factor VIII antigen is measured by immunologic assays, which detect normal and most abnormal factor VIII molecules. If the factor VIII antigen level is normal but the clotting activity is reduced, the patient has a dysfunctional factor VIII molecule. Such patients have antigen-positive hemophilia, also referred to as cross-reacting material (CRM)-positive.⁴⁰ Patients in whom both the factor VIII antigen level and activity are nearly undetectable are said to be CRM-negative.

DIFFERENTIAL DIAGNOSIS

VWD sometimes is confused with hemophilia A. The basic defect in VWD is reduced activity of von Willebrand factor (VWF), which acts as a carrier of factor VIII *in vivo* (Chap. 126). Thus, in VWD, factor VIII levels are reduced, although considerable variability exists. Although factor VIII is synthesized normally in patients with VWD, the half-life of factor VIII is markedly shortened because the VWF “carrier” molecule is decreased or absent. Other abnormalities in VWD that distinguish VWD from hemophilia A are decreased VWF antigen level, and decreased VWF activity, often measured using the ristocetin cofactor activity assay and a prolonged closure time using the platelet function analyzer PFA-100. In type III VWD, factor VIII levels may be very low (<5 percent of normal), making it difficult to distinguish from classical hemophilia. The lack of a sex-linked pattern of inheritance in the family will help in the differential diagnosis.

Another variant of VWD that is particularly difficult to distinguish from hemophilia A is VWD-Normandy, in which VWF multimers are normal but plasma factor VIII levels are low.⁴¹ Several mutations causing VWD-Normandy have been described, but all of them result in decreased binding of factor VIII to VWF.⁴² The result is shortening of the intravascular survival of factor VIII and thus reduced factor VIII activity. The Normandy variant of VWD should be suspected in patients with mild hemophilia A who do not exhibit a sex-linked recessive inheritance pattern.

Hemophilia A must be distinguished from other hereditary blood clotting factor deficiencies that exhibit a prolonged aPTT, including deficiencies of factors IX, XI, and XII, prekallikrein, and high-molecular-weight kininogen. Only deficiencies of factors VIII and IX cause chronic crippling hemarthroses with a family history suggestive of an X-linked bleeding disorder. Only specific assays can distinguish hemophilia A from factor IX deficiency (hemophilia B). Factor XI deficiency occurs in males and females and is a milder hemorrhagic disorder compared to severe hemophilia A or B. Factor XII deficiency can be confused with mild hemophilia A or B on screening laboratory tests, but specific assays distinguish them. Deficiencies of factor XII, prekallikrein, and high-molecular-weight kininogen can be distinguished from hemophilia because they are not associated with bleeding. Mild hemophilia A, with factor VIII levels of approximately 10 to 20 percent of normal, must be distinguished from combined deficiency of factors V and VIII.^{43,44} Both the PT and aPTT are moderately prolonged in the combined disorder.⁴⁴

THERAPY

General

General principles applicable to therapy for hemophilia A include avoidance of aspirin, nonsteroidal antiinflammatory drugs, and other agents that interfere with platelet aggregation. Acetaminophen or relatively specific cyclooxygenase (COX)-2 inhibitors such as celecoxib have been recommended, but these drugs can be harmful when taken in excessive doses or for prolonged periods. Patients should be advised

of the numerous nonprescription analgesics and herbals that contain aspirin or other antiplatelet agents. Addictive narcotic agents should be used with great caution and only when clearly indicated, because drug dependency can be a major problem for patients with hemophilia. In general, intramuscular injections should be avoided unless the patient receives adequate replacement therapy. In the absence of prophylactic therapy, patients with hemophilia A must be treated as early as possible to avoid bleeding complications. Surgical procedures in hemophilic patients should be scheduled early in the week to avoid “weekend crises.” Ample supplies of factor VIII should be available in the blood bank or pharmacy to ensure rapid access to treatment when needed. All hemophilic patients should have access to home treatment and periodic examinations at a comprehensive hemophilia treatment center. Prophylactic therapy is recommended in all severely affected patients, and it should be initiated before the onset of recurrent hemarthroses (primary prophylaxis) or as directed. Secondary prophylaxis for an established “target” joint may be necessary.⁴⁵

Factor VIII Replacement Therapy

Hemorrhagic episodes in patients with hemophilia A can be managed by replacing factor VIII. Several products are available for use in raising factor VIII to hemostatic levels (Table 123–2). Fresh-frozen plasma and

cryoprecipitate both contain factor VIII and once were the only products available for treatment. A disadvantage of plasma is that large volumes must be infused to achieve and maintain even minimal factor VIII levels. The highest factor VIII level that can be achieved with plasma is approximately 20 percent of normal, which is not always attainable or sufficient for hemostasis. Cryoprecipitate, containing approximately 80 U of factor VIII in 10 mL of solution, can be used to attain normal factor VIII levels, but individual bags of cryoprecipitate must be pooled; the factor VIII dose can only be estimated; and the product must be stored frozen. Several commercial lyophilized factor VIII concentrates, using cryoprecipitate of pooled normal human plasmas as starting material (2000 to 20,000 donors), are available and do not have the disadvantages of plasma and cryoprecipitate (Table 123–2). Factor VIII concentrates have been sterilized by heating in solution, by superheating to 80°C after lyophilization, and by exposure to organic solvent-detergents that inactivate lipid-enveloped viruses, including HIV and hepatitis B and C viruses, but do not inactivate parvovirus or hepatitis A.^{46,47} Parvovirus infection does not occur frequently in hemophilia A patients because parvovirus is transmitted by cellular elements of the blood. Nevertheless, seroconversion to B19 parvovirus has been observed in patients receiving plasma-derived concentrates undergoing solvent-detergent extraction or pasteurization.

Some of these products contain significant amounts of VWF (see Table 123–2). Plasma-derived factor VIII concentrates prepared by monoclonal antibody techniques, and subjected to viral inactivation techniques, are highly purified and, barring breakdown in manufacturing procedures, are considered to be safe in terms of transmission of viral diseases.

Factor VIII produced by recombinant DNA techniques is available, safe, and effective. There are new “third-generation” factor VIII products that are manufactured without exposure to animal or human protein. Although all factor VIII products, both recombinant and plasma-derived, are currently safe and effective, some physicians and patients prefer products that are not exposed to human or animal proteins during the manufacturing process.

The dose of factor VIII can be determined as follows. If 1 U of factor VIII per milliliter of plasma is considered 100 percent of normal, the dose required to raise the level to a given value depends upon

the patient’s plasma volume (approximately 5 percent of body weight in kilograms) and the level to which factor VIII is to be raised. Thus, the plasma volume of a 70 kg adult is approximately equivalent to 3500 mL (5 percent \times 70 kg = 3.5 kg = 3500 g, approximately equivalent to 3500 mL). To achieve normal factor VIII levels of 1 U/mL (100 percent), 3500 U of factor VIII should be given. This scenario assumes a 100 percent recovery of the administered dose. Recovery has approached 100 percent in studies, but depends upon the method of assay and the factor VIII standard used for comparison.⁴⁸ After the initial dose of factor VIII, further doses of factor VIII are based on a half-life of 8 to 12 hours. Thus, after a loading dose of 3500 U of factor VIII, a dose of 1750 U could be given in 12 hours. However, for practical purposes, the dose of factor VIII is based on the knowledge that 1 U of factor VIII per kilogram of body weight raises the circulating factor VIII level by approximately 0.02 U/mL. Thus, to raise the factor VIII level to 100 percent, that is, 1 U/mL, the dose of factor VIII required is approximately 50 U per kilogram of body weight, assuming the patient’s baseline factor VIII level is less than 1 percent of normal. The site and severity of hemorrhage determine the frequency and dose of factor VIII to be infused.

Table 123–3 summarizes the recommended doses of factor VIII for various types of hemorrhage.⁴⁸ These doses are not based on rigorous randomized studies, and recommendations vary among hemophilia centers. Given the high cost of factor VIII, some physicians prefer to use lower doses.

Factor VIII can be given as a constant infusion to hospitalized patients. Following a loading dose to raise factor VIII to the desired level, 150 to 300 U of factor VIII per hour can be infused. Factor VIII levels can be conveniently monitored in blood obtained from veins other than the vein into which factor VIII was infused intravenously.⁴⁹ In selected patients, factor VIII can be given outside the hospital in a continuous infusion using pump devices.⁵⁰

DDAVP (*Desmopressin*)

During the 1970s, 1-desamino-8-D-arginine vasopressin (DDAVP; desmopressin) was found to cause a transient increase in factor VIII in normal subjects and in patients with mild to moderate hemophilia. After a dose of DDAVP (0.3 mcg per kilogram body weight), given intravenously or subcutaneously, factor VIII levels increase two- to

TABLE 123–3. Doses of Factor VIII for Treatment of Hemorrhage*

Site of Hemorrhage	Desired Factor VIII Level (% of Normal)	Factor VIII Dose† (U/kg Body Weight)	Frequency of Dose‡ (Every No. of Hours)	Duration (Days)
Hemarthroses	30–50	~25	12–24	1–2
Superficial intramuscular hematoma	30–50	~25	12–24	1–2
Gastrointestinal tract	50–100	50	12	7–10
Epistaxis	30–50	~25	12	Until resolved
Oral mucosa	30–50	~25	12	Until resolved
Hematuria	30–100	~25–50	12	Until resolved
Central nervous system	50–100	50	12	At least 7–10 days
Retropharyngeal	50–100	50	12	At least 7–10 days
Retroperitoneal	50–100	50	12	At least 7–10 days

*Mild or moderately affected patients may respond to 1-desamino-8-D-arginine vasopressin (DDAVP), which should be used in lieu of blood or blood products whenever possible.

†Factor VIII may be administered in a continuous infusion if the patient is hospitalized. After initial bolus, approximately 2 to 5 U/kg/h of factor VIII usually are sufficient in an average-size adult. Bolus doses are given every 12 to 24 hours.

‡The frequency of dosing and duration of therapy can be adjusted, depending on the severity and duration of the patient’s bleeding episode.

threefold above baseline in most, but not all, mildly or moderately affected hemophilia A patients. Patients with severe hemophilia A do not respond to DDAVP.⁵¹ A concentrated intranasal spray of DDAVP also can be used (150 mcg in each nostril for adults and 150 mcg in one nostril for children weighing less than 50 kg). The degree of response to the drug should always be determined in patients before a bleeding episode, because occasionally mildly or moderately affected patients do not respond. The peak response to DDAVP usually occurs 30 to 60 minutes after dosing. In patients with mild or moderate hemophilia A and in carriers whose baseline factor VIII levels are less than 0.5 U/mL, DDAVP may be used in lieu of blood products. The mechanism by which DDAVP increases factor VIII is unknown.

Repeated administration of DDAVP results in a diminished response to the agent (tachyphylaxis). In many patients, the response to the second DDAVP dose averages 30 percent less than the response to the first dose, and the response rate may be even less after additional doses.⁵² DDAVP is a potent antidiuretic. As a result, hyponatremia has been reported in some patients whose water intake exceeds approximately 1 L per 24 hours after dosing. There is no convincing evidence to indicate that DDAVP administration is associated with thrombosis in hemophilic patients.

Antifibrinolytic Agents

Antifibrinolytic agents, such as ϵ -aminocaproic acid (EACA) and tranexamic acid, have been used to enhance hemostasis in patients with hemophilia A.^{53,54} Fibrinolytic inhibitors may be given as adjunctive therapy for bleeding from mucous membranes and are particularly valuable as adjunctive therapy for dental procedures. The usual oral dose of tranexamic acid for adults is 1 g four times per day. EACA can be given as a loading dose of 4 to 5 g followed by 1 g/h by continuous IV infusion in adults. Another regimen of EACA is 4 g every 4 to 6 hours orally for 2 to 8 days, depending upon the severity of the bleeding episode. Antifibrinolytic therapy is contraindicated in the presence of hematuria because clots resistant to lysis may obstruct the ureters.

Fibrin Glue

Fibrin glue, otherwise known as fibrin tissue adhesive, has been used as adjunctive therapy to factor VIII in hemophilic patients.⁵⁵ Briefly, fibrin glue contains fibrinogen, thrombin, and factor XIII. Fibrinolytic inhibitors are added to some commercial products. The fibrinogen-factor XIII mixture is placed on the injury site and clotted with a human thrombin solution containing calcium. As a result, the fibrin clot is crosslinked and anchored to tissue. It is especially useful for hemostasis in patients undergoing dental surgery who receive a preextraction bolus of factor VIII followed by application of fibrin glue to the tooth socket. Fibrin glue also has been used as adjunctive therapy to factor VIII following orthopedic procedures and circumcision. It is very valuable for controlling bleeding when applied to the bed of a surgical wound following removal of large pseudotumors. Some hemophilia centers prepare their own "homemade" fibrin glue using cryoprecipitate as a source of fibrinogen and factor XIII.

Treatment of Minor or Moderate Hemorrhage

On occasion, superficial cuts and abrasions are managed with local measures, that is, application of pressure sometimes suffices to control bleeding, although oozing may continue intermittently for several hours. Topical thrombin is of little value in this type of bleeding. In general, cautery should be avoided because bleeding may restart when the cauterized area is sloughed.

When replacement therapy for epistaxis is needed, the factor VIII level should be raised to approximately 30 to 50 percent of normal. For treatment of hematuria, patients should be instructed to drink large

quantities of fluids. If hematuria is mild, uncomplicated, and painless, factor VIII replacement may not be necessary unless the hematuria persists. Gross or protracted hematuria requires replacement therapy. In these patients, factor VIII levels of at least 50 percent of normal or higher are needed, probably because urine is rich in urokinase that rapidly lyses clots.

Hemophilic patients requiring endoscopic procedures first should be treated with factor VIII to raise levels to at least 0.5 U/mL before the procedure. Only one dose may be necessary if endoscopy is uncomplicated. In cases of biopsies, severe abrasions or perforations following endoscopy, factor VIII replacement should be continued until healing of the lesion is complete. For expanding soft-tissue hematomas, factor VIII therapy should be started immediately and maintained until the hematoma begins to resolve. With effective therapy, the patient usually experiences rapid relief from pain. For treatment of acute hemarthroses, prompt administration of factor VIII decreases the occurrence of extensive degenerative joint changes, deformity, and muscle wasting. For chronic synovitis and for bleeding into "target" joints, daily administration of factor VIII to raise levels to 100 percent of normal for 6 to 8 weeks ("secondary prophylaxis") is usually indicated.

Treatment of Major Nonsurgical Hemorrhages

Any hemorrhage in a patient with hemophilia A may become major, but the following hemorrhages are common and frequently life-threatening: retropharyngeal, retroperitoneal, and central nervous system bleeding, whether subdural, subarachnoid, or into the brain parenchyma.⁵⁶

For treatment of retropharyngeal bleeding, particularly that associated with a sensation of tightness in the throat, pain in the neck, dysphagia, or difficulty breathing, patients should receive factor VIII immediately in doses sufficient to raise factor VIII levels to normal (1.0 U/mL). Near-normal levels should be maintained until bleeding ceases and the hematoma begins to resolve. For retroperitoneal hemorrhage, early treatment is required, and therapy should be continued for 7 to 10 days; otherwise, bleeding may recur upon resumption of activity.

Immediate administration of factor VIII, sufficient to raise the level to normal, should be started upon the first sign of an intracranial hemorrhage or following a history of head trauma. Even asymptomatic patients with a history of head trauma should receive at least one dose of factor VIII as a prophylactic measure, and this dose should be given before diagnostic procedures such as a CT scan. Treatment of a known intracranial hemorrhage should be maintained for a minimum of 7 to 10 days, and the circulating factor VIII level should be kept normal throughout this period. Prolonged secondary prophylaxis is often indicated following an intracerebral hemorrhage, particularly in patients with HIV disease, who seem to have a high recurrence rate. Evacuation of subdural hematomas and surgical removal of hematomas involving the brain parenchyma can be performed, depending upon location. Despite aggressive replacement therapy, however, mortality from central nervous system bleeding is high.

Replacement of Factor VIII for Surgical Procedures

For major surgical procedures, factor VIII should be raised to normal levels before operation and maintained for 7 to 10 days or until healing is complete. Treatment can be started a few hours before surgery and continued intraoperatively using a continuous infusion or boluses every 8 to 12 hours. Postoperatively, factor VIII levels should be monitored at least one or two times per day to ensure that adequate levels are maintained. Because factor VIII may be "consumed" during surgery, factor VIII levels should be monitored intraoperatively and doses of factor VIII higher than normal may be required. Bone and joint surgery may require longer periods of factor VIII coverage. Replacement of knee, hip, ankle, and elbow joints may be required for intractable

pain associated with loss of function, and several weeks of replacement therapy may be needed postoperatively.⁵⁷

Home Therapy

Home therapy using available factor VIII concentrates was introduced in the United States in 1977 and was a major advance in the treatment of all forms of hemophilia.^{58,59} Current practice for home therapy is to treat patients at home using a regular prophylactic regimen. Patients, age 6 years and older, can be taught to treat themselves with factor VIII. The training of patients and their families for home therapy is best accomplished in a regional comprehensive hemophilia diagnostic and treatment center or an affiliate of one of these centers. Patients are given an adequate quantity of factor concentrates and the supplies required for intravenous administration. Prompt treatment of hemarthroses and hematomas made possible by home therapy has markedly improved the morbidity and mortality associated with hemophilia. In addition, the quality of life of hemophilia A patients has improved dramatically.^{59,60}

Prophylactic Therapy

The advent of stable and safe factor VIII concentrates has made prophylactic therapy for hemophilia A in severely affected patients feasible. Such therapy is now the treatment of choice for all severely affected hemophilia patients (unfortunately, such treatment is not available or affordable for all patients). Administration of 25 to 40 U of factor VIII per kilogram of body weight three times per week or every other day markedly decreases the frequency of hemophilic arthropathy and other long-term effects of hemorrhagic episodes.^{60–62} Primary prophylaxis is usually initiated before the age of 2 years or after the first joint bleed, which is usually when the child begins to walk. Central venous catheters may be required sometimes for very young children; however, they are associated with a risk of infections and thrombosis.⁶³ Secondary prophylaxis is started after the onset of hemarthrosis and can be used for short periods of time or to manage target joints. The consumption of factor concentrate is higher when patients are on prophylaxis when compared to on-demand but analysis of the economic impact of prophylactic therapy, weighing the benefits against the high costs of factor VIII concentrates, suggests the clinical benefit of prophylaxis is warranted, as evidenced by significant improvement in the clinical condition of patients and improvement in the quality of life.^{62,64}

COURSE AND PROGNOSIS

After the advent of factor VIII concentrates in the 1960s, the morbidity and mortality from bleeding in hemophilia were significantly reduced, and by the late 1970s the life expectancy of hemophilia A patients began to approach that of normal individuals in those populations. However, use of replacement therapy has not been without significant complications. Prior to 1985, common and serious adverse side effects of treatment included chronic liver disease resulting from hepatitis B and C and, from about 1978, infection with HIV.⁶⁵ Factor VIII concentrates were prepared from many thousands of donors, making contamination of factor VIII concentrates by bloodborne viruses highly likely. With the introduction of heat- or solvent-detergent-treated concentrates in 1985, contamination of blood products with these viruses has been eliminated for all practical purposes. However, AIDS became a leading cause of death in older patients with hemophilia.⁶⁵ Chronic liver disease in hemophilia A patients resulting from transfusion-related hepatitis B and C may be accelerated by HIV infection and by the associated hepatotoxicity of antiviral drug therapy.⁶⁶ Fortunately, patients treated prophylactically after 1985 can expect almost normal life spans free of the complications of hepatitis, AIDS, and other currently recognized bloodborne viral diseases. However, the development of inhibitor

antibodies against factor VIII has been, and continues to be, one of the more serious complications of replacement therapy.

Factor VIII Inhibitors

Other than the transmission of viral diseases by factor VIII infusions, the main complication of hemophilia A replacement therapy is the development of specific inhibitor antibodies that neutralize factor VIII.⁶⁷ The reported prevalence of anti-factor VIII inhibitors in severe hemophilia A patients is variable, ranging from 3.6 percent to 27 percent. In the white population the estimated prevalence is approximately 13 percent, compared to 27 percent and 25 percent in the black and Hispanic population, respectively.⁶⁸ The risk of inhibitor development is higher in patients with large deletions and nonsense mutations when compared to small deletions/insertions and missense mutations. Frequent testing for inhibitors in previously untreated patients receiving newer highly purified factor VIII products from plasma or by recombinant technology revealed the frequent occurrence of transient inhibitors to factor VIII, many of which were of low titer and did not necessitate cessation of treatment with the same product. Although still controversial, some believe that the risk of inhibitors does not appear to be higher with the use of highly purified products than the risk reported in earlier studies using products of intermediate purity that contain VWF.^{69–74} Some studies have reported that VWF is immunomodulatory, so that products containing VWF may be less likely to induce inhibitors compared to highly purified products. One outbreak of inhibitors in Europe appeared to be related to the neoantigenicity of an intermediate-purity plasma-derived factor VIII concentrate. Fortunately, inhibitors disappeared from affected patients when use of the product was stopped.⁷⁵

Table 123–4 lists the risk factors that have been associated with the development of inhibitors. They arise most frequently in severely affected patients, following treatment at an early age. Many have gross gene rearrangements or the intron 22 inversion abnormality of the factor VIII gene.

Factor VIII inhibitors are antibodies, most often of the immunoglobulin (Ig) G class and frequently restricted to the IgG₄ subclass.⁶⁷ Antibodies against the A₂ and C domains of factor VIII are most common. These antibodies interfere with the interactions of factor VIII with other hemostatic components.^{67,76}

Early diagnosis of factor VIII inhibitors is essential. Although the presence of an inhibitor can be suspected on clinical grounds, as when a patient does not respond to conventional doses of factor VIII,

TABLE 123–4. Risk Factors for Development of Anti-Factor VIII Antibodies in Hemophilia A Patients

Disease severity: 80% of hemophilia A patients with inhibitors have <1% factor VIII activity

Early exposure to factor VIII concentrates: majority of high-titer inhibitors develop after <90 days of exposure to factor VIII

Genetic factors

1. Family history of inhibitor development
2. Ethnic background: Blacks > Hispanics > whites
3. Molecular defects: inversion and crossing over defect in intron 22, gene deletions, and nonsense point mutations resulting in patients without factor VIII antigen

Method of purification of factor VIII concentrate

Adapted and modified from Roberts HR: Inhibitors and their management, in *Hemophilia & Other Bleeding Disorders*, edited by Rizza, G Lowe, p 371. WB Saunders, New York, 1997.

laboratory diagnosis is required for confirmation. Factor VIII inhibitors are time and temperature dependent *in vitro*. The prolonged aPTT of the plasma of a patient without an inhibitor is corrected when mixed 1:1 with normal plasma even after incubation at 37°C for 1 to 2 hours. In contrast, the aPTT of a 1:1 mixture of plasma from a patient with an inhibitor and normal plasma is significantly prolonged after incubation at 37°C for 1 to 2 hours. Specific diagnosis rests upon demonstrating that an appropriate dilution of the patient's plasma, when added to normal plasma, specifically neutralizes factor VIII and not other blood clotting factors that influence the aPTT (i.e., factors IX, XI, XII, prekallikrein, high-molecular-weight kininogen). The demonstration that the inhibitor is specific for factor VIII distinguishes it from inhibitors of other clotting factors, for example, the lupus anticoagulant, and nonspecific inhibitors. A common assay used for inhibitor detection and quantification is the Bethesda assay.⁷⁷ In the Bethesda assay, the patient's plasma is diluted such that, when the plasma is mixed with an equal volume of normal pooled human plasma and incubated for 2 hours at 37°C, the factor VIII activity in the mixture is decreased by 50 percent. A modification of the Bethesda assay is the Nijmegen assay, in which buffer is used instead of factor VIII-deficient plasma. This method has shown to be more dependable at detecting low concentration of inhibitors.⁷⁸

Several approaches to treatment of factor VIII inhibitors are available (Table 123-5). Use of these treatments requires knowledge of whether the patient with an inhibitor is a "high" or "low" responder and whether the bleeding episode requiring treatment is minor or major.⁶⁷

High-Responder Patients Approximately 60 percent of patients who have inhibitors are high responders. High responders are defined as patients whose inhibitor titer is higher than 5 Bethesda units (BU) at baseline or whose initial inhibitor titer is less than 5 BU but rises to greater than 5 BU after administration of factor VIII. Thus, high responders who are not treated with factor VIII for long periods may have a sustained high level of inhibitor, or they may have a very low to undetectable level of inhibitor until they are challenged with factor VIII.

Major bleeding episodes in a high-responder patient whose initial inhibitor titer is less than 5 BU can be treated with human factor VIII concentrate (see Table 123-5). When the initial titer is low, sufficient factor VIII can be administered in high doses to neutralize the inhibitor and attain adequate factor VIII levels for hemostasis. Although factor VIII inhibitor bypassing agents can be used (see below), they are not as reliable as factor VIII in achieving hemostasis, and their effect cannot be adequately monitored with specific laboratory tests. If factor VIII is used, a loading dose of 10,000 to 15,000 U may be required, followed by up to 1000 U of factor VIII per hour, depending upon the factor VIII level. One can expect an anamnestic response approximately 5 days after administration of factor VIII.

In high-responder patients whose initial inhibitor titer is less than 5 BU and who experience a minor bleeding episode, the agent of choice is a factor VIII inhibitor bypassing agent. Recombinant factor VIIa in

doses of 90 to 120 mcg per kilogram of body weight or higher every 2 to 3 hours is safe and effective in most hemorrhagic episodes.⁷⁹ The dosing frequency is based on a factor VIIa plasma half-life of approximately 2 to 3 hours. The mechanisms of action of factor VIIa have been investigated using *in vitro* techniques. After coagulation is initiated by the tissue factor-factor VIIa pathway, factor VIIa at recommended doses is hypothesized to activate factor X on the surface of activated platelets, even in the absence of additional tissue factor activity.⁸⁰ Factor Xa then can associate with factor Va and convert prothrombin to thrombin. Because activated platelets are localized to the site of vessel injury, thrombin generation by factor VIIa is localized to the site of bleeding. This process may account for the reported safety of factor VIIa.⁸⁰ Factor VIII inhibitor bypassing activity (FEIBA), a plasma-derived agent, has also been used successfully to treat bleeding episodes in inhibitor patients and is both safe and effective⁸¹ given at a recommended dose of 50 to 100 U per kilogram body weight every 8 to 12 hours (not to exceed 200 U per kilogram per day).

High-responder patients whose initial inhibitor titer is greater than 5 BU usually do not respond to even very high doses of human factor VIII. Thus, recombinant factor VIIa or FEIBA should be used.⁸¹ If these agents are not available, nonactivated prothrombin complex concentrates or plasma exchange with high dose replacement factor VIII can be considered.

Low-Responder Patients Low-responder patients are arbitrarily defined as patients whose inhibitor titer is less than 5 BU even after a challenge with factor VIII. For major bleeding episodes, high doses of human factor VIII can be used as recommended above. For minor bleeds, recombinant factor VIIa or FEIBA are recommended because some "low" responders may convert to high responders when they are challenged repeatedly with factor VIII.

Nonactivated or activated prothrombin complex concentrates both contain variable amounts of activated factors, including factors VIIa, IXa, and Xa. The activated products have higher concentrations of activated factors than do nonactivated products. FEIBA contains a complex of prothrombin and factor Xa that can bind to membrane surfaces and enhance thrombin generation in the absence of factors VIII or IX.^{80,81}

Surgery in Inhibitor Patients The question of whether major surgery can be performed in patients with hemophilia A or B with inhibitors arises now that joint replacement is possible.⁸² Knee, ankle, hip, and elbow replacements have been carried out successfully in patients with inhibitor antibodies using bypassing agents. Basically, the patient is given a loading dose of factor VIIa followed by bolus doses of factor VIIa and use of fibrin sealant and antifibrinolytic therapy until healing is complete. FEIBA has also been successfully used in surgery in hemophilic patients with inhibitors.⁸³

Immune Tolerance Removal of the antibody is the definitive goal of inhibitor management. Plasmapheresis, adsorption of the antibody on an affinity column during plasma exchange, and administration of

TABLE 123-5. Treatment of Inhibitors in Hemophilia A Patients

Type of Patient	Initial Titer	Minor Hemorrhage*	Major Hemorrhage*
High responder	<5 BU	Recombinant factor VIIa; FEIBA	Factor VIII [†] ; recombinant factor VIIa; FEIBA
High responder	>5 BU	Recombinant factor VIIa; FEIBA	Recombinant factor VIIa; FEIBA; plasma exchange

TABLE 123–6. Examples of Tolerance Protocols for Hemophilia A Inhibitor Patients with Good-Risk Factors

Immune Tolerance Protocols	Dose	Time to Negative Inhibitor
High-dose regimen	200 U/kg factor VIII per day	4.6 months
Low-dose regimen	50 U/kg factor VIII three times per week	9.2 months

Data from DiMichele DM: Immune tolerance in haemophilia: The long journey to the fork in the road. *Haemophilia* 159(2):123–134, 2012.

intravenous γ -globulin have been used in patients with an inhibitor. The Malmö protocol uses nearly all of these approaches in combination, including extracorporeal adsorption of antibody to a Sepharose A column, administration of cyclophosphamide, daily administration of factor VIII, and intravenous γ -globulin.⁸⁴

The most promising approach to eradication of an inhibitor is use of immune tolerance regimens. The basis of this approach is administration of frequent (daily or thrice weekly) doses of factor VIII until the inhibitor titer is undetectable.⁸⁵ Low- and high-dose regimens have been described (Table 123–6). Predictors of success have been described in clinical studies in patients with high titer inhibitors and include young age at detection of inhibitor; inhibitor titer less than 10 BU before starting immune tolerance induction (ITI); peak titer less than 100 BU after starting ITI; historical peak titer less than 200 BU; age less than 5 years old between diagnosis and start of ITI; and genotype (small deletions and insertions, and missense mutations). Factor VIII inhibitor bypassing agents are used for prevention and treatment of acute bleeds that occur during immune tolerance induction.

Other approaches to treatment of factor VIII inhibitors include immunosuppressive drugs, like cyclosporine and rituximab.^{85–87} However, these drugs, although occasionally successful, seem to be more effective in patients with acquired hemophilia resulting from autoantibodies against factor VIII.

Infectious Complications

Hepatitis Almost all multitransfused patients with hemophilia treated before 1985 were infected with one or more viruses that caused hepatitis. Although many infected patients did not suffer acute symptoms, at least 50 percent developed chronic persistent or chronic active hepatitis that in many cases, resulted in cirrhosis. Hepatitis C and B viruses are commonly associated with chronic liver disease. Many adult hemophilia patients treated with concentrates before 1985 have circulating antibodies to hepatitis B surface antigen, and hepatitis C. Hepatitis C infection progresses more rapidly in the presence of HIV infection. Until recently, therapy with pegylated interferon, and ribavirin reduced viral load and improve survival of many affected patients; however, newer approaches using serine protease inhibitors and nucleotide polymerase inhibitors has led to a high rate of sustained virologic responses.⁸⁸ All patients with hemophilia should be vaccinated against hepatitis A and hepatitis B.

Human Immunodeficiency Virus Many of the older, severely affected hemophilia A patients who were treated before 1985 have antibodies to HIV, indicating infection with the virus. The incidence of HIV antibodies in mildly affected patients is much lower and correlates with treatment with factor VIII concentrates before viral inactivation procedures were used. In one study, 14 percent of patients treated only with cryoprecipitate from 1979 to 1985 were infected with HIV, whereas 88 percent of patients treated with factor VIII concentrates became infected.⁸⁹ Screening of donor populations and new techniques

for preparing factor VIII concentrates since 1985 have eliminated the risk of HIV transmission.

Risk of Viral Disease Transmission By New Factor VIII Products

All available factor VIII concentrates, both plasma-derived and recombinant products, are considered safe and effective with almost no risk of transmitting currently known viral diseases. However, occasional exceptions have been observed. For example, solvent-detergent treatment does not inactivate viruses without lipid envelopes, including the hepatitis A virus and parvovirus. As a result, outbreaks of hepatitis A have been reported in patients receiving some solvent detergent–treated products. These outbreaks of viral diseases usually have been related to breakdowns in the manufacturing process.

Prions Prions are infectious particles consisting of proteinaceous material devoid of a nucleic acid genome.⁹⁰ They are thought to be variant forms of a normal protein with an altered conformation. The “infectious” nature of prions may result from their ability to bind to other proteins and induce similar conformational changes in them such that new “infectious” particles can be generated. Prions are responsible for several neurodegenerative disorders, including Creutzfeldt-Jakob disease (CJD) in humans, scrapie in sheep, and spongiform encephalopathy in cows. Prions are resistant to most currently available viral inactivation techniques. Removal of prion particles using iodine column chromatography has been claimed.⁹¹ Although prion diseases generally are transmitted by ingestion of infected neural tissues, a new variant of CJD appears to occur in people who have eaten beef from cows infected with a form of prion causing bovine spongiform encephalopathy. This form of CJD has been reported mainly in the United Kingdom and in certain other European countries and has been related to the bovine disease.⁹² For example, prions have been found in tonsillar tissue of patients with new-variant CJD, heightening concern about whether prions of this type might be transmitted by blood products.⁹³ Conclusive data about possible prion infection of hemophilic patients are lacking, so continued vigilance is necessary.

● HEMOPHILIA B (FACTOR IX DEFICIENCY, CHRISTMAS FACTOR DEFICIENCY)

ETIOLOGY AND PATHOGENESIS

Hemophilia B occurs in one of every 25,000 to 30,000 live male births. As with hemophilia A, hemophilia B is found in all ethnic groups and has no geographic predilection.

Factor IX is a vitamin K-dependent, single-chain glycoprotein consisting of 415 amino acids. It is activated by the factor VIIa–tissue factor complex, or factor XIa, forming the active enzyme factor IXa (Chap. 113). Once activated, factor IXa activates factor X in the presence of factor VIIIa, phospholipid (activated platelets), and calcium. Factor VIIIa is a necessary cofactor for activity of factor IXa. Therefore, deficiency of either factor IX or VIII leads to a similar lack of factor X-activating activity on the platelet surface. Factor Xa converts prothrombin to thrombin in the presence of factor Va, activated platelets, and calcium. Hemophilia B can result from either the absence or the dysfunction of factor IX molecules. Clinical severity of hemophilia B is roughly correlated with factor IX functional activity.

GENETICS AND MOLECULAR BIOLOGY

The factor IX gene is located on the long arm of the X chromosome. It is approximately 33 kb long, which is much smaller than the gene for factor VIII.⁹⁴ Because it is less complex, the factor IX gene has been studied in greater detail than the factor VIII gene. Figure 123–11 is a schematic of the gene and the protein product. The protein consists of a signal

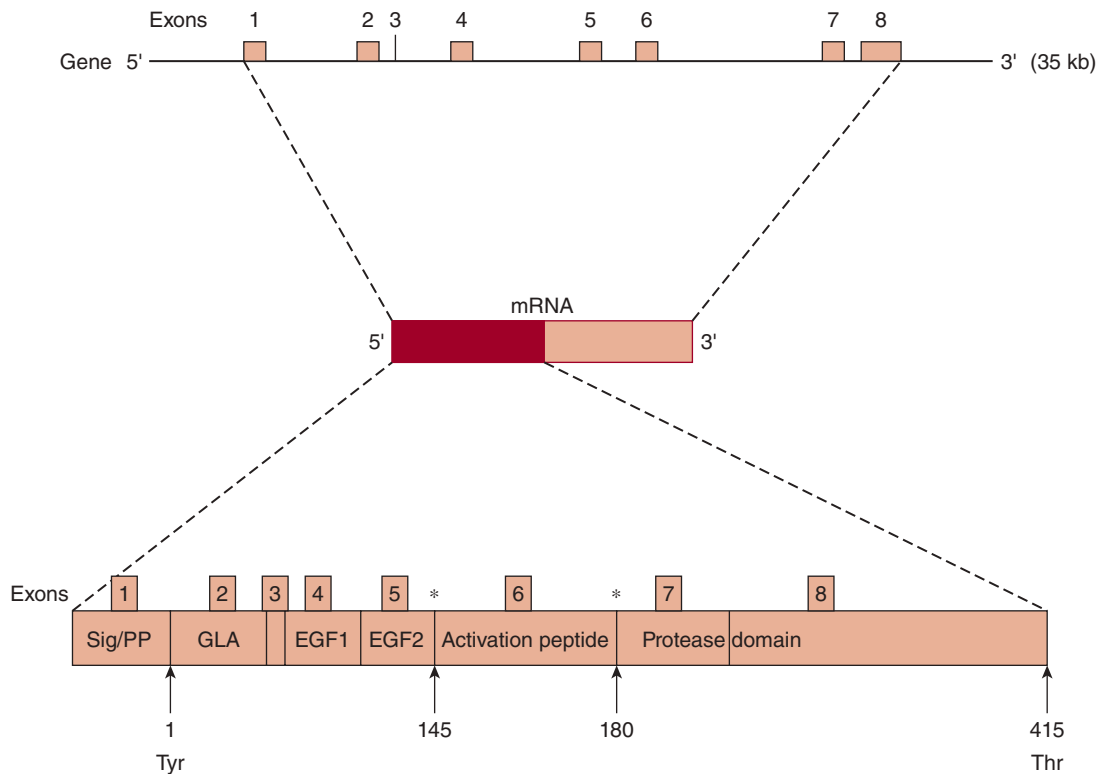

Figure 123–11. Schematic of the factor IX gene, the messenger RNA, and the protein. Exons are depicted by the tan boxes. The light 3' portion of the mRNA is untranslated. The diagram of the protein shows the domains and the exons that encode each portion of the protein. The cleavage sites of factor XIa or factor VIIa–tissue factor complex are indicated by *asterisks*.

peptide that targets the protein for secretion from the hepatocyte to the circulation. The propeptide is necessary for posttranslational modification of 12 aminoterminal glutamic acid residues by an intracellular vitamin K-dependent carboxylase. The propeptide is cleaved from the mature protein before it enters the circulation. The aminoterminal of factor IX contains 12 γ -carboxyglutamic acid (GLA) residues necessary for calcium-dependent lipid binding. The activation peptide is cleaved from the zymogen form of factor IX by either factor VIIa/tissue factor or factor XIa, resulting in the two-chain active enzyme, factor IXa β . The catalytic triad (His 221, Asp 229, ser 365) resides on the heavy chain (Chap. 113).⁹⁴

There are more than 1000 distinct mutations or deletions in the factor IX gene reported in the factor IX database, including more than 900 distinct amino acid substitutions and numerous complete gene deletions.^{95,96} More than 30 percent of factor IX mutations occur at CpG dinucleotides. These mutations often involve critical Arg residues that result in a dysfunctional molecule.^{96–99} Many mutations have been reported in more than one kindred, and some of these mutations derive from the same “founder.”¹⁰⁰ As predicted by genetic theory of X chromosome-linked recessive disorders, approximately one-third of mutations resulting in hemophilia B arise *de novo*.

Mutations in regulatory regions of the factor IX gene have been identified. Particularly interesting examples are mutations in the 5' promoter region that lead to the hemophilia B Leyden phenotype.¹⁰¹ This disorder is characterized by very low levels of factor IX antigen and activity at birth and during early childhood. The factor IX levels gradually rise to 60 percent of normal or greater following puberty, possibly caused by the age-related stability element/age-related increase element mediated genetic mechanism.¹⁰² Several different mutations in the promoter region of the factor IX gene disrupt binding of transcription factors, resulting in reduced transcription of the factor IX gene.^{101,103}

The hormonal changes occurring at puberty apparently can overcome the transcription defect and maintain hemostatic levels of factor IX.

Hemophilia B inheritance is similar to that of hemophilia A. All daughters of affected males are obligate carriers, whereas all sons are normal. Female carriers may have factor IX levels ranging from less than 10 to 100 percent of normal, but the mean level is approximately 50 percent. Carriers of hemophilia B usually are asymptomatic, except in cases of extreme X chromosome inactivation, X mosaicism, Turner syndrome, or testicular feminization.¹⁰⁴ When the level of factor IX activity is less than 25 percent of normal, abnormal bleeding may occur, especially after trauma and surgery.

Carrier Detection and Prenatal Diagnosis

Factor IX genotyping is achieved by direct sequencing. Prenatal diagnosis may be accomplished by analysis of DNA obtained by chorionic villus sampling as early as 8 to 10 weeks after conception.¹⁰⁵ This procedure also can be performed on fetal cells obtained by amniocentesis and is more accurate than fetal blood sampling for factor IX activity and factor IX antigen. Large deletions are relatively rare in severe hemophilia B, but are associated with a higher risk of factor IX inhibitors when present.

CLINICAL FEATURES

Bleeding episodes in patients with hemophilia B are clinically indistinguishable from patients with hemophilia A, although as stated elsewhere, the hemophilia B population as a whole seem to have fewer and less-severe complications than severely affected hemophilia A patients⁹ (see “Clinical Features” under “Hemophilia A” above). When patients are inadequately treated, repeated hemarthroses leading to chronic, crippling hemarthropathy occur. Hematoma formation with dissection

into surrounding tissues is possible. Hematuria, bleeding from mucous membranes, and other bleeding manifestations are as described in the section on hemophilia A. The physical, psychological, vocational, and social aspects of the disease are similar to those encountered with hemophilia A. Classification of hemophilia B is based on clinical severity and roughly correlates with the level of factor IX coagulant activity. Severe disease usually is associated with factor IX levels of less than 1 percent of normal; moderate disease is associated with factor IX levels of 1 to 5 percent; and mild disease is associated with factor IX levels ranging from 5 to 40 percent.

The occurrence of factor IX inhibitor antibodies is much less common in hemophilia B patients than in hemophilia A patients, and is very rare in nonsevere disease. Only approximately 3 percent of severely affected patients develop inhibitors.

LABORATORY FEATURES

The screening tests used in the diagnosis of hemophilia A also are used in the diagnosis of hemophilia B. In most cases of hemophilia B, PT is normal and aPTT is prolonged. However, specific assay of factor IX coagulant activity is required for definitive diagnosis. The most commonly used test is a one-stage clotting assay based on aPTT. Determination of factor IX antigen levels is valuable in further classifying the disorder.

DIFFERENTIAL DIAGNOSIS

Hemophilia B must be distinguished from hemophilia A. Both forms are inherited as X-linked recessive disorders, and both have almost identical hemorrhagic and clinical manifestations. The only method for differentiating hemophilia B from hemophilia A is performing specific assays for factors VIII and IX on the patient's plasma.

Inherited and acquired deficiencies of other vitamin K-dependent factors, liver disease, and warfarin overdose must be distinguished from hemophilia B. In these cases, not only factor IX but all other vitamin K-dependent clotting factors, including prothrombin, factor VII, and factor X, are decreased. Acquired antibodies specific for factor IX occur in nonhemophilic patients but are very rare.

THERAPY

Factor IX Replacement

The basic treatment of hemophilia B is replacement of factor IX. Several products are available for use (Table 123-7). The older factor IX-containing products often are referred to as prothrombin complex concentrates. These products, which are prepared from large pools of human plasma (several thousand donors), contain not only factor IX but also prothrombin, factors VII and X, and proteins C and S. In addition, the products may contain small amounts of activated factors, such as factors VIIa, IXa, and Xa. Some of these products are associated with thromboembolic events, presumably resulting from contamination with the activated components. Deep venous thrombosis (DVT) and disseminated intravascular coagulation have been reported in some patients who receive large doses of prothrombin complex concentrates, but these complications seem to occur less frequently with currently available purified factor IX products than with earlier preparations. Prothrombin complex concentrates are no longer the optimal choice for replacement therapy in hemophilia B, even though they are much less expensive than the highly purified factor IX concentrates. When prothrombin complex concentrates are used for replacement therapy, factor IX levels greater than 50 percent of normal should not be exceeded in order to minimize the risk of thrombosis. Use of these products in factor IX-deficient patients with liver dysfunction may be hazardous because the activated

factors contaminating these preparations may not be cleared efficiently by a diseased liver, and thrombosis might be induced.

Table 123-7 lists the highly purified factor IX products. Some products are prepared from human plasma; at present, three products are produced by recombinant DNA technology. Although all available factor IX concentrates are considered safe and effective, the recombinant product undergoes a final viral inactivation step. In addition, the recombinant products are not exposed to human albumin or bovine serum during preparation. Thus, even the theoretical risk of transmission of prion diseases is averted with this preparation. Some clinicians consider the recombinant product to be the agent of choice, although it has a major drawback in that the intravascular recovery of factor IX generally is lower than the recovery of highly purified factor IX product prepared from plasma.¹⁰⁶ The recombinant factor IX products are not thought to be thrombogenic. New factor IX products have been recently approved and others undergoing clinical trials or currently being developed, some of them with extended half-life (see Table 123-7).¹⁰⁷ Different technologies have been applied to extend the half-life of factor IX including Fc-fusion, recombinant albumin fusion and PEGylation (glycoPEGylation), so one can expect the number of available factor IX products to increase in the near future.

Dosing of Factor IX

The dose calculations for all factor IX products are different from those used in hemophilia A because intravascular recovery of factor IX is only approximately 50 percent, and the recovery is even lower with the recombinant product. The reason for this finding is unclear, but as factor IX binds to type IV collagen, a component of the vascular wall, infused factor IX adsorption may contribute to the reduced recovery.¹⁰⁸ The dose of factor IX can be estimated by assuming that 1 U of factor IX per kilogram body weight increases circulating factor IX by 1 percent of normal or 0.01 U/mL.¹⁰⁹ Thus, to achieve 100 percent of normal (using only highly purified factor IX products) in a severely affected patient, 100 U of factor IX per kilogram body weight should be given as a bolus,

followed by half this amount every 12 to 18 hours. Dosing should be monitored by assays of factor IX before and after bolus administration. Factor IX also can be administered as a constant infusion in hospitalized patients after the bolus administration. The dose of factor IX to be infused per hour can be estimated based on a factor IX half-life of 18 to 24 hours. Thus, in a 60-kg adult who receives highly purified factor IX, 6000 U of the factor should raise the factor IX level to approximately 100 percent of normal. Over the next 12 to 18 hours, the level decreases by approximately 50 percent. Thus, the patient needs approximately 3000 U of factor IX during that period or 250 U of factor IX per hour as an infusion.¹⁰⁹ These calculations are only estimates of average responses, so factor IX dosing should be monitored by factor IX assays and the dose adjusted appropriately. Prophylactic therapy for hemophilia B also can be attempted in individuals selected in the same manner as that described for hemophilia A patients. The prophylactic dose of factor IX is 25 to 40 U/kg of body weight two times per week or 50 to 100 U/kg every 7 to 10 days if using extended half-life products.

Although currently available factor IX concentrates are safe in terms of transmission of HIV and hepatitis B and C viruses, patients treated prior to 1985 may have been infected with these agents.

COURSE AND PROGNOSIS

Unless treated properly, severe hemophilia B is fraught with the same complications of recurrent hemorrhages as hemophilia A. Thus, hemarthroses and chronic hemophilic arthropathy are common in inadequately treated patients. In addition to joint deformities, chronic active hepatitis is common in patients treated before 1985. Approximately 50 percent of older and severely affected patients now are HIV-positive. Patients treated after 1985, when HIV testing became available, are not likely to have contracted HIV.

Patients with severe hemophilia B may develop inhibitory antibodies against factor IX, making treatment very difficult.^{110,111} Approximately 3 percent of patients with severe hemophilia B develop specific inhibitor antibodies, frequently restricted in immunoglobulin composition to the IgG₄ subclass and κ light chains.¹¹¹ Most inhibitors can be detected when the aPTT of a mixture of normal plasma and the patient's plasma is prolonged. In contrast to the inhibitors in hemophilia A patients, inhibitor antibodies against factor IX are not time and temperature dependent; thus, incubating the mixtures for 2 hours at 37°C usually is unnecessary. Inhibitors to factor IX can be quantitated by modifying the Bethesda method for detecting factor VIII inhibitors. Many patients with inhibitors have mutations that result in the absence of circulating factor IX antigen, most commonly because of deletions and nonsense mutations.

TREATMENT OF PATIENTS WITH FACTOR IX INHIBITOR ANTIBODIES

When the inhibitor titer is less than 5 BU/mL, the factor IX inhibitor possibly can be neutralized using large doses of highly purified factor IX concentrates. However, when the inhibitor titer is greater than 5 BU/mL, acute bleeding in patients should be treated with the same agents used to bypass factor VIII inhibitors (see Table 123–5). Recombinant factor VIIa in doses of 90 to 120 mcg per kilogram body weight administered intravenously every 2 to 3 hours can be used. Alternatively, FEIBA at a dose of 50 to 100 U per kilogram body weight every 8 to 12 hours (not to exceed 200 U/kg per day) or nonactivated prothrombin complex concentrates can be used.

Induction of immune tolerance can be attempted in hemophilia B patients using daily infusions of purified factor IX preparations. However, significant adverse reactions, including anaphylaxis and nephrotic syndrome, have been reported in severely affected patients

with inhibitors.¹¹² Of the reported cases, many patients were younger than 12 years of age, and suffered from severe hemophilia B as a result of large deletions of the factor IX gene. The nephrotic syndrome may be transient and remit upon cessation of factor IX replacement. The pathogenesis of the nephrotic syndrome is not known. Patients with hemophilia B and factor IX antibodies who experience anaphylaxis with factor IX infusions and have hemorrhage should be treated with factor VIIa concentrates because both unactivated prothrombin complex concentrates and FEIBA contain factor IX.¹¹²

Curative Approaches for Hemophilia: Liver Transplantation and Gene Therapy

Normal livers have been transplanted successfully into patients with hemophilia A or B, with resulting cure of the hemophilic condition.^{113,114} The procedure is most often performed for end-stage chronic viral hepatitis that afflicts many older hemophilic patients. However, given the obvious limitations of this approach, it cannot be considered a viable treatment option to treat hemophilia per se.

On the other hand, gene replacement therapy for hemophilia offers an ideal theoretical approach for prophylactic therapy or even for a definitive cure. Proof of concept of gene therapy as a viable long-term option for the treatment of hemophilia B has been established, as discussed below. Currently, however, the challenges associated with gene transfer of the much larger *FVIII* gene have slowed down progress in the development of gene therapy for hemophilia A, although these limitations are being addressed.

There are several approaches by which the defective gene encoding factor VIII or factor IX can be introduced into a congenitally deficient host (Chap. 29). Viruses have evolved to introduce genetic material into target cells, and are usually employed as the vector, or “Trojan Horse” to allow transfection or transduction of the genetic information.^{115,116} Several potential vectors have been used in clinical gene therapy studies for hemophilia and other single gene disorders over the past 2 decades, including adenoviruses, recombinant adeno-associated viral vectors (rAAVs), and retroviral vectors, which include the lentiviral vectors based on HIV-1. At present, rAAVs are favored by the majority of ongoing trials in hemophilia, although preexisting immunity to some of these naturally occurring serotypes, which limits their use, is quite prevalent (up to 40 percent) in human populations. Although concerns exist about oncogenic genotoxicity (also known as insertional mutagenesis) associated with the earlier generation lentiviral vectors, they also have theoretical benefits; specifically, they are capable of infecting both dividing and nondividing cells with resultant persistent expression after integration into the host cell genome. In addition, they avoid the vector-mediated cytotoxicity (such as hepatic transaminitis) and immunologic reactions associated with rAAV.¹¹⁷

Certain vectors (such as rAAV) can be injected intravenously—usually on a single occasion—with resultant tropism of the vector and its payload to the liver. Previously, gene transfer via multiple intramuscular injections was also evaluated, and while not unduly toxic, sustained levels of factor IX greater than 1 percent were not maintained long-term. These “*in vivo*” gene transfer protocols vary from “*ex vivo*” gene therapy, in which a specific type of cell is targeted before being reintroduced into the host. Target cells used for gene transfer in hemophilia have included human fibroblasts, hematopoietic stem cells, and platelets.

Despite a number of early phase clinical trials over 20+ years, it was not until 2011 that the first report of predictable and consistent maintenance of factor IX levels (in the range of 1 to 6 percent of normal) was achieved in six subjects with hemophilia B. The bleeding frequency and clotting factor usage was reduced by 90 percent in these patients. This experience, from the groups at University College London and St. Jude's Research Hospital in Memphis, Tennessee, was updated with a followup

of up to 3 years in the original cohort of six patients, together with an additional four treated individuals.¹¹⁸ The protocol consisted of a single intravenous injection of a self-complementary rAAV-8; at the highest vector doses used, biochemical transaminitis occurred in some of the patients. This hepatotoxicity was mediated by a host cytotoxic T-lymphocyte response to viral capsid antigens expressed on transfected hepatocytes. Fortunately, however, there was a consistently beneficial and prompt response to modest doses of oral prednisolone.

This milestone study has prompted a resurgent interest in gene therapy for hemophilia, with several phase I studies now underway. Remaining challenges include the use of purer vector preparations (with fewer empty capsids) and strategies to circumvent the natural immunity to AAV.¹¹⁶ These modifications should permit this approach to be applicable in a greater proportion of patients, and result in even higher long-term expression of factor IX.

Finally, utilization of the same approach to hemophilia A is limited by the inefficient expression of factor VIII, as well as the large size of the coding sequence, even in the absence of the B domain. However, the use of B-domain-deleted codon optimized factor VIII molecules has produced encouraging results in animal models of gene therapy. It is hoped that these preclinical data translate into persistent factor VIII expression levels in patients with hemophilia A. It remains to be seen how often inhibitors to factor VIII occur in these patients.

SPECIAL PROBLEMS ASSOCIATED WITH HEMOPHILIAS A AND B

Unusual problems are occasionally encountered in both hemophilia A and B. Some of these are discussed in a brief publication.¹¹⁹ For example, scuba diving can be dangerous in severely affected hemophiliacs and should be avoided. Hemophilic patients requiring laser treatment for visual problems may not require replacement therapy provided that a surgical incision is not required during such therapy. Carriers of either hemophilia A or B may have bleeding problems during delivery or surgery and will require replacement therapy. Carriers whose fetuses have hemophilia may require cesarean section if vaginal delivery is found to be difficult. Forceps and mechanical devices should be avoided during delivery of infants who are hemophilic. Some patients with hemophilia may also have another familial bleeding disorder, such as VWD.

Hemophilic patients that survived the HIV epidemic are aging and are developing comorbidities similar to nonhemophilia males, including hypertension, cardiovascular disease, renal failure, and dyslipidemias. The deficiency of either factor VIII or IX seems to provide some protection against thrombosis.¹²⁰ However, myocardial infarction has been reported in hemophilic patients even without treatment.¹²¹ DVT has also been reported following replacement therapy in both hemophilia A and hemophilia B. Acute DVT can be treated with heparin for 7 to 10 days as long as the patient receives factor replacement therapy. Thereafter, anticoagulation is not recommended. Thromboembolic episodes in hemophilia B are much less common since the advent of highly purified factor IX products.

The management of cardiovascular disease in the hemophilia population is a challenge.^{122,123} The use of antiplatelet therapy seems safe in mild and moderate individuals; for the severely deficient patient, however, prophylaxis with factor VIII or factor IX should be used. For anticoagulation with heparin or vitamin K antagonists, factor trough levels above 0.25 U/L are recommended. For the management of acute coronary syndromes and arrhythmias requiring intervention, replacement with adequate factor concentrate should be done without exceeding levels above 80 to 100 percent of normal. Radial artery access rather than femoral and bare metal stents are preferred over drug-eluting stents.

Individuals requiring valve replacement should receive a biologic rather than a mechanical valve when possible.

Hemophilia patients who have atrial fibrillation should undergo cardioversion when possible. If cardioversion is not successful, some physicians recommend treatment with aspirin but anticoagulants should be used with caution taking into consideration the severity of the hemophilia and the risk of stroke.

CHAPTER 124

INHERITED DEFICIENCIES OF COAGULATION FACTORS II, V, V+VIII, VII, X, XI, AND XIII

Flora Peyvandi and Marzia Menegatti*

SUMMARY

Rare bleeding disorders (RBDs), accounting for the 3 to 5 percent of patients with abnormal hemostasis, include the nonhemophilia inherited deficiencies of the coagulation factor II (prothrombin), factor V, combined factor V/VIII, factor VII, factor X, factor XI, factor XIII, and fibrinogen. The prevalence of RBDs is variable, both the relative frequency among the different factors and frequency in different regions of the world. The genetic transmission of these disorders is usually autosomal recessive. Bleeding manifestations caused by these inherited deficiencies are of variable severity and usually related to the extent of the decreased activity of the particular coagulation factor. Usually, only homozygous and compound heterozygous patients are symptomatic, although occasionally heterozygotes display a bleeding tendency. On the whole, the most typical symptom, common to all RBDs, is the occurrence of mucosal bleeding, while life-endangering bleeding, such as the central nervous system or umbilical cord bleeding, are more frequent only in the some deficiencies, such as afibrinogenemia and severe factor XIII and factor X deficiencies, characterized by very low or undetectable coagulant activity. Treatment of patients affected with the various coagulation factor deficiencies could be (1) on demand for spontaneous bleeding episodes, (2) after surgical procedures, and (3) for prevention (prophylaxis). Because of the rarity of these disorders and the technical limitations of laboratory testing and the lack of specific concentrates, a unified, evidence-based therapeutic approach to many such patients is not always clear. To overcome these limitations, new strategies, such as the creation of global partnerships and networking between treatment centers, have been developed to increase our knowledge and create platforms for researchers and clinicians to exchange information.

Acronyms and Abbreviations: aPTT, activated partial thromboplastin time; COPII, coat protein complex II; EGF, epidermal growth factor; ELISA, enzyme-linked immunosorbent assay; ERGIC, endoplasmic reticulum–Golgi intermediate compartment; FFP, fresh-frozen plasma; GGX, γ -glutamyl carboxylase; Gla, γ -carboxyglutamic acid; LMAN, mannose-binding lectin; MCFD, multiple combined-factor deficiency; PAR, protease-activated receptor; PCC, prothrombin complex concentrate; PPH, postpartum hemorrhage; PT, prothrombin time; TAFI, thrombin-activatable fibrinolysis inhibitor; TF, tissue factor; TT, thrombin time; VKORC1, vitamin K epoxide reductase–oxidase complex.

*The authors would like to thank Dr. U. Seligson and Dr. O. Salomon who wrote the chapter “Inherited Deficiencies of Coagulation Factors II, V, VII, X, XI, and XIII and Combined Deficiencies of Factors V and VIII and of the Vitamin K–Dependent Factors” contained in the previous edition of this book.

Rare congenital deficiencies of plasma proteins involved in blood coagulation, such as fibrinogen, prothrombin, and factors V, V+VIII, VII, X, XI, and XIII, generally lead to lifelong bleeding disorders. These disorders have been described in most populations with an incidence varying from one case in 500,000 for factor VII deficiency, to one case in 2 to 3 million for prothrombin and factor XIII deficiency.^{1,2} However, their relative frequency varies among populations, being higher in regions where consanguineous or endogamous marriages are common, partly as a result of increased high frequencies of specific mutant genes in these inbred populations.^{3–8} Two large surveys were made by the World Federation of Hemophilia (WFH; www.wfh.org) and the European Network of the Rare Bleeding Disorders (EN-RBD; www.rbdd.eu), with the aim of collecting epidemiologic data and providing information to hemophilia organizations and treatment centers to reduce and prevent complications of bleeding. Data collected by these surveys showed that factor VII and factor XI deficiencies are the most prevalent rare bleeding disorders (RBDs), each accounting for approximately one-third of all RBDs, while the rarest disorders are factor II (prothrombin) deficiency and combined deficiency of factors V and VIII (Table 124–1). The severity of bleeding manifestations in affected patients is variable. The most typical symptom, common to all RBDs, is bleeding from the mucosal tracts or at the site of invasive procedures; life- and limb-endangering symptoms, such as umbilical cord and central nervous system bleeding, recurrent hemarthroses, and soft tissue hematomas, occur with higher frequency only in some severe deficiencies.^{9–15} Although heterozygotes for the coagulation factor deficiencies usually do not manifest a bleeding tendency, some cases of postdelivery and post-dental-extraction bleeding in heterozygotes for factor X deficiency have been reported.¹⁶

LABORATORY DIAGNOSIS

The complexity of blood coagulation and the large number of proteins and nonprotein substances involved necessitate that a global test be used to simply and reproducibly assess its function: the screening tests such as prothrombin time (PT) and activated partial thromboplastin time (aPTT) are the first step in evaluating patients reporting a clinical and family history of bleeding. The PT interrogates the extrinsic coagulation pathway, its prolongation is indicative of the deficiency of factor VII; a normal aPTT is highly dependent on the intrinsic coagulation pathway, so that its prolongation is indicative of deficiencies of factors XI, VIII, IX, and XII. However, all patients homozygous or compound heterozygous for factor XI deficiency have aPTT values longer than 2 SD above the normal mean,¹⁷ while heterozygotes substantially overlap the normal range.^{17,18} Consequently, screening of patients for a hemostatic abnormality prior to surgery (which is recommended for Jewish patients because of the high prevalence of factor XI deficiency) identifies patients with severe factor XI deficiency. The prolongation of both the PT and aPTT indicates the lack of a factor belonging to the common pathway, including prothrombin, factor V or factor X. However, patients with factor X deficiency harboring mutations that cause a defect only in the tissue factor (TF) pathway will only display a prolonged PT and their aPTT will be normal. Other patients who carry mutations that only affect the intrinsic pathway activity of factor X, will exhibit a normal PT and prolonged aPTT.¹⁹ Abnormal results of either of these screening tests should be followed by mixing studies where equal amounts of patient plasma and normal plasma are mixed and retested; the relevant test time is normalized in patients with factor deficiencies, but is not corrected or only minimally corrected in patients with factor inhibitors. In case of correction, specific coagulation assays are then performed to make the diagnosis of the specific factor deficiency. To evaluate fibrinogen deficiency, all coagulation tests that depend on the formation of fibrin as the end point are necessary; hence,

TABLE 124-1. Worldwide Distribution of Rare Bleeding Disorders Derived from the World Federation of Haemophilia and the European Network of the Rare Bleeding Disorders Surveys

Deficiency	WFH Survey (%)	EN-RBD Database (%)
Fibrinogen	7	8
Factor II	1	1
Factor V	9	10
Factor V + Factor VIII	3	3
Factor VII	36	39
Factor X	8	8
Factor XI	30	24
Factor XIII	6	7

beside PT and aPTT, thrombin time (TT) has to be also performed. In factor XIII deficiency, PT and aPTT are normal. Diagnosis of factor XIII deficiency is established by demonstrating increased clot solubility in 5 M urea, dilute monochloroacetic acid, or acetic acid. However, this method, quantitative and not yet standardized, detects only severe factor XIII deficiency (with activity <5 percent), thus leading to a possible underdiagnosis of factor XIII deficiency. The factor XIII deficiency diagnosis protocol requires a number of assays, which test for both activity as well as antigen levels. In the case of estimation of factor XIII activity using quantitative (e.g., photometric assays, which measure the ammonia released during a transglutaminase reaction) or incorporation assays (dansylcadaverine-casein assay which measures the level of incorporation of a labeled amine into a protein substrate) during transglutaminase mediated cross linking,²⁰ the plasma blanking procedure is mandatory to avoid the factor XIIIa-independent ammonia release that could lead to incorrect results in the low-activity range (below 5 to 10 percent).^{21,22} Factor XIII A-subunit antigen can be measured by enzyme-linked immunosorbent assay (ELISA).²³ Factor antigen assays are not strictly necessary for diagnosis and treatment but are necessary to distinguish type I from type II deficiencies that become very important in fibrinogen or prothrombin deficiency, where normal antigen levels and reduced coagulant activity (dysfibrinogenemia and dysprothrombinemia) are associated with higher risk of thrombosis. Hereditary factor V deficiency is also a peculiar case that can be confused with combined deficiency of factor V + factor VIII because the two entities have similar manifestations, and are characterized by prolonged PT and aPTT. Consequently, assays of factor V and factor VIII are mandatory for making the distinction.

CLASSIFICATION

The development of guidelines for classification of RBDs has been historically hampered by a lack of sufficient knowledge about epidemiology and clinical outcomes, the difficulty in recognizing affected patients and collecting longitudinal clinical data, the limits of laboratory assays, and a lack of consensus concerning the criteria by which these disorders are classified. Classification of RBDs based on the residual level of plasma coagulant activity of the missing factor has considered for many years all RBDs as a single entity and a mild, moderate, or severe classification as in hemophilia was adopted (except for some disorders

such as afibrinogenemia and factor XIII deficiency). In 2012, the Rare Bleeding Disorders Working Group, under the umbrella of the Factor VIII & Factor IX Scientific and Standardisation Committee (SSC) of the International Society on Thrombosis and Haemostasis (ISTH), analyzed the results of data coming from four registries (EN-RBD, the United Kingdom Haemophilia Centre Doctors' Organization registry, the North American Rare Bleeding Disorders Registry, and the Indian registry) for a total of 4359 patients. Despite the large number of patients evaluated in this overview (both from the literature and the aforementioned registries), there is a large heterogeneity in the preassigned severity definitions for both coagulant activity and bleeding symptoms.²⁴ At the same time the EN-RBD, based on a cross-sectional study using data from 489 patients and involving 13 European treatment centers, for the first time evaluated the correlation between the coagulant residual plasma activity level and clinical bleeding severity in each RBD. Clinical bleeding episodes were classified into four categories of severity based on the location and the potential clinical impact, as well as the trigger of bleeding (spontaneous, after trauma or drug induced). By means of linear regression analysis, this study found a strong association between coagulant activity level and clinical bleeding severity for fibrinogen, combined factors V + VIII, X and XIII deficiencies. A weak association with clinical bleeding severity was present for factors V and VII deficiencies, while coagulation activity level of factor XI did not predict clinical bleeding severity. From the same study it also clear that the minimum level to ensure complete absence of clinical symptoms is different for each disorder, leading to the conclusion that RBDs should not be considered as a single class of disorders, but instead studies should focus on the evaluation of specific aspects of each single RBD and different from hemophilia.²⁵

MOLECULAR ANALYSIS

The molecular diagnosis of RBDs is based on the mutation search in the genes encoding the corresponding coagulation factor. Exceptions are the combined deficiency of coagulation factors V+VIII, caused by mutations in genes encoding proteins involved in the factor V and factor VIII intracellular transport (multiple combined-factor deficiency [MCFD] 2 and mannose-binding lectin [LMAN] 1) and the combined deficiency of vitamin K-dependent proteins (prothrombin and factors VII, IX, and X), caused by mutations in genes that encode enzymes involved in posttranslational modifications²⁶ and in vitamin K metabolism (γ -glutamyl carboxylase [GGCX] and vitamin K epoxide reductase-oxidase complex [VKORC1]).²⁷ Coagulant factors genes are located on different chromosomes except for the genes of factor VII (*F7*), factor X (*F10*), fibrinogen (*FGA*, *FGB*, *FGG*), and factor XI (*F11*) (Table 124-2). In particular *F10* lays only 2.8 kb downstream of the *F7* thus the combined deficiency of the two factors can be also the result of chromosomal abnormalities of the long arm of chromosome 13.²⁸ The strategy for molecular analysis is generally based on polymerase chain reaction amplification followed by Sanger sequencing of all exons, flanking intronic sequence and 5' and 3' untranslated regions. In contrast with hemophilia A, caused in approximately half of the patients by an inversion mutation involving introns 1 or 22 of the factor VIII gene, RBDs are often caused by mutations unique for each kindred and scattered throughout the genes. Information on already identified mutations causing RBDs is traceable from the mutation database on the ISTH website (<http://www.isth.org/?MutationsRareBleedin>). Missense mutations are the most frequent gene abnormalities, representing 50 to 80 percent of all identified mutations, except for LMAN1 variants where the most frequent mutations are insertions/deletions (50 percent). Insertion/deletion mutations represent 20 to 30 percent of the gene variations of the fibrinogen, factor V (*F5*), MCFD2, and factor XIII (*F13A*)

TABLE 124-2. General Genetic Features of Coagulation Factors

Deficiency	Gene	Chromosome	Reference
Factor II	<i>F2</i>	11p11–q12	58
Factor V	<i>F5</i>	1q21–25	84
Factors V + VIII	<i>LMAN1</i>	8q21.3–q22	112, 113, 126
	<i>MCFD2</i>	2p21–p16.3	26
Factor VII	<i>F7</i>	13q34	30, 151
Factor X	<i>F10</i>	13q34–qter	192
Factor XI*	<i>F11</i>	4q34–35	235, 236
Factor XIII	<i>F13A</i>	6p24–p25	293, 294
	<i>F13B</i>	1q31–q32.1	296, 297

*F11 gene is located on the same chromosome of fibrinogen genes (fibrinogen deficiency is not discussed in this chapter)

genes, and less than 15 percent of the remaining coagulation factor gene mutations. Splicing and nonsense mutations comprise 5 to 15 percent of all identified mutations in all coagulation factors, with a maximum rate of 20 percent in the *LMAN1* gene. Variants located in the 3' and 5' untranslated regions of the genes are the least-frequent types of mutation (<5 percent) found only at the fibrinogen, factor VII, factor XI, and factor XIII loci. The combined presence of more than one recessively transmitted coagulation factor defect may also rarely occur resulting in combined deficiency of factors VII and X^{31–33} and combined deficiency of factors VII and V, VIII, X, or XI.³⁴ Despite significant advances in our knowledge of the genetic basis of the RBDs, in 5 to 10 percent of patients affected with severe clotting factor deficiencies, no genetic defect can be found. In these patients, the use of next-generation sequencing might help to identify novel pathways in coagulation disorders.

TREATMENT

Treatment of RBDs is a difficult task because the absence of longitudinal clinical data and the limitations of available laboratory assays make it difficult to develop evidenced-based guidelines for the diagnosis and treatment of RBDs. A patient's personal and family history of bleeding are important guides for management. Dosages and frequency of treatment depend on the minimal hemostatic level of the deficient factor, its plasma half-life (see Table 124-3) and the type of bleeding episode. At variance with patients affected with hemophilia A or B who have vastly improved the quality of life from advances in the manufacture of safe and effective products,³⁵ patients with RBDs have seen less progress. The main treatments in RBDs are represented by replacement therapy of the deficient coagulation factor and nontransfusional adjuvant therapies (antifibrinolytic amino acids, estrogen/progestin). Fresh-frozen plasma (FFP) and cryoprecipitate are the backbone of RBD treatment, particularly in those countries with low economic resources. However, specific plasma-derived concentrates are currently available only for fibrinogen and factors VII, XI, and XIII, and they are licensed only in some European countries; replacement therapy of coagulation factors may require the prescription of unlicensed products that are not readily available.

Prothrombin and factor X deficiencies are often treated with prothrombin complex concentrates (PCCs), which often also contain uncontrolled amounts of factor II, factor VII, and factor X. Products to cover the need for a dedicated therapy of patients with factor V deficiency and to facilitate the prophylaxis scheme in patients with factor X deficiency are of recent production. Finally, only two recombinant products are currently available for treatment of RBDs: recombinant

factor VIIa (rFVIIa; see factor VII deficiency paragraph) and rFXIII (see "Factor XIII Deficiency" below). Although there are a number of reports available in the literature reporting on treatment on demand and by prophylaxis in RBDs,^{36,37} no clear cut guidelines are yet available apart from those of the United Kingdom Haemophilia Centre Doctors' Organization.³⁸ Table 124-3 shows available treatment for each deficiency and suggested dosages.

WOMEN WITH RARE BLEEDING DISORDERS

Women with RBDs require specific attention and care because in addition to experiencing the common associated bleeding symptoms, they may also experience bleeding complications from regular hemostatic challenges during menstruation, pregnancy, and childbirth, as well as from other gynecologic conditions, such as hemorrhagic ovarian cysts, endometriosis, hyperplasia, polyps, and fibroids. Menorrhagia, defined as blood loss of more than 80 mL per menstruation, is reported to be one of the most important symptoms in women with RBDs.^{39,40} Menstruation may be quite problematic for women with coagulation disorders who have excessive blood loss, which can have a major impact on their quality of life and employment.

Pregnancy and childbirth pose particular clinical challenges to women with RBDs, as apart from factor XI deficiency, detailed information about these issues and their management are very scarce and limited to just a few case reports.^{41,42} Pregnancy is accompanied by increased concentrations of fibrinogen, factor VII, factor VIII, factor X, and von Willebrand factor, particularly marked in the third trimester.^{43–47} In contrast, prothrombin, factor V, factor IX, and factor XIII are relatively unchanged.⁴³ All of these changes contribute to the hypercoagulable state of pregnancy and, in women with RBDs, contribute to improved hemostasis. Despite improved hemostasis, however, women with factor deficiencies do not achieve the same factor levels as those of women without factor deficiencies,³⁹ increasing the possibility of pregnancy loss or bleeding complications, especially if the defect is severe.

PROTHROMBIN DEFICIENCY

DEFINITION

Inherited prothrombin deficiency is one of the rarest coagulation factor deficiencies. It presents in two forms: type I, true deficiency (hypoprothrombinemia), and type II, in which a dysfunctional prothrombin

TABLE 124-3. Treatment of Inherited Coagulation Disorders

Deficient Factor	Plasma Half-Life	Recommended Trough Levels	On-Demand Dosages	Recommended Trough Levels After Publication of the EN-RBD Results to Maintain Patient Asymptomatic
Fibrinogen	2–4 days	0.5–1.0 g/L	Cryoprecipitate (5–10 bags) SD-treated plasma (15–30 mL/kg) Fibrinogen concentrate (50–100 mg/kg)	1 g/L
Prothrombin	3–4 days	20–30%	SD-treated plasma (15–20 mL/kg) PCC (20–30 units/kg) with dosing based on labeled factor IX units	>10%
Factor V	36 hours	10–20%	SD-treated plasma (15–20 mL/kg)	10%
Factors V and VIII	Factor V 36 hours Factor VIII 10–14 hours	10–15%	As for factor V	40%
Factor VII	4–6 hours	10–15%	Factor VII concentrate (30–40 mL/kg) PCC (20–30 units/kg) rFVIIa (15–30 mcg/kg every 4–6 hours)	>20%
Factor X	40–60 hours	10–20%	SD-treated plasma (10–20 mL/kg) PCC (20–30 units/kg) Factor X/factor IX concentrate (10–20 units/kg)	>40%
Factor XI	50 hours	15–20%	SD-treated plasma (15–20 mL/kg) Factor XI concentrate (15–20 units/kg)	15–20%
Factor XIII	9–12 days	2–5%	Cryoprecipitate (2–3 bags) SD-treated plasma (3 mL/kg) Factor XIII concentrate (50 units/kg for high hemorrhagic events)	30%

PCC, prothrombin complex concentrate; rFVIIa, recombinant factor VIIa; SD, solvent-detergent.

is produced (dysprothrombinemia). These autosomal recessive disorders are genetically heterogeneous, and characterized by a mild to moderate bleeding tendency. Both types of prothrombin deficiency impair the generation or function of thrombin, the central enzyme of the blood coagulation system.

PROTEIN

Prothrombin, approximate Mr 72,000, is structurally homologous with other members of the vitamin K-dependent proteins, factors VII, IX, and X, proteins C, S, and Z, and bone γ -carboxyglutamic acid (Gla) protein. Prothrombin is synthesized in the liver as a prepropeptide of 622 amino acids and its plasma concentration is 100 to 150 mcg/mL. The circulating protein in its mature form is a single chain glycoprotein of 579 residues, composed of the Gla domain (residues 1 to 37) and the catalytic domain (residues 272 to 579), where a light A chain is disulfide-bonded to the heavy B chain containing the catalytic triad. In the zymogen molecule there are several exodomains, such as two kringle domains—kringle 1 domain (F1; residues 38 to 155), kringle 2 domain (F2; residues 156 to 271)—and the prepropeptide regions.^{48,49} The prepropeptide domain is responsible for protein processing, targeting, and carboxylation, and it is removed prior to secretion from the cell. The Gla domain constitutes the aminoterminal of the mature prothrombin molecule and contains the 10 glutamic acid residues that are posttranslationally modified through action of vitamin K-dependent

carboxylase to Gla. As a result of this modification, prothrombin acquires the capacity to bind calcium and membranes containing acidic phospholipids. The kringle domain contains two extensively folded, disulfide-bonded “kringle” motifs. They are present in diverse proteins and are thought to mediate protein–protein interactions. For example, the second kringle mediates interaction of prothrombin with activated factor V.⁵⁰ Notably, previous data shows that the kringle 2 domain, generated from the precursor prothrombin that is endogenously expressed in human, mouse, and rat brains, including in dopaminergic neurons in the nervous system,^{51,52} is able to activate *in vitro* microglia cells and may be involved in the neuropathologic processes of dopaminergic neuronal death occurring in Parkinson disease.⁵² However, the real clinical significance of these *in vitro* findings is still to be unraveled. The catalytic domain contains the enzyme active site, which is responsible for fibrinogen cleavage. The residues characteristic for the serine protease family, His363, Asp419, and Ser525, constitute a charge relay system responsible for bond cleavage. The crystal structure of prothrombin has not been determined, but the crystal structure of human α -thrombin complexed with *D-Phe-Pro-Arg chloromethylketone* (an inhibitor that is a transition state analogue covalently bound to the enzyme) has been determined.⁵³

Prothrombin plays a central role in coagulation, functioning in both TF and contact activation pathways. Prothrombin is converted to its proteolytically active form thrombin by the prothrombinase complex consisting of activated factor X, factor Va, and phospholipid surface of

platelets and other cells. Two forms of thrombin are generated: meizothrombin, if prothrombin is cleaved at residue 320, and α -thrombin, if cleavage occurs first at residue 271, removing prothrombin fragment 1.2, and subsequently cleaved at residue 320. The α -thrombin A-chain (residues 272 to 320) formed by factor Xa cleavage is encoded by exons 8 and 9. The B-chain (residues 321 to 579) containing the catalytic site and regulatory elements is encoded by exons 9 to 14. Thrombin is a multifunctional serine protease. In addition to converting fibrinogen to fibrin, thrombin also exerts functions in the coagulation cascade, consisting of both pro- and anticoagulant effects⁵⁴ and activates platelets by cleavage of the protease-activated receptor (PAR)-1 and PAR-4, initiating signals leading to platelet adhesion and aggregation.^{55,56} Thrombin also stimulates wound healing through its action as a growth factor and its proangiogenic activity.⁵⁷

GENETICS

The prothrombin gene is located on the short (p) arm of chromosome 11.⁵⁸ It is 20-kb long and consists of 14 exons separated by 13 introns. Fifty-four mutations that cause prothrombin deficiency have been identified, of which 42 are missense, three nonsense, seven deletions/insertions, and two splicing mutations (see mutation database on the ISTH website, <http://www.isth.org/?MutationsRareBleedin> and Ref. 9). Type II deficiency (dysprothrombinemias) results from missense mutations that are located throughout the gene. As expected, many mutations are in the catalytic domain, imparting catalytic dysfunction on thrombin. Other mutations give rise to abnormally slow activation of prothrombin. Only about 10 mutations were identified in patients with type I deficiency, of which five were present in homozygotes. Globally, there is a clear prevalence of patients with a Latin/Hispanic origin, as nearly 70 percent of all patients with thrombin gene defects come from such areas (Barcelona, Padua, Segovia, and Puerto Rico).⁹

A number of polymorphisms have been identified in the prothrombin gene. One of these polymorphisms, a G>A change at nucleotide 20210 in the 3' untranslated region of the prothrombin gene, is associated with increased plasma levels of prothrombin and an increased tendency to venous thrombosis (Chap. 130).⁵⁹

CLINICAL MANIFESTATIONS

According to a recent classification by the SSC of the ISTH, prothrombin deficiency may be classified as severe, moderate, and mild corresponding to blood levels of less than 5 percent, 5 to 10 percent, and greater than 10 percent, respectively.²⁴ In severely prothrombin-deficient patients, bleeding may be marked, including spontaneous hemarthroses; less-severe patients may show mild to moderate mucocutaneous and soft-tissue bleeding that usually correlates with the degree of functional prothrombin deficiency. Heterozygous subjects, having plasma prothrombin levels between 30 and 60 percent of normal, are usually asymptomatic; however, occasionally, excessive bleeding after moderate-intensity trauma, tooth extractions, or after surgical procedures may occur. Patients with dysprothrombinemias show a variable bleeding tendency that is usually less severe than in type I deficiency. Women with prothrombin deficiency may suffer from menorrhagia. Because of the extreme rarity of such deficiency, reports on event during pregnancy/delivery are very scarce, being only one describing in four of eight pregnancies in a hypoprothrombinemic woman.⁶⁰ In the same report, one postpartum hemorrhage (PPH) episode on the four-term pregnancies was reported, despite administration of clotting factor concentrate⁶⁰; however, this data was not confirmed by a following Iranian series, including a total of 14 patients with the same deficiency (coagulant activity levels 4 to 10 percent).⁶¹

Undetectable plasma prothrombin probably is incompatible with life, as inferred from the partial embryonic and neonatal lethality of prothrombin knockout mice, which do not survive to adulthood.^{62,63}

THERAPY

Replacement therapy is needed only in severe patients, in case of bleeding or to ensure adequate prophylaxis before surgical procedures. In severe clinical settings, higher levels of prothrombin may be achieved with FFP, or with PCCs, which avoids the risk of volume overload sometimes associated with the use of FFP.⁶⁴ However, PCCs contain other vitamin K-dependent coagulation factors (VII, IX, and X) and small amounts of their activated forms, which could potentially induce thrombotic complications; those containing an amount of factor VII below 10 percent are commonly known as three-factor PCCs. These concentrates are heated or treated with solvent-detergent, processes that remove HIV, hepatitis B, hepatitis C, and other viruses, but which do not remove parvovirus B19 or hepatitis A virus⁶⁵⁻⁶⁷; the latter viruses can be effectively removed by dry heat and nanofiltration.⁶⁸ However, transmission of other possible bloodborne agents, such as prions causing Creutzfeldt-Jakob disease and its new variant, have not been totally eliminated. Bruises and mild superficial bleeding generally do not require replacement therapy. Antifibrinolytic agents (tranexamic acid and gabexate mesylate) have also been used for minor surgical procedures. The oral contraceptives have been shown to exert beneficial effects on menometrorrhagia in women characterized by prothrombin coagulant levels less than 3 percent.⁹ Thromboprophylaxis in dysprothrombinemic patients considered at high risk for a thrombotic event (e.g., orthopedic surgery) is a controversial issue. It is likely that administering low-molecular-weight heparin prophylactically to surgical patients at the same doses and schedules as those recommended for nondefect patients having similar procedures may be a valuable and safe procedure after correction of factor II deficiency by FFP or PCC infusion.

● FACTOR V DEFICIENCY

DEFINITION AND HISTORY

Hereditary factor V deficiency was initially termed parahemophilia because of its similarities with classical hemophilia.⁶⁹ In most of the affected individuals the phenotype is characterized by the concomitant deficiency of factor V activity and antigen (type I deficiency); however, approximately 25 percent of the patients have normal antigen levels (type II deficiency), thus indicating the presence of a dysfunctional protein.⁷⁰

PROTEIN

Factor V is synthesized by the liver⁷¹ and its plasma concentration is approximately 20 nM (7 mcg/mL).⁷²⁻⁷⁴ Factor V is a high-molecular-weight (Mr ~330,000), single-chain, large glycoprotein that consists of 2196 amino acids that bears significant, regional sequence homology to factor VIII. Analysis of the approximately 7-kb factor V complementary DNA showed that the protein is organized according to the following domain structure: A₁-A₂-B-A₃-C₁-C₂. The A and C domains have approximately 40 percent homology with analogous domains in factor VIII.^{74,75} The large B domain shows no homology with the corresponding B domain of factor VIII. Factor V is converted to its activated form following several proteolytic cleavages by thrombin⁷⁶ or factor Xa.⁷⁷ These cleavages remove the B domain and yield factor Va, which consists of a heavy chain (A₁-A₂ domains) associated by Ca²⁺ with a light chain (A₃-C₁-C₂ domains). The light chain contains

the binding sites for membrane phospholipids, prothrombin, and activated protein C; both light and heavy chains probably are necessary for factor Xa binding. Assembly of factors Va and Xa on the phospholipid membrane of platelets in the presence of calcium ions forms the prothrombinase complex, which catalyzes the conversion of prothrombin to thrombin. The contribution of factor Xa in the absence of factor Va to overall thrombin generation is relatively minor. Importantly, incorporation of the cofactor into the macromolecular enzyme complex enhances prothrombin activation by several orders of magnitude.⁷⁸

In addition to hepatocytes, the primary site of factor V secretion, approximately 20 percent of the protein in whole blood is localized in the α granules of platelets, where it is complexed with an extremely large protein, multimerin.⁷⁹ Megakaryocytes do not synthesize factor V; rather, endocytosis of plasma-derived factor V accounts for the platelet factor V pool.⁸⁰ Following endocytosis factor V is modified intracellularly; these changes to platelet factor V appear to provide the cofactor with unique physical and functional characteristics, which render it more procoagulant compared with its plasma counterpart.⁸¹ Platelet degranulation and release of platelet factor V at the site of vascular injury is thought to be a critical contributor to the local factor V concentration. Furthermore, there is some evidence that, because platelet factor V is locally released in high concentrations, it is less susceptible to inhibition and may function normally in hemostasis. Factor Va is inactivated by activated protein C through limited proteolysis at Arg506, Arg306, and Arg679 in the presence of protein S, calcium ions, and either platelet or endothelial cell membrane phospholipids.⁸² Partial protection from this cleavage is provided by factor Xa when bound to factor Va on the surface of platelets.⁸³

GENETICS

The factor V gene maps to chromosome 1q21–25.⁸⁴ It is greater than 80 kb in length and the coding sequence is divided into 25 exons, ranging in size from 72 to 2820 base pairs (bp), and 24 introns, varying between 0.4 kb and 11 kb.⁸⁵ The sequence encoding the large B domain is contained within exon 13.

A total of 132 distinct mutations of the factor V gene have been identified, of which 64 are missense, 36 are insertions/deletions, 17 are nonsense, 15 are splice site mutations, and one is a deletion of the whole gene (see <http://www.isth.org/?MutationsRareBleedin> and Ref. 10). Most mutations cause truncations and are localized throughout the gene. Several mutations have interesting features. One, a Tyr1702Cys transition, was identified in eight unrelated families, of whom six were Italian. The frequency of this mutant allele in Italy is 0.002.⁸⁶ Another mutation, an Ala221Val (New Brunswick) alteration, characterized in the homozygous state by activity and antigen levels of 29 and 39 percent of normal, respectively displays decreased stability of the expressed protein and was the first genetic defect reported to be associated with type II deficiency.⁸⁷ Additional mutations exhibit decreased secretion of the protein from producing cells.^{88,89} Remarkably, the Gln773ter and Arg1133ter mutations and a 4-bp deletion mutation, all present in exon 13 and predicted to result in partial truncation of the B-domain and complete truncation of the A3-, C1-, and C2-domains, cause no bleeding or only a mild bleeding tendency in affected patients having factor V antigen and activity levels 1 percent of normal.^{90–92}

Factor V Leiden (Arg506Gln) is a highly prevalent (up to 5 percent in some populations) polymorphism in the factor V gene that decreases the efficiency of factor Va inactivation by activated protein C.⁹³ Patients with factor V Leiden are at increased risk of unprovoked thrombosis,

with homozygotes at greater risk than heterozygotes. The *trans* association of factor V Leiden and a mutation in factor V that causes factor V deficiency results in a prothrombotic state comparable to factor V Leiden homozygosity. This is sometimes termed “pseudohomozygous” activated protein C resistance and does not cause bleeding despite low factor V antigen levels.⁹⁴ Among several polymorphisms detected in the factor V gene, His1299Arg in exon 13 is particularly interesting because it is associated with a reduced plasma factor V level and mild activated protein C resistance.⁹⁵ His1299Arg co-segregates with several other polymorphisms encoding several amino acid changes, together named R2 haplotype.⁹⁶ In two heterozygotes for factor V Arg506Gln mutation who presented with venous thrombosis, reduced factor V activity resulting from the His1299Arg polymorphism harbored by the non-Leiden chromosome, imparted a pseudohomozygous phenotype for activated protein C resistance.⁹⁷ Additional polymorphisms or mutations in the factor V gene have been observed to increase the risk of venous thrombosis.⁹⁸

In addition, there are at least two examples in which platelet factor V is reduced. In the Quebec platelet disorder, initially described as an autosomal dominant disorder with severe bleeding manifestations, platelet factor V levels are reduced because of enhanced proteolysis resulting from overexpression of urokinase-type plasminogen activator,⁹⁹ as they are in factor V New York.¹⁰⁰

CLINICAL MANIFESTATIONS

Factor V deficiency is inherited as an autosomal recessive trait. Heterozygotes, whose plasma factor V activity ranges between 25 and 60 percent of normal, usually are asymptomatic, although an American registry recorded mild bleeding in 50 percent of the cases.¹⁰¹ According to a recent classification by the SSC of the ISTH, factor V deficiency may be classified as severe, moderate, and mild when factor V levels are undetectable, less than 10 percent, and 10 percent or greater, respectively.²⁴

Common manifestations include ecchymoses, epistaxis, gingival bleeding, hemorrhage following minor lacerations, and menorrhagia.^{101–103} Severe deficiency typically presents at birth or in early childhood, but depending on factor levels some patients remain asymptomatic. Bleeding from other sites is less common, but instances of hemarthroses unrelated to trauma and intracerebral hemorrhage have been reported.¹⁰² Trauma, dental extractions, and surgery confer a high risk of excessive bleeding.

PPH occurs in more than 50 percent of pregnancies in women with factor V deficiency,^{104,105} especially those with low factor V activity levels. Venous and arterial thromboses have been described in patients with factor V levels ranging between 2 and 14 percent of normal.¹⁰⁶ Factor V deficiency deprives activated protein C of one of its essential substrates, thereby downregulating the inhibitory function of the protein C system.

Development of a functional factor V inhibitor after receiving plasma transfusions was reported in only two patients with hereditary deficiency; the inhibitor disappeared in one patient, but a low titer of the inhibitor persisted in the other patient.^{107,108} Factor V is indispensable for life, as was demonstrated by experimental knockout mice lacking the factor V gene, which die either in utero at embryonic day 9 or 10 because of defects in yolk-sac vasculature and somite formation; the remaining half develop to term but die of massive hemorrhage within hours of birth.¹⁰⁹ The expression of a minimal factor V activity because of the introduction of a liver-specific transgene, below the sensitivity threshold of the detection assay (<0.1 percent), leads to the survival of mice.¹¹⁰

THERAPY

Patients with epistaxis and gingival bleeding may respond to tranexamic acid (1 g four times daily), and local hemostatic measures may suffice for minor lacerations. Menorrhagia can also be managed directly using oral contraceptives, progestin-containing intrauterine devices, endometrial ablation, or hysterectomy. If these measures fail, severe spontaneous bleeding occurs, or surgery is performed, treatment option is limited to FFP replacement as no specific factor V concentrate is yet available on the market and factor V is not present in cryoprecipitate or PCCs. However, a new factor V concentrate has been developed for clinical use in patients deficient in factor V and preclinical studies are currently being performed for the orphan drug designation application to the European Medicine Agency (EMA) and the Food and Drug Administration (FDA) so as to make it available on the market as soon as possible.

COMBINED DEFICIENCY OF FACTORS V AND VIII

DEFINITION AND HISTORY

Combined deficiency of factors V and VIII (F5F8D) is completely separate from factor V deficiency and factor VIII deficiency. The latter two are transmitted with different patterns of inheritance (autosomal recessive for factor V, X-linked for factor VIII) and involve proteins encoded by two different genes (*F5* gene and *F8* gene). F5F8D was first described in 1954¹¹¹; however, the molecular mechanism of the association of the combined factor deficiency was not understood until late 1990s,^{112,113} when null mutations in the endoplasmic reticulum–Golgi intermediate compartment (*ERGIC*)-53 gene, now called the *LMAN1* gene, were determined to be causative. In 2003, a second locus associated with the deficiency in approximately 15 percent of affected families with no mutation in *LMAN1* was identified²⁶: the *MCFD2* gene encoding for a cofactor for *LMAN1*. Even if a debate were carried out on the possible existence of other loci involved in the intracellular transport of factors V and VIII and associated with the disease, until now previous biochemical studies failed to identify additional components of the *LMAN1*–*MCFD2* receptor complex,¹¹⁴ supporting the idea that F5F8D might be limited to the *LMAN1* and *MCFD2* genes.¹¹⁵ The disorder has been detected in many populations, but a relatively high frequency occurs among Tunisian and Middle Eastern Jews residing in Israel¹¹⁶ and among Iranians.¹¹⁷

PROTEIN

Factors V and VIII are essential coagulation factors that circulate in plasma as precursors. Upon limited proteolysis by thrombin or factor Xa and in concert with negatively charged phospholipid surfaces, factors VIIIa and Va exhibit profound cofactor activities for activation of factor X by factor IXa and for activation of prothrombin by factor Xa, respectively. Inactivation of factors Va and VIIIa is accomplished by activated protein C in the presence of protein S and phospholipids through several proteolytic cleavages at distinct sites. Factor V and factor VIII have similar domain organizations with partial homology (see “Factor V Deficiency” above).

The pathogenesis of combined deficiency of factors V and VIII puzzled investigators for more than 40 years. The enigma was resolved by the finding that the disease stems from the deficiency of either one of two interacting proteins, *LMAN1* and *MCFD2*, which play a role in the intracellular transport of factors V and VIII. *LMAN1* is a 53-kDa

type 1 transmembrane nonglycosylated protein with homology to leguminous lectin proteins.¹¹⁸ It displays different oligomerization states—monomer, dimer, and hexamer—which have been implicated in its exit/retention within the endoplasmic reticulum (ER), and is thought to bind correctly folded glycosylated cargo proteins, including factors V and VIII in the ER, recruiting the cargo for package into coat protein complex II (COPII)-coated vesicles and to transport them first to the ERGIC and then to the Golgi. *MCFD2* is a small (146 residues) soluble protein of 16 kDa with a signal sequence mediating translocation into the ER and two EF-hand motifs that may bind Ca^{2+} ions in the C-terminal region.¹¹⁹ *MCFD2* forms a Ca^{2+} -dependent 1:1 stoichiometric complex with *LMAN1*, which works as a cargo receptor for efficient ER–Golgi transfer of coagulation factors V and VIII during their secretion. Although several proteins have been identified as cargo of *LMAN1* (factor V, factor VIII, cathepsin C, cathepsin Z, nicastrin, and α_1 -antitrypsin),^{120–123} *MCFD2* is only known to be required for transport of the blood coagulation factors, suggesting a possible role for *MCFD2* as a specific recruitment factor for this subset of *LMAN1* cargo proteins.¹²⁴ The three-dimensional structure of the complex between *MCFD2* and the carbohydrate recognition domain (CRD) of *LMAN1* was determined and a model of functional coordination between the two proteins was proposed: *MCFD2* is converted into the active form upon complex formation with *LMAN1*, thereby becoming able to capture polypeptide segments of factors V and VIII. The coagulation factors bind the *LMAN1* oligomer in the ER, but are released upon arrival in the acidic post-ER compartments because the sugar-binding of ERGIC-53 is pH-dependent.¹²⁵

GENETICS

Homozygosity mapping and positional cloning in nine unrelated Jewish families demonstrated that the *LMAN1*, composed of 13 exons, localizes on the long arm of chromosome 18.^{112,113,126} Using a similar approach in other families with the combined factors V and VIII deficiency identified the short *MCFD2*, made up of four exons on the short arm of chromosome 2.²⁶ Thirty-four mutations identified in *LMAN1* predicted either a truncated protein product or no protein at all, being more than 90 percent deletion/insertion, null, or splicing mutations. In contrast, of the 22 mutations identified in the *MCFD2*, 11 are missense and 11 are null mutations. Missense mutations are located at the EF-2 domains, giving rise to defective binding to *LMAN1*.¹²⁷ A distinct founder haplotype was found in patients belonging to six unrelated families of Tunisian-Jewish origin bearing a donor splice-site mutation in intron 9 of *LMAN1*.^{112,127} All six families originated from an ancient Jewish community that has resided on the island of Djerba for more than 2 millennia. A survey of this community, which presently lives in Israel, disclosed that the mutation is prevalent at an allele frequency of 0.0107.¹²⁸ Another founder effect for a G insertion in exon 1 of *LMAN1* was observed in eight unrelated Jewish families of Middle Eastern origin.^{112,127} A Met to Thr mutation in *LMAN1* has been detected in several unrelated Italian families, implying another founder effect.¹²⁷

CLINICAL MANIFESTATIONS

Symptoms of F5F8D are generally mild. Comparison of relatively large cohorts of F5F8D in India, Iran, and Israel indicates that bleeding from trauma/surgery is the most frequently reported clinical manifestation.^{116,117,129,130} This observation likely reflects the fact that often F5F8D is brought to the attention of physicians following excessive bleeding during and after trauma, surgery, and labor. Homozygous patients exhibit spontaneous and posttraumatic bleeding. Menorrhagia, epistaxis, easy bruising, hemarthrosis and gingival hemorrhage

are commonly observed, and is unrelated to trauma in approximately 20 percent of cases.^{117,131} Hematuria, GI, and spontaneous CNS bleeding is less common.¹¹⁷ There is insufficient data on the incidence of bleeding during pregnancy and PPH in women with combined factor V+VIII.

Heterozygotes exhibit slight but significantly reduced mean levels of factors V and VIII.¹¹⁶ In a literature survey of 161 heterozygotes, 22 reported having significant bleeding manifestations.¹³² However, no correlation between the factor V or factor VIII levels and bleeding tendency was noted.²⁵

LMAN1 gene knockout mice duplicate the F5F8-deficient phenotype in humans, albeit with a milder presentation, resulting from a lesser reduction in plasma levels of factors V and VIII.¹³³ The partial perinatal lethality observed in *LMAN1*-deficient mice on some genetic backgrounds was unexpected and has been explained as the result of a further drop in the level of *LMAN1*-dependent protein(s) below a critical threshold, or because of a strain-specific difference in another cargo receptor whose function overlaps with *LMAN1*.

THERAPY

Because of the mild-to-moderate bleeding symptoms, treatment is on demand, depending on the severity of bleeding. According to a recent result from the EN-RBD project, however, the level of F5F8 to ensure the absence of bleeding symptoms should be greater than 40 percent.²⁵ The recommended therapy includes FFP, which provides factor V, and factor VIII concentrate, which compensates for the shorter half-life of plasma factor VIII. An antifibrinolytic agent such as tranexamic acid or ϵ -aminocaproic acid can be helpful in patients exhibiting menorrhagia, epistaxis, or gingival bleeding. DDAVP (1-deamino-8-D-arginine vasopressin, desmopressin) could be administered for less-severe bleeding. Patients with severe bleeding episodes or patients undergoing surgical procedures, including dental extractions, should receive FFP as replacement for factor V and cryoprecipitate or factor VIII concentrate as a source of factor VIII. DDAVP can be used to increase factor VIII level, but this treatment sometimes fails.¹³⁴

FACTOR VII DEFICIENCY

DEFINITION AND HISTORY

Factor VII was first identified as serum prothrombin conversion accelerator or proconvertin and its hereditary deficiency described by Alexander and colleagues in 1951.¹³⁵ Among the rare clotting factor deficiencies, the relative frequency of factor VII deficiency is high (see Table 124-1).^{101,102} A presumptive diagnosis can be easily made because, except for very rare cases of factor X deficiency only affecting the TF pathway of coagulation (see "Laboratory Diagnosis" below), factor VII deficiency is the only coagulation disorder that produces a prolonged PT and a normal aPTT.

PROTEIN

Human factor VII is a single-chain glycoprotein (Mr ~50,000) that is secreted from the liver parenchymal cells as a zymogen. The mature protein consists of 406 amino acids organized in three main domains: a Gla domain at the N-terminus containing 10 Gla residues, an epidermal growth factor (EGF) domain in the center, and a serine protease domain at the C-terminus.¹³⁶ Factor VII zymogen circulates in blood at an extremely low concentration (~500 ng/mL)¹³⁷ and has the shortest half-life of all coagulation factors (4 to 6 hours; see Table 124-3). Factor VII is converted to the activated form, factor VIIa, by cleavage of an Arg152-Ile153 bond, resulting in a two-chain molecule held together

by a disulfide bond. Factor VII can be converted to factor VIIa by factor Xa,¹³⁸ factor IXa,¹³⁹ factor XIIa,¹⁴⁰ thrombin,¹³⁸ and factor VIIa in the presence of TF, in an autoactivation reaction.¹⁴¹ Binding of factor VII to TF strikingly enhances these reactions.¹⁴²⁻¹⁴⁶

The initial generation of thrombin that heralds blood coagulation occurs when blood is exposed to TF present in the subendothelium in tissues, or on the surface of stimulated monocytes or microparticles. The exposed TF forms a complex with circulating factor VIIa and supports the initiation of coagulation by converting factors IX and X into their active forms (factor IXa and factor Xa).^{147,148} Following the generation of trace amounts of factor VIIa there is a feedback amplification of the signal, as factor VII bound to TF: factor VIIa is both self-activated, and activated by factor IXa and factor Xa. Hence, the TF-factor VIIa complex has two roles: to increase the conversion of factor VII to factor VIIa and to increase the proteolytic activity of factor VIIa toward its substrates, factors IX and X. Factors IXa and Xa may remain associated with cells that display the TF, or disseminate in the blood and bind to the surface of activated platelets, which form the initial platelet plug.¹⁴⁹

GENETICS

The factor VII gene (*F7*) spans approximately 12.8 kb¹⁵⁰ and is located on chromosome 13q34,^{30,151} 2.8 kb upstream from the factor X gene.¹⁵² The gene contains a prepro leader sequence and eight exons that encode the mature protein. Promoter and silencer elements of the 5' flanking region have been characterized.^{153,154} The disorder manifests in homozygotes or compound heterozygotes, some of which are also homozygotes for polymorphisms associated with reduced factor VII levels.^{155,156}

More than 240 mutations have been reported (see <http://www.isth.org/?MutationsRareBleedin> and Ref. 12). The mutations are distributed throughout the gene, and most are missense mutations (62.2 percent); other type of mutations are equally present (ranging from approximately 6.2 percent of mutations in 3'-5' untranslated region [UTR] to 12.3 percent of deletions/insertions [del/ins]). Most mutations causing factor VII deficiency have been observed in individual patients. However, one missense mutation (Ala244Val) was detected in 102 (84 percent) of 121 independent mutant alleles discerned in 88 unrelated patients in Israel.¹⁵⁷ Most subjects were of Iranian and Moroccan-Jewish origin and shared an identical haplotype, consistent with a founder effect. In the general Iranian-Jewish and Moroccan-Jewish populations, the prevalence of the Ala244Val allele are 0.023 and 0.025, respectively.¹⁵⁶ Several additional clusters of patients with a specific mutation were reported: (1) Ala294Val, with or without a deletion of nt C, at position 11128, prevails in patients from Poland and Germany but has also been identified in other Europeans^{158,159}; (2) 12 unrelated families from Norway who carry Gln100Arg¹⁶⁰; (3) IVS75G>A, which was detected in six unrelated patients from the Lazio region in Italy, all of whom bear the same haplotype, suggesting a founder effect¹⁶¹; and (4) Gly331Ser, which was identified in 10 Italian and four German patients on one haplotype.¹⁶² The widely distributed and common Arg304Gln mutation probably is a recurrent mutation.¹⁶³

Three polymorphisms in the factor VII gene are also associated with reduced plasma levels of the factor. The first polymorphism, an Arg353Gln substitution, results in impaired secretion of factor VII from cells¹⁶⁴ and gives rise to a 20- to 25-percent decrease in plasma factor VII level in heterozygotes and a 40- to 50-percent decrease in homozygotes.^{165,166} The second polymorphism associated with a diminished factor VII level is a decanucleotide insertion upstream from the 5' end of the gene at -323, which confers a 33 percent decrease in the promoter activity.¹⁵⁴ A third polymorphism associated with factor VII level is a hypervariable region 4 polymorphism (HVR4) in intron 7.¹⁶⁷ The variable number of tandem repeats (five to eight copies of 37 bp) apparently influences the splicing efficiency. The effect of the variable repeats on

factor VII level is less conspicuous than the decanucleotide insertion at the promoter region and the Arg353Gln polymorphism.

CLINICAL FEATURES

Bleeding manifestations occur in homozygotes and in compound heterozygotes for factor VII deficiency. However, a typical feature of this disease is its clinical heterogeneity: some patients do not bleed at all after major hemostatic challenge, while others with similar levels report frequent bleeding episodes. Life- or limb-endangering bleeding manifestations are relatively rare, the most frequent symptoms being epistaxis and menorrhagia. However, CNS bleeding was also reported to have high incidence (16 percent) in a series of 75 infants,¹⁶⁸ the authors concluding that the greatest risk factor for this development was trauma related to the birth process. In addition, heterozygotes who have partial factor VII deficiency may present with bleeding; a recent survey of 499 heterozygotes revealed that 19 percent reported pathologic bleeding.¹⁵⁵ Dental extractions, tonsillectomy, and surgical procedures involving the urogenital tracts frequently are accompanied by bleeding when no prior therapy is instituted. Normal pregnancy is accompanied by increased concentrations of fibrinogen and factor VII, nonetheless, cases of miscarriages and PPH, albeit at relatively low rates, have been observed in patients with factor VII deficiency.^{169,170}

Thrombotic episodes have also been reported in 3 to 4 percent of patients with factor VII deficiency, particularly in the presence of surgery and replacement treatment, but spontaneous thrombosis may also occur. A survey of 514 cases with severe or partial factor VII deficiency recorded seven patients with venous thrombosis and one patient with arterial thrombosis.¹⁷¹ Most of the cases presented with associated risk factors, mainly surgery, prolonged immobilization, and treatment with PCCs.¹⁷²

When factor VII is completely lacking, as in knockout mice, there is no embryonic lethality; however, fatal hemorrhage occurs perinatally.^{173,174}

THERAPY

As for all the other congenital bleeding disorders, replacement therapy is essential in patients who present with severe hemorrhage, such as hemarthrosis or intracerebral bleeding, surgical hemostasis, and for individuals with a bleeding history. Factor replacement therapy may also be used for prophylaxis in children with severe factor VII deficiency.¹⁷⁵ The EN-RBD study suggests a trough factor VII activity level of 25 percent is needed for patients to remain asymptomatic²⁵; prophylactic treatment is usually recommended for patients with major bleeding episodes such as CNS and gastrointestinal bleeding and hemarthroses. A number of replacement therapeutic options have been administered to patients with factor VII deficiency, including FFP, PCCs, plasma-derived factor VII concentrates (volume overload should be expected if plasma is used as the replacement material) and rFVIIa. rFVIIa has been successful in managing patients with hemarthroses and during surgery,^{176,177} and is the only treatment supported by substantial literature^{12,176} (see Table 124–3). PCCs containing activated clotting factors can be used, but they confer a risk of thrombosis,¹⁷⁵ while specific factor VII concentrates have been used successfully in series of patients.¹⁷⁵ The treatment of factor VII deficiency is sometimes challenging, because of the short *in vivo* half-life of factor VII, its low recovery, and its rapid clearance, which is more evident in children.¹⁷⁸ Because of these features, replacement regimens require frequent dosing. A significant rise in the factor VII level is observed during pregnancy in women with mild/moderate forms of factor VII deficiency (heterozygotes), but not in women with severe deficiency.^{179–182} Therefore, in women with mild/moderate

deficiency, replacement therapy may not be required during labor and delivery, while it would be required in women with low factor VII coagulant activity levels or a positive bleeding history who are more likely to be at risk of PPH.^{181,183–185} A recent review of the literature noted that hemorrhage rates were equivalent in women with and without prophylaxis, thus concluding that use of hemostatic prophylaxis should not be considered mandatory, but as part of an individualized discussion taking into consideration response to previous hemostatic challenges and mode of delivery.¹⁸⁶ Replacement therapy is unnecessary for minor bleeding episodes. Local hemostasis for skin lacerations and administration of an antifibrinolytic agent for menorrhagia, epistaxis, and gingival hemorrhage usually are sufficient to arrest bleeding. Asymptomatic patients undergoing minimally invasive surgery, such as dental procedures, can be successfully treated with tranexamic acid given both orally or intravenously at the usual dosages.

● FACTOR X DEFICIENCY

DEFINITION AND HISTORY

Inherited factor X deficiency was identified by two independent groups, each of which described a patient with a bleeding diathesis that could not be attributed to deficiencies in other known coagulation factors. The factor in both patients was subsequently named factor X.^{187–189}

PROTEIN

Factor X is mainly synthesized by the liver as a 488-amino-acid protein and circulates in plasma at a concentration of 8 to 10 mcg/mL.¹⁹⁰ Its primary structure is homologous to that of other vitamin K–dependent proteins, such as prothrombin, factor VII, factor IX, protein C, and protein S.¹⁹¹ The first 40-amino-acid residues, the prepropeptide, contain the hydrophobic signal sequences targeting the protein for secretion.¹⁹² The Gla domain forms the N-terminus of the mature protein and contains 11 Gla residues that are responsible for calcium and phospholipid binding.¹⁹³ Adjacent to the Gla domain is a short aromatic amino acid stack of predominantly hydrophobic amino acids, followed by the EGF domain, believed to mediate protein–protein interactions. The heavily glycosylated 52-amino-acid activation peptide of factor X separates the EGF domain from the C-terminal catalytic domain. Factor X undergoes proteolytic processing in the ER so that circulating factor is a two-chain, disulfide-linked protein consisting of a 17-kDa light chain made up of the Gla and EGF domains and a 40-kDa heavy chain made up of the activation and catalytic domains.¹⁹⁴ The heavy chain contains the activation peptide (residues 143 to 195) and the catalytic serine protease domain, structurally homologous to that of other coagulation serine proteases containing the catalytic site formed by residues His236, Asp282, and Ser379. The 52-residue activation peptide is released after factor X is converted to its active form factor Xa by the cleavage between residues Arg194 and Ile195. Physiologically factor X is activated by TF/factor VIIa (extrinsic pathway) and factor IXa/factor VIIIa (intrinsic pathway),¹⁹⁵ but it can also be activated *in vitro* by Russel viper venom.¹⁹⁶ In turn, factor Xa catalyzes thrombin formation. In presence of factor Va, Ca²⁺, and phospholipid membrane, factor Xa forms the prothrombinase complex that accelerates to 280,000-fold thrombin formation.¹⁹⁷

GENETICS

The factor X gene spans approximately 25 kb and is made up of eight exons.¹⁹² The factor X gene shows significant homology with the genes of other vitamin K–dependent serine proteases, which suggests all of these multidomain genes evolved from a common ancestral gene.¹⁹⁸

The currently described 105 mutations that cause factor X deficiency include large deletions, small frameshift deletions, nonsense mutation, and missense mutations; the missense mutations group is the largest (80 percent), while mutations in the 3′- and 5′-UTRs are completely absent (see <http://www.isth.org/?MutationsRareBleedin> and Ref. 13). Activation through the TF pathway may be affected when the mutations are located, for example, in the Gla domain, as in Glu7Gly (St. Louis II) or Glu19Ala.^{19,199,200} Activation through factor IXa is affected by, for example, Thr318Met (Roma).²⁰¹ Activation of factor X through Russell viper venom is almost intact in the Pro343Ser (Friuli) mutation.²⁰² Two interesting clusters of unrelated families were described in Algeria, with Phe31Ser mutation,²⁰³ and in the border region between Turkey and Iran, with the Gly222Asp mutation.²⁰⁴

CLINICAL MANIFESTATIONS

The clinical manifestations of factor X deficiency are related to the functional levels of the protein. According to the recent results of the EN-RBD study, strong associations between clinical bleeding severity and coagulation factor activity level were shown in factor X deficiency; consequently, patients with factor X activity levels less than 10 percent of normal have a higher occurrence of spontaneous major bleeding.²⁵ Bleeding occurs primarily into joints and soft tissues, from the umbilical cord and mucous membranes.²⁰⁵ The bleeding tendency may appear at any age, although patients with factor X activity less than 2 percent present early in life with, for instance, umbilical-stump or CNS hemorrhage.^{13,205,206}

In an analysis of 102 patients from Europe and Latin America, three mutations were associated with intracerebral hemorrhage (Gly380Arg, IVS7-1G>A, and Tyr163delAT) and Gly⁻²⁰Arg mutation was associated with severe hemarthrosis.²⁰⁵ The most common bleeding symptom reported at all levels of severity of the deficiency is epistaxis. Patients with severe deficiencies commonly experience hemarthrosis and hematomas, but gastrointestinal and umbilical cord bleeding, hematuria, and CNS bleeding also occur. In a small group of patients with factor X deficiency, one-third of heterozygous patients who had dental extraction, surgery, or delivery without prophylactic replacement therapy showed postoperative bleeding which required treatment.¹⁶ Menorrhagia is a common symptom affecting women with all degrees of severity and PPH was also reported in 4 of 14 pregnancies.²⁰⁷ Two successful pregnancies out of four pregnancies were reported in a woman only when receiving regular prophylaxis; the other two pregnancies, without regular prophylaxis, resulted in preterm labor (both babies died in the neonatal period).²⁰⁸ Other case reports, however, have described successful term pregnancies in women with severe factor X deficiency without antenatal prophylaxis.^{207,209} Knockout mice show partial embryonic lethality (E11.5–E12.5); complete absence of factor X is incompatible with murine survival to adulthood, but minimal factor X activity (range: 1 to 3 percent) is sufficient to rescue the lethal phenotype.^{210–212}

THERAPY

Therapy for inherited factor X deficiency usually is administration of heated and solvent-detergent-treated PCCs containing factor X, in addition to factors II, VII, and IX. Use of these concentrates carries a low risk of transmission of bloodborne viruses. However, a risk of thrombosis, including venous thromboembolism, diffuse intravascular coagulation, and myocardial infarction has been reported.

For soft-tissue, mucous membrane, and joint hemorrhage, the aim of treatment should be maintaining a factor X level that is at least 10 to 20 percent of normal. For more serious hemorrhage, a factor X level

that is greater than 40 percent of normal should be the goal.²⁵ In patients with particularly severe bleeding manifestations, prophylactic therapy should be considered. FFP also can be used to treat patients with factor X deficiency, however, the administration of FFP can be associated with complications, particularly in children and elderly patients with cardiac disease, because of fluid overload.³⁸ The arrival on the market of a new freeze-dried human factor X concentrate has facilitated prophylaxis in patients with factor X deficiency (Factor X P Behring)²¹³; however, factor X P Behring also contains factor IX, although in a known amount. A clinical trial investigating the pharmacokinetics of a new high-purity factor X concentrate has been completed (ClinicalTrials.gov identifier: 00930176).

● FACTOR XI DEFICIENCY

DEFINITION AND HISTORY

Factor XI deficiency initially was described as a “new hemophilia” in two sisters and their maternal uncle by Rosenthal and colleagues in 1953.²¹⁴ Because it manifested in both sexes—two sisters and their maternal uncle—the clinical features were not consistent with hemophilia A or B and was called hemophilia C.²¹⁵ The deficiency was erroneously thought to be transmitted as an autosomal dominant disorder with variable expressivity. Later studies clearly established that, in most cases, the mode of transmission of factor XI deficiency is autosomal recessive.²¹⁵ Affected subjects have been described in most populations, but the disorder is common in Jews, particularly those of Ashkenazi origin.²¹⁶

Factor XI deficiency as a result of a dysfunctional protein is rare, as only a few patients with deficiency of factor XI activity and seemingly normal antigen levels have been described thus far.^{217–220}

PROTEIN

Factor XI is a glycoprotein that consists of two identical 80-kDa polypeptide chains linked by a disulfide bond.²²¹ Each subunit contains 607 amino acids with a serine protease domain at the C-terminus and four tandem repeats of 90 or 91 amino acids, designated “apple domains,” at the N-terminus. The described crystal structure of factor XI dimer²²² defined the interface of the monomers in apple 4 domains in which three residues—Leu284, Ile290, and Tyr329—are essential for noncovalent binding between the monomers. This binding enables the formation of a disulfide bond between Cys321 residues in the fourth apple domain of each monomer.^{223,224}

Although factor XI is synthesized by the liver, very low levels of factor XI transcript can also be detected in megakaryocytes and platelets, renal tubules, and pancreatic islet cells.²²⁵ Factor XI circulates in blood as an equimolar complex with high-molecular-weight kininogen (HK)²²⁶ at a concentration of 3 to 7 mcg/mL. The importance of the factor XI–HK interaction is not fully understood. Activation of factor XI involves cleavage of an Arg369–Ile370 bond, yielding a heavy chain containing the four apple domains linked by a disulfide bond to a light chain that contains the catalytic domain.²²¹ The physiologic activator of factor XI during hemostasis has long been debated. The original scheme of the coagulation cascade—according to which factor XI is activated by factor XIIa through the intrinsic pathway (the “contact phase”)—was challenged by the observation that deficiencies of factor XII as well as of the other contact factors (HK and prekallikrein) are not associated with a bleeding diathesis.¹⁴

The major activator of factor XI *in vivo* is thrombin.^{227,228} Factor XI binds through its apple 3 domain to lipid rafts on platelets containing glycoprotein Ib–IX–V complex. This glycoprotein complex also binds thrombin; thus, both substrate and enzyme are colocalized at the same

site.²²⁹ Factor XI activation also can occur on the fibrin surface after a clot forms.²³⁰ Factor XIa, once generated, activates factor IX by limited proteolysis of two peptide bonds in the presence of calcium ions.²³¹ The presence of factor XI contributes to the activation of thrombin-activatable fibrinolysis inhibitor (TAFI), that once activated, removes terminal lysine residues from fibrin, which impairs binding of certain forms of plasminogen to fibrin and disrupts tissue plasminogen activator-induced plasmin generation in the blood clot.²³² Large amounts of thrombin are necessary for TAFI activation, but the reaction is substantially augmented when thrombin is bound to thrombomodulin.²³³ It follows that impaired generation of thrombin, for example, in inherited deficiency of factor VIII, IX, or XI, not only delays clot formation but also enhances premature lysis of clots.²³⁴ These data fit well with clinical observations in factor XI-deficient patients who are particularly susceptible to bleeding following injury at sites exhibiting local fibrinolytic activity.¹⁸

GENETICS

The 23-kb gene encoding for factor XI consists of 15 exons and 14 introns and is located on chromosome 4q34–35.^{235,236}

Three mutations, designated types I, II, and III, were first described in six Ashkenazi-Jewish patients with severe factor XI deficiency.²³⁷ The types II and III, a change in exon 5 at Glu117 leading to a stop codon and a change in exon 9 that results in a substitution of Phe283 by Leu, respectively, account for 95 percent of cases in Ashkenazi Jewish patients.²³⁷ Most patients with factor XI deficiency are Jewish.^{18,216,238} A recent study indicated that both type II and type III mutations are also prevalent in the Italian population, although at a much lower rate.²³⁹ In patients belonging to different ethnic groups, a significantly higher level of allelic heterogeneity has been reported. Remarkable exceptions are represented by some “closed populations” harboring mutations compatible with a founder effect: Cys38Arg in French Basques,²⁴⁰ Gln88Stop in French families from Nantes,²¹⁹ Cys128Stop in Britons,⁶ Ile436Lys in Northeastern Italy,²⁴¹ and Q263X in Korean patients.²⁴²

As of this writing, 220 mutations have been reported in non-Jewish and Jewish patients of various origins, including 154 missense, 23 nonsense, and 23 del/ins mutations, with the remaining being splice site (18 mutations) and 5'- and 3'-UTR (2 mutations). Inheritance of factor XI deficiency is usually autosomal recessive, as other RBDs, although some missense mutations exert a dominant negative effect through heterodimer formation between the mutant and wild-type polypeptides, resulting in a pattern of dominant transmission.²⁴³

CLINICAL FEATURES

Factor XI deficiency is the only RBD in which the EN-RBD study showed no association between clinical bleeding severity and coagulation factor activity level.²⁵ This disorder manifests as a mild to moderate bleeding manifestations and most bleeding episodes of patients with severe FXI deficiency are injury-related. Most bleeding manifestations of patients with severe FXI deficiency are injury-related. Some patients with severe factor XI deficiency may not bleed at all following trauma.²⁴⁴ The phenotype of bleeding is not correlated with the genotype but frequently with site of injury.^{18,238,244} Surgical procedures involving tissues with high fibrinolytic activity (urinary tract, tonsils, nose, tooth sockets) frequently are associated with excessive bleeding in patients with severe factor XI deficiency, irrespective of the genotype.²⁴⁵

Most women with severe factor XI deficiency are asymptomatic or minimally so. During 93 deliveries (85 vaginal, eight cesarean), 43 of 62 women did not experience PPH despite no prophylactic treatment,⁴¹ which was confirmed not to be mandatory for these women, by

a subsequent study of 33 women who had approximately 70 uneventful pregnancies out of 105 pregnancies. In the subsequent study, only three women had factor XI activity less than 15 IU/dL, and none of them had PPH.⁴²

Whether heterozygotes exhibit a bleeding tendency (except for those bearing mutations causing a dominant negative effect) is controversial because there are reports on both heterozygotes with no bleeding complications following a variety of surgical procedures, and reports that 20 to 48 percent of heterozygotes do bleed.^{215,238,243,246,247}

In regard to venous thrombosis, it was reported that in five patients, two developed pulmonary embolism following infusion of factor XI concentrate^{248–250} and a third patient developed thrombus in the inferior vena cava following cryptococcal infection. In contrast, severe factor XI deficiency was shown to confer protection against ischemic stroke.²⁵¹

Mice homozygous for a knockout factor XI allele show a tendency for slightly prolonged tail transection bleeding times and are protected from vessel-occluding fibrin formation after transient ischemic brain injury.^{252,253}

THERAPY

Available treatments for patients with the severe form of factor XI deficiency are FFP and factor XI concentrate. Factor XI concentrates currently available (Bio Products Laboratory, United Kingdom, and LFB Biomedicaments, France) are associated with thrombosis even after adding heparin to the antithrombin in the Bio Products Laboratory product, and antithrombin and heparin to the C1 esterase in the LFB Biomedicaments product.^{14,254} Therefore, it is advisable to monitor patients for clinical and laboratory signs of coagulation activation, in particular in elderly patients, in those with cardiovascular disease and in those undergoing surgery with thrombotic potential, especially when factor XI concentrate²⁵⁵ or rFVIIa is considered.^{256,257} In addition, the presence of an inhibitor, particularly in patients with less than 1 percent of factor XI activity and previously exposed to plasma, factor XI concentrates, or immunoglobulins, should be evaluated. Low doses of rFVIIa along with tranexamic acid seem promising in the treatment of patients with inhibitors. When procedures are planned at tissues exhibiting fibrinolytic activity, which is associated with higher risk of bleeding in comparison to sites without fibrinolytic activity, the use of antifibrinolytic agents alone or in combination with other treatments is recommended. Patients undergoing dental extractions do not require replacement therapy. No plasma replacement therapy is necessary during or after labor unless excessive bleeding occurs. Patients with factor XI deficiency and inhibitor do not bleed spontaneously. Acquired inhibitors that neutralize the activity of factor XI have been described in patients with severe factor XI deficiency and baseline activity of less than 1 IU/dL after being exposed to plasma,²⁵⁸ after injections of Rh immunoglobulin and without previous exposure to blood products,²⁵⁹ or after exposure to factor XI concentrates. Use of PCCs^{262,263} and rFVIIa¹⁷⁸ have been successful for major surgical procedures, and an *in vitro* study revealed that abnormal thrombin generation in the plasma of patients with an inhibitor was corrected by adding moderate amounts of rFVIIa.²⁶²

● FACTOR XIII DEFICIENCY

DEFINITION AND HISTORY

The first clinical report of factor XIII deficiency was in 1960²⁶⁵; since then, more than 500 cases of factor XIII deficiency have been identified worldwide, with an incidence of one individual in 1 to 3 million population.^{22,264} Congenital factor XIII deficiency is characterized by severe delayed spontaneous bleeding and recurrent abortion with normal coagulation screening tests.

PROTEIN

Factor XIII (fibrin-stabilizing factor) is a plasma transglutaminase that crosslinks γ -glutamyl- ϵ -lysine residues of fibrinogen chains, thereby stabilizing the fibrin clot. Plasma factor XIII is an Mr 340,000 heterotetramer composed of two catalytic A subunits and two carrier B subunits linked by noncovalent bonds. The average concentration of the A₂B₂ tetramer in plasma is approximately 22 mcg/mL, and its half-life is 9 to 14 days.²⁶⁵ Intracellularly, factor XIII is found as a homodimer composed of two A subunits (A₂).^{266,267} Factor XIII-A subunit is mainly synthesized in macrophages and megakaryocytes.^{266,267} Because factor XIII-A subunit lacks a signal sequence, it cannot be released by the classic secretory pathway through the Golgi apparatus. Conceivably, factor XIII-A subunit is released into the circulation from cells as a consequence of cell injury.²⁶⁸ Structurally, each A monomeric subunit (Mr ~82,000) is composed of an activation peptide, that is removed by thrombin cleavage of an Arg37-Gly38 bond in the presence of calcium ions, and four distinct domains: β -sandwich, central core, barrel 1, and barrel 2 regions. The central core domain contains a catalytic triad (common to the transglutaminase family) formed through hydrogen bond interactions between Cys314, His373, and Asp396.²⁶⁹⁻²⁷¹ It is structurally homologous with the α chain of tissue transglutaminase,²⁷² the α chain of keratinocyte transglutaminase,²⁷³ and band 4.2 of erythrocytes,²⁷⁴ although the latter lacks transglutaminase activity.

The site of synthesis for factor XIII-B subunit has been suggested to be the liver.²⁷⁵ The B subunit (Mr 76,500) is composed of 10 tandem repeats of complement control protein (CCP) modules designated as Sushi domains, which are also observed in proteins of the complement system.^{276,277} The two B subunits of factor XIII function as carrier proteins for the A subunits,^{278,279} stabilizing them in the circulation and regulating the calcium-dependent activation of factor XIII.

On activation by thrombin and Ca²⁺ the A and B subunits dissociate. Proteolytic activation by thrombin involves the cleavage of a N-terminal 37-residue activation peptide. The cleavage and the calcium binding both serve to induce structural changes that open up the catalytic triad to substrate access.²⁸⁰ This process is accelerated by fibrin.²⁸¹⁻²⁸³ The clot stabilizing effect of factor XIII is achieved by the crosslinking of fibrinogen chains, between the γ -carbonyl group of glutamine and the ϵ -amino group of lysine. In fibrin, this amide bond is located between A α -chain sequences and between γ -chain sequences²⁸⁴⁻²⁸⁸; factor XIIIa also crosslinks α_2 antiplasmin to the α -chain fibrin,²⁸⁹ thereby increasing the resistance of fibrin to plasmin degradation, and crosslinks fibronectin to the α -chain of fibrin,²⁹⁰ thereby affecting the mechanical properties of the clot and increasing cell adhesion.²⁹¹

In addition to fibrinogen and α_2 -antiplasmin, factor XIII has many other substrates, including fibronectin, vitronectin, collagen, factor V, von Willebrand factor, α_2 -antiplasmin, actin, myosin, vinculin, thrombospondin, plasminogen-activating inhibitor (PAI), TAFI 2, and AT1 receptor dimers of monocytes, implicating multiple and different roles for factor XIII in various systems other than coagulation.²⁹²

GENETICS

The gene for the factor XIII A-subunit is located on chromosome 6p24-p25.^{293,294} It spans more than 170 kb and is composed of 15 exons.²⁹⁵ The B-subunit gene is located on chromosome 1q31-q32.1.^{296,297} The gene for the B subunit spans 28 kb and is composed of 12 exons.²⁹⁷

One hundred and twenty-one mutations causing factor XIII A-subunit deficiency have been reported as of this writing, of which only one maps to the promoter region, 57 are missense, 11 are nonsense, 17 are splice-site, and 35 are del/ins mutants (<http://www.isth.org/?MutationsRareBleedin> and Ref. 298). A homozygous four-bases

insertion in exon 14 (c.2116insAAGA) introducing a frameshift that after seven altered amino acids results a stop codon and a protein with AQ3 truncated second β -barrel domain (p.Pro675TyrfsX7)²⁹⁹ has been reported to cause an extremely rare type II variant. The mutant protein lost its activity, but the plasma factor XIII antigen level was at the lower limit of the reference interval. This finding suggests that the C-terminal part of β -barrel 2 is essential for the expression of factor XIII activity.

Splice-site mutation in intron 5 (IVS5-1 G>A) seems to be the most common mutation as it has already been reported in six unrelated families from six different European countries, whereas the Arg660Pro was found in Palestinian Arabs, consistently with founder effects.^{264,300} It is likely that the Arg661stop mutation in Finnish patients and the Arg-77Cys mutation in Swiss patients are also a result of founder effects, although both are at CpG dinucleotides and therefore can be considered recurrent mutations.^{264,301,302} Another mutation, Ser295Arg, was identified in six Pakistani families and may also stem from a common founder, but this remains to be established.³⁰³ Six nonsynonymous/coding polymorphisms in the factor XIIIa1 (*F13A1*) gene,²⁵ Val34Leu in exon 2, Tyr204Phe in exon 5, Pro(CCA)331(CCC)Pro in exon 8, Glu(-GAA)567Glu(GAG) and Pro564Leu in exon 12, and Val650Ile and Glu651Gln in exon 14 have been analyzed in an association study. The study showed that only the Val34Leu is a true functional polymorphism and the rest are in linkage disequilibrium with this polymorphism. In this study, only haplotypes containing the "34L" allele affected factor XIII function.^{298,304} However, a larger number of synonymous/noncoding polymorphisms (>500) are known for the *F13A1* gene.³⁰⁴ Only 16 different mutations have been reported so far for the *FXIIIb* gene.²⁹⁸

CLINICAL MANIFESTATIONS

Factor XIII deficiency causes formation of blood clots that are unstable and susceptible to fibrinolytic degradation by plasmin. As a result, affected individuals have an increased tendency to bleed and rebleeding. Delayed umbilical cord bleeding reported in 80 percent of patients with factor XIII deficiency can be considered as diagnostic symptom of the deficiency. CNS bleeding is reported in approximately 30 percent of cases,^{305,306} making primary prophylaxis mandatory in patients affected with severe factor XIII deficiency. Ecchymoses, intramuscular and subcutaneous hematomas, oral cavity, mouth and gingival bleeding, and prolonged bleeding following trauma are also characteristic symptoms.³⁰⁵

Delayed wound healing occurs in approximately 15 percent of patients deficient in factor XIII. The exact mechanism by which factor XIII, or factor XIIIa, exerts its beneficial effect on wound healing is unknown. A proangiogenic effect of factor XIIIa was described, suggesting that decreased vascularization of wounds results in improper repair.³⁰⁶

In a review of the literature on 121 women with factor XIII deficiency, menorrhagia and ovulation bleeding were found to be common gynecologic problems, affecting 26 and 8 percent of women, respectively.³⁰⁷ Of 192 pregnancies, 127 (66 percent) resulted in a miscarriage and 65 (34 percent) reached viability stage, whereas of 136 pregnancies without prophylactic therapy, 124 (91 percent) resulted in a miscarriage and 12 (9 percent) progressed to viability stage. In affected women, formation of the cytotrophoblastic shell is impaired.³⁰⁸ Conceivably, factor XIII A-subunit deficiency at the implantation site abrogates fibrin/fibronectin crosslinking, which is essential for attachment of the placenta to the uterus.³⁰⁹

Placental abruption, preterm delivery, and PPH could be also problem if not adequately treated.³⁰⁹

No large clinical reports on heterozygous patients with factor XIII deficiency are available, thus not allowing to draw evidence-based conclusion on the prevalence of clinical symptoms in this group of patients. Recently, a subset of 28 heterozygotes for factor XIII deficiency among 350 carriers of an autosomal recessive inherited coagulation disorders show an association with prolonged or massive bleeding after minor trauma.³¹⁰ However, these data need to be confirmed in other cohorts of patients.

Factor XIII A-subunit knockout mice manifest no excess embryonic lethality or bleeding into the thoracic cavity, peritoneum, or skin, compatible with survival to adulthood. However, the survival rate of knockout males was markedly lower than that of the wild-types.³¹¹ Female factor XIII knockout mice show intrauterine bleeding during pregnancy, similar to women with severe factor XIII A-subunit deficiency who experience the same problem, as well as recurrent abortions. Factor XIII B knockout mice show a prolonged bleeding time at variance with patients with a complete factor XIII B-subunit deficiency, who report only mild bleeding symptoms and display normal bleeding times.^{312,313}

THERAPY

According to the EN-RBD results, blood levels of factor XIII that are 30 percent of normal are necessary to assure an asymptomatic state. This goal may be reached via a number of options. Many case reports show improved bleeding symptoms in patients on prophylactic therapy.³¹⁴ Plasma replacement therapy is highly satisfactory because of the long half-life of factor XIII (9 to 12 days). Plasma-derived, virus-inactivated concentrates of factor XIII are available³¹⁵ and are the treatment of choice. The development of adverse events after treatment is rare. The most dreaded adverse event is the development of inhibitors, although its incidence is rare.³¹⁶ A RBD registry created in North America discovered that 3 percent of factor XIII-deficient patients who received FFP or factor XIII concentrate treatment developed inhibitors.¹⁰² A new rFXIII₂ concentrate has become available and a phase III clinical trial (ClinicalTrials.gov identifier: 00713648) has been completed, establishing that rFXIII is safe and effective in preventing bleeding episodes in patients with congenital factor XIII A-subunit deficiency. The rFXIII was recently approved for the treatment of factor XIII A deficiency in Australia, Canada, the European Union, Switzerland, and the United States.³¹⁷

ACQUIRED DEFICIENCIES

Acquired coagulation factor deficiencies may occur in patients with liver disease, amyloidosis (specifically factor X),^{318,319} autoimmune disorders, patients on oral anticoagulant therapy, and, rarely, in patients who develop nonneutralizing antibodies that remove the protein from the circulation. Such antibodies directed against prothrombin³²⁰ and factor VII³²¹ have been described in patients with lupus anticoagulants. Rare instances of an acquired factor V inhibitor as a result of exposure to bovine thrombin preparations and drugs, or because of an unknown cause, should also be considered.³²² Acquired isolated factor X deficiency with severe bleeding manifestations occurs rarely because of the formation of specific antibodies with no underlying autoimmune disorder³²³ or in association with upper respiratory tract infections, burns, and leprosy.^{324–326} Inhibitors of factor X with no known precipitating factors have also been described.³²⁷ Acquired factor XIII deficiency with significant reductions in factor XIII levels (down to as low as 20 percent of normal) as a result of decreased synthesis or increased consumption, has been reported in several medical conditions, including

pulmonary embolism, Crohn disease, ulcerative colitis, Henoch-Schönlein purpura, liver cirrhosis, and sepsis. There are several case reports of an autoimmune bleeding disorder, designated as autoimmune/acquired hemorrhophilia, being caused by anti-factor XIII inhibitors.³²⁸ The anti-factor XIII inhibitors tend to be more severe than regular hemorrhagic-acquired factor XIII deficiency and requires both immunosuppressive therapy to eradicate autoantibodies and factor XIII replacement therapy to stop the bleeding.³²⁹

CHAPTER 125

HEREDITARY FIBRINOGEN ABNORMALITIES

Marguerite Neerman-Arbez and Philippe de Moerloose*

SUMMARY

Hereditary fibrinogen abnormalities make up two classes of plasma fibrinogen defects: (1) type I, afibrinogenemia or hypofibrinogenemia, in which there are low or absent plasma fibrinogen antigen levels (quantitative fibrinogen deficiencies), and (2) type II, dysfibrinogenemia or hypodysfibrinogenemia, in which there are normal or reduced antigen levels associated with disproportionately low functional activity (qualitative fibrinogen deficiencies). In afibrinogenemia, most mutations of the three encoding genes of fibrinogen chains are null. In some cases, missense or late-truncating nonsense mutations allow synthesis of the corresponding fibrinogen chain, but intracellular fibrinogen assembly and/or secretion is impaired. In certain hypofibrinogenemic cases, the mutant fibrinogen molecules are produced and retained in the rough endoplasmic reticulum of hepatocytes in the form of inclusion bodies, causing endoplasmic reticulum storage disease. Afibrinogenemia is associated with mild to severe bleeding, whereas hypofibrinogenemia is often asymptomatic. Thromboembolism may also occur and affected women may suffer from recurrent pregnancy loss. Hereditary dysfibrinogenemias are characterized by biosynthesis of a structurally abnormal fibrinogen molecule that exhibits reduced functional properties. Dysfibrinogenemia is commonly associated with bleeding, thrombosis, or both thrombosis and bleeding, but in many patients it is asymptomatic. Hypodysfibrinogenemia is a subcategory of this disorder. Certain mutations involving the C-terminus of the fibrinogen α chain are associated with amyloidosis, in which an abnormal fragment from the fibrinogen α C domain is deposited in the kidneys. The cause for thrombophilia in type II fibrinogen abnormalities often is uncertain but may involve defective calcium binding, impaired tissue-type plasminogen activator-mediated fibrinolysis, resistance to fibrinolysis, or reduced thrombin binding to fibrin. Replacement therapy with fibrinogen concentrates has proven to be useful for management of fibrinogen disorders but should be adapted to each patient, based on the personal and family history.

Acronyms and Abbreviations: FFP, fresh-frozen plasma; *FGA*, fibrinogen α -chain gene; *FGB*, fibrinogen β -chain gene; *FGG*, fibrinogen γ -chain gene; FpA, fibrinopeptide A; FpB, fibrinopeptide B; LMWH, low-molecular-weight heparin; PCR: polymerase chain reaction; TAFI, thrombin-activatable fibrinolysis inhibitor; t-PA, tissue-type plasminogen activator.

Several detailed and thoroughly annotated reviews of mutations causing inherited fibrinogen disorders have been published¹⁻³ and the previous version of this chapter published in the eighth edition⁴ contained tables compiling causative mutations identified before 2009. In addition, a registry for hereditary fibrinogen abnormalities⁵ can be accessed at <http://www.geht.org/databaseang/fibrinogen/> that lists variants reported in publications, conference abstracts, and submitted online, with original references. This chapter discusses the major molecular mechanisms leading to disease, as well as the laboratory and clinical aspects of fibrinogen disorders and their treatment, without listing all fibrinogen gene anomalies.

INTRODUCTION

Fibrinogen plays a major role in hemostasis as the precursor molecule for the insoluble fibrin clot (Fig. 125-1). In addition fibrinogen participates in numerous other biologic processes, such as inflammation, wound healing, and angiogenesis. Fibrinogen binds plasminogen, α -antiplasmin, fibronectin, and factor XIII, among other proteins. It also binds to platelets and supports platelet aggregation. After fibrinogen is converted to fibrin by thrombin, it provides nonsubstrate binding sites for thrombin; consequently, fibrinogen is sometimes termed *antithrombin I*.⁶ Fibrinogen also binds to vascular endothelial and other cells, plasma or tissue matrix components such as fibronectin and glycosaminoglycans, and peptide growth factors. Fibrin provides a template for assembly and activation of the fibrinolytic system components and is the major substrate for the enzyme plasmin (Chap. 135). Both fibrinogen and fibrin serve as substrates for plasma factor XIIIa that catalyzes covalent crosslinking/ligation.

STRUCTURE AND SYNTHESIS

Fibrinogen is a 340-kDa glycoprotein synthesized in hepatocytes⁷ that circulates in plasma at a concentration of 1.5 to 3.5 mg/mL (~4 to 10 μ M). Each fibrinogen molecule is approximately 45 nm in length. The core structure consists of two outer D regions (or D domains) and a central E region (or E domain) connected through coiled-coil connectors (Fig. 125-2).⁸ The molecule exhibits a twofold axis of symmetry perpendicular to the long axis, consisting of two sets of three polypeptide chains (α A, β β , γ) that are joined in their aminoterminal regions by disulfide bridges to form the E region. The outer D regions contain the globular C terminal domains of the β β chain (β C) and γ chain (γ C). The β C and γ C domains, which are highly conserved in vertebrates, are members of the FreD (fibrinogen-related domain) family of proteins. Unlike the β C and γ C domains, the C-terminal domains of the α A chain (α C) are intrinsically unfolded and flexible and tend to be noncovalently tethered in the vicinity of the central E region (Fig. 125-2). The three genes encoding fibrinogen β β (*FGB*), α A (*FGA*), and γ (*FGG*), ordered from centromere to telomere, are clustered in a region of approximately 50 kb on human chromosome 4.⁹ *FGA* and *FGG* are transcribed from the reverse strand, in the opposite direction to *FGB*. Alternative splicing¹⁰ results in two isoforms for the fibrinogen α chain: the common α A chain, encoded by exons 1 to 5, and an extended α A-E isoform, encoded by exons 1 to 6 which represents only 1 to 2 percent of transcripts. Alternative splicing for *FGG* also produces two transcripts: the major mRNA species contains all 10 exons and encodes the common γ chain (or γ A), while the minor product (γ') does not splice out intron 9 and the corresponding open reading frame replaces the four codons of exon 10 with 20 alternative codons. *FGB* encodes a single 1.9-kb transcript with a 1.5-kb coding sequence. Each gene is separately transcribed and translated to produce nascent polypeptides of 644 amino acids (α A), 491 amino acids (β β), and 437 amino acids (γ).

*The authors thank Dr. Alessandro Casini for helpful comments and suggestions.

Figure 125-1. Colorized scanning electron micrograph of a whole blood clot. The fibrin mesh is shown in green, and trapped platelets and erythrocytes are colored violet and red, respectively. (Used with permission of Yuri Veklich and John W. Weisel, University of Pennsylvania School of Medicine.)

During translocation of the single chains into the lumen of the endoplasmic reticulum (ER), a signal peptide is cotranslationally cleaved from each chain. The resulting chains have 625 amino acids ($A\alpha$), 461 amino acids ($B\beta$), and 411 amino acids (γ). Assembly proceeds in the ER with the formation of an $A\alpha$ - γ or $B\beta$ - γ intermediate. The addition of either a $B\beta$ or $A\alpha$ chain gives rise to a [$A\alpha B\beta\gamma$] half-molecule, which dimerizes to form the functional hexamer.¹¹ The protein undergoes several posttranslational modifications in the Golgi complex, including maturation of *N*-linked oligosaccharides, phosphorylation, hydroxylation, and sulfation.¹²

Following assembly, which is completed within minutes, the mature molecule is constitutively secreted into the circulation, where it exhibits a half-life of approximately 4 days.¹³ In addition to plasma fibrinogen, blood contains an internalized intracellular fibrinogen pool that is stored within platelet α granules. Both megakaryocytes and platelets are capable of internalizing plasma fibrinogen via the fibrinogen integrin $\alpha_{IIb}\beta_3$ receptor,¹⁴ which binds to a C-terminal platelet recognition sequence that is present on γA chains but is absent from γ' chains. Consequently, internalized platelet fibrinogen molecules contain only γA chains.¹⁵

● FIBRINOGEN CONVERSION TO FIBRIN AND NETWORK ASSEMBLY

Fibrin polymerization consists of several consecutive reactions, each affecting the ultimate structure and properties of the fibrin scaffold, which, in turn, determines the development and outcome of numerous diseases including coagulopathies and thrombosis.^{16,17} Conversion of fibrinogen to a fibrin clot¹⁸ occurs in three distinct phases: (1) enzymatic cleavage by thrombin to produce fibrin monomers; (2) self-assembly of fibrin units to form an organized polymeric structure; and (3) covalent crosslinking of fibrin by factor XIIIa. In the first phase of conversion to

fibrin, cleavage of fibrinogen at $A\alpha R35/G36$ ($R16/G17$)* and later $B\beta R44/G45$ ($R14/G15$) results in release of fibrinopeptides A (FpA) and B (FpB), respectively, thus exposing “A” knobs and “B” knobs (Fig. 125-3). The “A” knob located at the new aminoterminal end of the fibrin α chain starts with the GPRV amino acid sequence. The “A” knob in fibrin interacts with the constitutive complementary association site known as hole “a” in another molecule to initiate the fibrin assembly process. Hole “a” is encompassed by residues 363 to 405 (337 to 379) of the γ chain.

A knob-hole (A:a) interaction results in formation of double-stranded fibrils in which fibrin molecules become aligned in an end-to-middle, staggered overlapping arrangement (see Fig. 125-3).¹⁶⁻¹⁸ Fibrils subsequently undergo branching by lateral fibril associations in which two fibrils converge to form a four-stranded “bilateral” fibril junction. Progressive lateral associations among fibrils result in larger fibril bundles or fibers. A second type of junction, termed *equilateral branching*, is formed by three fibrils converging to form a three-member junction.¹⁹ Both types of branch junctions provide scaffolding for the clot network, the ultimate

*The recommendation of the Human Genome Variation Society (HGVS) is to number amino acid residues from the initiator Met, with the protein reference sequences representing the primary translation product, not the processed, mature, protein. This is the standard nomenclature used by geneticists. For fibrinogen, however, as for many other secreted proteins, such as the coagulation factors, this is not the nomenclature used in earlier publications (historically fibrinogen residues are numbered according to the secreted product lacking the signal peptide). In this text both nomenclatures are used: amino acid residues and substitutions are described first according to HGVS guidelines followed in brackets by the corresponding amino acid in the mature chain lacking the signal peptide. To convert from the HGVS nomenclature to the mature protein nomenclature, subtract 19 for $A\alpha$, 30 for $B\beta$, or 26 for γ . A one-letter abbreviation for amino acids is used in this chapter. A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; G, glycine; H, histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine.

Figure 125–2. Ribbon representation of native chicken fibrinogen²² modified from PDB file 1M1J (www.pdb.org/pdb/). α Chains are in green, β chains are in purple, and γ chains are in blue. The globular C-terminal domains of the $\beta\beta$ and $\gamma\gamma$ chains forming the D regions are shown, as well as the central E region, which contains the N-terminal portions of all three chains. Unlike the $\beta\beta$ and $\gamma\gamma$ domains, the C-terminal domains of the $\alpha\alpha$ chain (αC) are flexible and tend to be noncovalently tethered in the vicinity of the central E region.

structure of which is governed by several variables, including salt concentration, pH, fibrinogen concentration and thrombin concentration.^{16,17,20}

Fibrinopeptide B (FpB) release occurs more slowly than fibrinopeptide A (FpA) release and exposes another polymerization site known as the “B” knob beginning with the amino acid sequence GHRP. GHRP interacts with a constitutive hole “b” in the β chain encompassed by residues 427 to 462 (397 to 432). FpB cleavage is accelerated by fibrin polymerization, whereas FpA cleavage is independent of fibrin polymerization. B:b interactions are not required for lateral fibril associations, but they contribute to lateral association by inducing rearrangements in βC that allow $\beta\text{C}:\beta\text{C}$ contacts to occur.^{21,22}

The flexible αC domains also participate in fibrin polymerization.²³ Fibrin clots made from plasma fibrinogen molecules lacking more than 100 C-terminal residues from the αC domain display prolonged thrombin times, reduced turbidity, and produce thinner fibers, indicating that αC domains participate in lateral fibril associations. In addition, αC domains become dissociated as a result of FpB cleavage. This allows αC domains to participate in noncovalent interactions with other αC domains, thereby promoting lateral fibril associations and fibrin network assembly. Finally, additional self-associating sites in the D region participate in fibrin assembly. These are the D:D sites and γ_{XL} sites that promote end-to-end alignment of assembling fibrin units and factor XIIIa crosslinking, respectively.^{24,25}

CROSSLINKING BY FACTOR XIII

The clot formed by fibrin polymerization requires further stabilization to increase its mechanical strength and resist immediate degradation by the fibrinolytic pathway. Factor XIIIa (a heterotetramer FXIII-A2B2) is a transglutaminase that stabilizes the elongating protofibril by crosslinking adjacent γ chains through the formation of ϵ -(γ -glutamyl) lysine isopeptide bonds.²⁶ These occur between lysine 432 (406) of one γ chain and glutamine 424 (398) or 425 (399) of another chain. Crosslinking increases the resistance of the clot to deformation. The same process occurs, but at lower rate, between α chains and also between α chains and γ chains. In the presence of factor XIIIa, α -antiplasmin becomes covalently bound to the distal α chains of fibrin or fibrinogen.²⁶ The factor XIII binding site for fibrin has been characterized: residues in the A α -C domain, that is, 408 to 421 (389 to 402) bind a cleft in FXIII-A2 that is exposed only after cleavage of the activation peptide by thrombin.²⁷ Fibronectin is also incorporated into the fibrin clot. This occurs by noncovalent interactions between the two proteins through specific binding sites, followed by their covalent crosslinking with factor XIIIa.²⁸ Fibronectin incorporation appears to affect the adhesion and migration of cells at sites of fibrin deposition, thereby contributing to wound healing and other cell-dependent processes.

Figure 125–3. First steps of fibrinogen conversion to fibrin and fibrin assembly. **A.** Schematic of fibrinogen showing fibrinopeptides A (FpA) and B (FpB), the constitutive holes “a” and “b” in the globular C-terminal domains of the γ chains and β chains, respectively, and the “A” and “B” knobs, which are exposed only after FpA and FpB cleavage by thrombin. Here the globular βC and γC domains are shown separately, βC in purple, γC in blue as in Fig. 125–2. **B.** Self-assembly of fibrin units to form an organized polymeric structure. Here, for simplicity, the D regions are represented as a single globular unit.

FIBRINOLYSIS

Plasminogen and tissue-type plasminogen activator (t-PA) binding sites in the D regions (i.e., γ 337 to 350) (312 to 324), and α C domains (i.e., A α 167 to 179) (148 to 160), are cryptic in fibrinogen and become exposed during fibrin assembly or during formation of crosslinked fibrinogen fibrils (Chap. 135).^{29–30} Two phases can be distinguished in the t-PA induced lysis of a fibrin clot.³¹ In the first, slow, phase, t-PA activates plasminogen on the intact fibrin surface. The generation of C-terminal lysine residues in partially degraded fibrin (by plasmin) in the second phase of clot lysis may result in accumulation of plasminogen at the clot surface and a concomitant increase in lysis rate. Thrombin-activatable fibrinolysis inhibitor (TAFI) removes C-terminal lysine residues, resulting in a strongly reduced binding of plasminogen and in an inhibition of the second phase of clot lysis by a reduction of the activation of plasminogen on the fibrin surface. TAFI, as well as α -antiplasmin, lipoprotein(a), and histidine-rich glycoprotein, bind to fibrin and all have an inhibitory effect on fibrinolysis through various mechanisms.

ANTITHROMBIN ACTIVITY OF FIBRIN

Thrombin binds to its substrate, fibrinogen, through a fibrinogen recognition site in thrombin, referred to as exosite 1. The fibrin clot itself also exhibits significant thrombin-binding potential; this nonsubstrate binding potential of fibrin for thrombin is referred to as antithrombin activity I.⁶ This activity is defined by two classes of nonsubstrate thrombin-binding sites in fibrin, one of “low-affinity” in the E-region and the other of “high-affinity” in D regions of fibrin(ogen) molecules containing the variant γ' chain. Altogether, heterodimeric γ A/ γ' and homodimeric molecules γ'/γ' chains make up 8 to 15 percent of the total γ -chain population.¹⁰ Low-affinity thrombin-binding activity reflects thrombin exosite 1 binding in the E region of fibrin, whereas high-affinity thrombin binding to γ' chains takes place through exosite 2. The binding affinity of thrombin for γ' -containing fibrin molecules is increased by concomitant fibrin binding to thrombin exosite 1. Antithrombin I (fibrin) is an important inhibitor of thrombin generation that functions by sequestering thrombin in the forming fibrin clot, and also by reducing the catalytic activity of fibrin-bound thrombin. Vascular thrombosis may result from absence of antithrombin I (as in afibrinogenemia; see “Afibrinogenemia and Hypofibrinogenemia” below), reduced plasma γ' -chain content,³² or defective thrombin binding to fibrin as found in certain dysfibrinogenemias (see “Dysfibrinogenemia and Hypodysfibrinogenemia” below). In contrast, an increased susceptibility to arterial thrombosis has been reported when γ' -chain levels are significantly elevated. Moreover, thrombin bound to γ _A/ γ' -fibrin is protected from inhibition by antithrombin to a greater extent than thrombin bound to γ _A/ γ _A-fibrin. Thus, γ _A/ γ' -fibrin serves as a reservoir of active thrombin, which may contribute to the prothrombotic nature of thrombi.³³

AFIBRINOGENEMIA AND HYPOFIBRINOGENEMIA

DEFINITION, HISTORY, AND EPIDEMIOLOGY

Type I disorders (afibrinogenemia and hypofibrinogenemia) affect the quantity of fibrinogen in circulation. Type II disorders (dysfibrinogenemia and hypodysfibrinogenemia) affect the quality of circulating fibrinogen.¹ While the first dysfibrinogenemia mutation was identified as early as 1968,³⁴ the molecular basis of afibrinogenemia was elucidated much later.³⁵ This disorder is characterized by autosomal recessive inheritance and the complete absence of fibrinogen in plasma.

The disease, originally described in 1920,³⁶ has an estimated prevalence of approximately one in 1,000,000. In populations where consanguineous marriages are common, the prevalence of afibrinogenemia, is increased.³⁷ Because hypofibrinogenemia (fibrinogen levels below 1.5 g L⁻¹) is often caused by heterozygosity for a fibrinogen gene mutation, this is much more frequent than afibrinogenemia. If one applies the Hardy Weinberg binomial distribution of alleles in the population to afibrinogenemia, carriers of fibrinogen deficiency causing mutations could be as frequent as 1 in 500.

ETIOLOGY AND PATHOGENESIS

Since the identification of the first causative mutation for congenital afibrinogenemia in 1999,³⁵ approximately 100 distinct mutations, the majority in *FGA*, have been identified in patients with afibrinogenemia (in homozygosity or in compound heterozygosity) or in hypofibrinogenemia. Causative mutations can be divided into two main classes: null mutations with no protein production at all and mutations producing abnormal protein chains which are retained inside the cell.¹

Large Deletions

The first causative mutation for afibrinogenemia was identified in a nonconsanguineous Swiss family with two pairs of afibrinogenemic brothers.³⁵ In a first step toward establishing whether or not the disease was linked to the fibrinogen gene cluster on chromosome 4, haplotype data were obtained for five microsatellite markers surrounding this locus. One of these, FGAI3, a (TCTT)_n polymorphic marker located in intron 3 of the *FGA* gene, was found to be deleted in all four affected individuals and was hemizygous in the obligate carriers, implying that homozygous deletion of at least part of the *FGA* gene was responsible for the congenital afibrinogenemia in this family. Indeed, the genetic defect was found to be a recurrent deletion of approximately 11 kb of DNA, with breakpoints in *FGA* intron 1 and the *FGA*-*FGB* intergenic region, resulting in an absence of fibrinogen.

Three other large deletions in the fibrinogen gene cluster have been identified, all involving part of the *FGA* gene. These are: a deletion of 1.2 kb eliminating the entire *FGA* exon 4 in a Japanese patient³⁸; a deletion of 15 kb, with breakpoints situated in *FGA* intron 4 and in the *FGA*-*FGB* intergenic region in a Thai patient³⁹; and a 4.1-kb deletion encompassing *FGA* exon 1 in an Italian patient.⁴⁰ All patients were homozygous for the identified deletions except for the Thai patient, for whom complete maternal uniparental disomy was confirmed for the deleted chromosome 4.³⁹

Splice-Site Mutations

Several splice-site mutations have been identified in all three fibrinogen genes. In afibrinogenemic patients of European origin, the most common mutation is a donor splice mutation in intron 4, c.510+1G→T (previously described as IVS4+1 G→T).^{1,41} Haplotype data suggest that this mutation, like the *FGA* 11-kb deletion, is also recurrent, or a very ancient mutation, because the c.510+1G→T mutation is found on multiple discrete haplotypes.

Frameshift Mutations

Frameshift mutations have been identified in all three fibrinogen genes. *FGA* exon 5, the largest fibrinogen-coding exon has the most frameshift mutations. Interestingly, seven single base-pair deletions in *FGA* exon 5 result in usage of the same new reading frame. All seven mutations are predicted to encode a long stretch of aberrant amino acids before terminating at the same premature stop codon, 69 to 158 codons downstream.⁴² The aberrant amino acid sequence (if the abnormal protein is synthesized and stable, which remains to be determined) may lead to abnormal folding of the A α chain, thus affecting fibrinogen chain assembly or secretion.

Nonsense Mutations

Many nonsense mutations accounting for afibrinogenemia and hypofibrinogenemia have been identified. Of the nine nonsense mutations identified in *FGB*, four are located in *FGB* exon 8.⁴³ In particular, two *FGB* nonsense mutations—W467X (W437X) and W470X (W440X)—are localized very close to the β -chain C-terminus and are expected to cause the synthesis of β C chains truncated of only 25 and 22 residues, respectively.^{44,45} Expression studies in transfected COS cells performed for both mutations showed that the mutations allowed individual chain synthesis and intracellular assembly of the hexamer but impaired secretion, suggesting that an intact *FGB* C-terminal domain is necessary for fibrinogen secretion into the circulation.⁴⁶

Missense Mutations

Null mutations, that is, large deletions, frameshift, early truncating nonsense, and splice-site mutations account for the majority of afibrinogenemia alleles, as expected. Missense mutations leading to complete fibrinogen deficiency are therefore particularly interesting, revealing the functional importance of individual residues or three-dimensional structures. Missense mutations are clustered in the highly conserved C-terminal globular domains of the γ and B β chains.^{1,43} Expression studies in transfected cells for five *FGB* missense mutations, all identified in homozygosity or compound heterozygosity in afibrinogenemic patients, showed that these mutations, like the late-truncating nonsense mutations discussed previously, allowed individual chain synthesis and intracellular assembly of the hexamer but again impaired secretion.⁴⁷⁻⁵⁰ Further characterization of the *FGB* G444S (G414S) mutant using immunostaining for fibrinogen and visualization by confocal microscopy revealed that the secretion-impaired mutant was retained in the ER proving the existence of an efficient quality control mechanism for fibrinogen secretion.⁴⁶

Several missense mutations have been identified in *FGG* in heterozygosity in patients with hypofibrinogenemia. For the majority of these mutations, analysis of patient plasma fibrinogen by mass spectrometry confirmed absence of the mutant γ chain in the circulation. Others have been studied at the functional level in transfected cells: fibrinogen Matsumoto IV C179R (C153R) was found to impair intracellular hexamer assembly,⁵¹ whereas fibrinogen Bratislava W253C (W227C) was found to impair fibrinogen secretion.⁵²

Mutations Causing Hepatic Endoplasmic Reticulum Retention and Hypofibrinogenemia

In the majority of patients with afibrinogenemia or hypofibrinogenemia there is no evidence of intracellular accumulation of the mutant fibrinogen chain. This implies the existence of an efficient degradation pathway for fibrinogen mutants that allow individual chain synthesis and assembly but not secretion. Four mutations, all in *FGG*, are known to cause hypofibrinogenemia accompanied by hepatic storage disease. These are three missense mutations (fibrinogen Brescia, Aguadilla, and Al duPont,⁵³⁻⁵⁵ and a 15-bp deletion at the end of *FGG* exon 8 (fibrinogen Angers),⁵⁶ which creates a new *FGG* exon 8–intron 8 junction and donor splice site. All four mutations cause fibrinogen deficiency in the heterozygous state because of the absence of the mutant γ chain in patient plasma, but also progressive liver disease associated with hepatocellular cytoplasmic inclusions. The molecular mechanism by which these mutations, localized in the five-stranded β -sheet of γ C and hole “a,” which are crucial for fibrin polymerization, leads to impaired secretion, retention in the ER, and formation of aggregates remains to be determined.

CLINICAL FEATURES

Afibrinogenemia

Bleeding because of afibrinogenemia usually manifests in the neonatal period, with 85 percent of cases presenting umbilical cord bleeding,

but a later age of onset is not unusual. Bleeding may occur in the skin, gastrointestinal tract, genitourinary tract, or the central nervous system with intracranial hemorrhage being the major cause of death. Joint bleeding, which is common in patients with severe hemophilia, is less frequent: in a series of 72 patients with severe fibrinogen deficiency, hemarthrosis was observed in 25 percent of cases.⁵⁷ There is an intriguing susceptibility of spontaneous rupture of the spleen in afibrinogenemic patients. Bone cysts have also been described as a rare complication of afibrinogenemia and appear to benefit from prophylactic therapy with fibrinogen concentrate.⁵⁸

Menstruating women may experience menometrorrhagia but some have normal menses. First trimester abortion is usual in afibrinogenemic women. The importance of fibrinogen in pregnancy was demonstrated in studies with fibrinogen knockout mice that cannot carry fetuses to term.⁵⁹ Women may also have antepartum and postpartum hemorrhage. Hemoperitoneum after rupture of the corpus luteum has also been observed.

Paradoxically both arterial and venous thromboembolic complications are observed in afibrinogenemic patients. These complications can occur in the presence of concomitant risk factors such as a coinherited thrombophilic risk factor or after replacement therapy. However, in many patients, no known risk factors are present. Many hypotheses have been put forward to explain this predisposition to thrombosis. One explanation is that even in the absence of fibrinogen platelet aggregation is possible because of the action of von Willebrand factor and, in contrast to patients with severe hemophilia, afibrinogenemic patients are able to generate thrombin, both in the initial phase of limited production and also in the secondary burst of thrombin generation. In some patients, an increase of prothrombin activation fragments or thrombin–antithrombin complexes has been observed, which may reflect enhanced thrombin generation.⁶⁰ These abnormal levels can be normalized by fibrinogen infusions.

As previously mentioned, fibrin also acts as antithrombin I by both sequestering and downregulating thrombin activity.⁶ Thrombin which is not trapped by the clot is available for platelet activation and smooth muscle cell migration and proliferation, particularly in the arterial vessel wall. Thrombus formation is maintained in fibrinogen-deficient mice,⁶¹ and in fibrinogen-deficient zebrafish,⁶² but the thrombus is unstable and has a tendency to embolize. Similarly, the absence of fibrinogen in human plasma results in large but loosely packed thrombi under flow conditions.⁶³

Hypofibrinogenemia

Hypofibrinogenemia patients are very often heterozygous carriers of afibrinogenemia mutations.¹ These patients are usually asymptomatic with fibrinogen levels of approximately 1.0 g L⁻¹, levels which are in theory high enough to protect against bleeding and maintain pregnancy. However they can bleed when exposed to trauma, or if they have a second associated hemostatic abnormality. Hypofibrinogenemic women may also suffer from pregnancy loss.

LABORATORY FEATURES

The clinical diagnosis is established by functional and immunologic measurements of fibrinogen concentration backed by genetic analyses.

Phenotype Analysis

Absence of immunoreactive fibrinogen is essential for the diagnosis of congenital afibrinogenemia. All coagulation tests that depend on the formation of fibrin as the end point—that is, prothrombin time (PT), partial thromboplastin time (PTT), or thrombin time (TT)—are infinitely prolonged. Plasma activity of all other clotting factors is usually normal. Some abnormalities in platelet functions tests can be observed which

can be reversed upon addition of fibrinogen. Because fibrinogen is one of the main determinants of erythrocyte sedimentation, it is not surprising that afibrinogenemic patients have very low erythrocyte sedimentation rates. When skin testing is performed for delayed hypersensitivity, there is no induration because of the lack of fibrin deposition.

Hypofibrinogenemia is defined as a proportional decrease of functional and immunoreactive fibrinogen. Coagulation tests depending on the formation of fibrin as well as the assays used are variably prolonged, the most sensitive assay being the TT.

Genotype Analysis

The large number of mutations identified in patients with afibrinogenemia allows the design of an efficient flow-chart for mutation detection in new cases.⁶⁴ Two common mutations are found in individuals of European origin, both in *FGA*: the c.510+1G→T intron 4 donor splice-site mutation and the *FGA* 11-kb deletion, both found on multiple haplotypes. In all new patients of European origin, the *FGA* c.510+1G→T should be the first mutation to be screened. Southern blot or polymerase chain reaction (PCR) analysis of the *FGA* 11-kb deletion should also be performed, because it is the second most common mutation in patients of European origin and because of the risk of diagnostic error: a nonconsanguineous patient who appears to be homozygous for a mutation in *FGA* exons 2 to 6 may in reality be a heterozygous carrier of the large 11-kb deletion.⁶⁵ Given the high frequency of mutations in *FGA*, the other *FGA* exons (starting with exon 5) should then be studied for mutations before screening *FGB* (starting with exon 8) and *FGG* (starting with exons 7 and 8). The same strategy can also be applied to afibrinogenemic patients of non-European origin for whom recurrent mutations have yet to be identified. If the patient comes from a geographical region or population in which a mutation has already been identified, that mutation should be the first to be screened for. Screening of patients with hypofibrinogenemia can follow the same strategy apart from patients with ER fibrinogen-positive liver inclusions, for which four mutations in *FGG* are known so far to cause hepatic storage disease.

Prenatal diagnosis has been performed in a few cases.⁶⁶ This is important for families with afibrinogenemia and access to adequate treatment because the prenatal diagnosis of an affected infant allows initiation of treatment immediately after birth before the first bleeding manifestation.

Genotype–Phenotype Correlations: Potential Importance of Global Assays

Current diagnostic tests are appropriate for establishing the diagnosis but clearly additional tests are required for a more accurate prediction of the clinical phenotype of a patient and consequently the appropriate treatment. Indeed, although in afibrinogenemia all patients have unmeasurable functional fibrinogen, the severity of bleeding is highly variable amongst patients, even amongst those with the same genotype. Similarly, there is no clear relationship between the molecular defect and the risk of thrombosis.

One possible explanation for the observed variability of clinical manifestations is the existence of modifier genes/alleles: some variants may increase the severity of bleeding while others may ameliorate the phenotype. Such modifiers have yet to be identified. However, the common thrombophilias (e.g., factor V Leiden) most certainly play a role in decreasing the severity of bleeding. The existence of modifying genes/polymorphisms is also strongly suspected in the previously discussed cases of hypofibrinogenemia associated with fibrinogen inclusion bodies in hepatocytes. Indeed, all individuals heterozygous for one of the four *FGG* causative mutations have hypofibrinogenemia, but not all have fibrinogen aggregates and associated liver disease.

Global assays, such as thromboelastography and thrombin generation test, may provide a complementary and in some cases a better evaluation of an individual's hemostatic state. Such global assays could be useful for the design of individual therapeutic strategies.⁶⁷

DIFFERENTIAL DIAGNOSIS

Inherited afibrinogenemia and hypofibrinogenemia have to be distinguished from acquired disorders. These include disseminated intravascular coagulation, primary fibrinolysis, liver disease, and can be caused by certain drugs (e.g., thrombolytic agents and L-asparaginase). In addition, one should be aware that artifactually low levels of fibrinogen can be observed with samples that have clotted as a result of improper collection. In most cases, the clinical context as well as the association with other laboratory abnormalities will allow differentiation of inherited from acquired disorders. Identification of a causative mutation in one of the three fibrinogen genes will confirm the diagnosis.

THERAPY

Available Treatments and Modalities

Replacement therapy is effective in treating bleeding episodes in congenital fibrinogen disorders. Depending on the country of residence, patients receive fresh-frozen plasma (FFP), cryoprecipitate, or fibrinogen concentrates.⁶⁴ Fibrinogen concentrate preparations include safety steps for inactivation or removal of viruses, which make them safer than cryoprecipitate or FFP. Furthermore, more precise dosing can be accomplished with fibrinogen concentrates because their potency is known, in contrast to FFP or cryoprecipitates.

The conventional treatment is on demand, in which fibrinogen is administered as soon as possible after onset of bleeding. Another approach is primary prophylaxis that includes administration of fibrinogen concentrates from an early age to prevent bleeding and, in the case of pregnancy, to prevent miscarriage. Effective long-term secondary prophylaxis with administration of fibrinogen every 7 to 14 days (particularly after central nervous system bleeds) has been advocated. The frequency and dose of fibrinogen concentrates should be adjusted to maintain a level above 0.5 g L⁻¹.⁶⁴

The United Kingdom guidelines on therapeutic products for coagulation disorders⁶⁸ provide recommendations about the best treatment options (dosage, management of bleeding, surgery and pregnancy as well as prophylaxis). According to these guidelines, in case of bleeding fibrinogen levels should be increased to 1.0 g L⁻¹ and maintained above this threshold until hemostasis is secured, and above 0.5 g L⁻¹ until wound healing is complete. To increase the fibrinogen concentration of 1 g L⁻¹, a dose of approximately 50 mg/kg is required. The doses and duration of treatment also vary depending on the type of injury or operative procedure and on the patient's personal and familial history of bleeding and thrombosis.

Women with congenital afibrinogenemia are able to conceive and embryonic implantation is normal, but the pregnancy usually results in spontaneous abortion at 5 to 8 weeks of gestation unless fibrinogen replacement is given.⁶⁹ Maintaining the fibrinogen level above 0.6 g L⁻¹ and if possible higher than 1.0 g L⁻¹ is recommended. Lower fibrinogen concentrations (<0.4 g L⁻¹) have proven adequate to maintain pregnancy but not to avoid hemorrhagic complications. Continuous infusion of fibrinogen concentrate should be performed during labor to maintain fibrinogen higher than 1.5 g L⁻¹ (ideally greater than 2.0 g L⁻¹).⁷⁰ Thromboembolic events can occur, particularly with the use of cryoprecipitates that contain appreciable quantities of factor VIII and von Willebrand factor in addition to fibrinogen.

In addition to fibrinogen substitution, antifibrinolytic agents may be given, particularly to treat mucosal bleeding or to prevent bleeding following procedures such as dental extraction. Fibrin glue is useful to treat superficial wounds or following dental extractions. Oral contraceptive preparations are useful in case of menorrhagia. Oral iron preparations can be given in cases with associated iron-deficiency anemia. Routine vaccination against hepatitis, as well as a regular surveillance for both the disease and treatment-related complications in a comprehensive care setting, is highly recommended.⁶⁴

Finally, orthotopic liver transplantation is a possible rescue treatment for failure of fibrinogen replacement therapy. This procedure successfully restored normal hemostasis in an afibrinogenemic patient with severe Budd-Chiari syndrome and inferior cava vein thrombosis⁷¹ and in one of the four afibrinogenemic patients homozygous for the 11-kb *FGA* mutation.^{35,72}

Complications of Therapy

In many countries only FFP or cryoprecipitate are available, which is problematic because the viral inactivation process is in general not as efficient as it is for fibrinogen concentrates (although emerging non-viral pathogens such as the prion responsible for variant Creutzfeldt-Jacob disease must be considered, even for concentrates). Even if viral inactivation steps are performed, these preparations (particularly FFP) can induce volume overload. There is also a risk of transfusion-related acute lung injury, because of the presence of cytotoxic antibodies in the infused plasma.

Acquired inhibitors to fibrinogen after replacement therapy have been reported in only two cases. It is not clear why afibrinogenemic patients do not develop inhibitors more frequently. One explanation for some cases is that minute amounts of fibrinogen, which can only be detected by highly sensitive immunoassays, are present in the circulation.

One of the major complications in afibrinogenemic patients is thrombosis, which can occur spontaneously following blood component therapy. Some clinicians give small doses of heparin or low-molecular-weight heparin (LMWH) during administration of fibrinogen. Before surgery, patients with a thrombotic phenotype should be treated with compression stockings and LMWH. Successful use of lepirudin has been reported for an afibrinogenemic patient who suffered recurrent arterial thrombosis despite treatment with heparin and aspirin.⁷³ Thromboembolic complications are difficult to manage because both anticoagulants and fibrinogen preparations have to be administered.

New Preparations

The increasing need for fibrinogen preparations in congenital but also in acquired deficiencies has stimulated some companies to improve existing preparations or to develop new ones. A recombinant fibrinogen molecule is also under development.⁷⁴

● DYSFIBRINOGENEMIA AND HYPODYSFIBRINOGENEMIA

DEFINITION, HISTORY, AND EPIDEMIOLOGY

The second class of hereditary fibrinogen abnormalities comprises the type II disorders, that is, dysfibrinogenemia and hypodysfibrinogenemia. Dysfibrinogenemia is defined by the presence of normal levels of functionally abnormal plasma fibrinogen. Hypodysfibrinogenemia is defined by low levels of a dysfunctional protein. As in afibrinogenemia and hypofibrinogenemia, both are heterogeneous disorders caused by

many different mutations in the three fibrinogen-encoding genes. Dysfibrinogenemias and hypodysfibrinogenemias are autosomal dominant disorders. Most affected patients are heterozygous for missense mutations in the coding region of one of the three fibrinogen genes. Because the secreted fibrinogen hexamer contains two copies of each of the three fibrinogen chains, and the resulting fibrin network contains multiple copies of the molecule, heterozygosity for one mutant allele is sufficient to impair the structure and function of the fibrin clot (Fig. 125-4).

Figure 125-4. Scanning electron micrographs showing structural variations in clots formed from dysfibrinogens. **Top.** Control clot from normal purified fibrinogen clotted with thrombin showing relatively uniform distribution of fibers forming a branched network. **Middle.** Clot from fibrinogen Caracas I⁹⁶ showing very thin fibers, indicating a defect in lateral aggregation. **Bottom.** Clot from fibrinogen Caracas VI⁹⁷ showing a nonuniform distribution of thin and thick fibers in the clot, with bundles of fibers, larger pores, and more fiber ends than control clots. Magnification bar: 5 μ m. (Used with permission of John W. Weisel and Rita Marchi.)

As of this writing, more than 100 distinct mutations have been identified in patients with dysfibrinogenemia and hypodysfibrinogenemia. The described mutants are very often named after the city of origin of the family or the city of the laboratory characterizing the mutation. Many cases are asymptomatic and are only identified as a result of routine coagulation screening. Indeed, a compilation of approximately 250 cases revealed that 55 percent of patients were asymptomatic, 25 percent had a history of bleeding, and 20 percent, a tendency toward thrombosis.⁷⁵ However, our retrospective multicentric study of the long-term outcomes of 101 genotyped patients suggests that bleeding and thrombotic events are more frequent.⁷⁶

ETIOLOGY AND PATHOGENESIS

Dysfibrinogenemic abnormalities usually are reflected in one or more phases of the fibrinogen-fibrin conversion and fibrin assembly process, notably impaired release of fibrinopeptides and defective fibrin polymerization or factor XIIIa-mediated crosslinking.^{77,78} Other abnormalities involve abnormal tissue deposition such as in renal amyloidosis,⁷⁹ defective fibrinolysis,⁸⁰ abnormal interactions with platelets,^{77,80} and defective calcium binding.⁸¹

Mutations Resulting in Abnormal "A" Knobs or Deficient Fibrinopeptide Release

Fibrinogen Detroit was the first abnormal fibrinogen in which the specific mutation was identified at the protein level.³⁴ This *FGA* R38S (R19S) mutation is located in the "A" knob (i.e., GPRV) resulting in impaired fibrin polymerization and a bleeding tendency. Other substitutions involving residue R38 (R19) have been found to be associated with bleeding in some cases, for example, Munich I, R38N (R19N), and Mannheim I, R38G (R19G), and with thrombosis in other cases, for example, Aarhus and Kumamoto, which are also a result of R38G (R19G). The mechanism for thrombophilia remains unclear, but coexisting risk factors may contribute to the clinical manifestations. Furthermore, the inability of a mutant fibrin to effectively bind and sequester thrombin may play a role in such a clinical presentation. Bleeding that occurs under conditions involving defective fibrinopeptide release or production of a defective "A" knob is most likely related to the reduced polymerization potential of the mutant fibrins that are produced, with resulting defective clot formation.⁸²

Missense mutations at residue *FGA* R35 (R16) which is part of the thrombin cleavage site in the fibrinogen α chain appear to be the most common causative mutations accounting for dysfibrinogenemia, based on information compiled in the GEHT registry for hereditary fibrinogen abnormalities.⁵ The R35 (R16) residue can be mutated to either H (CGT→CAT) or C (CGT→TGT) leading to delayed or absent FpA release, respectively, and subsequent delayed polymerization. A prolonged reptilase time is observed for both variants. Most patients do not have a bleeding tendency. Some patients have been found to be homozygous for these mutations or phenotypically homozygous,⁶⁵ as a result of compound heterozygosity for an R35 (R16) missense mutation and the large 11-kb *FGA* deletion first characterized in afibrinogenemia. In these cases, a mild bleeding tendency is observed.

Missense mutations in *FGB* affecting FpB release have been identified,⁸³ but are much less common than those affecting FpA release.

Mutations Leading to Polymerization Defects in the D Region

Sites in the D region important for fibrin polymerization are affected in many dysfibrinogenemias. Mutations affecting hole "a" in the γ chain are numerous, while no naturally occurring mutation involving hole "b" in the β chain has been described, compatible with the view that A:

interactions are the driving force of fibrin polymerization.¹⁶ The interface for the end-to-end D:D site in the γ chain lies between R301 (R275) and S326 (S300), with T306 (T280) contacting R301 (R275) at the D:D interface. Mutations at the R301 (R275) residue to C (CGT→TGT) or H (CGT→CAT) are the second most common cause of dysfibrinogenemia, accounting for around 10 percent of fibrinogen variants.⁵ Impaired polymerization has been observed for all substitutions at this position. Most of these cases are asymptomatic, but some patients heterozygous for R301C (R275C) have thrombophilia, sometimes in association with an additional thrombotic risk factor such as factor V Leiden.⁸⁴

Mutations Accounting for Hypodysfibrinogenemia

Hypodysfibrinogenemia which is defined by low levels of a dysfunctional protein can be caused by different molecular mechanisms. One mechanism is heterozygosity for a single mutation that leads to synthesis of an abnormal fibrinogen chain which is secreted less efficiently than normal fibrinogen, for example, fibrinogen Kyoto IV.⁸⁵ Another mechanism is the presence of two different mutations with one mutation responsible for the fibrinogen deficiency (the "hypo phenotype") and one mutation responsible for the abnormal function of the molecule (the "dys phenotype"). For example, in fibrinogen Keokuk,⁸⁶ there is compound heterozygosity for the common afibrinogenemia splice-site mutation c.510G→T and a premature truncating nonsense mutation in *FGA* Q347X (Q328X). Another example is fibrinogen Leipzig II in which the common hypofibrinogenemia mutation *FGG* A108G (A82G) and *FGG* G377S (G351S) are located on the same allele.⁸⁷ Homozygosity for a single mutation, which allows reduced secretion of a functionally impaired molecule, has been described in fibrinogens Otago⁸⁸ and Marburg.⁸⁹ Finally, maternal uniparental disomy for a nonsense mutation in *FGB*, W323X (W293X), was found to be the cause of severe hypodysfibrinogenemia in a Chinese patient.⁹⁰

CLINICAL FEATURES

Patients with inherited dysfibrinogenemia are frequently asymptomatic and can be discovered incidentally because of abnormal coagulation tests. A compilation of more than 260 cases of dysfibrinogenemia revealed that 55 percent of the patients had no clinical complications while 25 percent exhibited bleeding, and 20 percent had a tendency to thrombosis, mainly venous.⁷⁵ However, when 2376 patients with deep vein thrombosis were screened for thrombophilia, the prevalence of dysfibrinogenemia was very low (0.8 percent) and hence testing for dysfibrinogenemia in patients with deep vein thrombosis is not recommended.⁹¹ Patients with dysfibrinogenemia associated with hemorrhage bleed most often after trauma, surgery, or during the puerperium.⁷⁶ Thrombosis may also occur during pregnancy and in the postpartum period. Women with dysfibrinogenemia can also suffer from spontaneous abortions. The problems during and after pregnancy are not necessarily correlated to the fibrinogen concentration.

Some mutations in the $A\alpha$ chain of fibrinogen are associated with a particular form of hereditary amyloidosis.^{79,92} The E545V (E526V) amino acid substitution is the most common of these mutations.⁹² The abnormal fibrinogen fragments form amyloid fibrils and the extracellular deposition of these fibrils leads to renal failure. Chronic renal dialysis is performed for managing renal failure. Renal transplantation can be envisaged as an alternative to chronic dialysis. However, continuous fibrinogen-related amyloid deposition ultimately results in allograft destruction. Combined liver and kidney transplantation prevents further amyloid deposition in the renal allograft and elsewhere but is associated with additional perioperative and subsequent risks.

LABORATORY FEATURES

Phenotype Analysis

Initial screening tests for fibrinogen dysfunction should include fibrinogen concentration, measured functionally and immunochemically, TT, and reptilase time. Dysfibrinogenemia is diagnosed by a discrepancy between clottable and immunoreactive fibrinogen. However, even in specialized laboratories, this diagnosis can be difficult because the sensitivity of the tests depends on the specific mutation, reagents, and techniques.^{93,94}

In classical dysfibrinogenemias, the functional assay of fibrinogen yields low levels compared with the immunologic assays, but levels are sometimes concordant and the functional level may even be normal (as well as TT). The determination of the precise nature of a fibrinogen defect has to be performed in highly specialized laboratories since it involves purification of fibrinogen, measurement of the rate of fibrinopeptide cleavage, analysis of fibrin monomer polymerization, and fibrinolysis. Thromboelastography, commonly used for decision making for fibrinolytic and anticoagulant therapy, may be particularly useful for investigation of dysfibrinogenemia. The thromboelastography signal is fibrin dependant, its amplitude is enhanced by platelets and reflects the stretch and recovery of the clot during its formation.⁹⁵

Genotype Analysis

The gold standard for the diagnosis of dysfibrinogenemia is the characterization of the molecular defect. However, although advances in DNA analysis have made mutation detection easier, it is not always clear whether the identified mutation is the cause of the presenting phenotype. Family studies showing segregation of the mutation with the phenotype, exclusion that the DNA alteration is a common polymorphism in the general population, and structural correlations are necessary for establishing the link between the DNA alteration and the disorder. As previously mentioned, two mutations “hotspots” are of prime interest in screening for dysfibrinogenemia mutations: residue R35 (R16) situated in *FGA* exon 2, and residue R301 (R275) in *FGG* exon 8. Other causative mutations are common in the surrounding residues. Thus, it is recommended to initially screen *FGA* exon 2 and *FGG* exon 8 in cases of dysfibrinogenemia. In our recent study of 101 dysfibrinogenemia cases,⁷⁶ 87 percent of the causative mutations were located in these two exons. Here, mutations of *FGG* R301 (R275) were more common than mutations of *FGA* R35 (R16), 52 percent and 23 percent, respectively.

Genotype–Phenotype Correlations

As previously discussed, the clinical manifestations of dysfibrinogenemia are highly variable and may relate in some cases to differences in clot strength, structure and stability.¹¹⁷ In a few cases, mutations are predictive of the clinical phenotype, such as the R573C (R554C) substitution in the A α chain (e.g., fibrinogens Chapel Hill III, Paris V, and Dusart) that predisposes patients to thrombosis. Impaired fibrinolysis exhibited by this dysfibrinogen appears to be responsible for the thrombotic complications. Other examples associated with thrombosis include dysfibrinogens Barcelona III, Haifa I, or Bergamo II as a result of the common γ R301H (R275H) mutation and Cedar Rapids I caused by γ R301C (R275C). However, in fibrinogen Cedar Rapids I, only patients heterozygous for both factor V Leiden and the *FGG* R301C (R275C) substitutions were symptomatic, suggesting that this mutation causes thrombosis when associated with another defect. On the other hand, several mutations in the aminoterminal region of the A α chain, such as fibrinogen Detroit R38S (R19S) and Mannheim I R38G (R19G), are associated with bleeding.

DIFFERENTIAL DIAGNOSIS

Inherited dysfibrinogenemia has to be distinguished from acquired dysfibrinogenemia. Liver diseases (e.g., cirrhosis, chronic active liver disease, hepatoma, liver failure) are the main causes of acquired dysfibrinogenemia. L-Asparaginase treatment also may result in the production of abnormal fibrinogen. In addition, there are a few case reports of acquired dysfibrinogenemia secondary to pancreatitis, paraneoplastic syndrome, and renal carcinoma. The acquired dysfibrinogenemias represent a heterogeneous group of disorders with multiple pathogenetic mechanisms, the most clearly defined fibrinogen abnormalities being an increase in carbohydrate content in patients with liver disease. These abnormal fibrinogens are usually characterized by prolonged thrombin and reptilase times, by abnormal fibrin monomer polymerization but with normal fibrinopeptide release. Fibrinogen concentration is variable.

In some cases no underlying disease is found, and to determine whether a fibrinogen abnormality is congenital or acquired may be difficult. The demonstration of the same fibrinogen abnormality in another family member is a strong argument for a congenital disorder. When measured in newborns, fibrinogen levels should be interpreted with caution because neonatal fibrinogen has an altered content of carbohydrate that can mimic dysfibrinogenemia in certain laboratory tests.

Rare cases of circulating autoantibodies to fibrinogen, for example in systemic lupus erythematosus and in patients receiving surgical sealants containing bovine fibrinogen, have also been reported.

THERAPY

Any treatment considered in patients with dysfibrinogenemia should be based on the personal and family history. Indeed, as already discussed, subjects with hereditary dysfibrinogenemias may be asymptomatic throughout their whole life or may suffer from bleeding and/or thrombotic complications.^{1,75,76} In patients who bleed, functional levels of fibrinogen should be raised above 1.0 g L⁻¹ and maintained above this threshold until hemostasis is secured and above 0.5 g L⁻¹ until wound healing is complete. Topical fibrin glue or antifibrinolytic agents may be used for superficial bleeds. In pregnant women with a bleeding phenotype, the recommendations for afibrinogenemia and hypofibrinogenemia can be followed. With a personal or familial history of thrombosis, thromboprophylaxis and antithrombotic treatments may be proposed after a careful analysis of each particular situation. Long-term management strategies for thrombophilic dysfibrinogenemia are the same as the strategies for patients with recurrent thromboembolism and may include long-term anticoagulant therapy.

CHAPTER 126

VON WILLEBRAND DISEASE

Jill Johnsen and David Ginsburg

SUMMARY

von Willebrand factor (VWF) is a central component of hemostasis, serving both as an adhesive link between platelets and the injured blood vessel wall and as a carrier for clotting factor VIII (FVIII). Abnormalities in VWF function result in von Willebrand disease (VWD), the most common inherited bleeding disorder in humans. The overall prevalence of VWD has been estimated to be as high as 1 percent of the general population, although the prevalence of clinically significant disease is probably closer to 1:1000. VWD is associated with either quantitative deficiency (type 1 and type 3) or qualitative abnormalities of VWF (type 2). The uncommon type 3 variant is the most severe form of VWD and is characterized by very low or undetectable levels of VWF, a severe bleeding diathesis, and a generally autosomal recessive pattern of inheritance. Type 1 VWD, the most common variant, is characterized by VWF that is normal in structure and function but decreased in quantity (in the range of 20 to 50 percent of normal). In type 2 VWD, the VWF is abnormal in structure and/or function. Type 2A VWD is associated with selective loss of the largest and most functionally active VWF multimers. Type 2A is further subdivided into group 1, as a result of mutations that interfere with biosynthesis and secretion, and group 2, in which the mutant VWF exhibits an increased sensitivity to proteolysis in plasma. Type 2B VWD is caused by mutations clustered within the VWF A1 domain, in a segment critical for binding to the platelet glycoprotein Ib receptor. These mutations produce a “gain of function” resulting in spontaneous VWF binding to platelets and clearance of the resulting platelet complexes, leading to thrombocytopenia and loss of the most active (large) VWF multimers. Type 2N VWD is characterized by mutations within the FVIII binding domain of VWF, leading to disproportionately decreased factor VIII and a disorder resembling mild to moderate hemophilia A, but with autosomal rather than X-linked inheritance. Type 1 VWD can often be effectively managed by treatment with DDAVP (1-deamino-8-D-arginine vasopressin, desmopressin), which produces a two- to threefold increase in plasma VWF level due to release from endothelial storage sites in the vessel wall. Response to DDAVP is generally poor in type 3 and some type 2 VWD variants. These disorders often require treatment with factor replacement in the form of VWF/FVIII concentrates containing large quantities of intact VWF multimers.

Acronyms and Abbreviations: ADAMTS13, a disintegrin and metalloprotease with thrombospondin type 1 motifs; aPTT, activated partial thromboplastin time; DDAVP, 1-desamino-8-D-arginine vasopressin or desmopressin; ER, endoplasmic reticulum; GP, glycoprotein; HHT, hereditary hemorrhagic telangiectasia; PCR, polymerase chain reaction; RIPA, ristocetin-induced platelet aggregation; VWD, von Willebrand disease; VWF, von Willebrand factor.

DEFINITION AND HISTORY

In 1926, Eric von Willebrand described a bleeding disorder in 24 of 66 members of a family from the Åland Islands.¹ Both sexes were afflicted, and the bleeding time was prolonged despite normal platelet counts and normal clot retraction. von Willebrand distinguished this condition from the other hemostatic diseases known at the time and recognized its genetic basis, calling the disorder “hereditary pseudo-hemophilia,” but incorrectly characterizing the inheritance as X-linked dominant. von Willebrand’s confusion about the inheritance pattern was probably the result of, at least in part, the greater recognition of bleeding symptoms in women because of the hemostatic stresses of menstruation and parturition. The proband in the original family, Hjördis, was 5 years old at the time of von Willebrand’s initial evaluation and ultimately died at age 13 years during her fourth menstrual cycle. Four of Hjördis’ sisters died between the ages of 2 and 4 years, and deaths in the family were also noted during childbirth.

An apparently similar disorder was independently reported in the United States by Minot and others in 1928. The original family in the Åland Islands was reexamined by von Willebrand and Jürgens in 1933, leading to the conclusion that the defect in this disorder was caused by an impairment of platelet function. It was not until 1953 that Alexander and Goldstein demonstrated reduced levels of coagulation factor VIII (FVIII) in von Willebrand disease (VWD) patients, along with prolonged bleeding time. This observation was confirmed by others, including studies of the original von Willebrand pedigree by Nilsson and coworkers. In the late 1950s, Nilsson and coworkers demonstrated that a fraction of plasma referred to as “I-O” could correct the FVIII deficiency and normalize the bleeding time, indicating that the defect in VWD was a result of the deficiency of a plasma factor rather than an intrinsic platelet abnormality. Infusion of fraction I-O promptly increased the FVIII level in a hemophilic patient, while in VWD the FVIII level rose gradually, peaking at 5 to 8 hours. Fraction I-O prepared from a hemophilia A patient was also shown to correct the defect in VWD, demonstrating that these disorders were caused by deficiencies of distinct plasma factors (reviewed in Refs. 2 and 3).

It was not until 1971 that Zimmerman, Ratnoff, and Powell prepared the first antibodies against what was thought to be a highly purified form of FVIII.⁴ This FVIII-related antigen was found to be normal in hemophilia A patients but decreased in VWD. This puzzle was finally resolved with the demonstration that von Willebrand factor (VWF) and FVIII are closely associated, with more than 98 percent of the mass of the complex made up of VWF (see section The Function of von Willebrand Factor below). Thus, antibodies raised against this complex predominantly recognize VWF. The first direct assay of VWF function was based on the observation that the antibiotic ristocetin induced thrombocytopenia and the demonstration by Howard and Firkin⁵ that ristocetin-induced platelet aggregation (RIPA) was absent in some VWD patients. Weiss and coworkers⁶ used this observation to develop a quantitative assay for VWF function that remains a mainstay of laboratory evaluation for VWD to this day. In 1973, several groups succeeded in dissociating VWF from FVIII procoagulant activity.^{7,8}

Final proof that VWF and FVIII are independent proteins encoded by distinct genes came with the complementary DNA (cDNA) cloning of the two molecules in 1984 and 1985.^{9–14} These discoveries also marked the beginning of the molecular genetic era for the study of VWF and FVIII, leading to the identification of gene mutations in many patients with hemophilia and VWD, as well as considerable insight into the structure and function of these related proteins.

Table 126–1 summarizes the current nomenclature and terminology for FVIII and VWF. VWD is a heterogeneous disorder with more

TABLE 126-1. von Willebrand Factor and Factor VIII Terminology**Factor VIII**

Antihemophilic factor, the protein that is reduced in plasma of patients with classic hemophilia A and most von Willebrand disease (VWD) and is measured in standard coagulation assays

Factor VIII activity (factor VIII:C)

The coagulant property of the factor VIII protein (this term is sometimes used interchangeably with factor VIII)

Factor VIII antigen (VIII:Ag)

The antigenic determinant(s) on factor VIII measured by immunoassays, which may employ polyclonal or monoclonal antibodies

von Willebrand factor (VWF)

The large multimeric glycoprotein that is necessary for normal platelet adhesion, a normal bleeding time, and stabilizing factor VIII

von Willebrand factor antigen (VWF:Ag)

The antigenic determinant(s) on VWF measured by immunoassays, which may employ polyclonal or monoclonal antibodies; *inaccurate designations of historical interest only* include factor VIII-related antigen (VIIR:Ag), factor VIII antigen, AHF antigen, and AHF-like antigen

Ristocetin cofactor activity (VWF:RCO)

The property of VWF that supports ristocetin-induced agglutination of washed or fixed normal platelets

von Willebrand factor collagen-binding activity (VWF:CB)

The property of VWF that supports binding to collagen, measured by enzyme-linked immunosorbent assay (ELISA)

than 20 variants described. The previous complex and confusing classification has been consolidated and simplified into six distinct types,¹⁵ as summarized in [Table 126-2](#). Type 3 VWD is associated with very low or undetectable levels of VWF and severe bleeding. Type 1 VWD is characterized by concordant reductions in FVIII activity, VWF antigen, and ristocetin cofactor activity, generally to the range of 20 to 30 percent of normal, but sometimes up to 50 percent of normal, in association with a normal VWF multimer distribution. Type 2 VWD is heterogeneous and further divided into four subtypes (2A, 2B, 2M, and 2N) by the nature of the VWF qualitative dysfunction. Type 2A VWD results from abnormal VWF secretion or proteolysis and is characterized by a disproportionately low level of ristocetin cofactor activity relative to VWF antigen and absence of large and intermediate-sized multimers. Type 2B VWD results from an abnormal VWF molecule with increased affinity for platelet glycoprotein Ib (GPIb), and can also be associated with reduced high-molecular-weight VWF multimers and thrombocytopenia. Functional abnormalities in VWF can also result in defective interactions with platelets, as in type 2M VWD, or decreased FVIII binding to VWF, designated type 2N VWD and characterized by mild to moderate FVIII deficiency. Many other subtypes have been reported, including platelet-type (pseudo-) VWD, which is actually an intrinsic platelet disorder caused by mutations in GPIb (Chap. 120). Finally, acquired forms of VWD also occur, such as in patients with antibodies to VWF or thrombocytosis secondary to myeloproliferative neoplasms, resulting in accelerated loss of circulating VWF.

ETIOLOGY AND PATHOGENESIS

VWF is synthesized exclusively in endothelial cells and megakaryocytes. The VWF monomer is assembled into higher-order multimers, a structure required for optimal adhesive function, and performs two major functions in hemostasis. First, VWF serves as the initial critical bridge between circulating platelets and the injured blood vessel wall, accounting for the apparent defect in platelet function and prolonged bleeding times historically observed in VWD patients. Second, VWF serves as the carrier in plasma for FVIII, ensuring its stability and localizing it to the initial platelet plug for participation in thrombin generation and fibrin clot formation (Chap. 113). This tight, noncovalent interaction between VWF and FVIII accounts for the copurification of these two molecules and the resulting initial confusion as to the origin of hemophilia and VWD. FVIII is encoded by the *F8* gene on the X chromosome (Chaps. 113 and 123), while VWF is encoded by the *VWF* gene on human chromosome 12.

THE VON WILLEBRAND FACTOR GENE AND COMPLEMENTARY DNA

The VWF cDNA was initially cloned from endothelial cells,¹¹⁻¹⁴ and the corresponding gene mapped to the short arm of chromosome 12 (12p13.3).¹¹ The VWF mRNA is approximately 9 kb in length, encoding a primary translation product of 2813 amino acid residues with an estimated Mr of 310,000. Comparison of the primary peptide sequence obtained from plasma VWF¹⁶ with the VWF cDNA sequence established the prepropolypeptide nature of VWF.¹⁷ Prepropolypeptide VWF is composed of a 22-amino-acid signal peptide, a 741-amino-acid precursor polypeptide known as the VWF propeptide (VWFpp), and the mature subunit.^{11,17-20} Cleavage of the 741-amino-acid propeptide from the amino terminus produces the mature VWF monomer subunit of 2050 amino acids ([Fig. 126-1](#)).

Analysis of the VWF sequence identifies four distinct types of repeated domains: three A domains, three B domains, two C domains, and four D domains,^{18,21} within which appear additional repeating motifs (schematic in [Ref. 22](#)). The first pair of D domains is tandemly arranged in the VWFpp, followed by a partial and full D domain at the N terminus of the mature subunit. The final complete D domain is separated by a segment of more than 600 amino acids containing the triplicated A domains. The repeated domain structure of VWF suggests that the gene may have evolved via a complex series of partial duplications, although exon structure is not highly conserved between homologous domains.

Comparison of the VWF amino acid sequence to other proteins identifies a superfamily of related proteins that share sequence similarity with the VWF A domains.²³ The common theme among these potentially evolutionarily related genes is a role in extracellular matrix or adhesive function. Consistent with this notion, VWF functional domains for binding to the platelet receptor GPIb and specific ligands within the extracellular matrix have been localized to the VWF A repeats. A potential relationship between the VWF C domains and portions of thrombospondin and procollagen has also been proposed.²⁴

The *VWF* gene spans 178 kb and is divided into 52 exons.²⁵ Exons range in size from 40 bases to 1.4 kb (exon 28). Exon 28 is unusually large, encoding the entire A1 and A2 domains and containing most of the known type 2A and all of the type 2B VWD mutations. The concentration of these defects within one exon has facilitated the identification of human mutations responsible for these VWD variants (see "Molecular Genetics of von Willebrand Disease," below). A partial, nonfunctional duplication of the *VWF* gene, termed a pseudogene, is located on human chromosome 22.²⁶ The pseudogene, known as *VWFPI*, duplicates the

TABLE 126-2. Classification of von Willebrand Disease

Type	Molecular Characteristics	Inheritance	Frequency	Factor VIII Activity	VWF Antigen	Ristocetin Cofactor Activity	RIPA	Plasma VWF Multimer Structure
Type 1	Partial quantitative VWF deficiency	Autosomal dominant, incomplete penetrance	1–30:1000; most common VWD variant (>70% of VWD)	Decreased	Decreased	Decreased	Decreased or normal	Normal distribution (mutant subunits permitted)
Type 3	Severe quantitative reduction or absence of VWF	Autosomal recessive (or codominant)	1–5:1,000,000	Markedly decreased	Very low or absent	Very low or absent	Absent	Usually absent
Type 2A	Qualitative VWF defect; loss of large VWF multimers, decreased VWF-dependent platelet adhesion	Usually autosomal dominant	~10–15% of clinically significant VWD	Decreased to normal	Usually low	Markedly decreased	Decreased	Largest and intermediate multimers absent
Type 2B	Qualitative VWF defect; increased VWF–platelet interaction (GPIb)	Autosomal dominant	Uncommon variant (<5% of clinical VWD)	Decreased to normal	Usually low	Decreased to normal	Increased to low concentrations of ristocetin	Largest multimers reduced/absent
Type 2M	Qualitative VWF defect; decreased VWF–platelet interaction, no loss of large VWF multimers	Usually autosomal dominant	Rare (case reports)	Variably decreased	Variably decreased	Decreased	Variably decreased	Normal and occasionally ultralarge forms
Type 2N	Qualitative VWF defect; decreased VWF–factor VIII binding capacity	Autosomal recessive	Uncommon; heterozygotes may be prevalent in some populations	Decreased	Normal	Normal	Normal	Normal
Platelet-type (pseudo-)	Platelet defect; decreased platelet-VWF interactions	Autosomal dominant	Rare	Decreased to normal	Decreased to normal	Decreased	Increased to low concentrations of ristocetin	Largest multimers absent

GPIb, glycoprotein Ib; RIPA, ristocetin-induced platelet aggregation; VWD, von Willebrand disease; VWF, von Willebrand factor.

Figure 126-1. Schematic of the human VWF gene, mRNA, and protein. The VWF gene and VWFp1 pseudogene are depicted at the top, with boxes representing exons and the solid black line representing introns. Schematics of the VWF mRNA encoding the full prepro-VWF subunit are depicted in the middle as bar and lettered boxes. The upper schematic denotes commonly annotated regions of internally repeated sequences; the lower schematic illustrates the multiple repeating motifs of VWF. The locations of signal peptide (sp) and VWF propeptide (VWFpp) cleavage sites are indicated by arrowheads. The approximate localizations for known VWF functional domains within the mature VWF subunit are indicated at the bottom. Numbers underneath the domains refer to amino acid residues numbered from the ATG start site; numbers in parentheses indicate the amino acid residue position in the mature VWF subunit. aa, Amino acids; chr, chromosome. (Adapted with permission from Ginsburg D, Bowie EJW. *Molecular genetics of von Willebrand disease*. Blood 79(10):2507–2519, 1992.)

middle portion of the *VWF* structural gene, spanning exons 23 to 34 and the intervening noncoding sequences. *VWFPI* is approximately 97 percent identical in sequence to the authentic *VWF* gene, indicating that it is of fairly recent evolutionary origin.²⁷ Gene conversion involving the *VWFPI* pseudogene, possibly through recombination with the large homologous exon 28 sequence, has been proposed as a mechanism for introducing mutations into the *VWF* gene.^{28–31}

VWF is synthesized exclusively in megakaryocytes and endothelial cells and, as a result, has frequently been used as a specific histochemical marker to identify cells of endothelial cell origin. Although generally assumed to mark all endothelial cells, VWF is expressed at widely varying levels among endothelial cells, depending on the size and location of the associated blood vessel.^{32,33} A careful survey in the mouse identified wide differences in the level of VWF mRNA, with 5 to 50 times higher concentrations in the lung and brain, particularly in small vessels, than in comparable vessels in the liver and kidney. In general, the higher levels of VWF mRNA and antigen were found in the endothelial cells of large vessels rather than in microvasculature, and in venous rather than arterial endothelial cells.³³

Specific DNA sequences within or near the proximal promoter of the *VWF* gene appear to be required for endothelial-specific gene expression,^{34–39} although it is likely that additional important regulatory elements exist outside of this region, some of which may lie at a great distance.⁴⁰ VWF is expressed in most, but not all, endothelial cells,⁴¹ and this vascular-bed specific gene expression program is likely a result of the concerted action of multiple regulatory elements. Endothelial *VWF* gene expression also appears to be upregulated by exposure to shear stress. The length of a polymorphic GT repeat in the proximal *VWF* promoter correlates with the magnitude of this response, and several other more distal DNA sequences are predicted to be involved in a shear stress response.⁴² However, this GT repeat does not appear to influence circulating VWF levels.⁴³

VON WILLEBRAND FACTOR BIOSYNTHESIS

The processing steps involved in the biosynthesis of VWF are similar in megakaryocytes and endothelial cells (reviewed in Refs. 46 and 47). VWF is first synthesized as a large precursor monomer polypeptide, depicted schematically in Fig. 126–1. VWF is unusually rich in cysteine, which accounts for 8.3 percent of its amino acid content. All cysteines in the mature VWF molecule are thought to be involved in disulfide bonds,⁴⁸ although these bonds may be exposed in circulating mature VWF by shear stress.⁴⁹ Pro-VWF monomers are assembled into dimers through disulfide bonds at both C termini, and only dimers are exported from the endoplasmic reticulum (ER).^{48,50,51}

Glycosylation begins in the ER, with 12 potential N-linked glycosylation sites present on the mature subunit and three on the propeptide. Extensive additional posttranslational modification of VWF occurs in the Golgi apparatus, including the addition of multiple O-linked carbohydrate structures, sulfation, and multimerization through the formation of disulfide bonds at the N termini of adjacent dimers. It is unusual for a protein to undergo extensive disulfide bond formation at this late stage, and this process appears to be catalyzed by disulfide isomerase activity present within the VWFpp.⁵² Mutations at either of two specific cysteines within the propeptide that are thought to be critical for disulfide isomerase activity, or a shift in the spacing between them, results in loss of multimer formation.⁵² An intermediate species with disulfide bonds between the propeptide and VWF D'D3 domain appears briefly in either the late ER or early Golgi,⁵³ which may position these domains for subsequent multimerization. The multimerization process appears to require the slightly acidic environment of the distal Golgi.⁵⁴ The VWFpp self-associates and may also serve to align VWF

subunits for multimer assembly.⁵⁵ However, the propeptide facilitates multimer assembly even when coexpressed as a separate molecule from the mature VWF monomer.^{56,57}

Propeptide cleavage occurs late in VWF synthesis or just prior to secretion. Cleavage occurs adjacent to two basic amino acids, Lys-Arg at positions –2 and –1. An Arg at position –4 is also required for recognition by the intracellular protease responsible for propeptide cleavage.⁵⁸ Multimerization and propeptide cleavage are not linked to each other. The multimers secreted by cultured endothelial cells contain both pro-VWF and mature subunits,^{59,60} and recombinant VWF with a point mutation inhibiting propeptide cleavage is still assembled into normal multimer structures.⁶¹ Although propeptide cleavage appears to occur primarily intracellularly, cleavage may also occur after secretion.

VWF is stored in tubular structures within the α -granules of platelets and within the Weibel-Palade bodies in endothelial cells^{62,63} (reviewed in Ref. 64). These large VWF structures form by tubular packing of the VWF N-terminal domains within the secretory granules.⁶⁵ Weibel-Palade bodies are derived from the Golgi apparatus and are found in most endothelial cells, although the number varies considerably between endothelial cell beds. It has been shown that VWF and FVIII colocalize in storage granules. Although VWF is not required to traffic FVIII to platelets,⁶⁶ VWF appears to play a role in trafficking FVIII to Weibel-Palade bodies in endothelial cells.^{67,68} Weibel-Palade bodies mature as they move to the periphery of the cell in an ordered process dependent on Rab proteins and Rab effector proteins, which act as chaperones and organizers of the various stages of Weibel-Palade body maturity and subsequent exocytosis (reviewed in Ref. 69). The transmembrane glycoprotein P-selectin is also found in the membranes of both the α -granule and the Weibel-Palade body.⁷⁰ The VWF D'D3 domain has been shown *in vitro* to associate with P-selectin and to be necessary for the recruitment of P-selectin to Weibel-Palade bodies.⁷¹ There appears to be heterogeneity within Weibel-Palade body populations both in relative content of VWF and P-selectin and in response to regulated secretion by different stimuli.⁷² In addition to VWF and P-selectin, the Weibel-Palade body also contains tissue-type plasminogen activator (t-PA), a thrombolytic secreted protein that also may be released distinctly from VWF,⁷³ and several other proteins that are known to participate in inflammation or angiogenesis (for a complete list of Weibel-Palade contents see Ref. 74).

VWF is secreted from endothelial cells continuously via constitutive and constitutive-like (or basal) pathways and upon stimulated release of storage granules via a classic regulated pathway.^{46,75} Regulated secretion of VWF from its storage site in the Weibel-Palade body is triggered by a number of secretagogues, including thrombin,⁷⁶ fibrin,⁷⁷ histamine,⁷⁸ the C5b-9 complement complex,⁷⁹ and several inflammatory cytokines.⁸⁰ Recent *in vitro* data suggests that there may also be suppression of regulated VWF secretion by statins.^{81,82} The secretagogue desmopressin acetate (DDAVP), a vasopressin analogue, is used clinically for its capacity to cause a marked release of VWF and FVIII *in vivo* by acting through type 2 vasopressin receptors to induce secretion from the Weibel-Palade bodies in endothelial cells.⁸³ Constitutive-like secretion of VWF occurs evenly at the luminal and abluminal surface, while regulated secretion from the Weibel-Palade body is highly polarized in the luminal direction (Fig. 126–2).^{75,84} While constitutively secreted multimers are of relatively small size, the multimers stored within the Weibel-Palade body are the largest, most biologically potent form.^{85,86} The VWF stored in platelet α -granules is also enriched for large multimers.⁸⁷ The N-terminal D domains appear to be required for VWF storage, with deletion of any of the individual domains resulting in constitutive secretion.^{88,89} It also appears that cleavage of the VWFpp is required for efficient formation of storage granules.⁹⁰

Figure 126-2. Schematic of von Willebrand factor (VWF) processing and secretion from endothelial cells. VWF dimers are formed in the endoplasmic reticulum, where VWF begins to be glycosylated. VWF dimers are transported to the Golgi, where the VWF undergoes further glycosylation and sulfation. Multimerization begins in the Golgi and continues within the secretory granules (Weibel-Palade bodies). A small amount of immature VWF is released constitutively (i.e., without regulation or storage) from endothelial cells as dimers or very small multimers. VWF is also released continuously from both the luminal and abluminal endothelial cell surfaces by constitutive-like (or basal) secretion. This VWF has been processed in the Golgi and may be transiently stored in an intermediate secretory granule or Weibel-Palade bodies. Mature VWF is packaged and stored as ultralarge multimers in Weibel-Palade bodies. This ultralarge VWF is released from the luminal surface of stimulated endothelial cells by regulated secretion. Once in circulation, VWF multimers undergo proteolysis by ADAMTS13 (a disintegrin and metalloprotease with a thrombospondin type 1 motif member 13) under moderate to high shear conditions. (Adapted with permission from Johnsen J, Lopez JA. VWF secretion: What's in a name? *Blood* 112(4):926–927, 2008.)

The concentration of VWF in plasma is approximately 10 mcg/mL, with approximately 15 percent of circulating VWF localized to the platelet compartment.⁹¹ Marrow transplants between normal and VWD pigs demonstrate that platelet VWF is derived entirely from synthesis within marrow megakaryocytes and does not contribute to the normal plasma VWF pool.^{92–94} These studies also demonstrate that both the plasma and the platelet VWF pools are required for full hemostasis, although the plasma pool appears to be more critical.

Plasma VWF is further processed in the circulation through cleavage by a specific protease, ADAMTS13 (*a disintegrin and metalloprotease with thrombospondin type 1 motifs–13*), resulting in reduction in the size of the largest multimers (reviewed in Ref. 95). After regulated secretion *in vitro*, ultralarge VWF multimers may anchor to the endothelial cell surface via P-selectin^{96,97} resulting in shear stress and VWF cleavage by ADAMTS13. The major proteolytic cleavage site maps to the peptide bond between Tyr1605 and Met1606 in the VWF A2 domain,⁹⁸ and recombinant VWF missing the A2 domain is resistant to proteolysis.⁹⁹ VWF carrying a subgroup of type 2A VWD mutations exhibits increased susceptibility to cleavage by this protease,¹⁰⁰ and this is the proposed mechanism for the selective loss of large VWF multimers in this group of patients (see “Molecular Genetics of von Willebrand Disease,” below). Increased VWF susceptibility to proteolysis by ADAMTS13 has also been described in a subset of type 1 VWD patients, but the clinical significance of this is unclear as increased proteolysis appears to only occur under certain conditions.¹⁰¹ Decreased ADAMTS13 activity, either because of congenital deficiency or acquired inhibitors, plays a central role in the pathophysiology of thrombotic thrombocytopenic purpura (Chap. 132).

THE FUNCTION OF VON WILLEBRAND FACTOR

VWF is a large multivalent adhesive protein that plays an important role in platelet attachment to subendothelial surfaces, platelet aggregation at sites of vessel injury, and stabilization of coagulation FVIII in the circulation. Not only is the interaction of VWF and FVIII important for

the protection of FVIII from inactivation or degradation, FVIII bound to VWF may localize to cells and/or sites where it can more readily participate in the promotion of blood coagulation and/or thrombus formation.

VWF is required for the adhesion of platelets to the subendothelium, particularly at moderate to high shear force. VWF performs this bridging function by binding to two platelet receptors, GPIb and GPIIb/IIIa, as well as to specific ligands within the exposed subendothelium at sites of vascular injury (reviewed in Ref. 103). Binding of VWF to its platelet receptors generally does not occur in the circulation under normal conditions. However, the interaction of VWF with exposed ligands in the vessel wall, combined with high shear stress conditions, facilitates VWF binding to platelet GPIb and subsequent platelet adhesion and activation. Activation of platelets leads to the exposure of the GPIIb/IIIa complex, an integrin receptor that can bind to fibrinogen, VWF, and other ligands, to form the platelet–platelet bridges required for thrombus propagation. Platelet adhesion to VWF immobilized at a site of injury appears to be a two-step process, with the initial tethering of the rapidly moving platelet dependent on the VWF–GPIb interaction and subsequent firm adhesion occurring through GPIIb/IIIa after platelet activation.¹⁰⁴ VWF may also play a role in inflammation by directly interacting with leukocytes,¹⁰⁵ but the clinical significance of this observation is not clear.

Von Willebrand Factor Binding to the Vessel Wall

VWF binds to the vessel wall at sites of vascular endothelial injury (reviewed in Ref. 106). VWF binds to several different types of collagens, including types I through VI. Distinct binding domains for the fibrillar collagens, types I and III, have been localized to specific segments within the VWF A1 and A3 repeats (see Fig. 126-1),^{107,108} and a potential third domain has been identified in the VWFpp.¹⁰⁹ Studies of recombinant VWF suggest that the A3 collagen-binding domain may be the most important.^{110,111} VWF has also been shown to bind to the nonfibrillar collagen type VI, which is resistant to collagenase¹¹² and

colocalizes with VWF in the subendothelium.¹¹³ Type VI collagen supports the binding of VWF under high shear through cooperative interactions between binding domains within the VWF A1 and A3 repeat.¹¹⁴ Although VWF binding has also been demonstrated to a number of other potential components of the subendothelium, including glycosaminoglycans,^{115,116} sulfatides,¹¹⁷ and VWF itself,¹¹⁸ the biologic significance of these interactions remains to be demonstrated.

Von Willebrand Factor Binding to Platelets

VWF interacts with platelets both to mediate platelet aggregation and platelet localization to sites of vascular injury (reviewed in Ref. 106). Circulating VWF does not spontaneously interact with platelets, but once bound to an injured vessel wall VWF is subjected to higher shear stresses and a platelet-binding site in the VWF A1 domain is uncovered. VWF interacts with a receptor complex on the surface of platelets composed of the disulfide-linked GPIIb α and GPIIb β chains noncovalently associated with GPIIX and GPV. The binding site for VWF is within a 293-amino-acid segment at the N-terminus of GPIIb and requires sulfation of several key tyrosine residues for optimal binding.¹¹⁹ The GPIIb binding domain within VWF lies within the A1 segment, within the disulfide loop formed between the cysteine residues at 1272 (amino acid 509 in mature VWF) and 1458 (695) (see Fig. 126–1).^{120,121} GPIIb binding to the A1 domain enhances proteolysis of recombinant VWF fragments by ADAMTS13 and suggests a feedback mechanism for limiting thrombus propagation *in vivo*.¹²² Scanning mutagenesis studies of recombinant VWF characterized a number of amino acid residues within the VWF A1 domain that are critical for binding to GPIIb and for interaction with botrocetin.¹²³ Several mutations were also identified that increase platelet binding, an effect similar to that of mutations associated with type 2B VWD (see “Molecular Genetics of von Willebrand Disease,” below). These natural and synthetic mutations cluster in a small area on the surface of the VWF A1 domain structure, as revealed by x-ray crystallographic studies.¹²⁴ The complexity of the VWF A1–GPIIb interaction is evidenced by the ability of gain-of-function and loss-of-function VWF A1 mutants to counterbalance each other in mice.¹²⁵ The structure of the A1 domain closely resembles that of other previously studied A domains, including the VWF A3 domain.^{126–128} The structure of GPIIb in complex with the VWF A1 domain provides insight into the structural basis for the gain of function mutations associated with type 2B VWD.¹²⁹ The abundant plasma protein β_2 -glycoprotein I can bind the VWF A1 domain when VWF is structurally open to GPIIb α binding. This may result in biologically relevant inhibition of the VWF-platelet interaction, as inhibitory anti- β_2 -glycoprotein I autoantibodies found in some patients with antiphospholipid antibody syndrome are associated with thrombosis.¹³⁰

Ristocetin binds to both VWF and platelets, but the mechanism by which it enhances the VWF/GPIIb interaction is still poorly understood.^{131,132} The snake venom botrocetin appears to induce GPIIb binding through a different alteration in the VWF A1 domain and is also used to study this interaction.¹²⁸ Heparin binds the VWF A1 domain within the loop formed by the disulfide bond formed between the residues Cys1272 and Cys1458,¹³³ where it appears to competitively inhibit VWF binding to GPIIb^{134,135} and enhance VWF proteolysis by ADAMTS13 *in vitro*.¹³⁶ Although it has been suggested that this may account for hemorrhage not predicted by conventional heparin monitoring, the clinical significance of the VWF-heparin interaction is not clear.

The arg-gly-asp-ser (RGDS) sequence at amino acids 2507 to 2510 of the mature VWF subunit serves as the binding site within VWF for GPIIb/IIIa. The GPIIb/IIIa complex, also known as integrin $\alpha_{IIb}\beta_3$, is a member of the integrin family of cell surface receptors. GPIIb/IIIa undergoes a conformational change to a high-affinity ligand-binding

Figure 126–3. von Willebrand disease (VWD) mutations. The von Willebrand factor domain locations of all reported mutations associated with type 2A, 2B, 2M, and 2N VWD. Lettering size represents the proportion of total mutations reported within the designated VWF domain for that subtype, with larger letters indicating more mutations. Shown below are the relative positions of the VWF gene exons. Type 1 and type 3 VWD associated mutations have been reported throughout the VWF gene. (Mutation data from Nichols WC and Ginsburg D: von Willebrand disease. *Medicine* (Baltimore) 76(1):1–20, 1997 and the VWD mutation database at www.vwf.group.shef.ac.uk.)

state following platelet activation which, in addition to VWF, can bind a number of other adhesive proteins, including fibrinogen. Although VWF is present in blood at much lower concentrations than is fibrinogen, evidence suggests that VWF may be a critical ligand. VWF participates in platelet tethering and adhesion to fibrin under flow conditions,^{104,137} where the C1C2 domains of VWF are required for fibrin binding.¹³⁸ An RGD sequence is also present in the VWFpp, although its functional significance is unknown.

The Interaction of von Willebrand Factor with Factor VIII

The noncovalent interaction between FVIII and VWF is required for the stability of FVIII in the circulation, as is evident from the FVIII levels of less than 10 percent that are observed in most severe VWD patients. Although each VWF subunit appears to carry a binding site for FVIII, the stoichiometry for the VWF–FVIII complex found in normal plasma is approximately one to two FVIII molecules per 100 VWF monomers.¹³⁹ FVIII bound to VWF is also protected from proteolytic degradation by activated protein C (reviewed in Ref. 140). FVIII also appears to increase the susceptibility of VWF to proteolysis by ADAMTS13 under shear conditions.¹⁴¹

The FVIII binding domain within VWF has been localized to the first 272 N-terminal amino acids of the mature subunit.¹⁴² In mice, expression of the VWF D’–D3 domains alone has been shown to be sufficient to stabilize FVIII levels.¹⁴³ Antibody studies suggest a particularly critical role for amino acids 841 to 859.^{144,145} The mutations identified in patients with type 2N VWD, in which VWF binding to FVIII is specifically affected (see “Molecular Genetics of von Willebrand Disease,” below), are all clustered in this region, including the most common type 2N mutation Arg854Gln.¹⁴⁶ The corresponding binding site for VWF on FVIII includes an acidic region at the N-terminus of the light chain (residues 1669 to 1689)¹⁴⁷ and requires sulfation of Tyr1680 for optimal binding.¹⁴⁸ Overlay of VWD 2N mutations with the crystal structure of the VWF A1–FVIII domains shows the 2N mutations clustered in a dynamic VWF TII’ domain (shown in Fig. 126–3), implicating a need for flexibility in this domain for normal FVIII binding.¹⁴⁹ Thrombin cleavage after Arg1689 in FVIII activates and releases FVIII from VWF. Thus, VWF may serve to efficiently deliver FVIII to the sites of clot formation, where it can complex with factor IXa on the platelet surface.

MOLECULAR GENETICS OF VON WILLEBRAND DISEASE

VWD is an extremely heterogeneous and complex disorder, with more than 20 distinct subtypes reported (referenced in Ref. 150). A large

number of mutations within the *VWF* gene have been identified (see Fig. 126–3). However, because of both the genetic complexity of VWD and the practical considerations of *VWF* gene sequencing in most clinical settings, a *VWF* gene mutation is not required for the diagnosis of VWD.¹⁵¹ A list is maintained by a consortium of VWD investigators and can be accessed through the Internet at <http://www.vwf.group.shef.ac.uk/>. These findings form the basis for the simplified classification of VWD outlined in Table 126–2¹⁵¹ and used throughout this chapter. Types 1 and 3 VWD are defined as pure quantitative deficiencies of VWF that are either partial (type 1) or complete (type 3). Type 2 VWD is characterized by qualitative abnormalities of VWF structure and/or function. The quantity of VWF found in type 2 VWD may be normal, but it is usually mildly to moderately decreased (see Table 126–2).

The diagnosis of VWD, particularly type 1 VWD, can be confounded by the incomplete penetrance of the disease and the wide range of VWF levels in normal populations (see “Laboratory Features” below). Nonpathogenic variation can impact laboratory assays *in vitro*, as is the case with Asp1472His, which alters VWF-ristocetin interactions but has no impact on hemostasis *in vivo*.¹⁵² Ethnicity should also be considered. European ancestries were overrepresented in the studies which informed laboratory cutoffs, while African Americans exhibit generally higher VWF and FVIII levels. Additionally, there are numerous *VWF* gene “mutations” previously thought to be causative of VWD which are now known to be common in African Americans^{153,154} who have normal VWF and FVIII levels,¹⁵³ including the Asp1472His variant.¹⁵⁵

Type 1 von Willebrand Disease

Type 1 VWD is the most common form, accounting for approximately 70 percent of patients with the disease. Type 1 VWD is generally autosomal dominant in inheritance and is associated with coordinate reductions in FVIII, ristocetin cofactor activity, and VWF antigen with maintenance of the full complement of multimers (Fig. 126–4).

Figure 126–4. Agarose gel electrophoresis of plasma von Willebrand factor (VWF). VWF multimers from plasma of patients with various subtypes of von Willebrand disease (VWD) are shown. The brackets to the left encompass three individual multimer subunits, including the main band and its associate satellite bands. *N* indicates normal control lanes. Lanes 5 through 7 are rare variants of type 2A VWD. The former designations for these variants are indicated in parentheses below the lanes (II C through E). (Adapted with permission from Zimmerman TS, Dent JA, Ruggeri ZM, Nannini LH: Subunit composition of plasma von Willebrand factor. Cleavage is present in normal individuals, increased in IIA and IIB von Willebrand disease, but minimal in variants with aberrant structure of individual oligomers (types IIC, IID, and IIE). *J Clin Invest* 1986 Mar;77(3):947–951.)

Subgroups within type 1 VWD have been proposed based on the relative levels of VWF present in the plasma and platelet pools,^{156–159} but with the exception in some circumstances for an accelerated VWF clearance phenotype (unofficially termed VWF type 1C¹⁶⁰), subtype distinctions in type 1 VWD are not generally used in clinical practice.

Type 1 VWF was previously assumed to simply represent the heterozygous form of type 3 VWD. However, in a large Canadian study, 48 percent of heterozygous carriers of type 3 VWD gene mutations carried a diagnosis of type 1 VWD, while the remainder were asymptomatic.¹⁶¹ Furthermore, in two large studies of type 1 VWD families, numerous putative *VWF* mutations were identified, but very few were predictive of VWF null alleles.^{31,162} Thus, some, but probably not all (see section Clinical Features below), type 1 VWD is the result of defects within the *VWF* gene. Studies of type 1 VWD mutations in patients, *in vitro*, and in animal models have characterized diverse mechanisms underlying type 1 VWD, including decreased VWF production,¹⁶³ retention of VWF in the ER,^{164,165} impaired VWF secretion,^{165,166} and decreased VWF survival.^{163,166,167} Mutations that give rise to defective VWF subunits that interfere in a dominant negative way with the normal allele may be particularly likely to cause symptomatic VWD in the heterozygote.¹⁶⁸ For example, mutations at several cysteine residues in the VWF D3 domain and in the VWFpp of patients with moderately severe type 1 VWD. VWF carrying one of these mutations is retained in the ER, where it is proposed to exert a dominant negative effect on VWF derived from the normal allele via heterodimerization and degradation.^{169,170}

To date, most mutation studies and genetic linkage analysis of type 1 VWD have been consistent with defects within the *VWF* gene. Although no single mutation can explain the majority of type 1 VWD, common *VWF* founder mutations can occur within populations, such as Tyr1584Cys identified in 14 percent of Canadian type 1 VWD patients, and possibly a similar proportion of patients in Europe.^{162,171} The Tyr1584Cys mutation is associated with decreased VWF survival, likely a result of increased susceptibility to proteolysis by ADAMTS13.^{172–175} These large multicenter studies of type 1 VWD families found candidate *VWF* mutations in 63 to 70 percent of families with type 1 VWD, leaving 37 to 40 percent of type 1 VWD index cases without a putative mutation in *VWF*.^{162,171} Cases with *VWF* gene mutations tend to be more severe and highly heritable, while cases without an identifiable *VWF* mutation generally have higher VWF antigen (VWF:Ag) levels (>30 IU/dL).³¹ In a large, multicenter European study of 150 type 1 VWD families, about one-third of cases historically diagnosed to have type 1 VWD were found to have abnormal multimers, and of these nearly all (95 percent) had a putative *VWF* gene mutation and significantly lower VWF:Ag, VWF ristocetin cofactor activity (VWF:RCO), assay of FVIII activity (FVIII:C), and VWF collagen-binding assay (VWF:CB) levels. Conversely, index cases with normal multimers had higher laboratory VWF values and fewer identifiable *VWF* mutations (55 percent), suggesting that the pathogenic mechanism(s) underlying this cohort of “true” type 1 VWD patients is more genetically complex.¹⁶² Given the complex biosynthesis and processing of VWF, defects at a number of other loci could also be expected to result in quantitative VWF abnormalities (reviewed in Ref. 176). This concept is supported by families with type 1 VWD in which bleeding histories and low ristocetin cofactor activities do not always cosegregate with genetic markers at the *VWF* locus,^{31,177} while one or more genetic factors outside the *VWF* locus may be associated with the variation in bleeding severity observed within VWD pedigrees.^{178,179} It is interesting to note that a spontaneous mouse model of type 1 VWD exhibits up to 20-fold reductions in plasma VWF as a result of an unusual mutation in a glycosyltransferase gene, leading to aberrant posttranslational processing of VWF and accelerated clearance from plasma.¹⁸⁰ Similar mechanisms affecting VWF survival, perhaps combined with altered proteolysis,^{181–183} may

explain the observed modifying effect of the ABO blood group glycosyltransferases on plasma VWF survival.¹⁸⁴ Additional genetic factors have been implicated to influence VWF via altered survival, including the clearance receptors CLEC4M and LRP1 (CD91) (reviewed in Ref. 185). The biologic consequences of VWF modifiers identified in normal populations are unclear, and studies are needed to determine their significance in VWD.

Type 3 von Willebrand Disease

Patients with type 3 VWD account for 1 to 5 percent of clinically significant VWD, have very low or undetectable levels of plasma and platelet VWF:Ag and VWF:RCO, and generally present early in life with severe bleeding.¹⁸⁶ FVIII coagulant activity is markedly reduced but usually detectable at levels of 3 to 10 percent of normal. Type 3 VWD has generally been considered an autosomal recessive disorder, but in a recent Canadian study of 100 individuals in 34 families, 48 percent of “carriers” had a diagnosis of type 1 VWD,¹⁶¹ suggesting the dominant type 1 VWD pattern of inheritance is common in type 3 VWD families.

Mutations associated with type 3 VWD have been reported throughout the VWF gene (<http://www.vwf.group.shef.ac.uk/>). Gross VWF gene deletion detectable by Southern blot^{26,187–190} or multiple ligation-probe amplification^{161,191} is the molecular mechanism for type 3 VWD in only a small subset of families. However, large deletions may confer an increased risk for the development of alloantibodies against VWF.^{26,189} A similar correlation between gene deletion and risk for alloantibody formation has been observed in hemophilia (Chap. 123). Comparative analysis of VWF genomic DNA and platelet VWF mRNA has identified nondeletion defects resulting in complete loss of VWF mRNA expression as a molecular mechanism in some patients with type 3 VWD.^{192,193} A number of nonsense and frameshift mutations that would be predicted to result in loss of VWF protein expression or in expression of a markedly truncated or disrupted protein have been identified in some type 3 VWD families.^{168,194–196} A frameshift mutation in exon 18 appears to be a particularly common cause of type 3 VWD in the Swedish population and has been shown to be the defect responsible for VWD in the original Åland Island pedigree.^{197,198} This mutation results in a stable mRNA encoding a truncated protein that is rapidly degraded in the cell.¹⁹⁹ This mutation also appears to be common among type 3 VWD patients in Germany,²⁰⁰ but not in the United States.²⁰¹

Type 2A von Willebrand Disease

Type 2A is the most common qualitative variant of VWD and is generally associated with autosomal dominant inheritance and selective loss of the large and intermediate VWF multimers from plasma (see Fig. 126–4). A 176-kDa proteolytic fragment present in normal individuals is markedly increased in quantity in many type 2A VWD patients. This fragment is consistent with proteolytic cleavage of the peptide bond between Tyr1605 and Met1606.^{98,202} Based on this observation, initial DNA sequence analysis in patients centered on VWF exon 28, in the region encoding this segment of the VWF protein, leading to the identification of the first point mutations responsible for VWD.²⁰³ Since that time, a large number of mutations have been identified, accounting for the majority of type 2A VWD patients.¹⁹⁴ Many of these mutations are clustered within a 134-amino-acid segment of the VWF A2 domain (between Gly1505 and Glu1638; see Fig. 126–3), and the most common, Arg1597Trp, appears to account for about one-third of type 2A VWD patients.^{194,195,204}

Type 2A VWD mutations have been grouped by two distinct molecular mechanisms. In the first subset, classified as group 1, the type 2A VWD mutation has been commonly considered a defect in intracellular transport, with retention of mutant VWF in the ER. In addition to retention or degradation of mutant VWF in the ER, type 2A mutations

can also disrupt intracellular processing and secretion via defective multimerization and/or loss of regulated storage.²⁰⁵ In the second subset, or group 2, mutant VWF is normally processed and secreted *in vitro*, and thus loss of multimers *in vivo* is presumed to occur based on increased susceptibility to proteolysis in plasma^{98,206–209} at the Tyr1605-Met1606 site cleaved by ADAMTS13.^{101,210} The susceptibility of type 2A VWD mutations to proteolysis by ADAMTS13 *in vitro* supports accelerated proteolysis as a mechanism for the loss of high-molecular-weight VWF multimers in these patients.²⁰⁴

The multimer structure of platelet VWF correlates well with the underlying type 2A mechanisms. Group 1 patients show loss of large VWF multimers within platelets as a result of defective synthesis, while group 2 patients have normal VWF multimers within the protected environment of the α granule.²⁰⁶ These observations confirm the earlier subclassification of type 2A VWD based on platelet multimers.¹⁵⁶ Subclassification into group 1 or 2 might be expected to predict response to DDAVP therapy, although this remains to be demonstrated.

In addition to the major classes of type 2A VWD described above, a number of rare variants historically classified as types IIC to IIH, type IB, and “platelet discordant” are included in the more general type 2A category. Most of these rare variants were distinguished on the basis of subtle differences in the multimer pattern (see Fig. 126–4; multimer changes relative to the location of type 2 mutations is reviewed in Ref. 211). The IIC variant is usually inherited as an autosomal recessive trait and is associated with loss of large multimers and a prominent dimer band. Several mutations have been identified in the VWFpp of these patients,^{212–214} presumably interfering with multimer assembly and/or trafficking to storage granules. A mutation at the C terminus of VWF, interfering with dimer formation, was described in a patient with the IID variant.²¹⁵ Most of the other reported variants of type 2A VWD are quite rare, often limited to single case reports.

Type 2B von Willebrand Disease

Type 2B VWD is usually inherited as an autosomal dominant disorder and is characterized by thrombocytopenia and loss of large VWF multimers. The plasma VWF in type 2B VWD binds to normal platelets in the presence of lower concentrations of ristocetin than does normal VWF and can aggregate platelets spontaneously. Accelerated clearance of the resulting complexes between platelets and the large, most adhesive forms of VWF accounts for the thrombocytopenia and the characteristic multimer pattern (see Fig. 126–4).

The peculiar functional abnormality characteristic of type 2B VWD suggested a molecular defect within the GPIb binding domain of VWF. For this reason, initial DNA sequence analysis focused on the corresponding portion of VWF exon 28.^{216,217} Type 2B mutations are located within the VWF A1 domain at one surface of the described crystallographic structure.^{124,129} The four most common mutations are clustered within a 36-amino-acid stretch between Arg1306 and Arg1341 (see Fig. 126–3); together, these account for more than 80 percent of type 2B VWD patients.¹⁹⁵ Functional analysis of mutant recombinant VWF^{218–222} confirms that these single-amino-acid substitutions are sufficient to account for increased GPIb binding and the resulting characteristic type 2B VWD phenotype. Structural studies of type 2B VWD mutations show that these residues interact with the leucine rich repeats of GPIb thought to be critical to the VWF A1–GPIb interactions under shear.²²³ Type 2B mutations have now been modeled extensively in mice, all of which exhibited accelerated VWF clearance, as expected.²²⁴ Type 2B VWD mice also had short-lived platelets, with evidence of macrophage-mediated platelet clearance.²²⁵ In these models, platelets were observed to be coated by type 2B VWF,²²⁵ a phenomenon that may contribute to a previously unsuspected acquired platelet function defect.²²⁶ Interestingly, mice with the same type 2B mutations exhibit variable loss

of large multimers²²⁴ and varying degrees of thrombocytopenia,²²⁷ similar to the variation observed in human pedigrees. Individual type 2B patients can also exhibit varying multimer structure and platelet counts over time. For example, two siblings with the Arg1306Trp mutation and abnormal multimers intermittently regained normal VWF multimer distribution during periods of thrombocytopenia.²²⁸

Families have been described that exhibit enhanced VWF binding to GPIb but a normal distribution of VWF multimers. These variants, previously referred to as type I New York, type I Malmö, and type I Sydney, are now all designated as type 2B VWD. Type I New York and type I Malmö are caused by the same *VWF* mutation, Pro1266Leu. This mutation is located within the cluster of type 2B mutations in the VWF A1 domain and results in a similar increase in platelet GPIb binding.²²⁹

Type 2N von Willebrand Disease

As described in Chap. 123, hemophilia A results from defects in the FVIII gene and is inherited in an X-linked recessive manner. Distinct from hemophilia A, families have been reported in which the inheritance of low FVIII appeared to be autosomal, based on the occurrence of affected females or direct transmission from an affected father.^{230,231} Several cases of an apparent autosomal recessive decrease in FVIII were shown to be caused by decreased VWF binding of FVIII,^{232–234} now referred to as VWD type 2N, after the Normandy province of origin of the first patient. DNA sequence analysis has identified more than 37 distinct mutations²³⁵ associated with this disorder, most located at the VWF N terminus (see Fig. 126–3) (curated in the Scientific and Standardisation Committee of the International Society on Thrombosis and Haemostasis VWF Database, <http://www.vwf.group.shef.ac.uk/>). One of these mutations, Arg854Gln, appears to be particularly common, may contribute to variability in the severity of type 1 VWD in some cases,²³⁶ and may also cause a VWF secretion defect.²³⁷ Rare cases of misdiagnosis of type 2N have led to treatment with recombinant FVIII for presumed hemophilia A, with poor responses and adverse clinical outcomes.²³⁸

Type 2M von Willebrand Disease

This category was classically reserved for rare VWD variants in which a defect in VWF platelet-dependent function leads to significant bleeding but VWF multimer structure is not affected (although some have subtle multimer abnormalities). Most contemporary type 2M variants are indeed associated with absent ristocetin cofactor activity but normal platelet binding with other agonists. A total of 28 type 2M VWD mutations have been described,²³⁵ including a number of other families with normal VWF multimers and disproportionately decreased ristocetin cofactor activity,^{239,240} families with a combination of defects in VWF:CB and VWF–GPIb interactions of varying severities,^{241,242} and mutations with isolated defects in VWF:CB with normal VWF:RCo activity.²³⁵ Several families have also been described with a VWD variant (VWD Vicenza) characterized by larger-than-normal VWF multimers and classified as either type 1 or type 2M VWD.²⁴³ Genetic linkage analysis indicates that the Vicenza defect lies within the VWF gene,²⁴⁴ and mutations within the VWF gene have been reported to be associated with VWD Vicenza.²⁴⁵ The underlying molecular mechanism responsible for the VWD Vicenza phenotype remains controversial,²⁴⁶ although recent kinetic modeling suggests that altered VWF survival alone could account for the VWF perturbations observed in this disorder.²⁴⁷

CLINICAL FEATURES

INHERITANCE

Type 1 VWD is generally transmitted as an autosomal dominant disorder, and accounts for approximately 70 percent of clinically significant VWD. However, disease expressivity is variable, and penetrance is

incomplete.¹⁶⁸ Laboratory values and clinical symptoms can vary considerably, even within the same individual, and establishing a definite diagnosis of VWD is often difficult. In two large families with type 1 VWD, only 65 percent of individuals with both an affected parent and an affected descendent had significant clinical symptoms.²⁴⁹ For comparison, 23 percent of the unrelated spouses of the patients, who presumably did not have a bleeding disorder, were judged to have a positive bleeding history.

A number of factors have long been known to modify VWF levels, including ABO blood group, secretor blood group, estrogens, thyroid hormones, age, and stress.^{250–252} ABO blood group is the best characterized of these factors. Genome-wide linkage has repeatedly confirmed strong linkage between the ABO locus and VWF levels (reviewed in Ref. 253). Mean VWF:Ag levels are approximately 75 percent for type O individuals and 123 percent for type AB individuals when compared to a pool of normal donor plasmas. Thus, it may be difficult to differentiate between a low-normal VWF value and mild type 1 VWD in blood group O individuals. In recent years, additional modifiers of VWF have been identified in large genetic association studies,^{254,255} including genes associated with VWF intracellular trafficking (*STXBP5*^{256,257}) and VWF clearance (*CLEC4M*²⁵⁸). Additionally, a genome-wide association study identified a novel genetic locus on chromosome 2 contributing to variation in plasma VWF.²⁵⁹ The variable expressivity and incomplete penetrance of type 1 VWD and overlap in VWF levels between mild type 1 VWD and normal populations has complicated the determination of accurate incidence figures for VWD, with estimates ranging from as high as 1 percent^{260,261} to as low as 2 to 10 per 100,000 population.²⁶²

In general, the type 2 VWD variants, which comprise 20 to 30 percent of all VWD diagnoses,²⁶³ are more uniformly penetrant. Type 2A and type 2B VWD account for the vast majority of patients with qualitative VWF abnormalities. Types 2A, 2B, and 2M are generally autosomal dominant in inheritance, although Type 2N and other rare cases of apparent recessive inheritance have been reported.

Estimates of prevalence for severe (type 3) VWD range from 0.5 to 5.3 per 1,000,000 population.^{264–266} Although this variant is frequently defined as autosomal recessive in inheritance, this is not a consistent finding. As described above, one or both parents of a severe VWD patient can be clinically asymptomatic and have entirely normal laboratory test results, although in many families one or both parents appear to be affected with classic type 1 VWD. Thus, in some families, severe VWD may represent the homozygous form of type 1 VWD. In this model, the apparent recessive inheritance in a subset of families could simply be the result of the incomplete penetrance of type 1 VWD. Alternatively, there may be a fundamental difference in the molecular mechanisms responsible for type 1 and type 3 VWD.¹⁶⁸

Compound heterozygosity (the presence of more than one VWF gene mutation) can occur, and the clinical presentation in such cases can depend on the interaction between the different mutant VWF proteins. Compound heterozygosity can impact response to therapy because of a complex VWD phenotype and has implications for genetic counseling. If compound heterozygosity is deduced from the family history and/or laboratory studies or discovered during genetic testing, the most recent update to the VWD nomenclature represents both types separated by a slash (/), such as VWD type 2B/2N.¹⁵¹

CLINICAL SYMPTOMS

Mucocutaneous bleeding is the most common symptom in patients with type 1 VWD.²⁴⁹ It is important to note that more than 20 percent of normal individuals may give a positive bleeding history.²⁶⁷ Bleeding assessment scores have evolved over many years,²⁶⁸ leading the International Society on Thrombosis and Haemostasis to propose a unified

Bleeding Assessment Test²⁶⁹ for research purposes. Although high bleeding scores are suggestive of a bleeding diathesis and can predict future bleeding,²⁷⁰ no bleeding questionnaire as yet is clearly diagnostic for VWD. These observations, together with the limited sensitivity and specificity of the currently available laboratory tests (see below), makes the diagnosis of mild VWD quite difficult and probably contributes to the wide range of prevalence figures for type 1 VWD currently in the literature. A National Heart Lung and Blood Institute Expert Panel has proposed clinical guidelines for evaluating patients to determine whether laboratory testing for VWD or other bleeding disorders is warranted.¹⁵⁰

Epistaxis occurs in approximately 60 percent of type 1 VWD patients, 40 percent have easy bruising and hematomas, 35 percent have menorrhagia, and 35 percent have gingival bleeding. Gastrointestinal bleeding occurs in approximately 10 percent of patients.¹⁵⁰ An apparent association between hereditary hemorrhagic telangiectasia (HHT) and VWD has been reported in several families. The causative genes in HHT were identified and are located on chromosomes 9q33–34, and 12q13²⁷¹ (Chap. 122), distinct from the VWF gene on chromosome 12p13. However, because inheriting VWD is likely to increase the severity of bleeding from HHT, the diagnosis is more likely to be made in patients inheriting both defects.²⁷² Mucocutaneous bleeding is common after trauma, with approximately 50 percent of patients reporting bleeding after dental extraction, approximately 35 percent after trauma or wounds, 25 percent postpartum, and 20 percent postoperatively. Hemarthroses in patients with moderate disease are extremely rare and are generally only encountered after major trauma. The bleeding symptoms can be quite variable among patients within the same family and even in the same patient over time. An individual may experience postpartum bleeding with one pregnancy but not with others, and clinical symptoms in mildly to moderately affected type 1 individuals often ameliorate by the second or third decade of life. Aside from an infrequent type 3 patient, death from bleeding rarely occurs in VWD.

Thrombocytopenia is a common feature of type 2B VWD and is not seen in any other form of VWD. Most patients only experience thrombocytopenia at times of increased VWF production or secretion, such as during physical effort, in pregnancy, in newborn infants, postoperatively, or if an infection develops. The platelet count rarely drops to levels thought to contribute to clinical bleeding.^{273,274} Infants with type 2B VWD may present with neonatal thrombocytopenia, which could be confused with neonatal alloimmune thrombocytopenia, neonatal sepsis, or congenital thrombocytopenia.

Patients who are homozygous or compound heterozygous for type 2N VWD generally have normal levels of VWF:Ag and VWF:RCO and normal VWF platelet adhesive function. However, FVIII levels are moderately decreased, resulting in a mild to moderate hemophilia-like phenotype.¹⁴⁶ In contrast to patients with classic hemophilia A (FVIII deficiency), these patients do not respond to infusion of purified FVIII and should be treated with VWF-containing concentrates.²⁷⁵ Heterozygotes for this disorder may have mildly decreased FVIII levels but are generally asymptomatic. Although type 2N VWD appears to be considerably less common than classic hemophilia A, it should be considered in the differential diagnosis of FVIII deficiency, particularly if any features suggest an autosomal pattern of inheritance. Although the FVIII level rarely drops below 5 percent, type 2N VWD mutation can be associated with FVIII levels as low as 1 percent, when co-inherited with a type 3 VWD allele.²⁷⁶ The latter observation further suggests that a diagnosis of type 2N VWD should also be considered in patients with marked reductions of FVIII.

Patients with type 3 VWD can suffer from severe clinical bleeding and experience hemarthroses and muscle hematomas, as in severe

hemophilia A (Chap. 123). After infusion of VWF-containing plasma fractions, some of these patients develop anti-VWF antibodies that neutralize VWF (reviewed in Ref. 277).

Other heritable coagulopathies can coexist with VWF deficiency. An evaluation for other factor deficiencies or platelet disorders should be considered in patients that have a suggestive family history, a bleeding phenotype out or proportion or inconsistent with an expected VWD pattern, or a poor response to therapy. In VWD patients with combination coagulopathies, treatment of both disorders may be necessary to achieve a good clinical result.²⁷⁸

● LABORATORY FEATURES

In the initial laboratory evaluation of patients suspected by history of having VWD, the following tests are routinely performed: assay of FVIII:C, VWF:Ag, and VWF:RCo. Other tests that are commonly used include RIPA, VWF:CB, and VWF multimer analysis. Routine coagulation studies, such as prothrombin time (PT) or activated partial-thromboplastin time (aPTT), are generally not useful in the evaluation of VWD. However, the aPTT can be prolonged in subjects with VWF deficiency,²⁷⁹ or in patients with homozygous type 2N VWD, because of the reduction in FVIII level. The wide range of normal and the considerable overlap with the levels observed in type 1 VWD make borderline levels difficult to interpret. A variety of concurrent diseases and drugs may modify the results of individual tests. Many conditions, such as recent exercise, age, pregnancy, time of the menstrual cycle, estrogen therapy, hypo- or hyperthyroidism, diabetes, uremia, liver disease, infection, myeloproliferative neoplasms, or malignancy can affect the FVIII activity, VWF:Ag, and ristocetin cofactor activity levels. These values can be regarded as acute-phase reactants, and even minor illnesses can increase the levels in a VWD patient to normal. Appropriate processing of laboratory specimens is also critical as VWF parameters can be artifactually skewed (either high or low) by phlebotomy conditions or specimen handling (reviewed in Ref. 150). Even controlling for many of these factors, the coefficients of variation of repeated VWF:Ag and ristocetin cofactor assays in a single person are quite large,²⁸⁰ and can be influenced by numerous factors including diurnal variation.²⁸¹ For this reason, repeated measurements are usually necessary, and the diagnosis of VWD or its exclusion should generally not be based on a single set of laboratory values.

The laboratory diagnosis of type 1 VWD can be confounded by the wide range of VWF levels in “normals” and borderline laboratory results. An alternative strategy is to classify some patients for whom the diagnosis of VWD is ambiguous as “low VWF,” recognizing that these patients may have an increased risk of bleeding without labeling them as type 1 VWD.^{282,283} In response to this need to distinguish those patients with VWD from nonbleeding individuals with moderately low levels of VWF (30 to 50 IU/dL), a threshold of less than 30 IU/dL has been recommended.¹⁵⁰ In clinical practice there remains wide variation in the assignment of normal VWF ranges and in the interpretation of laboratory results to make a VWD diagnoses.^{284–286}

FACTOR VIII

FVIII levels in VWD patients are generally coordinately decreased along with plasma VWF, although skewing of FVIII-to-VWF ratios can be observed.²⁸⁷ Levels in type 3 VWD generally range from 3 to 10 percent. In contrast, the levels in type 1 and the type 2 VWD variants (other than 2N) are variable and usually only mildly or moderately decreased. The FVIII level in type 2N VWD is more severely decreased, but rarely to less than 5 percent.

VON WILLEBRAND FACTOR ANTIGEN

Plasma VWF:Ag is usually quantitated by electroimmunoassay or an enzyme-linked immunosorbent assay (ELISA) technique. In type 1 VWD, the VWF:Ag assay usually parallels VWF:RCo, but it has lower specificity and sensitivity than the VWF:RCo assay. In patients with type 2 VWD, the VWF:Ag is variably decreased but can be normal (see Table 126–2).

RISTOCETIN COFACTOR ACTIVITY

The standard measure of VWF activity, the VWF:RCo quantitates the ability of plasma VWF to agglutinate platelets via platelet membrane GPIIb/IIIa in the presence of ristocetin.²⁸⁸ In the most common method, normal platelets washed free of plasma VWF are used either as fresh platelets or after formaldehyde fixation. This assay has long been reported to be the most sensitive and specific single test for the detection of VWD.²⁸⁹ Numerous alternative methods have been proposed as adjuncts or replacements of the standard platelet-based ristocetin cofactor activity assay. However, none as yet can serve as a surrogate for VWF:RCo (reviewed in Ref. 290).

Ristocetin cofactor activity is generally decreased coordinately with VWF:Ag and FVIII in type 1 VWD patients. In type 2 VWD variants, ristocetin cofactor activity can be disproportionately decreased, as is usually the case in type 2A variants (and sometimes type 2B), because of the greater dependence of the ristocetin-mediated platelet–VWF interaction on the presence of larger VWF multimers, and in type 2M, because of decreased VWF–platelet interactions (see Table 126–2). Thus, the VWF:RCo-to-VWF:Ag ratio has been proposed as a means to distinguish between type 1 and type 2 VWD, with a ratio of VWF:RCo-to-VWF:Ag of less than 0.7 being indicative of a qualitative (type 2) VWF defect.¹⁵¹ However, in patients with very low VWF:Ag levels this ratio may not be reliable because of the limits of sensitivity of most VWF:RCo assays. The VWF:RCo assay is uninformative in the presence of the VWF Asp1472His variant, which interferes with the VWF–ristocetin interaction *in vitro*.¹⁵⁵

RISTOCETIN-INDUCED PLATELET AGGLUTINATION

Similar to the ristocetin cofactor assay above, the RIPA assay also measures platelet agglutination caused by ristocetin-mediated VWF binding to platelet membrane GPIIb/IIIa. In the case of RIPA, ristocetin is added directly to patient platelet-rich plasma and platelet aggregation is measured. Hyperresponsiveness to RIPA results either from a type 2B VWD mutation or an intrinsic defect in the platelet (platelet-type or pseudo-VWD). In these disorders, patient platelet-rich plasma agglutinates spontaneously or at low ristocetin concentrations of only 0.2 to 0.7 mg/mL. At these concentrations, normal platelet-rich plasma does not agglutinate. Type 2B and platelet-type VWD can be distinguished by RIPA experiments performed with separated patient platelets or plasma mixed with the corresponding component from a normal individual or paraformaldehyde-fixed platelets. The RIPA is generally reduced in most other subtypes of VWD (see Table 126–2).

MULTIMER ANALYSIS

Analysis of plasma VWF multimers is critical for the proper diagnosis and subclassification of VWD (see Fig. 126–4). This is generally accomplished by agarose gel electrophoresis of plasma VWF to separate VWF multimers on the basis of molecular size, with the largest multimers

migrating more slowly than the intermediate or smaller multimers. The multimers may be visualized by autoradiography after incubation with ¹²⁵I-mono-specific antihuman VWF antibody or, more commonly, by nonradioactive immunologic techniques. The normal multimeric distribution is an orderly ladder of major protein bands of increasing molecular weight, going from the smallest to the largest VWF multimers (see Fig. 126–4). Each normal multimer has a fine structure consisting of one major component and two to four satellite bands.²⁹¹ Type 2B and most of the type 2A variants were initially distinguished from each other on the basis of subtle variations in the satellite band pattern. In a large European multicenter type 1 VWD study, careful analysis of VWF multimers in subjects historically diagnosed as type 1 VWD, including patients diagnosed at experienced centers, found one-third of “type 1” VWD patients had subtly abnormal multimers.²⁹² Although this previously would have required reclassification of these patients as type 2 VWD, the most recent update on the classification of VWD by the International Society on Thrombosis and Haemostasis Subcommittee on von Willebrand Factor expanded the category of type 1 VWD to permit subtle VWF multimer abnormalities.¹⁵¹ The authors of the European type 1 VWD study note that having samples from the index case, affected family members, and unaffected family members on one gel made qualitative defects more readily detectable, and that intermediate-resolution multimer gels were superior to low-resolution multimer gels in detecting abnormalities in this population. Use of VWF tests sensitive to VWF multimer structure have been proposed by some experts as proxies for VWF multimer testing, such as the VWF:RCo-to-VWF:Ag ratio (VWF RCo:Ag ratio) or VWF:CB assay.²⁹³ In studies comparing these approaches as surrogates for VWF multimer assays, the (VWF RCo:Ag ratio) ratio was found to be less sensitive than multimer gel techniques in identifying qualitative VWF defects,²⁹² while VWF:CB can detect some type 2M VWD patients who have normal VWF multimers.^{294,295} These observations support a continued important role for VWF multimer analysis in the laboratory evaluation of VWD.

ADDITIONAL LABORATORY TESTS

As a result of the variable sensitivity and specificity of laboratory testing for VWD, additional diagnostic studies may be useful in the classification of VWD patients. The VWF:CB measures VWF binding to collagen (type I, type III, type VI, or mixed) by ELISA. As above, assays based upon VWF:CB can complement the VWF:RCo in detecting type 2 VWD variants,^{296–299} and an abnormal VWF:CB-to-VWF:Ag ratio (VWF CB:Ag ratio) is suggestive of a qualitative VWF defect.¹⁵¹ Abnormalities in VWF:CB can reflect loss of high-molecular-weight multimers and/or the discrete loss of collagen binding caused by a type 2M mutation. Use of VWF:CB assays is expanding in clinical practice, with select sites including this test routinely in initial VWD diagnostic laboratory testing.

Another group of tests are included in the term VWF “activity” (VWF:Act). These tests seek to assess VWF–GPIIb binding capacity independent of ristocetin, usually by using antibodies to the VWF A1 domain in ELISAs. These tests are easily confused with the VWF:RCo, which has also been referred to as “VWF activity.” None of these tests measures activity; rather both VWF:RCo and VWF:Act are sensitive to VWF conformation. The VWF:Act does not always provide the same results as VWF:RCo, particularly with regards to type 2M VWD, and is not considered a substitute for the VWF:RCo (reviewed in Ref. 290).

When type 2N VWD is suspected, VWF:FVIII binding capacity can be measured.²³⁴ Specific assays of FVIII binding to VWF (VWF:FVIIIIB) have been developed and can be used to confirm the diagnosis of type 2N VWD.^{300,301} Type 2N carriers do not always exhibit a decrease in VWF:FVIIIIB, but a decreased VWF:FVIIIIB-to-VWF:Ag

ratio may correlate with heterozygosity for a type 2N *VWF* mutation.³⁰² Although this assay is widely used in European hemostasis laboratories, its availability in the United States is currently limited to a few specialized reference laboratories.

An assay measuring the VWFpp can be used to calculate the VWFpp:antigen ratio (VWFpp:Ag ratio) to detect a subset of VWD patients with decreased VWF survival. Good correlation has been reported between subjects with significantly shortened VWF half-life after DDAVP challenge and an increased VWFpp:Ag ratio.^{287,303,304} This assay is currently available in a few reference laboratories. A normal platelet VWF:Ag in the setting of decreased plasma VWF laboratory parameters also suggests an accelerated clearance phenotype such as that seen in VWD type Vicenza,³⁰⁵ but platelet VWF:Ag testing also is not widely available in clinical laboratories.

A number of other assays for VWF activity have been developed. The PFA-100 system, which measures platelet binding under high shear,^{306,307} is controversial in the diagnosis or monitoring of VWD. Although the PFA-100 is usually abnormal in type 2 VWD and in more severe type 1 and type 3 VWD cases, milder type 1 VWD and some type 2 VWD patients can have normal results.¹⁵⁰ Other VWF assays can measure binding of an antibody to the GPIb binding site on VWF as a proposed screening test for VWD.^{308–311} Additional assays can measure platelet agglutination induced by botrocetin (which is no longer commercially available) and other snake venom proteins.³¹² In the National Heart Lung and Blood Institute Expert Panel guidelines (<http://www.nhlbi.nih.gov/files/docs/guidelines/vwd.pdf>), none of these tests are recommended for screening for VWD.¹⁵⁰

With advances in understanding the molecular genetics of VWD, it is now possible to precisely diagnose and subclassify many variants of VWD on the basis of DNA mutations (reviewed in Ref. 313). DNA testing, particularly for type 2 VWD mutations which cluster within specific regions of the *VWF* gene (see Fig. 126–3), can be used to confirm the diagnosis and is available in specialized reference laboratories. The analysis of type 3 and type 1 VWD is more complex, as the currently known mutations are scattered throughout the gene²³⁵ and account only for a subset of patients.

The bleeding time is mentioned here for historical purposes only, as it was used as a screening test for VWD and other abnormalities of platelet function. Bleeding time varied considerably with the experience of the operator and a variety of other factors, did not prolong with FVIII deficiency, and correlated poorly with bleeding risk. Thus, the bleeding time is no longer recommended in the evaluation of VWD.¹⁵⁰

● PRENATAL TESTING

Given the mild clinical phenotype of most patients with the common variants of VWD, prenatal diagnosis for the purpose of deciding on terminating a pregnancy is rarely performed. However, type 3 VWD patients often have a profound bleeding disorder, similar to or more severe than classic hemophilia, and some families may request prenatal diagnosis. In those cases of VWD in which the precise mutation is known, DNA diagnosis can be performed rapidly and accurately by polymerase chain reaction (PCR) from amniotic fluid or chorionic villus biopsies (reviewed in Ref. 313) and would be expected to be compatible with new noninvasive prenatal testing methods.³¹⁴ In those cases where the mutation is unknown, diagnosis can still be attempted by genetic linkage analysis using the large panel of known polymorphisms within the *VWF* gene.³¹³ Although all cases of VWD analyzed to date appear to be linked to the *VWF* gene, the possibility of locus heterogeneity (i.e., a similar phenotype caused by a mutation in a gene other than *VWF*) should be considered.³¹⁵ As with all DNA testing, if prenatal testing is

being considered, genetic counseling should be provided before the decision to test is made as well as following the procedure.

● DIFFERENTIAL DIAGNOSIS

PLATELET-TYPE (PSEUDO-) VON WILLEBRAND DISEASE

Platelet-type (pseudo-) VWD is a platelet defect that phenotypically mimics VWD (Chap. 120). Patients have mucocutaneous bleeding, plasma VWF often lacks the largest multimers, RIPA is enhanced at low concentrations of ristocetin, and thrombocytopenia of variable degree is often present. Molecular analysis has identified missense mutations within the GPIIb α gene as the molecular basis for pseudo-VWD. These mutations are located within the segment of GPIIb that encodes the VWF binding domain and appear to induce the conformational change complementary to that produced in VWF by type 2B VWD mutations (reviewed in Ref. 316).

The specialized RIPA test should be performed at low ristocetin concentrations to distinguish type 2B and platelet type VWD from type 2A VWD. In this test, purified normal plasma VWF or cryoprecipitate added to platelet preparations from patients with platelet-type VWD causes platelet aggregation, distinguishing this disorder from type 2B VWD where patient platelets aggregate only at higher ristocetin concentrations. In addition, type 2B VWD plasma transfers the enhanced RIPA to normal platelets, whereas plasma from patients with platelet-type VWD interacts normally with control platelets.

ACQUIRED VON WILLEBRAND SYNDROME

Acquired VWD, or acquired von Willebrand syndrome (AVWS), is a relatively rare acquired bleeding disorder that usually presents as a late-onset bleeding diathesis in a patient with no prior bleeding history and a negative family history of bleeding (reviewed in Ref. 317). Decreased levels of FVIII, VWF:Ag, and VWF:RCo are common, and VWF multimers can be abnormal. AVWS is usually associated with another underlying disorder and has been reported to occur in patients with myeloproliferative neoplasms,³¹⁸ amyloidosis,³¹⁹ benign or malignant B-cell disorders,³²⁰ hypothyroidism,³²¹ autoimmune disorders,³²² several solid tumors (particularly Wilms tumor),³²³ cardiac or vascular defects (such as aortic stenosis),³²⁴ ventricular assist devices,³²⁵ or in association with several drugs, including ciprofloxacin and valproic acid.^{326,327}

The mechanisms that cause AVWS can generally be attributed to an associated medical condition. A variety of B-cell disorders have been associated with the development of anti-VWF autoantibodies. In most cases the AVWS appears to be due to rapid clearance of VWF induced by the circulating inhibitor, although these antibodies may also interfere with VWF function. Hypothyroidism results in decreased VWF synthesis.³²¹ In some cases of malignancy, AVWS is thought to be due to selective adsorption of VWF to the tumor cells or in myeloproliferative neoplasms, clearance/alterations of VWF by the high circulating platelet mass. AVWS associated with valvular heart disease, ventricular assist devices, or certain drugs, VWF may be lost by accelerated destruction or proteolysis under shear.^{325–327}

Although the VWF multimers in AVWS usually exhibit a type 2A pattern with relative depletion of the large multimer forms, AVWS can manifest as a wide range of VWD phenotypes.^{322,328} Distinguishing AVWS from genetic VWD can be difficult, as testing for the associated autoantibodies is generally not available in the clinical setting. The diagnosis often rests on the late onset of the disease, the absence of a family history, and the identification of an associated underlying disorder.

Management of AVWS is generally aimed at treating the underlying disorder. VWF levels and bleeding symptoms often improve with successful treatment of hypothyroidism or an associated malignancy. Refractory patients have been treated with glucocorticoids, plasma exchange, intravenous gamma globulin, rituximab, DDAVP, and VWF-containing FVIII concentrates.^{317,329}

● THERAPY, COURSE, AND PROGNOSIS

The mainstays of therapy for VWD are DDAVP, which induces secretion of both VWF and FVIII (reviewed in Ref. 330), and replacement therapy with VWF-containing plasma concentrates. The choice of treatment in any given patient depends upon the type and severity of VWD, the clinical setting, and the type of hemostatic challenge that must be met. Type 1 patients are most often treated with DDAVP alone, types 2A and 2B with a combination of DDAVP and a VWF-containing FVIII product, and type 2N and type 3 patients with VWF-containing concentrates.¹⁵⁰ A previous history of trauma or surgery and the success of previous treatment are important parameters to include in assessing the risk of bleeding. Prophylaxis is used in anticipation of hemostatic challenges,¹⁵⁰ such as dental extractions, and is efficacious in preventing recurrent bleeding in severe VWD patients.³³¹ Although in general there is a correlation between normal hemostasis and correction of VWF and FVIII activity, this does not occur in all cases.

DESMOPRESSIN

DDAVP is an analogue of antidiuretic hormone that acts through type 2 vasopressin receptors to induce secretion of FVIII and VWF, likely via cyclic adenosine monophosphate-mediated secretion from the Weibel-Palade bodies in endothelial cells.⁸³ When DDAVP is administered to healthy subjects, it causes sustained increases of FVIII and ristocetin cofactor activity for approximately 4 hours.³³² Patients with type 1 VWD treated with DDAVP release unusually high-molecular-weight VWF multimers into the circulation for 1 to 3 hours after the infusion.^{332,333} Therapy with DDAVP often increases the FVIII activity, VWF:Ag, and ristocetin cofactor activity to two to five times the basal level.

DDAVP has become a mainstay for the treatment of mild hemophilia and VWD³³⁴ because it is relatively inexpensive, widely available, and avoids the risks of plasma-derived products. Approximately 80 percent of type 1 VWD patients have excellent responses to DDAVP, although this figure may be substantially lower depending on the criteria for diagnosis and response.³³⁵ It is regularly used in the setting of mild to moderate bleeding and for prophylaxis of patients undergoing surgical procedures. DDAVP is administered at a dose of 0.3mcg/kg continuous intravenous infusion over 30 minutes. DDAVP is also available for subcutaneous injection (at the same 0.3mcg/kg dose) and in intranasal form (at a fixed dose of 300mcg for adults and 150mcg for children), which appears to be similar in efficacy to intravenous administration,^{336,337} although the response may be more variable.

The response to DDAVP in any given individual with VWD is generally reproducible and predicts response to future doses as long as the follow doses are at least 2 to 4 days later. In one study, 22 type 1 VWD patients showed a departure of less than 20 percent from the mean FVIII peak level calculated from two separate infusions. In addition, the consistency of response in one patient reliably predicted the future response of that patient and other affected family members.³³⁸ In a study of 77 type 1 VWD patients, DDAVP response was associated both with VWF mutation and baseline multimeric pattern, although subtle abnormalities in VWF multimers did not preclude a patient response to DDAVP. Interestingly, patients with the same VWF mutation did not necessarily exhibit the same degree of responsiveness to DDAVP, implying the

influence of other factors in the magnitude of DDAVP effect.³³⁹ For patients requiring repeated infusions of DDAVP, the FVIII activity and VWF responses may not be of the same magnitude as after the first infusion. Although this decay in response has considerable individual variability, after one infusion of DDAVP per day for 4 days it was found that the responses on days 2 to 4 were reduced approximately 30 percent compared to day 1.^{336–338,340}

Therefore, in patients for whom DDAVP is potentially the treatment of choice, a test dose should be given at the planned therapeutic dose and route in advance of the first required course of treatment with measurements of before and after VWF and FVIII:C levels to ensure an adequate therapeutic response. Sampling additional time points after DDAVP infusion should be considered as some type 1 and type 2 VWD patients have a significantly shortened VWF half-life and it may be more appropriate to treat with VWF replacement therapy in clinical scenarios requiring more durable therapy to maintain hemostasis. For patients with type 1 VWD who are undergoing surgical procedures, DDAVP can be administered 1 hour before surgery and approximately every 12 hours thereafter for up to two to four doses before loss of clinically significant response. Patients should be monitored for response of FVIII and ristocetin cofactor activity and side effects, particularly hyponatremia (and then should be water restricted), when DDAVP is administered at frequent intervals. VWF-containing FVIII concentrates should be available for infusion as backup.

Approximately 20 to 25 percent of patients with VWD do not respond adequately to DDAVP. Type 2 VWD patients are less likely to have a response than type 1 patients,^{341,335} and virtually no patients with type 3 VWD respond. The response to DDAVP of patients with type 2A VWD is variable. Although most patients respond only transiently, some patients exhibit complete hemostatic correction after DDAVP infusion.^{342,343} It has been hypothesized that the differences in DDAVP efficacy among type 2A patients may correspond to the type of mutation, with better responses predicted in patients with group 2 mutations. A prospective study of the biologic response to DDAVP in well-characterized VWD patients included type 2A VWD patients with both group 1 and group 2 defects. Although patients with group 2 mutations had greater improvements in VWF:RCO and shortening of bleeding times than patients with group 1 defects, neither groups could be classified as responders.³⁴¹

Common side effects of DDAVP administration are mild cutaneous vasodilation resulting in a feeling of heat, facial flushing, tachycardia, tingling, and headaches. The potential for dilutional hyponatremia, especially in elderly and very young patients and with repeat dosing, requires appropriate attention to fluid restriction, as it may result in seizures. There have been isolated reports of acute arterial thrombosis associated with administration of DDAVP, but the risk appears to be very low when judged against the total number of patients treated. DDAVP is contraindicated in patients with unstable coronary artery disease because of increased risk of thrombotic events, such as myocardial infarction.³⁴⁴ Patients receiving DDAVP at closely spaced intervals of less than 24 to 48 hours can develop tachyphylaxis.³⁴⁰

Many experts consider DDAVP to be contraindicated in the treatment of type 2B VWD, as the high-molecular-weight VWF released from storage sites has an increased affinity for binding to GPIIb and might be expected to induce spontaneous platelet aggregation and worsening thrombocytopenia.²²⁹ However, there are reports of DDAVP used successfully in type 2B VWD patients, with an associated shortening of bleeding times and variable thrombocytopenia.^{345,346} Although type 2N patients can exhibit increased FVIII:C levels after DDAVP, in some cases the FVIII:C levels rapidly decline, likely a result of the absence of stabilizing normal VWF, attenuating clinical efficacy. Type 2M patients generally do not have a satisfactory response to DDAVP.^{341,347}

VON WILLEBRAND FACTOR REPLACEMENT THERAPY

It is important to determine the response to DDAVP for each individual so as to avoid the unnecessary use of plasma products. For type 3 VWD patients and other patients unresponsive to DDAVP, the use of selected virus-inactivated, VWF-containing FVIII concentrates is generally safe and effective.¹⁵⁰ Humate-P, Alphanate, Wilate, and Koate are all acceptable commercial VWF-containing plasma concentrates that have been evaluated in VWD replacement therapy in clinical studies, and other VWF-containing FVIII concentrates may also be effective. A plasma-free recombinant VWF–recombinant FVIII combination (rVWF–rFVIII) shows promise in clinical trials and may become available in the near future.³⁴⁸ Cryoprecipitate was useful in the past, but because it is not generally treated to inactivate bloodborne pathogens, is less targeted to correcting the VWD hemostatic defect, and its administration is associated with a large volume load, it is less desirable. It is important to note that most standard FVIII concentrates and all recombinant FVIII products are not effective in VWD because they lack clinically significant quantities of VWF. Although such products can substantially increase circulating FVIII:C, the infused factor is short-lived in the circulation in the absence of stabilizing VWF.³⁴⁹ Only preparations that contain large quantities of VWF with well-preserved multimer structure are suitable for use in VWD patients.

In practice, VWD replacement therapy dosing and timing has been largely empiric. Recommendations for therapy have been outlined based upon the degree and nature of hemorrhage and experience in clinical practice.¹⁵⁰ The objective is to elevate FVIII:C and VWF:RCo until bleeding stops and healing is complete. In general, replacement goals of FVIII:C and VWF:RCo should be initial replacement to greater than 100 IU/dL and maintenance of greater than 50 IU/dL for 7 to 14 days for major trauma, surgery, or central nervous system hemorrhage; greater than 30 to 50 IU/dL for 3 to 5 days for minor surgery or bleeding; greater than 50 IU/dL for delivery and continued for at least 3 to 5 days in the postpartum period; greater than 30 to 50 IU/dL for 1 to 5 days for dental extractions and minor surgery; and greater than 20 to 50 IU/dL for mucous membrane bleeding or menorrhagia. Laboratory monitoring of posttreatment FVIII:C and VWF levels is important in guiding therapy and avoidance of suprathreshold replacement doses (>200 IU/dL VWF:RCo, >250 IU/dL FVIII), which are associated with an increased risk of thrombosis.^{150,350,351} Although thrombosis is rare overall, VWD patients on prolonged therapy or with central access catheters appear to be at higher risk.³⁵²

In patients who have concomitant thrombocytopenia associated with or in addition to VWD, it may be necessary to transfuse platelets in addition to factor concentrates. If clinical bleeding continues, additional replacement therapy must be given and searches undertaken for other hemostatic defects. Type 3 VWD patients receiving multiple transfusions can develop antibodies directed against VWF (reviewed in Ref. 277). Continued replacement with VWF-containing concentrates is contraindicated because of the risk of anaphylaxis. A variety of approaches to the management of VWD inhibitors, similar to the treatment of FVIII inhibitors in hemophilia A (Chap. 123), have been attempted. Immunosuppression, recombinant FVIII, and recombinant factor VIIa have been reported to be useful in patients with type 3 VWD who have developed anti-VWF antibodies.

OTHER NONREPLACEMENT THERAPIES

Fibrinolytic inhibitors, such as ϵ -aminocaproic acid or tranexamic acid, have been used effectively in some VWD patients. Antifibrinolytics are commonly used alone or in conjunction with DDAVP or a

plasma-derived VWF replacement product in patients with gynecologic bleeding, mucous membrane bleeding, or undergoing dental procedures.¹⁵⁰ Fibrinolytic inhibitors can be delivered systemically or topically and are generally well tolerated, but rarely can cause nausea or diarrhea and are contraindicated in patients with gross hematuria.

Estrogens or oral contraceptives have been used empirically in treating menorrhagia. In addition to their effects on the ovaries and uterus, some estrogens can increase plasma VWF levels. Patients with VWD frequently normalize their levels of FVIII, VWF:Ag, and VWF:RCo during pregnancy (Chap. 8). Postpartum hemorrhage within the first few days after parturition may be related to the relatively rapid return of FVIII and VWF activities to prepregnancy levels, and postpartum hemorrhage in all forms of VWD may occur as long as 1 month postpartum. In pregnant patients with type 1 VWD, the FVIII and ristocetin cofactor activities usually rise above 50 percent. These patients usually do not require any specific therapy at the time of parturition. In contrast, individuals who have 30 percent or less FVIII or variant forms of VWD are more likely to require prophylactic therapy before delivery. In a recent study, women receiving treatment for VWD postpartum were unexpectedly found not to have corrected to target levels.³⁵³ Therefore, laboratory testing is recommended at term and should be considered in the postpartum period in patients at risk for immediate and/or delayed bleeding complications or receiving therapy.

Recombinant activated factor VII (rFVIIa, or NovoSeven) has also been successfully used in VWD patients with severe hemorrhage refractory to VWF replacement therapy and in bleeding patients with anti-VWF antibodies (reviewed in Ref. 354). In the case of minor accessible bleeding, topical drugs such as fibrin sealants or topical bovine thrombin may also be considered when standard VWD therapies fail to provide adequate local hemostasis.¹⁵⁰

CHAPTER 127

ANTIBODY-MEDIATED COAGULATION FACTOR DEFICIENCIES

Sean R. Stowell, John S. (Pete) Lollar, and Shannon L. Meeks

SUMMARY

Clinically significant autoantibodies to coagulation factors deficiencies are uncommon, but can produce life-threatening bleeding and death. The most commonly targeted coagulation factor in autoimmunity is factor VIII. Acquired hemophilia A, which results from these antibodies, can either be idiopathic or associated with older age, other autoimmune disorders, malignancy, the postpartum period, and the use of drugs such as penicillin and sulfonamides. Bleeding in acquired hemophilia A is treated with factor VIII bypassing agents. The underlying autoimmune disorder frequently responds to immunosuppressive medication. Antiprothrombin antibodies usually are found in patients with lupus anticoagulant and are associated with bleeding. Antibodies of von Willebrand factor are found in patients with type 3 von Willebrand disease in response to infusion of plasma concentrates containing von Willebrand factor. Antibodies to factor V can occur as autoantibodies or as cross-reacting antibody factor V antibodies that develop after exposure to bovine thrombin products that are contaminated with factor V. Pathogenic autoantibodies also have been described that target thrombin, factor IX, factor XI, factor XIII, protein C, protein S, and the endothelial cell protein C receptor.

DEFINITION AND HISTORY

Antibodies directed against coagulation factors can develop as an acquired, autoimmune phenomenon. These “circulating anticoagulants” or “inhibitors” were recognized as early as 1906 as a cause of an acquired bleeding disorder.¹ The most common coagulation factor targeted in autoimmunity is factor VIII. The key feature that distinguishes antibody-mediated from other acquired coagulation factor deficiencies, such as impaired synthesis (e.g., a result of vitamin K deficiency) or increased consumption (e.g., in disseminated intravascular coagulation), is the ability of the patient’s plasma to inhibit the coagulation of normal plasma. Inhibitors also can develop in response to replacement therapy in patients with congenital coagulation factor deficiencies as discussed in Chap. 123.

Acronyms and Abbreviations: APC, activated protein C; aPCC, activated prothrombin complex concentrate; aPTT, activated partial thromboplastin time; BU, Bethesda units; CTLA4, cytotoxic T-lymphocyte associated protein 4; DAMP, damage-associated molecular patterns; EACH, European Acquired Hemophilia Registry; FEIBA, factor eight inhibitor bypassing agent; PAPP, pathogen-associated molecular patterns; rVIIa, recombinant activated factor VII.

ACQUIRED HEMOPHILIA A

DEFINITIONS AND EPIDEMIOLOGY

The incidence of autoantibodies to factor VIII, which is the most commonly targeted coagulation factor in autoimmunity, is 1.4 per million people per year.²⁻⁴ The associated clinical condition is called acquired hemophilia A. Approximately 40 to 50 percent of acquired hemophilia A patients have underlying conditions, including other autoimmune disorders (e.g., rheumatoid arthritis and systemic lupus erythematosus), malignancy, pregnancy, or a history consistent with a drug reaction.⁵ The remaining idiopathic cases most commonly occur in elderly patients of either sex with the median age at diagnosis being in the mid-70s.

MECHANISMS OF ANTIBODY DEVELOPMENT

Even though adaptive immunity provides a unique ability to recognize a nearly infinite range of antigenic determinants, mechanisms of immunologic tolerance exist that reduce the probability of autoimmunity.⁶ Self non-self discrimination provides the key foundation upon which immune activity can be specifically directed toward potential pathogens.⁶ However, self non-self discrimination alone does not possess the capacity to distinguish innocuous antigens from antigens associated with a real threat of infection.⁷ As a result, an elaborate network of innate immune factors also exist that recognize potential danger in the form of cellular injury or conserved determinants on pathogens themselves, often referred to as damage-associated molecular patterns (DAMPs) and pathogen-associated molecular patterns (PAMPs), respectively.^{7,8} Activation of immune cell function following exposure to PAMPs or DAMPs provide the necessary signals required for an efficient immunologic response to foreign antigen.⁷⁻⁹

The development of anti-factor VIII antibodies following factor VIII infusion in individuals with hemophilia A provides a classic example of the deleterious outcome of alloantibody formation following exposure to alloantigen. In this scenario, the factor VIII protein is foreign to the patients; consequently, central tolerance to the factor VIII protein does not occur. In contrast, acquired hemophilia results from loss of previous tolerance to a self antigen.¹⁰⁻¹²

For alloantibody development in patients with hemophilia A, individual variability in factor VIII levels accounts for some of the divergent level of tolerance to factor VIII observed. However, some individuals with undetectable levels of factor VIII antigen fail to generate factor VIII inhibitors, regardless of factor VIII exposure. Although these individuals would not be predicted to be tolerized to factor VIII, 70 to 80 percent of patients with baseline factor VIII levels of less than 1 percent do not develop an immune response to repeated dosing and are considered tolerized.¹³⁻¹⁶ For the 20 to 30 percent of patients who develop inhibitors there are both genetic and nongenetic risk factors for inhibitor development. Patients with a positive family history of inhibitors, those who have large factor VIII gene deletions, and nonwhites have a higher risk of inhibitor development.¹⁷⁻²⁰ The non-factor VIII genes—interleukin-10, tumor necrosis factor- α , and cytotoxic T-lymphocyte antigen 4-318 allele—are associated with inhibitor development.¹⁷⁻²⁰ Nongenetic risk factors, such as infusing factor at the time of a “danger” signal (e.g., a surgical procedure), intense factor exposure, and prophylaxis versus no prophylaxis, also are associated with inhibitor development.¹⁶ Patients who receive factor at the time of a “danger” signal may experience sufficient tissue injury to provide the necessary immune activation through DAMPs. Furthermore, it remains possible that low grade and potentially clinically undetectable infection may provide low levels of PAMPs that could likewise stimulate anti-factor VIII antibodies following factor VIII exposure. However, while PAMPs and/or DAMPs may provide the important immune activation signals,^{21,22}

several studies using animal models suggest that significant factor VIII antibody development can occur in the absence of known tissue injury or DAMP exposure.²³ Consistent with this, immune activation can occur in the apparent absence of DAMPs or PAMPs toward several model antigens.²⁴ Unique B-cell populations, especially those in the spleen, can rapidly respond to bloodborne antigens in the absence of any identifiable PAMPs or tissue injury, suggesting that these cells may be uniquely poised to respond to factor VIII.²⁵ Consistent with this, in experimental models, splenectomy can significantly inhibit factor VIII inhibitor development following factor VIII exposure,^{26,27} suggesting that several of these unique B-cell populations may be involved in the development of factor VIII antibodies irrespective of DAMP or PAMP exposure.^{25,26}

Although examples of antigens inducing B-cell activation in the absence of known DAMPs or PAMPs exist, most of these antigens require crosslinking of cell-surface B-cell receptors for efficient activation and therefore reflect highly repetitive antigenic structures.²⁸ In contrast, factor VIII represents a soluble antigen with little inherent predicted cross-linking ability. Most soluble antigen of this type actually induce tolerance following injection, likely because of the inability of soluble monovalent antigens to adequately crosslink and thereby stimulate B-cell receptors. Although factor VIII can exist in a soluble, monovalent form, it remains possible that factor VIII may form complexes with higher-molecular-weight species and thus form a network of factor VIII antigens that may serve as a suitable substrate for efficient B-cell receptor crosslinking and subsequent activation. Consistent with this, induction of tolerance to factor VIII by exposure to high levels of factor VIII may partially reflect a saturation of sites for factor VIII complex formation,²⁹ which may, in turn, result in B-cell exposure to high levels of soluble, monovalent factor VIII. However, if this occurs, studies suggest that it likely takes place independent of interactions with von Willebrand factor, the primary binding partner of factor VIII, or its own coagulant activity.³⁰ Clearly, there is much more to learn regarding the immunologic factors responsible for factor VIII inhibitor development.

In contrast to generating alloantibodies following factor VIII infusion, some patients generate autoantibodies against factor VIII, which can result in acquired factor VIII deficiency. As coagulation typically occurs at sites of inflammation and injury where DAMPs presumably are generated, tolerance to factor VIII may unfortunately be lost in these settings. Additionally, nonproteolytic and proteolytic degradation of coagulation proteins potentially could present neoepitopes. However, the fact that the development of acquired factor VIII deficiency is rare (1.4 per million population) provides a testimony to the ability of the immune system to discriminate efficiently between infectious non-self from noninfectious self.¹² Essentially, nothing is known about the breakdown of tolerance in patients that develop autoantibodies to coagulation factors.

MOLECULAR PATHOLOGY

Factor VIII inhibitors in congenital and acquired hemophilia nearly always consist of a polyclonal immunoglobulin (Ig) G population. Although IgG₄ accounts for only 5 percent of the total IgG in normal plasma, it usually is a major, but not the sole, component of the anti-factor VIII antibody population.³¹ IgG₄ antibodies do not fix complement, which has been cited as a reason that immune complex disease is not observed in factor VIII inhibitor patients. However, it is more likely that factor VIII simply is not present in sufficient quantity to form enough immune complex deposition to mediate tissue damage.

Factor VIII contains a sequence of domains designated A1-A2-B-ap-A3-C1-C2 (Chap. 123). During the activation of factor VIII by thrombin, the B and ap domains are released, producing an A1/A2/A3-C1-C2 activated factor VIII heterotrimer.³² Anti-factor VIII

antibodies in both congenital and acquired hemophilia A inhibitor are primarily directed to the A2 and C2 domains, although antibodies to all domains have been described.³³⁻³⁵ The similarity in the properties of antibodies in congenital and acquired hemophilia, which represent very different immunologic settings, suggests that intrinsic structural features in the factor VIII molecule are an important determinant driving the immune response. Epitope spreading from a single "problem" epitope, which has been implicated in some autoantibody phenomena,³⁶ does not appear to be a property of factor VIII inhibitors because anti-C2 antibodies can occur in the absence of anti-A2 antibodies and *vice versa*.

The only known biologic function of factor VIII is to become proteolytically activated and participate as a cofactor for factor IXa during intrinsic pathway factor X activation on phospholipid membranes. Theoretically, antibodies could inhibit factor VIII procoagulant function in several ways, including blocking the binding of factor VIIIa to factor IXa, factor X, or phospholipid, or by interfering with the proteolytic activation of factor VIII. Some anti-A2 antibodies map to a region bounded by Arg484-Ile508³⁷ and inhibit activated factor VIII by blocking its ability to bind factor X.³⁸ Anti-C2 antibodies bind to the NH₂-terminal half of the C2 domain.³⁹ Anti-C2 antibodies have been identified that inhibit the binding of activated factor VIII to phospholipid membranes,⁴⁰ which is critical for its interaction with the platelet surfaces. However, the C2 domain also apparently contributes to the binding of factor VIII to its activators, thrombin and factor Xa.⁴¹⁻⁴³ Consistent with this, anti-C2 inhibitors have been identified that block factor VIII activation.^{41,44}

Factor VIII inhibitors also have been identified in approximately 20 percent of normal healthy donors.⁴⁵ These inhibitors inhibit factor VIII activity in pooled normal plasma, but not autologous plasma, indicating that they are not autoantibodies, but rather alloantibodies directed against an unidentified polymorphism. Anti-factor VIII IgG also has been identified in all normal plasmas tested by affinity chromatography on immobilized factor VIII.⁴⁶ The increased sensitivity of the method is a consequence of its ability to resolve anti-factor VIII antibodies from anti-anti-factor VIII idiotypic antibodies that also are present. Idiotypic regulation has been proposed as a mechanism for controlling autoantibody activity *in vivo*.⁴⁷

CLINICAL FEATURES

Acquired hemophilia A patients usually present with spontaneous bleeding, which often is severe and life- or limb-threatening, although large cohort studies have shown that approximately 30 percent of patients do not require hemostatic management.^{2,48} Patients with acquired hemophilia are more likely to have a severe bleeding diathesis than congenital hemophilia A inhibitor patients.⁴⁹ Additionally, in contrast to patients with congenital hemophilia A, hemarthrosis in these patients is rare. The reasons for these differences is puzzling, especially in light of the fact that the properties of factor VIII inhibitors in the two patient populations is similar. As noted above, inhibitors can block factor VIII function in several ways. Conceivably, unidentified mechanistic differences in inhibitor action account for the difference in clinical severity. Factor VIII inhibitors sometimes resolve spontaneously. However, it is not possible to predict in which subset of patients this will occur.

LABORATORY FEATURES AND DIFFERENTIAL DIAGNOSIS

The new onset of an acquired bleeding disorder should immediately lead to screening tests that include an activated partial thromboplastin time (aPTT), a prothrombin time, and a platelet count. Patients with acquired hemophilia A have a prolonged aPTT resulting from decreased

or absent factor VIII activity in the intrinsic pathway of blood coagulation. The autoantibody inhibits the factor VIII in the plasma from normal individuals, which forms the basis of mixing study that is used to screen for inhibitors. The presence of a prolonged aPTT in a mixing study establishes the diagnosis of a circulating anticoagulant. Specific factor assays then are performed to determine whether a specific coagulation factor inhibitor or a lupus anticoagulant is present. The activity of other intrinsic pathway coagulation factors may be decreased in the presence of high titer factor VIII inhibitors. However, the levels of these factors normalize at increasing dilutions of patient plasma, whereas factor VIII activity remains decreased.

Once the identity of an inhibitor has been established, its titer is determined using the Bethesda assay.⁵⁰ Inhibitors frequently take minutes to hours to maximally inhibit factor VIII. Therefore, dilutions of patient plasma are preincubated with normal plasma for 2 hours at 37°C. The inhibitor titer is defined as the dilution of patient plasma that produces 50 percent inhibition of the factor VIII activity and is expressed in Bethesda units per milliliter (BU/mL). Inhibitors are classified informally as low titer or high titer when the titers are less than 5 BU/mL or greater than 5 to 10 BU/mL, respectively. The Bethesda assay has been modified by the addition of 0.1 M imidazole, pH 7.4, and by diluting test plasma into factor VIII-deficient plasma during the preincubation phase to prevent assay variation resulting from pH changes and adsorptive losses of factor VIII.⁵¹ This “Nijmegen” modification of the Bethesda assay decreases false-positive low-titer inhibitors.⁵² Patients with acquired hemophilia often have measurable residual factor VIII activity. This activity may cause an underestimate of the inhibitory titer. Preanalytical heat treatment has been proposed as a simple way to denature factor VIII to allow for more accurate determination of titer in both patients with acquired hemophilia A and patients with congenital hemophilia A who may have infused factor VIII.^{53,54}

Factor VIII inhibitors are classified based on the kinetics and extent of inactivation of factor VIII in plasma.⁵⁵ Type I inhibitors follow second-order kinetics and inactivate factor VIII completely, which would be expected for a simple bimolecular antigen-antibody reaction. Type II inhibitors inactivate factor VIII incompletely and display more complex kinetics of inhibition. Hemophilia A inhibitor patients and acquired hemophilia A patients tend to have type I and type II inhibitors, respectively.⁵⁶ However, the borderline between type I and type II inhibitors is not always clear and the distinction is not useful clinically. Additionally in a recent observational study of patients with acquired hemophilia in the United Kingdom, factor VIII levels and inhibitor titers at presentation were not predictive of the severity of bleeding events. The median factor VIII level and inhibitory titers were nearly identical for patients with fatal bleeding events compared to those who did not require treatment for their bleeding symptoms.²

TREATMENT

The severe bleeding that often is the presenting feature of this disorder requires urgent action to establish a diagnosis and initiate therapeutic measures. Ideally, this is carried out in a setting where factor VIII inhibitors can be identified and quantitated and where there is subspecialty expertise in the management of bleeding disorders. Invasive procedures should be performed only if absolutely necessary and venipuncture should be kept to a minimum given the risk of significant bleeding.⁵⁷

Treatment of patients with acquired hemophilia A depends on the inhibitor titer. Although no prospective trials are available, clinical experience indicates that patients with a factor VIII inhibitor titer of less than 5 BU/mL often are treated successfully with sufficient doses of recombinant or plasma-derived factor VIII to neutralize the inhibitor. Patients with titers between 5 and 10 BU/mL also may respond to factor VIII,

whereas those with titers greater than 10 BU/mL generally do not respond. Formulas exist to calculate the amount of factor VIII needed to treat a patient, but these are rough estimates at best. The efficacy of factor VIII concentrates was lower than that of bypassing agents in a large registry study, which was likely secondary to challenges in appropriately dosing the factor VIII concentrate.⁴⁸

Desmopressin can be administered by intravenous, subcutaneous, or intranasal routes and results in an increase in plasma von Willebrand factor levels and factor VIII activity.⁵⁸ Its potential use is in patients with baseline factor VIII levels greater than 5 IU/dL and minor bleeding. However, like factor VIII concentrates, response is not predictable and close monitoring of hemostatic efficacy and factor VIII levels is needed.

Factor VIII bypassing agents, which drive the coagulation mechanism through the extrinsic pathway, are the mainstays of management of patients with a high titer of an inhibitor. Two agents, recombinant activated factor VII (rFVIIa; NovoSeven RT) and plasma-derived anti-inhibitor coagulant complex (AICC; FEIBA VH Immuno, also called activated prothrombin complex concentrate [aPCC]) are commercially available and approved by the U.S. Food and Drug Administration for treatment of acquired hemophilia A. Although no comparative trials have been done, analysis of the European Acquired Haemophilia (EACH2) Registry showed similar hemostatic efficacy between rFVIIa and aPCC at approximately 90 percent.⁴⁸ Similar hemostatic efficacy between rFVIIa and aPCC has been seen in the treatment of congenital hemophilia A with inhibitors.⁵⁹ The recommended dose range of rFVIIa for the treatment of patients with acquired hemophilia is 70 to 90 mcg/kg repeated every 2 to 3 hours until hemostasis is achieved. aPCC is given at doses of 50 to 100 U/kg every 8 to 12 hours, but should not exceed 200 U/kg per day. Lower doses (50 to 75 U/kg) are used for mild bleeding, whereas higher doses (100 U/kg) are given for severe limb or life-threatening bleeding. Treatment should be continued until there are clear signs of clinical improvement.

Although there are similar rates of efficacy between the two available bypassing agents, not all patients respond. Additionally, there are no widely accepted methods available for predicting response to therapy or monitoring patients on therapy. The use of thromboelastography and the thrombin generation assays as a predictor of response to therapy in congenital hemophilia A and inhibitors has been reported but large clinical studies linking clinical data to outcome are lacking, leaving clinical response as the only available monitoring option.⁶⁰

The major serious adverse event associated with bypassing agents is thrombosis. The EACH2 Registry reported similar rates in patients treated with rFVIIa or aPCC.⁴⁸ However, the risk of thrombosis is considered low when used for approved indications at the recommended doses. The incidence of thrombosis in patients with acquired hemophilia A treated with bypassing agents appears higher than that for patients with congenital hemophilia. This is probably because of cardiovascular risk factors in the acquired hemophilia population given their age and associated medical conditions. Escalating doses of either bypassing agent or combination of the two agents should be done with caution, especially in older patients.

Factor VIII inhibitors usually cross-react poorly with porcine factor VIII.⁶¹ A commercial plasma-derived porcine factor VIII concentrate was useful in the treatment of factor VIII inhibitor patients for approximately 20 years,⁶² but was discontinued in 2004 because of viral contamination of the product. Porcine factor VIII has the advantage of potentially being guided by laboratory monitoring of recovery of factor VIII activity in plasma. However, the development of anti-porcine factor VIII antibodies may preclude its long-term use. A phase II/III clinical trial of a recombinant porcine factor VIII product has been completed in patients with acquired hemophilia A⁶³ and a phase II trial has been completed in congenital hemophilia inhibitor patients.⁶⁴

Although acquired inhibitors may remit spontaneously, fatal bleeding may occur up to several months after the initial diagnosis, even in patients who present with mild bleeding. Therefore, immunosuppressive therapy at the time of diagnosis to eradicate the inhibitor is recommended.⁵⁷ A variety of immunosuppressive agents have been used, including cyclophosphamide, azathioprine, cyclosporine, intravenous immunoglobulin, and rituximab. Immune tolerance induction using human factor VIII similar to what is done for patients with congenital hemophilia A and inhibitors has been used successfully. Additionally, plasmapheresis and immunoadsorption of the inhibitory antibody have been used.

First-line immunosuppressive regimens at many centers consist of glucocorticoids alone or glucocorticoids combined with cyclophosphamide.⁶⁵ No appropriately powered randomized studies have been performed, so the information available is from a single small randomized study, case reports, national surveys, and large registry data. The single randomized trial of 31 patients comparing prednisone and cyclophosphamide showed no difference in the treatment arms. A national registry study also showed no difference with 76 percent of patients achieving complete remission in the steroid arm and 78 percent in the steroids plus cytotoxic agent arm.⁶⁶ The EACH2 Registry has the largest reported experience with 331 patients and reported a higher rate of stable complete remission at 70 percent for patients treated with steroids and cyclophosphamide compared with 48 percent for steroids alone and 59 percent for rituximab containing regimens. Extensive analysis to control for potential confounding factors in this non-randomized study confirmed that stable complete remission was more likely with a steroid and cyclophosphamide than steroids alone (odds ratio of 3.25). The median time to remission was 5 weeks in patients treated with steroids alone or steroids and cyclophosphamide and 10 weeks in patients treated with rituximab. There have been no studies that have shown a difference in long-term outcomes including survival and sustained remission.^{57,67}

The rarity of this disease, the severity of bleeding at onset, and the delay in diagnosis of these patients has all contributed to the lack of controlled trials. Given the lack of controlled trial clinical management decisions are guided from the limited data available and clinical judgment.

● ACQUIRED ANTIBODIES TO OTHER COAGULATION FACTORS

ANTI-FACTOR V AND ANTITHROMBIN ANTIBODIES

Thrombin and factor V inhibitors are discussed together because of their frequent coexistence in immune responses to commercial products that contain thrombin. Thrombin products have been used widely in surgical and endoscopic procedures. It has been estimated that more than 500,000 patients are treated annually with products containing thrombin.⁶⁸ Thrombin is used either alone or as a component of fibrin sealants, which consist of fibrinogen and thrombin preparations that are mixed together at the wound site to form a topical fibrin clot.⁶⁹ Additionally, factor XIII sometimes is added to crosslink and stabilize the clot.

Fibrin sealants contain thrombin and fibrinogen derived from human plasma, whereas stand-alone thrombin products are prepared from bovine plasma. Both types of products are heavily contaminated with other plasma proteins, including factor V and prothrombin.^{70,71} Almost all patients exposed to bovine proteins develop a detectable immune response. In half of these patients antbovine antibodies

cross-react with human thrombin, factor V, or prothrombin.⁶⁸ Usually, these antibodies are subclinical.⁷² However, mild to life-threatening hemorrhage can occur, especially if the titer of anti-human factor V antibodies is high. The risk of bleeding is higher in patients who receive bovine thrombin products more than once because of the development of a secondary immune response.

There have been no clinical trials comparing the safety and efficacy of fibrin sealants to stand-alone thrombin products. Because fibrin sealants are composed mainly of human proteins, they may be less immunogenic. However, anti-factor V antibodies have been reported in a patient receiving fibrin sealant.⁷³ There currently is no stand-alone human thrombin product. It seems likely that the development of highly purified plasma-derived or recombinant products containing human thrombin in the presence or absence of human fibrinogen would decrease the incidence of antithrombin and anti-factor V antibodies.⁷⁰

Autoantibodies to thrombin are rare. However, the mechanisms of action of antithrombin antibodies have been studied extensively because of the wealth of information about thrombin structure and function.⁷⁴⁻⁷⁷ In contrast, approximately half of the 105 cases of inhibitory anti-factor V antibodies reported and reviewed between 1955 and 1997 appeared to be autoantibodies not associated with the exposure to bovine thrombin products.⁷² β -Lactam antibiotics also are associated with anti-factor V autoantibodies and may partly explain the increased incidence with surgery. In approximately 20 percent of cases of autoantibody formation, no underlying disease was identified. Anti-factor V autoantibodies have been identified rarely in patients with autoimmune diseases, solid tumors, and monoclonal gammopathies. In addition to autoantibody formation, alloantibodies to factor V have developed in patients with severe factor V deficiency in response to replacement therapy with fresh-frozen plasma.

Patients with inhibitory antibodies to factor V have prolonged prothrombin and aPTT, low factor V levels, and a normal thrombin time. The diagnosis of a factor V inhibitor is based on the specific loss of factor V coagulant activity when patient and normal plasma are mixed in a coagulation assay. The antibody titer can be defined as in the factor VIII Bethesda assay as the dilution of test plasma that produces 50 percent inhibition of factor V activity.

Not all patients with factor V inhibitors have hemorrhagic manifestations. Factor V inhibitors anecdotally produce a less serious bleeding disorder than factor VIII inhibitors. The relationship between inhibitor titer and bleeding has not been studied. The reported incidence of bleeding has been higher in patients with autoantibodies to factor V compared to anti-factor V antibodies in patients receiving bovine thrombin. However, this may reflect a bias resulting from the reason the patient sought medical attention.

Factor V contains an A1-A2-B-A3-C1-C2 domain structure that is homologous to factor VIII. Also, like factor VIII, the N-terminal half of the factor V C2 domain contains a phospholipid-binding site⁷⁸ that is necessary for normal procoagulant function⁷⁹ and is targeted by factor V inhibitors.^{80,81}

ANTI-PROTHROMBIN ANTIBODIES

Antiprothrombin antibodies are most commonly associated with the antiphospholipid syndrome. The antiphospholipid syndrome is caused by lupus anticoagulants, which are defined as antibodies that produce phospholipid-dependent prolongation of *in vitro* coagulation assays. Anionic phospholipids participate as cofactors for the lupus anticoagulant binding to protein antigens, primarily β_2 -glycoprotein I⁸² and prothrombin.⁸³ The antibody-antigen complexes compete for the binding of coagulation factors to the phospholipid present in coagulation assays and produce the lupus anticoagulant phenomenon.

The role of prothrombin in the generation of lupus anticoagulant activity initially was suggested from studies of a bleeding patient with severe hypoprothrombinemia. However, in the absence of hypoprothrombinemia, lupus anticoagulants do not produce a bleeding diathesis and bleeding in patients with lupus anticoagulants is uncommon.⁸⁴ Antiprothrombin antibodies are associated with an increased incidence of thrombosis in these patients.⁸⁵ In patients with antiprothrombin antibodies and hypoprothrombinemia, precipitating, noninhibitory antibodies are present and prothrombin antigen levels are low, indicating that the hypoprothrombinemia is the result of rapid clearance of antigen-antibody complexes.⁸⁶ However, most patients with lupus anticoagulants have demonstrable antiprothrombin antibodies but do not have hypoprothrombinemia.⁸⁷ Thus, antibody-mediated hypoprothrombinemia appears to represent a relatively uncommon evolution of the autoimmune response to prothrombin in patients with lupus anticoagulants.

ANTIBODIES TO COMPONENTS OF THE PROTEIN C SYSTEM

An acquired inhibitor to protein C associated with a fatal thrombotic disorder has been reported,⁸⁸ but evidently is rare. In contrast, there is a relatively high prevalence of pathogenic anti-protein S antibodies. Inhibitory antibodies to protein S were detected in five of 15 patients with acquired protein S deficiency.⁸⁹ Anti-protein S antibodies, but not antibodies to cardiolipin, β_2 -glycoprotein I, prothrombin, or protein C, appear to be a risk factor for acquired activated protein C (APC) resistance, defined as APC resistance in the absence of the factor V Leiden mutation, and for deep venous thrombosis.⁹⁰ Additionally, antibodies to the endothelial cell protein receptor have been identified that are associated with fetal death in patients with the antiphospholipid syndrome.⁹¹

ACQUIRED ANTIBODIES TO OTHER COAGULATION FACTORS

Clinically significant antibodies to coagulation factors other than factor VIII, factor V, and prothrombin that produce acquired bleeding disorders are sufficiently rare that they merit case reports, which are only incompletely listed here. In contrast to acquired hemophilia A, acquired hemophilia B is extremely rare.^{92,93} Patients with antifibrinogen antibodies have been identified either who are asymptomatic with abnormal laboratory values⁹⁴ or who have abnormal bleeding.⁹⁵ Patients with abnormal bleeding associated with acquired inhibitors to factor VII,⁹⁶ factor X,⁹⁷ factor XI,⁹⁸ or factor XIII^{98–107} also have been described. The development of alloantibodies against von Willebrand factor occurs in patients with type 3 von Willebrand disease in response to treatment with plasma concentrates that contain von Willebrand factor.¹⁰⁸ Acquired von Willebrand disease can be caused by adsorption of von Willebrand factor to tumor cells, loss of high-molecular-weight von Willebrand factor multimers as well as by autoantibodies to von Willebrand factor.¹⁰⁹

CHAPTER 128

HEMOSTATIC ALTERATIONS IN LIVER DISEASE AND LIVER TRANSPLANTATION

Frank W.G. Leebeek and Ton Lisman

SUMMARY

In patients with acute liver failure or chronic liver disease, many changes in the hemostatic system occur. The liver is the site of synthesis of nearly all coagulation factors, both pro- and anticoagulant proteins. A reduced synthesis function of the liver will lead to reduced levels of these factors in circulation. In addition, the liver is involved in the clearance of many activated coagulation factors and protein-inhibitor complexes from the circulation, which, in turn, can lead to activation of the coagulation system if liver function is impaired. Furthermore, the liver is involved in the synthesis and clearance of pro- and antifibrinolytic proteins, which may lead to a shift in the balance of the fibrinolytic system. Also primary hemostasis might be affected in liver disease because of thrombocytopenia and impaired platelet function, which is frequently encountered in these patients. It is evident that patients with liver disease have frequent bleeding episodes, mainly in the gastrointestinal tract, such as variceal bleeding. It has been a longstanding dogma that patients with liver disease are at a high risk of bleeding caused by the above mentioned hemostatic changes. However, in recent years this cause of the bleeding tendency has been questioned because of the concomitant reductions of pro- and anticoagulant factors and pro- and antifibrinolytic factors. More recent studies using more sophisticated coagulation tests showed that thrombin generation is normal in patients with chronic liver failure and that some may even have a prothrombotic phenotype. This led to the development of a model of a rebalanced hemostatic system in these patients, which may have immediate implications for treatment. Hematologists and other clinicians taking care of patients with acute liver failure or chronic liver disease, such as cirrhosis, are still faced with the questions whether these patients need correction of the changes in hemostasis before interventions such as paracentesis, biopsies, dental care, and surgery. It was generally believed that replacement therapy with frozen plasma or prothrombin complex concentrate was indicated. However, based on these new findings, physicians should now be more restrictive in the use of hemostatic agents and blood products in these patients both in liver disease and during liver transplantation.

Acronyms and Abbreviations: ADAMTS13, a disintegrin-like and metalloprotease with thrombospondin domain 13; aPTT, activated partial thromboplastin time; DDAVP, 1-deamino-8-D-arginine vasopressin; DIC, disseminated intravascular coagulation; FFP, fresh-frozen plasma; HAT, hepatic artery thrombosis; INR, international normalized ratio; ISI, international sensitivity index; MELD, model of end-stage liver disease; PAI-1, plasminogen activator inhibitor 1; PFA, platelet function analyzer; PT, prothrombin time; PVT, portal vein thrombosis; TAFI, thrombin-activatable fibrinolysis inhibitor; t-PA, tissue-type plasminogen activator; VWF, von Willebrand factor.

The liver plays a central role in the hemostatic system. Liver parenchymal cells are the site of synthesis of most coagulation factors (except factor VIII), the natural inhibitors of coagulation, including protein C, protein S, and antithrombin, and essential components of the fibrinolytic system, such as plasminogen, α_2 -antiplasmin, and thrombin activatable fibrinolysis inhibitor (TAFI). The liver also regulates hemostasis and fibrinolysis by clearing activated coagulation factors and coagulation factor-inhibitor complexes from the circulation. In addition, changes in primary hemostasis mediated by platelets, von Willebrand factor (VWF) and ADAMTS13 (a disintegrin-like and metalloprotease with thrombospondin type 1 repeats) may occur. Therefore, when acute or chronic liver dysfunction is present in patients with liver disease, complicated hemostatic derangement may occur, which can lead to bleeding, thrombosis, or neither bleeding nor thrombosis.

HEMOSTATIC ALTERATIONS IN CHRONIC LIVER DISEASE

PRIMARY HEMOSTASIS

More than 75 percent of patients with chronic liver disease, especially in moderate to severe cirrhosis (Child B and C) have reduced levels of platelets ($<150,000/\mu\text{L}$) and 13 percent have platelet counts between 50,000 and 75,000/ μL .¹ This may be caused by splenomegaly resulting in sequestration of platelets in the spleen, reduced synthesis of thrombopoietin by the diseased liver, or consumption coagulopathy.²⁻⁵ In addition, it has been suggested that autoantibodies against platelets may reduce the half-life of platelets in cirrhosis.⁶ Primary hemostasis may also be defective by a reduced platelet function. *In vitro* platelet aggregation studies in response to various agonists is frequently diminished in patients with liver disease. Defective platelet function may result from impaired signal transduction, acquired storage pool deficiency, proteolysis of platelet membrane proteins, and increased production of the endothelial-derived platelet inhibitors, nitric oxide and prostacyclin. (reviewed in Ref. 7). A reduced hematocrit may contribute to defective platelet-vessel wall interaction. Platelet adhesion defects were also found under conditions of flow, but were in some studies attributed to thrombocytopenia and a low hematocrit.⁸⁻¹⁰ Platelet procoagulant activity measured by a thrombin generation assay using platelet-rich plasma was similar in patients and healthy controls, which casts additional doubt on the extent of the functional defects of platelets in patients with liver disease.¹¹

VWF antigen levels are strongly elevated in patients with liver disease. It has been suggested that this is the result from endothelial damage possibly mediated by endotoxemia (bacterial infection).^{12,13} VWF mRNA and protein expression in the liver itself are substantially increased in cirrhosis, but VWF ristocetin cofactor activity is variable.^{10,14-16} The high levels of VWF may ameliorate the hemostatic defect caused by thrombocytopenia and platelet function defects.¹³ In a flow-based model, platelet adhesion to collagen was normalized in thrombocytopenia because of the high levels of VWF in cirrhotic plasma. In patients with liver disease the regulation of VWF multimer size and activity can be impaired because of reduced synthesis of the VWF-cleaving protease ADAMTS13 by stellate cells in the liver.¹⁷ Several studies showed, however, that the most active high-molecular-weight multimers of VWF are diminished in plasma of patients with cirrhosis, which may be mediated by plasmin or other proteases.^{18,19} Classical tests of primary hemostasis, such as bleeding time, which is becoming obsolete as a result of its assay-variability and inability to predict bleeding, may still be abnormal in patients with liver disease. Also newer global tests of primary hemostasis, such as platelet function analyzer (PFA), show prolonged closure times with various agonists, but its value in prediction of bleeding in liver disease is unknown.²⁰

SECONDARY HEMOSTASIS: COAGULATION AND ANTICOAGULATION

The liver is the site of synthesis of most procoagulant proteins. As a result, decreased levels of coagulation factors II, V, VII, IX, X, and XI are commonly observed in patients with liver failure.²¹ In contrast, factor VIII levels are increased, which may be related to the elevated level of its carrier protein VWF and to decreased clearance of factor VIII from the circulation by the liver low-density lipoprotein-related receptor.¹⁴ Factor VIII is synthesized primarily in hepatic sinusoidal endothelial cells, whose function is preserved in liver disease.^{14,22} Acquired vitamin K–dependent carboxylation deficiency may lead qualitative defects in coagulation factors. Because of vitamin K deficiency or decreased production of gamma-glutamyl carboxylase, circulating vitamin K–dependent coagulation factors II, VII, IX, and X may be deficient in γ -carboxylated glutamic acid residues in their GLA domains, giving rise to impaired function of these factors.²³ On the other hand, levels of anticoagulant protein C, protein S, antithrombin, heparin cofactor II, and α_2 -macroglobulin are also decreased in patients with liver disease.²⁴ Fibrinogen levels are frequently in the normal range in patients with chronic liver disease, but may be decreased in patients with decompensated cirrhosis or acute liver failure.²⁵ A qualitative defect in fibrinogen may be found in patients with liver disease.²⁶ Screening tests of coagulation, such as the prothrombin time (PT) or activated partial thromboplastin time (aPTT), are frequently prolonged in patients with chronic liver disease. These results have been traditionally interpreted to reflect a hypocoagulable state. The PT and aPTT are sensitive to levels of procoagulant proteins in plasma, but not to the natural anticoagulants, proteins C, protein S, and antithrombin. The use of a more sophisticated test of coagulation, such as total thrombin generation test, illustrates the limitation of the PT and aPTT. In a thrombin-generation test measuring the total amount of thrombin generated during coagulation, decreased total thrombin generation is measured in patients with cirrhosis compared to controls.^{11,27,28} Yet, when measured in the presence of thrombomodulin to enable protein C activation and thereby also taking into account the contribution of the main inhibitor of coagulation protein C, thrombin generation was indistinguishable from controls, despite abnormal conventional coagulation tests. Others found normal thrombin generation without addition of thrombomodulin and even increased thrombin generation with addition of thrombomodulin.^{29,30} These results suggest that thrombin generation *in vivo* can be normal in patients with liver failure, and that a prolonged PT does not per se indicate a bleeding risk. These findings indicate that a concomitant decrease of pro- and anticoagulant factors result in a rebalanced hemostatic system.³¹

Despite the limitations of the use of the PT in patients with liver disease the international normalized ratio (INR), which is a derivative of the PT, is still used in prognostic scores for patients with acute or chronic liver disease. The model of end-stage liver disease (MELD) score is used to prioritize patients for liver transplantation. The INR was originally developed and validated only to monitor anticoagulant therapy with vitamin K antagonists. The interlaboratory variation of the INR in patients with liver disease is substantial, and its use results in significant differences in MELD scores when a single patient sample is tested in different laboratories using various PT reagents.^{32,33} The use of alternative international sensitivity index (ISI) values obtained by calibration against plasma samples from patients with liver disease was shown to decrease this variability.^{34,35}

FIBRINOLYSIS

Except for tissue-type plasminogen activator (t-PA) and plasminogen-activator inhibitor (PAI)-1, all proteins involved in fibrinolysis, both

pro- and antifibrinolytic, are synthesized by the liver.³⁶ Therefore, chronic liver disease leads to decreased plasma levels of plasminogen, α_2 -antiplasmin, TAFI, and factor XIII. Plasma levels of t-PA are elevated as a result of increased secretion from endothelial cells and/or reduced clearance by the diseased liver. Plasma levels of PAI-1 also are increased but not to the same extent as t-PA, which may lead to a shift in balance in the fibrinolytic system.³⁷ It has long been assumed that most patients with chronic liver disease had accelerated fibrinolysis. This was based on *in vitro* assays, including various clot lysis assays and on measurements of increased fibrin(ogen) degradation products, D-dimer and plasmin–antiplasmin complexes (reviewed in Ref. 36). However, more recent studies found no evidence of hyperfibrinolysis in the majority of patients with cirrhosis despite decreased levels of TAFI and elevated D-dimer levels.^{38,39} This conclusion was recently challenged by a study that used two assays to detect fibrinolysis in patients with various degrees of severity of cirrhosis. In both tests approximately 40 percent of patients had evidence of hyperfibrinolysis, and in 60 percent of the patients, one of the tests revealed an increased fibrinolytic capacity, especially in those with severe liver dysfunction.⁴⁰ Hyperfibrinolysis in patients with cirrhosis may also occur secondary to low-grade disseminated intravascular coagulation (DIC) induced by endotoxemia and is manifested by concomitant increased levels of prothrombin fragment 1+2, fibrinopeptide A, D-dimer, thrombin–antithrombin complex, and plasmin–antiplasmin complex.⁴¹ However, it has been argued that the increased levels of these markers may result from their decreased clearance by the liver rather than from DIC. In patients with liver disease who presented with gastrointestinal bleeding or soft-tissue bleeding after trauma, *in vitro* signs of increased fibrinolysis have been reported.^{42,43}

● A REBALANCED HEMOSTATIC SYSTEM IN CHRONIC LIVER DISEASE

It has been a longstanding dogma that patients with liver disease are at a high risk of bleeding due to reduction of synthesis of coagulation factors and other changes in hemostasis. More recent studies using more sophisticated coagulation tests have shown that thrombin generation is normal in patients with chronic liver failure and that some may even have a prothrombotic phenotype.^{24,27,44} Because both procoagulant and anticoagulant proteins decline in patients with chronic liver diseases, it has been postulated that the hemostatic system is rebalanced (Table 128-1).^{24,31,45} In addition reductions of platelet number and impairment of platelet function is counteracted by high levels of VWF and in many patients the decline in profibrinolytic factors is balanced by the reduction of inhibitors of fibrinolysis.^{13,38} This led to the model of a rebalanced hemostatic system in these patients, which has important implications for treatment.^{24,31} This model also explains why most patients with liver disease usually do not exhibit severe bleeding manifestations—neither during minor invasive procedures, such as biopsies and paracentesis, nor during major surgeries, including liver transplantation.^{46,47} Furthermore, patients with liver disease may even have increased risk of venous thromboembolism, not only liver-specific thrombosis, but also deep vein thrombosis.⁴⁸⁻⁵⁰ The hemostatic balance in patients with liver disease is, however, quite delicate and vulnerable to be tipped toward bleeding or thrombosis. So far it is impossible to identify which patients are more prone to bleeding or to thrombosis based on current laboratory assays. The complex changes in hemostasis encountered in patients with liver disease are depicted in Table 128-1. The delicate hemostatic balance in patients with liver disease may be changed by comorbidities, such as bacterial infections and renal failure frequently observed in these patients. It is of major importance to treat these comorbidities so as to reduce the risk of bleeding and thrombosis.⁵¹

TABLE 128–1. Changes in the Hemostatic System in Patients with Liver Disease That Contribute to Bleeding (Left) or Contribute to Thrombosis (Right)

Changes That Impair Hemostasis	Changes That Promote Hemostasis
PRIMARY HEMOSTASIS	
Thrombocytopenia	Elevated levels of VWF
Platelet function defects	Decreased levels of ADAMTS13
Enhanced production of nitric oxide and prostacyclin	
SECONDARY HEMOSTASIS	
Low levels of factors II, V, VII, IX, X, and XI	Elevated levels of factor VIII
Vitamin K Deficiency	Decreased levels of protein C, protein S, antithrombin, α_2 -macroglobulin, and heparin cofactor II
Dysfibrinogenemia	
FIBRINOLYSIS	
Low levels of α_2 -antiplasmin, factor XIII, and TAFI	Low levels of plasminogen Increase in PAI-1 levels
Elevated t-PA levels	

ADAMTS13, a disintegrin-like and metalloprotease with thrombospondin domain 13; PAI-I, plasminogen activator inhibitor 1; TAFI, thrombin-activatable fibrinolysis inhibitor; t-PA, tissue-type plasminogen activator; VWF, von Willebrand factor.

HEMOSTATIC ALTERATIONS IN ACUTE LIVER FAILURE

Patients presenting with acute liver failure, for instance in acetaminophen intoxication, have profound changes in the hemostatic system. A severe decrease of coagulation factors is observed, with strongly increased INR.⁵² However, an intact thrombin generation has been observed in acute liver failure patients and hardly any changes were observed using thromboelastography.^{53,54} In contrast to chronic liver disease, patients with acute liver failure frequently have normal platelet counts. Highly elevated levels of VWF are observed and strongly decreased levels of ADAMTS13. This imbalance may lead to a prothrombotic state.⁵⁵ In patients with acute liver failure, there is an increased level of PAI-1, and reduced levels of plasminogen which is consistent with a hypofibrinolytic state.^{53,56} A strong increase of procoagulant microparticles has been observed in acute liver failure.⁵⁷ Spontaneous bleeding is not frequently encountered in patients with acute liver failure.⁵⁸

HEMOSTATIC ALTERATIONS DURING LIVER TRANSPLANTATION

Liver transplantation performed in patients in acute or chronic liver failure has always been complicated by significant and sometimes life-threatening bleeding problems requiring massive use of coagulation factors and erythrocyte transfusion.⁵⁹ Therefore blood products were also transfused before and during transplantation to correct the hemostatic dysfunction. Improved surgical techniques and anesthesiologic care have led to a remarkable reduction of blood loss during liver transplantation. Currently, no blood transfusion is given in up to

50 to 80 percent of patients undergoing a liver transplantation, depending on the center.^{60,61} This improvement is also because of a better understanding of the coagulation profile during the various stages of the surgical intervention. During the first stage of liver transplantation, the removal of the diseased liver, no significant worsening of the preoperative hemostatic status occurs.⁶² After removal of the diseased liver, the so-called anhepatic stage, significant hemostatic changes occur. Because activated coagulation factors are not cleared from the circulation, DIC can develop, with consumption of platelets and coagulation factors and secondary hyperfibrinolysis. Moreover, hyperfibrinolysis may also occur as a result of defective clearance of t-PA.⁶³ The most severe hemostatic changes during liver transplantation occur immediately after reperfusion of the donor liver. Platelets are trapped in the graft, giving rise to an aggravation of thrombocytopenia and causing damage to the graft by induction of endothelial cell apoptosis.⁶⁴ Release of tissue factor and t-PA from the reperfused graft causes DIC with primary or secondary fibrinolysis.⁶⁵ Moreover, the graft also releases heparin-like substances that can inhibit coagulation.⁶⁵ In addition, other factors such as hypothermia, metabolic acidosis, and hemodilution adversely affect hemostasis during this phase.

During transplantation, the balance between VWF and ADAMTS13 changes because levels of VWF remain high, the functional properties of VWF improve, and the levels of ADAMTS13 decline, which may partially compensate for the hemostatic dysfunction.⁶⁶ The platelet count and hemostatic proteins are at their nadir after reperfusion and rise gradually during the early postoperative period. However, the levels of procoagulant factors rise more rapidly than the levels of anticoagulant factors, which results in a temporary hypercoagulable state.⁶⁷ A transiently increased level of PAI-1 immediately after surgery can result in a hypofibrinolytic state that may aggravate the hypercoagulable status.

CLINICAL PROBLEMS ENCOUNTERED IN PATIENTS WITH LIVER DISEASE

BLEEDING IN PATIENTS WITH LIVER DISEASE

Although sophisticated hemostatic tests have now shown that disorders of primary hemostasis, a hypocoagulable status, and hyperfibrinolysis are generally not encountered or are only seen in a minority of patients with chronic liver disease, bleeding still may occur in these patients.²⁴ This is because individual patients still may have a compromised hemostatic function or because patients bleed for nonhemostatic reasons.⁶⁸ The most severe bleeding manifestation in patients with liver disease is bleeding from ruptured esophageal varices. This results from local vascular abnormalities and portal hypertension and not from deranged hemostasis. Occasionally, impaired hemostasis does cause easy bruising, purpura, epistaxis, gingival bleeding, menorrhagia and gastrointestinal bleeding. Also in acute liver failure bleeding has frequently been reported in the past, but more recent studies clearly indicate that spontaneous bleeding occurs rarely.⁵⁸

HEMOSTATIC MANAGEMENT OF PATIENTS WITH LIVER DISEASE

Hemostatic Management of Bleeding Episodes

Variceal bleeding in patients with liver disease should be immediately managed by local interventions, such as endoscopy and rubber band ligation or even shunt (transjugular intrahepatic portosystemic shunt [TIPS]) placement.⁶⁹ Fluid resuscitation should be given in case of hypotension and restricted blood transfusion in case of severe drop of hemoglobin level.⁷⁰ Because there is no evidence that changes in hemostasis are associated with the risk of variceal bleeding, treatment with coagulation factor concentrates is not indicated.

Infusion of plasma may even lead to more bleeding as a result of an increase of portal pressure.^{71,72} Upper gastrointestinal bleeding from peptic ulcer disease also occurs frequently in patients with liver disease. Infusion of recombinant factor VIIa did not result in reduction of blood loss or mortality in randomized clinical studies in patients with upper gastrointestinal bleeding and is not indicated.⁷² Recently the use of hemostatic powder was used in patients who did not respond to other measures and was successfully used in some cases, but its value should be tested in larger randomized studies before it will be registered and can be recommended in this setting.^{73,74} The most important intervention is to prevent variceal bleeding by prophylactic measures, such as rubber band ligation.

Minor bleeding, including bruising, purpura and gingival bleeding occur more frequently in patients with liver disease, but do not always need treatment, or can be managed by local measures. Mucocutaneous bleeding, such as epistaxis, can be treated with fibrinolysis inhibitors, for instance tranexamic acid, and menorrhagia by oral contraceptives. In case of bleeding in patients with severe thrombocytopenia ($<50,000/\mu\text{L}$) platelet transfusion should be given, as would also be indicated in patients without underlying liver disease.

Hemostatic Management Before Interventions and Surgical Procedures

Traditional guidelines have advised not to perform invasive procedures in patients with liver disease when routine hemostatic tests are abnormal unless they are corrected by blood products or pharmacologic prohemostatic agents. The rationale for such a prophylactic approach has been questioned for several reasons. First and most important because abnormal coagulation tests in patients with liver disease are not necessarily associated with a bleeding risk.²⁴ As mentioned before, these results have been traditionally interpreted to reflect a hypocoagulable state, but appeared to have no impact on the bleeding risk after invasive procedures.⁷⁵⁻⁷⁷ For instance, in a large prospective study there was no evidence that prolongation of the INR was associated with bleeding after large-volume paracentesis in patients with liver disease and ascites.⁷⁵ Furthermore normalization of traditional coagulation tests is rarely achieved by infusion of plasma products and the efficacy of prophylactic treatment has not been proven.^{78,79} In addition, transfusion of blood products carry a substantial risk of allergic reactions, volume overload and potential transmission of pathogens.⁸⁰ Consequently, the current guideline of the American Association for the Study of Liver Diseases (AASLD) do not recommend the routine use of fresh-frozen plasma (FFP) transfusion for prophylactic correction of an abnormal PT before interventions, such as liver biopsy,⁸¹ whereas other guidelines advise the use of FFP with low grade of evidence.⁸² Vitamin K is generally recommended in patients with liver disease and prolonged INR, however its clinical benefit has been questioned.⁸³

Thrombocytopenia in patients with cirrhosis is often mild and does not cause spontaneous bleeding or bleeding following minimally invasive procedures. There is little evidence that tests showing platelet dysfunction, including prolonged bleeding time or closure time measured with the PFA-100 predict bleeding in patients with cirrhosis. Nevertheless, an early study showed that a prolonged bleeding time was associated with a fivefold increase in the risk of bleeding after liver biopsy.⁸⁴ Although shortening of the bleeding time was achieved by administration of 1-deamino-8-D-arginine vasopressin (DDAVP) in patients with liver disease,⁸⁵ no effect of DDAVP was observed in patients with bleeding from esophageal varices or on the blood loss in patients undergoing hepatectomy⁸⁶ or liver transplantation.⁸⁷ Although this has not been addressed in many studies yet, it has been shown that bleeding complications during interventional procedures are associated with a low preprocedural platelet count.^{88,89} If platelet counts are below

$50 \times 10^9/\text{L}$, platelet transfusion is recommended before any intervention, as in other patients without underlying liver disease.⁹⁰ In case of neurosurgical interventions platelets should be transfused up to a level of $100 \times 10^9/\text{L}$.⁹¹ A novel strategy to improve primary hemostasis in patients with hepatitis C is the administration of a thrombopoietin analogue (Eltrombopag). In the ELEVATE study, a short course of Eltrombopag was used to elevate the platelet count prior to invasive procedures. Use of Eltrombopag was associated with a higher rate of thrombosis, but no difference in bleeding was observed in this study, which may be related to the highly elevated VWF levels in patients with liver disease.^{92,93} Eltrombopag is not indicated for the treatment of thrombocytopenia in patients with chronic liver disease before surgical interventions.

In individuals with generalized mucosal bleeding symptoms, which may be indicative of disorders of primary hemostasis or hyperfibrinolysis, treatment with fibrinolysis inhibitors such as tranexamic acid after the procedure should be considered.^{68,89} Tranexamic acid is also advised in case of dental extractions because of the high fibrinolytic activity in the oral mucosa.

The use of fibrin sealant has been studied to reduce blood loss in patient undergoing liver surgery. Although these products reduce the time to hemostasis when applied on the transected liver surface, no improvement in postoperative complications was observed. Therefore its value in these settings has not yet been established.⁹⁴

Hemostatic Management During Liver Transplantation

For many years excessive blood loss during liver transplantation has been recognized as an important cause of morbidity and mortality; consequently, transfusion of a combination of blood products has been advocated for correction of the hemostatic derangements.⁵⁹ Experiments in experimental animal models have shown that the quality of the graft determines the extent of hemostatic changes following reperfusion.^{59a} Indeed, blood loss following graft reperfusion is substantially increased in recipients of "extended criteria" donor livers (i.e., grafts with poorer quality because of, e.g., elevated donor age or prolonged cold ischemia times).^{59b}

Because prophylactic transfusion of blood products may be associated with serious side effects, many centers have discontinued to attempt to improve hemostatic functions by administration of blood products prior to liver transplantation.⁶⁰ Liver transplantation procedures can now be performed without a requirement for transfusion of blood products in a substantial proportion of patients. One study reported that 79 percent of patients could be transplanted without the use of any blood product, provided the patient's central venous pressure was controlled through restriction of volume replacement, and by using intraoperative phlebotomy during the transplantation.⁶¹ Increased experience and improvements in surgical technique, anesthesiologic care, and better graft preservation methods have contributed to a steady decrease in blood transfusion requirements. When uncontrolled bleeding does occur, packed red cells, platelets, FFP, or fibrinogen concentrate can be transfused guided by laboratory values or thromboelastography.⁹⁵ Hyperfibrinolysis is thought to contribute significantly to impaired hemostasis during the anhepatic and reperfusion phases.⁶³ Use of synthetic antifibrinolytic agents, such as tranexamic acid (a lysine analogue) and aprotinin (a serine protease inhibitor) have reduced red cell and plasma transfusion.^{96,97} Aprotinin was taken off the market in 2008 because of severe adverse events and mortality in patients undergoing cardiac surgery.⁹⁸

THROMBOSIS IN PATIENTS WITH LIVER DISEASE

Deep Vein Thrombosis and Pulmonary Embolism

The reappraisal of changes in the hemostatic system in patients with liver disease has indicated that the coagulopathy of liver disease may not

only reflect a reduced bleeding risk, but may even lead to a prothrombotic state.⁹⁹ Studies indicate that deep vein thrombosis and pulmonary embolism can occur in patients with cirrhosis.^{48,100} A large nationwide population-based case-control study in Denmark indicated that patients with liver disease have a substantially increased risk for venous thromboembolism compared to controls with an odds ratio of 1.7 for patients with cirrhosis, and an odds ratio of 1.9 for patients with other liver diseases.⁴⁸ Between 0.5 and 1.8 percent of all hospitalized patients with cirrhosis developed venous thrombosis. Therefore liver disease should not be considered a contraindication for thromboprophylaxis with low-molecular-weight heparin (LMWH). Thromboprophylaxis is warranted in patients that are immobilized or undergo surgery and in hospitalized patients with active cancer. Treatment of venous thromboembolism in patients with liver disease is difficult, because of a higher risk of bleeding associated with anticoagulant treatment than in healthy individuals, although recent data suggest that therapeutic dose LMWH is safe.^{101–104} This, again, indicates that the balanced hemostatic system in patients with cirrhosis involves a narrow safety margin. Furthermore, the choice of anticoagulant may be difficult. LMWH or unfractionated heparin may be difficult to monitor as a result of low levels of antithrombin. Anti-factor Xa measurement seems to be unreliable in patients with liver disease because of analytical problems.^{102,105} Also monitoring of treatment with vitamin K antagonists is difficult and may not be reliable based on the preexistent prolongation of the PT as a result of the underlying disease.⁴⁴ Considering the lack of studies, it is advised however to maintain the INR between 2.0 and 3.0.²⁴

Portal Vein Thrombosis

Patients with advanced liver disease may develop thrombosis in the portal and mesenteric veins. These complications are not only related to decreased levels of the natural inhibitors of coagulation, antithrombin, protein C, and protein S, but occur also more often in individuals carrying common inherited thrombophilia's such as factor V Leiden mutation and prothrombin G20210A variant.^{106,107} A decreased blood flow in the splanchnic venous circulation because of portal hypertension has also been indicated as a risk factor for portal vein thrombosis (PVT). The prevalence of PVT in patients with cirrhosis increases with the progression of the disease, being less than 1 percent in patients with compensated cirrhosis, and 8 to 25 percent in liver transplantation candidates.^{44,108} Prophylactic treatment of patients with cirrhosis with low-dose of LMWH reduced the risk of PVT and even increased survival.¹⁰¹ The optimal treatment of PVT in cirrhosis patients remains to be established. Although randomized trials are still lacking, treatment with anticoagulants, such as LMWH or vitamin K antagonists may prevent progression of thrombosis and may achieve recanalization in patients with PVT with or without cirrhosis.^{109,110} However not all patients with cirrhosis and PVT will benefit and an individualized approach seems warranted.¹¹¹ Recently the new direct oral anticoagulants have been approved for use in patients with venous thrombosis. Their use is not yet recommended in patients with liver disease, but recently some case reports have been published in patients with splanchnic vein thrombosis.¹¹²

Thrombosis Following Liver Transplantation

Following liver transplantation, both immediate and delayed thrombotic complications frequently occur.¹¹³ Hepatic artery thrombosis (HAT) occurs in 1.6 to 8.9 percent of patients and may lead to graft failure, requiring retransplantation.^{114,115} Thrombosis of the portal vein or inferior caval vein are much less common.¹¹⁶ Although HAT has been considered a surgical complication, recent evidence suggests that excessive coagulation activation or inherited thrombophilia also may contribute to HAT.¹¹⁷ Postoperative use of anticoagulants has been limited

in liver transplant recipients as a result of the perceived bleeding risk. However, thrombotic complications do occur, and liver-related thrombosis in particular, such as HAT and PVT, are of concern as they often lead to graft loss. A single, uncontrolled retrospective study showed aspirin to substantially reduce the risk of posttransplantation HAT, without increase of bleeding.¹¹⁸ Pulmonary emboli and intracardiac thrombosis may occur during liver transplantation, indicating that the hemostatic system may also tip toward thrombus formation during this procedure.¹¹⁹ Whether or not other anticoagulants will prevent postoperative thrombosis remains to be established.

Role of Coagulation in Fibrosis of the Liver

Thrombin, the key mediator of coagulation, also has several cellular effects mediated by protease-activated receptors (PARs). These PARs are expressed on hepatic stellate cells (HSCs), which are mediators of liver fibrosis. Thrombin generation leads to activation of HSCs and fibrogenesis.¹²⁰ Indeed, patients with prothrombotic phenotypes, such as carriers of the factor V Leiden mutation of antithrombin-deficient individuals were shown to have enhanced progression of liver fibrosis in viral hepatitis.^{121,122} In line with these observations, fibrogenesis may be reduced by using anticoagulant treatment, however this has to be established in clinical studies.⁴⁴

CHAPTER 129

DISSEMINATED INTRAVASCULAR COAGULATION

Marcel Levi and Uri Seligsohn

SUMMARY

When procoagulants are produced or introduced into the blood and overcome the anticoagulant mechanisms of coagulation, intravascular thrombin is generated systemically, which can lead to disseminated intravascular coagulation (DIC). The clinical manifestations of intravascular coagulation include (1) multiorgan dysfunction caused by microthrombi; (2) bleeding caused by consumption of platelets, fibrinogen, and other coagulation factors; and (3) secondary fibrinolysis. Exposure of blood to tissue factor is the most common trigger. This event can occur when mononuclear cells and endothelial cells are induced to generate and express tissue factor during the systemic inflammatory response syndrome (e.g., Gram-negative and Gram-positive infections, fungemia, burns, severe trauma), or when contact is established between blood and tissue factor constitutively present on membranes of cells foreign to blood (e.g., malignant, placental, brain, adventitial cells, or traumatized tissues). Laboratory features include thrombocytopenia, reduced levels of fibrinogen and other coagulation factors (leading to prolonged partial thromboplastin, prothrombin, and thrombin times), and elevated levels of D-dimer and fibrin(ogen) degradation products. Several underlying disorders affect these hemostatic parameters and can lead to a false-positive diagnosis of DIC (e.g., liver disease–related coagulation abnormalities and thrombocytopenia) or to a false-negative diagnosis (e.g., pregnancy-related high fibrinogen levels). Reexamining these variables every 6 to 8 hours may permit a specific diagnosis. Early detection, vigorous treatment of the underlying disorder, and support of vital functions are essential for survival of affected patients. Blood component therapy is effective in patients who bleed excessively, whereas heparin administration is indicated in a limited number of circumstances. Intravascular coagulation and the underlying disorders causing it contribute to a high rate of mortality. The severity of the organ dysfunction and extent of hemostatic failure, as well as increasing patient age, have been associated with a grave prognosis.

Acronyms and Abbreviations: APACHE, acute physiology and chronic health evaluation; APC, activated protein C; APL, acute promyelocytic leukemia; aPTT, activated partial thromboplastin time; ARDS, adult respiratory distress syndrome; AT, antithrombin; DIC, disseminated intravascular coagulation; EPCR, endothelial protein C receptor; FDP, fibrinogen degradation product; HELLP, hemolysis, elevated liver enzymes, low platelet count; IL, interleukin; LCAD, long-chain acyl-coenzyme A dehydrogenase; LPS, lipopolysaccharide; PAI, plasminogen-activator inhibitor; PAR, protease-activated receptor; TAFI, thrombin-activatable fibrinolysis inhibitor; TAT, thrombin–antithrombin; TF, tissue factor; TFPI, tissue factor pathway inhibitor; TNF, tumor necrosis factor; t-PA, tissue-type plasminogen activator.

DEFINITION AND HISTORY

Disseminated intravascular coagulation (DIC) is a clinicopathologic syndrome in which widespread intravascular coagulation occurs as a result of exposure or production of procoagulants insufficiently balanced by natural anticoagulant mechanisms and endogenous fibrinolysis. Perturbation of the endothelium in the microcirculation along with stimulated inflammatory cells and release of inflammatory mediators play a key role in this mechanism. DIC may cause tissue ischemia from occlusive microthrombi, and bleeding from the consumption of platelets and coagulation factors and, in some cases, an excessive fibrinolytic response. DIC complicates a variety of disorders, and the complexity of its pathophysiology has made it the subject of a voluminous literature.¹⁻⁷

In 1834, Dupuy reported that injection of brain material into animals caused widespread clots in blood vessels, thus providing the first description of DIC.⁸ In 1865, Trousseau described the tendency to thrombosis, sometimes disseminated, in cachectic patients with malignancies.⁹ In 1873, Naunyn showed that disseminated thrombosis could be evoked by intravenous injection of dissolved red cells, and Wooldridge demonstrated that the procoagulant involved was a substance contained in the stroma of the red cells.¹⁰⁻¹²

In 1955, Ratnoff and associates described the hemostatic abnormalities, which we would currently classify as DIC, that occur in women with fetal death or amniotic fluid embolism.¹³ The mechanism by which DIC can lead to bleeding was clarified only in 1961, when Lasch and coworkers introduced the concept of consumption coagulopathy, and McKay established that DIC is a pathogenetic feature of a variety of diseases.¹⁴ Sizable series of cases were first described in the late 1960s, following the introduction of defined laboratory criteria for DIC.¹⁵ Yet despite the vast experience that has been accumulated, DIC still constitutes a major clinicopathologic and therapeutic challenge.

PATHOLOGY

Diffuse multiorgan bleeding, hemorrhagic necrosis, microthrombi in small blood vessels, and thrombi in medium and large blood vessels are common findings at autopsy, although patients who had unequivocal clinical and laboratory signs of DIC may not have had confirming postmortem findings.^{16,17} Conversely, some patients in whom clinical and laboratory signs were not consistent with DIC had typical autopsy findings.^{18,19} This occasional lack of correlation among clinical, laboratory, and pathologic findings is partly a result of extensive postmortem changes in the blood, for example, excessive fibrinolysis, but remains unexplained in most instances.¹⁷ Organs most frequently involved by diffuse microthrombi are the lungs and kidneys, followed by the brain, heart, liver, spleen, adrenal glands, pancreas, and gut. Specific immunohistologic techniques and ultrastructural analysis have revealed that most thrombi consist of fibrin monomers or polymers in combination with platelets. In addition, involvement of activated mononuclear cells and other signs of inflammatory activation are frequently present.²⁰ In cases of long-lasting DIC, organization and endothelialization of the microthrombi are often observed. Acute tubular necrosis is more frequent than renal cortical necrosis.¹⁶

A significant proportion of patients with chronic DIC have non-bacterial thrombotic endocarditis involving mainly the mitral and aortic valves.¹⁹ Moreover, in a retrospective pathologic study, approximately 50 percent of patients with nonbacterial thrombotic endocarditis had DIC.¹⁸ These heart lesions can be a source of arterial embolization, leading to infarction of the brain, kidneys, and myocardium.

● PATHOGENESIS

INFLAMMATION AND ENDOTHELIUM IN DISSEMINATED INTRAVASCULAR COAGULATION

Various triggers cause an hemostatic imbalance that gives rise to a pro-coagulant state (Fig. 129–1). The most important mediators responsible for this imbalance are cytokines.²¹ There is an extensive crosstalk between coagulation and inflammatory systems, whereby inflammation leads to activation of coagulation, and coagulation stimulates inflammatory activity.²² These interactions are highlighted in sepsis-induced systemic activation of coagulation and inflammation that lead to specific organ dysfunctions.²³ The endothelium of the capillary bed is the most important interface in which the interaction between inflammation and coagulation takes place. Endothelial cells may be a source of tissue factor and can thereby be involved in the initiation of coagulation activation. All physiologic anticoagulant systems and various adhesion molecules that may modulate both inflammation and coagulation are connected to the endothelium. In sepsis, endothelial glycosaminoglycans present in the glycocalyx are downregulated by proinflammatory cytokines, thereby impairing the functions of antithrombin (AT), tissue factor pathway inhibitor (TFPI), leukocyte adhesion, and leukocyte transmigration. Because the glycocalyx also plays a role in other endothelial functions, including maintenance of the vascular barrier function, nitric oxide-mediated vasodilation, and antioxidant activity, all these processes can be impaired in DIC (see “Role of Oxidative Stress and Vasoactive Molecules” below).^{24,25} Moreover, specific disruption of the glycocalyx results in thrombin generation and platelet adhesion within a few minutes.^{26,27}

Figure 129–1. Schematic presentation of pathogenetic pathways involved in the activation of coagulation in disseminated intravascular coagulation (DIC). In DIC, both perturbed endothelial cells and activated mononuclear cells may produce proinflammatory cytokines that mediate coagulation activation. Activation of coagulation is initiated by tissue factor expression on activated mononuclear cells and endothelial cells. In addition, downregulation of physiologic anticoagulant mechanisms and inhibition of fibrinolysis by endothelial cells further promote intravascular fibrin deposition. PAI-1, plasminogen-activator inhibitor type 1.

Endothelial perturbation constitutes a *sine qua non* for most patients with DIC. Following injury or infection, the integrity of the endothelium is compromised, mononuclear cells are activated by cytokine and hormonal signals, additional cytokines and surface receptors are upregulated, procoagulant proteins and platelets are activated, the endothelium changes from an anticoagulant to procoagulant surface, and fibrinolysis is impeded. This sequence of events is typical for the *systemic inflammatory response syndrome* and can lead to microvascular thrombosis with ensuing multiorgan dysfunction and eventually to multiorgan failure.

ROLE OF CYTOKINES AND TISSUE FACTOR

Tissue factor (TF) plays a central role in the initiation of inflammation-induced coagulation in DIC.²⁸ Blocking TF activity completely inhibits inflammation-induced thrombin generation in experimental models of endotoxemia or bacteremia.^{29,30} Most cells constitutively expressing TF are found in tissues not in direct contact with blood, such as the adventitial layer of larger blood vessels. TF becomes exposed to blood upon disruption of the vascular integrity, or when cells present in the circulation, such as monocytes, are triggered to express TF. The *in vivo* expression of TF is dependent on interleukin (IL)-6 generation; inhibition of IL-6, unlike inhibition of other proinflammatory cytokines, completely abrogates TF-dependent thrombin generation in experimental endotoxemia.^{21,31} In severe sepsis, monocytes, stimulated by proinflammatory cytokines, express TF, which leads to systemic activation of coagulation.³² Even in experimental low-dose endotoxemia in healthy subjects, a 125-fold increase in TF mRNA levels in blood monocytes can be detected.³³ A potential alternative source of TF may be endothelial cells, polymorphonuclear cells, and other cell types. It is hypothesized that TF from these sources is shuttled between cells through microparticles derived from activated mononuclear cells.³⁴ However, it is unlikely that cells other than monocytes synthesize TF in substantial quantities.^{32,35} Tumor necrosis factor (TNF)- α and IL-1, also generated during inflammation, impair the physiologic anticoagulant pathways.^{31,36,37}

AMPLIFYING ROLE OF THROMBIN AND PLATELETS

The TF-factor VIIa complex catalyzes the conversion of factor X to Xa, and factor Xa, in turn, forms the prothrombinase complex with factor Va, prothrombin (factor II), and calcium ions, thereby generating thrombin, and converting fibrinogen into fibrin. The TF-factor VIIa complex can also activate factor IX, and factor IXa forms the tenase complex with activated factor VIII and calcium ions, generating additional factor Xa, thereby forming an essential amplification loop of thrombin generation. The assembly of the prothrombinase and tenase complexes are markedly facilitated if a suitable phospholipid surface is available, such as the membrane of activated platelets. In the setting of inflammation-induced activation of coagulation, platelets can be activated directly by endotoxin or by proinflammatory mediators, such as the membrane of platelet-activating factor. Thrombin itself is one of the strongest platelet activators (Chap. 115).

Activation of platelets may also accelerate fibrin formation by another mechanism. The expression of TF on monocytes is markedly stimulated by the presence of platelets and granulocytes in a P-selectin-dependent reaction.³⁸ This effect may be the result of nuclear factor kappa B (NF- κ B) activation induced by binding of activated platelets to neutrophils and mononuclear cells.³⁹ This cellular interaction also markedly enhances the production of IL-1 β , IL-8, monocyte chemoattractant protein (MCP)-1, and TNF- α .⁴⁰

Thrombin generated by the TF pathway amplifies both clotting and inflammation through the following activities: (1) it activates platelets,

giving rise to platelet aggregation and augmenting platelet functions in coagulation; (2) it activates factors VIII, V, and XI, yielding further thrombin generation; (3) it activates proinflammatory factors via protease-activated receptors (PARs); (4) it activates factor XIII to factor XIIIa, which crosslinks fibrin clots; (5) it activates thrombin-activatable fibrinolysis inhibitor (TAFI), making clots resistant to fibrinolysis; and (6) it increases expression of adhesion molecules, such as L-selectin, thereby promoting the inflammatory effects of leukocytes.⁴¹

Paradoxically, at low concentrations, thrombin exhibits both anti-inflammatory and anticoagulant effects because it binds to thrombomodulin and activates protein C to the activated form, which, in turn, downregulates inflammation and serves as an “off switch” for further thrombin generation (Chap. 116).

ROLE OF COAGULATION PROTEASES IN UPREGULATING INFLAMMATION

Coagulation proteases and protease inhibitors not only interact with coagulation proteins, but also with specific cell receptors to induce signaling pathways. In particular, protease interactions that affect inflammatory processes may be important in critically ill patients. Coagulation of whole blood *in vitro* results in a detectable expression of IL-1 β mRNA in blood cells,⁴² and thrombin markedly enhances endotoxin-induced IL-1 activity in culture supernatants of guinea pig macrophages.⁴³ Similarly, clotted blood produces IL-8 *in vitro*.⁴⁴

Factor Xa, thrombin, and fibrin can also activate endothelial cells, eliciting the synthesis of IL-6 and IL-8.^{45,46} Coagulation proteases such as thrombin, factor Xa, and factor VIIa-TF complex induce inflammatory upregulation via leukocyte, endothelial cell, and platelet PAR-1, PAR-2, PAR-3, and PAR-4, which are located on leukocytes, endothelial cells, and platelets.⁴⁷ PARs have an extracellular domain, seven transmembrane domains, and an intracellular domain that is coupled to specific G-proteins that transmit signaling. PAR-1, PAR-3, and PAR-4 are

activated by thrombin through cleavage of a specific aminoterminal bond creating a tethered ligand that activates the receptor. PAR-2 can be cleaved by factor Xa-TF-factor VIIa complex and by other proteases.⁴⁸ Activated PARs then lead through mitogen-activated protein kinase and NF- κ B signaling pathways to cell motility, shape change, proliferation, endogenous secretagogue release, and apoptosis. The activated protein C (APC)-endothelial protein C receptor complex (see “Role of Natural Anticoagulant Pathways” below) appears to be the “off switch” for PAR activation by the proteases. These counterbalances determine the magnitude of coagulation and inflammatory upregulation by PARs. For example, factor VIIa-TF binding to PAR-2 in the lungs is proinflammatory and appears to play a role in acute respiratory distress syndrome (ARDS), raising the possibility that TFPI might be therapeutic in this circumstance.⁴⁹ This finding is consistent with data from animal studies demonstrating that TFPI can protect baboons from a LD100 of *Escherichia coli*, likely by impeding factor VIIa-TF activation of PAR-2 and thereby attenuating release of IL-6 and other proinflammatory agents.

ROLE OF FIBRINOGEN AND FIBRIN

Fibrinogen and fibrin directly influence the production of proinflammatory cytokines and chemokines (including TNF- α , IL-1 β , and MCP-1) by mononuclear cells and endothelial cells.⁵⁰ Fibrinogen-deficient mice display inhibition of macrophage adhesion and less thrombin-mediated cytokine production *in vivo*. The effects of fibrinogen on mononuclear cells seem to be mediated by toll-like receptor-4, which is also the receptor of endotoxin.

ROLE OF NATURAL ANTICOAGULANT PATHWAYS

Procoagulant activity is regulated by three important anticoagulant pathways: AT, the protein C system, and TFPI. In DIC, the function of all three pathways can be impaired (Fig. 129-2).⁵¹

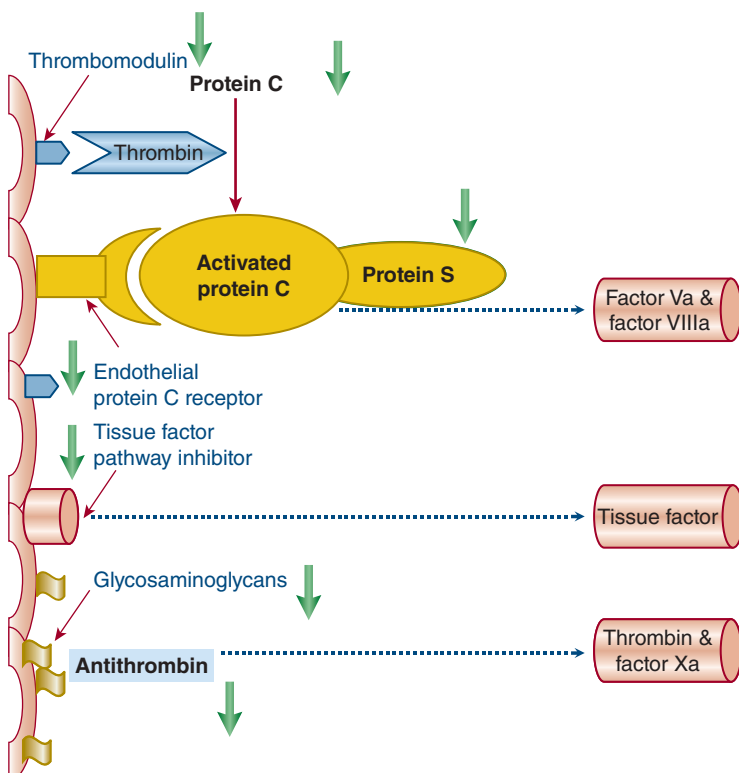

Figure 129-2. Schematic of the three important physiologic anticoagulant mechanisms and their point of impact in the coagulation system. In sepsis, these mechanisms are impaired by various mechanisms (green arrows). The protein C system is dysfunctional as a result of low levels of zymogen protein C, downregulation of thrombomodulin and the endothelial protein C receptor, and low levels of free protein S because of acute phase-induced high levels of its binding protein (i.e., C4b-binding protein). There is a relative insufficiency of the endothelial cell-associated tissue factor pathway inhibitor. The antithrombin system is defective because of low levels of antithrombin and impaired glycosaminoglycan expression on perturbed endothelial cells.

The serine protease inhibitor AT is the main inhibitor of thrombin and factor Xa. Without heparin, AT neutralizes coagulation enzymes in a slow, progressive manner.⁵² Heparin induces conformational changes in AT that result in at least a 1000-fold enhancement of AT activity. Thus, the clinical efficacy of heparin is attributed to its interaction with AT. Endogenous glycosaminoglycans, such as heparan sulfate, also promote on the vessel wall AT-mediated inhibition of thrombin and other coagulation enzymes. During severe inflammatory responses, AT levels are markedly decreased because of impaired synthesis, degradation by elastase from activated neutrophils, and consumption as a consequence of ongoing thrombin generation.⁵³ Proinflammatory cytokines also cause reduced synthesis of glycosaminoglycans on the endothelial surface, thereby reducing AT function.⁵⁴

APC appears to play a central role in the pathogenesis of sepsis and associated organ dysfunction.⁵⁵ There is ample evidence that decreased function of the protein C pathway contributes to the derangement of coagulation in sepsis.^{49,56} The circulating zymogen protein S is activated by thrombin when it is bound to thrombomodulin at the endothelial cell surface.⁵⁷ APC acts with its cofactor protein S and degrades the essential cofactors Va and VIIIa, and hence, is an effective anticoagulant. The endothelial protein C receptor (EPCR) accelerates the activation of protein C several-fold, and also serves as a receptor for APC, thereby augmenting APC's anticoagulant and antiinflammatory activities.⁵⁸

In patients with severe inflammation, the protein C pathway malfunctions at virtually all levels. Plasma levels of the zymogen protein C are decreased because of impaired synthesis, consumption, and degradation by proteolytic enzymes, such as neutrophil elastase.⁵⁹⁻⁶¹ Furthermore, a significant downregulation of thrombomodulin, caused by proinflammatory cytokines such as TNF- α and IL-1, results in diminished protein C activation.^{62,63} Low levels of free protein S may further compromise the function of the protein C system. In plasma, 60 percent of protein S is complexed with a complement regulatory protein, C4b-binding protein (C4bBP), and exhibits no activity. The remaining protein S in plasma is free and functional. It was suggested that increased plasma levels of C4bBP caused by the acute phase reaction in inflammatory diseases results in a relative protein S deficiency, which further contributes to a procoagulant state during sepsis. Indeed, infusion of C4bBP in combination with a sublethal dose of *E. coli* into baboons resulted in a lethal response with severe organ damage because of DIC.⁶⁴

In sepsis, the EPCR is downregulated, which further impairs the function of the protein C pathway.⁶⁵ Sepsis can also cause resistance toward APC because of a substantial increase in factor VIII levels.⁶⁶

A third inhibitory mechanism of thrombin generation involves TFPI, the main inhibitor of the TF-factor VIIa complex and factor Xa. The role of TFPI in the regulation of inflammation-induced coagulation activation is not completely clear. Administration of recombinant TFPI blocks inflammation-induced thrombin generation in humans, and pharmacologic doses of TFPI prevent mortality during systemic infection and inflammation in experimental animals suggesting that TFPI can modulate TF-mediated coagulation.^{67,68}

NATURAL ANTICOAGULANTS AND INFLAMMATION

AT possesses antiinflammatory properties, many of which are mediated by its actions in the coagulation cascade.⁶⁹ By inhibiting thrombin, AT blunts activation of many inflammatory mediators released by platelets and endothelial cells that recruit and activate leukocytes.⁷⁰ At high concentrations, AT also possesses potent antiinflammatory properties that are independent of its anticoagulant activity.⁷⁰ Another effect of AT is the induction of prostacyclin release from endothelial cells.⁷¹⁻⁷³

Prostacyclin inhibits platelet activation and aggregation, blocks neutrophil tethering to blood vessels, and decreases endothelial cell production of various cytokines and chemokines.⁷⁴

AT also interacts directly with leukocytes and lymphocytes. It binds to receptors, such as syndecan-4, on the cell surfaces of neutrophils, monocytes, and lymphocytes, thereby blocking the adhesion of these cells to endothelial cells, their activation and migration. This effect, in turn, ameliorates the severity of capillary leakage and subsequent organ damage.

The protein C system also has an important function in modulating inflammation.^{75,76} Blocking the protein C pathway in septic baboons exacerbates the inflammatory response, and in contrast, administration of APC ameliorates the inflammatory activation upon the intravenous infusion of *E. coli*.⁷⁷ Support for the notion that APC has antiinflammatory properties comes from *in vitro* observations, demonstrating an APC binding site on monocytes, that may mediate downstream inflammatory processes,^{78,79} and from experiments showing that APC can block NF- κ B nuclear translocation, which is a prerequisite for increased proinflammatory cytokine levels and adhesion molecules.⁸⁰ These *in vitro* findings are supported by *in vivo* studies in mice with targeted disruption of the protein C gene. In these mice with genetic deficiencies of protein C, endotoxemia was associated with a more marked increase in proinflammatory cytokines and other inflammatory responses as compared with wild-type mice.^{81,82}

It is likely that the antiinflammatory effects of APC are mediated by the EPCR.⁷⁵ Binding of APC to EPCR influences gene expression profiles of cells by inhibiting NF- κ B nuclear translocation.^{79,80} The EPCR-APC complex itself can translocate from the plasma membrane into the cell nucleus, which may be another mechanism of modulating gene expression, although the relative contribution of this nuclear translocation and cell surface signaling is uncertain.⁵⁶ Like APC, EPCR itself may have antiinflammatory properties. Blocking the EPCR with a specific monoclonal antibody aggravates both the coagulation and the inflammatory response to *E. coli* infusion.⁶⁵

Apart from the effect on cytokine levels, APC causes diminished leucocyte chemotaxis and adhesion to the activated endothelium.⁸³⁻⁸⁵ A localized antiinflammatory effect of APC has been demonstrated in the lung.⁸⁶ One mechanism for this effect may be inhibition of the expression of platelet-derived growth factor in the lung.⁸⁷ Also, APC protects against the disruption of endothelial cell barrier in sepsis.⁸⁸⁻⁹⁰ APC also inhibits endothelial cell apoptosis by a mechanism that seems to be mediated by binding of APC to EPCR and requires PAR-1.^{91,92} Signaling through this pathway can affect Bcl-2 homologue protein, which can inhibit apoptosis, and further suppresses p53, that is a proapoptotic transcription factor.^{93,94}

DYSREGULATION OF FIBRINOLYSIS

In experimental models of DIC, fibrinolysis is initially activated but subsequently inhibited, because of an increased release of plasminogen activator inhibitor-I (PAI-1) by endothelial cells.⁹⁵ These effects are mediated by TNF- α and IL-1.^{96,97} In a study of 69 DIC patients (31 with multiorgan failure), higher levels of tissue-type plasminogen activator (t-PA) antigen and PAI-1 with depressed levels of α_2 -antiplasmin were observed in patients with DIC and multiorgan failure compared to DIC patients without multiorgan failure.⁹⁸ This finding supports the conclusion that fibrinolysis is an important mechanism in preventing multiorgan failure.

Experiments in mice with targeted disruptions of genes encoding components of the plasminogen-plasmin system confirm that fibrinolysis plays a major role in inflammation. Mice with a deficiency of plasminogen activators have more extensive fibrin deposition in

organs when challenged with endotoxin, whereas PAI-1 knockout mice, in contrast to wild-type controls, have no microvascular thrombosis upon endotoxin administration.⁹⁹

TAFI, like PAI-1, may play a role in impeding fibrinolysis and in augmenting formation of microvascular thrombi. Studies in a DIC cohort demonstrated very low levels of TAFI proportionate to thrombin generation in such patients, particularly in those with infection-associated DIC.¹⁰⁰ Hence, TAFI may contribute (along with PAI-1) to microvascular thrombosis-induced ischemia in organs resulting in multiorgan dysfunction.

ROLE OF OXIDATIVE STRESS AND VASOACTIVE MOLECULES

Superoxides and hydroxyl radicals are generated during sepsis and other organ injury states that predispose to DIC. Each is a proinflammatory agent that may lead to recruitment of neutrophils, formation of chemotactic factors, lipid peroxidation, and stimulation of NF- κ B, which induces cytokine upregulation.¹⁰¹ In addition, formation of peroxynitrite by these radicals exacerbates inflammation by (1) deactivating superoxide dismutase, which ordinarily would eliminate these superoxides and other radicals, and (2) exerting damaging effects on deoxyribonucleic acid, nicotinamide adenine dinucleotide, and ATP. For example, evidence indicates that the poor response to pressors in shock-like states associated with DIC may be directly related to their deactivation by superoxides.

Adding further insult, high levels of superoxide impair vascular response to nitrous oxide, thereby creating an imbalance in the signaling to vascular cells. Because of the strategic importance of an intact endothelium for attenuating any microangiopathic process, the most devastating effect of excessive generation of superoxides and associated free radicals may be their role in inducing endothelial apoptosis, which exacerbates capillary leak.¹⁰¹

Vasoactive substances play a critical role in the evolution of DIC. The vasodilatory agent nitric oxide (NO) and the vasoconstrictor endothelin have been measured in experimental rat models of DIC induced by both TF infusion and lipopolysaccharide (LPS) infusion.¹⁰² LPS infusion increased both NO and endothelin remarkably, whereas TF infusion increased NO more than did LPS but did not stimulate endothelin significantly. The differential stimuli–response mechanisms may explain why LPS-induced DIC so prominently displays tissue infarction leading to multiorgan dysfunction (e.g., sepsis) compared to DIC that is predominately induced by TF exposure (e.g., head trauma).

METABOLIC MODULATION OF COAGULATION IN DISSEMINATED INTRAVASCULAR COAGULATION

Because there is a tight relationship between plasma lipoproteins and coagulation, it has been suggested that lipoprotein metabolism modulates coagulation in DIC.¹⁰³ *In vitro* experiments showed that plasma large very-low-density lipoprotein, small very-low-density lipoprotein, intermediate-density lipoprotein, and low-density lipoprotein stimulate activation of coagulation by supporting factor VII activation or by stimulating monocytes to express TF.¹⁰⁴ Lipid infusion potentiates in animals endotoxin-induced coagulation activation, as indicated by increased plasma levels of prothrombin fragments 1 and 2, thrombin–AT III complex, and PAI-1.¹⁰⁵ High-density lipoprotein (HDL) exerts opposite effects. Administration of recombinant HDL (rHDL) ameliorates the inflammatory response, inhibits coagulation, and augments fibrinolysis,¹⁰⁶ as reflected by reduced thrombin generation and increased levels of t-PA antigen following administration of endotoxin.

Endogenous lipid levels may have similar effects. Human subjects with low endogenous HDL-cholesterol plasma levels injected with small doses of endotoxin had a more pronounced increase in markers of coagulation activation in comparison with subjects with high endogenous HDL levels.¹⁰⁷ Also, patients heterozygous for familial hypercholesterolemia whose low-density lipoproteins level is increased were more prone to activation of coagulation upon an inflammatory stimulus.¹⁰⁸

Hyperglycemia and hyperinsulinemia, as seen in type 2 diabetes mellitus and the associated metabolic syndrome, affect hemostasis.^{109–111} In these circumstances, there is a marked decrease of endogenous fibrinolysis because of increased upregulation of plasma levels of PAI-1. Also, a modulatory effect of glucose/insulin on coagulation in an inflammatory setting has been described. Inflammation-induced TF gene expression was elevated in the brain, lung, kidney, heart, liver, and adipose tissues of diabetic mice compared with controls. Administration of insulin to lean mice induced enhanced inflammation-driven TF mRNA in the kidney, brain, lung, and adipose tissue.¹¹² In a hyperglycemic normoinsulinemic study in healthy subjects, there was an increased sensitivity toward endotoxin exhibited by upregulation of TF expression.¹¹³ Strict glucose regulation in critically ill patients improves survival and reduces morbidity that is probably related to a better control of the derangement of coagulation and a faster resolution of coagulation abnormalities.¹⁰³

CONSUMPTION OF HEMOSTATIC FACTORS

The widespread generation of thrombin in DIC induces deposition of fibrin, which leads to the consumption of substantial amounts of platelets, fibrinogen, factors V and VIII, protein C, AT, and components of the fibrinolytic system. This situation results in massive depletion of these components that is further aggravated because of their decreased synthesis by the liver, which frequently is affected in DIC. Depending on the magnitude and nature of component depletion, bleeding, enhanced thrombosis, or both can result. Bleeding can be promoted by fibrinolysis-derived fibrin degradation products (FDPs) that exhibit anticoagulant and antiplatelet aggregation effects (see Fig. 129–1). Microangiopathic hemolytic anemia also occurs as a result of blood cells passing through vessels that are partially occluded by thrombi.

CLINICAL FEATURES

Numerous disorders can provoke DIC, but only a few constitute major causes, as can be inferred from retrospective clinical studies (Table 129–1).¹¹⁴ Infectious diseases and malignant disorders together account for approximately two-thirds of DIC cases in the major series (Table 129–2). Trauma was a major cause of DIC in some series, probably reflecting the specialized nature of the clinical practice in those centers.¹¹⁵

Clinical manifestations are attributable to DIC, the underlying disease, or both (Table 129–3). Bleeding manifestations were common in all series of DIC cases, but considerable variation existed in the relative frequency of shock and of dysfunction of the liver, kidney, lungs, and central nervous system. These variations probably reflect the different nature of the underlying disorders in the respective series.

BLEEDING

Acute DIC frequently is heralded by hemorrhage into the skin at multiple sites.¹¹⁵ Petechiae, ecchymoses, and oozing from venipunctures, arterial lines, catheters, and injured tissues are common. Bleeding also may occur on mucosal surfaces. Hemorrhage may be life-threatening, with massive bleeding into the gastrointestinal tract, lungs, central nervous system, or orbit. Patients with chronic DIC usually exhibit only minor skin and mucosal bleeding.

TABLE 129-1. Clinical Conditions That May Be Complicated By Disseminated Intravascular Coagulation

Infectious diseases
Purpura fulminans
Malignancy
Solid tumors
Leukemias
Trauma
Brain injury
Burns
Liver diseases
Heat stroke
Severe allergic/toxic reactions
Snake bites
Vascular abnormalities/Hemangiomas
Kasabach-Merritt syndrome
Other vascular malformations
Aortic aneurysms
Severe immunologic reactions (e.g., transfusion reaction)
Obstetrical conditions
Abruptio placentae
Amniotic fluid embolism
Preeclampsia/eclampsia
HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome
Sepsis during pregnancy
Acute fatty liver

THROMBOSIS AND THROMBOEMBOLISM

Extensive organ dysfunction can result from microvascular thrombi or from venous and/or arterial thromboembolism (Table 129-4). For example, involvement of the skin can cause hemorrhagic bullae, acral necrosis, and gangrene. Thrombosis of major veins and arteries and pulmonary embolism occur but are rare. Cerebral embolism can complicate nonbacterial thrombotic endocarditis in patients with chronic DIC.

SHOCK

Both the diseases underlying DIC and the DIC itself can cause shock. For example, septicemia and excessive blood loss because of trauma or obstetric complications by themselves can cause shock. Whatever the cause of shock, its advent in cases with DIC is a serious adverse event.

RENAL DYSFUNCTION

Renal cortical ischemia induced by microthrombosis of afferent glomerular arterioles and acute tubular necrosis related to hypotension are the major causes of renal dysfunction in DIC. Oliguria, anuria, azotemia, and hematuria were observed in 25 to 67 percent of cases in all series (see Table 129-3).

LIVER DYSFUNCTION

Hepatocellular dysfunction sufficient to cause jaundice has been reported in 20 to 50 percent of patients with DIC.^{4,115} Infectious diseases and prolonged hypotension contribute to hepatic dysfunction.

CENTRAL NERVOUS SYSTEM DYSFUNCTION

Microthrombi, macrothrombi, emboli, and hemorrhage in the cerebral vasculature all have been held responsible for the nonspecific neurologic symptoms and signs displayed by patients with DIC.¹¹⁶ These manifestations include coma, delirium, transient focal neurologic symptoms, and signs of meningeal irritation. Careful exclusion of causes other than DIC is essential.

PULMONARY DYSFUNCTION

Symptoms and signs of respiratory dysfunction in DIC range from transient hypoxemia in mild cases to pulmonary hemorrhage and ARDS in severe cases.¹¹⁷⁻¹¹⁹ Pulmonary hemorrhage is heralded by hemoptysis, dyspnea, and chest pain. Physical examination reveals rales, wheezing, and occasionally a pleural friction rub. Chest imaging shows diffuse infiltration resulting from excessive intraalveolar hemorrhage. ARDS is characterized by tachypnea, auscultatory silence, hypoxemia, low lung compliance, normal wedge pressure, and “white lungs” on chest images.¹²⁰ It stems from severe damage to the pulmonary vascular endothelium, which permits egress of blood components into the pulmonary interstitium and alveoli. This situation leads to intraalveolar hyaline membrane formation and severe respiratory insufficiency. ARDS can be caused by septic shock, severe trauma, fat embolism, amniotic fluid

embolism, and heat stroke, all of which can also incite DIC. Yet only a fraction of patients with ARDS exhibit signs of DIC. When DIC and ARDS are simultaneously triggered, each aggravates the other. Regardless of the mechanism, ARDS is a serious complication in patients with DIC.

MORTALITY

Both DIC and its underlying disorders contribute to the high mortality rate. Mortality correlates independently with the extent of organ dysfunction,¹¹⁵ the degree of hemostatic failure,¹²¹ and increasing age.¹²² Mortality rates in major series of patients with DIC ranged from 31 to 86 percent,¹²¹⁻¹²⁴ whether or not heparin was administered. Of note, there is a clear correlation between the severity of DIC and the mortality rate.^{121,123,124} In patients with sepsis, the presence of DIC is one of the strongest predictors of 28-day mortality.¹²⁴

TABLE 129-4. Organ Dysfunction Associated with Severe Disseminated Intravascular Coagulation

Organ	Manifestation
Skin	Purpura, bleeding from injury sites, hemorrhagic bullae, focal necrosis, acral gangrene
Cardiovascular	Shock, acidosis, myocardial infarction, cerebrovascular events, thromboembolism in all types and caliber blood vessels
Renal	Acute renal insufficiency (acute tubular necrosis), oliguria, hematuria, renal cortical necrosis
Liver	Hepatic failure, jaundice
Lungs	Adult respiratory distress syndrome, hypoxemia, edema, hemorrhage
Gastrointestinal	Bleeding, mucosal necrosis and ulceration, intestinal ischemia
Central nervous system	Coma, convulsions, focal lesions, bleeding system
Adrenals	Adrenal insufficiency (hemorrhagic necrosis)

LABORATORY FEATURES AND DIAGNOSIS

No single laboratory test is sensitive or specific enough to allow a definite diagnosis of DIC (Table 129-5). However, some sophisticated laboratory tests, for example, thrombin-AT complex, prothrombin fragment 1.2, are sensitive to ongoing activation of coagulation pathways. Determination of soluble fibrin in plasma is one of the best parameters for detection of ongoing DIC¹²⁵⁻¹²⁸; when the concentration is above a defined threshold, a diagnosis of DIC is likely.^{129,130} Most of the other parameters show a sensitivity of 90 to 100 percent for the diagnosis of DIC but have a rather low specificity,¹³¹ and a wide discordance among various assays.¹³² FDPs may be detected by specific enzyme-linked immunosorbent assays or by latex agglutination assays, allowing rapid and bedside determination.¹³³ None of the available assays discriminates

TABLE 129-5. Routine Laboratory Value Abnormalities in Disseminated Intravascular Coagulation

Test	Abnormality	Causes Other Than DIC Contributing to Test Result
Platelet count	Decreased	Sepsis, impaired production, major blood loss, hypersplenism
Prothrombin time	Prolonged	Vitamin K deficiency, liver failure, major blood loss
aPTT	Prolonged	Liver failure, heparin treatment, major blood loss
Fibrin degradation products	Elevated	Surgery, trauma, infection, hematoma
Protease inhibitors (e.g., protein C, AT, protein S)	Decreased	Liver failure, capillary leakage

aPTT, activated partial thromboplastin time, AT, antithrombin; DIC, disseminated intravascular coagulation.

between degradation products of crosslinked fibrin and fibrinogen, a situation that may cause spuriously high results.^{134,135} The specificity of high levels of FDPs is therefore limited and many other conditions, such as trauma, recent surgery, inflammation or venous thromboembolism, are associated with elevated FDPs.

Newly developed tests are aimed at the detection of neoantigens on degraded crosslinked fibrin, one of which detects an epitope related to plasmin-degraded crosslinked γ -chain, associated with D-dimer formation. These tests better differentiate degradation of crosslinked fibrin from fibrinogen or fibrinogen degradation products.¹³⁶ D-dimer level is substantially elevated in patients with DIC, but this poorly distinguishes patients with DIC from patients with venous thromboembolism, recent surgery, or inflammatory conditions.^{133,137}

In routine practice, simple laboratory tests in conjunction with clinical considerations are used for establishing the diagnosis of DIC. The simple tests include platelet count, prothrombin time, fibrinogen level, and fibrin-related markers, such as FDP or D-dimer. Caution should be exercised when using these laboratory parameters in the algorithms described below, because an underlying disease by itself can cause an abnormality. For example, impairment of hemostasis and/or thrombocytopenia unrelated to DIC can arise from hepatic disease and from marrow involvement by leukemia. Impaired hemostasis also may occur normally in the neonatal period. Conversely, the elevated levels of some hemostatic components that are normally observed during pregnancy may obscure the presence of DIC. These limitations in laboratory diagnosis of DIC can be overcome by repeated testing, thereby following the dynamics of the process.

A scoring system utilizing the simple laboratory tests has been developed by the subcommittee on DIC of the International Society on Thrombosis and Haemostasis,¹³⁸ and Table 129-6 summarizes a five-step diagnostic algorithm to calculate a DIC score. Tentatively, a score of 5 or more is compatible with DIC, whereas a score of less than 5 may

TABLE 129-6. Diagnostic Algorithm for the Diagnosis of Overt Disseminated Intravascular Coagulation*

DIC, disseminated intravascular coagulation.

*According to the Scientific Standardization Committee of the International Society of Thrombosis and Haemostasis.¹³⁸

Data from Taylor FBJ, Toh CH, Hoots WK, et al: Towards definition, clinical and laboratory criteria, and a scoring system for disseminated intravascular coagulation. *Thromb Haemost* 86(5):1327–1330, 2001.

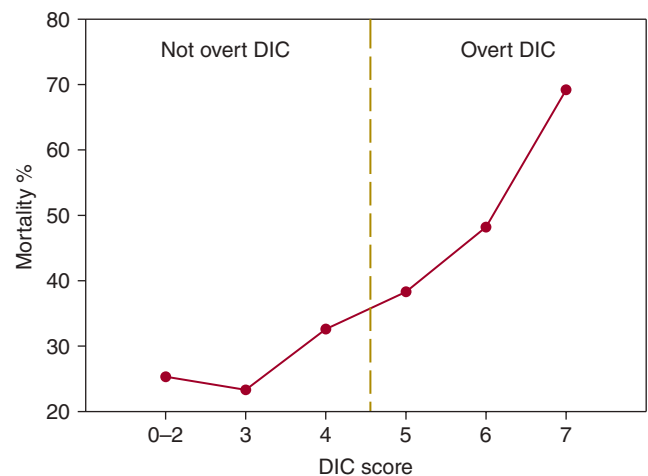

Figure 129-3. Number of points on the International Society of Thrombosis and Haemostasis disseminated intravascular coagulation (DIC) score and 28-day mortality in patients with severe sepsis. Data were derived from the placebo group (n = 840) in the ProWess trial on the efficacy of activated protein C in sepsis.

be indicative but is *not* affirmative for nonovert DIC. By using receiver-operating characteristics curves, an optimal cutoff for a quantitative D-dimer assay was determined, thereby optimizing sensitivity and the negative predictive value of the system.¹³¹ Prospective studies show that the sensitivity of the DIC score is 93 percent, and the specificity is 98 percent.¹²³ The severity of DIC according to this scoring system is related to the mortality in patients with sepsis (Fig. 129-3).¹²⁴ Linking prognostic determinants from critical care measurement scores such as acute physiology and chronic health evaluation (APACHE-II) to DIC scores is an important means to assess prognosis in critically ill patients. In addition, certain biochemical indicators of organ dysfunction may imply a DIC risk. For example, serial assessment of arterial lactate has proved to be a reliable prognostic indicator of DIC development among patients with the systemic inflammatory response syndrome.¹³⁹

Criteria for less-overt DIC have been more difficult to establish.^{138,140} In the algorithm for nonovert DIC, the global coagulation tests are scored as with the overt DIC algorithm; however, when scoring by the algorithm is being serially repeated, improvement in any laboratory test confers a negative score (rather than a zero or neutral score). This “trend” scoring allows longitudinal assessment of the patient’s microangiopathy and, when therapy has been instituted, inference on whether the therapy has improved the course of the disease.^{121,141} Measurements of several markers for assessing the risk of progression from nonovert to overt DIC and prediction of multiorgan dysfunction are potentially valuable and in the future can be accommodated in the nonovert DIC score. For example, impaired fibrinolysis may play a particularly important role in multiorgan dysfunction resulting from DIC of sepsis.¹⁴² Therefore, assaying PAI-1, plasmin–antiplasmin complexes, or TAFI in septic patients may be important. Another highly sensitive early marker of impending DIC is a monoclonal antibody against APC that identifies a calcium ion-dependent epitope involved in factor Va inactivation.¹⁴³ Whether serial measurement of von Willebrand factor-cleaving protease also will identify individuals at risk early in their disease course, or will help differentiate individuals with microangiopathy who are not prone to progress, needs further data.^{144,145}

Techniques, such as rotational thrombelastography (ROTEM) enable bedside performance of this test and has again become popular recently in acute care settings.¹⁴⁶ The theoretical advantage of

thrombelastography (TEG) over conventional coagulation assays is that it provides an idea of platelet function as well as fibrinolytic activity. Hyper- and hypocoagulability as demonstrated with TEG was shown to correlate with clinically relevant morbidity and mortality in several studies, although its superiority over conventional tests has not unequivocally been established.¹⁴⁷ Even though there are no systematic studies on the diagnostic accuracy of TEG for the diagnosis of DIC, the test may be useful for assessing the global status of the coagulation system in critically ill patients.¹⁴⁸

● SPECIFIC UNDERLYING DISORDERS

INFECTIOUS DISEASES

Bacterial infections are among the most common causes of DIC.^{5,149} Certain patients are particularly vulnerable to infection-induced DIC, such as immune-compromised hosts, asplenic patients whose ability to clear bacteria, particularly pneumococci and meningococci, is impaired, and newborns whose coagulation inhibitory systems are immature. Infections are frequently superimposed on trauma and malignancies, which themselves are potential triggers of DIC. In addition, infections can aggravate bleeding and thrombosis by directly inducing thrombocytopenia, hepatic dysfunction, and shock associated with diminished blood flow in the microcirculation.¹⁵⁰ Clinically overt DIC may occur in 30 to 50 percent of patients with Gram-negative sepsis.^{151,152} DIC is similarly common in patients with Gram-positive sepsis.^{153,154} Extreme examples of sepsis-related DIC are (1) group A streptococcus toxic shock syndrome, characterized by deep tissue infection, vascular collapse, vascular leakage, and multiorgan dysfunction; a streptococcal M protein forms complexes with fibrinogen, and these complexes bind to β_2 integrins of neutrophils leading to their activation¹⁵⁵; and (2) meningococemia, a fulminant Gram-negative infection characterized by extensive hemorrhagic necrosis, DIC, and shock. The extent of hemostatic derangement in patients with meningococemia correlates with prognosis.^{156,157} More frequent Gram-negative infections associated with DIC are caused by *Pseudomonas aeruginosa*, *E. coli*, and *Proteus vulgaris*. Patients affected by such bacteremias may have only laboratory signs of activated coagulation or may present with severe DIC, especially when shock develops.^{158,159}

Severe secondary deficiency of a disintegrin-like metalloprotease with thrombospondin type 1 repeats (ADAMTS13), the von Willebrand cleaving protease, occurs in patients with sepsis-induced DIC and is associated with a high incidence of acute renal failure.¹⁶⁰

Among the Gram-positive infections, *Staphylococcus aureus* bacteremia can cause DIC accompanied by renal cortical and dermal necrosis. The mechanism by which DIC is elicited may be related to an α -toxin that activates platelets and induces IL-1 secretion by macrophages.¹⁶¹ *Streptococcus pneumoniae* infection is associated with the Waterhouse-Friderichsen syndrome,¹⁶² particularly in asplenic patients. Initiation of DIC in these conditions is ascribed to the capsular antigen of the bacterium and to antigen-antibody complex formation.¹⁶³ Other Gram-positive bacteria that can cause DIC are the anaerobic clostridia. Clostridial bacteremia is a highly lethal disease characterized by septic shock, DIC, renal failure, and hemolytic anemia.¹⁶⁴

Activation of the coagulation system has also been documented for nonbacterial pathogens, that is, viruses (causing hemorrhagic fevers),^{164,165} protozoa (Malaria),^{166,167} and fungi.¹⁶⁸ Common viral infections, such as influenza, varicella, rubella, and rubeola, rarely are associated with DIC.¹⁶⁹ However, purpura fulminans associated with DIC has been reported in patients with infections and either hereditary thrombophilias,^{170,171} or acquired antibodies to protein S.¹⁷² Other viral infections can cause “hemorrhagic fevers” characterized by fever,

hypotension, bleeding, and renal failure. Laboratory evidence of DIC can accompany Korean, rift valley, and dengue-related hemorrhagic fevers.^{173–175} Release of TF from cells in which viruses replicate²⁸ and increased levels of proinflammatory cytokines have been suggested as mechanisms for initiation of the TF pathway in these conditions.¹⁶³

PURPURA FULMINANS

Purpura fulminans is a severe, often lethal form of DIC in which extensive areas of the skin over the extremities and buttocks undergo hemorrhagic necrosis.¹⁷⁶ The disease affects infants and children predominantly, and occasionally adults.^{177,178} Diffuse microthrombi in small blood vessels, necrosis, and occasionally vasculitis are present in biopsies of skin lesions. Onset can be within 2 to 4 weeks of a mild infection such as scarlet fever, varicella, or rubella, or can occur during an acute viral or bacterial infection in patients with acquired or hereditary thrombophilias affecting the protein C inhibitory pathway.^{156,177} Homozygous protein C deficiency presents in neonates soon after birth as purpura fulminans, with or without extensive thrombosis.^{179,180} Patients affected by purpura fulminans are acutely ill with fever, hypotension, and hemorrhage from multiple sites; they frequently have typical laboratory signs of DIC.¹⁷⁷ Excision of necrotic skin areas and grafting are indispensable at a later stage.

SOLID TUMORS

Trousseau was the first to describe the propensity to thrombosis of patients with cancer and cachexia, and evidence for malignancy-related primary fibrinolysis and/or DIC was provided 75 years ago.^{9,181,182}

In 182 patients with malignant disorders, excessive bleeding was recorded in 75 cases, venous thrombosis in 123, migratory thrombophlebitis in 96, arterial thrombosis in 45, and arterial embolism resulting from nonbacterial thrombotic endocarditis in 31.¹⁸³ Multifocal hemorrhagic infarctions of the brain, caused by fibrin microemboli and manifested as disorders of consciousness, have been described. Patients with solid tumors and DIC are more prone to thrombosis than to bleeding, whereas patients with leukemia and DIC are more prone to hemorrhage. The incidence of DIC in consecutive patients with solid tumors was 7 percent.¹⁸⁴

Solid-tumor cells can express different procoagulant molecules including TF, which forms a complex with factor VII(a) to activate factors IX and X, and a cancer procoagulant, a cysteine protease with factor X activating properties.^{185,186} In breast cancer, TF is expressed by vascular endothelial cells as well as the tumor cells.^{187,188} TF also appears to be involved in tumor metastasis and angiogenesis.^{189–191} Cancer procoagulant is an endopeptidase that can be found in extracts of neoplastic cells but also in the plasma of patients with solid tumors.^{192,193} The exact role of cancer procoagulant in the pathogenesis of cancer-related DIC is unclear.

Interactions of P- and L-selectins with mucin from mucinous adenocarcinoma can induce formation of platelet microthrombi and probably constitute a third mechanism of cancer-related thrombosis.¹⁹⁴ Depending on the rate and quantity of exposure or influx of shed vesicles from tumors containing TF, a nonovert or overt DIC develops.^{39,195,196} For instance, a patient may be asymptomatic or present with venous thromboembolism if the tumor cells expose or release TF slowly or intermittently and the ensuing utilization of fibrinogen and platelets is compensated by increased production of these components. Conversely, massive thrombosis or severe bleeding may supervene in a patient whose circulation is delayed by TF.^{184,186}

Another mechanism by which tumor cells may contribute to the pathogenesis of DIC is by expressing fibrinolytic proteins.^{197,198} Despite

the ability of many malignant cells to express urokinase-type plasminogen activator and t-PA, most tumors induce a hypofibrinolytic state. Because DIC is commonly characterized by a shutdown of the fibrinolytic system, mostly because of high levels of PAI-1, this may represent an alternative mechanism for the development of DIC in cancer.

Virtually all pathways that contribute to the occurrence of DIC are driven by cytokines. IL-6 has been identified as one of the most important proinflammatory cytokines that is able to induce TF expression on cells.^{21,199} Indeed, inhibition of IL-6 results in an inhibition of endotoxin-stimulated activation of coagulation. In contrast, changes in fibrinolysis and microvascular physiologic anticoagulant pathways are mostly dependent on TNF- α .²⁰⁰⁻²⁰² Other cytokines that participate in the systemic activation of coagulation are IL-1 β and IL-8, whereas antiinflammatory cytokines, such as IL-10, are able to inhibit DIC.²⁰³⁻²⁰⁵ Because many types of tumors have the ability to synthesize and release cytokines or to stimulate other cells to activate the cytokine network, it is likely that cytokine-dependent modulation of coagulation and fibrinolysis plays a role in cancer-related DIC.

Patients with solid tumors are vulnerable to risk factors and additional triggers of DIC that can aggravate thromboembolism and bleeding.¹⁸² Risk factors include advanced age, stage of the disease, and use of chemotherapy or antiestrogen therapy.¹⁹⁷ Triggers include septicemia, immobilization, and involvement of the liver by metastases that impede the function of the liver in controlling DIC. Microangiopathic hemolytic anemia frequently is induced by DIC in patients with malignancies and is particularly severe in patients with widespread intravascular metastases of mucin-secreting adenocarcinomas.²⁰⁶

LEUKEMIAS

Numerous reports on DIC and fibrinolysis complicating the course of acute leukemias have been published. In 161 consecutive patients who presented with acute myeloid leukemia, DIC was diagnosed in 52 (32 percent).²⁰⁷ In acute lymphoblastic leukemia, DIC was diagnosed in 15 to 20 percent.²⁰⁸ Some reports indicate that the incidence of DIC in acute leukemia patients might further increase during remission induction with chemotherapy.²⁰⁹ In patients with acute promyelocytic leukemia (APL), DIC is present in more than 90 percent of patients at the time of diagnosis or after initiation of remission induction.^{210,211}

The pathogenesis of hemostatic disturbance in APL is related to properties of the malignant cells and their interaction with the host's endothelial cells.^{192,208} APL cells express TF and the cancer procoagulant that can initiate coagulation, and they release IL-1 β and TNF- α , which downregulate endothelial thrombomodulin, thereby compromising the protein C anticoagulant pathway. APL cells also express increased amounts of annexin II, which mediates augmented conversion of plasminogen to plasmin (Chap. 135). The overall results of these processes are DIC and hyperfibrinolysis, followed by major bleeding that can lead to death.²¹² All-*trans*-retinoic acid, used for induction and maintenance therapy of APL, inhibits *in vitro* and *in vivo* the deleterious effect of APL cells and has led to a reduced frequency of early hemorrhagic death; however, all-*trans*-retinoic acid may induce thrombotic complications.^{192,213}

TRAUMA

When DIC complicates trauma, it usually occurs in severely injured patients. Extensive exposure of TF to the blood circulation and hemorrhagic shock probably are the most immediate triggers of DIC in such instances, although direct proof of this mechanism is lacking. An alternative hypothesis is that cytokines play a pivotal role in the occurrence of DIC in trauma patients. In fact, the changes in cytokine levels are

virtually identical in trauma patients and septic patients.²¹⁴ The levels of TNF- α , IL-1 β , PAI-1, circulating TF, plasma elastase derived from neutrophils, and soluble thrombomodulin all can be elevated in patients with signs of DIC, predicting multiorgan dysfunction (ARDS included) and death.^{215,216} Careful monitoring of laboratory signs of DIC, reduced fibrinolytic activity, and perhaps low AT levels also are useful for predicting the outcome of such patients.²¹⁷

DIC can be aggravated in patients with severe trauma who require massive blood replacement because stored blood components are diluted and do not contain sufficient amounts of viable platelets and factors V and VIII. Moreover, in such patients, there is an activation of fibrinolysis that further aggravate bleeding in combination with acidosis, and hypotension.²¹⁸⁻²²¹ Infection commonly occurs in such patients and may contribute to the DIC.

The time interval between trauma and medical intervention correlates with the development and magnitude of DIC. Experience during wars proved that fast evacuation and prompt medical care reduce the risk of DIC.²²²⁻²²⁴

BRAIN INJURY

Brain injury can be associated with DIC, most likely because the injury exposes the abundant TF of brain to blood. Specimens of contused brain, obtained during surgery in patients with head injury and of liver, lungs, kidneys, and pancreas obtained during autopsy, revealed microthrombi in arterioles and venules.^{225,226} In adults and children with head injuries, a high rate of mortality occurred when DIC was present.²²⁷ A laboratory DIC score has predictive value for prognosis in patients with head injuries, thereby supplementing the Glasgow coma score.²²⁸ Bleeding in patients with DIC that is related to brain injury can be managed by replacement therapy.

BURNS

TF exposed to blood at sites of burned tissue, the systemic inflammatory response syndrome induced by the burn, and the common presence of superimposed infections, all can trigger DIC.²²⁹ Bleeding, laboratory tests indicative of DIC, and vascular microthrombi in biopsies of undamaged skin have been described in patients with extensive burns.²³⁰ Kinetic studies with labeled fibrinogen and labeled platelets disclosed that, in addition to systemic consumption of hemostatic factors, significant local consumption occurs in burned areas.²³¹ Laboratory signs of DIC are associated with organ failure; the extent of protein C and AT deficiencies correlates with a poor outcome.²³⁰ A clinicopathologic study of 139 patients who died during treatment for a severe burn disclosed that 18 percent had cerebral infarctions caused by septic arterial occlusions or DIC and approximately 4 percent had intracranial hemorrhage.²³²

LIVER DISEASES

Very complicated derangements of hemostasis occur in patients with severe liver disease and during liver transplantation (Chap. 129). Synthesis of most coagulation factors and natural anticoagulants (protein C, protein S, and AT) and of the main components of the fibrinolytic system (plasminogen, TAFI, and α_2 -antiplasmin) is reduced. The capacity of the liver to clear the circulation of activated factors IX, X, and XI, and of t-PA is decreased. Moreover, thrombocytopenia is common as a result of hypersplenism and decreased production of thrombopoietin by the liver. The similarities between the hemostatic defects observed in patients with liver disease and in patients with DIC are striking and have evoked an ongoing controversy as to whether or not DIC contributes to hemostatic derangements associated with liver disease.²³³

Several laboratory and clinical observations support the hypothesis that DIC accompanies hepatic disorders. They include a shortened half-life of radiolabeled fibrinogen and prolongation of fibrinogen half-life by administration of heparin^{234,235}; failure of replacement therapy to significantly increase the levels of hemostatic factors (suggesting continuous consumption); and increased blood levels of D-dimer, thrombin-AT (TAT) complexes, and fibrinopeptide A, all consistent with ongoing thrombin generation.²³⁶⁻²³⁸

Other observations and considerations argue against the hypothesis that DIC accompanies liver diseases. They include (1) a very low incidence (2.2 percent) of microthrombosis in the tissues of patients who die of liver disease and (2) causes other than, or inconsistent with, DIC for the deranged findings in liver disease.²³⁷ Examples of alternative explanations include the following: (1) a prolonged thrombin time may result from acquired dysfibrinogenemia²³⁹; (2) low levels of coagulation factors and inhibitors may result from reduced synthesis²⁴⁰; (3) increased FDP levels may be a consequence of primary fibrinogenolysis induced by reduced synthesis of α_2 -antiplasmin and PAI-1 and by decreased clearance of t-PA; (4) factor VIII levels are commonly increased rather than decreased²⁴¹; (5) the kinetic data show that the apparently excessive consumption of fibrinogen can be explained by loss of fibrinogen into extravascular spaces²⁴²; and (6) fibrinogen and plasminogen do not appear to be removed rapidly when labeled endogenously by⁷⁵ Se-selenomethionine.²⁴³

A third hypothesis maintains that patients with liver disease usually do not present with DIC but are extremely sensitive to the various triggers of DIC because of their impeded capacity to clear procoagulants and to synthesize essential components of the coagulation, inhibitory, and fibrinolytic systems. Patients with primary or metastatic liver disease who undergo a peritoneovenous shunt operation for severe ascites are more likely to develop DIC than are patients with ascites who undergo the same procedure because of other causes.²⁴⁴

What, then, should be the approach to patients with liver disease and bleeding without an apparent local cause? First, possible underlying causes of DIC should be considered and identified, and then a hemostatic profile should be examined at frequent intervals so as to detect any dynamic changes that may be helpful in recognizing DIC. The sensitive assays that reflect thrombin generation (TAT complex and prothrombin fragments 1.2) or concomitant thrombin and plasmin generation (D-dimer), as well as finding a normal or decreased level of factor VIII may help establish the diagnosis of DIC in a patient with liver disease.²⁴⁵

HEAT STROKE

In 1841, James Wellstead published his book *Travels to the City of the Caliphs* (currently known as Baghdad) and vividly described that on an extremely hot day in the Persian Gulf the decks of the ship *Liverpool* resembled a slaughterhouse, so numerous were the bleeding patients.²⁴⁶ This is probably one of the first written reports on the occurrence of DIC in humans who suffer from heatstroke.²²⁹ Heat stroke is a syndrome characterized by a rise in body temperature to higher than 42°C, which follows collapse of the thermoregulatory mechanism. The following predisposing factors have been identified: high environmental temperature, strenuous physical activity, infection, dehydration, and lack of acclimatization.^{247,248} Extensive hemorrhage, unclottable blood, and venous engorgement were found as early as 1838 in postmortem examinations of patients who died of heat stroke.²⁴⁶ Investigations confirm that a severe hemorrhagic diathesis and multiple organ failure often accompany heat stroke.^{229,249-251} Diffuse fibrin deposition and hemorrhagic infarctions are found in fatal human cases. DIC associated with profound fibrin(ogen)olysis is evident in patients with heat stroke. The possible triggers of DIC in patients with heat stroke include endothelial cell damage and TF released from heat-damaged tissues.²⁴⁹

In a series of 18 critically ill patients from Paris with heat stroke during the 2003 heat wave in Western Europe that caused numerous deaths in France alone,²⁵¹ patients had very high levels of IL-6 and IL-8. In addition, there was a striking activation of white blood cells, as demonstrated by β_2 -integrin upregulation and increased production of reactive oxygen species. All patients also had evidence of a significant systemic activation of coagulation and DIC was present in approximately 35 percent of patients. There was a marked correlation between the extent of inflammation and coagulation activation and the clinical severity of the heat stroke.

The severity of the syndrome and the stage of its development affect the type and magnitude of hemostatic alterations. Thus, in a study of 56 patients, three groups were discernible: nonbleeders, bleeders without DIC but with slight consumption of hemostatic factors, and bleeders with typical signs of DIC.²⁵² Prompt cooling and support of vital functions have substantially reduced the high mortality that was commonly observed in early studies.

SNAKE BITES

Several species of snakes belonging to the Viperidae family produce venoms that have a wide range of activities affecting hemostasis. Prominent among these species are the *Vipera*, *Echis* (*E. carinatus* or *E. coloratus*), *Aspis*, *Crotalus*, *Bothrops*, and *Agkistrodon*. Venoms of these snakes contain enzymes or peptides that exert the following activities²⁵³⁻²⁵⁵: (1) thrombin-like activity, cleaving fibrinopeptide A from the A α chain of fibrinogen (*Agkistrodon rhodostoma*); (2) activation of prothrombin even in the absence of calcium ions (*E. carinatus*); (3) activation of factors X and V (Russell viper venom); (4) fibrinogenolytic activity (*Agkistrodon acutus*); (5) induction of thrombocytopenia by platelet aggregation; (6) inhibition of platelet aggregation by the low-molecular-weight arginine-glycine-aspartic acid-containing peptides from a variety of snake species; (7) activation of protein C; and (8) activities causing damage to endothelial cells, leading to bleeding, tissue ischemia, and edema. Interestingly, victims of snake bites rarely experience excessive bleeding or thromboembolism, in spite of the serious derangements in hemostatic tests and findings that are sometimes consistent with DIC.²⁵⁶⁻²⁵⁸

The major symptoms and signs related to envenomation are vomiting, diarrhea, apprehension, hypotension, local swelling, ischemia, and necrosis. Consequently, treatment for victims of snake bites consists of immediate immobilization, administration of antivenom and fluids, and other general measures to preserve vital functions. Local incisions, cooling, and application of tourniquet should be avoided.²⁵³

HEMANGIOMAS

In 1940, Kasabach and Merritt described the association between giant hemangioma and a bleeding tendency occurring mainly in infants. The pathogenesis and management of this syndrome have been reviewed.²⁵⁹ Studies using radiolabeled fibrinogen and platelets provided evidence that within the hemangioma, consumption of platelets and fibrinogen occurs because of localized intravascular clotting and excessive fibrinogenolysis.^{260,261} Conceivably, concomitant local activation of the coagulation pathway and release of large amounts of t-PA by the abnormal endothelium lining the tumor vessels occur. Microangiopathic hemolytic anemia and laboratory signs of DIC and fibrinolysis have been demonstrated in patients with giant hemangiomas.²⁶² Accelerated growth of these hemangiomas in infants is associated with augmented consumption of hemostatic factors, and can be effectively treated with glucocorticoids. Radiotherapy and interferon- α are also effective, but should only be used in life-threatening circumstances after failure of glucocorticoid therapy because of severe adverse events.²⁶³ Spontaneous

mild to moderate bleeding manifestations have been observed, but severe bleeding generally occurs only after surgery or trauma.

Extensive vascular malformation may persist and cause pain, probably resulting from thrombosis, and bleeding following trauma, which is related to the localized or generalized consumption of clotting factors and platelets and hyperfibrinolysis.²⁶⁴ Graded permanent elastic compression, when possible, and low-molecular-weight heparin constitute the only effective treatment in such cases.

AORTIC ANEURYSM

An association between aortic aneurysm and DIC is well documented.^{265,266} In a series of patients with aortic aneurysm, 40 percent had elevated levels of FDPs, but only 4 percent had significant bleeding and laboratory evidence of DIC.²⁶⁵ Several factors predispose patients with aortic aneurysms to the development of DIC: a large surface area, dissection, and expansion of the aneurysm.²⁶⁷ Clinical and laboratory signs of DIC should be carefully sought in patients with an aortic aneurysm because bleeding may seriously complicate surgical repair of the aneurysm.^{267,268} The initiation of localized and generalized intravascular coagulation can be ascribed to activation of the TF pathway by the abundant amounts of TF present in atherosclerotic plaques.²⁶⁹ When patients present with significant bleeding or when surgery is planned, hemostatic defects should be sought and ongoing coagulation activation may be corrected by (low-molecular-weight) heparin.²⁷⁰ Stent-grafting, which is a common procedure for repair of aortic aneurysms, was complicated by DIC and death in two patients, of whom one had cirrhosis and the other underwent a lengthy procedure.²⁷¹ However, a study of 31 such patients failed to detect DIC following stent-grafting of thoracic aneurysms.²⁷²

TRANSFUSION REACTION

DIC accompanies incompatible blood transfusion, in which massive hemolysis is commonly associated with excessive bleeding with widespread thrombosis in fatal cases (Chap. 138). The trigger of DIC in these cases cannot be simply ascribed to the release of red cell stroma, as patients with massive oxidative hemolysis because of glucose-6-phosphate dehydrogenase deficiency do not develop DIC.²⁷³ Rather, extensive antigen-antibody reaction appears to cause DIC as a result of release of elastase and TNF- α from neutrophils, and activation of monocytes that release TNF- α express TF and complement, with assembly of the membrane attack complex inflicting damage to endothelial cells.^{274,275}

DISSEMINATED INTRAVASCULAR COAGULATION DURING PREGNANCY

Pregnancy predisposes patients to DIC for at least four reasons: (1) pregnancy itself produces a hypercoagulable state, manifested by evidence of low-grade thrombin generation, with elevated levels of fibrin monomer complexes and fibrinopeptide A; (2) during labor, leakage of TF from placental tissue into the maternal circulation causes a hypercoagulable state; (3) pregnancy is associated with reduced fibrinolytic activity because of increased plasma levels of PAI-1; and (4) pregnancy is associated with a decline in the plasma level of protein S. DIC may be difficult to diagnose during pregnancy because of the high initial levels of coagulation factors such as fibrinogen, factor VIII, and factor VII.^{276,277} Progressive reductions in these factors, however, can confirm or exclude the diagnosis of DIC in suspected cases. Thrombocytopenia may be particularly helpful in determining whether DIC is present, provided other causes of thrombocytopenia are excluded.²⁷⁸

Abruptio Placentae

The dramatic clinical presentation of abruptio placentae was first reported by DeLee in 1901,²⁷⁹ but the immediate cause of sudden

rupture of uterine spiral arteries and detachment of the placenta is still unknown. Placental abruption is a leading cause of perinatal death.²⁸⁰ Older multiparous women or patients with one of the hypertensive disorders of pregnancy are thought to be at highest risk. The severe hemostatic failure accompanying abruptio placentae is the result of acute DIC emanating from the introduction of large amounts of TF into the blood circulation from the damaged placenta and uterus.²⁸¹ Amniotic fluid is able to activate coagulation *in vitro*, and the degree of placental separation correlates with the extent of DIC, suggesting that leakage of thromboplastin-like material from the placental system is responsible for the occurrence of DIC. Abruptio placentae occurs in 0.2 to 0.4 percent of pregnancies,²⁸² but only 10 percent of these cases are associated with DIC.²⁷⁸ Different grades of severity are found among those who develop DIC, with only the more severe forms resulting in shock and fetal death. Rapid volume replenishment and evacuation of the uterus is the treatment of choice.²⁸⁰ Transfusion of cryoprecipitate, fresh-frozen plasma, and platelets should be given when profuse bleeding occurs. However, in the absence of severe bleeding, administration of blood components may not be necessary because depleted coagulation factors increase rapidly following delivery. Heparin or antifibrinolytic agents are not indicated.

Amniotic Fluid Embolism

This rare catastrophic disorder, described by Steiner and Lushbaugh in 1941, occurs only in one in 8000 to one in 80,000 deliveries.²⁸³ A maternal mortality rate of 86 percent was reported in a 1979 review of 272 cases, but in a later population-based study, the maternal mortality (26.4 percent) was significantly lower.^{284,285} Patients predisposed to amniotic fluid embolism are multiparous women whose pregnancies are postmature with large fetuses and women undergoing a tumultuous labor after pharmacologic or surgical induction. Apparently, amniotic fluid is introduced into the maternal circulation through tears in the chorioamniotic membranes, rupture of the uterus, and injury of uterine veins.²⁸⁴ The trigger of DIC probably is TF present in amniotic fluid.^{286,287} The mechanical obstruction of pulmonary blood vessels by fetal debris, meconium, and other particulate matter in the amniotic fluid enhances local fibrin-platelet thrombus formation and fibrinolysis. The extensive occlusion of the pulmonary arteries and an acute anaphylactoid response reminiscent of severe systemic inflammatory response syndrome provoke sudden dyspnea, cyanosis, acute cor pulmonale, left ventricular dysfunction, shock, and convulsions. These symptoms are followed within minutes to several hours by severe bleeding in 37 percent of patients.²⁸⁴ Hemorrhage is particularly severe from the atonic uterus, puncture sites, gastrointestinal tract, and other organs. The best prospect for decreasing mortality lies in early termination of parturition in patients at high risk and prevention of hypertonic and tetanic uterine contractions during labor. When the syndrome is recognized, immediate termination of pregnancy under pulmonary and cardiovascular support is essential.

Preeclampsia and Eclampsia

Thrombocytopenia described in early reports of eclampsia and widespread deposition of fibrin in blood vessels observed in fatal cases were interpreted as evidence of DIC triggered by placental TF exposure to the circulation.¹ A critical analysis of the literature concluded that the thrombocytopenia in these patients stems from endothelial injury rather than DIC.²⁸⁸ However, other investigators provided evidence for significant DIC in preeclampsia and eclampsia.^{289,290} Moreover, in a large series of patients, a good correlation was noted between the clinical severity and abnormalities in platelet counts and FDPs.²⁹¹ Also consistent with DIC were results of assays of sensitive parameters of thrombin generation and activation of fibrinolysis, such as TAT complexes, D-dimer, and fibrinopeptide B β 1-42. Despite these observations, administration

of heparin to patients with preeclampsia and eclampsia has not resulted in convincing benefits.²⁹²

HELLP Syndrome

The syndrome of hemolysis (H), elevated liver enzymes (EL), low platelet count (LP), and severe epigastric pain is a complication of pregnancy-induced hypertension.²⁹³ Seventy percent of the cases occur during the third trimester of pregnancy and 30 percent occur during the postpartum period.²⁹⁴ HELLP syndrome occurs more often in whites, multipara, and women older than 35 years.²⁹² Liver biopsy findings of fibrin deposition in hepatic blood vessels and laboratory tests consistent with DIC in a significant proportion of patients imply that DIC plays a role in the pathogenesis of the syndrome.^{294–296} Hepatic imaging in 33 patients revealed subcapsular hematomas in 13 and intraparenchymal hemorrhage in 6.²⁹⁷ What actually triggers DIC in these cases is not known but has been related to endothelial dysfunction.²⁹² Multiple organ dysfunctions manifested by acute renal failure, ascites, pulmonary edema, and severe hemorrhage resulting from DIC may develop, leading to significant maternal and perinatal mortality rates. Management of patients with HELLP syndrome consists of supportive care, careful monitoring, and blood component replacement therapy. With few exceptions, immediate delivery, not necessarily by cesarian section, is indicated. HELLP syndrome tends to recur in subsequent gestations.²⁹⁸

Sepsis During Pregnancy

Gram-negative bacteria, group A streptococci, and *Clostridium perfringens* are among the more common causes of sepsis during pregnancy. These infections are frequently associated with fulminant DIC. The pathogens gain entry into the circulation during abortion, via amnionitis that may follow invasive procedures or rupture of membranes, by endometritis developing during labor, and by way of the urinary tract. Approximately 40 percent of bacteremic patients experience shock, which is associated with significant mortality.²⁹⁹ In addition, a high rate of bleeding and organ dysfunction affects the kidneys, lungs, and central nervous system.

Treatment of all cases of sepsis-related DIC should include antibiotics, support of vital functions, and surgical intervention to remove any local nidus of infection. Abortion or hysterectomy may be considered.

Dead Fetus Syndrome

Several weeks after intrauterine fetal death, approximately one-third of patients may exhibit laboratory signs of DIC, occasionally accompanied by bleeding.^{278,300} Apparently, TF from the retained dead fetus or placenta slowly enters the maternal circulation and initiates DIC, which sometimes is accompanied by significant fibrinolysis.¹³ This complication currently is rarely observed because labor is induced promptly after the diagnosis of fetal death is made. However, if labor induction is unavoidably delayed, serial blood coagulation tests should be performed.

The entity of fetal death and DIC can occur following the demise of one of multiple gestations. If it occurs at term, therapy is started as discussed. If it occurs prior to fetal maturity, prolonged administration of heparin can be useful. Interestingly, when selective termination of the life of an anomalous fetus is performed in women with multiple pregnancies, hemostatic abnormalities develop in only approximately 3 percent of cases.³⁰¹

Acute Fatty Liver

Acute fatty liver of pregnancy is a rare disorder that occurs during the third trimester of pregnancy.³⁰² It can lead to hepatic failure, encephalopathy, and death of the mother and fetus.^{303–306} In 15 to 20 percent of cases, acute fatty liver of pregnancy is associated with fetal homozygosity or compound heterozygosity for long-chain acyl-coenzyme A dehydrogenase (LCAD) deficiency.³⁰⁷ Infants born with LCAD deficiency

fail to thrive and are prone to liver failure and death. LCAD is one of four enzymes taking part in β -oxidation of fatty acids in mitochondria. When it is deficient, accumulation of medium- and long-chain fatty acid occurs. One predominant mutation (G1528C) accounts for 65 to 90 percent of cases with the deficiency. The precise mechanism by which LCAD deficiency in the fetus causes the severe liver disease in the heterozygous mother is unclear. The acute fatty liver disease of pregnancy is characterized by severe liver dysfunction, renal failure, hypertension, and signs of DIC.^{304,308} The typical histologic feature is microvesicular fatty infiltration of the liver. Exceedingly low levels of AT and other laboratory signs of DIC were observed in a series of 28 patients, but no definite clinical benefit from AT concentrate infusion was achieved.³⁰⁸ The primary therapy for these patients is early delivery and supportive care, which yield a maternal survival of 90 percent and perinatal survival of more than 85 percent.^{304,309} Pancreatitis is a potentially lethal complication of acute fatty liver of pregnancy.³¹⁰

NEWBORNS

Newborns have a limited capacity to cope with triggers of DIC for several reasons: (1) their ability to clear soluble fibrin and activated factors is reduced; (2) their fibrinolytic potential is decreased because of a low plasminogen level; and (3) their capacity to synthesize coagulation factors and inhibitors is limited.^{311,312} Criteria for diagnosis of DIC in newborns are different from those for diagnosis in adults.³¹³ Important to consider are the physiologic hemostatic findings common at this age, which include low levels of the vitamin K-dependent factors, reduced AT and protein C levels, and prolonged thrombin time. The laboratory evidence of DIC in the newborn is based on the progressive decline of hemostatic parameters, thrombocytopenia, and reduced levels of fibrinogen, factor V, and factor VIII.^{311,314,315}

DIC occurs in sick neonates and particularly in those who are premature. More than one underlying cause usually can be identified in newborns with DIC. The most frequent underlying conditions are sepsis, hyaline membrane disease (respiratory distress syndrome), asphyxia, necrotizing enterocolitis, intravascular hemolysis, abruptio placentae, and eclampsia.^{312,316}

Bleeding from multiple sites is the most common manifestation of DIC in newborns, with intracranial hemorrhage being the most life-threatening condition. No clinical manifestations of DIC are apparent in approximately 20 percent of neonates,³¹⁴ so a high index of suspicion in patients at risk is essential.

THERAPY

Controlled studies of patients with DIC are difficult to perform in view of the variabilities in DIC triggers, clinical presentations, and grades of severity. [Figure 129–4](#) shows general guidelines for management of patients with DIC, but decisions regarding treatment must be individualized after careful consideration of all clinically important aspects.

TREATMENT OF UNDERLYING DISORDERS AND VITAL SUPPORT

The survival of patients with DIC depends on vigorous treatment of the underlying disorder to alleviate or remove the inciting injurious cause. For sepsis-induced DIC, treatment includes aggressive use of intravenous organism-directed antibiotics and source control (e.g., by surgery or drainage). Other examples of vigorous treatment of underlying conditions are cancer surgery or chemotherapy, uterus evacuation or even hysterectomy in patients with abruptio placentae, resection of aortic aneurysm, and debridement of crushed tissues.

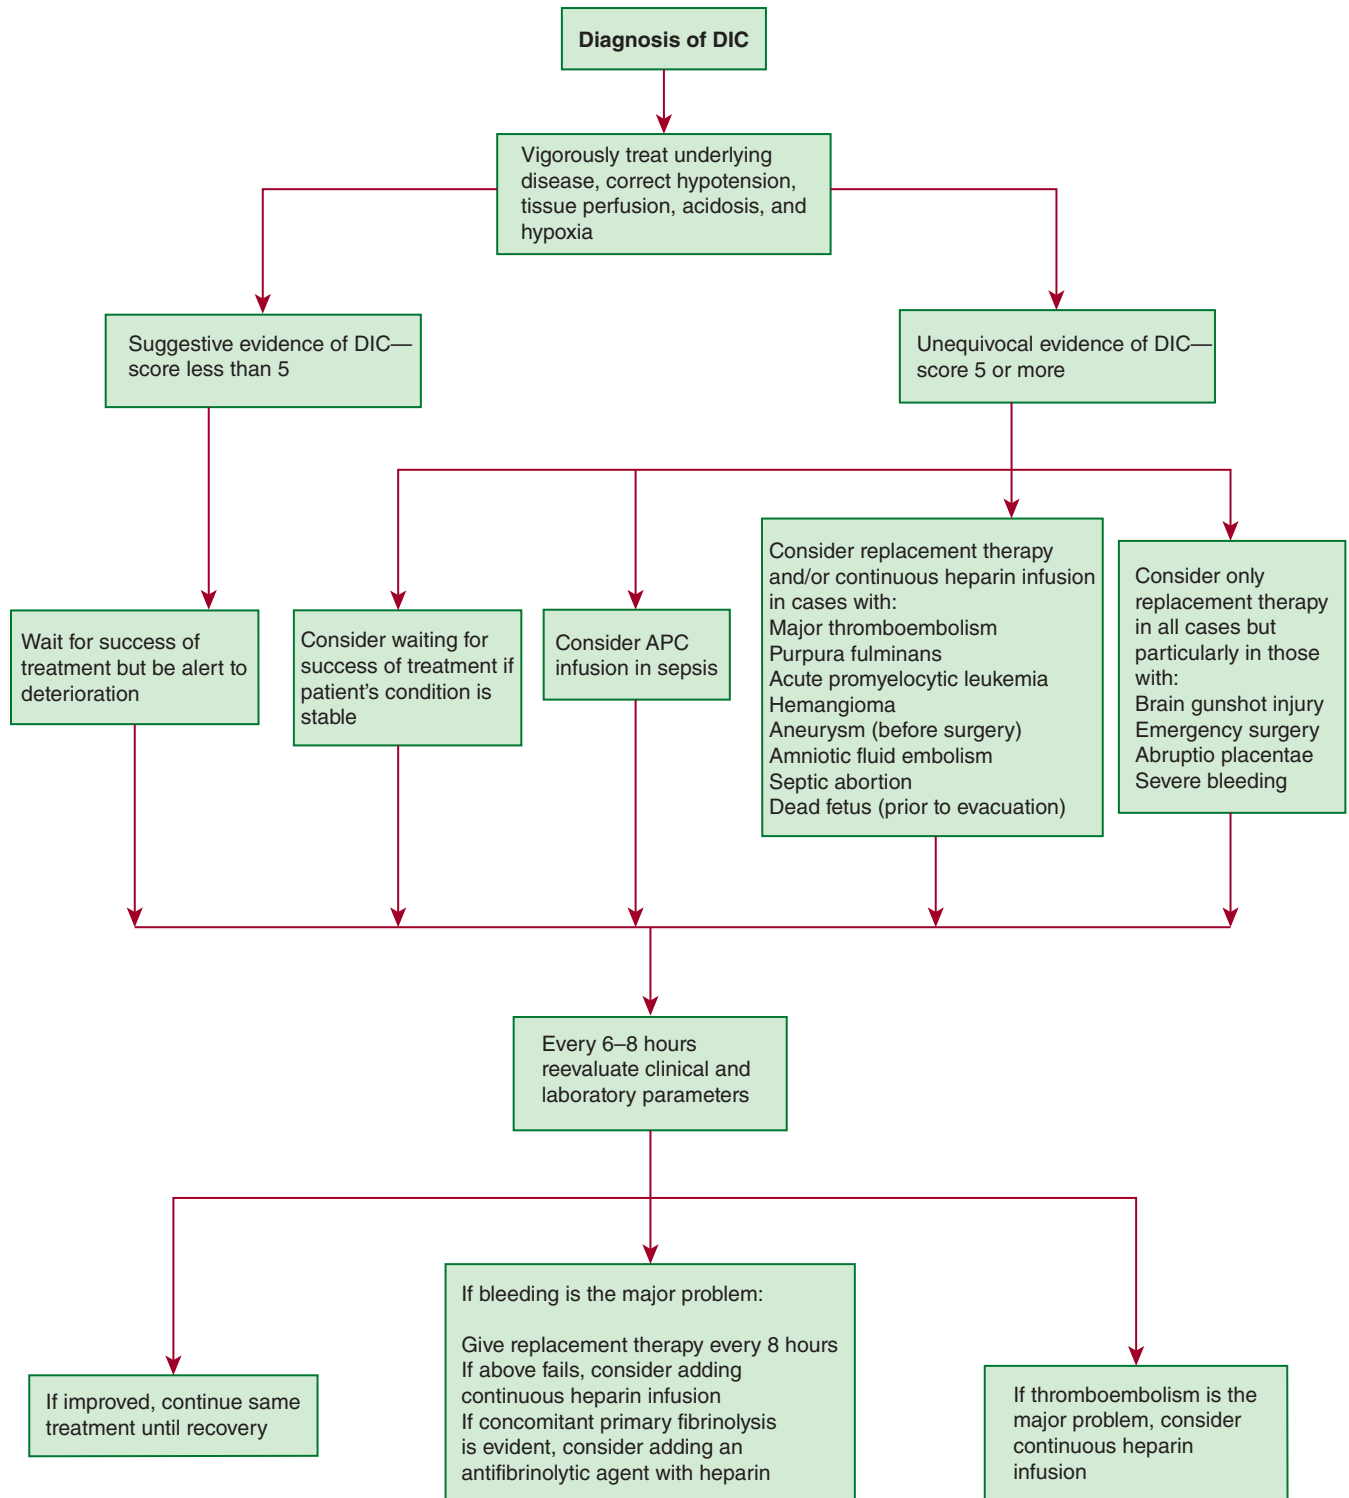

Figure 129-4. General guidelines for initial treatment and follow up of patients with disseminated intravascular coagulation (DIC). The success of management is related to taking rapid, vigorous measures against the underlying disease, support of vital functions, close clinical observation, thoughtful consideration in each individual patient, availability of 24-hour coagulation laboratory services, and an adequate supply of platelet concentrate, cryoprecipitate, fresh-frozen plasma, and packed red cells for replacement therapy. Heparin, when indicated, should be administered by continuous infusion. The basis and limitations of each of the outlined recommendations are detailed throughout the text. APC, activated protein C.

Intensive support of vital functions is required. Volume replacement and correction of hypotension, acidosis, and oxygenation may improve blood flow and oxygen delivery to the microcirculation. Careful monitoring of pulmonary, cardiac, and renal function enables prompt institution of supportive measures, such as use of a respirator for respiratory support, inotropic and vasoactive drugs for improvement of organ perfusion, renal function, and maintenance of electrolyte balance.

BLOOD COMPONENT THERAPY

Treatment of the underlying disease and vital support are necessary but usually insufficient to treat DIC or forestall progression of nonovert DIC to overt DIC. Additional supportive treatment directly aimed at the coagulation system may be required. These interventions include replacing the coagulation factors, natural anticoagulant, fibrinolytic proteins, and platelets that are actively consumed during DIC.³¹⁷

Low levels of platelets and coagulation factors may increase the risk of bleeding. However, plasma or platelet substitution therapy should not be instituted on the basis of laboratory results alone; it is indicated only in patients with active bleeding and in those requiring an invasive procedure or are at risk for bleeding complications.^{318,319} The suggestion that administration of blood components might “add fuel to the fire” has never been proven in clinical or experimental studies. The presumed efficacy of treatment with plasma, fibrinogen concentrate, cryoprecipitate, or platelets is not based on randomized controlled trials but appears to be rational therapy in bleeding patients or in patients at risk of bleeding who have a significant depletion of these hemostatic factors.³¹⁹ One of the major challenges of infusion of fresh-frozen plasma in these dire circumstances is the propensity of the added volume, which is necessary to correct the coagulation defect, to exacerbate capillary leak. This situation can increase the risk of inducing or worsening pulmonary edema and, by extension, predispose to ARDS, and induce ascites. Coagulation factor concentrates, such as prothrombin complex concentrate, may partially overcome this obstacle, but do not contain essential factors, such as factor V. Moreover, caution is advocated with the use of prothrombin complex concentrates in DIC, as it may worsen the coagulopathy because of traces of activated factors that are present in these concentrates. Specific deficiencies of coagulation factors, such as fibrinogen, may be corrected by administration of purified coagulation factor concentrates.

Platelet transfusion is often required in patients with DIC to prevent bleeding into already ischemic or damaged organs (particularly the central nervous system). The threshold platelet count that should prompt transfusion is patient and disease specific. Cryoprecipitate can be used to rapidly raise the fibrinogen and factor VIII levels, particularly when bleeding is part of the DIC and fibrinogen level is less than 1 g/L. Cryoprecipitate has at least four to five times the mass of fibrinogen per milliliter of infusate compared to fresh-frozen plasma. Fresh-frozen plasma contains fibrinogen in sufficient amounts for treatment of patients with mild to moderate hypofibrinemia.

Replacement therapy for thrombocytopenia should consist of 5 to 10 units of platelet concentrate or single-donor apheresis-derived platelets to raise the platelet count to 20 to 30 × 10⁹/L, and in patients who need an invasive procedure, to 50 × 10⁹/L.

RESTORATION OF PHYSIOLOGIC ANTICOAGULANT PATHWAYS

Because the levels of the physiologic anticoagulants are reduced in patients with DIC, restoration of these inhibitors may be a rational approach.^{49,320} Based on successful preclinical studies, the use of AT concentrates and heparin in patients with DIC has been examined mainly in randomized controlled trials, that included patients with sepsis, septic

shock, or both. All trials have shown some beneficial effect in terms of improvement of laboratory parameters, shortening of the duration of DIC, or even improvement in organ function.^{6,321,322} In several small clinical trials, use of very high doses of AT concentrate showed a modest reduction in mortality, but without being statistically significant.^{323–325} A large-scale, multicenter, randomized controlled trial also showed no significant reduction in mortality of patients with sepsis.³²⁶ Interestingly, post hoc subgroup analyses of the latter study indicated some benefit in patients who did not receive concomitant heparin, but this observation needs validation. In a small randomized trial in patients with burns and DIC, AT administration decreased mortality, reduced multiple organ failure, and improved coagulation parameters compared to placebo-control patients.³²⁷

Because a decreased function of the protein C system contributes to the pathogenesis of DIC, therapy by an APC concentrate was predicted to be beneficial.³²⁸ Indeed, a dose-ranging controlled trial using continuous infusion of recombinant human APC disclosed that a dose of 24 mcg/kg per hour was optimal, judged by a decrease of D-dimer level in plasma.³²⁹ A subsequent phase III trial of APC concentrate in patients with sepsis was prematurely stopped because of efficacy in reducing mortality in these patients.³³⁰ All-cause mortality at 28 days after inclusion was 24.7 percent in the APC group versus 30.8 percent in the control group (a 19.4 percent relative risk reduction). Amelioration of coagulation abnormalities and less organ failure were noted in patients who received the concentrate.³³¹ However, meta-analyses of subsequent trials concluded that the basis for treatment with APC, even in patients with a high disease severity, was not very strong.^{332,333} A recently completed placebo-controlled trial in patients with severe sepsis and septic shock was prematurely stopped because of the lack of any significant benefit of APC.³³⁴ Subsequently, the manufacturer of APC has decided to withdraw the product from the market, which has resulted in a revision of current guidelines for treatment of DIC.³³⁵

HEPARIN ADMINISTRATION AND OTHER ANTICOAGULANTS

Although the question of heparin therapy in patients with DIC has been studied by several investigators, this therapy remains controversial. Experimental studies show that heparin can at least partly inhibit the activation of coagulation in DIC.^{336,337} However, a beneficial effect of heparin on clinically important outcome events in patients with DIC has not been demonstrated in controlled clinical trials.³³⁸ Also, the safety of heparin treatment is debatable in DIC patients who are prone to bleeding. A large trial in patients with severe sepsis showed a slight, but nonsignificant benefit, of low-dose heparin on 28-day mortality in patients with severe sepsis.³³⁹

Notwithstanding these considerations, administration of heparin is beneficial in some categories of chronic DIC, such as metastatic carcinomas, purpura fulminans, and aortic aneurysm (prior to resection). Heparin also is indicated for treating thromboembolic complications in large vessels and before surgery in patients with chronic DIC (see Fig. 129–4). Heparin administration may be helpful in patients with acute DIC when intensive blood component replacement fails to improve excessive bleeding or when thrombosis threatens to cause irreversible tissue injury (e.g., acute cortical necrosis of the kidney or digital gangrene).

Heparin should be used cautiously in all these conditions. In patients with chronic DIC because of metastatic carcinoma or aortic aneurysm, continuous infusion of heparin 500 to 750 U/h without a bolus injection may be sufficient. If no response is obtained within 24 hours, escalating dosages can be used. In hyperacute DIC cases, such as mismatched transfusion, amniotic fluid embolism, septic abortion,

and purpura fulminans, intravenous bolus injection of 5000 to 10,000 U heparin may be given simultaneously with replacement therapy with blood products. Some experts would not administer a bolus dose of heparin even under these circumstances. Continuous infusion of 500 to 1000 U/h heparin may be necessary to maintain the benefit until the underlying disease responds to treatment.³³⁹

Theoretically, the most logical anticoagulant agent to use in DIC is directed against TF activity. Potential agents include recombinant TFPI, inactivated factor VIIa, and recombinant nematode anticoagulant protein c2 (NAPc2), a potent and specific inhibitor of the ternary complex of TF-factor VIIa and factor Xa.³⁴⁰ Phase II trials of recombinant TFPI in patients with sepsis showed promising results,³⁴¹ but a phase III trial did not show an overall survival benefit in patients who were treated with TFPI.^{341,342}

Recombinant human soluble thrombomodulin binds to thrombin to form a complex that inactivates thrombin's coagulant activity and activates protein C, and thus, is a potential drug for the treatment of patients with DIC. In a phase III randomized double-blind clinical trial in patients with DIC, administration of the soluble thrombomodulin had a significantly better effect on bleeding manifestations and coagulation parameters than heparin.³⁴³ Ongoing trials with soluble thrombomodulin focus on DIC, organ failure, and mortality rate.

INHIBITORS OF FIBRINOLYSIS

Patients with DIC should not be treated with antifibrinolytic agents such as ϵ -aminocaproic acid or tranexamic acid because these drugs block fibrinolysis that preserves tissue perfusion in patients with DIC. Use of these agents in patients with DIC has been complicated by severe thrombosis.^{344,345}

A different situation prevails in patients with DIC accompanied by primary fibrino(geno)lysis, as in some cases of APL, giant hemangioma, heat stroke, amniotic fluid embolism, some forms of liver disease, and metastatic carcinoma of the prostate. In these conditions, the use of fibrinolytic inhibitors can be considered,³⁴⁶ provided (1) the patient is bleeding profusely and has not responded to replacement therapy and (2) excessive fibrino(geno)lysis is observed, that is, rapid whole blood clot lysis or a very short euglobulin lysis time. In such circumstances, use of antifibrinolytic agents should be preceded by replacement of depleted blood components and continuous heparin infusion (see Fig. 129–4).

CHAPTER 130

HEREDITARY THROMBOPHILIA

Saskia Middeldorp and Michiel Coppens

SUMMARY

Thrombophilia refers to laboratory abnormalities that increase the risk of venous thromboembolism (VTE). Over the last several decades numerous factors have been identified. The most prevalent examples of hereditary forms of thrombophilia include the factor V Leiden and prothrombin G20210A mutations; deficiencies of the natural anticoagulants antithrombin, protein C, and protein S; persistently elevated levels of coagulation factor VIII; and mild hyperhomocysteinemia. Taken together, some form of hereditary thrombophilia can be identified in more than 50 percent of patients with VTE who are without obvious reasons for VTE, such as trauma or prolonged stasis. Moreover, hereditary thrombophilia has been associated with arterial cardiovascular disease and obstetric complications such as (recurrent) pregnancy loss and preeclampsia. The high yield of thrombophilia testing has led to widespread testing for these abnormalities in patients. Nevertheless, thrombophilia testing remains a topic of ongoing debate, mostly because of the lack of therapeutic consequences. While hereditary thrombophilia is a clear risk factor for a first VTE, the risk for recurrent episodes is hardly increased compared with nonaffected patients and prolonged anticoagulation is not warranted unless VTE is recurrent. A similar lack of therapeutic consequences applies to patients with arterial cardiovascular disease and women with obstetric complications. Thrombophilia testing in asymptomatic relatives of patients with VTE may be useful in families with antithrombin, protein C, or protein S deficiency, or for siblings of patients who are homozygous for factor V Leiden, and is limited to women who intend to become pregnant or who would like to use oral contraceptives. Careful counseling with knowledge of absolute risks helps patients to making an informed decision in which their own preferences can be taken into account.

To our knowledge, the term *thrombophilia* was first used by Nygaard and Brown in 1937, when they described sudden occlusion of large arteries, sometimes with coexistent venous thrombosis.¹ In 1956, Jordan and Nandorff extensively reviewed their own and previously

published cases on the familial tendency in thromboembolic disease.² The term *thrombophilia* was then used to describe patients with prominent manifestations of venous thromboembolism (VTE; venous thrombosis in any site or pulmonary embolism) such as recurrent spontaneous VTE, VTE at young age, a strong family history of VTE, or thrombosis in an unusual site, such as the splanchnic veins or cerebral sinuses. Currently, the term *thrombophilia* is generally used for laboratory abnormalities, usually in the coagulation system, which increase the risk of VTE. Thrombophilia can be either acquired or hereditary. An example of acquired thrombophilia is the antiphospholipid syndrome, which is characterized by a tendency toward venous or arterial thrombosis or pregnancy complications, in combination with persistent lupus anticoagulant or antibodies to cardiolipin or β_2 -glycoprotein-1 (Chap. 131). Furthermore, there are many acquired and transient conditions that lead to a prothrombotic state, including cancer, surgery, strict immobilization, pregnancy and the postpartum period, and the use of estrogen-containing medication, such as oral contraceptives and hormone replacement therapy.

Patients with hereditary thrombophilia have an increased risk of developing VTE and just like in patients without thrombophilia, approximately half of patients will develop their first episode in relation to an acquired prothrombotic risk factor. Moreover, despite young age being a criterion for thrombophilia and the mean age at time of a first thrombosis being approximately 10 years lower than in the general population, the majority of patients with thrombophilia will have the first episode later in life.³ The theoretical concept is that patients with thrombophilia have an intrinsic prothrombotic state, which in itself is insufficient to cause thrombosis, but may lead to an event when superimposed upon (clinical) risk factors, including increasing age.³

The role of hereditary thrombophilia in arterial cardiovascular disease has been extensively studied.^{4,5} Most of those studies did not demonstrate significant associations between hereditary thrombophilia and arterial disease with the exception of patients with events before the age of 55 years.⁵ Moreover, the relative risk increase was very modest (odds ratios [OR] of 1.1 to 1.8) in studies that did find significant associations, indicating that hereditary thrombophilia is not a major risk factor for arterial cardiovascular disease.⁴

Like the acquired antiphospholipid syndrome, most hereditary thrombophilias are also modestly associated with pregnancy related disorders such as (recurrent) miscarriage, stillbirth, intrauterine growth retardation, preeclampsia and the hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome of pregnancy, although for later pregnancy complications this association is controversial.⁶⁻⁸

In the past decades, hereditary thrombophilia has evolved from a very rare genetic disorder to a prevalent trait. This evolution is a direct consequence of increasing insight into the blood coagulation system, as well as advanced genetic research tools that allowed the search for abnormalities in candidate coagulation proteins and their encoding genes. At present, some form of thrombophilia can be identified in about half of the patients presenting with VTE. Likely inspired by the high yield of thrombophilia testing, testing has increased tremendously for various indications,⁹ but whether the results of such tests help in the clinical management of patients has still not been settled.^{10,11} This chapter provides an overview of the most important hereditary thrombophilias and of the history of thrombophilia research. It reviews the risks associated with the most commonly tested thrombophilias and provides guidance on the indications and potential implications of the results of thrombophilia testing in various patient groups.

Acronyms and Abbreviations: 95% CI, 95% confidence interval; APC, activated protein C; ASA, acetylsalicylic acid; HELLP, hemolysis, elevated liver enzymes, low platelets; LMWH, low-molecular-weight heparin; MTHFR, methylenetetrahydrofolate reductase; OR, odds ratio; VKA, vitamin K antagonist; VTE, venous thromboembolism; VWF, von Willebrand factor.

HISTORY, CLASSIFICATION, PATHOPHYSIOLOGY, AND PREVALENCE OF THROMBOPHILIA

HISTORY OF THROMBOPHILIA RESEARCH

Research into thrombophilia began with the investigation of candidate coagulation proteins and their genes in highly thrombophilic families and linking abnormalities with the clinical phenotype within these families. As a next step, findings were confirmed in case-control studies, which yielded risk increases compared to controls, often derived from the general population. For clinicians and patients however, absolute risk estimates were needed to guide decisions regarding prevention or treatment. These were sought again in family studies of consecutive probands with a specific thrombophilic defect. The major progress in genetic and bioinformatics techniques now allows investigation in populations of patients with VTE, as well as in thrombophilic families.^{12–14}

In 1965, deficiency of the natural anticoagulant antithrombin became the first hereditary thrombophilia when Egeberg reported a Norwegian family with a remarkable tendency to VTE.¹⁵ Deficiencies of the other anticoagulant proteins, that is, protein C and protein S, were discovered as hereditary risk factors for VTE in the early 1980s.^{16,17} By that time, genes could be cloned and numerous mutations in the genes encoding antithrombin, protein C, and protein S had been identified as underlying causes of low plasma levels of the anticoagulant proteins.^{18–20} Another decade later, in 1993, Dahlbäck and colleagues described the phenomenon of activated protein C (APC) resistance, a poor anticoagulant response to APC, in a Swedish family with an increased tendency to develop VTE.²¹ The genetic basis for this APC resistance was discovered independently in several laboratories in 1995 and is caused by a single point mutation in the factor V gene which was termed *factor V Leiden*.^{22–25} In 1996, genetic analysis of prothrombin revealed a G-to-A transition at position 20210 that was more common in patients with VTE and a strong family history of this disease than in healthy controls without VTE.²⁶ In the 1970s, it was found that individuals with non-O blood group have an increased risk of VTE.²⁷ Individuals with non-O blood group have higher levels of von Willebrand factor (VWF) and factor VIII than people with blood group O, which was the presumed mechanism of increased risk. In 1995, data from the Leiden Thrombophilia Study, a case-control study of patients with VTE and matched healthy controls, demonstrated that increased factor VIII (FVIII) activity, but not VWF activity, was independently associated with an increased risk of VTE.²⁸ Homocysteine is an intermediary amino acid formed by the conversion of methionine to cysteine. Homocystinuria or severe hyperhomocysteinemia is a rare autosomal recessive disorder characterized by severe elevations in plasma and urine homocysteine concentrations. This disease is characterized by developmental delay, osteoporosis, ocular abnormalities, and severe occlusive vascular disease. About half of the vascular complications are of venous origin.²⁹ Mild hyperhomocysteinemia was therefore studied as a risk factor for VTE in the 1990s and homocysteine levels exceeding the 95th percentile of the normal population were confirmed to be a risk factor for VTE.³⁰

Since then, numerous genetic variants that increase the risk of VTE to a more or lesser extent have been identified and are variably included in diagnostic panels of thrombophilia testing.³¹ Essentially, the majority of hereditary thrombophilias exert their effect either by upregulation of procoagulant clotting factors, or by downregulation of anticoagulant factors (Fig. 130–1). An overview of the common hereditary thrombophilias that increase the risk at least twofold, and their prevalence in patients with VTE and in the general population is presented in Table 130–1. For these more common thrombophilias a large

Figure 130–1. Regulation of blood coagulation. Coagulation is initiated by a tissue factor (TF)–factor VIIa complex that can activate factor IX or factor X. At high TF concentrations, factor X is activated primarily by the TF-VIIa complex, whereas at low TF concentrations, the contribution of the factor IXa–factor VIIIa complex to the activation of factor X becomes more pronounced. Coagulation is maintained through the activation by thrombin of factor XI. The coagulation system is regulated by the protein C pathway. Thrombin activates protein C. Together with protein S, activated protein C (APC) is capable of inactivating factors Va and VIIIa, which results in a downregulation of thrombin generation and consequently in an upregulation of the fibrinolytic system. The activity of thrombin is controlled by the inhibitor antithrombin. The *solid arrows* indicate activation and the *broken arrows* inhibition.

number of clinical studies provided reliable estimates of the relative and absolute risk for VTE.

CLASSIFICATION, PATHOPHYSIOLOGY AND PREVALENCE OF COMMON HEREDITARY THROMBOPHILIA

Deficiencies of the Natural Anticoagulants Antithrombin, Protein C, and Protein S

Deficiencies of the natural anticoagulants antithrombin, protein C, and protein S, were among the first established hereditary thrombophilias. For antithrombin and protein C, two types of deficiencies are distinguished. In type I deficiency, levels of both antigen and activity are

TABLE 130–1. Prevalence of Common Hereditary Thrombophilia

	General Population	Patients with VTE
Antithrombin, protein S, or protein C deficiency	1% ^{42–44}	7% ⁴¹
Factor V Leiden	Whites 4–7% ^{46,118} Nonwhites 0–1%	21% ²²
Prothrombin G20210A	Whites 2–3% ^{56,119} Nonwhites 0–1%	6%
Elevated FVIII:c levels	11% ²⁸	25% ²⁸
Mild hyperhomocysteinemia	5% ³⁰	10% ³⁰

FVIII, factor VIII; VTE, venous thromboembolism.

reduced and in type II, antigen levels are normal, but one or more functional defects in the molecule lead to a decreased activity. Type II antithrombin deficiencies are further subdivided according to the site of the defect in antithrombin. The defect is located in the thrombin binding domain (i.e., the reactive site) in type IIa deficiency, in the heparin binding domain in type IIb deficiency, and type IIc deficiency comprises a pleiotropic group of mutations.³² Interestingly, patients with type IIb deficiency seem to have a significantly lower risk of VTE than other types.³² Protein S circulates in two forms: free protein S (approximately 40 to 50 percent) which functions as a cofactor for APC, and protein S bound to complement component C4b-binding protein. In type I deficiency, total and free antigen levels and activity are all reduced, in type II deficiency, total and free antigen are normal, but activity is reduced, and in type III deficiency, activity and free antigen are reduced, while total antigen is low to normal. Type I and type III are probably phenotypic variants of the same disease as family members with the same DNA mutation can present with either type I or type III deficiency.³³ Whether this classification into various subtypes is truly clinically relevant for any of the deficiencies of the natural anticoagulants is largely unknown. Moreover, most laboratory panels now only test the activity of antithrombin, protein C, or protein S, and thereby do not distinguish between different types of deficiencies. Homozygous antithrombin deficiency is extremely rare and the only reported cases involve type IIb deficiencies.³⁴ Homozygous type I deficiency has never been described in humans and is believed to be incompatible with life. Complete antithrombin deficiency in knockout mice leads to embryonic death.³⁵ Homozygous protein C and protein S deficiencies are also very rare and these are associated with neonatal purpura fulminans and massive thrombosis.^{36,37} In a similar fashion, warfarin-induced skin necrosis has been described in patients with heterozygous protein C or S deficiencies after initiation of vitamin K antagonists (VKAs).^{38,39} The concept is that after VKA initiation vitamin K-dependent protein C and S levels drop sooner than levels of factors II, IX, and X, thereby temporarily causing a paradoxical procoagulant state.⁴⁰ This is, however, a rare clinical complication, possibly resulting from concomitant treatment with (low-molecular-weight) heparin in the acute phase of VTE. Deficiencies can be caused by a large number of mutations, that are recorded in occasionally updated databases.^{18–20} Overall, deficiencies of the natural

anticoagulants are rare (see Table 130–1). In cohorts of consecutive patients with VTE, the prevalence of a deficiency of one of the natural anticoagulants is below 10 percent.⁴¹ In the general population, the prevalence of the deficiencies combined is approximately 1 percent.^{42–44}

Factor V Leiden/Factor V G1691A

In 1993, Dahlbäck and colleagues first described APC resistance in a Swedish family with a high tendency of VTE.²¹ In the original paper, Dahlbäck proposed that APC resistance was best explained by an hereditary deficiency of a previously unrecognized cofactor to APC, after having ruled out several possible mechanisms, including deficiencies of protein S and protein C, or linkage with polymorphisms in the FVIII or VWF genes. He then showed that this "cofactor" was identical to coagulation factor V.²¹ Soon thereafter, several laboratories independently from each other reported the underlying genetic defect, a single G-to-A substitution in the gene of factor V at nucleotide position 1691, resulting in an amino acid change from Arginine (Arg) to Glutamine (Gln) at position 506, the first cleavage site of factor Va for APC^{22–25} (Fig. 130–2). The mutation was named factor V Leiden after the city in the Netherlands in which the group with the first publication was located.²² The proteolytic inactivation of activated factor V (FVa) is approximately 10 times slower for Gln506-FVa compared with Arg506-FVa, which explains the partial, but not full, resistance to APC.⁴⁵ Factor V Leiden is the most common hereditary thrombophilia. In unselected consecutive patients with VTE, the prevalence is 20 to 25 percent.²² The prevalence in the general population varies considerably between different ethnic groups. Factor V Leiden is very rare among Asians and Africans but has a high prevalence (approximately 5 percent) among whites (see Table 130–1).⁴⁶ Within Europe, the prevalence is higher in the north than in the south.⁴⁶ This implies a founder effect that suggests that the mutation occurred after the separation of non-Africans from Africans and after the divergence of whites and Asians. Studies using linkage disequilibria between factor V Leiden and specific markers indicate that the mutation occurred around 21,000 years ago.⁴⁷ The high prevalence of factor V Leiden suggests an evolutionary benefit.⁴⁸ The presumed mechanism is reduced peripartum and menstrual blood loss in affected female carriers.^{49,50} More recently, factor V Leiden was associated with increased sperm counts and a shorter conception time in affected male

Figure 130–2. Pathophysiology of the factor V Leiden mutation. **A.** Activated protein C inactivates factor Va by cleaving the protein at the Arginine (Arg)⁵⁰⁶ cleavage site. **B.** In carriers of the factor V Leiden mutation, a point mutation in the gene coding for factor V, causes replacement of the amino acid Arginine by Glutamine (Gln) at position 506 of the protein, making factor Va resistant to inactivation by activated protein C (i.e., APC resistance).

and female carriers, suggesting another evolutionary benefit.⁵¹⁻⁵³ The mechanism for this increased fertility is unknown.

Prothrombin G20210A

The prothrombin G20210A mutation was discovered in 1996 by genetic analysis of the prothrombin gene in families with a strong tendency of VTE and confirmed in a case-control study of patients with VTE.²⁶ The mutation is located in the 3'-untranslated region of the prothrombin gene and augments translation and stability of prothrombin messenger RNA.⁵⁴ This leads to an average 32 percent higher blood levels of the zymogen prothrombin that is structurally identical to the protein produced by patients with the wild-type gene.²⁶ In unselected patients with VTE, the prevalence of prothrombin G20210A is approximately 6 percent.⁵⁵ Like factor V Leiden, the prothrombin G20210A mutation is found largely in whites and genetic linkage disequilibrium studies date the mutation back to 24,000 years ago.^{47,56} Within Europe, the prevalence of the mutation increases from 3 to 5 percent in Southern Europe and the Middle East to 1 to 2 percent in Northern Europe, which opposes the observed geographical gradient of factor V Leiden.⁵⁶

Increased Levels of Factor VIII

Most of coagulation FVIII circulates in complex with VWF. Therefore, determinants of VWF, including ABO-blood group and endothelial stimulation, indirectly also determine FVIII levels.⁵⁷ Furthermore, many other factors have been associated with high FVIII levels, including increasing age, high body mass index, diabetes mellitus, and hypertriglyceridemia.⁵⁷ High FVIII levels are part of acute phase reactions and sustained increases are observed during pregnancy, surgery, chronic inflammation, malignancy, liver disease, hyperthyroidism, renal disease. In most of these conditions, there is a concordant increase of FVIII and VWF levels.⁵⁷ Apart from ABO blood group, the genetic causes of high FVIII levels are largely unknown. Nevertheless, persistence over time and familial clustering of high FVIII levels in patients with VTE implies that genetic factors are prevalent. In a family study of consecutive patients with persistently elevated levels of FVIII of at least 150 percent and venous or arterial thrombosis, the prevalence of high FVIII in first degree family members was 40 percent, which is almost in the range to what one would expect from an autosomal dominant inheritance.⁵⁸ Despite the uncertainty about the mechanisms of high FVIII levels, the association between high FVIII levels and venous thrombosis is well established. The very clear dose-dependent relationship between FVIII levels and the risk of VTE suggests that elevated FVIII is causative for thrombosis.²⁸ Interestingly, increased FVIII levels in patients with VTE are usually not influenced by acute-phase reactions.⁵⁷ The prevalence of elevated FVIII levels is high: 25 percent of patients with a first episode of deep-vein thrombosis and 11 percent of healthy control subjects have FVIII levels of 150 percent or higher.²⁸ Hence, an increased level of FVIII is the most common familial, albeit not monogenetic, thrombophilia with an estimated population attributable risk of 15 percent.⁵⁷ Whether measurement of FVIII levels should be part of a hereditary thrombophilia panel is debatable as FVIII levels may be transiently increased by a multitude of external factors including the acute VTE episode itself (Table 130-2). This leads to a significant proportion of "false-positive" test results, a necessity for repeat testing, and potentially unnecessary concern among tested patients.

Mild Hyperhomocysteinemia

Homocysteine is an intermediate in the metabolism of the amino acids methionine and cysteine and participates in several metabolic pathways. Some of the enzymes involved in homocysteine metabolism are dependent on vitamin B₆, folic acid, and vitamin B₁₂, and deficiencies lead to hyperhomocysteinemia. A polymorphism in the enzyme

TABLE 130-2. Acquired Conditions That Can Yield False-Positive Thrombophilia Test Results

Test	Acquired Conditions That Can Cause Abnormal Test Results
Increased activated protein C (APC) resistance	Pregnancy, use of oral contraceptives, stroke, presence of lupus anticoagulant, increased factor VIII levels, autoantibodies against APC
Factor V Leiden	—
Prothrombin G20210A	—
Hyperhomocysteinemia	Deficiencies of folate (vitamin B ₁₁), vitamin B ₁₂ , or vitamin B ₆ , old age, renal failure, excessive consumption of coffee, smoking
Increased factor VIII levels	Pregnancy, use of oral contraceptives, exercise, stress, older age, acute phase response, liver disease, hyperthyroidism, cancer
Decreased level of protein C	Liver disease, use of vitamin K antagonist (VKA), vitamin K deficiency, childhood, disseminated intravascular coagulation, presence of autoantibodies against protein C
Decreased level of free protein S	Liver disease, use of VKA, vitamin K deficiency, pregnancy, use of oral contraceptives, nephrotic syndrome, childhood, presence of autoantibodies against protein S, disseminated intravascular coagulation
Decreased level of antithrombin	Use of heparin, thrombosis, disseminated intravascular coagulation, liver disease, nephrotic syndrome

methylenetetrahydrofolate reductase (MTHFR), c.C677T, leads to an alanine to valine substitution at position 222 resulting in a variant enzyme with reduced activity and increased thermolability. Homozygosity for this polymorphism leads to 24 percent increased homocysteine levels and is the most common genetic cause of mild hyperhomocysteinemia.⁵⁹ The prevalence is 10 to 20 percent in whites and 10 percent in Orientals, but it is rare in Africans.⁶⁰ Many other conditions are associated with hyperhomocysteinemia, including renal failure, hypothyroidism, smoking, excessive coffee consumption, inflammatory bowel disease, psoriasis, and rheumatoid arthritis.⁶¹ Severe hyperhomocysteinemia (plasma levels exceeding 100 $\mu\text{mol/L}$), also named homocystinuria, is a rare autosomal recessive disorder clearly associated with vascular occlusive disease.²⁹ Because of this association, mildly increased levels (exceeding the 95th percentile of the normal population) were studied as a risk factor for venous and arterial thrombosis. In the Leiden Thrombophilia Study mild hyperhomocysteinemia was associated with a 2.5-fold increased risk of first VTE.³⁰ Interestingly, the association of homocysteine levels with VTE was stronger in men than in women and increased with age.³⁰ The mechanism by which hyperhomocysteinemia would lead to thrombosis is unknown. A 2005 meta-analysis that included more than 50 studies with more than 8000 cases of VTE confirmed the association of VTE with hyperhomocysteinemia and also demonstrated a 20 percent higher VTE risk in MTHFR 677TT carriers compared with 677CC carriers.⁶²

The association between homocysteine levels is again under scrutiny in newer studies. The single largest case-control study of more than 4000 patients with a first VTE found no association between MTHFR 677TT and VTE.⁶³ Furthermore, a family study of probands with mild hyperhomocysteinemia and venous or arterial thrombosis found that the association between homocysteine and VTE disappeared after adjustment for FVIII levels.⁶⁴ Finally, homocysteine lowering by B vitamins did not reduce the incidence of recurrent events both in patients with VTE as well as in patients with arterial cardiovascular disease.^{65,66} As a result of these studies, homocysteine testing (either its levels of polymorphisms) as part of a thrombophilia panel has been largely abandoned.

PITFALLS IN LABORATORY TESTING FOR HEREDITARY THROMBOPHILIA

Testing for hereditary thrombophilia is performed in many patients, or family members of patients, with various thromboembolic diseases or pregnancy complications.⁹ However, it is important to realize that many acquired, often transient, conditions may affect the test results. Most known is the use of VKAs, which reduces the levels of anticoagulant factors protein C and protein S, which can thereby mimic severe deficiencies. Another example is pregnancy that reduces free protein S levels and increases APC resistance and FVIII levels.⁶⁷ However, other factors can also affect test results and should be considered in the interpretation of results or, better yet, in the timing of testing. Table 130–2 presents an overview of acquired conditions that can yield false-positive thrombophilia tests. For deficiencies of the natural anticoagulants as well as for elevated FVIII levels, repeated testing should be performed to exclude spuriously abnormal tests. Genetic testing for deficiencies of the natural anticoagulants is not performed because of the large number of known mutations. The hereditary nature of deficiencies must be established by confirming the abnormality in a first-degree family member.

HEREDITARY THROMBOPHILIA AND THE RISK OF DISEASE

VENOUS THROMBOEMBOLISM

The relative risk of a first episode of VTE in individuals with a form of common hereditary thrombophilia ranges from 2 to 11 (Table 130–3). These figures were derived from family and population-based cohort or case-control studies.¹¹ Individuals homozygous for the prothrombin G20210A or factor V Leiden mutations are at higher risk for VTE than

heterozygotes. Likewise, patients with combined thrombophilic disorders have a higher risk of VTE than those with a single defect.¹¹ One can estimate the absolute risk of VTE by multiplying the relative risk with the absolute incidence in cohorts from the general population, in which the risk of first VTE is approximately 0.2 to 0.3 per 100 person-years.⁶⁸ Because this may however lead to imprecise estimates, it is preferable to use absolute risk estimates derived from cohort studies. Retrospective cohort studies may produce less-reliable incidence estimates because retrospective studies carry the risk of (unconscious) selection of patients and data and the clinical diagnosis of VTE may not have been confirmed by objective tests. Prospective cohort studies of asymptomatic carriers of hereditary thrombophilic defects are probably better suited to estimate the true incidence of thrombosis in thrombophilic patients. It is important to note that cohort studies have been mainly performed in relatives of (consecutive) patients with a particular thrombophilic defect. Absolute risk estimates from family studies are higher than from population based studies. Even in the absence of any hereditary thrombophilia, the risk of VTE is still twofold increased in first degree family members of patients with VTE.⁶⁹ This suggests cosegregation of other, unmeasured or unknown thrombophilias. Table 130–4 presents absolute risk estimates for a first-episode VTE for asymptomatic carriers with a family history of VTE. These risk estimates can be used to counsel both affected and unaffected family members about their risk of VTE. These studies also provide absolute risk estimates for VTE associated with exogenous additional risk factors such as surgery, trauma or immobilization, and pregnancy or use of hormonal contraception (Table 130–4). These incidences are derived from retrospective family studies, as prospective studies are limited by shorter followup duration and reduced power.

Thrombophilia and the Risk of Recurrent Venous Thromboembolism

Regardless of thrombophilia, the absolute risk of a recurrent episode is much higher than the risk of a first episode of VTE. The most important determinant of recurrence is the presence of transient clinical risk factors during the time of the first episode.⁷⁰ After an unprovoked first episode of VTE, the risk of recurrence is approximately 10 percent in the first year after cessation of anticoagulation and approximately 5 percent per year thereafter.⁷⁰ The risk is lower after VTE that was associated with a transient risk factor, with an incidence in the first 2 years of 0.7 percent per year for surgery-provoked VTE and 4.2 percent per year for VTE provoked by estrogen use, pregnancy, temporary immobilization, or trauma.⁷⁰ Other determinants for recurrence are male sex, proximal

TABLE 130–3. Relative Risk Estimates for Common Hereditary Thrombophilias and Venous or Arterial Thrombosis and Pregnancy Complications

	Relative Risk			
	First VTE	Recurrent VTE	Arterial Thrombosis	Pregnancy Complications
Antithrombin deficiency	5–10	1.9–2.6	No association	1.3–3.6
Protein C deficiency	4–6.5	1.4–1.8	No consistent association	1.3–3.6
Protein S deficiency	1–10	1.0–1.4	No consistent association	1.3–3.6
Factor V Leiden	3–5	1.4	1.3	1.0–2.6
Prothrombin G20210A	2–3	1.4	0.9	0.9–1.3
Persistently elevated FVIII	2–11	6–11	–	4.0
Mild hyperhomocysteinemia	2.5–2.6	2.6–3.1	–	No consistent association

FVIII, factor VIII; VTE, venous thromboembolism.

Risk estimated are derived from studies reviewed in detail elsewhere.¹¹

TABLE 130-4. Absolute Incidences for a First Episode of Venous Thromboembolism in Asymptomatic Family Members of Consecutive Patients with Venous Thromboembolism

	Incidence Any VTE (% Per Year)	Surgery, Trauma, Immobilization (% Per Episode)	Pregnancy (% Per Pregnancy Including Postpartum Period)	Oral Contraceptive Use (% Per Year of Use)
Antithrombin, protein C, or protein S deficiency ¹²⁰				
Affected family members	1.0 (0.7–1.4)	8.1 (4.5–13.2)	4.1 (1.7–8.3)	4.3 (1.4–9.7)
Unaffected family members	0.1 (0.0–0.2)	0.9 (0.3–3.2)	0.5 (0.0–2.8)	0.7 (0.0–3.3)
Factor V Leiden ¹²¹				
Affected family members	0.5 (0.3–0.6)	1.8 (0.7–4.0)	2.1 (0.7–4.9)*	0.5 (0.1–1.4)

[†]The population risk of pregnancy-related VTE is 0.2% per pregnancy.¹⁰³

(vs. distal) deep venous thrombosis (DVT), and elevated D-dimer levels after stopping anticoagulation.⁷⁰

Although individuals with hereditary thrombophilia have a higher risk of developing a first episode of VTE, the risk increases for recurrent events in patients with prior VTE are much lower. Numerous case-control studies in VTE patients with a specific thrombophilia with nonthrombophilic VTE patients as controls yield relative risks of 1.5 to 2.0 for most hereditary thrombophilias.^{71–76} Patients develop VTE when the combination of individual susceptibility (including hereditary thrombophilia) and acquired, sometimes transient, risk factors are sufficient to cause VTE. This individual susceptibility is constant throughout life. Therefore, patients with a previous episode of VTE have proven to have sufficient individual susceptibility, irrespective of hereditary thrombophilia being part of that susceptibility. This explains why the risk for recurrence is at best only marginally increased for carriers of hereditary thrombophilia.⁷⁷

ARTERIAL THROMBOEMBOLIC DISEASE

The increased risk of VTE in patients with hereditary thrombophilia has led to many studies investigating the association of thrombophilia with arterial thromboembolic disease. Factor V Leiden and prothrombin G20210A are the most extensively studied as risk factors for arterial disease. The largest meta-analysis of case-control studies of patients with myocardial infarction found an OR of 1.17 (95% confidence interval [95% CI] 1.08 to 1.28) for factor V Leiden (60 studies with 42,390 patients) and 1.31 (95% CI 1.12 to 1.52) for prothrombin G20210A (40 studies with 26,087 patients).⁴ The association between these mutations and myocardial infarction is stronger when analyses are limited to patients with myocardial infarction below the age of 55 years with ORs of 1.34 (95% CI 0.94 to 1.91) for factor V Leiden and 1.86 (95% CI

1.00 to 3.51) for prothrombin G20210A.⁵ Meta-analyses of studies in patients with ischemic stroke have shown similar modest risk increases in patients with factor V Leiden or prothrombin G20210A.⁷⁸

Deficiencies of the natural anticoagulants are less prevalent than factor V Leiden and prothrombin G20210A and as a result, the association with arterial thromboembolic disease has not been extensively studied. Although various case reports of patients with antithrombin, protein C, or protein S deficiency have been published, most case-control studies have failed to demonstrate a significant association with myocardial infarction and ischemic stroke.⁷⁹ A retrospective cohort study of 552 first-degree family members of patients with venous or arterial thrombosis and a deficiency of either antithrombin, protein C or protein S found no increased risk of arterial cardiovascular disease in affected family members older than age 55 years.⁸⁰ However, in persons younger than age 55 years, protein C and protein S were associated with a five- to ninefold increased risk, whereas antithrombin deficiency did not confer an increased risk.⁸⁰

Several case-control studies have found associations with elevated FVIII levels and myocardial infarction.⁵⁷ Furthermore, prospective cohort studies of healthy individuals have demonstrated marginally increased risks of myocardial infarction and stroke in patients with elevated FVIII levels (ORs between 1.0 and 1.4).⁵⁷ In a prospective family study of asymptomatic first-degree family members of patients with elevated FVIII and either VTE or premature arterial thrombosis, the risk of arterial thromboembolism was increased 4.5-fold compared with family members with normal FVIII levels.⁸¹ However, elevated FVIII levels are associated with several well-known risk factors for arterial cardiovascular disease, including obesity, high glucose levels, increasing age, chronic inflammatory diseases, and renal disease.⁵⁷ It is possible that studies evaluating the association between elevated FVIII and arterial

thromboembolic disease have not been able to sufficiently adjust for known and unknown confounders. Moreover, acute myocardial infarction and ischemic stroke may cause acute-phase reactions that transiently increase FVIII levels, hampering interpretation of case-control or retrospective cohort studies. However, patients with hemophilia A, a genetic cause of decreased FVIII levels, have an approximate 80 percent lower risk of death from ischemic heart disease, indicating a potential causal relation between FVIII levels and arterial thrombosis.⁸²

Mild hyperhomocysteinemia and MTHFR 677TT have been extensively studied in relation to arterial thromboembolic disease. A meta-analysis of studies that included more than 5000 patients with ischemic heart disease and more than 1000 patients with ischemic stroke demonstrated a significant correlation between homocysteine level and the risk of arterial thrombosis.⁸³ The risk increase in was higher in retrospective studies than in prospective studies in which homocysteine levels are measured before the thrombotic episodes. This could, in part, be explained by the observed association between hyperhomocysteinemia and other well-known risk factors for arterial cardiovascular disease, including smoking, chronic inflammatory disorders, and renal failure.⁶¹ Like with elevated FVIII levels, it is uncertain whether studies that investigate the relation between homocysteine and arterial cardiovascular disease have been able to sufficiently adjust for confounding variables. The association between MTHFR 677TT and ischemic heart disease has shown mixed results with no association in studies in North American patients and a modest 16 percent risk increase in studies in European patients.⁸⁴ It was initially hypothesized that this difference is attributable to a lower dietary folate intake in Europe. However, this hypothesis conflicts with the results of trials in patients with vascular disease in whom homocysteine lowering with folic acid and B vitamins did not reduce the risk of recurrent episodes.⁶⁶

PREGNANCY COMPLICATIONS

Although many studies have observed a relationship between hereditary thrombophilia and pregnancy complications, including recurrent miscarriage, late pregnancy loss, preeclampsia, intrauterine growth restriction, and placental abruption, this should be regarded as controversial. Most associations are modest in strength and vary with type of thrombophilia and type of pregnancy complication.^{85,86} Furthermore, the most recent and larger prospective cohort studies found lower ORs for hereditary thrombophilia than older and smaller case-control studies, which may point to a bias in the observed associations.^{87,88} The mechanisms of how thrombophilia would lead to pregnancy complications remain largely unknown. It is unlikely that mere hypercoagulability with thrombosis of placental vasculature is the pathophysiologic substrate for an association with thrombophilia. Animal and *in vitro* studies have implicated a role for both procoagulant and inflammatory pathways in pregnancy failure and interesting effects of acetylsalicylic acid (ASA) and heparin.⁸⁹ For instance, in a murine high-risk pregnancy model, heparin rescued factor V Leiden-associated placental failure, but this was independent of anticoagulation.⁹⁰

CLINICAL IMPLICATIONS OF THROMBOPHILIA INCLUDING TESTING

GENERAL CONSIDERATIONS OF THROMBOPHILIA TESTING

Several arguments against testing for thrombophilia should be considered.¹⁰ First, an obvious disadvantage of testing for thrombophilia is the high cost. Although two studies concluded that testing for thrombophilia

in some scenarios could be cost-effective, the underlying assumptions from inconsistent observational studies seriously hamper their interpretation.^{91,92} Second, although the psychological impact and consequences of knowing that one is a carrier of a (genetic) thrombophilic defect are considered limited, a qualitative study described several negative effects of both psychological and social origins.^{93,94} Difficulties in obtaining life or disability insurance are frequently encountered by individuals who are known carriers of thrombophilia, regardless of whether they are symptomatic or asymptomatic.⁹³ Third, the most compelling argument against testing is the potential false reassurance that may arise from a negative thrombophilia test for individuals who come from families with a thrombotic tendency. For example, Table 130-4 indicates that in these families, women without thrombophilia have a markedly increased risk of oral contraceptive-related VTE compared to pill users from the general population (0.7 percent in women with a natural anticoagulant deficiency versus 0.04 percent per year of use), reflecting a selection of families with a strong thrombotic tendency in which yet unknown thrombophilias have co-segregated.

The following paragraphs discuss the potential scenarios for thrombophilia testing in more detail.

TESTING FOR THROMBOPHILIA TO MODIFY THE RISK OF A FIRST VENOUS THROMBOEMBOLISM

Having a family history of VTE is a poor predictor of the presence of thrombophilia.^{69,95} Still, a potential advantage of testing patients with VTE for thrombophilia may be the identification of asymptomatic family members in order to take preventive measures if tested positive, and to withhold such measures if relatives have tested negative. An important requisite is that a test result indeed dichotomizes carriers and non-carriers in terms of their risk for a first episode of VTE.

Based on the absolute risks for a first episode of VTE (see Table 130-4), it is clear that the 1 to 3 percent annual major bleeding risk associated with continuous oral anticoagulant treatment outweighs the risk of VTE.^{96,97} Table 130-4 also shows that during high-risk situations such as surgery, immobilization, trauma, pregnancy, and the postpartum period, and during the use of oral contraceptives, the absolute risk is generally low, with the exception of women with a natural anticoagulant deficiency who use oral contraceptives or are pregnant.

Estimates of the effect of avoidance of oral contraceptives on the number of prevented episodes of VTE by means of thrombophilia testing can be calculated for women who have a positive first-degree relative with VTE in whom the thrombophilic defect is known.⁹⁸ To avoid one VTE event, 28 women with antithrombin, protein C or protein S deficiency, and a positive family history for VTE would need to refrain from oral contraceptives, and to identify these women, 56 female relatives would need to be tested.⁹⁸ For factor V Leiden or the prothrombin 20210A mutation, approximately 333 women would need to avoid oral contraceptives and 666 female relatives would need to be tested. Although the number of tested women for the natural deficiencies seems quite acceptable, the major argument against this scenario is that a normal level of antithrombin, protein C, or protein S in women from these families does not exclude a strongly increased risk of VTE during oral contraceptive use, as compared to the general population (see Table 130-4). The same, but to a lesser extent, is true for women from thrombophilic families who do not carry either the factor V Leiden or prothrombin mutation, but here also the number needed to screen is unacceptably high.

Table 130-5 indicates the estimated number needed to test to initiate prophylactic measurements around pregnancy, again applicable

TABLE 130–5. Estimated Number of Asymptomatic Thrombophilic Women Who Should Use Low-Molecular-Weight Heparin Prophylaxis During Pregnancy and/or the Postpartum Period to Prevent Pregnancy-Related Venous Thromboembolism, and Estimated Number Needed to Test

Thrombophilia	Risk of VTE Per Pregnancy*, %	Risk Difference Per 100 Women	Number Using Prophylaxis to Prevent 1 VTE [†]	Number of Female Relatives to Be Tested
Antithrombin, protein C, or protein S deficiency				
Deficient relatives	4.1 [‡]	3.6	28	56
Nondeficient relatives	0.5 [‡]			
Factor V Leiden or prothrombin 20210A mutation, heterozygous				
Relatives with the mutation	2.0 [‡]	1.5	66	132
Relatives without the mutation	0.5 [‡]

Homozygous relatives	16.0	15.5	6	24
Relatives without the mutation	0.5 [§]			

VTE, venous thromboembolism.

*Antepartum and postpartum combined.

[†]These estimates apply to women with a positive family history of VTE and assume an unrealistic 100% efficacy of prophylaxis with low-molecular-weight heparin.

[‡]Based on family studies as outlined in Table 130–4.

[§]Summary estimate of the data as outlined in Table 130–4, combined for factor V Leiden and prothrombin mutation.

to women from thrombophilic families. Only for women with antithrombin, protein C, or protein S deficiency, or those who are homozygous for factor V Leiden (Table 130–5), the risks of 4 and 16 percent respectively during pregnancy and the postpartum period may outweigh the nuisance of daily subcutaneous low-molecular-weight heparin (LMWH) injections with frequently occurring skin reactions, and the very small risk for severe complications of anticoagulant therapy during pregnancy.^{99–102} Furthermore, the numbers in Table 130–5 underestimate the number of women that need to use prophylaxis (and be tested prior to this decision) in order to avoid pregnancy-related VTE, because a 100 percent efficacy of prophylaxis is assumed in these calculations. Whether the absolute risks of pregnancy-related VTE justifies prophylaxis for 8 months during pregnancy, or the shorter postpartum period of 6 weeks is a matter of the physicians' and patients' preference.¹⁰² The risk of pregnancy-related VTE in women from these families who do not have the hereditary thrombophilic defect is approximately 0.5 percent, compared to 0.2 percent in the general population.¹⁰³ Hence, withholding prophylaxis to women from thrombophilic families who do not have the defect is supported by evidence from well-designed studies of individuals in the same clinical context.

THROMBOPHILIA TESTING IN PATIENTS WITH VENOUS THROMBOEMBOLISM

Thrombophilia testing is most often considered in patients with VTE, particularly if they are young, have recurrent episodes, have thrombosis at unusual sites, or have a positive family history for the disease. However, although such a strategy may lead to an increased yield of testing, the main question is whether a positive test result should alter management. As previously discussed, thrombophilia is a very poor predictor of recurrent VTE, and whether the very modest risk increase warrants prolongation of the duration of anticoagulation, particularly after

provoked VTE, is a matter of debate.^{70,104} Furthermore, given the rarity of homozygous or double heterozygous thrombophilias in unselected patients with VTE, the efficiency of testing is obviously very low.^{10,105} A randomized controlled trial of testing for thrombophilia in patients with a first episode of VTE would provide the ultimate evidence to decide whether this is justified, but no such trials have been successfully performed.¹⁰⁶ To investigate whether testing for thrombophilia reduced the risk of recurrent VTE, 197 patients who had had a recurrent event were compared to 324 patients who did not have a recurrence.¹⁰⁷ The OR for recurrence was 1.2 (95% CI 0.9 to 1.8) for tested versus non-tested patients, indicating that testing, with real life clinical decisions based on the outcome of testing, did not reduce the risk of recurrent VTE in patients after a first episode.

THROMBOPHILIA TESTING IN PATIENTS WITH ARTERIAL CARDIOVASCULAR DISEASE

The association between hereditary thrombophilia and arterial cardiovascular disease is questionable, or at least much weaker than for VTE. The association is stronger in patients with events before the age of 55 years. As a result, thrombophilia test panels are often ordered in with arterial cardiovascular disease. In a survey among Dutch physicians that ordered thrombophilia tests in 2000 consecutive patients in 2003 and 2004, arterial cardiovascular disease, mainly ischemic stroke, was the indication for testing in 23 percent of patients.⁹ Interestingly, only 54 percent of those patients were younger than 50 years of age. Testing for hereditary thrombophilia in patients with (premature) arterial cardiovascular disease could only be justified if the test results would mandate different secondary prevention. However, more vigorous secondary prevention such as long-term dual antiplatelet therapy or oral anticoagulation instead of ASA monotherapy is not beneficial for most patients with arterial cardiovascular events, mainly because of the increased

risk of bleeding. Whether such a strategy is beneficial for patients with hereditary thrombophilia has never been tested, but is very unlikely given the very modest risk increases associated with hereditary thrombophilia. Therefore, testing in this setting is not justified.

THROMBOPHILIA TESTING IN WOMEN WITH PREGNANCY COMPLICATIONS

Thrombophilia testing in women with pregnancy complications would be indicated if a test result would alter management. However, to date, testing for hereditary thrombophilia in this setting cannot be justified^{10,102} for the following reasons. For women at moderate to high risk of preeclampsia, ASA provides a modest benefit in reducing the risk of preeclampsia, but this is regardless of the presence of hereditary thrombophilia.^{102,108} Whether anticoagulant treatment with heparin or LMWH improves the chance of a successful pregnancy outcome in women with pregnancy complications is presently unknown as results from randomized clinical trials are extremely inconsistent.^{109–113} It is also uncertain whether presence of hereditary thrombophilia is a prerequisite for an assumed beneficial effect, if any. Only three randomized controlled trials have been exclusively dedicated to women with hereditary thrombophilia and recurrent miscarriage, a single fetal loss, or late pregnancy complications. The first trial found promising results in women with heterozygous factor V Leiden mutation, prothrombin G20210A mutation, or protein S deficiency and a single previous pregnancy loss after 10 weeks gestation.¹¹⁴ Women who were allocated to enoxaparin had a much higher chance of a livebirth than those allocated to ASA (86 percent and 29 percent, respectively; OR 15.5; 95% CI 7 to 34), but several methodologic issues were raised, and the results of this single study have not been confirmed by other trials.^{102,115} Second, in the FRUIT trial, women with hereditary thrombophilia and a history of preeclampsia or intrauterine growth restriction requiring delivery before 34 weeks of gestation, were randomized between dalteparin with ASA and ASA alone.¹¹⁶ The primary outcome (recurrence of a hypertensive disorder, e.g., preeclampsia, HELLP, or eclampsia) did not differ between the two groups, but none of the women in the LMWH/ASA group developed recurrent hypertensive disorders prior to 34 weeks gestational age, whereas six women in the ASA-only group delivered before 34 weeks because of recurrent hypertensive disorders (risk difference 8.7 percent; 95% CI 1.9 to 15.5 percent). Finally, the TIPPS study included thrombophilic women at high risk for pregnancy complications or at increased risk of VTE and randomized them between dalteparin and no dalteparin.¹¹³ The primary composite outcome (severe or early onset preeclampsia, small-for-gestational-age infant, pregnancy loss, or VTE) did not differ between the groups. Hence, to date, there is no evidence from sufficiently powered and adequately designed clinical trials that justify use of heparin to improve pregnancy outcome in women with hereditary thrombophilia, and heparin should only be given in the context of a clinical trial.¹¹⁷

CONCLUSIONS

The knowledge about the hereditary contribution to the etiology of VTE has increased tremendously over the past decades. Still, testing for thrombophilia serves only a limited purpose and should not be performed on a routine basis. Thrombophilia testing in asymptomatic relatives may be useful in families with antithrombin, protein C, or protein S deficiency, or for siblings of patients who are homozygous for factor V Leiden, and is limited to women who intend to become pregnant or who would like to use oral contraceptives. Careful counseling with knowledge of absolute risks helps patients make an informed decision in which their own preferences can be taken into account, and in which

the clinician should be cautious to not provide false reassurance in case of a negative test result. Observational studies show that patients who have had VTE and have thrombophilia are at most at a slightly increased risk for reoccurrence. Other determinants, including circumstances during the first VTE, elevated D-dimer levels, and male sex, are better predictors of recurrent VTE.⁷⁰ Furthermore, no beneficial effect on the risk of recurrent VTE was observed in patients who had been tested for inherited thrombophilia. In the absence of trials that compared routine and prolonged anticoagulant treatment in patients testing positive for thrombophilia, testing for such defects to prolong anticoagulant therapy cannot be justified. Finally, there is at present no reason to test patients with arterial cardiovascular disease, or women with recurrent miscarriage or late pregnancy complications for hereditary thrombophilia, in the absence of evidence-based guidelines for changes in management.

CHAPTER 131

THE ANTIPHOSPHOLIPID SYNDROME

Jacob H. Rand and Lucia Wolgast

SUMMARY

The antiphospholipid (aPL) syndrome (APS) is an acquired thrombophilic disorder in which patients have vascular thrombosis and/or pregnancy complications attributable to placental insufficiency, accompanied by laboratory evidence for the presence of antiphospholipid antibodies in blood. The disorder is referred to as *primary APS* when it occurs in the absence of systemic lupus erythematosus (SLE), and *secondary APS* in its presence. Any portion of the circulatory tree can be affected, although the most frequently affected vessels are the deep veins of the lower extremities. Abnormalities that have been reported in association with the syndrome include virtually all other autoimmune disorders, immune thrombocytopenia, acquired platelet function abnormalities, hypoprothrombinemia, acquired inhibitors of coagulation factors, livedo reticularis, heart valve abnormalities, atherosclerosis, pulmonary hypertension, and migraine. Rare patients have a catastrophic form of APS (CAPS) in which there is disseminated thrombosis in large- and small-vessel thrombi, often after a triggering event such as infection or surgery, and often with multiorgan ischemia and infarction.

APS is a misnomer, the main antigenic targets for thrombogenic aPL antibodies are epitopes on phospholipid-binding proteins, the most important of which appears to be β_2 -glycoprotein I (β_2 GPI). The syndrome is identified by persistent abnormalities of laboratory tests for antibodies against these phospholipid-protein cofactor complexes, detected by immunoassays and by coagulation assays (also known as “lupus anticoagulant assays”) that, paradoxically, report the inhibition of phospholipid-dependent coagulation reactions. Long-term warfarin anticoagulant therapy is the usual treatment for thrombosis in patients with APS, although there is some controversy about whether treatment of patients with APS stroke might be better treated with aspirin. Patients with recurrent spontaneous pregnancy losses and APS generally are treated with aspirin and heparin for prophylaxis against deep vein thrombosis

Acronyms and Abbreviations: aCL, anticardiolipin; APC, activated protein C; aPL, antiphospholipid; APS, antiphospholipid syndrome; aPTT, activated partial thromboplastin time; ARDS, acute respiratory distress syndrome; ASIA, autoimmune/autoinflammatory syndrome induced by adjuvants; AVWS, acquired von Willebrand syndrome; BFP syphilis test, biologic false-positive serologic test for syphilis; β_2 GPI, β_2 -glycoprotein I; CAPS, catastrophic APS; CMV, cytomegalovirus; dRVVT, dilute Russell viper venom time; ELISA, enzyme-linked immunosorbent assay; HCQ, hydroxychloroquine; Ig, immunoglobulin; IL, interleukin; LA, lupus anticoagulant; LDL, low-density lipoprotein; LMWH, low-molecular-weight heparin; MAPK, mitogen-activated protein kinase; NOACs, new oral anticoagulants; RVV, Russell viper venom; SCR, short consensus repeat; SLE, systemic lupus erythematosus; TLR, toll-like receptor; TM, thrombomodulin; t-PA, tissue-type plasminogen activator; UFH, unfractionated heparin; VWF, von Willebrand factor.

during their pregnancies and the postpartum period. CAPS patients have a high mortality and, in addition to anticoagulants, often require plasmapheresis and immunosuppressive agents. Patients without clinical manifestations of APS or a history of SLE should generally not undergo diagnostic screening for aPL antibodies and, if tested and found to be positive, should not be committed to antithrombotic therapy solely on the basis of laboratory abnormalities.

DEFINITION AND HISTORY

The antiphospholipid (aPL) antibody syndrome (APS) is a disorder in which vascular thrombosis or pregnancy complications attributable to placental insufficiency occur in patients with laboratory evidence for antibodies directed against proteins that bind to phospholipids. The syndrome was first proposed to be a distinct entity, “the anticardiolipin (aCL) syndrome,” in 1985¹ and soon was renamed APS.² While precise data are not available, the syndrome is thought to affect approximately 10 percent of patients with venous thrombosis,^{3,4} and approximately 20 percent of women with three unexplained fetal losses before 12 weeks of gestation, or at least one intrauterine fetal death after 12 weeks of gestation.⁵

The term “aPL antibodies” can refer to (1) antibodies that recognize protein-phospholipid complexes as in cofactor-dependent aCL assays, (2) antibodies that recognize the proteins directly as in anti- β_2 glycoprotein I assays (anti- β_2 GPI), (3) an abnormal coagulation test in several assays that report inhibition of phospholipid-dependent coagulation reactions, collectively as termed *lupus anticoagulant* (LA) tests, and (4) antibodies that recognize phospholipid directly as in syphilis and are not associated with the APS disease entity.

A brief review of the history of APS⁶⁻⁸ helps explain the confusing terminology (Table 131-1); the reader is referred to references 6 to 8 for more detailed accounts. In retrospect, the first assay for aPL auto-antibodies was Moore and Mohr’s report of the “biologic false-positive” serologic tests for syphilis (BFP syphilis test) in 1952⁹; this abnormality came to be associated with systemic lupus erythematosus (SLE).¹⁰ The contemporaneous introduction, of the activated partial thromboplastin time (aPTT), which used cephalin, a phospholipid extract of animal brains, as the “partial thromboplastin” (distinct from the “complete thromboplastin,” tissue factor, and phospholipid),¹¹ led to the recognition of a unique type of anticoagulant in patients with SLE, that was frequently associated with BFP syphilis tests.¹² Because of its initial association with SLE this phenomenon was misnamed LA.¹³ It became recognized that the LA was purely an *in vitro* phenomenon that was not limited to SLE and that was not associated with bleeding complications unless another hemostatic defect was present.⁶ Furthermore, the LA came to be associated with recurrent pregnancy losses^{14,15} and with thrombotic and embolic manifestations.¹⁶ The development, in 1983, of the aCL antibody assay, that measured antibodies against the anionic phospholipid, cardiolipin (diphosphatidylglycerol), the primary antigen in the syphilis test reagent,¹⁷ was the advance that led to the identification of a new syndrome. Within a few years, it became recognized that aPL antibodies did not bind phospholipids directly but instead were directed against proteins that bound to the phospholipid, primarily β_2 GPI (see “Pathogenesis” below). This information became important in helping to unravel the mechanisms for APS and in advancing diagnostic testing toward the goal of distinguishing between the syndrome and incidental false-positive tests. Table 131-2 describes the current consensus investigational criteria for diagnosing APS.¹⁸

Most patients with elevated aPL antibodies do not have the syndrome; elevated aPL antibody levels can occur in patients with several

TABLE 131-1. Paths of Development of Antiphospholipid Assays: Historical Summary

Immunoassay Path	Coagulation Path
1950s: Syphilis testing	1950s: Partial thromboplastin time inhibitor 1970s: Lupus anticoagulant (LA)
1980s: Antiphospholipid (aPL) antibody enzyme-linked immunosorbent assay (ELISA; e.g., anticardiolipin [aCL] immunoassays)	1980s: Recognition that LAs are inhibitors of phospholipid-dependent coagulation reactions
1990s: Anticofactor ELISA (anti- β_2 -glycoprotein I [β_2 GPI], antiprothrombin, etc.)	
2005: Demonstration that antibodies against domain I of β_2 GPI are associated with increased risk of thrombosis	2004: Demonstration that resistance to the anticoagulant effect of annexin A5 correlates with thrombosis in antiphospholipid syndrome

types of infections that induce formation of antibodies recognizing anionic phospholipids directly, patients taking medications such as chlorpromazine or procainamide, and even in normal healthy individuals. Testing of patients who have neither clinical manifestations of the disorder or SLE for aPL antibodies should be discouraged because it incurs the risk of inappropriate diagnostic and treatment decisions.

TABLE 131-2. Sydney Investigational Criteria for Diagnosis of Antiphospholipid Syndrome

Clinical

- Vascular thrombosis (one or more episodes of arterial, venous, or small vessel thrombosis). For histopathologic diagnosis, there should **not** be evidence of inflammation in the vessel wall.
- Pregnancy morbidities attributable to placental insufficiency, including three or more otherwise unexplained recurrent spontaneous miscarriages, before 10 weeks of gestation. Also, one or more fetal losses after the 10th week of gestation, stillbirth, episode of preeclampsia, preterm labor, placental abruption, intrauterine growth restriction or oligohydramnios that are otherwise unexplained.

Laboratory

- aCL or anti- β_2 GPI IgG and/or IgM antibody present in medium or high titer on two or more occasions, at least 12 weeks apart, measured by standard ELISAs.
- Lupus anticoagulant in plasma, on two or more occasions, at least 12 weeks apart detected according to the guidelines of the International Society of Thrombosis and Hemostasis Scientific Standardization Committee on Lupus Anticoagulants and Phospholipid-Dependent Antibodies.
- "Definite APS" is considered to be present if at least one of the clinical criteria and one of the laboratory criteria are met.

aCL, anticardiolipin; aPL, antiphospholipid; β_2 GPI, β_2 -glycoprotein I; ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin.

Data from Miyakis S, Lockshin MD, Atsumi T et al: International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS). *J Thromb Haemost* 4:295–306, 2006.

ETIOLOGY AND PATHOGENESIS

ETIOLOGY

As with most autoimmune conditions, the etiology of APS is not understood. It has been demonstrated that even normal healthy individuals have memory B cells that produce aPL antibodies. In a study of patients with infectious mononucleosis, 10 to 60 percent of immunoglobulin (Ig) M aPL-producing cells expressed CD27, the marker of memory B cells.¹⁹ The affinity of aPL antibodies for their target becomes increased by the inclusion of amino acids lysine, arginine, and asparagine within the complementary determining regions of the heavy and light chains.²⁰

Although antibodies against anionic phospholipid moieties arise during the course of infections such as syphilis and Lyme disease, those are distinct from antibodies generated by patients with the syndrome because they generally recognize phospholipid epitopes directly (also referred to as "cofactor independent") and are not associated with the clinical manifestations of the syndrome. There are intriguing hints for molecular mimicry mechanisms and that infection and vaccination-induced APS could be related to autoimmune/autoinflammatory syndrome induced by adjuvants (ASIA).²¹ aPL antibodies have been reported in patients who developed thrombosis after varicella infection,^{8,22,23} and in patients with hepatitis C.^{24,25} aPL antibodies were reported in a patient with cytomegalovirus (CMV) infection, mesenteric and femoropopliteal thrombosis.^{26,27} β_2 GPI cofactor-dependent antibodies against cardiolipin, phosphatidyl serine, and phosphatidyl ethanolamine have been identified in sera from patients with parvovirus B19.²⁸ Bacterial infections are a predisposing risk factor for the catastrophic form of APS (CAPS).²⁹ A high proportion of HIV-1 patients have aPL antibodies; more than 40 percent in one study, in which 18 percent had aCL and 30 percent had anti- β_2 GPI (mostly of the IgA isotype),³⁰ however, positivity for these antibodies was not associated with thrombosis. A link has been proposed between the cardiac valvular disease in acute rheumatic fever and the presence of aPL antibodies.³¹ aCL antibodies having β_2 GPI dependence and LA activity have been generated in rabbits immunized with lipid A and lipoteichoic acid, suggesting that some bacteria can contribute to the production of pathogenic aPL antibodies.³² It has also been proposed that cellular apoptosis, with the resulting exposure of anionic phospholipids on cell surfaces, may trigger the generation of aPL antibodies.^{33–35} Molecular mimicry between β_2 GPI-related synthetic peptides and structures within bacteria, viruses, and tetanus toxoid³⁶ have been demonstrated in an experimental model for APS.³⁷ Mice immunized with a CMV-derived peptide developed aPL antibodies and thrombosis, and showed evidence for endothelial cell activation.³⁸

Reports of familial clustering of raised aPL antibody levels³⁹ indicate that genetic susceptibility can play a role in their development. In one study of 84 APS patients, more than 35 percent had at least one relative, and more than 20 percent had two or more relatives, with evidence of at least one clinical feature of APS, such as thrombosis or recurrent fetal loss.⁴⁰

PATHOGENESIS

Experimental Evidence That Antiphospholipid Antibodies Are Pathogenic

It has been clearly established in a number of experimental animal models for APS that aPL antibodies play a causal role in the development of thrombosis and pregnancy loss.^{41–45} Although it is reasonable to assume that the same holds for the human disorder, the epitopic specificities of the autoantibodies that cause disease and the mechanisms by which they produce clinical manifestations require further elucidation.

Antigenic Specificities

Antibodies against phospholipid that arise during the immunologic response to syphilis and other infections (with the notable exception of leprosy⁴⁶) recognize anionic phospholipid epitopes directly,⁴⁷ whereas pathogenic aPL antibodies recognize phospholipid-binding proteins, primarily β_2 GPI.^{48,49}

β_2 GPI (also named apolipoprotein H), a member of the complement control protein or short consensus repeat superfamily,⁵⁰ is a highly glycosylated single-chain plasma protein composed of 326 amino acids, with a molecular weight of approximately 50 kDa (Fig. 131-1). β_2 GPI has five short consensus repeat (SCR) stretches of approximately 60 amino acids⁴⁵ (also referred to as complement control protein [CCP] repeats). Epitopic specificities for individual domains may have pathogenic and prognostic significance (see “Immunoassays” below).⁵¹⁻⁵⁴

The affinity of β_2 GPI for anionic phospholipids derives from cationic residues from its aminoterminal that have affinity for anionic polar heads of phospholipids and a hydrophobic loop which inserts into the lipid bilayer. β_2 GPI has five domains for which antibodies have been identified. IgG antibodies against an epitope comprising Gly40-Arg43 in the domain I of β_2 GPI have been reported to have a stronger correlation with thrombosis than antibodies against other epitopes.⁵¹ Recent data support the concept that β_2 GPI undergoes conformational changes that may be important for the APS disease process. By transmission electron microscopy, unbound β_2 GPI appears to be in a closed conformation because of the affinity of a portion of carboxyterminal domain V for the protein's aminoterminal domain I, where the phospholipid binding site is located near the carboxy-terminus of SCR domain V (see Fig. 131-1).⁵⁵ The binding of β_2 GPI to anionic phospholipid membranes, requires a conformational change which exposes an epitope in domain I that had been cryptic in the unbound conformation (see Fig. 131-1).⁵⁵

Although β_2 GPI bind to phospholipids, its role in aPL-mediated cell signaling (described in the section Proposed Pathogenic Mechanisms), is mediated via binding to toll-like receptors (TLRs) and not by direct binding to the lipid bilayer.

While the *in vivo* biologic function(s) of the protein has (have) not been defined, several interesting properties have been demonstrated. The molecule binds to apoptotic cells,⁵⁶ and may play a role in their phagocytosis and clearance.⁵⁷ β_2 GPI binds to oxidized low-density

Figure 131-1. Schematic of the conformational states of β_2 GPI. The unbound protein is in a closed conformation in which the epitope on domain I (DI) is shielded by a portion of domain V (DV). Binding to phospholipid membranes via a “barb,” consisting of a hydrophobic loop formed by Ser311 to Lys317, near the carboxyterminus of DV, requires the protein to open and exposes an immunogenic epitope near the aminoterminal portion of the molecule. (Reproduced with permission from Rand JH A snappy new concept for APS. *Blood* 2010 Aug 26;116(8):1193–1194.)

lipoprotein (LDL) and may play a role in its clearance.⁵⁸ β_2 GPI binds to lipopolysaccharide and the scavenged complex is taken up by monocytes/macrophages.⁵⁹ β_2 GPI reduces platelet adhesion to collagen in flow chambers by interfering with the platelet–von Willebrand factor (VWF) interaction by binding to its A2 domain, thereby interfering with its binding to the platelet glycoprotein Ib complex.⁶⁰ β_2 GPI may also promote fibrinolysis as a cofactor for tissue-type plasminogen activator (t-PA) via its SCR domain V, which increases fibrinolytic activity.⁶¹ The protein may have a further effect on fibrinolysis by binding to endothelial cells via annexin A2, a protein that also serves as a receptor for plasminogen and t-PA.⁶² Homozygous β_2 GPI-null mice have not been demonstrated to display a thrombotic phenotype.⁶³ However, the protein may play a role—though not a critical one—in the reproductive process, as there was a reduction in the number of viable implantation sites in β_2 GPI-null mice and reduced fetal weight and fetal-to-placental weight ratio in late gestation, suggesting compromised placental function.⁶⁴

In addition to β_2 GPI, a number of other antigenic targets have been identified for aPL, including, but not limited to, prothrombin, coagulation factor V, protein C, protein S, annexin A2, annexin A5, high- and low-molecular-weight kininogens, and factors VII/VIIa and vimentin–cardiolipin complex.⁶⁵⁻⁶⁸

Proposed Pathogenic Mechanisms

Table 131-3 and Fig. 131-2 summarize several of the main current hypotheses for pathogenic mechanisms in APS. The mechanisms of the human APS disease process have been difficult to elucidation, mainly for two reasons: (1) The phenotypes of vascular thrombosis and pregnancy morbidity are not unique to APS, so it is difficult to ascertain whether the candidate mechanism is playing a causal role or is incidental. (2) Antibodies isolated from APS patients recognize a multiplicity of antigenic determinants^{69,70} that can have a broad range of effects, so it is difficult to determine which specificities and effects are responsible for disease manifestations in humans.

TABLE 131-3. Proposed Pathogenic Mechanisms for Antiphospholipid Syndrome

- I. Disruption of endothelial surface and annexin A5 anticoagulant shield
- II. Enhanced cell signaling
 - A. Mediated by antibodies against annexin A2
 - B. Mediated by antibodies to ApoE2R
 - C. Induction of endothelial surface proadhesive molecules
 - D. Induction of tissue factor expression on monocytes and endothelial cells
 - E. Complement-mediated signaling and injury
- III. Impeding of fibrinolysis and endogenous anticoagulation
 - A. Interference with plasminogen and tissue plasminogen activator
 - B. Interference with components of the protein C activation pathway
- IV. Activation of platelets
 - A. Interference with β_2 -glycoprotein I dampening of von Willebrand factor–mediated platelet adhesion
- V. Other mechanisms
 - A. Mammalian target of rapamycin complex pathway–mediated vasculopathy

Disruption of the Endothelial Surface and Annexin A5 Anticoagulant Shield Annexin A5 is a potent anticoagulant protein with high affinity for phospholipid membranes that contain anionic phospholipids, specifically phosphatidyl serine.⁷¹ Annexin A5 forms two-dimensional crystals over the phospholipid bilayers that shield them from binding coagulation factors⁷² and it has been proposed that the protein may play a thrombomodulatory role on the surfaces of cells lining the placental and systemic vasculatures. Annexin A5 is highly expressed on the apical membranes of placental syncytiotrophoblasts, the location where maternal blood interfaces with fetal cells.⁷³ Pregnant annexin A5-null mice develop placental infarctions of fetuses and yield reduced litter sizes.⁷⁴ Pregnant mice treated with anti-annexin A5 antibodies developed placental necrosis, fibrosis, and pregnancy loss.⁷⁵ Dissociation of annexin A5 from the surface of human placental trophoblasts and human umbilical vein endothelial cells accelerates the coagulation of plasma exposed to those cells.⁷⁶ Annexin A5 binds to the surfaces of endothelial cells and inhibits thrombin formation.⁷⁷

aPL antibody-antigen complexes disrupt the crystallization of annexin A5 and displace the protein from phospholipid membrane surfaces (Fig. 131-3).⁷⁸⁻⁸¹ In contrast to the LA phenomenon, aPL antibodies

Figure 131-2. Multiple pathogenic mechanisms of aPL antibodies. (1) On a disrupted endothelial surface, anti- β_2 GPI- β_2 GPI complexes bind through the cationic domain V of β_2 GPI to anionic structures, such as heparan sulfate to provide a prothrombotic surface. (2) In addition, anti- β_2 GPI- β_2 GPI complexes activate endothelial cell receptors such as ApoE2, TLR2/TLR4 and annexin A2 to promote downstream signaling pathways involving p38 mitogen-activated protein kinase (p38 MAPK) and nuclear factor- κ B (NF- κ B), leading to the upregulation of tissue factor (TF) and adhesion molecules (AM) and a proinflammatory/prothrombotic phenotype. (3) Anti- β_2 GPI- β_2 GPI complexes also impede fibrinolysis and anticoagulation by impeding plasmin, annexin A5 anticoagulant activity, and the protein C (Prot C) pathways. (4) Anti- β_2 GPI- β_2 GPI complexes bind to directly to activate platelets (Plt) and promote aggregation.

accelerate coagulation reactions in systems that include annexin A5.^{78,82-85} IgG fractions from APS patients reduce the quantity of annexin A5 on cultured placental trophoblasts^{76,86} and endothelial cells^{76,87} and accelerate the coagulation of plasma exposed to these cells.⁷⁶ This effect of aPL antibodies on annexin A5 binding has been correlated with IgG antibodies that recognize a specific epitope—domain I of β_2 GPI in patients with APS who have thrombosis⁵² and spontaneous pregnancy losses. Figure 131-2 includes a model for this mechanism.

Binding to Endothelial Surface Receptors Enhances Cell Signaling aPL antibodies can bind, injure, and activate cultured vascular endothelial cells.⁸⁸⁻⁹¹ Cultured endothelial cells incubated with aPL antibodies with specificity for cell surface β_2 GPI express increased levels of cell adhesion molecules⁹² triggered by their binding to cell surface β_2 GPI.⁹³ Annexin A2 serves as a receptor for β_2 GPI,⁶² and anti- β_2 GPI antibodies may thereby stimulate expression of tissue factor on endothelial cells.⁹⁴ In animal models, the signaling effects of aPL antibodies were significantly reduced in mice treated with an anti-annexin A2 monoclonal antibody and also in annexin A2-null transgenic mice.⁹⁵ These effects of the aPL antibodies may be mediated by TLR-4 of the innate immunity system,^{96,97} although there are data indicating participation of other

Figure 131-3. Disruption of annexin A5 shield by monoclonal anti-phospholipid antibodies and β_2 -glycoprotein I (β_2 GPI). Atomic force microscopy picture showing the effect of a monoclonal aPL antibody on a preformed annexin A5 crystal. The figure demonstrates the smooth lipid bilayer covered by the annexin A5 crystals, disrupted by antibody- β_2 GPI complexes (white circles) and exposing anionic phospholipids (black holes) to coagulation factors and accelerated coagulation. (Modified with permission from Rand JH, Wu XX, Quinn AS, et al: Human monoclonal anti-phospholipid antibodies disrupt the annexin A5 anticoagulant crystal shield on phospholipid bilayers: evidence from atomic force microscopy and functional assay. *Am J Pathol* 163(3):1193-1200, 2003.)

TLRs, particularly TLR-2.⁹⁸ This binding results in downstream signaling that involves TRAF6 (tumor necrosis factor receptor-associated factor 6) and MyD88 (myeloid differentiation factor 88).⁹⁹ Increased expression of tissue factor is mediated by p38 mitogen-activated protein kinase (MAPK).¹⁰⁰

Binding of autoantibodies to annexin A2 may also promote thrombosis by inhibiting fibrinolysis. APS patients have increased titers of antibodies against annexin A2, an endothelial surface receptor for t-PA, and plasminogen.¹⁰¹ The blocking of annexin A2 by aPL antibodies impedes plasmin generation in a t-PA–dependent generation assay, and inhibits cell surface plasmin generation on human umbilical vein endothelial cells.⁹⁴ Several additional mechanisms have been identified by which aPL antibodies can interfere with fibrinolysis. β_2 GPI is a cofactor for t-PA–mediated activation of plasminogen, and aPL antibodies against β_2 GPI interfere with its binding to t-PA, thereby downregulating plasminogen activation.⁶¹ Finally, fibrinolysis may also be impaired by autoantibodies directed against the catalytic site of plasmin or t-PA,^{102,103} by an increased level of plasminogen activator inhibitor-1,¹⁰⁴ and by inhibition of autoactivation of factor XII with ensuing reductions of kallikrein and urokinase.¹⁰⁵

Apolipoprotein E receptor 2 (apoER2), a member of the LDL-receptor family is found on endothelial surfaces,¹⁰⁶ monocytes,¹⁰⁷ and platelets, and may also serve as receptor for anti- β_2 GPI- β_2 GPI complexes where it can also trigger the phosphatidylinositol 3'-kinase (PI3K)/Akt pathway¹⁰⁸ and increase tissue factor and cell adhesion molecule expression. IgG-mediated dimerization of β_2 GPI and binding to ApoER2' increases the sensitivity of platelets to agonists of aggregation.¹⁰⁹

Complement-Mediated Injury Complement activation may play a role in the APS disease process. The IgG₂ subtype of aPL most closely correlates with thrombosis.^{110,111} Blockade of complement activation using a C3 convertase inhibitor or genetic deletion of C3 protected mice from pregnancy complications induced by aPL antibodies.^{112–114} These effects involve the aPL-stimulated expression of tissue factor by myeloid cells,¹¹⁵ and to involve proteinase-activated G-protein-coupled receptor (PAR)-2 signaling,¹¹⁶ indicating that complement activation can be pathogenic via both direct injury and downstream signaling.

Induction of Tissue Factor Activity in Leukocytes aPL antibodies can promote tissue factor expression by leukocytes.^{115,117–119} The specific binding site on these cells has not been elucidated.

Inhibition of Fibrinolysis and Endogenous Anticoagulation aPL antibodies can interfere with fibrinolysis in several ways. Antibodies against annexin A2, an endothelial surface receptor for t-PA and plasminogen, can interfere with binding of plasminogen and t-PA and thereby reduce plasmin formation and fibrinolysis.^{94,101,103} Monoclonal aPL antibodies derived from APS patients can directly inhibit plasmin's enzymatic activity.¹⁰² β_2 GPI is a cofactor for t-PA–mediated activation of plasminogen,¹²⁰ and anti- β_2 GPI can interfere with this activity. Also, it has been reported that women with APS have significantly increased levels of circulating plasminogen activator inhibitor-1 (PAI-1), implying impaired fibrinolysis.¹⁰⁴

Interference with Components of the Protein C Activation Pathway The protein C pathway (Chaps. 114 and 139) is initiated by thrombin binding to thrombomodulin (TM), which activates protein C bound to the endothelial protein C receptor (EPCR). Activated protein C (APC), together with free protein S, then proteolyzes coagulation factors Va and VIIIa. APC also modulates signaling events by interfering with PAR-1 signalling.^{121,122} aPL antibodies can interfere with the activation of protein C by TM–thrombin and with the activity of APC, as well as protect factors Va and VIIIa from proteolysis by APC.⁶⁵ Acquired APC resistance has been described in APS plasmas¹²³ and has been correlated with anti- β_2 GPI domain I antibodies,¹²⁴ a risk factor for

thrombosis. The presence of antibodies against EPCR in APS patients was proposed to be a risk factor for fetal death.¹²⁵

Antiphospholipid Antibodies Activate Platelets An experimental animal model that includes *in vivo* imaging has provided data indicating that aPL-induced thrombosis is a consequence of platelet activation that then promotes endothelial activation and fibrin formation.¹²⁶ aPL antibodies can induce platelet aggregation,¹²⁷ an effect that might be promoted via signaling through apoER2 receptors; the β_2 GPI binding site for apoER2 on platelets was localized to its domain V.¹²⁸ As described above (see “Antigenic Specificities”), β_2 GPI also has a dampening effect on platelet adhesion by interfering with the platelet–VWF interaction, and consequently aPL antibodies, by interfering with this β_2 GPI-mediated dampening, can increase platelet adhesion in flow systems.⁶⁰

Other Mechanisms APS patients have been shown to have autoantibodies against tissue factor pathway inhibitor.¹²⁹ Some aPL antibodies cross-react with heparin and heparinoid molecules, which are highly polyanionic, and hence, inhibit their contribution to antithrombin activity.⁶⁹ aPL antibodies show cross-reactivity against oxidized LDL¹³⁰ and are associated with an increased risk of atherosclerosis.¹³¹ Antibodies against β_2 GPI-oxidized LDL complexes have been proposed to be atherogenic by reducing their clearance.¹³² Finally, in addition to promoting thrombosis, aPL antibodies may contribute to other vascular lesions by stimulating the mammalian target of rapamycin complex (mTORC) pathway (Fig. 131–4).¹³³

Figure 131–4. Pathogenesis of vasculopathy in the antiphospholipid syndrome. In addition to promoting thrombosis, antiphospholipid antibodies also trigger vasculopathy by binding to vascular endothelial cells and activating the mammalian target of rapamycin (mTOR) signaling pathway. Extracellular and intracellular signals through the phosphatidylinositol 3'-kinase (PI3K)–Akt pathway activate mTOR pathway which regulates cell growth, proliferation and survival. The mTOR enzyme is a component of two complexes, mammalian target of rapamycin complex (mTORC) 1 and mTORC2. The activity of mTORC1 is regulated by a subunit of the regulatory-associated protein of mTORC1 (RAPTOR), whereas the activity of mTORC2 is regulated by a subunit of the rapamycin-insensitive companion of mTOR (RICTOR). (Modified with permission from Eikelbloom JW, Weitz JI: *The mTORC pathway in the antiphospholipid syndrome*. *N Engl J Med* 371(4):369–371, 2014.)

CLINICAL FEATURES

Table 131–4 summarizes the clinical features of APS. Patients generally present with thrombotic manifestations, that is, evidence for vasoocclusion or end-organ ischemia or infarction, and/or pregnancy losses and complications attributable to placental insufficiency. The usual age at presentation with thrombosis is approximately 35 to 45 years. Except for patients with SLE, men and women are equally susceptible to thrombotic manifestations. No differences have been observed between the arterial and venous distributions of thromboses of primary and secondary APS patients.¹³⁴

SYSTEMIC VASCULAR THROMBOSIS

Patients can present with spontaneous venous and/or arterial thrombosis or embolism in any site; however, about half of all patients have deep vein thrombosis of the lower extremities.^{135,136} Other sites of venous thromboembolic events include pulmonary embolism, thoracic veins (superior vena cava, subclavian vein, or jugular vein), and abdominal or pelvic veins.¹³⁶ Approximately one-fourth of patients present with arterial thromboses; the remainder present with concurrent arterial and venous thrombosis.¹³⁶ Patients may also present with stroke, cerebral venous thrombosis, upper-extremity venous thrombosis,¹³⁵ myocardial infarction, adrenal infarction, acalculous gallbladder infarction, aortic thrombosis with renal infarction,¹²⁰ and mesenteric artery thrombosis.^{137,138} Thrombosis may occur spontaneously or in the presence of some other risk factor such as estrogen replacement therapy, oral contraceptives,^{134,139} vascular stasis, surgery, or trauma. Women are at particularly high risk for venous thrombosis during pregnancy and in the postpartum period.¹³⁴ Some APS patients with venous thrombosis have concurrent genetic thrombophilic conditions such as the factor V Leiden variant, and it has been postulated that this may increase the risk of thrombosis.^{140–143} Concurrent positivity for all three aPL antibody

Figure 131–5. Average annual rates of first cardiovascular events (including venous thromboembolism) among antiphospholipid (aPL) antibody–negative and aPL antibody–positive populations. Concurrent positivity for all three aPL antibody assays—that is, “triple positivity” for the aCL antibody assay, anti- β_2 GPI antibody assay, and the lupus anticoagulant assay—is a highly significant risk factor for a first thrombotic event. (Modified with permission from Pengo V, Ruffatti A, Legnani C et al: Incidence of a first thromboembolic event in asymptomatic carriers of high-risk antiphospholipid antibody profile: A multicenter prospective study. *Blood* 118(17):4714–4718, 2011.)

assays—that is, the aCL antibody assay, anti- β_2 GPI antibody assay, and the LA assay—appears to be a highly significant risk factor for having an initial thrombotic event (Fig. 131–5).¹⁴⁴ If this finding is confirmed, it could identify a group of patients who might warrant consideration for prophylactic treatment. A history of having had a thromboembolic event is probably the most significant risk factor for recurrence of venous thromboembolism in APS, with a reported frequency that reached approximately 30 percent in patients followed for 4 years after the first episode.¹⁴⁵ The risk of recurrent thromboembolism correlates with the titer of antibodies,^{145,146} and with the presence of LA. In addition, it appears that the presence of anti- β_2 GPI domain I antibodies significantly increase the risk of thrombosis, compared to patients who have antibodies that are not domain I dependent and LA that is not domain I dependent.⁵¹

SYSTEMIC LUPUS ERYTHEMATOSUS AND OTHER AUTOIMMUNE CONDITIONS

APS patients frequently present with other autoimmune conditions. A significant proportion of SLE patients have elevated aPL antibodies, with estimates ranging between 12 and 30 percent for aCL antibodies and 15 and 34 percent for LA antibodies.¹⁴⁷ APS has been associated with the concurrence of other autoimmune conditions including, but not limited to, rheumatoid arthritis,¹⁴⁸ Sjögren syndrome,¹⁴⁹ myasthenia gravis,¹⁵⁰ Budd-Chiari syndrome in the setting of SLE,¹⁵¹ Graves disease,¹⁵² autoimmune hemolytic anemia, progressive systemic sclerosis,¹⁵³ Evans syndrome,¹⁵⁴ Takayasu arteritis,¹⁵⁵ polyarteritis nodosa,¹⁵⁶ and immune thrombocytopenia (see section Thrombocytopenia below and also Chap. 117).

STROKE AND OTHER NEUROLOGIC CONDITIONS

The most common neurologic manifestations of APS are stroke or transient ischemic attacks (TIAs), which were the initial presentation of up to 30 percent of adults with APS in a large European cohort.¹⁵⁷ In the European Catastrophic Antiphospholipid Antibody Syndrome (CAPS)

TABLE 131–4. Clinical Manifestations Associated with APS

- Venous and arterial thromboembolism*
- Pregnancy complications attributable to placental insufficiency, including spontaneous pregnancy losses as detailed in Table 132–3, intrauterine growth restriction, preeclampsia, preterm labor, and placental abruption*
- Thrombocytopenia
- Thrombotic and embolic stroke*
- Cerebral vein thrombosis*
- Livedo reticularis, necrotizing skin vasculitis
- Coronary artery disease
- Valvular heart disease
- Kidney disease
- Pulmonary hypertension
- Acute respiratory distress syndrome
- Atherosclerosis and peripheral artery disease
- Nonthrombotic retinal disease
- Adrenal failure, hemorrhagic adrenal infarction*
- Budd-Chiari syndrome, mesenteric and portal vein obstructions, hepatic infarction, esophageal necrosis, gastric and colonic ulceration, gallbladder necrosis*
- Catastrophic antiphospholipid syndrome with thrombotic microangiopathy*

*Manifestations that qualify as consensus criteria for diagnosis of antiphospholipid syndrome.¹⁸

Registry, cerebral manifestations occurred in 62 percent of patients and caused 13 percent of deaths.¹⁵⁸ Recurrent strokes are more likely in patients with APS and other risk factors for cerebrovascular disease, such as cigarette smoking, hypertension hyperlipidemia, oral contraceptive use, and SLE.^{159,160}

Most APS patients with stroke have arterial thromboembolic occlusive events that are clinically indistinguishable from the more common arteriosclerotic strokes. APS should be suspected in young patients with TIAs or stroke, particularly when the more typical risk factors for cerebrovascular disease are absent.¹⁶¹ Cerebral venous thrombosis is less common in APS patients and presents at a younger age, and is more extensive than in non-APS patients with the disorder.¹⁶² In one series of 40 cases of cerebral venous thrombosis, three patients (8 percent) had elevated aPL antibody levels.¹⁶³ Superior sagittal sinus thrombosis has been reported with primary APS.¹⁶⁴

There is controversy about whether migraines in patients with aPL antibodies should be regarded as thromboocclusive events.¹⁶⁵ Other neurologic abnormalities reported to be associated with aPL antibodies include seizures/epilepsy,¹⁶⁶ chorea, Guillain-Barré syndrome, transient global amnesia, dementia, diabetic peripheral neuropathy, and orthostatic hypotension.¹⁶⁷ Recurrent acute transverse myelopathy has been described with APS.¹⁶⁸⁻¹⁷² However, in one study of 315 SLE patients, including 10 with a history of transverse myelopathy, that disorder was not associated with aPL antibodies.¹⁷³ Multiple sclerosis patients have a high incidence of elevated aCL antibody levels (in one series, 9 percent had IgG antibodies and 44 percent had IgM antibodies),¹⁷⁴ however, no clinical distinctions were found between aPL-positive and aPL-negative patients and the antibodies do not appear to be associated with thrombosis. Patients with psychotic disorders have an increased prevalence of LA and aCL antibodies, even in the absence of treatment with antipsychotic drugs.¹⁷⁵

CATASTROPHIC ANTIPHOSPHOLIPID SYNDROME

CAPS is a relatively infrequent but devastating presentation of APS, is characterized by severe widespread vascular occlusions.¹⁷⁶ Diagnostic criteria for CAPS include evidence of involvement of at least three organs, systems, and/or tissues; development of manifestations simultaneously or in less than 1 week; histopathologic confirmation of small-vessel occlusion; and laboratory confirmation of the presence of aPL antibodies.¹⁷⁷ According to the CAPS Registry, a web-based database of 433 patients with CAPS (<https://ontocrf.costaisa.com/en/web/caps/>), the majority of CAPS patients are female (69 percent), in their late thirties (mean age of 38.5 years), but the condition can present at any age (range: 0 to 85 years). In half of the CAPS cases, the patients' catastrophic event was their first APS manifestation. Precipitating factors of CAPS include infections, drugs (sulfur-containing diuretics, captopril, and oral contraceptives), surgical procedures, and cessation of prior anticoagulant therapy. In 26.9 percent of cases, the patients also had SLE. The most frequently affected organ was the kidney (73 percent of episodes), followed by lungs (58.9 percent), the brain (55.9 percent), the heart (49.7 percent), and the skin (45.4 percent). Other organs were also affected, including the peripheral vessels, intestines, spleen, adrenal glands, pancreas, retina, and marrow. Patients present with evidence for severe multiorgan ischemia/infarction, often with concurrent disseminated microvascular thrombosis. Patients with CAPS can present with renal insufficiency, respiratory failure resulting from acute respiratory distress syndrome (ARDS) and pulmonary emboli, cerebral manifestations such as encephalopathy, stroke and seizures, cardiac problems such as heart failure, myocardial infarction and valvular defects, and skin complications such as livedo reticularis and skin necrosis.¹⁷⁸ Most

patients show histologic evidence of microangiopathy mainly affecting small vessels of the kidneys, lungs, brain, heart, and liver. Only a minority of patients experience large-vessel occlusions. Laboratory evidence for disseminated intravascular coagulation is frequently present. An LA is present in 81.7 percent of patients, and the aCL IgG is the most common positive aPL antibody.¹⁷⁸ Improved treatment has reduced mortality from approximately 50 percent to approximately 20 percent.¹⁷⁶ Relapse is rare in survivors. The only identified predictive factor for adverse outcome is underlying SLE.¹⁷⁹

PREGNANCY LOSSES, OBSTETRIC COMPLICATIONS, AND INFERTILITY

At this time, aPL screening of otherwise asymptomatic with no history of prior complications obstetrical patients is not warranted because of the high frequency of false-positive tests; most studies have estimated the prevalence of aPL antibodies among general obstetric populations to be approximately 5 percent or less and most of these aPL-positive patients are not clinically affected.¹⁸⁰

Among obstetric patients with recurrent fetal losses, approximately 16 to 38 percent have aPL antibodies. In addition, pregnant women with elevated aPL antibodies had significantly more obstetric complications, including preeclampsia, abruptio placentae, miscarriage, prematurity, intrauterine fetal demise, intrauterine growth restriction, and oligohydramnios, than aPL antibody-negative pregnant women.¹⁸¹⁻¹⁸³ In approximately half of patients, the pregnancy losses occur in the first trimester. Other patients present with later losses, most in the second trimester, but some even later, including stillbirth. Pregnancy complications attributable to APS include three or more recurrent spontaneous first trimester miscarriages, one or more fetal losses during the second trimester, stillbirth, episode of preeclampsia, preterm labor, placental abruptio, intrauterine growth restriction, and oligohydramnion.¹⁸⁴⁻¹⁸⁶ Pregnant patients with APS are also more prone to developing deep vein thrombosis during pregnancy or the puerperium. Rarely, pregnant patients develop CAPS.^{187,188} The best predictor for pregnancy loss in a patient who tests positive for aPL antibodies has been demonstrated to simply be a previous history of pregnancy loss, complications, or thrombosis.^{146,189} A recent study reported that any aPL antibody-positive women with an unexplained early loss prior to 10 weeks have a higher risk of complications in their second pregnancy¹⁹⁰ but the degree of laboratory abnormalities were not associated with increased risk. Positivity by more than one assay appears to correlate with increased pregnancy morbidities.^{182,191} Histologic abnormalities were found in many, but not all, placentas of aPL patients.¹⁹² Studies of placental pathology in patients with aPL antibodies, but without a prior history of fetal loss, showed that approximately half had evidence of uteroplacental vascular pathology, approximately half had evidence of thrombotic occlusion, and approximately one-third had chronic villitis and/or decidual plasma cell infiltrates.^{193,194}

Overall, it appears that the presence of aPL antibodies does not affect the success rate of implantation. Although one group has reported data that indicated that women with recurrent implantation failure were more likely to have positive assays for aPL antibodies compared to fertile negative controls,¹⁹⁵ a review of 29 studies showed mixed results.¹⁹⁶ Many of the studies were noted to have limitations, including problems with study design and statistical power. The current consensus is that aPL antibodies are not a cause of infertility.¹⁹⁷ Recently, the 14th International Congress on Antiphospholipid Antibodies Task Force also concluded that "there are no data to support the inclusion of infertility as criteria for APS and investigation of APS in patients with infertility should not be done in routine clinical practice, being reserved only for research purposes."¹⁹⁶

CUTANEOUS MANIFESTATIONS

The cutaneous manifestations of APS may comprise the first signs of APS in some patients.^{198,199} Livedo reticularis is relatively common, occurring in 24 percent of a series of 1000 aPL patients,²⁰⁰ and occasionally presents in a necrotizing form.²⁰¹ Noninflammatory vascular thrombosis is the most frequent histopathologic feature. Necrotizing vasculitis, livedoid vasculitis, thrombophlebitis, cutaneous ulceration and necrosis, erythematous macules, purpura, ecchymoses, painful skin nodules, and subungual splinter hemorrhages, anetoderma (macular atrophy), discoid lupus erythematosus, and cutaneous T-cell lymphoma have all been reported.

CORONARY ARTERY DISEASE

aPL antibodies are associated with increased susceptibility to coronary artery disease,²⁰² particularly premature atherosclerosis.^{203,204} APS should be considered in patients who lack the usual risk factors for coronary artery disease and in patients with evidence for thrombotic or embolic coronary artery occlusion that lack angiographic evidence of atherosclerotic disease. aPL antibodies appear to be a risk factor for adverse outcomes following all coronary revascularization procedures,²⁰² and for restenosis after percutaneous transluminal coronary angioplasty.^{205,206} An ultrasound study of carotid arteries provided evidence supporting an association of aPL antibodies with premature atherosclerosis; relatively young primary APS patients (mean age: 37 ± 11 years) had significantly increased intimal medial thickness compared to control non-APS groups.²⁰⁷

VALVULAR HEART DISEASE

Approximately 35 percent of patients with primary APS have cardiac valvular abnormalities detected by echocardiography.²⁰⁸ In one study, approximately 20 percent of cardiac patients with valvular heart disease had evidence for aPL antibodies compared with approximately 10 percent of matched control subjects.²⁰⁹ Valvulopathy includes leaflet thickening, vegetations, regurgitation, and stenosis.²¹⁰ The mitral valve is mainly affected, followed by the aortic valve.²¹¹ Histologically, APS valvular lesions consist mainly of superficial or intravalvular fibrin deposits in association with variable degrees of vascular proliferation, fibroblast influx, fibrosis, and calcification. These can result in valve thickening, fusion, and rigidity, and lead to functional abnormalities.²¹² Deposits of immunoglobulins, including aCL antibodies, and of complement components are commonly found in the affected valves.²¹³

PERIPHERAL VASCULAR DISEASE

Approximately one-third of patients with peripheral arterial disease undergoing bypass grafting procedures had elevated aPL antibody levels (mostly aCL antibodies).²¹⁴ Intraarterial thromboembolic events are common at presentation of these patients and may complicate surgical management. However, these patients did not have an increased risk for reocclusion, a finding that was attributable to the use of anticoagulant therapy.

PULMONARY MANIFESTATIONS

Patients with APS may present with *in situ* thrombosis in pulmonary vessels. aPL antibodies are associated with pulmonary hypertension.²¹⁵ In one prospective trial of 38 consecutive patients with precapillary pulmonary hypertension, approximately 30 percent had aPL antibodies with various phospholipid specificities.²¹⁶ An interinstitutional study of 687 patients with chronic thromboembolic pulmonary hypertension reported that aPL antibodies were a significant risk factor.²¹⁷ The

majority of patients with CAPS (see “Catastrophic Antiphospholipid Syndrome” above) have dyspnea, and most of these individuals have ARDS.²¹⁸

ABDOMINAL MANIFESTATIONS

The liver is the most frequently affected abdominal organ in APS, with occlusion of hepatic vessels, including those supplying the biliary tree.²¹⁹ aPL antibody levels frequently are elevated in patients with chronic liver disease of various causes. In one prospective study of patients with liver disease, approximately half of patients with alcoholic liver disease and one-third of patients with chronic hepatitis C virus had elevated aPL antibody levels. The frequency was even higher in patients with more severe cirrhosis.²²⁰ A review reported that approximately 20 percent of patients with chronic hepatitis B and hepatitis C had aPL antibodies, most of which were cofactor independent.²²¹ Some patients with hepatitis C present with true autoimmune aPL antibodies, the most common features reported being intraabdominal thrombosis and myocardial infarction.²²²

Reported gastrointestinal manifestations of APS also include esophageal necrosis with perforation, intestinal ischemia and infarction, pancreatitis, and colonic ulceration. Primary biliary cirrhosis,²²³ acute acalculous cholecystitis with gallbladder necrosis,^{224,225} and giant gastric ulceration are associated with APS.²²⁶ APS has been reported in patients with mesenteric inflammatory venoocclusive disease²²⁷ and in patients with mesenteric and portal venous obstruction.²²⁸

THROMBOCYTOPENIA

Approximately 20 to 40 percent of patients with APS have varying degrees of thrombocytopenia. The decrease in platelet count is generally mild or moderate and is rarely significant enough to cause bleeding complications or affect anticoagulant therapy.^{229,230} The majority of patients with APS and thrombocytopenia have antibodies against $\alpha_{IIb}\beta_3$ integrin and/or glycoprotein Ib-IX complex.²³¹ Patients presenting with immune thrombocytopenic purpura frequently have elevated aPL antibodies, and these patients are more prone to thrombosis.²³² aPL antibodies and antibodies against platelet membrane glycoprotein were present simultaneously in approximately 70 percent of patients with immune-mediated thrombocytopenia.²³³ Thrombocytopenia itself is not protective against thrombosis in these patients. In a prospective cohort study, 5-year thrombosis-free survival of aPL-positive and aPL-negative immune thrombocytopenic purpura patients were 39 percent and 98 percent, respectively.²³⁴

BLEEDING

The presence of a concurrent hemostasis defect needs to be considered when patients with APS exhibit a bleeding tendency (Table 131–5). Acquired hypoprothrombinemia with severe bleeding has been reported.^{235,236} This diagnosis may be missed when coagulation abnormalities are attributed only to the LA effect, so a specific assay

TABLE 131–5. Causes of Bleeding in Antiphospholipid Syndrome

- Hypoprothrombinemia
- Thrombocytopenia
- Acquired platelet function abnormality
- Acquired inhibitor to specific coagulation factor, e.g., factor VIII
- Acquired von Willebrand syndrome

for prothrombin should be performed when the prothrombin time is prolonged. Other causes of bleeding in APS include acquired thrombocytopathies, thrombocytopenia (see “Thrombocytopenia,” above), acquired inhibitors against specific coagulation factors, such as factor VIII, and the acquired von Willebrand syndrome (AVWS).

RETINAL ABNORMALITIES

The diagnosis of aPL antibody retinopathy should be suspected in patients with diffuse retinal vasooclusion, particularly when characterized by involvement of arteries and veins, neovascularization at presentation, and symptoms of systemic rheumatologic disease.²³⁷ aPL antibodies were present in 5 to 33 percent of patients with retinal vein occlusion.^{238,239} Cilioretinal artery occlusion,²⁴⁰ optic neuropathy,²⁴¹ and severe vasoocclusive retinopathy²⁴² have been described with APS.

KIDNEY DISEASES

APS may affect the renal system. Patients may present with renal artery stenosis and/or thrombosis, renal infarction, renal vein thrombosis, and glomerulonephritis that is distinct from vasoocclusive disease.^{200,243} An entity named “APS nephropathy” has been described, which consists of a vasoocclusive disease of small-size intrarenal vessels.²⁴⁴ This nephropathy features fibrous intimal hyperplasia, focal cortical atrophy, and thrombotic microangiopathy. A review of 29 consecutive renal biopsies from patients with primary APS, performed at two institutions over 22 years, described 20 cases of APS nephropathy and nine cases with other distinct pathologic features.²⁴³ These features included membranous nephropathy, minimal change disease/focal segmental glomerulonephritis, mesangial C3 nephropathy, and pauci-immune crescentic glomerulonephritis.

ANTIPHOSPHOLIPID SYNDROME AND AIDS

Although patients with HIV-1 infection frequently have elevated aPL antibody levels, they do not often have thrombotic manifestations. A review indicated that approximately 50 percent of HIV-1 patients test positive for aPL antibodies, most of which are not cofactor dependent.²²¹ HIV-infected patients with manifestations of APS have also presented with avascular bone and cutaneous necrosis.²²²

ANTIPHOSPHOLIPID SYNDROME IN CHILDREN

Increasingly, APS has become recognized in children,²⁴⁵ in whom diverse clinical features are common. The results of a European registry have been reported.²⁴⁶ Review of 121 cases indicated that although the thrombotic manifestations were similar to adults with APS, there was a difference between children with primary APS and the secondary APS; the children with primary APS were younger and had a higher frequency of arterial thrombotic events, whereas the children with secondary APS patients had a higher frequency of venous thrombotic events associated with hematologic and skin manifestations. CAPS has been reported in children, but is rare.^{247,248}

Thrombosis is rare in newborns delivered from mothers with APS, and only a few cases are reported, mostly associated with other prothrombotic factors.²⁴⁹ aPL antibodies have been found in up to 30 percent of offspring of mothers with APS.²⁵⁰

In a recent European prospective study, 17 percent of neonates born to APS mothers were premature; however, no specific complications were found during the 5-year followup.²⁵¹ The study did show a higher rate of neurodevelopmental abnormalities with learning disabilities similar to two retrospective reports where learning disabilities without other neurodevelopmental abnormalities were present in 15 to 20 percent of cases.^{252,253}

OTHER MANIFESTATIONS

Acute adrenal failure secondary to bilateral infarction of the adrenal glands has been reported as the first manifestation of primary APS.²⁵⁴ Adrenal hemorrhage has been reported.²⁵⁵ aPL antibodies have been associated with marrow necrosis.²⁵⁶

LABORATORY FEATURES

Diagnosis of APS requires the demonstration of antibodies against phospholipids and/or relevant protein cofactors (Table 131-6). The current tests for APS recommended by the most recent consensus on investigational criteria¹⁸ and the Scientific Standardization Committee of the International Society of Thrombosis and Hemostasis are aCL, anti- β_2 GPI (IgG and IgM), and LA.²⁵⁷ The laboratory diagnosis of APS frequently is problematic, with limitations that have been detailed.^{258,259} aCL IgG and IgM assays are the most sensitive, but the least specific. Anti- β_2 GPI IgG and IgM assays are more specific but less sensitive. LA assays, of which the dilute Russell viper venom time (dRVVT) is the most common, generally tend to be the least sensitive but the most specific. The current recommended tests are less than ideal because they are empirically derived tests and do not yet measure antibodies directed against disease specific epitopes or functional parameters that correlate with disease mechanisms. Despite these limitations, positivity for all three criteria assays (“triple positivity”) has been correlated with an increased risk for a future thrombotic event (see Fig. 131-5).¹⁴⁴ Investigational criteria have been developed to identify patients with

TABLE 131-6. Diagnostic Tests for Antiphospholipid Syndrome

Immunoassays

Anticardiolipin IgG and IgM antibodies*
Anti- β_2 GPI IgG and IgM antibodies*
Serologic test for syphilis (“biologic false-positive”)
Antiphosphatidyl serine antibodies
Antiprothrombin antibodies

Coagulation Tests[†]

Dilute Russell viper venom time with mixing incubations and neutralization with excess phospholipid
aPTT with mixing incubation and neutralization with excess phospholipids
aPL-sensitive and -insensitive reagents and platelet neutralization procedure
Kaolin clotting time
Dilute prothrombin time (a.k.a tissue thromboplastin inhibition test)
Hexagonal phase array test
Textarin/ecarin test

aPL, antiphospholipid; APS, antiphospholipid syndrome; aPTT, activated partial thromboplastin time; β_2 GPI, β_2 -glycoprotein I; Ig, immunoglobulin; LA, lupus anticoagulant.

*Recommended by the International Society on Thrombosis and Haemostasis (ISTH) Scientific and Standardisation Committee (SSC) Subcommittee on Lupus Anticoagulants and Antiphospholipid Antibodies.²⁵⁸

[†]The committee recommended that two coagulation assays be performed if LA or APS are suspected, preferably the dilute Russell viper venom time (dRVVT) and aPTT.

the “definite” autoimmune APS (see Table 131–3).¹⁸ Because no single test is sufficient for diagnosing the disorder, a panel of tests, including antibodies against cardiolipin, and β_2 GPI, and coagulation tests for LA should be performed when APS is suspected.²⁵⁷ The investigational criteria require that positive results have to be obtained on two or more occasions at least 12 weeks apart to qualify for diagnosis.

IMMUNOASSAYS

Anticardiolipin Antibody Assays

Most patients with APS are identified by elevated levels of aCL antibodies, a test with high sensitivity but poor specificity. The prevalence of positive tests in the asymptomatic healthy population has generally ranged from approximately 3 to 10 percent. In a prospective study of 2132 consecutive Spanish patients with venous thromboembolism, 4.1 percent had elevated levels of aCL antibodies (i.e., about the same prevalence as in the asymptomatic healthy population),²⁶⁰ but in a group of healthy young women in another study, the prevalence of elevated levels of aCL was 18.2 percent.²⁶¹ Many individuals have antibody levels that are elevated in response to infections that are not associated with thrombotic complications. Patients with syphilis, Lyme disease, and other infections may be misdiagnosed with APS based on elevated aCL antibody levels when concurrent stroke or arterial thrombosis is present, so these conditions must always be ruled out in susceptible patients. In a systematic literature review, 15 of 28 studies showed significant associations between aCL antibodies and thrombosis.²⁶² In all cases, a correlation existed between high antibody titers and a high risk of thrombosis. Elevated levels of aCL antibodies, whether high or low titer, were significantly associated with both myocardial infarction and cerebral stroke. Only high-titer aCL antibodies significantly increased the risk of deep vein thrombosis. During a 10-year followup of patients with elevated levels of aCL antibodies, approximately 50 percent of patients who presented with the antibodies but without clinical manifestations of the syndrome subsequently developed the APS.²⁶³ The presence of elevated titers of aCL antibodies 6 months after an episode of venous thromboembolism is a predictor for increased risk of recurrence and of death.¹⁴⁵ Women with aCL IgM antibodies, or with an aCL IgG antibody titer less than 20 IgG-binding units, and without a positive LA do not appear to be at risk for APS.²⁶⁴ In contrast, women with an aCL IgG titer greater than 20 binding units or a positive LA were more likely to develop complications.²⁶⁴ With respect to pregnancy losses, a meta-analysis of 25 studies on aPL antibodies in women with recurrent fetal losses showed a significant correlation with increased aCL IgG, and particularly with the LA.²⁶²

With respect to stroke, elevated levels of aCL antibodies of IgG or IgM isotype were reported to be significant risk factors.²⁶⁵ aPL antibodies also are an independent risk factor for stroke in young women.²⁶⁶

Approximately 20 percent of patients taking procainamide have moderate to high levels of aCL antibodies.²⁶⁷ In these patients, the antibodies are associated with anti- β_2 GPI specificity. There have been case reports of associated thrombosis.²⁶⁸ Treatment with chlorpromazine has been associated with the development of aCL antibodies,²⁶⁹ although more recent data indicate that aPL antibodies are frequently elevated in patients with severe psychiatric disorders whether or not they are treated with antipsychotic medications.²⁷⁰

Anti- β_2 Glycoprotein I Antibody Assays

β_2 GPI is believed to be the major protein cofactor for aPL antibodies. Enzyme-linked immunosorbent assays (ELISAs) for anti- β_2 GPI antibodies are considered to be more specific but less sensitive to APS than to aCL assays.²⁷¹ In a systematic literature review, 34 of 60 studies showed significant associations between anti- β_2 GPI antibodies and

thrombosis.²⁶² None of the studies were prospective. Of the 10 studies that included multivariate analysis, only two confirmed that anti- β_2 GPI IgG antibodies were independent risk factors for venous thrombosis. Anti- β_2 GPI antibodies were more often associated with venous than arterial thrombosis. Anti- β_2 GPI IgA antibodies were significantly associated with thrombosis.

Although these antibodies usually are present in conjunction with abnormal aCL and antiphosphatidyl serine antibodies, some patients with APS present solely with antibodies to β_2 GPI.^{272,273} Despite their higher specificity for APS (98 percent), β_2 GPI antibodies alone cannot be relied upon for the diagnosis because of their low sensitivity (40 to 50 percent).^{274,275} Also, interlaboratory variability is a significant problem with anti- β_2 GPI antibody assays.²⁷⁶

Epitope-specific anti- β_2 GPI antibodies, not yet in general use, may offer a better predictive value for diagnosis and prognosis of APS. A recent analysis of 198 samples from patients with a variety of autoimmune conditions revealed that the 52 patients with anti- β_2 GPI IgG antibodies could be divided into those that recognize domain I alone and those with reactivity for all domains⁵¹; the former were positive for LA and were associated with an increased risk for thrombosis. As mentioned earlier, positivity for this assay has been correlated with positivity for a functional coagulation assay that measures resistance to annexin A5 anticoagulant activity.⁵²

Assays for Antibodies Against Prothrombin and Phosphatidyl Serine

Prothrombin is considered the second major cofactor for aPL antibodies. In a systematic literature review, 17 of 46 studies showed significant associations between antiprothrombin antibodies and thrombosis.²⁶² Of the eight studies that included multivariate analysis, two confirmed that antiprothrombin antibodies were independent risk factors for thrombosis, and three other studies showed that antiprothrombin antibodies added to the risk borne by LA or aCL antibodies. A recent study indicated that the sensitivity of antiprothrombin immunoassays in the primary aPL syndrome is too low to warrant inclusion in recommendations for APS testing.²⁷⁷

Tests for antibodies against phosphatidyl serine have been hypothesized to be more relevant than antibodies against cardiolipin, because the latter are present in intracellular membranes, whereas phosphatidyl serine is exposed on syncytialized cells, on apoptotic cells, and on activated platelets. Antibodies against phosphatidyl serine were reported to correlate more specifically with APS than aCL antibodies, particularly in arterial thrombosis.^{278,279} However, antiphosphatidyl serine antibody tests are not included as an international consensus criterion.²⁵⁷

Newer studies indicate that assays for detecting autoantibodies that recognize prothrombin complexed to the anionic phospholipid, phosphatidyl serine, may have improved utility for diagnosing APS by identifying patients suspected for the disorder but with negative results in the conventional assays; in one series of 728 patients who were suspected of having APS but tested negative by conventional assays, 41 were found to be positive for anti-prothrombin/phosphatidyl serine.²⁸⁰ It has also been suggested that positivity for these assays may correlate with positivity for LA assays.²⁸¹

Assays for Antibodies Against Other Phospholipids

Some investigators have advocated testing for antibodies against a panel of phospholipids other than cardiolipin,^{282–285} but others have disagreed.²⁸⁶ Although one review has indicated that measurement for antiphosphatidyl ethanolamine antibodies may identify some patients whose conventional tests are negative for aPL antibodies,²⁸⁷ the current consensus holds that no benefit has been demonstrated for tests for antibodies against panels of different phospholipids.²⁵⁷

COAGULATION TESTS

Lupus Anticoagulants

One of the most intriguing aspects of APS is the LA phenomenon.^{288,289} The various LA tests all report the inhibition of phospholipid-dependent blood coagulation reactions,⁶ but by different detection methods. These include modifications of the aPTT test with LA-sensitive and LA-insensitive reagents, the kaolin clotting time, the dRVVT, the tissue thromboplastin inhibition time, the hexagonal phase array test, and the platelet neutralization procedure. Readers who are interested in the latest consensus recommendations on details of the procedures are directed to reference 257.

The results of LA tests can be so variable that even specialized laboratories will disagree as to the results of LA tests. For example, three surveys in the United Kingdom have shown that although most laboratories agreed on identification of plasmas containing strong positive LA activity, they frequently have disagreed about samples with a weak LA activity.²⁸⁶

Despite these limitations, the presence of a positive LA appears to be the strongest predictive diagnostic test for future thrombosis. In a meta-analysis of the risk for aPL-associated venous thromboembolism in individuals with aPL antibodies without an underlying autoimmune disease or previous thrombosis, the mean odds ratios were 1.6 for aCL antibodies, 3.2 for high titers of aCL, and 11.0 for LA.²⁹⁰ In a systematic literature review, 12 of 12 studies showed significant associations between LA and thrombosis, with odds ratios from 5.7 to 9.4.²⁶² LA increased the risks of arterial and venous events to the same extent. Positivity for both LA and aCL, but not for aCL alone, predicted a higher risk of recurrent thromboocclusive events in patients with first ischemic stroke.¹³⁵ In a prospective study of pregnant women, the PROMISSE study (Predictors of Pregnancy Outcome: Biomarkers in Antiphospholipid Antibody Syndrome and Systemic Lupus Erythematosus study), LA was the primary predictor of adverse pregnancy outcome after 12 weeks' gestation in aPL-associated pregnancies; aCL antibody and anti- β_2 GPI, did not predict adverse pregnancy outcome if LA was not also present.²⁹¹

In patients with SLE as well, the presence of LA activity is more predictive and more specific for the occurrence of thrombosis or pregnancy loss than aCL assays.²⁹² This was also found in a meta-analysis of women without autoimmune conditions who had recurrent pregnancy losses.²⁹³

Dilute Russell Viper Venom Time

dRVVT is considered to be one of the most sensitive of the LA tests. The assay uses Russell viper venom (RVV) in a system containing limiting quantities of diluted rabbit brain phospholipid. RVV directly activates coagulation factor X, leading to formation of fibrin clot. LA prolongs dRVVT by interfering with assembly of the prothrombinase complex; however, the prolongation is reversed by adding excess phospholipid to the reaction (sometimes referred to a "confirmatory test"). To ensure that prolongation of the clotting time is not a result of a factor deficiency, the procedure includes mixture of patient and control plasmas. Anticoagulant therapy with heparin, warfarin, or direct thrombin inhibitors can yield falsely abnormal test results.

Activated Partial Thromboplastin Time Tests

Prolongation of the aPTT detects some LAs, and prolonged aPTTs in otherwise healthy individuals are most frequently caused by LAs.²⁹⁴ The various commercial aPTT reagents vary widely with regard to sensitivity to LA, so it is important to know the characteristics of the particular reagent(s) that is (are) being used. When the aPTT of a particular plasma sample is prolonged and not correctable by immediate mixture

with normal plasma, the presence of an LA should be suspected, especially if the patient does not have bleeding symptoms. The LA needs to be differentiated from inhibitors of specific coagulation factors and from anticoagulants such as heparin. Besides specific assays to exclude the latter two possibilities, the clinician should check whether the aPTT normalizes when an LA-insensitive aPTT reagent is used or when the assay is performed using frozen washed platelets as the source of phospholipid, a procedure referred to as the platelet neutralization procedure. The effects of incubation with normal plasma may be helpful in differentiating LAs from coagulation factor inhibitors. aPTTs performed on mixtures of normal plasma and plasma containing a factor VIII inhibitor usually show no prolongation immediately after mixing but marked prolongation following incubation for 1 to 2 hours at 37°C, whereas LA-containing plasmas usually prolong the aPTT immediately after mixing with normal plasma and show no further prolongation with incubation. The clinician should be aware that both types of anticoagulants, LA and specific coagulation factor inhibitors, may coexist in rare patients and yield confusing laboratory results. Specific coagulation factor inhibitor assays and using an aPTT reagent that is insensitive to LA are helpful for clarifying most of these cases. LAs may result in artifactual decreases in contact activation pathway coagulation factor assays, because these assays are based on aPTT. Consequently, these patients are sometimes misdiagnosed as having multiple coagulation factor deficiencies. This problem can be handled by repeating the coagulation factor assays following dilution of the plasma samples; this usually results in complete or partial normalization of coagulation factor levels with progressive dilution. The use of an aPTT reagent that is insensitive to LA for specific factor assays is another way to solve this problem.

Other Methods for Detecting Lupus Anticoagulant

The dilute prothrombin time (dPT) (also known as the tissue thromboplastin inhibition test [TTIT]) is essentially a prothrombin time assay done with diluted tissue factor-phospholipid complex. It can be performed with standard or recombinant tissue factor.^{295,296} The results are expressed as a ratio of the patient-to-control clotting times.

The kaolin clotting time (KCT) depends on the ability of aPL antibodies to block the coagulant activity of trace amounts of phospholipid present in centrifuged plasma. Some authors maintain that the KCT-LA test reflects dependence on prothrombin as a cofactor and is less likely to be associated with thrombosis than the dRVVT, which appears to be more dependent on β_2 GPI.^{297,298} The hexagonal phase array test is based on a prior idea that aPL antibodies recognize phosphatidyl ethanolamine directly in the hexagonal phase array configuration but not in the lamellar phase. Although this assay remains in use, the correction of the prolonged clotting time with hexagonal phase phosphatidyl ethanolamine is probably similar to the confirmatory step used in the other LA assays, that is, a result of the excess of phospholipid in the reaction.

The textarin/ecarin test depends on the difference in phospholipid dependence of coagulation mechanisms triggered by two snake venoms: textarin, which activates prothrombin via a phospholipid-dependent pathway, and ecarin, which activates prothrombin directly without phospholipid.²⁹⁶

Annexin A5 Resistance Assay

In addition to the various LA tests, there is a coagulation test that reports on a thrombogenic mechanism—resistance to annexin A5 anticoagulant activity.⁸⁰ This assay has been correlated with an immunoassay for IgG antibodies against domain I of β_2 GPI.⁵² The assay has two stages: a first, in which a tissue factor-phospholipid suspension is exposed to test plasma, and a second, in which the washed suspension is used to coagulate pooled normal plasma in the presence and absence of annexin A5. Patients with annexin A5 resistance show a less-than-expected annexin

A5 anticoagulant effect, reported as a reduction in the annexin A5 anticoagulant ratio. In contrast to the lupus “anticoagulant” effect, this assay measures and reports a procoagulant effect for the antibodies.⁷⁰ (*Disclosure: One of the authors (J.H.R.) is inventor of this assay, U.S. Patents #6284475 and #7252959.*)

DIFFERENTIAL DIAGNOSIS

Chapters 133 and 134 address the general subject of vascular thrombosis and its differential diagnosis. When vascular occlusion occurs in the setting of a known autoimmune disorder such as SLE, the possibility of a vasculitis, rather than a thrombotic condition, should be considered. Patients with CAPS may, at first, appear to have other multisystem vasoocclusive disorders, such as thrombotic thrombocytopenic purpura or disseminated vasculitis, and may also manifest laboratory findings of disseminated intravascular coagulation.

The differential diagnosis of a prolonged aPTT includes hereditary and acquired coagulation factor deficiencies, inhibitors to coagulation proteins (e.g., acquired hemophilia A; Chap. 128), and the presence, or use, of anticoagulants. The diagnosis of LA is substantiated through plasma mixing studies and specific factor assays. A positive immunoassay for aPL—that is, aCL and/or anti- β_2 GPI antibodies—helps confirm the diagnosis.

When an elevated level aPL antibody level is detected, the clinician must exclude the possibility of an infectious etiology for the antibodies; these occur frequently in syphilis, Lyme disease, HIV-1, and hepatitis C. Occasional patients may have artifactually elevated antibodies from increased polyclonal immunoglobulin levels.²⁹⁹ In such cases, diagnosis is aided by specific tests for suspected infection, quantitative measurement of serum immunoglobulins, and subtraction of background controls using uncoated microtiter wells. Antipsychotic or other medications should be excluded as causative agents.

PREGNANCY COMPLICATIONS

A systematic review of treatments given to maintain pregnancy in women with prior miscarriages and APS concluded that combined unfractionated heparin and aspirin may reduce pregnancy loss by 54 percent compared to aspirin alone.³⁰⁰ Three trials of aspirin alone showed no significant reduction in pregnancy loss³⁰⁰; intravenous immunoglobulin, whether in combination with or without unfractionated heparin (UFH) and aspirin, was associated with an increased risk of pregnancy loss or premature birth when compared to UFH or low-molecular-weight heparin (LMWH) combined with aspirin.

Taking together the available data, women with a history of three or more spontaneous pregnancy losses and evidence of aPL antibodies should be treated with a combination of low-dose aspirin (75 to 81 mg/day) and prophylactic doses of UFH (i.e., 5000 U every 12 hours subcutaneously). Treatment should be started as soon as pregnancy is documented and continued until delivery so as to reduce the rate of late complications.^{183,301} In especially high-risk situations, induction of early delivery may be necessary. Unfractionated heparin at the prophylactic dosage of 5000 U q12h subcutaneously should be started approximately 4 to 6 hours after delivery, if significant bleeding has ceased, and continued at least until the patient is fully ambulatory. Many physicians recommend continuing prophylactic therapy for 6 weeks after delivery even if the patients have not experienced thrombosis. For patients who experienced thromboembolism, prophylaxis by heparin or oral anticoagulant therapy is warranted for at least 6 weeks after delivery.

Although treatment with LMWH has become widely used for recurrent fetal loss as a replacement for prophylactic dose UFH, a prospective randomized controlled trial has questioned the benefit of

LMWH treatment versus aspirin therapy. In the LMWH/aspirin group 35/47 (77.8%) had a livebirth, and in the aspirin group 34/43 (79.1 percent) had a livebirth ($p = 0.7$).³⁰²

The presence of positive aPL laboratory assays alone is not an indication for treatment in pregnant women without a history of spontaneous pregnancy losses, other attributable pregnancy complications, thrombosis, or SLE. Therefore, the inclusion of aPL tests in routine prenatal testing panels should be discouraged.

Although prednisone was reported to possibly improve the outcome of pregnancy in women with APS, those benefits are associated with significant toxicity.³⁰³ Glucocorticoids or intravenous IgG should be considered only for patients who are refractory to anticoagulant therapy, who have a severe immune thrombocytopenia or a significant contraindication to heparin therapy. Treatment with the combination of prednisone and heparin is associated with an increased risk of osteopenia and vertebral fractures.³⁰⁴

THERAPY, COURSE, AND PROGNOSIS

There is general agreement that APS patients with recurrent spontaneous thrombosis require long-term, and perhaps lifelong, anticoagulant therapy and APS patients with recurrent spontaneous pregnancy losses require antithrombotic therapy for most of the gestational period. There are differences of opinion among experts regarding the approaches to treatment of patients with a single thrombotic event, patients with a history of thrombotic events in the distant past (>5 years), patients with stroke, and patients with thrombotic events that were associated with a provocative factor such as trauma, surgery, stasis, pregnancy, and estrogens.

THROMBOSIS

The accumulated evidence from randomized controlled trials indicates that patients with APS and thrombosis should be treated with warfarin for the long-term, and maintained at a therapeutic international normalized ratio (INR) of 2.0 to 3.0.³⁰⁵ Patients with arterial thrombosis may require a higher anticoagulant intensity as a retrospective study showed that a higher intensity (INR >3.0) was necessary for preventing recurrences in this group of patients, but this issue is controversial.³⁰⁶ Two other studies reported no benefit for high-intensity warfarin but the number of patients with arterial thrombosis was not high.^{299,305} The issue of appropriate antithrombotic treatment of aPL-associated stroke is even more controversial. One major study concluded that there was no benefit for warfarin anticoagulation compared to aspirin therapy.³⁰⁷

For patients treated acutely with intravenous UFH, care must be taken to determine whether the patient has a preexisting LA that can interfere with aPTT monitoring of heparin levels. This problem can be circumvented by using an LA-insensitive aPTT reagent or be avoided by treatment, where appropriate, with a LMWH.

An important practical consequence of the LA effect is that prothrombin time and INR results can be artifactually elevated in some patients with APS and LAs treated with warfarin anticoagulant therapy.³⁰⁸ A multicenter study reported that all but one of the commercial thromboplastins in use at nine centers provided acceptable INR values for APS patients with LA.³⁰⁹ New thromboplastins should be checked for their responsiveness to LA prior to their use in monitoring oral anticoagulant treatment in patients with APS. Chromogenic factor X (CFX) assays can be used as an alternative to INR for APS patients, especially in patients with a prolonged baseline prothrombin time prior to initiating warfarin therapy, those who are persistently positive for LA and those patients who continue to have recurrent venous thromboembolism

(VTE).³¹⁰ Therapeutic CFX values range from 20 to 40 percent; thus, a CFX of 40 percent would approximate an INR of 2.0, and a CFX of 20 percent would approximate an INR of 3.0.

New oral anticoagulants (NOACs), either direct factor Xa or thrombin inhibitors, are effective for treatment of VTE.³¹¹ However, their use specifically in APS patients has not been thoroughly evaluated. In two recent case studies, NOACs have failed to prevent thrombosis in APS patients. Of six APS patients studied, five suffered recurrent VTE and one suffered a recurrent TIA after transitioning to NOACs.^{312,313} At the time of writing, a prospective randomized controlled trial of warfarin versus rivaroxaban named “RAPS” (Rivaroxaban in Antiphospholipid Syndrome) is ongoing in patients with thrombotic APS (study ISRCTN68222801). Until the trial is concluded (expected completion in 2015), caution should be applied in using NOACs for APS patients.

Fibrinolytic treatment has been reported for patients with primary APS and extensive thrombosis of the common femoral and iliac veins extending to the lower vena cava,³¹⁴ acute ischemic stroke,³¹⁵ and acute myocardial infarction.³¹⁶

The antimalarial drug hydroxychloroquine (HCQ) is associated with reduced risk of thrombosis in patients with APS^{271–273,317–319} and SLE.^{319–321} The potential effectiveness of this treatment has been supported by an animal model for aPL thrombosis³²² and by a recent report that HCQ directly disrupts aPL IgG- β_2 GPI complexes,³²³ and also reverses the aPL antibody-mediated disruption of annexin A5 binding on phospholipid bilayers³²⁴ and on human placental syncytiotrophoblasts.³²⁵ In a longitudinal cohort study consisting of 272 patients with the APS and 152 taking HCQ (17 of 272 patients on warfarin, 203 were on prednisolone, 112 on azathioprine, 38 on aspirin) investigators found fewer thrombotic complications for patients on HCQ (odds ratio [OR] 0.17, 95% confidence interval [CI] 0.07 to 0.44; $p < 0.0001$).³²⁶ In asymptomatic aPL antibody-positive patients with SLE, primary prophylaxis with aspirin and HCQ appeared to reduce the frequency of thrombotic events.³²⁷ A published prospective, nonrandomized study compared oral anticoagulant plus HCQ versus oral anticoagulant alone. In this study, 30 percent (6/20) of patients had a thrombotic event if they were on oral anticoagulant alone, despite therapeutic range INR, versus no thrombotic events in the oral anticoagulant plus HCQ group (0/20). This study, however, was limited given the small number of patients studied and short followup.³²⁸ Recently, the natural 4-aminoquinolone, quinine, was shown *in vitro* to disrupt the immune complexes bound to phospholipid layers.³²⁹ However, both HCQ and quinine will require clinical testing in appropriately designed clinical trials. A prospective randomized controlled trial comparing HCQ to placebo in aPL-positive patients without a prior history for thrombosis is currently in progress.

Other proposed treatments for APS include statins, rituximab and vitamin D. Statins have immunomodulatory, antiinflammatory and antithrombotic properties that may benefit APS patients. In recent studies, APS patients treated with statins demonstrated downregulation of tissue factor and reduced proinflammatory/prothrombotic markers such as interleukin-1 β , vascular endothelial growth factor, tumor necrosis factor α , interferon-inducible protein 10, and soluble CD40L.^{330,331} It has been suggested that a B-cell inhibitor such rituximab may be useful in reducing aPL antibody titers in APS patients. The Rituximab in Antiphospholipid Syndrome (RITAPS) trial did not show reduction in aPL antibody profiles by rituximab; however, rituximab may be effective in controlling noncriteria manifestations of APS.³³² Because low vitamin D levels correlate with arterial and venous thrombosis as well as noncriteria APS manifestations,^{333–335} it is recommended that vitamin D deficiency (<10 to 20 ng/mL) and insufficiency (<30 ng/mL) be corrected in aPL antibody-positive patients.³³⁶

Conventional anticoagulant therapy is usually not sufficient for treatment of CAPS; these patients require aggressive treatment because

of the high mortality.¹⁷⁶ Treatment for CAPS is directed toward the thrombotic events and suppression of the cytokine cascade. This includes anticoagulation with heparin and immunosuppressive therapy in the form of high-dose glucocorticoids. A triple therapy strategy of anticoagulation, glucocorticoids, and either intravenous immunoglobulin or plasma exchange or both has improved outcomes. Cyclophosphamide is recommended for patients with CAPS and inflammatory features of SLE or high-titer aPL antibodies. Rituximab may be useful in refractory or relapsing cases of CAPS.¹⁷⁸

PREGNANCY COMPLICATIONS

The current approach to treating pregnant women with APS and recurrent pregnancy losses or the other aPL antibody-associated complications of pregnancy includes daily low-dose aspirin (75 to 81 mg/day) and either UFH or LMWH.^{300,337,338} Although clinical studies have shown efficacy with UFH, most clinicians treat with LMWH because it has a better pharmacokinetic profile and a lower risk of heparin-induced thrombocytopenia and osteopenia. Heparin is then withheld when labor begins or 24 hours prior to a cesarean section. Anticoagulation is resumed 6 weeks postpartum because of the increased risk of VTE in this time period.³⁰¹ Interestingly, the current standard of care for pregnant APS patients is based on two randomized controlled trials conducted prior to 2000 that included only 150 patients. Newer trials show conflicting results, with some showing no difference in prevention of pregnancy loss in APS patients receiving aspirin alone versus aspirin and LMWH,³⁰² and others showing a small benefit.³³⁹ With this management, the likelihood of a good pregnancy outcome in women with APS has been estimated to be approximately 75 to 80 percent.

Other treatment modalities such as glucocorticoids or intravenous IgG (IVIG) should be considered only for patients who are refractory to anticoagulant therapy, who have a severe immune thrombocytopenia, or who have a significant contraindication to heparin therapy. The addition of glucocorticoids has shown no clear benefits and has been associated with premature rupture of membranes or preeclampsia; however, a newer study showed that for patients with refractory APS, the addition of low-dose prednisolone (10 mg) from time of a positive pregnancy test up to 14 weeks' gestation may help to increase livebirth rates.³⁴⁰ Although the addition of IVIG has not been shown to be superior to heparin and aspirin in large multicenter clinical trials,³⁴¹ it has shown some efficacy in patients with refractory APS in small case studies.^{342,343}

CHAPTER 132

THROMBOTIC MICROANGIOPATHIES

J. Evan Sadler

SUMMARY

Thrombotic microangiopathy is a general term for the combination of microangiopathic hemolytic anemia and thrombocytopenia, often accompanied by signs and symptoms consistent with disseminated microvascular thrombosis. Thrombotic thrombocytopenic purpura (TTP) refers to thrombotic microangiopathy, without an obvious predisposing condition, and without oliguric renal failure. TTP is caused by autoantibodies to ADAMTS13 (a disintegrin and metalloprotease with a thrombospondin type 1 motif member 13), a plasma metalloprotease that normally cleaves von Willebrand factor (VWF) and regulates VWF-dependent platelet aggregation. Inherited deficiency of ADAMTS13 causes congenital TTP, which typically responds to plasma infusion. Most patients with acquired TTP respond to plasma exchange, although many have relapsing disease. Hemolytic uremic syndrome (HUS) refers to thrombotic microangiopathy that usually causes oliguric or anuric renal failure. Ingestion of *Shiga* toxin-producing *Escherichia coli* can cause the most common or “typical” form of HUS that is usually preceded by bloody diarrhea. Inherited or acquired defects in the regulation of the alternative complement pathway cause HUS referred to as “atypical” because it occurs without a prodrome of bloody diarrhea. Secondary thrombotic microangiopathy can occur in association with metastatic cancer, infections, organ transplantation, and certain drugs. These variants of thrombotic microangiopathy differ in pathogenesis and prognosis, but can be difficult to distinguish because their clinical features often overlap.

● THROMBOTIC THROMBOCYTOPENIC PURPURA

DEFINITION AND HISTORY

Thrombotic thrombocytopenic purpura (TTP) refers to thrombotic microangiopathy without another apparent cause and without acute renal failure, although mild or modest renal insufficiency may be seen.

Acronyms and Abbreviations: ADAMTS, a disintegrin and metalloprotease with thrombospondin repeats; aHUS, atypical hemolytic uremic syndrome; ANA, anti-nuclear antibody; APS, antiphospholipid syndrome; aPTT, activated partial thromboplastin time; CFH, complement factor H; CFHR, complement factor H-related protein; DDAVP, desmopressin; DGKE, diacylglycerol kinase ϵ ; Gb3, globotriaosylceramide 3; HELLP, hemolysis, elevated liver enzymes, low platelet count; HIT, heparin-induced thrombocytopenia; HUS, hemolytic uremic syndrome; LDH, lactate dehydrogenase; MCP, membrane cofactor protein; MMACHC, methylmalonic aciduria and homocystinuria type C protein; PT, prothrombin time; SLE, systemic lupus erythematosus; STEC, *Shiga* toxin-producing *Escherichia coli*; Stx, *Shiga* toxin; TM, thrombomodulin (gene name *THBD*); TTP, thrombotic thrombocytopenic purpura; VEGF, vascular endothelial growth factor; VWF, von Willebrand factor.

Tissue injury can affect almost any organ but often results in neurologic damage. TTP is associated with autoantibodies against the plasma metalloprotease ADAMTS13 (a member of the “a disintegrin and metalloprotease with thrombospondin repeats” family) that reduce plasma ADAMTS13 activity to less than 10 percent of normal.

Eli Moschcowitz reported the first detailed description of TTP in 1924.¹ The patient was a 16-year-old girl with fever, severe anemia, leukocytosis, petechiae, and hemiparesis. Her renal function was not impaired, but the urine contained albumin, hyaline casts, and granular casts. She became comatose and died 2 weeks after her first symptoms. At autopsy, hyaline thrombi were found diffusely in terminal arterioles and capillaries, particularly of the heart and kidney. For many years, patients with similar findings were said to have Moschcowitz disease. The name *TTP* was proposed in 1947² and widely adopted thereafter.

In 1966, a review of 272 published cases defined the major clinical features of TTP.³ Most patients were females between the ages of 10 and 39 years. The symptoms and physical findings included thrombocytopenia, hemolytic anemia with numerous fragmented red cells or schistocytes, neurologic findings, renal damage, and fever. Mortality exceeded 90 percent; the average hospital stay was only 14 days before death, and 80 percent of patients lived fewer than 90 days after the onset of symptoms. However, dramatic recoveries occurred in some cases following splenectomy.

This grim prognosis was recorded before a report in 1976 that whole blood exchange transfusions induced prompt remissions in eight of 14 patients.⁴ Similar responses were described after plasmapheresis with plasma replacement.⁵ One remarkable case report showed that plasmapheresis was effective if the replacement fluid was plasma or cryoprecipitate-depleted plasma, but ineffective if the replacement fluid contained just albumin.⁶ Furthermore, simple plasma infusions without plasmapheresis could induce sustained remissions, suggesting that replacement of a missing plasma factor sometimes was sufficient to ameliorate TTP.⁶

These reports led to the widespread adoption of plasma therapy for TTP, and two studies published in 1991 provided compelling evidence for its efficacy. Plasma infusion was associated with 91 percent survival in 108 patients, an impressive improvement over historical experience.⁷ The same year, a prospective randomized comparison of plasma exchange and plasma infusion in 102 patients with TTP was reported.⁸ Long-term survival was 78 percent for the plasma exchange group and 63 percent for the plasma infusion group, a significant difference in favor of plasma exchange.

A link between TTP and von Willebrand factor (VWF) was proposed in 1982, based on studies of four patients with chronic relapsing TTP.⁹ Their plasma VWF multimers were much larger than those of healthy controls and similar in size to the VWF multimers secreted by endothelial cells. Patients with TTP were proposed to lack a depolymerase activity, perhaps a protease or a reductase, that shortens newly secreted VWF multimers *in vivo* and produces the multimer distribution of normal plasma. The absence of this depolymerase would cause the persistence of “unusually large” VWF, which promotes intravascular platelet aggregation, thrombocytopenia, and microvascular thrombosis. Plasma exchange therapy could provide the missing depolymerase activity, or remove other factors that provoke clinical relapses.

A candidate depolymerase was identified in 1996, when a metalloprotease in plasma was shown to cleave VWF multimers subjected to high fluid shear stress or to mild protein denaturants.^{10,11} Soon thereafter, children with congenital TTP were shown to have inherited deficiency of this metalloprotease,¹² and adults with acquired TTP were shown to have autoantibody inhibitors of the enzyme.^{13,14} The VWF cleaving protease was purified,^{15,16} cloned,^{17,18} and named ADAMTS13, a new member of the ADAMTS family of metalloproteases. Simultaneously,

the *ADAMTS13* locus was identified by linkage analysis in families affected by congenital TTP and causative *ADAMTS13* mutations were characterized.¹⁹

ETIOLOGY AND PATHOGENESIS

TTP is caused by unregulated VWF-dependent platelet thrombosis. Large VWF multimers mediate platelet adhesion at sites of vascular injury by binding to connective tissue and to glycoprotein Ib (GPIb) on the platelet surface (Chap. 120). The VWF subunit from which multimers are constructed has a modular structure consisting of five types of conserved structural motifs (Fig. 132-1). VWF multimers bind to collagen through domain A3, and to platelet GPIb through domain A1. When platelets bind to VWF under conditions of high fluid shear stress, the VWF multimer is stretched and the Tyr¹⁶⁰⁵-Met¹⁶⁰⁶ bond within domain A2 becomes accessible to ADAMTS13, which cleaves it and thereby can release any adherent platelets. ADAMTS13 deficiency prevents this feedback inhibition of platelet adhesion and leads to widespread microvascular thrombosis. ADAMTS13 levels greater than 10 percent appear sufficient to prevent thrombotic microangiopathy.

ADAMTS13 deficiency in TTP is caused by polyclonal autoantibodies against ADAMTS13, usually immunoglobulin (Ig) G but occasionally IgA or IgM.^{13,14} These antibodies almost always bind the ADAMTS13 spacer domain, and often bind to the CUB domains and first thrombospondin-1 repeat; they bind less frequently to other thrombospondin-1 repeats, the metalloprotease domain, or the propeptide.²⁰⁻²² Most patients have autoantibodies that inhibit ADAMTS13 activity. The rest have noninhibitory antibodies that are likely to mediate clearance of ADAMTS13 from the circulation.²³

EPIDEMIOLOGY

The annual incidence of TTP reportedly is two to six per million population in the United States and approximately 2.2 per million in the United Kingdom.^{24,25} Seasonal or geographical trends have not been observed

consistently. The demographics of TTP are similar to those of systemic lupus erythematosus (SLE). TTP is relatively uncommon before age 20 years, with a peak incidence between ages 30 and 50 years.^{24,25} Across many reports the female-to-male ratio averages approximately 2:1, but female preponderance is more pronounced below age 50 years and the ratio approaches equality above age 60 years.^{24,25} Other risk factors for TTP include African ancestry^{26,27} and obesity.^{27,28} Women have a tendency to present during late pregnancy or peripartum (reviewed in Refs. 29 and 30). HLA-DRB1*11 is overrepresented severalfold in whites with TTP.^{31,32}

CLINICAL FEATURES

The onset of TTP can be dramatically acute or insidious, developing over weeks. Approximately one-third of patients have symptoms of hemolytic anemia.^{3,29} Thrombocytopenia typically causes petechiae or purpura; oral, gastrointestinal or genitourinary bleeding is less common but can be severe. Many patients describe an antecedent upper respiratory tract infection or flu-like illness. Abdominal pain and tenderness are common. Nausea, vomiting, and diarrhea may occur, but bloody diarrhea is uncommon.

Systemic microvascular thrombosis typically affect the kidney, heart, brain, pancreas, adrenals, skin, spleen, marrow, and most other tissues except the lungs, which are spared. Renal involvement is common, but acute renal failure occurs in fewer than 10 percent of cases.^{26,27,29} Neurologic findings can be transient or persistent and may include headache, visual disturbances, vertigo, personality change, confusion, lethargy, syncope, coma, seizures, aphasia, hemiparesis, and other focal sensory or motor deficits.^{3,29} The frequency of neurologic findings or fever has decreased from more than 90 percent to approximately 50 percent over the past 40 years,^{3,8,26,27,29} probably because these features no longer are recognized as necessary to diagnose TTP.

The symptoms of TTP sometimes can be quite atypical, either at first presentation or upon relapse. Thrombocytopenia without hemolytic anemia may herald the onset of disease. In rare instances, visual disturbances, pancreatitis, stroke, or other thrombosis may

Figure 132-1. Structure of von Willebrand factor (VWF). Multimeric VWF (*top*) is composed of identical subunits with four kinds of structural motifs, including three A domains, six C domains and a homologous D4N domain, two complete and one partial D domains, and a cystine knot (CK) domain. Subunits (*middle*) are linked into multimers by disulfide bonds between C-terminal CK domains and N-terminal D3 domains. Domain A1 (*bottom*) binds platelet glycoprotein Iba (GPIba), domain A3 binds collagen in extracellular matrix, and domain A2 contains a Tyr-Met bond that is susceptible to cleavage by ADAMTS13 (a disintegrin and metalloprotease with a thrombospondin type 1 motif member 13).

precede overt thrombotic microangiopathy by days to months.^{33–36} Macrovascular venous or arterial thrombosis occurs in up to one-half of patients.³⁷

Cardiac involvement may cause chest pain, myocardial infarction, congestive heart failure or arrhythmias.^{29,38,39} Direct pulmonary involvement is uncommon but severe acute respiratory distress syndrome may occur, possibly secondary to cardiac failure.²⁹ Gastrointestinal symptoms are common and can include abdominal pain, nausea, vomiting, and diarrhea.^{3,29} Physical examination may suggest acute pancreatitis or mesenteric ischemia. Infrequent findings include Raynaud phenomenon, arthralgia, myalgia, and retinal hemorrhage or detachment.^{3,29}

LABORATORY FEATURES

The symptoms and signs of TTP are nonspecific. The diagnosis depends on laboratory testing to document microangiopathic hemolytic anemia and thrombocytopenia, without another predisposing cause. Anemia is almost universal with a mean hemoglobin of approximately 8 g/dL.^{27,40} Thrombocytopenia typically is severe, with a mean platelet count of approximately $20 \times 10^9/L$.^{26,27,40} Hemolysis is indicated by an elevated reticulocyte count and serum lactate dehydrogenase (LDH), undetectable serum haptoglobin, and increased total and unconjugated bilirubin. Coombs test is almost always negative.^{7,8} Renal microvascular injury is common with microhematuria, granular or red cell casts, and proteinuria, but the serum creatinine is often normal and seldom greater than 2 mg/dL.^{7,8,27,40} Approximately 50 percent of patients have a positive anti-nuclear antibody (ANA) test.⁴⁰

Almost all patients have normal values for plasma fibrinogen, prothrombin time (PT) and activated partial thromboplastin time (aPTT),^{7,8} reflecting a minor role of blood coagulation in TTP. Evidence of myocardial damage is common, with elevated troponin levels.^{38,39}

The characteristic morphological feature of TTP on the blood film is a marked increase in schistocytes. Schistocytes are helmet cells, or small irregular triangular or crescent shaped cells with pointed projections, that lack central pallor (Chap. 2).⁴¹ Patients with TTP often have markedly increased schistocytes; in a study of six patients, schistocytes comprised a mean of 8.3 percent of all red cells with a range of 1 percent to 18.4 percent.⁴² Spherocytes also may be seen.

ADAMTS13 activity is characteristically less than 10 percent and this degree of acquired ADAMTS13 deficiency appears to be specific for TTP.^{13,14,43,44} If adult patients with thrombotic microangiopathy are selected with no plausible secondary cause, no diarrheal prodrome, and no features suggestive of hemolytic uremic syndrome (HUS) (e.g., oliguria, severe hypertension, dialysis, serum creatinine >3.5 mg/dL), then at least 80 percent of those selected have ADAMTS13 activity less than 10 percent of normal. The majority of patients with severe ADAMTS13 deficiency have autoantibody inhibitors^{13,14,26,45} and almost all patients have autoantibodies that bind ADAMTS13 by enzyme-linked immunosorbent assay (ELISA).

Depending on the clinical context, laboratory tests should be considered to detect conditions that may cause thrombotic microangiopathy by mechanisms other than ADAMTS13 deficiency such as pregnancy, cobalamin deficiency, SLE and other autoimmune diseases, antiphospholipid syndrome (APS), HIV, and *Shiga* toxin-producing organisms.

The histologic appearance of microvascular lesions in TTP is consistent with a pathophysiologic role of VWF-dependent platelet thrombosis. Amorphous thrombi and subendothelial hyaline deposits may be found in the small arterioles and capillaries of any organ, but are particularly common (in order of decreasing severity) in the myocardium, pancreas, kidney, adrenal gland and brain. The liver and lung are relatively spared. The lesions consist mainly of platelets and VWF, with little

fibrin and few inflammatory cells. They often include focal endothelial cell proliferation.^{46,47}

DIFFERENTIAL DIAGNOSIS

The diagnosis of TTP should be entertained for any patient with microangiopathic hemolytic anemia and thrombocytopenia, without evidence for disseminated intravascular coagulation, and without features associated with *Shiga* toxin-producing *Escherichia coli* (STEC)-HUS such as a prodromal diarrheal illness and acute oliguric or anuric renal failure. These criteria can only be approximate, however, because many diseases associated with secondary thrombotic microangiopathy can produce overlapping clinical and laboratory findings. As a consequence, making a diagnosis of TTP can be a challenge and a wide differential diagnosis often must be considered (Table 132–1).

Schistocytes occur in a variety of conditions besides TTP, although the level seldom enters the 1 to 18 percent range typical of TTP. For example, schistocytes were seen in the blood film of 58 percent of healthy controls, with a mean of 0.05 percent and a range of 0 to 0.27 percent of all red cells.⁴² Up to 0.6 percent schistocytes were observed in patients with chronic renal failure, preeclampsia, or properly functioning

TABLE 132–1. Classification and Differential Diagnosis of Thrombotic Microangiopathy

Thrombotic Thrombocytopenic Purpura (TTP)

Autoimmune, with antibodies against ADAMTS13

Congenital Thrombotic Thrombocytopenic Purpura (Upshaw-Schulman Syndrome)

Inherited ADAMTS13 deficiency, with mutations in *ADAMTS13*

Shiga Toxin-Producing *Escherichia Coli* Hemolytic Uremic Syndrome (STEC-HUS)

Atypical Hemolytic Uremic Syndrome (aHUS)

Alternative complement pathway defects

Diacylglycerol kinase ϵ (DGKE) defects

Secondary Thrombotic Microangiopathy

Disseminated intravascular coagulation

Infections (viral, bacterial, fungal)

Streptococcus pneumoniae

Tissue transplant-associated

Chemotherapy or radiation injury

Tissue rejection

Graft-versus-host disease

Cancer

Pregnancy associated (preeclampsia, eclampsia, HELLP [hemolysis, elevated liver enzymes, low platelet count] syndrome)

Autoimmune disorders

Systemic lupus erythematosus and other vasculitides

Antiphospholipid syndrome

Drugs (commonly implicated)

Immune (quinine, ticlopidine)

Toxic (cyclosporine, tacrolimus, mitomycin C, gemcitabine)

Cobalamin metabolic defects

Malignant hypertension

Mechanical hemolysis (e.g., malfunctioning aortic or mitral valve prosthesis)

prosthetic heart valves.⁴² Severe hemolysis and marked schistocytosis occur in patients with defective mechanical heart valves. Patients receiving marrow allografts or autografts for a variety of indications had a mean of 0.7 percent schistocytes 6 weeks after transplantation, with a range of 0 to approximately 4 percent schistocytes.^{48,49} Approximately 10 percent of patients had at least 1.3 percent schistocytes, placing them at risk for a diagnosis of thrombotic microangiopathy.⁴⁹

ADAMTS13 levels are normal to moderately decreased in newborns, during pregnancy, after surgery, and in chronic liver cirrhosis, chronic renal insufficiency, acute inflammatory states, and a variety of thrombocytopenic disorders other than TTP.^{44,50} Severe sepsis may sometimes cause acquired severe ADAMTS13 deficiency, although the incidence and clinical significance of the finding remain uncertain.⁵¹ Some patients with acute viral hepatitis, severe liver cirrhosis⁵² or venoocclusive disease after stem cell transplantation⁵³ have had severe ADAMTS13 deficiency (<10 percent) at least transiently, which is consistent with the synthesis of ADAMTS13 in liver.¹⁷⁻¹⁹

THERAPY

Plasma Exchange

The mainstay of therapy for TTP is plasma exchange, which removes antibody inhibitors of ADAMTS13 and replenishes the enzyme. After diagnosing TTP, or determining that the diagnosis is sufficiently likely to justify treatment, plasma exchange therapy should be started as soon as feasible. Studies establishing the value of plasma therapy have excluded secondary thrombotic microangiopathy,^{7,8} so the efficacy of plasma exchange has been demonstrated directly only for TTP. The optimal dose of plasma is not known, but a common practice is to perform plasma exchange once daily at a volume of 40 or 60 mL/kg, equivalent to 1.0 or 1.5 plasma volumes. For refractory disease, the intensity of plasma exchange can be increased to 1 plasma volume twice daily.⁵⁴ Prompt treatment is important and if plasma exchange must be delayed more than a few hours, plasma should be given by simple infusion at 20 to 40 mL/kg total dose per day, consistent with the patient's ability to tolerate the fluid load.⁵⁵

The replacement fluid should contain ADAMTS13. Satisfactory results have been obtained with fresh-frozen plasma,^{7,8} plasma cryosupernatant,⁵⁶⁻⁵⁸ and various pathogen-inactivated plasma products.⁵⁹ The incidence of allergic reactions and transfusion-associated lung injury may be lower with solvent/detergent-treated plasma than with fresh-frozen plasma,⁶⁰ but the incidence of thrombosis may be increased with some preparations.^{59,61} Cryosupernatant is depleted in the largest VWF multimers but has normal ADAMTS13 levels,⁶² which could make cryosupernatant particularly suitable for the treatment of TTP. Nevertheless, small randomized trials suggest that cryosupernatant is not superior to fresh-frozen plasma for the initial treatment of TTP.^{56,57} Methylene blue-treated plasma may be less effective than fresh-frozen plasma,^{59,63} despite having a similar concentration of ADAMTS13.⁵⁹

Plasma exchange should be continued daily until the patient has a treatment response as shown by a platelet count greater than $150 \times 10^9/L$ for at least 2 days.⁵⁵ Whether plasma exchange then should be simply stopped or tapered is not known. A typical strategy is to reduce the frequency of plasma exchange to every other day (or twice per week) for several days. If the disease remains quiescent, then treatment can be stopped and the patient monitored closely for recurrence. Alternatively, plasma exchange can be stopped abruptly with monitoring for recurrent thrombocytopenia over several days.

Glucocorticoids

TTP is an autoimmune disease and the use of glucocorticoids is logical, although a beneficial effect has not been demonstrated conclusively.

Common practice is to give prednisone or equivalent at a total daily dose of 1 mg/kg, in one or two doses, for the duration of plasma exchange, followed by tapering. An alternative regimen is methylprednisolone 1 g intravenously daily for 3 days.⁵⁵

Antiplatelet Agents

The use of antiplatelet agents in TTP is controversial. Aspirin and dipyridamole often are combined with plasma exchange but have not been shown conclusively to modify the course of TTP.^{8,64} Low-dose aspirin (e.g., 80 mg/day) has been suggested for thromboprophylaxis, once the platelet count exceeds $50 \times 10^9/L$.⁵⁵

Platelet Transfusion

Transfusion of platelets may correlate with acute deterioration and death in TTP.^{7,29,65,66} Therefore, platelet transfusions are relatively contraindicated and should be reserved for the treatment of life-threatening hemorrhage, preferably after plasma exchange treatment has been initiated. Platelets generally need not be given prophylactically before establishing venous access for plasma exchange.^{67,68} Platelets have been transfused before emergency surgery, immediately after preparation by intensive plasma exchange.⁶⁵

Rituximab

TTP that is refractory to plasma exchange usually responds to rituximab (e.g., 375 mg/m² weekly for 4 doses). At least 80 percent of patients have complete responses within 1 to 3 weeks of starting treatment,⁶⁹ including a normal ADAMTS13 level and disappearance of anti-ADAMTS13 antibodies (if present). Relapses occur in a minority of patients after successful treatment, usually after intervals of 6 months to 4 years, and most such patients respond to retreatment.

Acute reactions to rituximab are controlled by premedication with glucocorticoids, antihistamines, and analgesics. Because rituximab is removed by plasma exchange, it should be administered immediately after plasma exchange to maximize the interval until the next plasma exchange.

Rituximab has been given together with plasma exchange at the time of initial diagnosis, which may shorten the time to treatment response and reduce the incidence of relapse.^{55,69,70} Rituximab also has been administered preemptively to patients with persistent or recurrent severe ADAMTS13 deficiency after achieving remission of TTP, and this approach may prevent subsequent relapses.^{70,71}

In some settings, rare but serious complications associated with rituximab have included bronchospasm, hypotension, serum sickness, susceptibility to infections, and progressive multifocal leukoencephalopathy.⁷² Such events have been very rare for patients with autoimmune diseases like TTP.^{73,74}

Patients who have not been vaccinated for hepatitis B should be screened for hepatitis B infection before receiving rituximab. Those with evidence of past infection should be considered for antiviral prophylaxis as well as monitoring for hepatic injury and viral reactivation for 6 to 12 months after treatment.⁷⁴

Splenectomy

Splenectomy can result in lasting remissions or reduce the frequency of relapses for some patients with TTP that is refractory to plasma exchange or immunosuppressive therapy, presumably by removing a major site of anti-ADAMTS13 antibody production.^{75,76} Laparoscopic splenectomy can be performed safely in most patients regardless of platelet count.⁷⁷

Other Treatments

Anecdotal experience suggests that vincristine may be beneficial for refractory TTP, although its efficacy is difficult to assess. Dosing

schedules have included 2 mg intravenously on day 1 followed by 1 mg on days 4 and 7,⁷⁸ or 2 mg intravenously per week for 2 to 14 weeks.⁷⁹ Prostacyclin analogues^{80,81} or high-dose intravenous immunoglobulins^{82,83} have been used without convincing evidence of efficacy.

Although cyclosporine can cause secondary thrombotic microangiopathy, apparent responses, with normalization of ADAMTS13 activity, have been observed with cyclosporine 2 to 3 mg/kg daily in two divided doses as an adjunct to plasma exchange.⁸⁴

Other treatments have included oral or intravenous cyclophosphamide, oral azathioprine,⁵⁵ bortezomib,⁸⁵ mycophenolate,⁸⁶ *N*-acetylcysteine,⁸⁷ combination chemotherapy with cyclophosphamide, doxorubicin, vincristine, and prednisone,⁸⁸ and autologous stem cell transplantation.⁸⁹ Agents that prevent the binding of VWF to platelets are under development and may prove useful for the treatment of TTP.^{90,91}

Supportive Therapy

Daily laboratory monitoring should include complete blood count with platelet count, LDH, electrolytes, blood urea nitrogen and creatinine. Because of the high incidence of cardiac damage,²⁹ continuous electrocardiographic monitoring and periodic assessment of cardiac enzymes should be considered. Patients should receive supplemental folic acid and vaccination for hepatitis B.⁵⁵ Allergic reactions, metabolic alkalosis, and hypocalcemia associated with plasma exchange should be prevented or treated by appropriate adjustments in therapy.

After the platelet count increases to above $50 \times 10^9/L$, prophylaxis for venous thromboembolism may be instituted with low-molecular-weight heparin⁶¹ and low-dose aspirin.⁵⁵

COURSE AND PROGNOSIS

The platelet count normalizes after a median of 11 plasma exchanges, with a wide range of four to 55 sessions.⁹² Normalization of serum LDH lags behind the platelet count by approximately 9 days and persistent elevation of LDH does not correlate with the risk of exacerbation or relapse.⁹³

Exacerbations are defined as TTP recurring within 30 days after a treatment response and 25 to 50 percent of patients have an acute exacerbation within 2 weeks that requires further treatment with plasma exchange. Some have repeated exacerbations over several months.⁹⁴ A durable treatment response, lasting more than 30 days, is achieved eventually in approximately 80 percent of patients.⁹²

Relapses, defined as recurrences more than 30 days after a complete response, occur in up to one-third of patients within 2 years after treatment with plasma exchange and glucocorticoids alone. Most relapses occur during the first year, but have occurred 13 years or more after diagnosis.^{26,94} Evaluation for relapsing TTP should be considered for any symptom compatible with thrombotic microangiopathy, especially in association with a common trigger of relapse such as infection, surgery, or pregnancy.^{34,95} Relapsing patients typically respond to plasma exchange. Relapses in TTP are associated with severe ADAMTS13 deficiency and detectable ADAMTS13 autoantibody inhibitors. Conversely, patients without severe ADAMTS13 deficiency at diagnosis rarely relapse (approximately 9 percent across several studies) (reviewed in Ref. 96).

Serious catheter-related complications of plasma exchange therapy occur in approximately 26 percent of patients with TTP and include pneumothorax and hemorrhage, cardiac perforation, venous thrombosis, catheter thrombosis, and bacterial or fungal infections.⁹⁷

Hives or pruritic reactions to fresh-frozen plasma occur in one- to two-thirds of patients but usually can be managed by premedication with antihistamines. High-volume plasma exchange causes metabolic

alkalosis and hypocalcemia, and may cause unintentional platelet removal. Serious complications attributable to plasma are less common, occurring in approximately 4 percent of patients, and include bronchospasm, anaphylaxis, hypotension, hypoxia, and serum sickness.⁹⁷

The mortality rate for TTP treated with plasma exchange ranges from 10 to 20 percent. Most deaths occur within a few days after presentation, and almost all occur within the first month.^{7,8,26,94}

Late sequelae of TTP may include long-term deficits in quality of life and cognition in many patients,^{98,99} severe persistent neurologic deficits in 5 to 13 percent,¹⁰⁰ chronic renal insufficiency in up to 25 percent,¹⁰⁰ and dialysis dependent renal failure in 3 to 8 percent of patients.^{100,101}

● CONGENITAL THROMBOTIC THROMBOCYTOPENIC PURPURA

DEFINITION AND HISTORY

Congenital TTP, or Upshaw-Schulman syndrome, refers to TTP that is caused by inherited deficiency of ADAMTS13.

Schulman and colleagues¹⁰² and Upshaw¹⁰³ first described a congenital disorder resembling TTP characterized by autosomal recessive inheritance and chronic relapsing thrombotic microangiopathy from infancy. Congenital TTP, or Upshaw-Schulman syndrome, shared many features with acquired TTP in adults, including the consistent response to plasma.¹⁰³

ETIOLOGY AND PATHOGENESIS

Congenital TTP is caused by homozygosity or compound heterozygosity for inactivating mutations in the *ADAMTS13* gene¹⁹ on chromosome 9q34 (reviewed in Ref. 104). The mutations usually impair the synthesis or secretion of ADAMTS13. As yet no evidence convincingly indicates locus heterogeneity in congenital TTP.

EPIDEMIOLOGY

Congenital TTP is autosomal recessive and affects the genders almost equally.¹⁰⁵ The prevalence of congenital TTP is approximately one per million population in Japan¹⁰⁶ and appears to be similar elsewhere. Congenital TTP accounts for a few percent of patients presenting with TTP.

CLINICAL FEATURES

The clinical features of congenital TTP are similar to those of acquired TTP, except for age of onset. Most children with congenital ADAMTS13 deficiency have neonatal jaundice and hemolysis but no evidence of ABO blood group or Rh incompatibility. Approximately half of the children continue to have a chronic relapsing course from infancy. The remaining children usually develop symptoms in their late teens or early twenties. In either case, acute exacerbations often are triggered by infections, otitis media, surgery, or other inflammatory stress.^{105,107} Patients may suffer an acute attack after receiving desmopressin (DDAVP), which stimulates the release of VWF from endothelial cell stores; one such patient was receiving a low dose of intranasal DDAVP for enuresis.¹⁰⁸ As in acquired TTP, most patients with congenital TTP have some renal involvement with proteinuria, hematuria, or a mildly elevated serum creatinine during acute attacks. Chronic renal failure can occur, usually after a prolonged course of relapsing disease.¹⁰⁷

Females often present during their first pregnancy, possibly because VWF levels are increased late in pregnancy. If untreated, pregnancies usually end in spontaneous abortion, stillbirth or premature delivery.

TTP usually occurs in the third trimester or postpartum, whereas fetal loss is most common in the second trimester.¹⁰⁹

LABORATORY FEATURES

Severe congenital ADAMTS13 deficiency (<5 percent) is characteristic of congenital TTP. Alloantibodies to ADAMTS13 as a consequence of treatment with plasma are extremely rare in congenital TTP; only one such patient has been reported.¹¹⁰ Other laboratory findings in congenital TTP are similar to those in acquired TTP. The histologic features of congenital TTP are similar to those of acquired TTP.¹¹¹

DIFFERENTIAL DIAGNOSIS

For patients presenting during early childhood, other causes of thrombotic microangiopathy to consider include STEC-HUS, atypical HUS and secondary thrombotic microangiopathy associated with disorders that are characteristic of childhood. For adolescents and adults, the differential diagnosis is the same as for acquired TTP (see Table 132-1).

Testing of stool and urine for STEC should be considered for all patients with thrombotic microangiopathy because a significant fraction of patients with STEC infection never have bloody diarrhea.

THERAPY

Congenital TTP can be treated with periodic infusions of fresh-frozen plasma or an equivalent virucidally treated product, if available. The half-life of ADAMTS13 is 2 to 3 days¹¹² and the level of ADAMTS13 required to avoid symptoms is approximately 5 percent of normal; 5 to 20 mL/kg of plasma every 2 to 3 weeks usually is sufficient to maintain ADAMTS13 at a greater than 5 percent level and prevent symptoms.^{105,107} Patients with severe allergic reactions to plasma have been treated successfully with plasma-derived factor VIII/VWF concentrates that contain significant amounts of ADAMTS13.⁵⁵

Pregnancy Management

Fetal loss and premature birth can be prevented by plasma infusions 10 mL/kg every 2 weeks beginning at 8 weeks of gestation, increasing to weekly in the second trimester. Any sign of thrombotic microangiopathy is an indication to increase the volume or frequency of plasma infusion. Plasma exchange may be necessary to avoid fluid overload.^{55,109}

COURSE AND PROGNOSIS

The severity of congenital TTP varies considerably and correlates to some extent with the underlying genotype and residual plasma ADAMTS13 activity. Patients with ADAMTS13 activity of less than 2.5 percent of normal tend to have their first TTP episode in childhood, have more than one episode of TTP per year, and require regular plasma prophylaxis. Conversely, patients with ADAMTS13 activity of 2.5 to 6.0 percent tend to present in adulthood and have infrequent episodes of disease.^{113,114} Some of these patients have prolonged symptom-free intervals and can be treated on demand. However, inadequately treated patients are at risk for developing chronic renal failure and stroke.⁵⁵

● SHIGA TOXIN ESCHERICHIA COLI-ASSOCIATED HEMOLYTIC UREMIC SYNDROME

DEFINITION AND HISTORY

HUS refers to thrombotic microangiopathy that mainly affects the kidney and usually causes oliguric or anuric renal failure. Ingestion of

STEC causes HUS (STEC-HUS) that is usually associated with a prodrome of diarrhea. Other names in the literature for STEC-HUS include diarrhea-associated HUS (D+HUS) and “typical” HUS.

In 1955, the term *HUS* was proposed for thrombotic microangiopathy occurring in children and associated with acute anuric renal failure, which is uncommon in TTP.¹¹⁵ HUS was often preceded by a diarrheal illness and, unlike TTP in adults, the prognosis was relatively favorable. Most patients survived and recovered normal renal function with only supportive care.¹¹⁶ Although cases were known to cluster in endemic areas, the cause of HUS was unknown until 1983, when *E. coli* O157:H7 was shown to express a *Shiga*-like toxin and cause epidemic hemorrhagic colitis that could evolve into HUS.¹¹⁷⁻¹¹⁹

ETIOLOGY AND PATHOGENESIS

STEC may make two types of *Shiga* toxin (Stx) that are similar in structure and function to ricin. Stx1 is identical to *Shigella dysenteriae* serotype 1 toxin. Stx2 is approximately 50 percent identical in sequence to Stx1 and occurs in several closely related forms. Both toxins consist of pentameric B subunits that bind globotriaosylceramide (Gb3) on cell surfaces and a single A subunit that is responsible for cytotoxicity. Pathogenic *E. coli* almost always express a variant of Stx2 and approximately two-thirds express Stx1.¹²⁰

When STEC colonize the gut they damage the epithelium and secrete Stx that is delivered to target organs through the blood, probably by neutrophils. Stx bound to Gb3 on cell surfaces is endocytosed and transported in a retrograde fashion through the secretory pathway to the endoplasmic reticulum, where the A subunit is translocated into the cytoplasm. The A subunit is an *N*-glycosidase that removes a specific base from the large ribosomal subunit, which inhibits protein synthesis and activates a response pathway that leads to apoptosis. The observed predilection for renal injury is a result of the relatively high expression of Gb3 on renal tubular epithelial, mesangial, and glomerular endothelial cells.

EPIDEMIOLOGY

STEC-HUS can occur at any age but affects mainly children younger than age 5 years and is rare before age 6 months. The disease occurs sporadically and in epidemics, associated with ingestion of foods or other materials contaminated with Stx-producing bacteria. *E. coli* O157:H7 accounts for at least 80 percent of cases in many series, but STEC-HUS can be caused by other toxin-bearing *E. coli* serotypes^{121,122} or by *S. dysenteriae* type 1. Most cases occur in summer and autumn in rural environments. The incidence is approximately 10 to 30 per million children per year, but depends on the risk of exposure, which varies considerably with the time of year, location, and other factors. STEC-HUS is a common cause of chronic renal failure in children.¹²⁰

CLINICAL FEATURES

Patients develop abdominal pain, tenderness and diarrhea between 2 and 12 days after ingesting STEC, with a mean incubation period of 3 to 7 days and a median of 3 days. The diarrhea usually becomes bloody within 1 to 3 days, at which time patients are typically afebrile. Nausea and vomiting are common. The abdominal pain is greater than is typical for other causes of gastroenteritis, and defecation is often painful. Most patients recover spontaneously within a few days. Of children younger than 10 years of age with bloody diarrhea and *E. coli* O157:H7 infection, approximately 15 percent will develop STEC-HUS with the acute onset of microangiopathic hemolytic anemia, thrombocytopenia, and renal injury an average of 7 days (range: 5 to 13 days) after the start of diarrhea.¹²⁰

LABORATORY FEATURES

Aside from signs of dehydration or electrolyte imbalances from diarrhea or vomiting, laboratory testing may be unremarkable before bloody diarrhea develops. Thrombocytopenia and hemolysis with associated laboratory abnormalities develop after bloody diarrhea and usually before renal failure. The platelet count falls to an average of $40 \times 10^9/L$. Renal signs may include a rising creatinine, proteinuria, hematuria, hypertension, and oliguria or anuria. Usually the PT and aPTT are normal or minimally prolonged, plasma fibrinogen is normal or elevated, and fibrin degradation products may be moderately elevated.^{120,123} ADAMTS13 levels are normal.^{124,125}

Stool should be cultured on selective media for *E. coli* O157:H7 and tested for Stxs to detect non-O157 strains. STEC in the stool are found in at least 90 percent of patients during the first 6 days but in less than 30 percent of patients at later times. Fecal leukocytes are not always present and generally are not abundant.¹²⁰

Serologic testing for antibodies to STEC surface antigens at diagnosis and after 2 weeks can facilitate the diagnosis of STEC-HUS if stool cultures are not informative. Titers rise after infection and persist for 8 to 12 weeks.

STEC-HUS mainly affects the renal cortex, which often shows extensive necrosis. Lesions occur less frequently in the pancreas, brain, adrenal glands, and myocardium. The thrombi of HUS typically involve glomerular capillaries and arterioles and are composed mainly of fibrin and red cells with few platelets.^{47,126}

DIFFERENTIAL DIAGNOSIS

Unlike STEC-HUS, bloody diarrhea caused by *Salmonella*, *Shigella*, or *Clostridium difficile* is likely to be accompanied by fever and prostration. Coinfection with STEC and *C. difficile* can occur. Otherwise the differential diagnosis of apparent STEC-HUS includes unusual presentations of other causes of thrombotic microangiopathy (see Table 132-1).

THERAPY

Patients with acute bloody diarrhea should be admitted to the hospital for diagnosis and management of presumed STEC infection as well as infection control. Early intravenous hydration to maintain renal perfusion protects against the development of HUS.¹²⁰ Most patients require red cell transfusions. Daily monitoring of hemoglobin, platelet count, electrolytes, blood urea nitrogen (BUN), and creatinine is important.

The risks and benefits of antibiotic use in STEC-HUS may depend on the stage of illness. Antibiotics should not be used early in the course of acute diarrheal illness caused by *E. coli* O157:H7 because antibiotics increase the risk of HUS.¹²⁷ However, retrospective analysis of a 2011 outbreak of *E. coli* O104:H4 infection suggests that treatment with multiple antibiotics after the development of HUS may have reduced the incidence of seizures and death.¹²⁸

Antimotility agents and narcotics increase the risk of HUS and neurologic complications. Nonsteroidal antiinflammatory drugs and antihypertensives that reduce renal perfusion such as angiotensin-converting enzyme inhibitors and angiotensin receptor blockers should be avoided. No convincing data indicate that antiplatelet agents, anticoagulants, plasma exchange, glucocorticoids, rituximab, or an inhibitor of the terminal components of complement, eculizumab, add benefit to supportive therapy and dialysis, for children or adults.^{58,120,128}

COURSE AND PROGNOSIS

Patients often have a degree of diffuse vascular injury and may become edematous with intravenous hydration. Consequently more sodium

than expected may be required for adequate volume replacement, and monitoring for fluid overload and hypertension is essential. A rising platelet count signals the end of the period of risk for developing HUS. For patients with HUS, hemolysis can persist as the HUS resolves and require additional red cell transfusions.

Extrarenal involvement is common, although the incidence of specific complications varies widely. Depending on the outbreak, central nervous system involvement (seizures, coma, or stroke) occurs in 10 to 65 percent of cases and is more common in older patients. Cardiac dysfunction is associated with ischemia or congestive heart failure. Patients may require mechanical ventilation for seizures, coma, pulmonary edema, or pneumonia. Gastrointestinal involvement can include hemorrhagic colitis, necrosis, perforation, peritonitis, pancreatitis, diabetes mellitus, and rectal prolapse.^{120,128,129}

The incidence of death and end-stage renal failure also varies widely, but correlates with the need for initial dialysis and central nervous system involvement. In a meta-analysis of more than 3400 patients with STEC-HUS, an average of 9 percent died and 3 percent developed permanent end-stage renal failure 1 or more years later. Another 25 percent had persistent hypertension, proteinuria, or chronic renal insufficiency.¹³⁰

Inability to detect STEC may not strongly affect the clinical course. In a study of 268 patients with HUS, 59 percent had prodromal diarrhea plus bacteriologic or serologic evidence of infection by STEC; 21 percent had only diarrhea, and 10 percent had only positive bacteriologic or serologic studies. All three groups had similar outcomes: approximately 1 percent died and 73 percent recovered normal renal function. In contrast, the 11 percent of patients with neither diarrhea nor documented STEC infection had a significantly worse outcome; 10 percent died and only 34 percent recovered normal renal function.¹²¹ Most of these latter patients probably had “atypical hemolytic uremic syndrome (aHUS),” which has a distinct cause and prognosis.

● ATYPICAL HEMOLYTIC UREMIC SYNDROME

DEFINITION AND HISTORY

Diarrhea-negative or *aHUS* is not associated with diarrhea or Stx-producing organisms and occurs in patients without an obvious predisposing condition.

Reporting on patients seen in southern Africa in 1965, Barnard and Kibel first distinguished typical diarrhea-associated HUS from “atypical” patients who did not have diarrhea.¹³¹ In the 1970s, Kaplan proposed that recurrent familial cases of HUS represented a distinct genetic illness.^{132,133} By 1993, aHUS was an accepted diagnosis of uncertain cause,¹³⁴ although increased consumption of complement C3 and deficiency of factor H had been described in some patients.¹³⁵ In 1998, Warwicker and colleagues showed that mutations in complement factor H (CFH) caused familial HUS,¹³⁶ and mutations in other proteins of the alternative complement pathway quickly followed. These results provided a rationale for treating aHUS with inhibitors of complement activation, which has proved very effective.¹³⁷

ETIOLOGY AND PATHOGENESIS

The alternative complement pathway drives the pathogenesis of aHUS. Complement component C3 is spontaneously converted to C3b at a low rate and deposited on cell surfaces. Under normal circumstances this C3b is promptly cleaved and inactivated by the serine protease factor I, and this reaction is accelerated by factor H or membrane

TABLE 132–2. Complement Defects in Atypical Hemolytic Uremic Syndrome

Gene or Subgroup	Prevalence in aHUS	Low C3	Progression to End-Stage Renal Disease	Death
<i>CFH</i>	25–30%	50–60%	50–60%	5–20%
<i>CFI</i>	4–10%	20–50%	~60%	0–10%
<i>MCP</i>	7–10%	6–30%	6–35%	0%
<i>CFB</i>	<1.5%	≤100%	~50%	0%
<i>C3</i>	4–8%	70–80%	55–70%	0%
<i>THBD</i> (TM)*	<5%	~50%	~50%	~30%
Anti-complement factor H antibody	3–7%	~40%	30–60%	0%
No mutation	30–50%	~20%	~40%	3–7%

Based on outcomes after 5 years from the International Registry of Recurrent and Familial HUS/TTP¹³⁸ and after 3 years from the French Study Group for aHUS.¹³⁹

**THBD* is the gene for thrombomodulin.

cofactor protein (MCP, CD46). These cofactors are structurally and functionally similar, but factor H is a plasma protein whereas MCP is a transmembrane protein found on the surface of almost all cells. If not restrained by these inhibitors, C3b interacts with factor B to form a potent C3 convertase that amplifies the deposition of C3b, which attracts phagocytes and promotes membrane attack complex formation on renal glomerular and arteriolar endothelium and basement membrane. The resultant vascular damage causes thrombotic microangiopathy.

Heterozygous mutations in alternative complement pathway proteins have been identified in 60 to 70 percent of patients with aHUS (Table 132–2). These include loss-of-function mutations in factor H, MCP, factor I, complement factor H-related proteins 1 and 3 (CFHR1, CFHR3), and thrombomodulin (TM); and gain-of-function mutations in factor B and C3. In addition, autoantibodies to factor H have been identified in some patients with aHUS, often in association with mutations in CFHR1 and CFHR3. Patients sometimes have mutations at more than one locus, or a combination of autoantibodies to CFH and mutations.^{138,139}

Homozygous or compound heterozygous mutations in diacylglycerol kinase ϵ (DGKE) cause aHUS with high penetrance that presents before 1 year of age with hypertension, hematuria, and proteinuria. How DGKE mutations cause aHUS is not established. DGKE mutations may account for a few percent of aHUS.¹⁴⁰

EPIDEMIOLOGY

Atypical HUS affects approximately 5 percent as many children as develop STEC-HUS, with an estimated incidence of two per million population per year.¹⁴¹ Approximately one-half of patients are younger than age 18 years. Approximately 60 percent of affected children have their first episode of aHUS before age 2 years, and 25 percent before age 6 months. In contrast, STEC-HUS is rare before age 6 months. Most adults have their first episode of aHUS between ages 20 and 40 years. Childhood aHUS affects males and females equally, whereas onset in adults disproportionately affects females mainly because of disease triggered by pregnancy. Analysis of relatives of probands shows that the penetrance

of aHUS may be approximately 50 percent for mutations in any of the predisposing genes.^{138,139}

CLINICAL FEATURES

Approximately 20 percent of patients have a subacute or chronic course of mild anemia, variable thrombocytopenia and relatively normal renal function. However, patients usually present acutely with thrombotic microangiopathy and renal failure, sometimes with progressive hypertension. Most patients report a possible triggering event such as a viral or bacterial upper respiratory infection, gastroenteritis, or pregnancy. aHUS is not classically preceded by bloody or painful diarrhea.^{138,139}

Women with pregnancy-associated aHUS usually present postpartum. Most of the rest develop symptoms in the third trimester, sometimes complicated by fetal loss and preeclampsia.¹⁴²

Extrarenal symptoms occur in 10 to 20 percent of patients. Central nervous system involvement is most common. Myocardial infarction, pancreatitis, and necrosis of skin or digits have been reported. Extrarenal involvement is relatively uncommon for aHUS caused by MCP mutations.^{138,139}

LABORATORY FEATURES

Patients have the laboratory findings characteristic of microangiopathic hemolysis, as observed for TTP and STEC-HUS. The mean platelet count in aHUS is $40 \times 10^9/L$, typically higher than in TTP. Serum creatinine can be markedly elevated, with microhematuria and proteinuria if the patient is not anuric.

Complement C4 is usually normal and C3 may be low, consistent with activation of the alternative complement pathway, but the likelihood of a low C3 level varies considerably and depends on the involved locus (see Table 132–2). Approximately 3 to 7 percent of patients have autoantibodies against CFH that can be detected by ELISA. In favorable cases, flow cytometry on peripheral blood leukocytes can identify cell-surface MCP deficiency for patients with *MCP* mutations. Assays of CFH and CFI may be useful to identify specific deficiencies, but patients are usually heterozygous and mutations at these loci may not clearly decrease the factor levels.^{138,139}

DNA sequencing should be considered to detect mutations in *CFH*, *CFI*, *MCP*, *C3*, *CFB* and *TM* before renal transplantation because the risk of relapse and need for subsequent prophylaxis depends on the affected locus. Candidate mutations in one of these loci or antibodies to CFH can be found in approximately 70 percent of patients with aHUS. Sequencing of *DGKE* should be considered for patients presenting before age 1 year.

As in STEC-HUS, renal lesions in aHUS are rich in fibrin but poor in platelets or VWF.

DIFFERENTIAL DIAGNOSIS

Signs and symptoms consistent with aHUS may occur in TTP or STEC-HUS, and distinguishing among these entities is important because they are treated differently. Correct diagnosis is not always straightforward. For example, MCP mutations may cause thrombotic microangiopathy without renal insufficiency that resolves coincidentally during a course of plasma exchange and therefore resembles TTP except for normal ADAMTS13 activity.¹⁴³ Infection with STEC may be difficult to document, and some patients with STEC-HUS do not have a diarrheal prodrome.¹²¹

Secondary causes of thrombotic microangiopathy should be considered (see Table 132–1). For children, conditions that usually present in that age group deserve special attention such as *Streptococcus pneumoniae* infections and inherited cobalamin defects.

THERAPY

Plasma Exchange

For patients without a previous diagnosis of aHUS, plasma exchange should be started at 1 to 2 volumes daily for adults or 50 to 100 mL/kg for children.¹⁴¹ Plasma exchange can induce responses at least transiently for patients with deficiency of plasma complement proteins or autoantibodies to CFH but not for deficiency of the membrane protein MCP. If an isolated MCP mutation is identified, plasma exchange can be stopped.

Eculizumab

After excluding severe ADAMTS13 deficiency, STEC and secondary causes of thrombotic microangiopathy, plasma exchange can be stopped and eculizumab started for presumptive aHUS at 900 mg intravenously every week for 4 weeks, followed by 1200 mg in week 5 and every other week thereafter, in many cases indefinitely. For patients younger than 18 years of age, doses are adjusted based on body weight. Supplementary doses are recommended during plasma exchange or infusion,¹³⁷ but concurrent plasma exchange and eculizumab is not beneficial and should be avoided.

Adverse reactions to eculizumab during the treatment of aHUS have included infections, fever, hypertension, headache, diarrhea, abdominal pain, nausea, and vomiting. Adverse reactions are common but seldom require discontinuation of therapy.

Ideally, patients should be vaccinated against *Neisseria meningitidis* at least 2 weeks before treatment. If timely vaccination is not possible or the available vaccine does not cover prevalent strains, then antibiotic prophylaxis should be considered. Children also should be vaccinated for *S. pneumoniae* and *Haemophilus influenzae* type b.

Rituximab

Rituximab and glucocorticoids can be added to eculizumab for treatment of aHUS caused by autoantibodies to CFH. If the autoantibodies are eradicated, then eculizumab can be discontinued.

Renal Transplantation

Patients with end-stage renal disease that does not improve on eculizumab may be treated by renal transplantation. Living related donors generally are not used because the donated kidney may be at risk for aHUS and the donor may have the same risk factors as the recipient and develop aHUS after donation.

Mutation screening should be performed before transplantation to guide subsequent therapy. Unless patients are treated preemptively with eculizumab, aHUS recurs predictably in transplanted kidneys. Isolated MCP deficiency is an exception because normal membrane-bound MCP in the transplanted kidney protects it from complement attack. HUS has not recurred after renal transplantation in children with DGKE mutations.^{141,144}

Liver transplantation or combined liver-kidney transplantation can cure aHUS caused by deficiency of plasma complement proteins that are synthesized in the liver. However, the risk and complications of liver transplantation can be avoided by prophylactic treatment with eculizumab after renal transplantation.^{141,144}

COURSE AND PROGNOSIS

Treatment of aHUS with just plasma exchange and supportive care is associated with up to 8 percent mortality during the first episode of disease and rapid progression to end stage renal failure in many survivors. Mortality at 1 year appears substantially higher for children but progression to end-stage renal failure is more common for adults. MCP mutations are associated with a less-aggressive clinical course: patients may improve during plasma exchange but have similar outcomes without

plasma exchange, with 90 percent alive and dialysis free after several years (see Table 132–2).^{138,139}

Treatment with eculizumab is associated with sustained resolution of thrombotic microangiopathy, improvement in renal function and prevention of relapses. The platelet count normalizes in approximately 50 percent of patients by day 7 and in 80 to 90 percent of patients by week 26. Earlier initiation of eculizumab is associated with greater improvement in renal function.¹³⁷

Most patients are likely to need lifelong treatment to prevent recurrent thrombotic microangiopathy and progressive renal failure. Some patients with aHUS and no remaining renal function may still benefit from eculizumab to prevent the progression of neurologic or other extrarenal injury. Patients with MCP mutations can have a relatively mild course with normal renal function and long intervals between exacerbations; they may not need chronic prophylaxis with eculizumab.^{138,139}

DGKE mutations are associated with the development of nephrotic syndrome,¹⁴⁰ which is otherwise uncommon in aHUS. Case reports suggest that aHUS caused by DGKE mutations is associated with complement activation and can respond to plasma therapy.^{145,146} The efficacy of eculizumab is not known. HUS has not recurred after renal transplantation in children with DGKE mutations.^{140,145,146}

SECONDARY THROMBOTIC MICROANGIOPATHY

Secondary thrombotic microangiopathy occurs in patients with predisposing medical conditions such as metastatic cancer, malignant hypertension, systemic infection, solid-organ or hematopoietic stem cell transplantation, vasculitis, catastrophic APS, radiation exposure, chemotherapy, certain other drugs, inherited or acquired metabolic disorders, and various causes of disseminated intravascular coagulation. Endothelial injury may be a common cause, although the mechanism of disease varies and in most cases is not understood.

The clinical features of secondary thrombotic microangiopathy usually are dominated by the predisposing illness, and the most important clinical intervention is correcting the underlying “primary” condition. The clinical history and laboratory testing can identify most causes of secondary thrombotic microangiopathy. Severe ADAMTS13 deficiency almost never occurs in secondary thrombotic microangiopathy, and treatment with plasma exchange, rituximab, or eculizumab is not known to be beneficial.

DISSEMINATED INTRAVASCULAR COAGULATION

Conditions resulting in disseminated intravascular coagulation sometimes cause microangiopathic changes and thrombocytopenia with little change in blood coagulation tests, which can suggest a diagnosis of TTP.

INFECTIONS

Infections may trigger disease in patients with severe ADAMTS13 deficiency, but infections typically cause secondary thrombotic microangiopathy by other mechanisms. Secondary thrombotic microangiopathy caused by infections may respond to antimicrobial or antiviral therapy, but not to plasma exchange.

Thrombotic microangiopathy, often with acute renal failure, is a rare complication of invasive infections with *S. pneumoniae* in children. A surveillance study in Atlanta, Georgia, identified HUS in 0.6 percent of pneumococcal infections in children younger than 2 years of

age.¹⁴⁷ Patients usually have complicated pneumococcal pneumonia or meningitis, with normal plasma fibrinogen and normal or minimally prolonged PT and aPTT. The pathophysiology is thought to involve bacterial neuraminidase, made by *S. pneumoniae* and some other organisms, which removes sialic acid residues from cell surface glycoproteins and exposes Thomsen-Friedenreich antigen (T antigen). T antigen is recognized by naturally occurring antibodies that fix complement, causing hemolysis and damaging the renal microvasculature. Because donor blood usually contains high levels of antibodies against T antigen, red cells and platelets should be washed before transfusion, and plasma should not be used as a replacement fluid. Exchange transfusion has been proposed to stop hemolysis by replacing T-antigen-bearing red blood cells and removing circulating neuraminidase, but the efficacy of this treatment is uncertain.¹⁴⁸

TISSUE TRANSPLANTS

Recipients of solid-organ transplants can develop thrombotic microangiopathy, often dominated by renal involvement associated with immunosuppression by cyclosporine or tacrolimus.¹⁴⁹ These drugs appear to damage renal endothelial cells directly and can cause neurotoxicity, adding another feature suggestive of TTP. Similarly, hematopoietic stem cell transplant recipients may develop thrombotic microangiopathy associated with high-dose chemotherapy or radiation, immunosuppressive drugs, graft-versus-host disease, or infections. ADAMTS13 levels are normal¹⁵⁰ and plasma therapy is ineffective.¹⁵¹

CANCER

Thrombotic microangiopathy occurs in a small fraction of patients with cancer, most commonly with adenocarcinoma of the pancreas, lung, prostate, stomach, colon, ovary, breast, or unknown primary site that usually is widely metastatic. These cancers also are associated with Trousseau syndrome or paraneoplastic hypercoagulability and thrombosis. Patients often have variable prolongation of the PT and aPTT and increased fibrin degradation products. The thrombosis of Trousseau syndrome may respond to anticoagulation with heparin but not warfarin.^{152,153} Abundant schistocytes also have been described in acute erythroleukemia.¹⁵⁴ Plasma exchange is ineffective.^{26,27,153}

PREGNANCY-ASSOCIATED THROMBOTIC MICROANGIOPATHY

The differential diagnosis of thrombotic microangiopathy in pregnancy includes preeclampsia, eclampsia, HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count), acute fatty liver of pregnancy, abruptio placenta, amniotic fluid embolism, and retained products of conception (Chap. 129). Severe ADAMTS13 deficiency has not been observed in these conditions.¹⁵⁵ Pregnancy also can trigger disease in patients with congenital or acquired ADAMTS13 deficiency or defects in the alternative complement pathway.

AUTOIMMUNE DISORDERS

Autoimmune thrombocytopenia may be confused with TTP if other causes of microangiopathic hemolytic anemia are present. Asymptomatic thrombocytopenia also may sometimes be the only finding in TTP. Patients have been described in whom TTP and autoimmune thrombocytopenia appeared to occur simultaneously or sequentially.¹⁵⁶ Evan syndrome (autoimmune hemolytic anemia with autoimmune thrombocytopenia) usually can be distinguished from TTP by a positive Coombs test and the prominence of spherocytes relative to schistocytes in the

blood film. Heparin-induced thrombocytopenia (HIT) may sometimes resemble TTP (Chap. 118).

SLE can cause autoimmune hemolysis and thrombocytopenia, and lupus vasculitis can cause microangiopathic changes, renal insufficiency, and neurologic defects consistent with TTP. Vasculitis associated with other autoimmune disorders can pose a similar diagnostic problem. Although ADAMTS13 deficiency is uncommon among patients with SLE,¹⁵⁷ in rare cases they develop autoimmune ADAMTS13 deficiency and TTP that responds to plasma exchange.¹⁵⁸ Conversely, patients with TTP and autoantibodies against ADAMTS13 may have other markers of autoimmune disease, including ANA or anti-DNA antibodies, polyarthritis, discoid lupus, or ulcerative colitis.^{101,159}

Thrombotic microangiopathy can develop in patients with APS, with or without concurrent SLE.

Thrombotic microangiopathy occurs in patients with progressive systemic sclerosis, particularly in association with acute scleroderma renal crisis and malignant hypertension. Treatment with angiotensin-converting enzyme inhibitors may be effective.¹⁶⁰

DRUG-INDUCED THROMBOTIC MICROANGIOPATHY

Nearly 80 drugs are associated with thrombotic microangiopathy, and evidence supports a definite or probable causal association for approximately 44 of them. Three drugs (quinine, cyclosporine, tacrolimus) account for 60 percent of the patient reports with definite evidence.¹⁶¹ Some agents cause disease by an immune mechanism and others by direct toxicity; a few drugs reportedly act by either mechanism. With the exception of ticlopidine-induced disease, plasma exchange appears to be ineffective or possibly harmful for drug-induced thrombotic microangiopathy.¹⁶²

Immune Mechanisms

Quinine is the most common cause of drug-induced thrombotic microangiopathy. Most patients are women. Severe thrombotic microangiopathy occurs suddenly within several hours after ingestion of a quinine tablet or a beverage containing it such as tonic water, with fever, abdominal and back pain, nausea, vomiting, diarrhea, rash, and oliguric renal failure. Neurologic changes are common.¹⁶³ ADAMTS13 levels are normal.¹⁶⁴ The mechanism involves a broad range of quinine-dependent antibodies against platelets, endothelium, and other cells. Most patients recover with normal renal function over several weeks, although some develop end stage renal disease.

The antiplatelet drug ticlopidine is unusual because it induces autoantibody inhibitors of ADAMTS13, effectively causing TTP that responds to plasma exchange.¹⁶⁵ The related thienopyridine drugs clopidogrel, prasugrel and ticagrelor do not appear to cause thrombotic microangiopathy by this mechanism.

Direct Toxicity

Cyclosporine and tacrolimus are structurally distinct immunosuppressive drugs that indirectly inhibit calcineurin and suppress T-cell activation. Both agents cause dose-dependent nephrotoxicity, neurotoxicity, and thrombotic microangiopathy.^{166–168} The renal damage is thought to involve toxic effects on endothelium.¹⁶⁶ Thrombotic microangiopathy can develop during the first few weeks of treatment, although graft rejection, graft-versus-host disease, or systemic infections can cause similar microangiopathic changes. The thrombotic microangiopathy often remits with dose reduction or substitution of other immunosuppressive drugs and may not recur if therapy with cyclosporine or tacrolimus is reinstated.

Mitomycin C is an alkylating agent that is used for anal carcinoma and for some adenocarcinomas. It appears to cause dose-dependent

nephrotoxicity, with renal failure occurring in approximately 16 percent of patients who receive a cumulative dose of at least 50 mg.¹⁶⁹ About half of the patients with renal toxicity also develop thrombotic microangiopathy, usually 4 to 8 weeks after the latest dose. Mitomycin C-induced thrombotic microangiopathy does not respond to plasma exchange and has a high mortality rate of approximately 70 percent within 4 months of onset.¹⁷⁰

Gemcitabine is a nucleoside analogue often used for carcinoma of the pancreas, bladder, or lung. Thrombotic microangiopathy with renal failure occurs with an incidence of approximately 0.3 percent.¹⁷¹ The median time to develop thrombotic microangiopathy is 7 months with a median cumulative dose of 22 g/m², although the range of doses is broad and very low doses have been associated with thrombotic microangiopathy.¹⁷² Death or disability usually results from cancer progression or renal failure, not from extrarenal manifestations of thrombotic microangiopathy.

Drugs that inhibit vascular endothelial growth factor (VEGF) signaling like sunitinib and bevacizumab are associated with proteinuria, hypertension, and mild thrombotic microangiopathy that usually improve when the drug is discontinued. Inhibition of VEGF produced within the kidney appears to damage glomerular endothelium.¹⁷³ In some cases disease has responded to an angiotensin receptor blocker, allowing continued treatment with the VEGF inhibitor.¹⁷⁴

COBALAMIN METABOLIC DEFECTS

Cobalamin C deficiency is a rare autosomal recessive condition caused by mutations in the *MMACHC* (methylmalonic aciduria and homocystinuria type C protein) gene. Clinical features may include developmental delay, ataxia, seizures, cognitive impairment, pulmonary hypertension, thrombotic microangiopathy and renal failure. Symptoms usually appear during infancy but can occur later in childhood or rarely in adulthood. Laboratory studies show elevated plasma methylmalonic acid and homocysteine, low plasma methionine, and normal or elevated plasma vitamin B₁₂. Treatment with high-dose hydroxycobalamin and betaine may reverse or prevent HUS.¹⁷⁵

The abnormal red cell and platelet morphology in adults with severe vitamin B₁₂ deficiency rarely may suggest thrombotic microangiopathy.

MALIGNANT HYPERTENSION

Malignant hypertension is associated with microangiopathic hemolytic anemia, thrombocytopenia, neurological symptoms and renal insufficiency.¹⁷⁶

MECHANICAL HEMOLYSIS

A malfunctioning aortic or mitral valve prosthesis may sufficiently increase the fluid shear stress experienced by the blood to cause significant hemolysis, with schistocytes and thrombocytopenia, suggesting a diagnosis of thrombotic microangiopathy.^{41,42} Such patients also are likely to have acquired von Willebrand syndrome.

CHAPTER 133

VENOUS THROMBOSIS

Gary E. Raskob, Russell D. Hull, and Harry R. Buller

SUMMARY

Venous thromboembolism, consisting of deep vein thrombosis and/or pulmonary embolism, is a common disorder with an estimated 900,000 patients each year in the United States and more than 1 million each year in the European Union. Approximately one-third of these cases are fatal pulmonary emboli, and the remaining two-thirds are nonfatal episodes of symptomatic deep vein thrombosis or pulmonary embolism. The majority of fatal events occur as sudden death, underscoring the importance of prevention as the critical strategy for reducing death from pulmonary embolism. Of the nonfatal cases, approximately 60 percent present clinically as deep vein thrombosis and 40 percent present as pulmonary embolism. Most clinically important pulmonary emboli arise from proximal deep vein thrombosis of the leg (popliteal, femoral, or iliac vein thrombosis). Upper-extremity deep vein thrombosis also may lead to clinically important pulmonary embolism. The clinical features of deep vein thrombosis and pulmonary embolism are nonspecific. Objective diagnostic testing is required to confirm or exclude the presence of venous thromboembolism. A validated assay for plasma D-dimer, if available, provides a simple, rapid, and cost-effective first-line exclusion test in patients with low, unlikely, or intermediate clinical probability. Compression ultrasonography is highly sensitive and specific for clinically important deep vein thrombosis and is the primary imaging test for symptomatic patients. Compression ultrasonography of the proximal veins performed at presentation, and if normal, repeated once 5 to 7 days later, can safely exclude clinically important deep vein thrombosis. In centers with the expertise, a single comprehensive evaluation of the proximal and calf veins with duplex ultrasonography is sufficient. In patients with suspected pulmonary embolism, computed tomographic angiography, with or without additional testing using computed tomographic venography or compression ultrasonography of the legs, provides a definitive basis to give or withhold antithrombotic therapy in 90 percent of patients. Anticoagulant therapy is the preferred treatment for most patients with acute venous thromboembolism. Initial treatment with heparin or low-molecular-weight heparin, followed by long-term treatment with an oral vitamin K antagonist such as warfarin, is highly effective for preventing recurrent venous thromboembolism, and has been the traditional standard care. More recently, the direct oral anticoagulants including the thrombin inhibitor dabigatran, and the factor Xa inhibitors rivaroxaban, apixaban, and edoxaban, have been established to be as effective and safer than

traditional standard anticoagulant therapy. Rivaroxaban and apixaban can be used as a single drug approach. Dabigatran and edoxaban are preceded by at least 5 days of heparin or low-molecular-weight heparin treatment. The direct oral anticoagulants are preferred over the vitamin K antagonists in most new patients commencing anticoagulant therapy. In cancer patients with venous thromboembolism, treatment with low-molecular-weight heparin for at least 6 months is the recommended approach. Thrombolytic therapy is indicated for patients with pulmonary embolism who present with hypotension or shock, and in selected patients who have impaired right ventricular function who are at high risk of hemodynamic collapse. Insertion of a vena cava filter is indicated for patients who have an absolute contraindication to anticoagulant therapy or who have recurrent venous thromboembolism despite adequate anticoagulant treatment. Anticoagulant treatment should be continued for at least 3 months in all patients, and 3 months is a sufficient duration for patients with first episode of venous thromboembolism secondary to a reversible risk factor. Indefinite anticoagulant therapy should be considered for patients with unprovoked (idiopathic) venous thromboembolism, and those with recurrent venous thromboembolism.

DEFINITION AND EPIDEMIOLOGY

Venous thrombosis commonly develops in the deep veins of the leg or the arm or in the superficial veins of these extremities. Venous thrombosis of superficial veins is a relatively benign disorder unless extension into the deep venous system occurs. Confusingly, one of the major deep veins in the leg is called the superficial femoral vein. Thrombosis involving the deep veins of the leg is divided into two prognostic categories: (1) calf vein thrombosis, in which thrombi remain confined to the deep calf veins, and (2) proximal vein thrombosis, in which thrombosis involves the popliteal, femoral, or iliac veins.¹

Pulmonary emboli originate from thrombi in the deep veins of the leg in 90 percent or more of patients. Other less common sources of pulmonary embolism (PE) include the deep pelvic veins, renal veins, inferior vena cava, right side of the heart, and axillary veins. Most clinically important pulmonary emboli arise from proximal deep vein thrombosis (DVT) of the leg. Upper-extremity DVT also may lead to important PE.² DVT and/or PE are referred to collectively as *venous thromboembolism (VTE)*.

VTE is a common disorder.³ The estimated annual incidence of clinically evident VTE ranges between 0.75 and 2.7 per 1000 population based on studies done in North America, Western Europe, Australia, and Argentina.³ The literature indicates a strong and consistent association of increasing incidence of VTE with increasing age. The annual incidence increased to between 2 and 7 per 1000 population among those 70 years of age, and to between 3 and 12 per 1000 population among those 80 years of age or older.³ Although the incidence is lower in individuals of Chinese and Korean ethnicity,³ their disease burden is not low because of population aging. The high incidence of VTE in the elderly likely reflects the high prevalence of comorbid acquired risk factors in these patients, especially malignancy, heart failure, and surgery or hospitalization for medical illness, which account for the majority of the population-attributable risk of VTE in older individuals.

VTE causes a major burden of disease across low-, middle-, and high-income countries. VTE associated with hospitalization was the leading cause of premature death and years lived with disability in low- and middle-income countries, and second in high-income countries, and responsible for more premature death and disability than nosocomial pneumonia, catheter-related bloodstream infections, and adverse drug events.³

Acronyms and Abbreviations: aPTT, activated partial thromboplastin time; CDT, catheter-directed thrombolysis; CT, computed tomography; CTA, computed tomographic angiography; CTV, computed tomographic venography; DOAC, direct-acting oral anticoagulant; DVT, deep vein thrombosis; ELISA, enzyme-linked immunosorbent assay; INR, international normalized ratio; LMW, low molecular weight; PE, pulmonary embolism; PIOPED, Prospective Investigation of Pulmonary Embolism Diagnosis; VTE, venous thromboembolism.

The direct ascertainment of deaths from VTE is difficult because of the low rate of autopsy in most countries, and because autopsy studies have consistently demonstrated that PE is often not diagnosed antemortem. The strongest evidence comes from the study by Cohen and colleagues, who used an incidence-based model in six European countries to estimate that there were 534,454 deaths related to VTE across the European Union in 2004.⁴ A similar approach applied to the data from the United States suggested approximately 300,000 deaths from VTE each year.⁵ The majority of deaths from VTE occur as sudden death, underscoring the critical role of prevention for reducing death from VTE.

Effective prophylaxis against VTE is available for most high-risk patients. Use of prophylaxis is more effective for preventing death and morbidity from VTE than is treatment of the established disease. Evidence-based recommendations for prevention are available.⁶⁻⁹ Multifaceted interventions with alerts, such as computerized reminders or stickers on patient charts, are effective for increasing the prescription of appropriate thromboprophylaxis in hospitalized adult medical or surgical patients.¹⁰ There is also evidence that inclusion of VTE risk assessment at the time of hospital admission and the provision of appropriate prophylaxis is effective for reducing VTE-related death and readmission with nonfatal VTE.^{11,12}

Historically, the majority of the disease burden from VTE occurred in hospitalized patients. The burden of illness from VTE has shifted to the community setting such that most patients now present as outpatients to their primary care physician or to the emergency department. The main reason for this shift is the greatly reduced length of hospital stay for most surgical procedures or medical conditions, such that patients are discharged from the hospital either before the period of risk of VTE has ended or who have subclinical venous thrombi that subsequently evolve to symptomatic DVT or PE. The shift in burden of illness from the hospital to the community setting has led to an emphasis on effective and safe methods for outpatient prophylaxis, diagnosis and treatment.

ETIOLOGY AND PATHOGENESIS

Venous thrombi are composed mainly of fibrin and red blood cells, with variable numbers of platelets and leukocytes. The formation, growth, and breakdown of venous thromboemboli reflect a balance between thrombogenic stimuli and protective mechanisms. The thrombogenic stimuli first identified by Virchow in the 19th century are (1) venous stasis, (2) activation of blood coagulation, and (3) vascular damage. The protective mechanisms are (1) inactivation of activated coagulation factors by circulating inhibitors (e.g., antithrombin and activated protein C), (2) clearance of activated coagulation factors and soluble fibrin polymer complexes by mononuclear phagocytes and the liver, and (3) lysis of fibrin by fibrinolytic enzymes derived from plasma and endothelial cells.

PE occurs in at least 50 percent of patients with documented proximal vein thrombosis.¹ Many of these emboli are asymptomatic. The clinical importance of PE depends on the size of the embolus and the patient's cardiorespiratory reserve. Usually only part of the thrombus embolizes, and 30 to 70 percent of patients with PE detected by angiography also have identifiable DVT of the legs.^{13,14} DVT and PE are not separate disorders but a continuous syndrome of VTE in which the initial clinical presentation may be symptoms of either DVT or PE. Therefore, strategies for diagnosis of VTE include both tests for detection of PE (e.g., computed tomography [CT] or lung scanning)¹³⁻¹⁶ and tests for DVT of the legs (e.g., ultrasonography)¹⁷⁻¹⁹ (see "Objective Testing for Pulmonary Embolism" and "Objective Testing for Deep Vein Thrombosis" below).

TABLE 133-1. Risk Factors for Thromboembolism*

Acquired	Hereditary Thrombophilias*
Advancing age (age >40 years)	Activated protein C resistance
History of prior thromboembolic event	Prothrombin G20210A
Recent surgery	Antithrombin deficiency
Recent trauma	Protein C deficiency
Prolonged immobilization	Protein S deficiency
Certain forms of cancer	Dysfibrinogenemia
Congestive heart failure	
Recent myocardial infarction	
Paralysis of legs	
Use of female hormones	
Pregnancy or postpartum period	
Varicose veins	
Obesity	
Antiphospholipid antibody syndrome**	
Hyperhomocysteinemia	

*See also Chap. 130

**See also Chap. 131

Acquired and inherited risk factors for VTE have been identified²⁰⁻²³ and are shown in Table 133-1 (Chap. 130). Aging is the dominant risk factor for VTE (population attributable risk >90 percent).²³ Comorbidities, such as malignancy and heart failure, contribute to a higher population-attributable risk in older patients (≥ 65 years).²³ The risk of VTE increases when more than one risk factor is present.²⁴

Activated protein C resistance is the most common hereditary abnormality predisposing to VTE. The defect results from substitution of glutamine for arginine at residue 506 in the factor V molecule, making factor Va resistant to proteolysis by activated protein C. The gene mutation is commonly designated *factor V Leiden* and follows autosomal dominant inheritance. Patients who are homozygous for the factor V Leiden mutation have a markedly increased risk of VTE and present with clinical thromboembolism at a younger age (median age: 31 years) than those who are heterozygous (median age: 46 years).^{20,22} Factor V Leiden is present in approximately 5 percent of the normal population of European descent, 16 percent of patients with a first episode of DVT, and up to 35 percent of patients with unprovoked (idiopathic) DVT.^{20,22,25} Prothrombin G20210A is another common gene mutation that predisposes to VTE. It is present in approximately 2 to 3 percent of apparently healthy individuals and in 7 percent of those with DVT.²² An inherited abnormality cannot be detected in up to 40 to 50 percent of patients with unprovoked DVT, suggesting that as yet undefined gene mutations are present that have an etiologic role (Chap. 130).

CLINICAL FEATURES

VENOUS THROMBOSIS

The clinical features of DVT include leg pain, tenderness, and swelling, a palpable cord representing a thrombosed vessel, discoloration, venous distention, prominence of the superficial veins, and cyanosis.

The clinical diagnosis of DVT is highly nonspecific because each of the symptoms or signs can be caused by nonthrombotic disorders. The rare exception is the patient with phlegmasia cerulea dolens (occlusion of the whole venous circulation, extreme swelling of the leg, and compromised arterial flow), in whom the diagnosis of massive iliofemoral thrombosis is obvious. This syndrome occurs in less than 1 percent of patients with symptomatic venous thrombosis. In most patients, the symptoms and signs are nonspecific. In 50 to 85 percent of patients, the clinical suspicion of DVT is not confirmed by objective testing.^{17–19} Patients with minor symptoms and signs may have extensive deep venous thrombosis. Conversely, patients with florid leg pain and swelling, suggesting extensive DVT, may have negative results by objective testing.

Although the clinical diagnosis is nonspecific, prospective studies have established that patients can be categorized as low, moderate, or high probability for DVT using a clinical prediction rule that incorporates signs, symptoms, and risk factors. A systematic review²⁶ of the studies found that the prevalence of DVT in the low, moderate, and high probability categories, respectively, was 5 percent (95 percent confidence interval [95% CI]: 4 to 8 percent), 17 percent (95% CI: 13 to 23 percent), and 53 percent (95% CI: 44 to 61 percent). The prevalence in the pretest category of “low probability” is not sufficiently low to withhold further diagnostic testing and treatment, and the prevalence in the “high probability” category is not sufficiently high to give anticoagulant therapy without performing further diagnostic testing. Consequently, the key role for clinical pretest categorization is for use within integrated diagnostic strategies employing measurement of D-dimer and venous imaging.

PULMONARY EMBOLISM

The clinical features of acute PE include the following symptoms and signs that may overlap: (1) transient dyspnea and tachypnea in the absence of other clinical features; (2) pleuritic chest pain, cough, hemoptysis, pleural effusion, and pulmonary infiltrates noted on chest radiogram caused by pulmonary infarction or congestive atelectasis (also known as *ischemic pneumonitis* or *incomplete infarction*); (3) severe dyspnea and tachypnea and right-side heart failure; (4) cardiovascular collapse with hypotension, syncope, and coma (usually associated with massive PE); and (5) several less common and nonspecific clinical presentations, including unexplained tachycardia or arrhythmia, resistant cardiac failure, wheezing, cough, fever, anxiety/apprehension, and confusion. All of these clinical features are nonspecific and can be caused by a variety of cardiorespiratory disorders. Patients can be assigned to categories of pretest probability using implicit clinical judgement, or clinical decision rules such as the Geneva score or approach of Wells.^{27–30} However, the prevalences of PE in these categories are not sufficiently low or high to withhold further investigation altogether, and the measurement of D-dimer and/or diagnostic imaging is mandatory to exclude or confirm the presence of PE. The assessment of clinical pretest probability is an important first step in integrated diagnostic strategies that employ, for example, D-dimer, computed tomographic angiography (CTA), and objective testing for DVT.^{27–30}

LABORATORY FEATURES

VTE is associated with nonspecific laboratory changes that constitute the acute-phase response to tissue injury. This response includes elevated levels of fibrinogen and factor VIII, increases in leukocyte and platelet counts, and systemic activation of blood coagulation, fibrin formation, and fibrin breakdown, with increases in plasma concentrations of prothrombin fragment 1.2, fibrinopeptide A, complexes of thrombin–antithrombin, and fibrin degradation products. All of these

changes are nonspecific and may occur as a result of surgery, trauma, infection, inflammation, or infarction. None of the above reported laboratory changes can be used to establish the diagnosis of VTE or predict its development with high probability. The fibrin breakdown fragment D-dimer can be measured by an enzyme-linked immunosorbent assay (ELISA) or by a latex agglutination assay. Some of these assays have a rapid turnaround time and some are quantitative. A negative D-dimer result is useful for excluding the diagnosis in many patients with suspected DVT or suspected PE (see “Objective Testing for Deep Vein Thrombosis” and “Objective Testing for Pulmonary Embolism” below).^{16,27,28,31} A positive result is highly nonspecific.

DIFFERENTIAL DIAGNOSIS OF DEEP VEIN THROMBOSIS

The differential diagnosis in patients with clinically suspected DVT includes muscle strain or tear, direct twisting injury to the leg, lymphangitis or lymphatic obstruction, venous reflux, popliteal cyst, cellulitis, leg swelling in a paralyzed limb, and abnormality of the knee joint. An alternate diagnosis frequently is not evident at presentation, so excluding DVT is not possible without objective testing. The cause of symptoms often can be determined by careful followup once DVT has been excluded by objective testing. In approximately 25 percent of patients, however, the cause of pain, tenderness, and swelling remains uncertain even after careful followup.¹⁹

OBJECTIVE TESTING FOR DEEP VEIN THROMBOSIS

D-DIMER ASSAY

Measurement of plasma D-dimer has been extensively evaluated as an exclusion test in patients with clinically suspected DVT.³¹ The different D-dimer assays (ELISA, quantitative rapid ELISA, latex agglutination, and whole-blood agglutination) have different sensitivities, specificities, and likelihood ratios for DVT. ELISA and quantitative rapid ELISA have high sensitivity (96 percent) and negative likelihood ratios of approximately 0.10 for DVT in symptomatic patients. Thus, for excluding DVT in symptomatic patients with a low or intermediate clinical pretest probability, a negative D-dimer result by a quantitative rapid ELISA technique is as diagnostically useful as a negative result by duplex ultrasonography.³¹ Measurement of D-dimer using an appropriate assay method can also be combined with ultrasonography imaging. If the two tests are negative at presentation, repeat ultrasonography imaging is unnecessary.³² Use of the D-dimer test for patient care decisions depends on the local availability of an appropriate assay that has high sensitivity and has been validated by clinical outcome studies. The use of age-adjusted D-dimer cut-off levels for a negative result enhance the clinical utility of the test. [Figure 133–1](#) shows a practical approach for the diagnosis of suspected DVT.

IMAGING TESTS

The objective diagnostic imaging tests that have a role in patients with clinically suspected DVT are ultrasonography and venography. Both of these tests have been validated by properly designed clinical trials, including prospective studies with long-term followup that have established the safety of withholding anticoagulant treatment in patients with negative test results.^{17–19,33} Ultrasonography is the preferred imaging test for most patients. The role of venography is for selected patients,

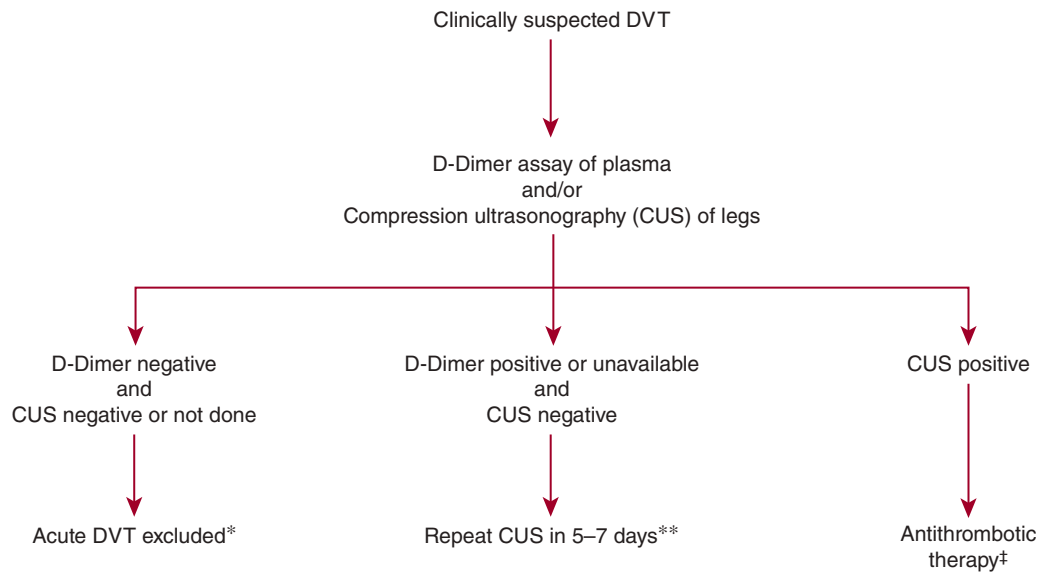

Figure 133-1. Diagnosis of patients with suspected first episode of deep vein thrombosis (DVT). *Negative D-dimer can be used to exclude acute DVT, without the need for further diagnostic testing with compression ultrasonography (CUS), if the patient has low, unlikely, moderate, or intermediate clinical probability.^{26,31} Ultrasonography should be performed in patients with a high clinical probability. A negative D-dimer can also be used with a negative CUS at presentation to exclude acute DVT without the need for a repeat CUS.^{32,34} **CUS is performed with imaging of the common femoral vein in the groin and of the popliteal vein in the popliteal fossa extending distally 10 cm from midpatella. A repeat CUS is required in 5 to 7 days to detect extending calf vein thrombi.¹⁷ In centers with the expertise, a single negative result of full-leg duplex ultrasonography (CUS plus flow evaluation) is sufficient to exclude acute DVT.^{18,34} †CUS that indicates noncompressibility of deep vein segments is highly predictive of DVT (>95%) and provides an indication for antithrombotic therapy in most patients. If CUS is positive at a single site isolated in the groin, additional testing with venography, computed tomography, or magnetic resonance imaging should be performed because of the potential for false-positive CUS results from disorders producing vein compression in the groin (e.g., tumor mass).

such as those in whom ultrasonography is unavailable or inconclusive. Ultrasonography using vein compression is effective for identifying patients with proximal vein thrombosis. Compression ultrasonography of the proximal veins performed at presentation (and, if normal, repeated once 5 to 7 days later) is a safe approach in symptomatic patients.¹⁷ In centers with experienced ultrasonography staff, a single comprehensive evaluation of the proximal and calf veins with duplex ultrasonography is sufficient and, if negative, a repeat test is not required.¹⁸ A randomized trial supports the equivalence of a comprehensive whole-leg color-coded Doppler ultrasonography approach to that of an approach using combined D-dimer testing and repeated ultrasonography for the management of suspected DVT.³⁴

The positive predictive value of a positive ultrasonography result isolated to the calf veins may vary among centers based on expertise and thrombosis prevalence. Therefore, the number of repeat ultrasonography evaluations avoided by evaluating the calf veins may be partially offset by an increased number of patients with positive ultrasonography results confined to the calf, for whom additional diagnostic testing and/or anticoagulant treatment is required. Most patients with a negative ultrasonographic result at presentation require a followup visit to establish the alternate diagnosis and to guide further care, so the return visit for repeat ultrasonography at 5 to 7 days may have added practical value.¹⁷

Diagnosis of acute recurrent DVT is particularly challenging because recurrent symptoms such as pain and swelling are common in patients with DVT despite adequate anticoagulant therapy, and because both ultrasonography and venography have limitations for excluding the presence of acute recurrent DVT.³⁵ Compression ultrasonography may remain abnormal for 1 year in 50 percent of patients, and for even longer in some patients,³⁶ because of persistent noncompressibility of the vein caused by fibrous organization of the original thrombus.

Venography is of limited value for excluding the diagnosis of recurrent DVT because of obliteration or recanalization of the previously affected venous segments or nonfilled venous segments. Thus, measurement of plasma D-dimer may be particularly useful as an exclusion test in patients with suspected acute recurrent DVT. However, use of D-dimer must be evaluated separately in this patient group because many patients with a past history of VTE are receiving long-term oral anticoagulant therapy, which has the potential to cause a false-negative D-dimer result. Promising initial results were obtained in one study,³⁷ but further studies in larger numbers of patients are needed before using a negative D-dimer alone to exclude acute recurrent DVT can be routinely recommended.

● DIFFERENTIAL DIAGNOSIS OF PULMONARY EMBOLISM

The differential diagnosis in patients with suspected PE includes cardiopulmonary disorders for each of the modes of presentation (see “Pulmonary Embolism” above). For the presentation of dyspnea and tachypnea, they include atelectasis, pneumonia, pleuritis, pneumothorax, acute pulmonary edema, bronchitis, bronchiolitis, and acute bronchial obstruction. For pulmonary infarction exhibited by pleuritic chest pain or hemoptysis, they include pneumonia, pneumothorax, pericarditis, pulmonary or bronchial neoplasm, bronchiectasis, acute bronchitis, tuberculosis, diaphragmatic inflammation, myositis, muscle strain, and rib fracture. For the clinical presentation of right-side heart failure, they include myocardial infarction, myocarditis, and cardiac tamponade. For cardiovascular collapse, they include myocardial infarction, acute massive hemorrhage, Gram-negative septicemia, cardiac tamponade, and spontaneous pneumothorax.

● OBJECTIVE TESTING FOR PULMONARY EMBOLISM

The objective diagnostic imaging tests include CT, CTA, radionuclide lung scanning, selective pulmonary arteriography, and objective testing for DVT. Measurement of plasma D-dimer is useful as an exclusion test in patients with an unlikely or intermediate clinical probability.

D-DIMER ASSAY

The assay for plasma D-dimer is useful as an exclusion test, provided an appropriately validated test is available. A negative result by the rapid quantitative ELISA for D-dimer has a negative likelihood ratio similar to that of a normal perfusion scan.³¹ A positive D-dimer result is not useful diagnostically. Several management studies have found that PE can be excluded without performing imaging studies in patients with a low, intermediate, or unlikely clinical probability.³⁸ When combined with pretest clinical probability assessment, the use of an age-adjusted D-dimer cutoff value instead of a fixed D-dimer cutoff of 500 mcg/mL, improves the utility of the test, and enables more patients to have the diagnosis of PE safely excluded.³⁹

COMPUTED TOMOGRAPHY IMAGING AND ANGIOGRAPHY

CT imaging is the primary imaging test for the diagnosis of PE in most centers. Single-detector spiral CT is highly sensitive for large emboli (segmental or larger arteries), but is much less sensitive for emboli in subsegmental pulmonary arteries^{16,40}; such emboli may be clinically important in patients with severely impaired cardiorespiratory reserve. Therefore, a negative result by single-detector spiral CT should not be used alone to exclude the diagnosis of PE. A filling defect of a segmental or larger artery on single-detector spiral CT is associated with a high probability (>90 percent) of PE.⁴⁰

The development of multidetector row CT, together with the use of contrast enhancement, has established CT as the preferred diagnostic imaging test in most patients.^{41–43} Contrast-enhanced CTA has the advantage of providing clear results (positive or negative), with a low rate of nondiagnostic test results, good characterization of nonvascular structures for alternate or associated diagnoses, and the ability to simultaneously evaluate the deep venous system of the legs (computed tomographic venography [CTV]).

The accuracy and clinical utility of multidetector CTA and combined CTA-CTV were evaluated in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) II study.⁴³ Among 824 patients with a reference diagnosis and a completed CT study, CTA was inconclusive in 51 (6 percent) because of poor image quality. The sensitivity of CTA was 83 percent and the specificity was 96 percent. CTA-CTV was inconclusive in 87 (11 percent) of 824 patients because the image quality of either CTA or CTV was poor. Multidetector CTA-CTV had a higher sensitivity (90 percent) than CTA alone (83 percent), with similar specificity (~95 percent for both testing techniques). Positive results on CTA in combination with a high probability or intermediate probability of PE by the clinical assessment, or normal findings on CTA with a low clinical probability had a predictive value (positive or negative) of 92 to 96 percent.⁴³ Such values are consistent with those generally considered adequate to confirm or rule out the diagnosis of PE. Additional testing is necessary when the clinical probability is discordant with CTA or CTA-CTV imaging results.⁴⁵

Figure 133–2 summarizes the approach to diagnosis of suspected PE using CTA or CTA-CTV as the primary imaging test. A high-quality image by CTA is sufficient to establish or exclude the diagnosis of PE

with high predictive value in most patients, and withholding anticoagulant therapy based on a negative CTA alone is associated with a low rate of subsequent VTE on followup.⁴⁴ Objective testing for DVT is useful in patients in whom the CTA image is of poor quality or inconclusive, and in patients who also have symptoms suggesting DVT. CTV has the advantage of being easily performed at the time of CTA, but incurs the risk of added radiation exposure for the patient. Compression ultrasonography can also be used, and avoids added radiation exposure and can be performed serially if needed.

RADIONUCLIDE LUNG SCANNING

Radionuclide lung scanning continues to have a role in the diagnosis of suspected PE. A normal perfusion lung scan excludes the diagnosis of clinically important PE.^{15,45} A normal perfusion lung scan is found in approximately 10 percent of all patients with suspected PE seen at academic health centers or tertiary referral centers. A high-probability lung scan result (i.e., large perfusion defects with ventilation mismatch) has a positive predictive value for PE of 85 percent and provides a diagnostic end point to give antithrombotic treatment in most patients.^{15,46,47} A high-probability lung scan is found in approximately 10 to 15 percent of symptomatic patients. For patients with a history of PE, careful comparison of the lung scan results to the most recent lung scan is required to ensure the perfusion defects are new. Further diagnostic testing is indicated for patients with a high-probability lung scan who have a “low” pretest clinical suspicion, and in those who are at high risk for major bleeding, to reduce the likelihood of a false-positive diagnosis.

The major limitation of lung scanning is that the results are inconclusive in most patients, even when considered together with the pretest clinical probability.¹⁵ The nondiagnostic lung scan patterns are found in approximately 70 percent of all patients with suspected PE.^{13,15,47} These lung scan results have historically been called “low probability” (matching ventilation–perfusion abnormalities or small perfusion defects), “intermediate probability,” or “indeterminate” (because the perfusion defects correspond to an area of abnormality on chest radiograph). Further diagnostic testing is required in most of these patients because, regardless of the pretest clinical suspicion, the posttest probabilities of PE associated with these lung scan results are neither sufficiently high to give antithrombotic treatment nor sufficiently low to withhold therapy. The uncommon exception is the patient with a low clinical suspicion and a so-called low-probability lung scan result. However, even in these patients, objective testing for DVT with ultrasonography and/or measurement of plasma D-dimer is without risk for the patient and may provide added diagnostic value (see “Objective Testing for Deep Vein Thrombosis” below). A randomized trial has established that CTA is not inferior to using ventilation–perfusion lung scanning for excluding the diagnosis of PE when either test is used in an algorithm together with venous ultrasonography of the legs.⁴⁸

In centers where CTA is available, the major role for lung scanning is in select patients; for example, in younger women to reduce radiation exposure to the breast. Lung scanning can be useful in such patients who are less likely to have comorbid cardiorespiratory disorders and therefore a higher proportion of diagnostic scan results (normal or high probability).

MAGNETIC RESONANCE ANGIOGRAPHY

The accuracy of magnetic resonance angiography for diagnosing PE, with or without the addition of magnetic resonance venography, was evaluated in the PIOPED III study.⁴⁹ This was a prospective study of 371 adults with suspected PE recruited from seven hospitals and their emergency services. Magnetic resonance angiography was technically inadequate in 25 percent of patients (92 of 371); this rate ranged from

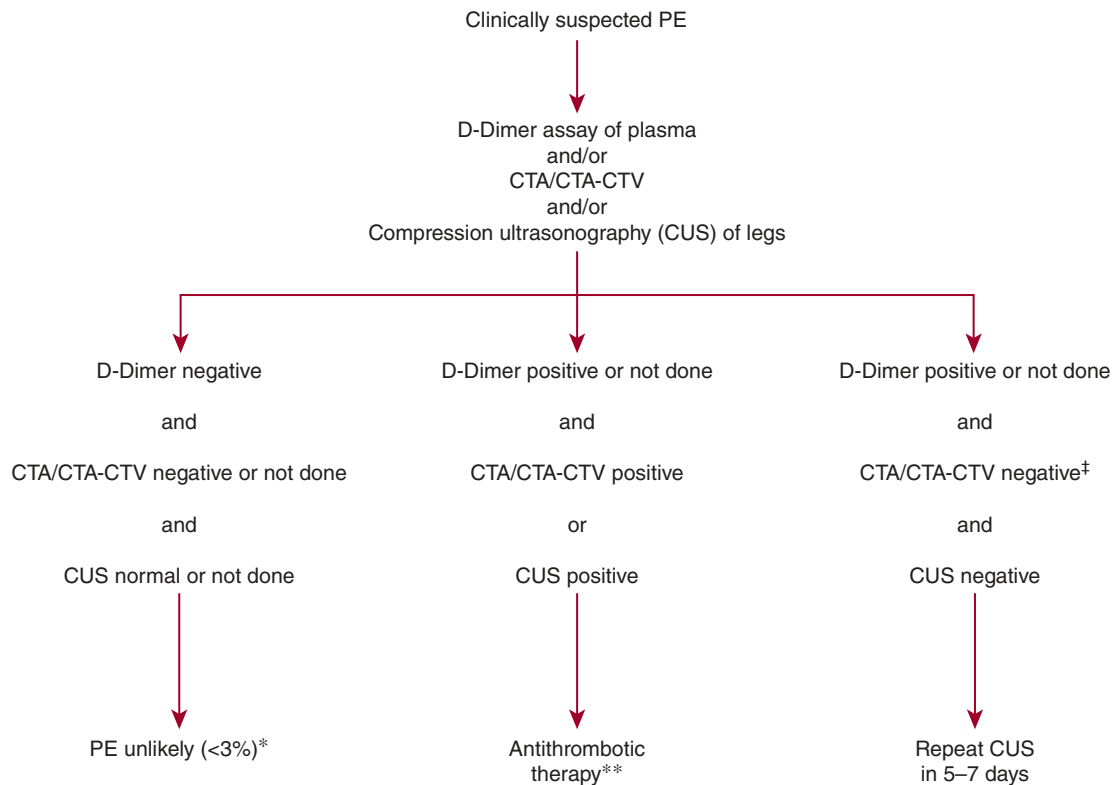

Figure 133-2. Integrated strategy for diagnosis of patients with suspected pulmonary embolism (PE) using computed tomographic angiography (CTA) as the primary imaging test. *Negative D-dimer alone can be used as an exclusion test with high negative predictive value (>96%) in patients with low or moderate probability by the clinical assessment.^{27,30,31} Patients with a high clinical probability should undergo imaging with CTA or combined CTA-computed tomographic venography (CTV). **Positive results on CTA or combined CTA-CTV, in patients with a high or moderate probability of pulmonary embolism by the clinical assessment, have positive predictive value of 90% or more for venous thromboembolism. Similarly, abnormal results by compression ultrasonography (CUS) of the proximal deep veins of the legs have high positive predictive value for proximal vein thrombosis and provide an indication to give antithrombotic therapy. If the patient has a low probability by the clinical assessment, positive results by CTA or CTA-CTV in the main or lobar pulmonary arteries are still highly predictive (97%) for the presence of pulmonary embolism⁴³; further testing is recommended for patients with low clinical probability and positive CTA results only of segmental or subsegmental arteries, and the options include pulmonary arteriography or serial CUS. †Negative results by CTA or by combined CTA-CTV have high negative predictive value (96%) in patients with low probability by the clinical assessment.⁴³ For patients with moderate clinical probability, the negative predictive value for combined CTA-CTV is also high (92%), but slightly lower for CTA alone (89%)⁴³; in CTA-alone group, and in patients with a high probability by the clinical assessment, serial CUS or pulmonary arteriography are recommended options.

11 percent to 52 percent among the centers. If a technically adequate image was obtained, magnetic resonance angiography had a sensitivity of 78 percent and a specificity of 99 percent, and combined magnetic resonance angiography and venography had a sensitivity of 92 percent and a specificity of 96 percent. However, 52 percent of patients (194 of 370) had technically inadequate results with the combined approach.⁴⁹ Based on these findings, magnetic resonance angiography has a very limited role in the diagnosis of PE. In centers that routinely perform it well with a high rate of technically adequate images, magnetic resonance angiography and venography may be useful for patients in whom CTA or lung scanning are contraindicated.

PULMONARY ANGIOGRAPHY

Pulmonary angiography using selective catheterization of the pulmonary arteries is a relatively safe technique for patients who do not have pulmonary hypertension or cardiac failure.^{13,15} If the expertise is available, pulmonary angiography should be used when other approaches are inconclusive and when definitive knowledge about the presence or absence of PE is required, because the risk of angiography in properly

selected patients is less than the risk of unnecessary anticoagulant therapy.

OBJECTIVE TESTING FOR DEEP VEIN THROMBOSIS

Objective testing for DVT is useful in patients with suspected PE, particularly those with nondiagnostic lung scan results^{33,47} or inconclusive CT results.⁵⁰ Detection of proximal vein thrombosis by objective testing provides an indication for anticoagulant treatment, regardless of the presence or absence of PE, and prevents the need for further testing. However, a negative result by objective testing for DVT does not exclude the presence of PE.^{13,14} If the patient has adequate cardiorespiratory reserve, then serial ultrasonography testing for proximal vein thrombosis can be used as an alternative to pulmonary angiography in patients with nondiagnostic lung scan or inconclusive CT results, and withholding anticoagulant therapy is safe if repeated ultrasonography testing of the legs is negative.^{33,47,50} The rationale is that the clinical objective in such patients is to prevent recurrent PE, which is unlikely in the absence of proximal vein thrombosis. Selective pulmonary angiography should

be done among patients with features suggesting a possible alternate source of embolism to proximal DVT of the leg (e.g., upper-extremity thrombosis, renal vein thrombosis, pelvic vein thrombosis, or right-heart thrombus).

● THERAPY, COURSE, AND PROGNOSIS

CLINICAL COURSE OF VENOUS THROMBOEMBOLISM

Proximal Vein Thrombosis

Proximal vein thrombosis is a serious and potentially lethal condition. Untreated proximal vein thrombosis is associated with a 10 percent rate of fatal PE. Inadequately treated proximal vein thrombosis results in a 20 to 50 percent risk of recurrent VTE events.⁵¹ Prospective studies of patients with clinically suspected DVT or PE indicate that new VTE events on followup are uncommon (≤ 2 percent) among patients in whom proximal vein thrombosis is absent by objective testing.^{17,32,33,47,50} The aggregate data from diagnostic and treatment studies indicate that the presence of proximal vein thrombosis is the key prognostic marker for recurrent VTE.

Calf Vein Thrombosis

Thrombosis that remains confined to the calf veins is associated with low risk (≤ 1 percent) of clinically important PE. Extension of thrombosis into the popliteal vein or more proximally occurs in 15 to 25 percent of patients with untreated calf vein thrombosis.¹ Patients with documented calf vein thrombosis should either receive anticoagulant treatment to prevent extension or undergo monitoring for proximal extension using serial ultrasonography.

Postthrombotic Syndrome

The postthrombotic syndrome is a frequent complication of DVT.⁵² Patients with the postthrombotic syndrome complain of pain, heaviness, swelling, cramps, and itching or tingling of the affected leg. Ulceration may occur. The symptoms usually are aggravated by standing or walking and improve with rest and elevation of the leg. A prospective study documented a 25 percent incidence of moderate-to-severe postthrombotic symptoms 2 years after the initial diagnosis of proximal vein thrombosis in patients who were treated with initial heparin and oral anticoagulants for 3 months.⁵³ The study also demonstrated that ipsilateral recurrent venous thrombosis is strongly associated with subsequent development of moderate or severe postthrombotic symptoms. Thus, prevention of ipsilateral recurrent DVT likely reduces the incidence of the postthrombotic syndrome. Application of a properly fitted graded compression stocking, as soon after diagnosis as the patient's symptoms will allow, can improve edema and pain in the acute stage of DVT and may also help control or relieve symptoms in patients who develop the postthrombotic syndrome. Conflicting findings have been found in randomized trials of graded compression stockings for preventing the development of the postthrombotic syndrome.^{54,55}

Chronic Thromboembolic Pulmonary Hypertension

Chronic thromboembolic pulmonary hypertension is a serious complication of PE. Historically, thromboembolic pulmonary hypertension was believed to be relatively rare and to occur only several years after the diagnosis of PE. A prospective cohort study provides important information on the incidence and timing of thromboembolic pulmonary hypertension.⁵⁶ The results indicate that thromboembolic pulmonary hypertension is more common and occurs earlier than previously thought. On prospective followup of 223 patients with documented PE, the cumulative incidence of chronic thromboembolic pulmonary

hypertension was 3.8 percent at 2 years after diagnosis, despite state-of-the-art treatment for PE. The strongest independent risk factors were a history of PE (odds ratio: 19) and idiopathic PE at presentation (odds ratio: 5.7).⁵⁶

OBJECTIVES AND PRINCIPLES OF ANTITHROMBOTIC TREATMENT

The objectives of treatment in patients with established VTE are to (1) prevent death from PE, and (2) prevent morbidity from recurrent DVT or PE, especially the postthrombotic syndrome and chronic pulmonary hypertension.

For most patients, these objectives are achieved by providing adequate anticoagulant treatment. Thrombolytic therapy is indicated in selected patients (see “Thrombolytic Therapy” below). Use of an inferior vena cava filter is indicated to prevent death from PE in patients in whom anticoagulant treatment is absolutely contraindicated and in other selected patients (see “Anticoagulant Therapy” below). These recommendations and those below are linked to the strength of the evidence from clinical trials and evidence-based guidelines.^{9,30,57,58}

ANTICOAGULANT THERAPY

Anticoagulant therapy is the treatment of choice for most patients with proximal vein thrombosis or PE.^{9,57,58} Patients with proximal DVT require both adequate initial anticoagulant treatment with heparin or low-molecular-weight (LMW) heparin and adequate long-term anticoagulant therapy to prevent recurrent VTE.^{51,59,60} Anticoagulant therapy for at least 3 months is required to prevent a high frequency (15 to 25 percent) of symptomatic extension of thrombosis and/or recurrent venous thromboembolic events.^{51,60,61} Adequate anticoagulant treatment reduces the incidence of recurrence during the first 3 months after diagnosis to 5 percent or less.^{51,59-61}

The absolute contraindications to anticoagulant treatment include intracranial bleeding, severe active bleeding, recent brain, eye, or spinal cord surgery, and malignant hypertension. Relative contraindications include recent major surgery, recent cerebrovascular accident, active gastrointestinal tract bleeding, severe hypertension, severe renal or hepatic failure, and severe thrombocytopenia (platelets $< 50 \times 10^9/L$).

Parenteral Anticoagulants

Heparin and Low-Molecular-Weight Heparin Initial therapy with continuous intravenous heparin was the standard approach to treatment of VTE during the 1970s and 1980s. During the 1990s, LMW heparin given by subcutaneous injection once or twice daily was evaluated by clinical trials and shown to be as effective and safe as continuous intravenous heparin for the initial treatment of patients with proximal DVT and submassive PE.^{57,58,62} The advantage of LMW heparin is that it does not require anticoagulant monitoring. LMW heparin given subcutaneously once or twice daily is preferred over intravenous unfractionated heparin for the initial treatment of most patients with either DVT or PE.^{57,58} LMW heparin enables outpatient therapy for many patients with uncomplicated DVT and selected patients with PE. Intravenous unfractionated heparin remains a useful approach for initial anticoagulant therapy in patients with severe renal failure. Initial treatment with LMW heparin or unfractionated heparin should be continued for at least 5 days. [Table 133-2](#) lists the specific LMW heparin regimens for the treatment of VTE.

If unfractionated heparin is used for initial therapy, it is important to achieve an adequate anticoagulant effect, defined as an activated partial thromboplastin time (aPTT) above the lower limit of therapeutic range within the first 24 hours.^{63,64} Failure to achieve an adequate aPTT effect

TABLE 133-2. Anticoagulant Drug Regimens for Treatment of Venous Thromboembolism

Drug	Regimen
LOW-MOLECULAR-WEIGHT HEPARINS	
Enoxaparin	1.0 mg/kg BID*
Dalteparin	200 IU/kg once daily [†]
Tinzaparin	175 IU/kg once daily [‡]
Nadroparin	6150 IU BID for 50–70 kg 4100 IU BID if patient weighs <50 kg 9200 IU BID if patient weighs >70 kg
Reviparin	4200 IU BID for 46–60 kg 3500 IU BID if patient weighs 35–45 kg 6300 IU BID if patient weighs >60 kg
INDIRECT FACTOR Xa INHIBITOR	
Fondaparinux	7.5 mg once daily if patient weight 50–100 kg 5.0 mg once daily if patient weight <50 kg 10.0 mg once daily if patient weight >100 kg
DIRECT ORAL ANTICOAGULANTS	
Dabigatran	150 mg BID after 5 days of parenteral low-molecular-weight heparin or heparin
Rivaroxaban	15 mg BID for 21 days, then 20 mg once daily Taken with food
Apixaban	10 mg BID for 7 days, then 5 mg BID After 6 months, 2.5 mg BID for extended therapy
Edoxaban	60 mg once daily after 5 days of parenteral low-molecular-weight heparin or heparin [§]

*A once-daily regimen of 1.5 mg/kg can be used but probably is less effective in patients with cancer.

[†]After 1 month, can be followed by 150 IU/kg once daily as an alternative to an oral vitamin K antagonist for long-term treatment.

[‡]This regimen can also be used for long-term treatment as an alternative to an oral vitamin K antagonist.

[§]30 mg once daily if patient's creatinine clearance is 30–50 mL/min or weight is ≤60 kg or if patient is taking strong P-glycoprotein inhibitor drugs.

early during therapy is associated with a high incidence (25 percent) of recurrent VTE.⁶³ Two-thirds of the recurrent events occur between 2 and 12 weeks after the initial diagnosis despite treatment with oral anticoagulants, and the initial management with either unfractionated heparin or LMW heparin is critical to the patient's long-term outcome.^{63,64}

Fondaparinux The synthetic pentasaccharide fondaparinux, which is an indirect inhibitor of factor Xa, has been evaluated by large randomized clinical trials.^{65,66} These studies indicate fondaparinux is as effective and safe as LMW heparin for treatment of established DVT and as effective and safe as intravenous heparin for treatment of symptomatic PE. Fondaparinux is given subcutaneously once daily at a dose of 7.5 mg for patients weighing between 50 and 100 kg (85 percent of all patients evaluated in the clinical trials), 5 mg for patients weighing less than 50 kg, and 10 mg for patients weighing more than 100 kg.^{65,66}

Oral Anticoagulants

Vitamin K Antagonists Oral anticoagulant treatment using a vitamin K antagonist (e.g., sodium warfarin) has been the standard approach for long-term treatment in most patients for more than 60 years. Treatment

with a vitamin K antagonist is started with initial heparin or LMW heparin therapy and overlapped for 4 to 5 days.

The preferred intensity of the anticoagulant effect of treatment with a vitamin K antagonist has been established by clinical trials.^{69–72} The dose of vitamin K antagonist should be adjusted to maintain the international normalized ratio (INR) between 2.0 and 3.0. High-intensity vitamin K antagonist treatment (INR 3.0 to 4.0) should not be used because it has not improved effectiveness in patients with the antiphospholipid syndrome and recurrent thrombosis⁷¹ and has caused more bleeding.⁷² Low-intensity therapy (INR 1.5 to 1.9) is not recommended because it is less effective than standard-intensity treatment (INR 2.0 to 3.0) and does not reduce bleeding complications.⁷⁰

Long-term treatment with LMW heparin is indicated for select patients in whom vitamin K antagonists are contraindicated (e.g., pregnant women), and in patients with concurrent cancer for whom LMW heparin regimens are more effective.^{67,68}

Direct Oral Anticoagulants Oral anticoagulants that bind directly to the target coagulation enzyme of either thrombin or factor Xa have been evaluated in phase III clinical trials for the treatment of patients with VTE (Chap. 25).^{73–78} The advantages of these drugs are: (1) they can be administered orally once or twice daily without the need for anticoagulant monitoring and dose titration; (2) they have fewer clinically relevant drug interactions; (3) because of a fast onset of anticoagulant action, similar to that of LMW heparin, they can simplify treatment for many patients by replacing the standard approach of a parenteral drug (heparin, LMW heparin or fondaparinux) followed by an oral vitamin K antagonist with a single drug given for both initial and long-term therapy; and (4) they result in less clinically important bleeding. Table 133-2 lists the direct-acting oral anticoagulant (DOAC) regimens that have been evaluated by clinical trials for the treatment of established VTE.

Six phase III clinical trials evaluating the DOACs for the treatment of acute VTE have been completed and published.^{73–78} Table 133-3 outlines the design features of these trials and the efficacy and bleeding results. Each of these trials met the prespecified criteria for noninferiority of the efficacy of the DOAC for preventing recurrent VTE.

The six trials included more than 27,000 patients with acute VTE, and meta-analyses of these studies has been done.⁷⁹ The meta-analyses provide added clinically useful information regarding specific major bleeding outcomes (intracranial bleeding and fatal bleeding), and regarding the risk-to-benefit profile in key patient subgroups commonly encountered by the clinician. These subgroups are patients presenting with symptomatic PE or symptomatic DVT, the elderly (age ≥75 years), the obese, patients with moderate renal impairment (creatinine clearance 30 to 49 mL/min), and patients with cancer. The DOACs were associated with clinically important reductions in major bleeding (relative risk [RR] 0.61), intracranial bleeding (RR 0.37), and fatal bleeding (RR 0.36).⁷⁹ For each of these outcomes, the results are consistent among the trials; none of the trials have a point estimate for these outcomes in favor of the vitamin K antagonists (supplementary data online⁷⁹). The number of patients who would need to be treated with a DOAC rather than a vitamin K antagonist to avoid one event of intracranial bleeding is 588, and for fatal bleeding is 1250. In view of the large number of VTE patients each year, and the devastating nature of these bleeding events, these are important impacts on population health. The results of cost-effectiveness studies have shown the DOACs to be cost-effective.

Regarding the key patient subgroups evaluated, the noninferior efficacy of the DOACs was consistent across all subgroups, with possibly superior efficacy in the elderly and in cancer patients.⁷⁹ The safety advantage of reduced major bleeding was also consistent across the subgroups, except possibly in cancer patients, in whom the pooled estimate of a 33 percent risk reduction did not achieve statistical significance.

bw, Body weight; CrCl, creatinine clearance; CRNM, clinically relevant non-major bleeding; Hep, heparin; LMW, low molecular weight; P-gp, P-glycoprotein; VKA, vitamin K antagonist; VTE, venous thromboembolism.

*During overall study period. On-treatment rates were 1.6% for edoxaban and 1.9% for heparin/warfarin. The analysis for all the other studies used rates on treatment.

**Either warfarin or acenocoumarol was used for the vitamin K antagonist therapy.

§Rates are for the composite of major and clinically relevant nonmajor bleeding.

Adapted with permission from Raskob G, Büller H, Prins M, et al: Edoxaban for the long-term treatment of venous thromboembolism: Rationale and design of the Hokusai-venous thromboembolism study—Methodological implications for clinical trials. *J Thromb Haemost* 11(7):1287–1294, 2013.

The DOACs are preferred over vitamin K antagonists in most new patients commencing anticoagulant treatment for VTE. The exceptions are patients with severe renal impairment (creatinine clearance <30 mL/min), because they were not included in the clinical trials, and cancer patients, because only relatively small numbers of selected cancer patients were included, and because clinical trials comparing DOACs to the currently recommended standard therapy with LMW heparin have not been performed. For patients already taking long-term vitamin K antagonist therapy who are well controlled with a high proportion of time in therapeutic range, and for whom regular anticoagulant monitoring is not a burden, switching treatment to a DOAC is not indicated unless a clinical reason develops.

Some practical issues remain incompletely resolved. Rivaroxaban and apixaban can be used as a single-drug approach, whereas dabigatran and edoxaban are preceded by at least 5 days of heparin or LMW heparin treatment. Whether DOAC monotherapy is sufficient for

the full spectrum of VTE severity, or whether “lead-in” heparin treatment is preferred in some patients, such as those with PE who have right ventricular dysfunction,⁷⁸ remains uncertain. The DOACs currently lack a specific reversal agent. In general, this should not be a reason to withhold from most patients the benefit of significantly reduced risks of major bleeding, intracranial bleeding and fatal bleeding with the DOACs. For the near term, vitamin K antagonists may be preferred in patients in whom prompt and measurable reversal of the anticoagulant effect will be required because of planned surgery or invasive procedures. Multiple rapid reversal agents for the DOACs are currently in development. Because the DOACs do not require laboratory monitoring, patients receiving DOACs may have less-frequent contact with their physician or anticoagulation clinic, and nonadherence to the prescribed therapy may not be detected as readily. Physicians and health systems should employ evidence-based strategies to enhance adherence and should evaluate patients at intervals to assess if ongoing anticoagulant

therapy is appropriate and adhered to. The effectiveness and safety of the DOACs compared with LMW heparin treatment in cancer patients with VTE has not been evaluated, and LMW heparin remains indicated for these patients.

Duration of Anticoagulant Therapy

Anticoagulant treatment should be continued for at least 3 months in all patients with VTE.^{9,57,58,80} Stopping treatment at 4 to 6 weeks resulted in an increased incidence of recurrent VTE during the following 6 months (absolute risk increase: 8 percent).^{57, 80–82} In contrast, treatment for 3 to 6 months resulted in a low rate of recurrence during the following 1 to 2 years (annual incidence 3 percent).^{80–82}

The decision to stop anticoagulant therapy, or continue treatment after 3 months is influenced mainly by the patient's clinical presentation of thromboembolism as either "provoked," which refers to VTE occurring in association with known risk factors, or "unprovoked," in which identifiable risk factors for VTE are absent. Approximately 20 to 40 percent of all symptomatic patients present as unprovoked VTE.

In patients with a first episode of DVT or PE provoked by a reversible risk factor (e.g., surgery), treatment for 3 months is usually sufficient if the risk factor(s) is no longer present. If the risk factor(s) persist, for example prolonged immobility or cancer, treatment should be continued until the risk factor is reversed. It has been a customary practice to treat patients with PE for 6 months rather than 3 months, but the clinical trials indicate there is little to no added benefit of doing so, with a small but additional risk of bleeding.⁸⁰ Thus, for patients with DVT or PE provoked by a risk factor that has reversed, 3 months is sufficient and recommended over longer therapy.⁵⁷

Patients with a first episode of unprovoked VTE should be considered for indefinite anticoagulant therapy.^{57,58} The term "indefinite" refers to continued treatment without a scheduled stopping date; treatment may be stopped in the future if the patient's risk-to-benefit profile or preference for continued treatment changes. The decision to stop or continue anticoagulation after 3 months in patients with a first episode of unprovoked VTE should take into consideration the risk of recurrent VTE, the risk of bleeding, and patient preference. If indefinite anticoagulant treatment is chosen, the risks and benefits of continuing such treatment should be reassessed at periodic intervals.⁵⁷

There has been significant research to develop strategies to aid the clinician in assessing the risk of recurrent VTE in patients with unprovoked VTE. The presence of residual DVT assessed by compression ultrasonography,⁸³ elevated levels of plasma D-dimer after discontinuing anticoagulant treatment,⁸⁴ and male gender⁸⁵ are associated with an increased incidence of recurrent thromboembolism. The challenge, however, has been to identify the subgroup of patients with a sufficiently low annual risk of recurrence to warrant stopping anticoagulant therapy. Palaretti and colleagues evaluated an approach for patients with a first episode of unprovoked VTE or VTE associated with a minor risk factor (e.g., estrogens, pregnancy, or travel related thrombosis) which combined evaluation of the presence or absence of residual thrombosis by ultrasonography with serial D-dimer measurement to guide the decision to stop or continue anticoagulant therapy.⁸⁶ Patients in whom residual vein thrombosis was absent after 3 months of treatment, or in those with residual vein thrombosis who had been treated for at least 1 year, and who had serially negative D-dimer measurements for 3 months after stopping vitamin K antagonist treatment, had an annual rate of recurrent VTE of 3 percent during followup off anticoagulant therapy; this compared to 0.7 percent per year in 373 patients who resumed anticoagulation because of an elevated D-dimer measurement, and 8.8 percent per year among the 109 patients with elevated D-dimer who did not continue anticoagulant therapy.⁸⁶ An annual risk of recurrent VTE of 3 percent may be low enough to discontinue therapy in patients in

whom the annual risk of bleeding, especially major bleeding, is similar or higher. However, if the risk of major bleeding is low, for example 1 percent per year or lower, then the annual risk of recurrent VTE of 3 percent may not be sufficiently low to stop anticoagulation, especially if the patient's preference is on avoiding further recurrent VTE events.

A variety of thrombophilic conditions have been identified and can be evaluated in the laboratory. These include deficiencies of the naturally occurring inhibitors of coagulation such as antithrombin, protein C, and protein S; specific gene mutations including factor V Leiden and prothrombin 20210A; elevated levels of coagulation factor VIII; and the presence of antiphospholipid antibodies (Chap. 131). The role of the presence or absence of thrombophilia in guiding decisions about duration of therapy has been controversial and is incompletely resolved. Indefinite anticoagulant treatment should be considered in patients with a first episode of VTE and antiphospholipid antibodies or the presence of one or a combination of the more potent thrombophilias (deficiency of antithrombin, protein C or protein S, homozygous factor V Leiden, or prothrombin 20210A gene mutation, or one of these with a family history of VTE). Again, patient preference is important to the decision.

The DOACs have been evaluated by randomized trials for the extended treatment of patients with VTE who have completed an initial course of 6 months of anticoagulant therapy.^{75,87–89} Most of the patients in these trials had unprovoked VTE at their initial presentation and all had clinical equipoise about the benefit to risk tradeoff of receiving extended anticoagulant therapy. The results of the trials are consistent. The DOACs produced 80 percent or greater reductions in the annual incidence of recurrent VTE of 7 to 9 percent per year in patients receiving placebo to approximately 2 percent per year in those given DOACs.^{75,87–89} The rates of major bleeding were 0.1 to 0.7 percent. Clinically relevant nonmajor bleeding occurred in 3 to 4 percent of patients.^{75,87–89} In the AMPLIFY Extension trial,⁸⁹ the rate of major bleeding for the 2.5 mg apixaban regimen was 0.2 percent per year, compared with 0.5 percent for placebo. The low rates of major bleeding, coupled with the advantage of not requiring laboratory monitoring of the anticoagulant effect, will likely tip the balance in favor of extended treatment for more patients with unprovoked VTE.

Aspirin has also been evaluated for the extended treatment of patients with a first episode of unprovoked VTE who have received a course of 6 months or more of anticoagulant therapy.^{90,91} Aspirin produced a statistically significant 42 percent RR reduction in recurrent VTE in one study (from 11.2 percent to 6.6 percent per year),⁹⁰ and a nonsignificant ($p = 0.09$) 26 percent RR reduction in the second study (from 6.5 percent to 4.8 percent per year).⁹¹ The rates of major bleeding for aspirin (0.5 to 0.6 percent per year) were similar to placebo. Although intuitive to the clinician, there is no data to indicate that aspirin causes less major bleeding than the DOACs, although it is likely that the efficacy for preventing recurrent VTE is significantly less (only about half as effective as the DOACs).

Oral anticoagulant treatment should be given indefinitely for most patients with a second episode of unprovoked VTE,^{57,58,92} because stopping treatment at 3 to 6 months in these patients results in a high incidence (21 percent) of recurrent VTE during the following 4 years.⁹² The risk of recurrent thromboembolism during 4-year followup was reduced by 87 percent (from 21 percent to 3 percent) by continuing anticoagulant treatment⁹²; this benefit is partially offset by the risk of bleeding.

Anticoagulant Therapy of Venous Thromboembolism in Cancer Patients

Use of LMW heparin for long-term treatment of VTE has been evaluated in clinical trials.^{67,68} The studies indicate that long-term treatment with subcutaneous LMW heparin for 3 to 6 months is at least as effective as, and in cancer patients is more effective than, an oral vitamin K antagonist adjusted to maintain the INR between 2.0 and 3.0.

Therefore, patients with VTE associated with concurrent cancer should be treated with LMW heparin for the first 3 to 6 months of long-term treatment.^{9,57,58} The patients then should receive anticoagulation indefinitely or until the cancer resolves. The regimens of LMW heparin that are established as effective for long-term treatment are dalteparin 200 U/kg once daily for 1 month, followed by 150 U/kg daily thereafter, or tinzaparin 175 U/kg once daily.

Anticoagulant Therapy During Pregnancy

LMW heparin or adjusted-dose subcutaneous heparin are the options for anticoagulant therapy of pregnant patients with VTE.⁹⁴⁻⁹⁶ LMW heparin is preferred because it has the safety advantages of causing less thrombocytopenia and probably less osteoporosis than unfractionated heparin. An additional advantage is that LMW heparin is effective when given once daily, whereas unfractionated heparin requires twice-daily injection. A study indicates no major change in the peak anti-factor Xa levels over the course of pregnancy in most patients treated with a once-daily therapeutic LMW heparin regimen (tinzaparin 175 U/kg).⁹⁶ Measurement of the anti-factor Xa level may provide reassurance that major drug accumulation is not occurring. However, the appropriate dose adjustments in response to a decreased anti-factor Xa level are uncertain. The DOACs have not been evaluated in pregnant patients. Evidence-based guidelines for antithrombotic therapy during pregnancy are available.⁹⁴

Side Effects of Anticoagulant Therapy

Bleeding Bleeding is the most common side effect of anticoagulant therapy. Bleeding can be classified as major or clinically relevant non-major according to standardized international criteria. *Major bleeding* is defined as clinically overt bleeding resulting in a decline of hemoglobin of at least 2 g/dL, transfusion of at least 2 U of packed red cells, or bleeding that is retroperitoneal or intracranial, or occurs into other critical spaces. The rates of major bleeding in contemporary clinical trials of initial therapy with intravenous heparin, LMW heparin, or fondaparinux are 1 to 2 percent.^{65,66,73-78} Patients at increased risk of major bleeding are those who have undergone surgery or experienced trauma within the previous 14 days; those with a history of gastrointestinal or intracranial bleeding, peptic ulcer disease, or genitourinary bleeding; and those with miscellaneous conditions predisposing to bleeding, such as thrombocytopenia, liver disease, and multiple invasive lines.

Major bleeding occurs in approximately 1 to 2 percent of patients during the first 3 months of oral anticoagulant treatment using a vitamin K antagonist and in 1 to 3 percent per year of treatment thereafter.⁹⁷ A meta-analysis suggests the clinical impact of major bleeding during long-term oral vitamin K antagonist treatment is greater than widely appreciated.⁹⁷ The estimated case fatality rate for this major bleeding is 13 percent, and the rate of intracranial bleeding was 1.15 per 100 patient-years. These risks are important considerations in the decision about extended or indefinite anticoagulant therapy in patients with VTE. As noted above, clinical trials of the DOACs and meta-analysis indicate clinically important lower rates of bleeding, including major, intracranial, and fatal bleeding than the vitamin K antagonists.⁷³⁻⁷⁹

Heparin-Induced Thrombocytopenia (See also Chap. 118.) Heparin or LMW heparin may cause thrombocytopenia. In large clinical studies of acute VTE treatment, thrombocytopenia occurred in less than 1 percent of more than 2000 patients treated with unfractionated heparin or LMW heparin.⁶⁶ Nevertheless, heparin-induced thrombocytopenia can be a serious complication when accompanied by extension or recurrence of VTE or the development of arterial thrombosis. Such complications may precede or coincide with the fall in platelet count and are associated with a high rate of limb loss and a high mortality. Heparin in all forms should be discontinued when the diagnosis of heparin-induced thrombocytopenia is made on clinical grounds, and treatment with an

alternative anticoagulant, such as danaparoid, bivalirudin, or argatroban, should be initiated. The DOACs have potential to be useful for anticoagulant therapy in patients with heparin-induced thrombocytopenia, but their use has not been evaluated by clinical trials in this patient group.

Heparin-Induced Osteoporosis Osteoporosis may occur as a result of long-term treatment with heparin or LMW heparin (usually after more than 3 months). The earliest clinical manifestation of heparin-associated osteoporosis usually is nonspecific low back pain primarily involving the vertebrae or the ribs. Patients also may present with spontaneous fractures. Up to one-third of patients treated with long-term heparin may have subclinical reduction in bone density. Whether these patients are predisposed to future fractures is not known. The incidence of symptomatic osteoporosis in clinical trials of LMW heparin treatment for 3 to 6 months was very low and are not increased compared to warfarin treatment. Patients with osteoporosis or fractures often had other risk factors such as bone metastases.

Other Side Effects of Heparin Heparin or LMW heparin may cause elevated liver transaminase levels. These elevations are of unknown clinical significance and usually return to normal after the heparin or LMW heparin is discontinued. Awareness of this biochemical effect is important so as to avoid unnecessary interruption of heparin therapy and unnecessary liver biopsies in patients who may develop elevated transaminase levels during heparin or LMW heparin therapy. Additional rare side effects of heparin include hypersensitivity and skin reactions, such as skin necrosis, alopecia, and hyperkalemia occurring as a result of hypoaldosteronism.

THROMBOLYTIC THERAPY

Thrombolytic therapy is indicated for patients with PE who present with hypotension or shock, and for select patients with PE who have evidence of right ventricular dysfunction and are at high risk of hemodynamic collapse.³⁰ Thrombolytic therapy provides more rapid lysis of pulmonary emboli and more rapid restoration of right ventricular function and pulmonary perfusion than does anticoagulant treatment.^{30,98,99} Effective regimens are 100 mg of recombinant tissue plasminogen activator by intravenous infusion over 2 hours (50 mg/h), or 30 to 50 mg (depending on body weight) of tenecteplase given as a single bolus injection.^{98,99} Heparin then is given by continuous infusion once the thrombin time or aPTT is less than twice the control value.^{98,99} The starting infusion dose is 1000 U/h. Chapters 25 and 135 provide further details of thrombolytic therapy.

The recently reported PEITHO trial⁹⁹ evaluated the effectiveness and safety of thrombolysis with tenecteplase followed by anticoagulant therapy compared with anticoagulant therapy alone in 1006 patients with PE and evidence of both right ventricular dysfunction by echocardiography or CT scan, and evidence of myocardial injury by the results of troponin I or troponin T measurement. The primary outcome of death or hemodynamic compensation (or collapse) within 7 days occurred in 13 of 506 patients (2.6 percent) given thrombolysis, compared with 28 of 499 (5.6 percent) receiving anticoagulant therapy alone ($p = 0.02$).⁹⁹ Stroke occurred in 12 patients (2.4 percent) in the thrombolysis group, compared with one (0.2 percent) in the anticoagulant alone group ($p = 0.003$). Extracranial bleeding occurred in 32 patients (6.3 percent) given thrombolysis, and in six patients (1.2 percent) receiving anticoagulant therapy alone ($p < 0.001$). At day 7, death had occurred in six patients (1.2 percent) given thrombolysis and in nine patients (1.8 percent) given anticoagulant therapy alone; the corresponding rates at day 30 were 2.4 percent and 3.2 percent, respectively.⁹⁹ The findings indicate thrombolytic therapy prevented hemodynamic decompensation, but increased the risk of major bleeding and stroke. The study was not large enough to resolve the key question of whether thrombolysis will improve survival. At present, the risk of thrombolysis outweighs

the benefit for most patients with PE who do not have hypotension but who do have evidence of right ventricular dysfunction. Further trials are needed in this group of patients.

The role of thrombolytic therapy in patients with DVT is limited. Thrombolytic therapy may be indicated in patients with acute massive proximal vein thrombosis (phlegmasia cerulea dolens with impending venous gangrene) or in occasional patients with extensive iliofemoral vein thrombosis who have severe symptoms because of venous outflow obstruction. Thrombolytic therapy can be given by systemic infusion or catheter-directed infusion. Catheter-directed thrombolysis (CDT) is probably effective for reducing the incidence of the postphlebotic syndrome.¹⁰⁰ Although it was hoped that the catheter-directed approach might be associated with a lower risk of major bleeding, particularly intracranial bleeding, than systemic injection, comparative effectiveness research data suggest the risks of bleeding still outweigh the benefits of this approach.¹⁰¹ From a national database of more than 90,000 patients with a principal diagnosis of proximal DVT or thrombosis involving the vena cava, the outcomes of the 3600 patients who received CDT with a similar number of propensity-matched patients treated with anticoagulation alone were compared. The CDT patients were more likely to have intracranial bleeding (0.9 percent vs. 0.3 percent), and transfusion (11.1 percent vs. 6.5 percent), and more likely to have filter placement (34.8 percent vs. 15.6 percent) and to experience PE (17.9 percent vs. 11.4 percent).¹⁰¹ The important message from this analysis of CDT use in practice is that the rate of intracranial bleeding is appreciable (0.9 percent) and not sufficiently low to recommend the use of CDT for DVT, other than exceptional circumstances such as threatened limb viability.

INFERIOR VENA CAVA FILTER

Insertion of an inferior vena cava filter is indicated for patients with acute VTE and an absolute contraindication to anticoagulant therapy and also indicated for the rare patients who have objectively documented recurrent VTE during adequate anticoagulant therapy.

Insertion of a vena cava filter is effective for preventing PE. However, use of a permanent filter results in an increased incidence of recurrent DVT 1 to 2 years after insertion (increase in cumulative incidence at 2 years increases from 12 percent to 21 percent).¹⁰² Therefore, if the indication for filter placement is transient, such as a contraindication to anticoagulation as the result of a temporary high risk of bleeding, a retrievable vena cava filter should be used. A retrievable filter can then be removed in the several weeks to months later, once the filter is no longer required. If a permanent filter is placed, long-term anticoagulant treatment should be given as soon as safely possible to prevent morbidity from recurrent DVT.

CHAPTER 134

ATHEROTHROMBOSIS: DISEASE INITIATION, PROGRESSION, AND TREATMENT

Emile R. Mohler III and Andrew I. Schafer

SUMMARY

The consequences of atherosclerotic vascular disease are the leading cause of morbidity and mortality in the developed countries of the world and are rapidly approaching that status in the developing world. This chapter reviews the pathologic mechanisms of atherosclerotic disease development and progression, and details the interaction of these processes with the coagulation system. The earliest morphologically visible lesion of arterial atherosclerosis, the fatty streak, already is an advanced metabolic and immunologic locus that manifests as abnormalities of vascular tone, inflammation, cellular growth, and endothelial cell dysfunction. After years to decades, the lesions advance to form plaques that grow and eventually either impinge on the arterial lumen or rupture. Rupture of a vulnerable plaque is a catastrophic event that, through activation of both platelets and the coagulation cascade, triggers thrombosis, which leads to complete occlusion, and unless collateral circulation has already been established, results in tissue ischemia. Based on an increased understanding of the pathogenesis and consequences of atheromatous plaque development and progression, medical management of atherothrombotic syndromes has improved and is reviewed for the coronary, cerebrovascular, and peripheral arteries.

Acronyms and Abbreviations: ACC, American College of Cardiology; ACCP, American College of Chest Physicians; ACS, acute coronary syndrome; AHA, American Heart Association; apo, apolipoprotein; aPTT, activated partial thromboplastin time; CABG, coronary artery bypass graft; CAD, coronary artery disease; CAPRIE, Clopidogrel Versus Aspirin in Patients at Risk of Ischaemic Events; CCL, CC chemokine ligand; CK, creatine kinase; CVD, cardiovascular disease; ECG, electrocardiogram; eNOS, endothelial nitric oxide synthase; EPC, endothelial progenitor cell; EV, extracellular vesicle; HAART, highly active antiretroviral therapy; HDL, high-density lipoprotein; hsCRP, high-sensitivity C-reactive protein; IFN, interferon; Ig, immunoglobulin; IL, interleukin; LDL, low-density lipoprotein; Lp-PLA₂, lipoprotein phospholipase A₂; MCP, monocyte chemoattractant protein; MHC, major histocompatibility complex; MI, myocardial infarction; NO, nitric oxide; NOX, nicotinamide adenine dinucleotide phosphate oxidase; NSTEMI, non-ST-segment elevation myocardial infarction; PAD, peripheral arterial disease; PAI, plasminogen-activator inhibitor; PCI, percutaneous coronary intervention; SLE, systemic lupus erythematosus; SNP, single nucleotide polymorphisms; TF, tissue factor; TFPI, tissue factor pathway inhibitor; TGF, transforming growth factor; Th, T helper; t-PA, tissue-type plasminogen activator; VCAM, vascular cell adhesion molecule; VLDL, very-low-density lipoprotein; VWF, von Willebrand factor.

ATHEROSCLEROSIS

Atherothrombosis describes a disease process that begins with atherosclerosis and predisposes to thrombosis in the artery. In the 1850s, Virchow¹ described atherosclerosis as an inflammatory and prothrombotic process. Rokitansky, and later Duguid, posited that atherosclerotic lesions are initiated by incorporation of platelet lipids into the vessel wall (“encrustation”) following thrombosis. It was subsequently demonstrated that insudation of plasma lipoproteins is responsible for most of the lipid content of the atherosclerotic lesions. In 1913, Anitschkow noted atherosclerosis developing in rabbits fed a relatively high cholesterol diet. Although the involvement of inflammation in atherosclerosis has been known for more than 100 years, the molecular mechanisms of atherosclerotic disease initiation and progression have become clearer only in the recent past.² It is now understood that the classical disagreement between the “lipid” hypothesis and the “inflammation” hypothesis of atherogenesis can be reconciled because there is direct linkage between cholesterol deposition and arterial inflammation in the process.^{3,4}

Lipid accumulation in the arterial intima, termed a *fatty streak*, can occur in adolescents and may progress in paroxysmal fashion to a hemodynamically significant lesion causing arterial insufficiency. Autopsy studies of young soldiers and young trauma victims indicated that occult coronary atherosclerotic plaques are commonly present in healthy individuals in their teens and twenties.^{5,6} In addition, intracoronary ultrasonograph studies demonstrated the presence of coronary atherosclerosis in 37 percent of healthy heart donors age 20 to 29 years, 60 percent of those age 30 to 39 years, and 85 percent of those older than age 50 years.⁷ Several theories are espoused for this propitious condition. One well-recognized theory is the *response to injury hypothesis* whereby the inciting event that predisposes to atherosclerosis is injury to the endothelial lining of the artery. This hypothesis was formulated in animal studies that showed vessel narrowing and intimal thickening after endothelial denudation with angioplasty.^{8,9} However, human pathologic studies of early atherosclerotic plaques indicate that endothelium is structurally present but is dysfunctional. The dysfunctional state of endothelium induces abnormalities in vascular tone, inflammation, growth, and thrombosis. Atherosclerotic risk factors contribute to endothelial dysfunction and promote atherosclerosis. This section describes the mechanisms responsible for endothelial dysfunction and the impact of atherosclerotic risk factors.

ATHEROSCLEROTIC RISK FACTORS

Increasing age, male gender, and heredity are the major atherosclerotic cardiovascular disease risk factors that cannot be modified (Table 134-1). Abnormal lipids, smoking, improperly controlled hypertension, improperly controlled diabetes mellitus, abdominal obesity, physical inactivity, and psychosocial factors are established risk factors that can be modified, accounting for most of the risk of myocardial infarction worldwide in both sexes and at all ages.¹⁰

In addition to these traditional risk factors, newer risk factors have been recognized.¹¹ With the use of highly active antiretroviral therapy (HAART), HIV-infected patients have demonstrated a dramatic overall increase in life expectancy.¹² At the same time, HAART-treated HIV patients also have an increased risk of developing premature cardiovascular disease over time. Both HIV viral proteins and the antiretroviral drugs themselves cause endothelial dysfunction. They activate cell signaling cascades, induce oxidative stress, disturb mitochondrial function, alter gene expression, and impair lipid metabolism in vascular cells, macrophages, and adipocytes.^{13,14}

TABLE 134-1. Cardiovascular Risk Factors That Cause Impaired Endothelium-Dependent Vasodilation

Smoking
Dyslipidemia
Hypertension
Diabetes mellitus
Hyperhomocysteinemia

Cardiovascular morbidity and mortality is also recognized to be exceedingly high in patients with chronic renal failure.^{15,16} Increased risk of premature atherosclerotic cardiovascular disease in patients on chronic hemodialysis has been known for many years, but recent studies point to an increased risk even at early stages of chronic kidney diseases. Low glomerular filtration rates and/or proteinuria are independently associated with increased rates of cardiovascular disease.¹⁷ Other factors, such as sympathetic overactivity,¹⁸ are likely to contribute to the pathophysiology of cardiac risk in these patients. Among other emerging risk factors is obstructive sleep apnea, in which treatment may improve cardiovascular outcomes.¹⁹

ENDOTHELIAL DYSFUNCTION

Cardiovascular risk factors and abnormal blood rheology are thought to result in endothelial dysfunction that predisposes the aorta and arteries to atherosclerotic plaque development, sparing the arterioles and capillaries (Fig. 134-1). *Endothelial dysfunction* is a term that encompasses perturbations in the diverse physiologic functions of normal arteries, including regulation of vascular tone, inflammation, growth, and preservation of blood fluidity. Lipid accumulation²⁰ and endothelial

dysfunction are intimately connected and seminal to the initiation and progression of atherosclerosis. Endothelial dysfunction occurs early in the development of plaque and is systemic in nature, afflicting vessels throughout the arterial circulation without gross evidence of atherosclerotic plaque formation. Emerging data indicate that proatherosclerotic genes are upregulated and antiatherosclerotic genes are downregulated in areas of turbulent blood flow, as seen at branch points of arteries,²¹ resulting in vascular adhesion molecule expression and recruitment of monocytes.²² The atherosclerotic plaque initially may expand outward rather than inward into the vessel wall, making some significant lesions difficult to visualize by angiography. The components of the mature atherosclerotic lesion include smooth muscle cells, macrophages, T lymphocytes, and calcification, in addition to accumulation of lipoproteins.²³ Neutrophils and mast cells also are implicated in the atherosclerotic process.²² Later in the process, increased activity of matrix metalloproteinases in the atherosclerotic cap predisposes to plaque rupture or ulceration, resulting in tissue factor (TF) exposure and platelet adhesion, culminating in thrombus formation.²⁴ The thrombus may undergo endogenous fibrinolysis with plaque healing or become occlusive and produce organ damage (e.g., myocardial infarction [MI]). In severe lesions, lamellar bone, presumably from endochondral calcification, may appear.²⁵ There is evolving evidence that extracellular vesicles (EVs), also known as microparticles, are involved in the atherosclerotic process.²⁶ The following sections describe in detail the major manifestations of endothelial dysfunction that occur early in the atherosclerotic process.

Abnormal Vascular Tone

The importance of the endothelium in maintaining vascular tone was first recognized when endothelial cells of rabbit aorta were inadvertently removed and resulted in paradoxical vasoconstriction after administration of acetylcholine.²⁷ The major endothelium-dependent vasodilator normally produced was found to be nitric oxide (NO), a free

Figure 134-1. Schematic showing the life span of the atherosclerotic plaque, beginning with the fatty streak and resulting in a thrombotic event. Cardiovascular risk factors and disturbed blood flow at branch points of vessels are thought to cause endothelial dysfunction that results in atherosclerotic plaque development in the aorta and conduit arteries. Early lipid accumulation in the intimal layer is called the *fatty streak*. A series of stimuli, including lipid peroxidation, are thought to signal adhesion molecule expression on the endothelium, which results in monocyte adhesion and diapedesis into the intimal space. The monocytes develop into macrophages and become sessile with accumulation of lipid (foam cells). Smooth muscle cells, primarily from the media, enter the plaque and participate in cap formation. The plaque accumulates hydroxyapatite mineral and forms calcific deposits. Matrix metalloproteinases also accumulate in the lesion and may predispose to plaque rupture or ulceration resulting in tissue factor exposure and thrombus formation. Risk factor modification favors a more stable plaque, which may have relatively less lipid accumulation and more sclerotic tissue than an unstable plaque. Severe lesions may even develop lamellar bone. ACS, acute coronary syndrome; MI, myocardial infarction; TIA, transient ischemic attack.

radical gas with multiple physiologic properties,²⁸ including inhibition of platelet aggregation and inflammation and stimulation of angiogenesis. Numerous studies indicate that the endothelium does not vasodilate appropriately in the setting of traditional and emerging cardiovascular risk factors. Cardiovascular risk factors are thought to reduce NO availability through a variety of mechanisms, including increased oxidative stress, through generation of reactive oxygen species, and in so doing create an environment conducive to development of atherosclerosis.²⁹ Major sources of reactive oxygen species are nicotinamide adenine dinucleotide phosphate (NADPH) oxidases (NOXs). The catalytic subunits of the NOXs are the NOX proteins and are found in atherosclerotic lesions.³⁰ A reduction in NO synthesis is thought to occur because of decreased availability of tetrahydrobiopterin, an essential cofactor for synthesis of NO.³¹ Administration of sepiapterin, a substrate for tetrahydrobiopterin, improves endothelial dysfunction.³² Also, recent evidence indicates that the transcription factor p53 and the adaptor protein Shc both play essential roles in impairing endothelium-dependent vascular relaxation.³³ High cholesterol levels are thought to produce oxygen free radicals that may inactivate NO. NO synthases are the enzymes responsible for converting L-arginine to NO (Fig. 134–2) (Chap. 115). The enzyme may be perturbed by modified low-density lipoprotein (LDL), resulting in decreased NO production. Supplementation of the diet with L-arginine leads to improvement in endothelial-dependent vasodilation.³⁴ Elevated levels of asymmetric dimethylarginine, an endogenous competitive inhibitor of NO synthase, found in patients with hypercholesterolemia and diabetes, also may result in decreased NO availability.³⁵ Oxidized LDL is thought to increase the elaboration of asymmetric dimethylarginine by endothelial cells and decrease its degradation by the enzyme dimethylarginine dimethylaminohydrolase.³⁶ Administration of acetylcholine to patients with elevated serum LDL³⁷ and relatively low high-density lipoprotein (HDL)³⁸ may result in abnormal vasoconstriction, which can be reversed with nitroglycerin (an endothelium-independent vasodilator).³⁹ Intravenous infusion of HDL improves endothelial-mediated vasodilation through improved

NO availability.⁴⁰ The decreased vasodilatory capacity because of dyslipidemia may facilitate the development of coronary ischemia.

Impaired endothelial vasodilation is noted with advanced aging,⁴¹ when the hands are exposed acutely to cold, and during mental stress. The impairment may be mediated by increased production of endothelin, a potent vasoconstrictor.⁴² Sex differences are also seen in endothelial function as women in middle age tend to have more endothelial vasodilation than men at any age.⁴³ Proinflammatory cytokines may induce formation of endothelial-derived EVs making them a surrogate marker for endothelial dysfunction⁴⁴ and a biomarker for cardiovascular events.⁴⁵ Infection with concomitant inflammation is associated with impaired endothelial vasodilation. For example, repeated infection with *Chlamydia pneumoniae* results in endothelial dysfunction via impaired NO availability.⁴⁶ The combination of coronary artery disease and elevated serum levels of high-sensitivity C-reactive protein (hsCRP) is an independent predictor of abnormal endothelial vasoreactivity.⁴⁷ External radiation therapy also results in endothelial dysfunction and may explain the increased risk of atherosclerosis in patients receiving mantle irradiation for Hodgkin lymphoma.⁴⁸

Endothelial Inflammation

The endothelium does not routinely interact with inflammatory cells but is poised to express adhesion molecules after stimulation with inflammatory mediators. An inflammatory response is thought to begin in the vessel wall after “invasion” of pathogenic lipoproteins.⁴⁹ The presence of lipoproteins, especially oxidized LDL, results in expression of adhesion molecules such as vascular cell adhesion molecule (VCAM)-1 on the luminal surface of endothelial cells, leading to adherence of monocytes (Fig. 134–3).⁵⁰ Endothelial cell expression of adhesion molecules and accumulation of monocytes can be regarded as endothelial dysfunction because these events may occur in the absence of morphologic changes in the vessel wall. Inflammation may develop without the demonstrable presence of an external microbial pathogen. It is now recognized that diseases with inflammatory component such as psoriasis and systemic lupus erythematosus (SLE) confer an increased risk for atherosclerosis and MI.⁵¹ The complex interactions of inflammation and the endothelium on the initiation and progression of atherosclerosis are reviewed in more detail in “Inflammation and Atherosclerosis” below.

Abnormal Control of Vascular Growth: Smooth Muscle Cells and Extracellular Matrix

Normal endothelium inhibits vascular smooth muscle cell proliferation.⁵² The specific function of vascular smooth muscle cells in atherosclerosis is unclear. However, evidence indicates that, in early atherosclerosis, vascular smooth muscle cells contribute to the development of atheroma through production of proinflammatory mediators such as CC chemokine ligand (CCL)2 (previously termed *monocyte chemoattractant protein*, or MCP-1) and VCAMs. Although smooth muscle cells primarily play a role in modulating vascular tone, they also are involved in the control of extracellular matrix formation and degradation through matrix modulators such as proteases, protease inhibitors, matrix proteins, and integrins (Fig. 134–4).

The importance of vascular smooth muscle cells in controlling the synthesis of matrix molecules is evident at the clinical level. They provide a thick, fibrous cap that promotes stability and inhibits plaque rupture and ulceration. Factor VII-activating protease, thought to play a role in coagulation and fibrinolysis, is also a potent inhibitor of vascular smooth muscle cell proliferation, and migration *in vitro* and local application of factor VII-activating protease (but not Marburg I variant) in animal models reduces neointima formation.⁵³ Furthermore, it has been localized to unstable atherosclerotic plaques and may contribute to plaque instability.

Figure 134–2. Vascular tone depends on endothelial production and release of various vasoconstricting and vasodilating substances. The endothelial-derived vasodilators include nitric oxide (NO) and prostacyclin. NO is generated from the amino acid L-arginine by constitutive endothelial NO synthase (eNOS, or NOSIII). The enzyme is stimulated by blood flow across the endothelial surface (shear stress) or by chemical mediators, such as acetylcholine, which stimulate receptors on the endothelial surface. NO diffuses to the underlying smooth muscle cells (SMCs), where it stimulates guanylate cyclase to generate cyclic guanosine V monophosphate (cGMP), which causes smooth muscle relaxation and vasodilation. It also diffuses into blood, where it increases intraplatelet cGMP and thereby inhibits platelet adhesion and aggregation.

Figure 134-3. Atherosclerotic lesion initiation is stimulated by oxidized low-density lipoprotein (OxLDL). Induction of inflammatory gene products in vascular cells is activated by the transcription factor nuclear factor- κ B, which results in increased expression of cellular adhesion molecules. The adhesion molecules have specific functions for endothelial leukocyte interaction. The selectins tether and trap monocytes and other leukocytes. Vascular cell adhesion molecule-1 (VCAM-1) and intracellular adhesion molecule-1 (ICAM-1) mediate firm attachment of these leukocytes to the endothelial layer. OxLDL also augments expression of monocyte chemoattractant protein-1 (MCP-1 or CCL2) and macrophage colony-stimulating factor (M-CSF). MCP-1 mediates the attraction of monocytes and leukocytes and facilitates diapedesis through the endothelium into the intima. M-CSF is an important cytokine for the transformation of monocytes to macrophage foam cells. Macrophages express scavenger receptors and internalize oxidized low-density lipoprotein (LDL) during their transformation into foam cells. Smooth muscle cells migrate from the media into the intima and participate in the formation of a fibrous atheroma. (Adapted with permission from S Kinlay, AP Selwyn, P Libby: *Inflammation, the endothelium, and the acute coronary syndromes*. *J Cardiovasc Pharmacol* 32[Suppl 3]:S62, 1998.)

Evidence indicates that vascular smooth muscle cells that undergo apoptosis, especially at the shoulder region of the plaque, may create a more unstable cap.⁵⁴ Both intact vascular smooth muscle cells and fibroblasts are thought to stabilize plaques through modulation of extracellular calcification and formation of a fibrocalcific plaque.

Vascular smooth muscle cells arise primarily from the medial layer and are considered monoclonal in origin.⁵⁵ Evidence also indicates that vascular smooth muscle cells may originate from the adventitia.⁵⁶ The rate and timing of smooth muscle cell replication is unclear. It may occur at a constant low rate throughout the development of the atherosclerotic lesion or episodically at a higher rate. Animal studies indicate that new intimal cells may originate from outside the vessel wall from subpopulations of marrow- and non-marrow-derived circulating cells.⁵⁷ Smooth muscle progenitor cells circulating in blood may contribute to the arterial remodeling that occurs after angioplasty and after bypass graft surgery.⁵⁸

Vascular proliferation and inflammation are linked processes. Inflammation-induced impaired NO bioactivity contributes to vascular smooth muscle proliferation.² Overexpression of NO synthase results in reduction of atherosclerotic or restenotic lesion formation in rabbits through both inhibition of vascular smooth muscle cell proliferation and inhibition of adhesion and chemoattractant molecule expression, with subsequent reduction of vascular mononuclear cell infiltration.⁵⁹ Thus, the vascular smooth muscle cell participates in the atherosclerotic process by affecting lipoprotein retention, modulating inflammation, and controlling plaque stability through formation of the fibrous cap. Several vascular disorders involve vascular smooth muscle proliferation as the primary pathophysiologic mechanism, including in-stent restenosis, transplant vasculopathy, and vein bypass graft failure.⁶⁰ The control of smooth muscle proliferation is thought to involve NR4A nuclear receptors that are expressed in atherosclerotic lesion macrophages, smooth muscle cells, and endothelial cells, and are induced by atherogenic stimuli. Inhibition of the transcriptional activity of the NR4A nuclear receptors results in enhanced smooth muscle proliferation.⁶¹

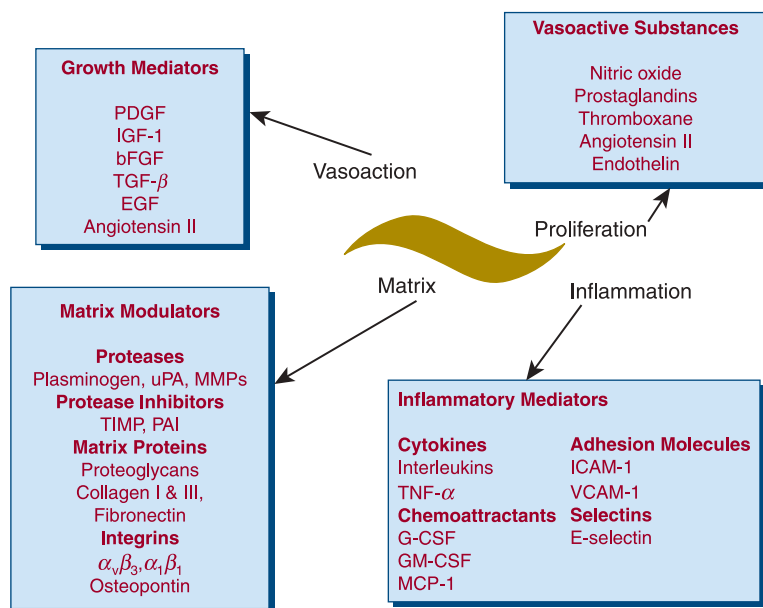

Figure 134-4. Vascular smooth muscle cells mediate vascular proliferation, inflammation, matrix composition, and contraction. Many of these mediators have multiple functions. For example, angiotensin is a vasoconstrictor, but it also stimulates proliferation and inflammation. This is only a partial list of mediators secreted by vascular smooth muscle cells. bFGF, Basic fibroblast growth factor; EGF, epidermal growth factor; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; ICAM, intracellular adhesion molecule; IGF, insulin-like growth factor; MCP, monocyte chemoattractant protein; MMPs, matrix metalloproteinases; PAI, plasminogen-activator inhibitor; PDGF, platelet-derived growth factor; TGF- β , transforming growth factor- β ; TIMP, tissue inhibitor of metalloproteinases; TNF, tumor necrosis factor; uPA, urokinase-type plasminogen activator; VCAM, vascular cell adhesion molecule. (Adapted with permission from Dzau VJ, Braun-Dullaeus RC, Sedding DG: *Vascular proliferation and atherosclerosis: New perspectives and therapeutic strategies*. *Nat Med* 8(11):1249–1256, 2002.)

The NR4A nuclear receptors are also expressed in vein segments exposed to arterial pressure and it is postulated that they are responsible for an inhibitory feedback mechanism that occurs in activated vascular cells. Drug-eluting vascular stents that release agents such as sirolimus and paclitaxel interfere with the cell cycle and inhibit restenosis in part via decreased smooth muscle cell proliferation.⁶²

Abnormal Endothelial Control of Blood Fluidity

Endothelial cells normally elaborate a number of antithrombotic substances. Some of these substances are released into blood whereas others are properties of the unactivated endothelial cell surface. These antiplatelet, anticoagulant, and profibrinolytic activities of endothelium, some of which also possess vasodilatory properties (e.g., prostacyclin, NO), act in concert to promote blood fluidity under normal circumstances. Acute activation or chronic dysfunction of endothelial cells alters the hemostatic balance, transforming them from predominantly antithrombotic to prothrombotic cells.⁶³

To this end, endothelial cells modulate the activities of thrombin in health and disease. In the presence of intact and normally functioning endothelium, the prothrombotic actions of thrombin are quenched and the antithrombotic actions of the enzyme predominate. Thrombin binds to thrombomodulin, an integral membrane protein expressed by endothelial cells, and activates protein C (accelerated in the presence of endothelial protein C receptor, another endothelial cell protein) (Chap. 116). Activated protein C, in concert with its cofactor, protein S, has anticoagulant and profibrinolytic actions. It degrades by proteolytic digestion factors Va and VIIIa, and inactivates plasminogen-activator inhibitor (PAI)-1. Simultaneously, by binding to thrombomodulin, enzymatically active procoagulant thrombin is removed from the circulation, thereby limiting its availability to catalyze fibrin formation. Endothelial dysfunction causes loss of thrombomodulin activity from the vascular surface. In fact, increased circulating plasma levels of free (truncated) thrombomodulin represent a marker of endothelial damage. In addition to the role of thrombomodulin in clearance of circulating thrombin, the procoagulant activity of thrombin is normally blocked by endothelial cells through the action of antithrombin, which binds to heparin-like glycosaminoglycans on their luminal surface, thereby catalyzing the inactivation of thrombin by antithrombin. Like thrombomodulin, this thrombin-neutralizing action of endothelial heparan sulfate glycosaminoglycans is lost with endothelial dysfunction.

Endothelial cells do not normally express TF, but they do so upon activation by inflammatory cytokines or exposure to endothelium-activating levels of homocysteine or free thrombin. The procoagulant effects of expression of TF by dysfunctional endothelial cells are potentially compounded by the loss of TF pathway inhibitor (TFPI), which normally is synthesized by endothelial cells. Studies show that monocyte-derived EVs (or microparticles) express TF and platelet-derived EVs express phosphatidylserine and thus support coagulation complex formation.⁶⁴ There is also evidence that P-selectin on platelets binds to P-selection protein ligand-1 on EVs.⁶⁵

Normal endothelium is profibrinolytic. It synthesizes and releases tissue-type plasminogen activator (t-PA); it possesses binding sites for t-PA and plasminogen to provide a surface for the concentrated assembly of the fibrinolytic complex and thereby enhance local plasmin generation; and it fails to produce significant amounts of PAI-1. This profibrinolytic state is converted to an antifibrinolytic state in the presence of endothelial dysfunction. In activated or dysfunctional endothelium, PAI-1 gene expression and PAI-1 secretion are induced; simultaneously, the profibrinolytic properties of normal endothelium are lost (Chap. 135).

The antithrombotic profile of normal endothelium also manifests through the elaboration of several antiplatelet substances. NO is constitutively released into blood by normal endothelial cells and inhibits

platelet adhesion and aggregation by stimulating platelet soluble guanylyl cyclase and raising intraplatelet levels of cyclic guanosine monophosphate (see Fig. 134–2).⁶⁶ Physiologic flow and shear forces maintain the activity of endothelial (endothelium-derived) NO synthase (eNOS)⁶⁷ under normal circumstances. Vascular cell-derived carbon monoxide, a product of heme catabolism by heme oxygenase, may have similar antiplatelet activity.^{68,69} Prostacyclin (prostaglandin I₂) likewise is released basally by normal endothelial cells and inhibits platelet aggregation by inducing platelet adenylyl cyclase and raising intraplatelet levels of cyclic adenosine monophosphate.⁷⁰

NO, carbon monoxide, and prostaglandin I₂ are labile autacoids, acting only in the immediate vicinity of their release into blood from endothelial cells. An endothelial surface ecto-adenosine diphosphatase (CD39) also blocks platelet activity by metabolizing and disposing of platelet agonist adenosine diphosphate (ADP).⁷¹ In endothelial dysfunction, these various antiplatelet activities are lost, and endothelial release of von Willebrand factor (VWF) is increased, which promotes platelet adhesion. In the case of NO, oxidative stress in the microenvironment of endothelial dysfunction actually “uncouples” eNOS activity^{68,72} to preferentially generate superoxide over NO. Oxygen free radicals bind any remaining available NO to produce the toxic product peroxynitrite. Bioactive NO is further reduced in endothelial dysfunction by the presence of asymmetric dimethylarginine, which competes to block eNOS and limit NO production.^{67,73}

Progenitor Cells and Atherosclerosis

Endothelial progenitor cells (EPCs) are heterogenous in origin and participate in endothelial cell regeneration and neovascularization of ischemic tissue. The mobilization of EPCs from the marrow is stimulated by hypoxia, cytokines such as vascular endothelial growth factor, hormones such as erythropoietin, and statin drugs, whereas mobilization is inhibited in the diabetic state.⁷⁴ The role of EPCs in atherosclerosis is unclear as there are conflicting data.²² A study in apolipoprotein (apo) E^{-/-} mice showed that there is rapid turnover of endothelial cells in atherosclerosis-prone areas and marrow derived EPCs are recruited to sites of atheroprogession.⁷⁵

INFLAMMATION AND ATHEROSCLEROSIS

Innate Immunity and Atherosclerosis

The endothelial response to injury manifests as a chronic inflammatory response that involves both innate and adaptive immunity.⁷⁶ Innate immunity provides the first line of defense for the host and involves several cell types, most importantly macrophages and dendritic cells, which express a limited number of highly conserved sensing molecules such as scavenger receptors and toll-like receptors.^{76,77} Microbial infection can be detected by pathogen-associated molecular patterns, which are present in bacteria, viruses, and yeasts, but not in mammalian cells, and are recognized by the toll-like receptors.⁷⁸ Ligation of a pathogen or other substances containing pathogen-associated molecular patterns (such as lipopolysaccharides, aldehyde-derivatized proteins, mannans, teichoic acids) elicits endocytosis or activation of endothelial cells (e.g., through nuclear factor- κ B) that results in an inflammatory response (Chaps. 17 and 18).^{77,79} Proinflammatory cytokines, such as tumor necrosis factor, nuclear factor- κ B and interleukin (IL)-1, magnify the innate inflammatory response.

Innate defense involves soluble factors, such as complement, which is involved in atherosclerotic lesion formation. hsCRP has been found to be an important and independent predictor for cardiovascular events.⁸⁰ Natural antibodies that are generated in the absence of known antigen stimulation, mainly immunoglobulin (Ig) M, provide an immediate response against bacteria and viruses but also may be involved in atherosclerosis. For example, innate B lymphocytes, the so-called

B1 cells, express a restricted set of germline-encoded antigen receptors that may bind oxidized LDL.

Adaptive Immunity and Atherosclerosis

Compared to innate immunity, adaptive immunity is slower but more precise (Chap. 77).⁷⁶ T cells can be activated by dendritic cells and macrophages, whereas most antigens cannot stimulate B cells without assistance from CD4+ T cells, which recognize the peptide-major histocompatibility complex (MHC) complexes on B cells. By genetic recombination, the number of T-cell and B-cell receptors that can be formed is almost unlimited and far exceed the number of pattern recognition receptors used by the innate immune system. Most CD4+ cells are cytokine-secreting T-helper (Th) cells and express $\alpha\beta$ -T-cell receptors, which interact with MHC class II molecules. A smaller number of Th cells express $\gamma\delta$ -T-cell receptors, which interact with the nonpolymorphic, nonclassic MHC molecules, CD1, which present certain antigens (particularly lipids and glycolipids). Th cells are classified according to the cytokines they secrete. Th1 cells secrete interferon (IFN)- γ and IL-2 and promote cell-mediated immunity (Chap. 78). Th2 cells secrete IL-4, IL-5, IL-10, and IL-13, and help B cells produce antibodies. CD8+ T cells are primarily cytotoxic killer cells, although they can secrete cytokines, such as tumor necrosis factor- α , IFN- γ , and lymphotoxin. Some thymus-independent antigens can activate these cells without the help of T cells. Oxidized LDL is considered such an antigen because it expresses multiple copies of oxidation-specific epitopes on a single LDL particle.

Adhesion Molecules and Atherosclerosis

Monocyte recruitment to inflammatory foci initially involves the expression of endothelial cell selectins, which mediate monocyte rolling on the endothelium (see Fig. 134-3). The rolling phenomenon is followed by a firmer attachment to endothelial cells mediated by integrins. Perhaps the most important of these is VCAM-1, which is upregulated in cultured endothelial cells in the presence of oxidized LDL. The appearance of this molecule before the development of grossly visible atherosclerotic lesions supports oxidized LDL as an initial recruiter of macrophages. The finding of reduced atherosclerosis in VCAM-1-deficient mice further supports the important role of macrophages and VCAM-1 in the pathogenesis of atherosclerosis.^{81,82} Other adhesion molecules, such as P-selectin and intracellular cell adhesion molecule-1, also may be involved in monocyte adhesion at sites of lesion formation.⁸³ The entry of monocytes into the vascular intima leads to their differentiation into resident macrophages. Here they take up cholesterol that has also accumulated in the vascular intima, thereby becoming cholesterol-engorged foam cells.⁸⁴ It has been demonstrated that the accumulation of macrophage foam cells in established atherosclerotic lesions actually originates mainly from the proliferation of macrophages within the lesion rather than from the recruitment of circulating monocytes.⁸⁵ Platelet-derived EVs contain and deliver the chemokine “regulated upon activation, normal T-cell expressed and secreted” (RANTES) to activate endothelium in atherosclerosis to promote attraction of monocytes.⁸⁶

Lipoprotein Phospholipase A₂ and Atherosclerosis

Lipoprotein phospholipase A₂ (Lp-PLA₂) is an inflammatory enzyme belonging to the large family of phospholipases that are capable of hydrolyzing the sn-2 ester bond of phospholipids of cell membranes and lipoproteins.⁸⁷ This enzyme, produced by macrophages, circulates bound to LDL and in the intimal space of the artery can produce oxidized fatty acids and lysophosphatidyl choline. These molecules have a range of potentially atherogenic effects, including chemoattraction of monocytes, increased expression of adhesion molecules, and

inhibition of endothelial NO production.⁸⁸ Although originally designated as platelet-activating factor acetylhydrolase because of its ability to degrade platelet-activating factor, the clinical importance of this effect is not thought significant. Numerous epidemiologic studies show that Lp-PLA₂ is a significant biomarker associated with cardiovascular events. The selective inhibition of Lp-PLA₂ with the drug darapladib reduced development of advanced coronary atherosclerosis in diabetic and hypercholesterolemic swine.⁸⁹ A phase 2 clinical study of patients with cardiovascular disease showed that sustained inhibition of plasma Lp-PLA₂ activity with background of intensive atorvastatin therapy resulted in reduction in IL-6 and hsCRP after 12 weeks of darapladib 160 mg, suggesting a possible reduction in inflammatory burden.⁹⁰ However, a prospective double-blind phase III trial of 15,828 patients, darapladib did not reduce the composite end point of cardiovascular death, MI, or stroke. There was a significant reduction in major coronary events and total coronary events.⁹¹

Immune Cells and Atherosclerosis

Macrophages are essential for the clearance of modified lipoproteins and the efflux of lipoprotein-derived cholesterol to HDL receptors for reverse cholesterol transport, the process by which HDL removes cholesterol from cells. Multiple lines of evidence indicate that macrophages promote lesion initiation and progression. For example, hypercholesterolemic mice become markedly resistant to atherosclerosis if they are bred to macrophage-deficient animals.⁹²

The earliest grossly visible sign of atherosclerosis is the fatty streak, which is composed mainly of macrophage foam cells containing relatively large amounts of cholesterol. Foam cells also can derive from smooth muscle cells, as these cells can express scavenger receptors when appropriately activated.^{93,94} Formation of the fatty streak is thought to begin with adherence of circulating monocytes to activated endothelial cells at sites in the arterial system prone to atherosclerotic disease, such as at branch points in vessels. Multiple chemoattractant molecules have been identified in these nascent lesions, which recruit monocytes and induce their diapedesis into the subendothelial space where they further differentiate into macrophages. As noted above, however, more recent evidence indicates that microenvironment-supported macrophage proliferation *in situ* within the atherosclerotic lesion is likewise a key event in atherogenesis.⁸⁴

The chemoattractant CCL2 (MCP-1) facilitates recruitment of monocytes to atherosclerotic lesions, as noted in studies of mouse models of atherosclerosis, such as apoE-/- or LDL receptor (LDLR-/-)-deficient mice fed a Western-style diet. When these mice are crossed to the model lacking CCL2, or its receptor CCR-2, lesion development decreases significantly.⁹⁵⁻⁹⁷

Macrophages and T cells were once thought to be the only inflammatory cells to significantly promote angiogenesis. More recent data showing that neutrophils are found at sites of plaque rupture or erosion and in thrombus from patients with acute coronary artery syndromes indicate that they also have an important role in atherothrombosis.¹⁸ Mast cells have been found in the adventitia of lesions and in areas of plaque hemorrhage; they have been implicated in macrophage apoptosis, increased vascular permeability, degradation of HDL and reduced cholesterol efflux.²² Neutrophils and mast cells are recruited to atherosclerotic lesions in response to CXC-chemokine receptor 2 (CXCR2) signals. The mobilization of neutrophils to atherosclerotic lesions is inhibited by CXC-chemokine receptor 4 (CXCR4) and its ligand CXC-chemokine ligand 12 (CXCL12; also known as stromal-derived factor (SDF) 1). A subset of CD31+ T cells, so called T_{ang} cells, was shown to promote endothelial repair and revascularization, and to be inversely correlated with age and cardiovascular disease (CVD) risk in patients undergoing coronary angiography.⁹⁸

Lipid Peroxidation and Atherosclerosis

Macrophages control the amount of cholesterol loading by downregulating the native LDL receptor. Therefore, knowing how cholesterol is taken up into macrophages is important. Cell culture experiments revealed a “foam cell paradox,” in which macrophages engulf only modified lipids. Treatment of native LDL with copper or acetic anhydride (causing acetylation) led to increased LDL uptake through use of the scavenger receptor, leading to the formation of lipid-laden macrophages. These experiments led to the peroxidation theory of atherosclerosis,⁹⁴ whereby LDL modification is an essential step in the development of foam cells. Although the precise mechanisms responsible for LDL oxidation remain unclear, enzymes including myeloperoxidase, inducible NO synthase, and NADPH oxidases are involved in the process.^{99,100} Of note, macrophages express each of these enzymes, which normally are used as antimicrobial reactive oxygen species essential for innate immunity.¹⁰¹ Thus, accumulation of cholesterol in the macrophage occurs via scavenger (not LDL) receptors of oxidized (and not native) LDL. Myeloperoxidase is an enzyme thought to cause lipid peroxidation in the intimal space and circulating levels are associated with adverse clinical outcomes in the setting of acute coronary syndromes and predictive of major adverse cardiovascular events.⁹⁹

Scavenger Receptors and Atherosclerosis

Conserved pattern recognition receptors expressed by macrophages include scavenger receptors A and B1 and CD36, all of which internalize oxidized LDL.^{102,103} Macrophages express various genes in response to oxidized LDL, including peroxisome proliferator-activated receptor- γ and adenosine triphosphate-binding cassette transporter A1, which profoundly influence macrophage-mediated inflammation and atherosclerotic activity.

Cell culture studies indicate that scavenger receptor A recognizes acetylated LDL but, unlike the LDL receptor, is not downregulated in response to increased cholesterol content and thus likely accounts for foam cell formation.¹⁰⁴ However, no evidence indicates that acetyl LDL is generated *in vivo*, indicating other modifications of LDL, such as oxidation, may be required for foam cell formation.^{105,106} Another scavenger receptor presumed to be involved in the atherosclerotic process is CD36, a receptor that avidly binds oxidized LDL.

Circulating IgG and IgM antibodies against products of lipid peroxidation are present in the plasma of animals and humans.¹⁰⁷ These antibodies closely correlate with measures of lipid peroxidation and with atherosclerotic progression and regression in murine models.¹⁰⁸ Immunization of hypercholesterolemic rabbits and mice with products of oxidized LDL, such as malonyldialdehyde LDL or copper-oxidized LDL, inhibits the progression of atherosclerotic lesion formation.^{109–112} These experiments have been interpreted to indicate that an immunologic response to oxidized LDL components can alter the atherosclerotic process.

Leukocyte-derived 5-lipoxygenase also contributes to atherosclerosis susceptibility in mice.¹¹³ Animal studies indicate the importance of lipoxygenases in atherosclerosis as disruption of the 12,15-lipoxygenase gene diminishes atherosclerosis in apoE-deficient mice, and overexpression of 15-lipoxygenase in vascular endothelium accelerates early atherosclerosis in LDL receptor-deficient mice.^{114,115} This enzyme is under study as a potential target to inhibit the atherosclerotic process.¹¹⁶

Gut Microbiome There are newer data indicating that intestinal microbes are involved in cardiometabolic diseases.¹¹⁷ Systemic inflammation is activated in the setting of chronic bacterial translocation (secondary to increased intestinal permeability) leading to macrophage influx into adipose tissue resulting in insulin resistance and nonalcoholic fatty liver disease. The increased inflammation may also be secondary to trimethylamine-*N*-oxide via influx of macrophages

and cholesterol accumulation via upregulation of macrophage scavenger receptors and reduction in reverse cholesterol transport. Thus, gut microbiota may accelerate atherosclerosis risk.

Accumulation of Low-Density Lipoprotein in the Vascular Wall

Three potential factors lead to accumulation of LDL in the vascular wall: increased permeability of the endothelium, prolonged retention of lipoproteins in the intima, and slow removal of lipoproteins from the vessel wall.¹¹⁸ Rabbits fed a high-cholesterol diet develop aortic wall lesions at specific lesion-susceptible sites; however, endothelial permeability is not increased at those sites, indicating that LDL is selectively retained in these regions.^{119,120} Retention of LDL molecules likely results from their adherence to proteoglycans in the vessel wall.¹²¹ LDL genetically engineered to not bind to proteoglycans is hypothesized to be less atherogenic than native LDL.²⁰

Oxidized LDL and its products, oxidized phospholipids and oxysterols, have other properties that make them potentially proatherogenic.¹²² These properties include proinflammatory characteristics, such as chemotactic signaling for monocytes, smooth muscle cells, and T lymphocytes (but not for B lymphocytes or neutrophils, neither of which is found in lesions) and increased expression of VCAM-1 on, and stimulation of CCL2 release from, endothelial cells.¹²³ Oxidized LDL also may contribute to instability of the atherosclerotic plaque via induction of type 1 metalloproteinase expression and increase in TF activity.¹²⁴ For oxidized LDL to be a ligand for the scavenger receptor, extensive degradation of the polyunsaturated fatty acid in the sn-2 position of phospholipids by oxidation is essential.

To test the oxidized LDL hypothesis, several clinical studies have been conducted using antioxidant vitamins, most commonly vitamin E; however, most of the completed studies gave negative results.^{125,126} At the present time, treatment with vitamin E does not appear to be beneficial in preventing cardiovascular events.

High-Density Lipoprotein and Atherosclerosis

A low level of HDL cholesterol is a strong predictor of adverse cardiovascular events, presumably because the low level is associated with insufficient reverse cholesterol transport. Animal studies using liver-directed gene transfer of human apoA-apoI resulted in significant promotion of reverse cholesterol transport and regression of preexisting atherosclerotic lesions in LDL receptor-deficient mice.^{127,128} The HDL level may not be as important as amount of reverse cholesterol transport. For example, the capacity of HDL to accept cholesterol from macrophages is predictive of atherosclerotic burden.¹²⁹ However, HDL has additional antiatherogenic properties that may confer protection against atherosclerosis.¹³⁰ For example, HDL is protective against oxidation of LDL, at least in part because of paraoxonase, an enzyme physically associated with HDL that degrades organophosphates.¹³¹ Paraoxonase polymorphisms are associated with increased risk of CVD, also indicating that oxidized LDL is an important factor in atherosclerotic development.¹³²

Research studies currently are evaluating novel ways to increase HDL levels or to use apoA-apoI variants and mimetics that hopefully will cause regression of atherosclerosis. So far, initial clinical studies were not successful. Cholesteryl ester transfer protein promotes the transfer of cholesteryl esters from antiatherogenic HDLs to proatherogenic apoB-containing lipoproteins, including very-low-density lipoproteins (VLDLs), VLDL remnants, intermediate-density lipoproteins, and LDLs. A deficiency of this molecule results in increased HDL levels and decreased LDL levels, a lipid profile that is antiatherogenic. A large clinical study in humans showed that inhibition of the transfer protein with torcetrapib increased HDL levels but was associated with increased

mortality and hypertension.¹³³ It is supposed that the increase in mortality was a result of an off-target effect of the drug increasing blood pressure and not because of cholesterol ester transfer protein inhibition. Clinical trials evaluating the effect of other inhibitors of cholesteryl ester transfer protein on atherosclerosis and cardiovascular events have not shown clinical efficacy thus far. Along similar lines, delivery of a mutant form of apoA1 (apoA1 Milano) resulted in regression of plaque size as measured by intravascular ultrasound in a small phase II clinical trial.¹³⁴ However, studies evaluating the effect of apoA1 mimetics on atherosclerosis also have not shown compelling data regarding reducing plaque size or cardiovascular events.¹³⁵

CD40, CD40 Ligand, and Atherosclerosis

Studies indicate that human atherosclerotic lesions express the immune mediator CD40 and its soluble ligand, sCD40L. Increasing evidence indicates that the CD40–sCD40L signaling pathway plays a central role in several inflammatory processes, including atherosclerosis and graft rejection following transplantation.¹³⁶ Interruption of CD40 signaling in hyperlipidemic mice reduces the size of aortic atherosclerotic lesions and their lipid, macrophage, and T-lymphocyte content.¹³⁷ Atorvastatin, lovastatin, pravastatin, and simvastatin reduce IFN- γ -induced CD40 expression in a dose-dependent manner. Activation of atheroma-associated cells with human recombinant sCD40L is reduced when cells are treated with statins. In addition, retrospective *ex vivo* immunostaining of human carotid atherosclerotic lesions of patients treated with simvastatin for more than 3 months revealed less CD40 expression and atheroma-associated cells compared with patients who were not treated with the drug. A reduction in sCD40L is associated with pravastatin or cerivastatin therapy.¹³⁸ These findings support the notion that statins are antiinflammatory, in addition to their cholesterol-lowering effects.

Transforming Growth Factor- β and Atherosclerosis

Transforming growth factor (TGF)- β is a cytokine secreted by macrophages, smooth muscle cells, and the Th3 subset of Th cells that has multiple regulatory functions. TGF- β is speculated to contribute to plaque stabilization because it stimulates collagen synthesis and is fibrogenic. One study found that inhibition of TGF- β signaling by neutralizing antibodies led to a larger plaque size with an unstable phenotype.¹³⁹ Further studies are needed to clarify the role of TGF- β in atherosclerotic plaque initiation and growth.

ABO Blood Type and Cardiovascular Risk The ABO blood group is determined from presence of A and B antigens on the surface of the red blood cells and is thought to confer cardiovascular risk.¹⁴⁰ These antigens are also expressed on the surface of platelets and the endothelium and consist of terminal carbohydrate molecules which are synthesized by the sequential action of the ABO glycosyltransferases. Genetic studies showed that carriers of single nucleotide polymorphisms (SNPs) that mark non-O blood group types have higher levels of plasma VWF when compared to O individuals. Epidemiologic and genetic studies show that the non-O blood group is associated with adverse cardiovascular events. One study demonstrated that the SNP rs514659 was associated with coronary artery diseases (CADs) when complicated by MI but not with CAD without MI, suggesting that the primary relationship of ABO to clinical CAD is through modulation of coronary thrombosis or plaque rupture in patients with established coronary atherosclerosis rather than through primary promotion of atherosclerosis per se.

Infection and Atherosclerosis

Several infectious agents have been implicated as pathogens in atherosclerosis.¹⁴¹ A well-studied infectious pathogen is *C. pneumoniae*. Animals infected with this agent develop atherosclerosis, and patients

with CVD have higher titers of antibodies against this pathogen. Viruses, such as herpes simplex and cytomegalovirus, also are implicated in human atherosclerotic lesion formation. Gingivitis as a consequence of poor dental hygiene or smoking may lead to cellular immune activation and provoke atherosclerosis by cytokines or antibodies.¹⁴² Endogenous proteins, such as heat shock proteins, also are implicated in atherosclerosis. One study showed that progression of carotid disease correlated with antibodies against heat shock proteins 65 and 60.¹⁴³

Splenectomy and Atherosclerosis

The relationship between the immune system and atherosclerosis is complex, as evident from an animal study that showed that splenectomy of cholesterol-fed apoE-/- mice led to significantly increased atherosclerosis.¹⁴⁴ This proatherogenic effect was rescued by transfer of either purified B cells or T cells from the spleens of atherosclerotic apoE-/- donors. A long-term study of soldiers who underwent splenectomy after trauma found the soldiers had a twofold increased incidence of CAD, providing evidence that the spleen has antiatherogenic activity.¹⁴⁵ Further studies are needed to determine if splenectomy significantly impacts the atherosclerotic process, and if so, by what mechanism.

Genetics and Myocardial Infarction

Atherosclerotic disease is a complex human trait involving multiple genes and environmental factors. Through the study of linkage analysis of families and sibling pairs as well as candidate genes and genome-wide association studies, the genetic predisposition to MI is starting to be understood.¹⁴⁶ The clinical importance of this knowledge is the potential identification of markers of disease for risk prediction and potential intervention to lower the risk of atherosclerotic-based cardiovascular events.

The use of genome-wide linkage analyses of families or sib-pairs has identified chromosomal loci linked to or genetic variations in the arachidonic 5-lipoxygenase-activating protein gene (*ALOX5AP*)¹⁴⁷ and leukotriene A₄ hydrolase gene (*LTA₄H*).¹⁴⁸ The genes are both involved in inflammation-related pathway of leukotriene B₄ production. Interestingly, a small molecule inhibitor of ALOX5AP was shown to reduce leukotriene production and plasma levels of C-reactive protein.

Several association studies of unrelated individuals have identified genetic variations that confer susceptibility to atherosclerotic disease and cardiovascular events. Studies using genome-wide linkage analysis identified four SNPs on chromosome 9p21.3 that were associated with MI in white cohorts.^{146,149} Other genetic polymorphisms also contribute to increased risk of CVD through a variety of mechanisms.¹⁵⁰

ATHEROSCLEROTIC PLAQUE

Plaque Classification

The American Heart Association classification of atherosclerotic plaques into types I through VIII is based on lesion composition and structure (Fig. 134–5).²³ Types I through III atherosclerotic plaques have foam cells organized in a fatty streak, ranging from those not visible on close examination (type I) to those that are apparent on examination (type III). Types I through III lesions are small and clinically silent, whereas types IV through VI lesions may obstruct the lumen and produce a clinical event. Type IV lesions contain a confluent pool of lipid and in most patients do not cause anginal symptoms because of the ability of the artery to remodel outward. Type V lesions contain a fibromuscular cap resulting from replacement of tissue disrupted by accumulated lipid and hematoma or organized thrombotic deposits. Type VI lesions involve thrombosis that may be either mural or obstructive. Of note, a type IV lesion may develop type VI changes without ever passing through a type V change and accumulating significant fibrous tissue. Plaques that are

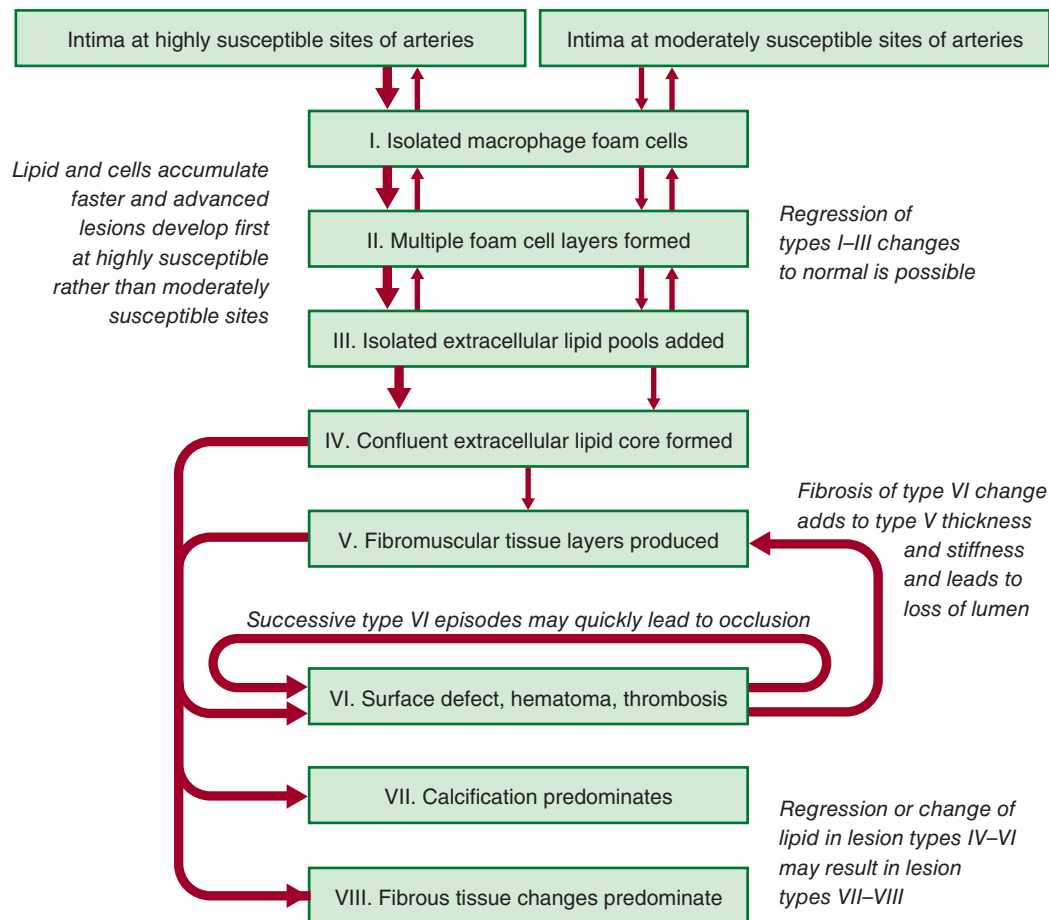

Figure 134-5. Flow diagram in center column indicates pathways in evolution and progression of human atherosclerotic lesions. Roman numerals indicate histologically characteristic types of lesions. The direction of arrows indicates sequence in which characteristic morphologies may change. From type I to type IV, changes in lesion morphology occur primarily because of increasing accumulation of lipid. The loop between types V and VI illustrates how lesions increase in surfaces. Thrombotic deposits may develop repeatedly over varied time spans in the same location and may be the principal mechanism for gradual occlusion of medium-sized arteries.

complex and primarily composed of calcium are type VII lesions or, if fibrous tissue predominates, are type VIII lesions.

Vulnerable Plaque and the Vulnerable Patient

The pathologic mechanisms responsible for converting chronic coronary atherosclerosis to an acute coronary event result, in part, from *plaque disruption*, a term that was synonymously used with *plaque rupture*.^{151,152} The term *vulnerable plaque* was used by Muller and colleagues^{153,154} to describe rupture-prone plaques as the underlying cause of most clinical coronary events. The current definition for “vulnerable plaque” includes all thrombosis-prone plaques and those with a high probability of undergoing rapid progression, thus becoming culprit plaques (Fig. 134-6).¹⁵⁵ Criteria for development of the vulnerable plaque have been proposed based on histopathologic study of culprit plaques (Table 134-2).¹⁵⁵ The major criteria involve the presence of active inflammation, a thin cap with large lipid core, endothelial denudation with superficial platelet aggregation, a fissured plaque, and stenosis greater than 90 percent. The minor criteria for a vulnerable plaque include superficial calcified nodule, glistening yellow plaque, intraplaque hemorrhage, endothelial dysfunction, and outward (positive) remodeling. Some studies indicate plaques that are heavily calcified and without a significant lipid core are more stable.^{25,48}

An important concept concerning plaque remodeling is that atherosclerotic plaques commonly grow outward (positive remodeling) before a luminal stenosis occurs. Therefore, a contrast dye coronary angiogram

may underestimate the plaque burden in the vessel. Arterial thrombosis may result from plaque hemorrhage (majority of events) or occur in an area of endothelial denudation (30 to 40 percent) without breach of the intimal space.¹⁵⁶ Thrombosis has also been reported in plaques that have a superficial calcified nodule protruding into the lumen.¹⁵⁶ Most atherosclerotic plaques that underlie a fatal or nonfatal MI are, as shown by angiography, less than 70 percent stenosed.¹⁵⁷ Some patients have more than one vulnerable plaque, which underscores the importance of medical therapy in addition to coronary revascularization.¹⁵⁸ Several technologies are currently being tested to identify the location of the vulnerable plaque.¹⁵⁹ Hopefully these developing technologies will shed more light on the natural history of the vulnerable plaque and afford the ability to conduct studies using local or regional antiatherosclerotic therapy.

Because of the dynamic interaction of atherosclerotic plaque with circulating blood, the term *cardiovascular vulnerable patient* has been proposed to define subjects susceptible to an acute coronary syndrome (ACS) or sudden cardiac death based on atherosclerotic plaque or blood or myocardial vulnerability.¹⁶⁰ The vulnerable (thrombogenic) blood includes serum markers of atherosclerosis and inflammation, such as hsCRP, inflammatory cytokines (e.g., IL-6, sCD40L), EVs, and hypercoagulable factors. The blood markers of vulnerability that reflect the hypercoagulable state include those of the fibrinolytic system and platelets (Table 134-3).¹⁶¹ Patients may have an MI because of a non-fatal or fatal arrhythmia as a result of coronary atherosclerosis or other

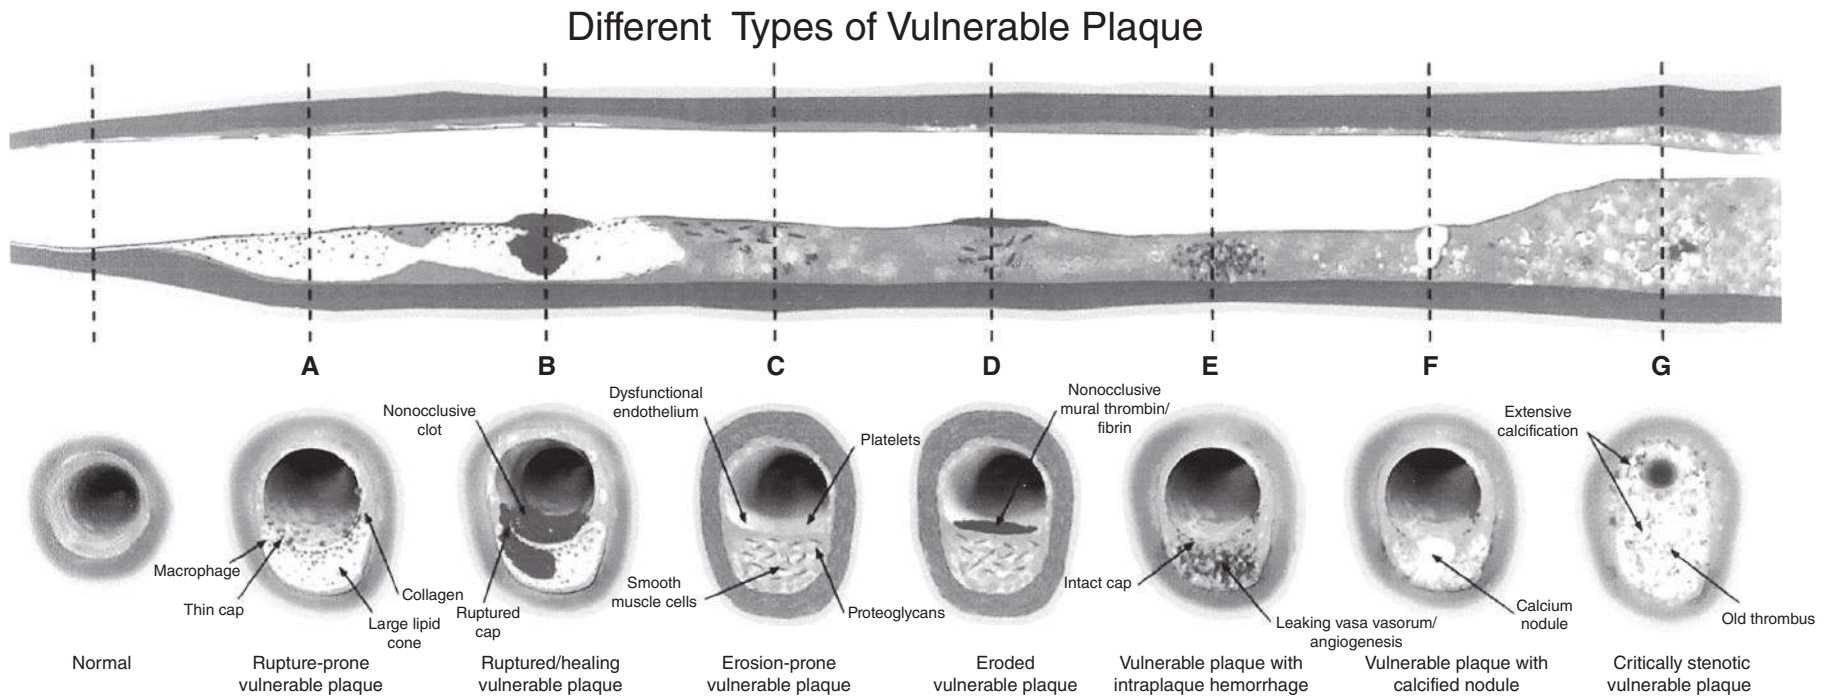

Figure 134-6. Different types of vulnerable plaque as underlying cause of acute coronary events and sudden cardiac death. **A.** Rupture-prone plaque with large lipid core and thin fibrous cap infiltrated by macrophages. **B.** Ruptured plaque with subocclusive thrombus and early organization. **C.** Erosion-prone plaque with proteoglycan matrix in a smooth muscle cell-rich plaque. **D.** Eroded plaque with subocclusive thrombus. **E.** Intraplaque hemorrhage secondary to leaking vasa vasorum. **F.** Calcific nodule protruding into the vessel lumen. **G.** Chronically stenotic plaque with severe calcification, old thrombus, and eccentric lumen. (Reproduced with permission from Naghavi M, Libby P, Falk E et al: From vulnerable plaque to vulnerable patient: A call for new definitions and risk assessment strategies: Part I. *Circulation* 108(14):1664-1672, 2003.)

TABLE 134–2. Criteria for Defining the Vulnerable Plaque, Based on the Study of Culprit Plaques

MAJOR CRITERIA
Active Inflammation (monocyte/macrophage and sometimes T-cell infiltration)
Thin cap with large lipid core
Endothelial denudation with superficial platelet aggregation
Fissured plaque
Stenosis >90%
MINOR CRITERIA
Superficial calcified nodule
Glistening yellow
Intraplaque hemorrhage
Endothelial dysfunction
Outward (positive) remodeling

Reproduced with permission from Naghavi M, Libby P, Falk E, et al: From vulnerable plaque to vulnerable patient: A call for new definitions and risk assessment strategies: Part I. *Circulation* 2003 Oct 7;108(14):1664-1672.

nonatherosclerotic disease, such as hypertrophic cardiomyopathy or right ventricular dysplasia. Thus, a vulnerable patient should be considered from the standpoint of the combined presence of a vulnerable atherosclerotic plaque, vulnerable blood (prone to thrombosis), and/or vulnerable myocardium (prone to life-threatening arrhythmia).

Arterial Thrombosis

Atherothrombosis refers to the occurrence of thrombosis upon atherosclerotic lesions,¹⁶¹ the typical setting for arterial thrombosis. It represents the acute event that converts chronic atherosclerosis—a silent, asymptomatic, progressive disease—into symptomatic, life-threatening

TABLE 134–3. Blood Hypercoagulability Factors That May Contribute to Patient Vulnerability to Coronary Heart Disease Events

1. Markers of blood hypercoagulability Decreased anticoagulation factors (e.g., proteins C and S and antithrombin) Prothrombotic gene polymorphisms (e.g., factor V Leiden, G20210A prothrombin mutation) Increased coagulation factors (e.g., fibrinogen, factor VII, factor VIII, von Willebrand factor)
2. Increased platelet activation (e.g., gene polymorphisms of platelet integrin $\alpha_{IIb}\beta_3$, integrin $\alpha_2\beta_1$, glycoprotein Ib/IX)
3. Decreased endogenous fibrinolysis activity (e.g., reduced tissue-type plasminogen activator, increased plasminogen-activator inhibitor (PAI)-1, certain PAI-1 polymorphisms)
4. Other thrombogenic factors (e.g., anticardiolipin antibodies, thrombocytosis, sickle cell disease, polycythemia, diabetes mellitus, hyperhomocysteinemia, hypercholesterolemia)
5. Increased viscosity
6. Transient hypercoagulability (e.g., smoking, dehydration, infection, adrenergic surge, cocaine, estrogens, postprandial)

Data from Naghavi M, Libby P, Falk E, et al: From vulnerable plaque to vulnerable patient: A call for new definitions and risk assessment strategies: Part I. *Circulation* 2003 Oct 7;108(14):1664-1672.

TABLE 134–4. Pathophysiologic Differences Between Arterial and Venous Thrombi

	Arterial Thrombosis	Venous Thrombosis
Underlying vasculature	Abnormal • Atherosclerosis • Vasculitis • Trauma	Normal
Thrombus pathology	Occlusive or nonocclusive (mural thrombi in large arteries)	Occlusive
	“White thrombus” composed mainly of platelets	“Red thrombus” composed mainly of fibrin, red cells
Pathophysiology	Local shear stress and thrombogenic vascular surface	Stasis and hypercoagulability

clinical complications, including acute MI, stroke, and critical limb ischemia. The previous section described in detail the current concepts of the consecutive stages of atherosclerotic lesion development.

However, thrombosis is not simply the final occlusive event. It also contributes to atherosclerosis lesion development. Intraplaque hemorrhage and *in situ* thrombosis localizes thrombin activity within plaques. Thus, atheroma evolution is not only a proliferative process but also involves thrombosis.¹⁶²

Pathobiology of Arterial Thrombi

Fundamental pathologic and pathophysiologic distinctions exist between arterial and venous thrombi (Table 134–4). Arterial thrombi usually are occlusive in smaller arteries and arterioles. Nonocclusive mural thrombi often occur in the lumina of the heart chambers and large arteries, such as the aorta and the iliac and common carotid arteries. In any arterial vessel, however, thrombi develop almost invariably upon preexisting abnormal intimal surfaces, which typically are atherosclerotic lesions. Less commonly, arterial thrombosis is superimposed on other forms of vascular disease, such as vasculitis or traumatic injury.¹⁶³ Thus, in the high-flow and high-pressure arterial system, thrombi form in response to increased local shear forces and exposure of thrombogenic substances on damaged vascular surfaces. Arterial thrombi, referred to as *white thrombi*, are composed mainly of platelets and relatively little fibrin or red cells. Leukocytes are likewise actively recruited into growing, platelet-rich arterial thrombi.¹⁶⁴

Thus, at sites of atherosclerotic plaque rupture, circulating platelets are activated not only by thrombogenic substances exposed to them by a disrupted plaque but also directly by the locally increased shear forces the platelets encounter.⁸⁵ At any given point in the circulation, shear rates are maximal adjacent to the vessel wall (measured as “wall shear rates”), and they are minimal in the center of the vessel lumen where velocity of flowing blood is the greatest. Normally, wall shear rates are in the range of 300 to 800 s^{-1} in large arteries, and they increase to about 500 to 1600 s^{-1} in arterioles of the microcirculation. However, in pathologically stenotic vessels the wall shear rates can reach 10,000 s^{-1} or even higher. Increased shear stress in the microenvironment of an atherosclerotic plaque is usually compounded by turbulent blood flow. These locally abnormal hemodynamic forces can directly activate platelets as they pass through the region. Disturbed flow can simultaneously cause localized endothelial dysfunction.¹⁶⁵

High shear stresses, especially in the presence of marked shear gradients around stenotic sites, are sufficient to cause the release of VWF

from endothelial cells, and promote the unfolding and binding of VWF to its receptors on platelet surface glycoprotein (GP) Ib-V-IX. This interaction, which does not occur in the normal circulation, mediates the adhesion of platelets to the intimal surface and triggers GPIb-V-IX–dependent platelet thrombus formation. The mechanisms of arterial thrombogenesis are further elaborated below in the section on “Platelet Activation.”

In contrast, wall shear rates are much lower in the venous circulation where the hemodynamic forces are insufficient to directly activate platelets.¹⁶⁶ Venous thrombi are almost always occlusive and may form virtual casts of the vessel in which they arise. Unlike the setting for arterial thrombi, gross vascular damage generally is not found at sites of venous thrombosis. Any ultrastructural abnormalities of adjacent endothelium likely are the consequences rather than the causes of thrombus formation. Therefore, in the low-flow and low-pressure venous system, reduced blood flow (stasis) and systemic activation of the coagulation cascade play the primary pathophysiologic roles. Venous thrombi are composed predominantly of red cells enmeshed in fibrin and contain relatively few platelets; hence, they have been described pathologically as *red thrombi*.

The generalizations described are consistent with the following clinical observations: (1) hereditary hypercoagulable states (also called “thrombophilias”), characterized by chronic hyperactivity of the coagulation system, are primarily associated with venous rather than arterial thrombosis; and (2) anticoagulants that prevent fibrin formation (e.g., heparin, warfarin) are generally used to prevent venous thrombosis, whereas antiplatelet agents (e.g., aspirin) are more effective in preventing arterial thrombosis. The differences between arterial and venous thrombosis are not, however, absolute because both types of thrombi are composed of different amounts of platelets, fibrin, and leukocytes. In addition, all thrombi continually undergo propagation, organization, embolization, lysis, and rethrombosis, and this dynamic remodeling results in their constantly changing compositions.

Site-Specific Arterial Thrombosis

The model of atherothrombosis described is best characterized in coronary arteries. This pathophysiology may not be entirely applicable to arterial thrombosis at other sites. It cannot be assumed that the local determinants of thrombosis that are operative in the coronary arteries are identical to those encountered in the cerebrovascular and peripheral arterial circulations. Basic regional differences may involve (1) distribution and composition of atherosclerotic lesions, (2) variable local rheology, and (3) underlying vascular cell heterogeneity.

Atherosclerosis is highly localized within the systemic vasculature. Lesion formation particularly affects the carotid artery bifurcation, coronary arteries (especially the left coronary artery bifurcation), abdominal aorta (especially its posterior wall downstream of the renal arteries, but with little disease usually present in the upstream thoracic aorta), and profunda femoral arteries. These lesion-prone sites in the arterial circulation correspond to regions where wall shear stress is very low and may even oscillate between positive and negative directions (i.e., reversal of flow) during the cardiac cycle. A strong correlation exists between local hemodynamic conditions of low shear stress and the development of atherosclerotic plaque formation and intimal thickening.^{167–169} However, as arteries become progressively diseased and as stenoses develop at these sites, local hemodynamics change. Stenotic flows are characterized by sharp increases in shear rate that achieve their peak just upstream of the stenosis throat, with development of intensive turbulence downstream of the stenosis. The mechanisms of platelet activation and accumulation that initiate arterial thrombosis at these high-shear sites are further described in “Platelet Activation” below.

Striking heterogeneity is seen in the composition of atherothrombotic plaques, even within the same individual. In addition to plaque composition, the basic structural differences between specific arteries

contribute to differences in thrombogenic substrates that are exposed upon arterial injury. For example, carotid and iliac arteries contain relatively more elastic fibers and proportionately fewer smooth muscle cells than coronary arteries.¹⁷⁰ Furthermore, ACSs typically result from disruption of only modestly stenotic, lipid-rich plaques, whereas disruption-prone, high-risk plaques in the carotid arteries usually are severely stenotic. Thus, a proposed more appropriate term is *high-risk plaque* rather than *vulnerable plaque* (which connotes its composition) to define a disruption-prone or thrombosis-prone plaque in different parts of the circulation.¹⁷¹

The pathophysiology of arterial thrombosis at different sites in the circulation may also be determined in part by vascular bed-specific heterogeneity of endothelial and smooth muscle cells. Endothelial cell-derived anticoagulant and procoagulant activities are differentially expressed throughout the vascular tree. Endothelial cell heterogeneity throughout the circulation is a function of varying organ- and tissue-specific microenvironments, hemodynamic forces, and site-specific changes in epigenetic footprinting. The heterogeneity of endothelial cells and the vascular bed-specific signaling pathways that control endothelial gene expression have been considered to play an important role in the localization of arterial thrombosis.¹⁷² Heterogeneity of vascular smooth muscle cells likewise exists throughout the arterial tree. They vary in embryonic origin, sources of progenitors, and lineage. With subsequent development, they acquire various phenotypes that can be traced to preferential sites within vessel walls.¹⁷³

Less is known about the pathophysiology of cerebrovascular thrombosis, and even less about peripheral arterial thrombosis, than about coronary artery thrombosis. Future research in these areas should permit the development of more rational antithrombotic strategies in noncoronary artery thrombosis.

Overview of Arterial Thrombotic Process

Arterial thrombosis typically occurs in the presence of underlying atherosclerosis (hence the term “atherothrombosis”). Less frequently, however, it may also occur in nonatherosclerotic arteries, such as in the setting of vasculitis.

Atherothrombosis Disruption of an atherosclerotic plaque triggers an explosive cascade of events that results in the formation of a platelet-rich thrombus at the site of arterial injury.⁵⁷ Focal loss of the antithrombotic and the vasodilatory properties of endothelium is compounded by plaque rupture or erosion. These events induce the local activation of platelets and the coagulation system by exposure of blood to previously encrypted thrombogenic substances (e.g., subendothelial cells, such as smooth muscle cells and fibroblasts; subendothelial structures, such as collagen; and subendothelial prothrombotic substances, such as TF, from all of which flowing blood is normally insulated by the barrier of a healthy endothelial monolayer). The local milieu for thrombus formation is aggravated by focal vasoconstriction, rapidly increased shear forces, and platelet-mediated recruitment of leukocytes. Platelet and coagulation activation are inseparable, reciprocally self-amplifying processes. Activation of platelets generates procoagulant properties on their cell surfaces. Combined with non-platelet-dependent local activators of the coagulation cascade, platelet activation culminates in the formation of thrombin, which itself is a potent stimulus for further platelet activation. Superimposed on these local determinants of arterial thrombosis, the thrombotic process may be modulated by systemic, circulating factors. The factors include the systemic state of activation of platelets and coagulation, which may be governed by acquired or genetic factors and by hormonal influences (e.g., adrenergic state).

Arterial thrombi generally are localized to the site of acute vascular injury. They are prevented from extending beyond this site by the

restoration of hemostatic balance that promotes blood fluidity along healthy endothelial surfaces immediately adjacent to the site of injury. Thrombus propagation may occur, however, through a bloodborne pool of thrombogenic substances that originate at the site of vascular injury and thrombosis. These substances can be in the form of platelets, leukocytes, red cells, sloughed endothelial cells, other cellular microparticles, and circulating active TF derived from leukocytes activated within the thrombus.^{174,175} In fact, cellular microparticles¹⁷⁶ constitute the main reservoir of bloodborne TF, the principal initiator of coagulation.

Thrombus persistence within an artery depends on the local balance between prothrombotic, antithrombotic, and fibrinolytic factors. Ulcerated and thrombotic atherosclerotic plaques, particularly in the aorta, tend to persist or recur.¹⁷⁷ Atherosclerotic plaques of the aortic arch have been detected in almost one-third of patients with cryptogenic stroke. Although aortic arch atheroma are more frequent and more severe causes of cryptogenic stroke in individuals older than 55 years of age, patent foramen ovale (and presumably paradoxical embolism) are more strongly associated with cryptogenic stroke in those younger than 55 years of age.¹⁷⁸

Advances in the development of coronary stents have created a new form of arterial thrombosis that usually can only be prevented by administration of two different platelet inhibitors (e.g., aspirin in combination with a thienopyridine derivative, such as clopidogrel or prasugrel). Although drug-eluting stents that deliver sirolimus or paclitaxel have been successful in reducing the problem of restenosis that is caused by smooth muscle cell proliferation and intimal hyperplasia following the coronary intervention, they have actually increased the occurrence of “late stent thrombosis” compared to bare metal stents. This form of arterial thrombosis, which typically occurs after discontinuation of (dual) antiplatelet therapy, is probably caused by eluting drugs interfering with endothelialization of the stent surface.¹⁷⁹

Thrombosis in Nonatherosclerotic Arteries Thrombosis may occur in arteries that are affected by vasculitis.¹⁸⁰ As both SLE and atherosclerosis are immune-driven processes, it is to be expected that some patients with active SLE are more susceptible to accelerated atherosclerosis (and related atherothrombosis) resulting from autoantibody-mediated proatherogenic mechanisms.^{181,182} However, even in the absence of underlying atherosclerosis, various types of arterial thrombosis can complicate active vasculitis. For example, patients with SLE may have MI with angiographically normal coronary arteries. Giant cell arteritis, which characteristically targets the extracranial carotid and vertebral arteries, leads to inflammation and necrosis of the arterial wall and subsequent arterial occlusions in a distribution that is quite different from that of atherosclerosis. Takayasu arteritis has an unusual predilection for the aortic arch and its branches, leading to panarteritis, medial layer enlargement with luminal narrowing, and sometimes thrombotic occlusion. Other types of vasculitis and autoimmune processes that may cause arterial thrombosis include polyarteritis nodosa, Behçet disease, and antiphospholipid antibody syndrome.

Arterial thrombosis in the absence of atherosclerosis is also seen with immune- and nonimmune disorders of platelets and/or the vascular endothelium, such as heparin-induced thrombocytopenia (with arterial thrombosis most commonly occurring in the aorta, iliofemoral arteries, as well as in cerebral and coronary arteries),¹⁸³ and in the myeloproliferative neoplasms (e.g., essential thrombocythemia, polycythemia vera; Chaps. 84 to 86).^{184–186}

Platelet Activation

Disruption of an advanced atherosclerotic plaque results in abrupt exposure of highly thrombogenic material to flowing blood. This process leads locally to both thrombin generation and platelet activation, which operate simultaneously in a mutually self-amplifying process.

As noted above in the section on “Pathobiology of Arterial Thrombi” plaque rupture and the development of new intimal surface irregularities also suddenly alter local rheologic characteristics, increasing local shear rates. Increased shear stress resulting from sudden changes in degree of stenosis following rupture is compounded by increased focal vasoconstriction induced by thrombin, thromboxane A₂, and other vasoactive substances released in the milieu of acute injury.

At high shear rates (>1000 s⁻¹), platelets must be initially tethered to the vascular surface through a shear-activated interaction between the platelet membrane GPIIb/IIIa (of the GPIIb-IX-V complex) and its adhesive ligand, VWF.^{187–189} Platelet adhesion also involves collagen binding to platelet collagen receptors (integrin $\alpha_2\beta_1$ and GPVI). Other matrix constituents that become exposed to platelets and serve as adhesive ligands include fibronectin, laminin, fibrinogen, and fibrin. These initial adhesive interactions induce intracellular signaling pathways that activate platelets. High shear stress also activates platelets both directly,¹⁹⁰ as noted previously, and by lowering the threshold of platelet activation by chemical agonists to which platelets are simultaneously exposed in the microenvironment of the arterial thrombus.¹⁹¹ Thus, following adhesion, platelets are explosively activated by several interacting pathways: (1) intracellular signaling initiated by the adhesion event itself, (2) direct action of locally increased shear stress, and (3) agonists released (e.g., ADP, thromboxane A₂) and generated (e.g., thrombin) at the site of vascular injury.

Finally, the occlusive arterial platelet thrombus is created by the aggregation of platelets. This process is mediated by several alternative ligands (VWF, fibrinogen, fibronectin) that bind to their activated receptors in the platelet integrin $\alpha_{IIb}\beta_3$ complex. Stability of the platelet aggregate is conferred by additional ligand–receptor interactions, including CD40L binding to integrin $\alpha_{IIb}\beta_3$.¹⁹² Platelet thrombus stabilization is designed to counteract shear forces that promote not only the formation of arterial thrombi but also their embolization.

The importance of the inflammatory component of arterial thrombosis,¹⁶⁴ which is characterized by complex interactions among leukocytes, endothelial cells, and platelets, is increasingly being recognized. Activated platelets recruit leukocytes to the site of vascular damage, promoting their adhesion to endothelium and their activation on endothelium-bound chemokines. In fact, the presence of leukocytosis in myeloproliferative neoplasms is a better predictor of pathologic thrombosis than the platelet count.

Tissue Factor and Phospholipids

Tissue factor is a cell-surface-bound transmembrane protein that normally is not exposed to circulating blood. When expressed, TF initiates coagulation by binding to factor VIIa and activates factors IX and X, thereby triggering the common pathway of coagulation and the formation of thrombin. Strong evidence indicates that TF is the principal thrombogenic factor in the lipid-rich core of atherosclerotic plaques. While much of this TF is associated with monocytes/macrophages and vascular smooth muscle cells, more recent studies suggest that TF-positive microparticles are the most abundant sources of TF in atherosclerotic plaques. The main inhibitor of TF-mediated coagulation is TFPI. In atherosclerotic plaques TFPI colocalizes with TF and therefore may play an atheroprotective role.^{162,193}

Upon rupture of the atherosclerotic plaque, exposure of vascular TF to flowing blood initiates the coagulation cascade. Coagulation reactions are accelerated on the surfaces of activated platelets, microparticles, and on other activated cells in the microenvironment of vascular injury. The surfaces of these activated cells express anionic phospholipids, particularly phosphatidylserine. Apoptotic cells, with which advanced lesions are enriched, likewise translocate phospholipids from the inner to the outer leaflet of the cell membrane.¹⁹⁴ Plasma lipoproteins can provide a

phospholipid surface for the assembly of enzymatic complexes of the coagulation cascade; in particular, oxidized LDL, LDL, and VLDL have procoagulant effects.^{195,196} In contrast, HDL has multiple antithrombotic actions, including suppression of the coagulation cascade, stimulation of fibrinolysis, and stimulation of endothelial cell release of prostacyclin and NO, which are inhibitors of platelet activation.¹⁹⁷

Arterial thrombosis is triggered by the acute exposure of circulating blood to TF and anionic phospholipids, leading to explosive thrombin formation. Thrombin, a potent platelet agonist, further fuels the platelet activation process described in the previous section. These reactions create a self-amplifying process that is tightly localized to the site of vascular injury. The arterial thrombus is further contained to this site by the restoration of normal, antithrombotic endothelium in adjacent areas of the vessel wall.

Systemic Factors

As described above in “Overview of Arterial Thrombotic Process,” the pathophysiology of arterial thrombosis is primarily determined by local, “solid-state” factors that operate in concert in the immediate microenvironment of acute vascular injury, typically disruption of an atherosclerotic plaque. However, interindividual differences in systemic, circulating factors can modify susceptibility to the focal formation of an arterial thrombus.¹⁹⁸ Systemic determinants of blood thrombogenicity (i.e., hypercoagulability) can enhance the local risk of arterial thrombosis. There is increasing evidence for an association between venous and arterial thrombosis, with several studies now showing that patients with venous thromboembolism (deep vein thrombosis and/or pulmonary embolism) are at increased risk of having coexisting asymptomatic atherosclerosis or subsequent symptomatic atherothrombotic events. Conversely, patients with clinically overt atherosclerotic CVD are at increased risk of venous thromboembolism.^{199–201} In addition to certain thrombophilic abnormalities, such as antiphospholipid antibody syndrome, hyperhomocysteinemia, and the myeloproliferative neoplasms, which are known to predispose individuals to both venous and arterial thromboembolism, some traditional cardiovascular risk factors (e.g., advanced age, obesity, metabolic syndrome, abnormal lipid profiles, immobility, estrogens) also appear to be independent risk factors for venous thromboembolism.^{39,202–204}

Genetic determinants of the coagulation system may exert modifying effects on susceptibility to arterial thrombosis. The known hypercoagulable states that predispose to venous thrombosis (e.g., factor V Leiden, prothrombin gene mutation, antithrombin deficiency, protein C and protein S deficiencies) generally are weakly²⁰⁵ or not at all associated with increased risk of arterial thrombosis. However, decreased mortality from ischemic heart disease has been noted in patients with hemophilia A or B and even in carriers of hemophilia.²⁰⁶ This finding most likely results from reduced arterial thrombotic tendency in these individuals because early atherogenesis itself does not appear to be significantly affected by the coexistence of hemophilia.²⁰⁷ Conversely, some epidemiologic studies have correlated elevated levels of fibrinogen and some other coagulation factors with both subclinical atherosclerosis and clinical cardiovascular events,^{208,209} although cause-and-effect relationships between elevated levels of hemostatic factors and cardiovascular risk have not been established.

Several lines of evidence suggest that genetic determinants of increased platelet reactivity likewise enhance focal determinants of arterial thrombosis. Animal models of atherosclerosis in pigs and mice with von Willebrand disease suggest that an extremely low or absent VWF level exerts a protective effect on the development and distribution of atherosclerotic lesions,^{210,211} although these observations are inconclusive. Whether or not von Willebrand disease protects against development of human atherosclerosis remains in dispute.

Platelet membrane glycoproteins are highly polymorphic and can be recognized as alloantigens or autoantigens. Polymorphisms in platelet membrane glycoprotein receptors have been considered to increase platelet reactivity, thereby potentially contributing to susceptibility to arterial thrombosis.^{212,213} The first such genetic variation reported involves the HPA-1a/HPA-1b polymorphism, which results in a Leu33Pro substitution in the β_3 subunit of the platelet integrin $\alpha_{IIb}\beta_3$ complex. The 33Pro (HPA-1b) allele was found to be associated with risk of MI in young individuals.²¹⁴ Most, but not all, subsequent studies have agreed that the HPA-1b allele represents an inherited risk factor for ACS.²¹³ Other platelet receptor polymorphisms that have been inconclusively linked to risk of CVD include three different polymorphisms of the integrin α_{IIb} (HPA-3), GPIb gene, and a polymorphism of the collagen receptor integrin $\alpha_2\beta_1$. However, as is the case for the soluble hemostatic factors, lack of a clear relationship among genotype, phenotype, and clinical manifestations has failed to establish convincing cause-and-effect relationships for any of these genetic variations.

Although none of these individual hemostatic proteins or platelet polymorphisms plays a clear, dominant role in the pathophysiology of arterial thrombosis, future application of platelet proteomics²¹⁵ and genomics are likely to reveal new disorders of platelet activation associated with arterial thrombosis.

High blood levels of catecholamines likely contribute systemically to localized arterial thrombus formation. Catecholamines may be increased by physical or emotional stress or by cigarette smoking, thereby triggering acute cardiovascular events in these settings. In addition to their vasoactive actions, catecholamines are direct platelet agonists and enhance shear stress-induced platelet activation.^{191,216}

Changes in lipid metabolism may exert systemic prothrombotic actions. The thrombogenicity of lipoprotein(a) has been attributed to its structural similarity to plasminogen, leading to reduced plasmin formation and impaired thrombolysis.¹⁶³ Elevated LDL cholesterol can contribute to blood hypercoagulability.²¹⁷ The prothrombotic state of diabetes involves multiple mechanisms, including platelet hyperreactivity and increased leukocyte procoagulant activity.¹⁷⁷

● ISCHEMIC VASCULAR DISEASE

MYOCARDIAL INFARCTION

MI is a term that reflects necrosis of cardiac myocytes caused by prolonged ischemia. In the past, MI was defined by the combination of two of three characteristics: typical symptoms (i.e., chest discomfort), a rise in serum enzymatic markers derived from myocardial cells, and a typical electrocardiographic pattern involving the development of Q waves. The advent of sensitive and specific serologic biomarkers and precise imaging techniques has led to the development of revised criteria for MI.²¹⁸ For example, patients can be diagnosed with a “ST-segment elevation MI”²¹⁹ or “non-Q-wave or non-ST-segment elevation” MI (NSTEMI)²²⁰ if certain criteria are met. The criteria agreed upon by the American College of Cardiology for acute, evolving, or recent MI²¹⁸ are as follows:

1. Typical rise and gradual fall (troponin) or more rapid rise and fall (creatinine kinase-MB isoform) or biochemical markers of myocardial necrosis with at least one of the following: (A) ischemic symptoms; (B) development of pathologic Q waves on the electrocardiogram (ECG); (C) electrocardiographic changes indicative of ischemia (ST segment elevation or depression); or (D) coronary artery intervention (e.g., coronary angioplasty).
2. Pathologic findings of an acute MI.

The criteria for established MI²¹⁸ (i.e., event that occurred in the past) is any one of the following:

1. Development of new pathologic Q waves on serial ECGs. The patient may or may not remember previous symptoms. Biochemical markers of myocardial necrosis may have normalized, depending on the length of time since the infarct developed.
2. Pathologic findings of a healed or healing MI.

Clinical Features of Acute Coronary Syndromes

Stable angina pectoris is ischemic discomfort symptomatology caused by a narrowed coronary artery that does not allow sufficient oxygen delivery to meet the metabolic demands of the myocardium. *Unstable angina* is defined clinically as a change in the pattern of stable angina to more frequent or more severe symptoms, uninterrupted angina symptoms for 20 minutes or more, or the development of angina at rest. The term *acute coronary syndrome* has evolved as a useful description of the spectrum of patients presenting with angina pectoris caused by unstable angina through MI.²²⁰ The underlying pathologic mechanism for the development of ACS is usually a vulnerable atherosclerotic plaque with either plaque rupture or plaque ulceration leading to thrombosis. Unstable angina and NSTEMI are differentiated by pathologic elevation in the levels of cardiac biomarkers that confirm MI.

Angina pectoris can be associated with other symptoms, such as diaphoresis, dizziness, nausea, clamminess, and fatigue. Some patients with ACS present with atypical symptoms rather than chest pain. The presentation may be dyspnea alone, nausea and/or vomiting, palpitations/syncope, or cardiac arrest. Rarely, patients with diabetes mellitus and other patients have a “silent MI” diagnosed incidentally on ECG or cardiac imaging study.

The initial ECG is often not diagnostic in patients with ACS. In one clinical study, the ECG was not diagnostic in approximately 45 percent and was normal in 20 percent of patients who subsequently were shown to have experienced an acute MI.²²¹ ST-segment elevation and Q waves are consistent with ST-segment elevation myocardial infarction (STEMI), but other conditions, such as acute pericarditis with early repolarization variant and hypertrophic cardiomyopathy with Q waves, may mimic the ECG manifestations of STEMI.

Laboratory Features of Acute Myocardial Infarction

A variety of serum biomarkers are used to evaluate patients with suspected acute MI. The three most commonly used tests are (1) troponin I and troponin T, (2) creatine kinase (CK) and its isoform CK-myocardial band (MB), and (3) myoglobin. An elevated serum concentration of one or more of the three biomarkers is seen in almost all patients with acute MI. The preferred biomarkers are the troponins because the troponin assays are more specific than the other tests.

Therapy for Acute Coronary Syndromes

Therapy for Acute Myocardial Infarction The initial management of patients with STEMI depends upon prompt recognition and therapy to reduce morbidity and mortality. A carefully coordinated plan of care is essential for optimal results in patients with STEMI, given that multiple therapies usually are initiated simultaneously. The goals of therapy are to reduce ischemic pain, stabilize hemodynamic status, and quickly establish myocardial reperfusion. The American College of Cardiology (ACC)/American Heart Association (AHA) guidelines for management of patients with acute MI are available at the ACC website.²²²

Antiplatelet Agents Unless contraindicated, all patients with acute MI should be given antiplatelet therapy. The Antiplatelet Trialists' Collaboration indicated a 30 percent reduction in vascular events with

an absolute benefit of 38 vascular events prevented per 1000 patients at 1 month with antiplatelet therapy.²²⁰ Aspirin 325 mg/day or a P2Y₁₂-receptor antagonist such as clopidogrel is commonly used in the setting of MI. Vorapaxar, a protease-activated receptor-1 (PAR-1) antagonist, is indicated for the reduction of thrombotic events in patients with a history of MI or with peripheral artery disease (PAD).²²³ Contraindications to antiplatelet therapy include active bleeding, coagulopathy, and severe, untreated hypertension (a relative contraindication). The combination of dipyridamole and aspirin has not been proven to provide incremental clinical benefit over aspirin alone.

β -Adrenergic Blockade The control of heart rate with β -adrenergic blocker agents has been efficacious in the setting of acute MI or unstable angina.²²² According to guidelines, oral β -blocker should be initiated during the first 24 hours of care of STEMI. Intravenous administration of β -blockers should be given only to selected, hemodynamically stable patients according to guidelines.

Management of Chest Pain A cornerstone of ischemic pain management has been intravenous nitroglycerin (beginning at 5 to 10 mcg/min) in combination with morphine sulfate if necessary. Nitroglycerin also may improve hypertension and symptoms of heart failure, if present. Intravenous nitroglycerin therapy has not been proven to improve mortality and usually is discontinued within 24 to 48 hours of presentation.²²² Patients who have taken drugs (e.g., sildenafil) for erectile dysfunction within the preceding 24 hours are at increased risk for vasodilation and hypotension, so caution is advised in these patients when intravenous nitroglycerin is given.

Reperfusion Therapy The overriding goal of treatment of STEMI is restoration of myocardial blood flow and salvage of myocardial tissue. A decision should be made immediately whether the patient will undergo a primary (direct) percutaneous coronary intervention (PCI) or receive a fibrinolytic agent. The currently preferred approach is PCI, but the relative advantages and limitations of each therapy should be considered. The most important factor to consider is whether PCI is immediately available. Several randomized trials indicate enhanced survival with PCI compared to fibrinolysis, with a lower rate of intracranial hemorrhage and recurrent MI.^{224,225} Transfer to a center that can provide PCI, if necessary, should be accomplished in less than 2 hours.²²⁶

Fibrinolytic therapy should be given immediately if PCI cannot be performed promptly.²¹⁹ Prior to fibrinolysis, the patient should be initially assessed for possible contraindications, which include active bleeding, history of cerebrovascular disease, intracranial neoplasm, drug allergy, and trauma. A systolic blood pressure greater than 175 torr is a relative contraindication but should not prohibit therapy, especially if the pressure can be rapidly controlled. Many different fibrinolytic regimens with different dosing schemes are available. Streptokinase was the first thrombolytic agent tested but has proved less effective than alteplase.²²⁷ In addition, streptokinase is antigenic and can cause an allergic reaction, particularly with repeat administration. Other thrombolytic agents, such as tenecteplase and reteplase, have reportedly similar results compared to alteplase.²²⁸ Tenecteplase is popular on hospital formularies because of its relatively easy single-bolus administration and reported lower rate of noncerebral bleeding.²²⁹

Anticoagulation Heparin, both unfractionated and low molecular weight, is commonly used in patients with STEMI.²¹⁹ The exact role of heparin therapy with different fibrinolytic agents is evolving. Patients who undergo primary PCI usually are given unfractionated heparin 7500 U subcutaneously twice daily or low-molecular-weight heparin, for example, enoxaparin, 1 mg/kg twice daily unless contraindications are evident. For patients receiving intravenous unfractionated heparin, the recommended dose is an initial 60 to 70 U/kg bolus (maximum: 5000 U) followed by 12 to 15 U/kg per hour (maximum: 1000 U/h) as continuous

infusion with monitoring of the activated partial thromboplastin time (aPTT) measured at 6 hours. The heparin dose is adjusted to maintain an aPTT between 50 and 75 seconds.

Current guidelines recommend maintaining the aPTT at 50 to 75 seconds for short-term use. Heparin should be continued beyond this period only in the case of high risk of systemic or venous thromboembolism. Patients can be switched to a subcutaneously administered heparin or converted to oral warfarin during the high-risk period. The anticoagulant drugs unfractionated heparin, enoxaparin, fondaparinux, and bivalirudin are all excreted by the kidneys; consequently, although the first dose is usually safe, longer-term therapy should be guided by assessment of creatinine clearance.²³⁰ The Coumadin-Aspirin Reinfarction Study (CARS) did not show a significant benefit with the combination of low-dose warfarin (1 or 3 mg) and aspirin 80 mg daily compared to aspirin 160 mg daily monotherapy on cardiovascular morbidity in patients who had an MI.²³¹

Statins All patients with MI should be started on a 3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitor (statin) unless the MI was caused by a nonatherosclerotic process such as coronary vasospasm, vasculitis, or embolus. Numerous studies indicate that statins reduce the risk of subsequent MI by approximately 30 to 50 percent.²³² Current evidence suggests that a serum LDL level less than 80 mg/dL with statin treatment is more efficacious in retarding atherosclerotic disease progression than a serum LDL level of 100 mg/dL or above.²³³ Other nonstatin drugs, such as ezetimibe, PCSK9 inhibitors, and microsomal triglyceride transfer protein inhibitors, also reduce cholesterol levels but relative reduction in cardiovascular events compared to statins is not yet clear.

Therapy for Unstable Angina Pectoris and Non-ST-Elevation Myocardial Infarction The distinction between unstable angina and NSTEMI initially may be difficult because levels of troponins and/or CK-MB may not be elevated until hours after presentation. Similar to STEMI, the initial treatment of unstable angina and NSTEMI includes supplemental oxygen, pain control, and bed rest.²³⁰ Nitrates, given either intravenously or subcutaneously, are the treatment of choice for angina pectoris. Oral β -blockers also are routinely given to patients with unstable angina to relieve symptoms of angina and to reduce the risk of progression to MI.

Treatment of unstable angina and NSTEMI involves administration of an antiplatelet agent and anticoagulation.²³⁰ Fibrinolytic therapy is not beneficial in patients with unstable angina, and its use is associated with unacceptably high bleeding risk. Antiplatelet treatment, most commonly aspirin at a dose of 325 mg daily, was shown in the Antithrombotic Trialists' Collaboration to reduce the combined end point of subsequent nonfatal MI, nonfatal stroke, or vascular death (8.0 percent vs. 13.3 percent) in patients with non-ST-segment elevation ACS.²³⁴ Clinical trials involving patients with non-ST-segment elevation ACS have demonstrated significantly reduced cardiovascular events and mortality with aspirin administration, mostly at a lower dose of 80 to 100 mg orally once per day.^{235–237} Some patients do not benefit from aspirin, and this finding has generated an interest as to whether these patients are "aspirin resistant." Nonrandomized studies indicate that aspirin resistance may occur, but because of the limitations of these studies, the definition and prognostic significance of this phenomenon are uncertain.²³⁸

The thienopyridine clopidogrel (75 mg/day) is effective in reducing the risk of MI and mortality in patients with unstable angina.²²⁰ The combination of aspirin and clopidogrel has been tested in patients with NSTEMI and unstable angina. The combination of these antiplatelet agents resulted in improved survival and decreased progression to MI.²³⁹ The patients with non-ST-segment elevation ACS who underwent PCI benefited the most from the combination of aspirin

and clopidogrel.²⁴⁰ However, the combination was associated with an increase in major bleeding and reoperation for bleeding in patients who underwent coronary artery bypass grafting (CABG). Therefore, a 5-day, but preferably a 7-day, period off clopidogrel is recommended before CABG.²⁴¹

A meta-analysis of randomized clinical trials found that intravenous platelet integrin IIb/IIIa inhibitors substantially benefited patients with non-ST-segment elevation ACS undergoing coronary intervention.²⁴² The integrin $\alpha_{IIb}\beta_{IIIa}$ receptor antagonist abciximab (ReoPro) is a monoclonal antibody fragment that reduces short-term and long-term clinical events in patients with ACS undergoing angioplasty with or without stent placement. Other platelet integrin $\alpha_{IIb}\beta_{IIIa}$ antagonists, such as tirofiban and Integrilin, also are effective and safe in treating unstable angina when combined with heparin anticoagulation.²⁴³ Guidelines from an ACC/AHA task force recommend administration of an integrin $\alpha_{IIb}\beta_{IIIa}$ inhibitor, in addition to aspirin and heparin, for patients with unstable angina/NSTEMI undergoing planned PCI.²²⁰

Unfractionated heparin reduces the rate of MI and death, and relieves anginal pain, when used in combination with an antiplatelet agent.²²⁰ Intravenous heparin usually is given as a 5000-U bolus followed by continuous infusion. Low-molecular-weight heparins can be substituted for unfractionated heparin. Some studies have shown superior efficacy of low-molecular-weight heparins, but other studies have not indicated a significant difference. Direct thrombin inhibitors, such as hirudin and bivalirudin, have been shown to reduce the rate of death, nonfatal MI, and refractory angina compared to heparin.^{244,245} The American College of Chest Physicians (ACCP) recommends lepirudin (recombinant hirudin), argatroban, bivalirudin, or danaparoid in patients with a history of heparin-associated thrombocytopenia,²⁴⁶ although some of these agents are no longer available in the United States.

Therapy for Stable Angina Pectoris Patients with stable angina pectoris can be treated with either medical management or revascularization.²⁴⁷ Limited clinical trial data comparing revascularization, either percutaneous or surgical, to medical therapy are available. The older trials evaluating percutaneous and surgical revascularization were limited by several factors: antiplatelet treatment, angiotensin-converting enzyme inhibitors, and aggressive lipid lowering with statins were not given as background medical therapy of angina. Given these limitations, determining whether revascularization is better than medical management for long-term care of patients with stable angina in modern practice is difficult.

Both PCI and coronary bypass surgery significantly reduce angina. The Coronary Artery Surgery Study (CASS) showed more patients remained symptom-free after CABG compared to medical therapy 5 years after the procedure.²⁴⁸ At 10 years, however, no significant difference in symptoms was observed. Clinical trials showed significant improvement in angina with PCI compared to medical therapy; however, patients who underwent the former had similar rates of death and MI as those undergoing medical therapy and were less likely to have angina and more likely to have undergone a coronary bypass graft.²⁴⁹

Restenosis is a complex process involving inflammation, cellular proliferation, thrombosis, and matrix deposition. Restenosis occurring after PCI may result in flow-limiting luminal narrowing in 20 to 30 percent of therapeutically dilated vessels.²⁵⁰ Numerous pharmacologic agents, including heparin,²⁵¹ have been given in an attempt to reduce the restenosis rate but have met with limited or no success. Intraarterial radiation (brachytherapy) reduces the restenosis rate but is cumbersome to perform because of radiation safety issues and has fallen out of favor. Drug-eluting arterial stents, including the

immunosuppressive macrocyclic lactone rapamycin (sirolimus)²⁵² and the chemotherapeutic agent paclitaxel (Taxol),²⁵³ significantly reduce the rate of restenosis. Because drug-eluting stents were not available at the time of the previous clinical trials, extrapolating the benefits of PCI versus CABG or over medical therapy is difficult. The medical management of patients with stable angina pectoris should include antiplatelet therapy, statin drug treatment, a β -blocker, an angiotensin-converting enzyme inhibitor, and a long-acting nitrate.

PERIPHERAL ARTERY DISEASE

PAD is a term that encompasses any arterial disease of the lower extremities, upper extremities, and iliac vessels. It most commonly results from atherosclerosis. Patients who have atherosclerotic disease that compromises blood flow to the extremities may present with exertional pain in a muscle group, called *claudication* (derived from the Latin *claudicare* meaning “to limp”). Claudication is an intermittent but reproducible discomfort of a defined group of muscles that is induced by exercise and relieved with rest.²⁵⁴ Acute limb ischemia is a relatively rare problem in patients with PAD. In general, it is caused by *in situ* thrombosis or an embolic event from arrhythmias, such as atrial fibrillation, or after manipulation of an artery or aorta with a catheter. Approximately 4 percent of patients with claudication progress to *critical limb ischemia*, which is defined as rest pain and/or foot ulceration that heralds impending tissue loss.

The 5-year mortality rate is estimated to be 30 percent in patients with lower-extremity PAD.²⁵⁵ Approximately 75 percent of mortality results from a cardiovascular event, such as MI or stroke.²⁵⁵ The ankle-brachial index is a noninvasive measure of limb vascular pressure in the lower extremities and has been noted in several studies to be predictive of cardiovascular events.²⁵⁴ However, a decreased index is not just a predictor; it also is a physical finding that indicates significant atherosclerotic plaque burden is present. Other noninvasive imaging studies for PAD include the combination of segmental pressures and pulse volume recordings, duplex Doppler ultrasound, computed tomographic angiography and magnetic resonance imaging.^{256,257}

Medical therapy for patients with PAD includes risk-factor modification, antiplatelet therapy, and treatment of claudication symptoms with exercise rehabilitation and possible pharmacologic agents. The risk factors for development of peripheral atherosclerosis include cigarette smoking, diabetes mellitus, hypertension, and dyslipidemia.²⁵⁸ Aggressive management of risk factors for PAD is recommended to prevent disease progression.²⁵⁹ Treatment with antiplatelet agents reduces the risk of cardiovascular events, such as MI and stroke, in patients with PAD.²⁵⁵ The Antithrombotic Trialists' Collaboration evaluated 9214 patients with PAD enrolled in 42 trials and found that use of antiplatelet drugs, such as aspirin 75 to 325 mg/day, resulted in a proportional reduction of 23 percent in serious vascular events.²³⁴ Evaluation of patients with PAD in the Physicians' Health Study found that aspirin 325 mg every other day decreased the need for peripheral artery surgery.²⁶⁰ However, no difference between the aspirin and placebo groups with regard to development of claudication was observed. Several studies have evaluated the ADP receptor blockers ticlopidine and clopidogrel. Clopidogrel was evaluated in 19,185 patients in the Clopidogrel Versus Aspirin in Patients at Risk of Ischaemic Events (CAPRIE) study.²⁶¹ A dose of clopidogrel 75 mg/day had a modest but significant advantage over aspirin 325 mg/day in preventing stroke, MI, and peripheral vascular disease. Subgroup analysis revealed that the patients with PAD benefited the most with clopidogrel treatment. One study evaluating the effect of aspirin, 100 mg, compared to placebo in asymptomatic patients with diabetes mellitus and PAD found no benefit in reducing cardiovascular events.²⁶² The PAR-1 antagonist,

vorapaxar, is approved to prevent cardiovascular events in patients with PAD.²²³ The clinical consensus is that antiplatelet therapy should be offered to all patients with PAD unless contraindicated by allergy or comorbidities.²⁶³

The options for treating claudication symptoms include exercise rehabilitation, pharmacologic agents, and a revascularization procedure. Several studies indicate exercise rehabilitation improves the symptoms of claudication, and a supervised program is better than an unstructured program, and comparable to percutaneous revascularization.^{264,265} Two drugs are approved by the FDA for treatment of claudication symptoms: pentoxifylline, a methylxanthine derivative that may improve abnormal red cell deformability and reduce blood viscosity, and cilostazol, a type III phosphodiesterase inhibitor with antiplatelet and vasodilating properties. Cilostazol is generally considered more effective than pentoxifylline for improving walking distance in patients with claudication.²⁶⁶ The addition of cilostazol to either aspirin or clopidogrel does not increase the bleeding risk.²⁶⁷ A revascularization procedure in patients with stable, intermittent claudication generally is reserved for those with severe lifestyle-limiting symptoms or manifestation of critical limb ischemia.

CEREBROVASCULAR DISEASE

The etiology of ischemic stroke is multifactorial and can be categorized into embolic, small-vessel disease, large-vessel disease, and cryptogenic. Carotid artery disease accounts for approximately 30 percent of strokes. Major risk factors for developing carotid artery atherosclerosis are hypertension, diabetes, smoking, and dyslipidemia.²⁶⁸ Emerging risk factors for stroke include hyperhomocysteinemia and an elevated plasma level of lipoprotein(a). An elevated hsCRP level is a risk factor associated with ischemic stroke in both men and women. However, at this time hsCRP is not routinely measured as an additional marker for increased risk of stroke. Similar to CAD and PAD, control of atherosclerotic risk factors is essential in the primary prevention of stroke in patients with evidence of carotid atherosclerosis and for those who have undergone carotid endarterectomy.^{269,270}

Carotid endarterectomy is indicated for patients with symptoms and a greater than 50 percent stenosis²⁷¹ or for patients who are asymptomatic with a greater than 60 to 99 percent stenosis of the common carotid or internal carotid arteries.²⁷² Carotid stent with embolic protection is a therapy used for treatment of carotid atherosclerosis in selective patients.²⁷³

Two antiplatelet drug regimens are approved for prevention of stroke: clopidogrel (Plavix) and the combination of aspirin 25 mg and dipyridamole 200 mg daily. Approval of clopidogrel is based on the CAPRIE study, which showed a reduction in the combined end point of stroke, MI, and death in patients treated with clopidogrel 75 mg/day compared to those treated with aspirin 325 mg/day.²⁶¹ The FDA indication for dipyridamole/aspirin is primarily based on the European Stroke Protection Study 2, which noted a reduction in stroke with the combination of dipyridamole 200 mg and aspirin 25 mg given together (Aggrenox) twice per day.²⁷⁴ The Prevention Regimen for Effectively Avoiding Second Strokes (PROFESS) trial was a secondary stroke-prevention trial comparing the combination of aspirin and extended-release dipyridamole (Aggrenox) versus clopidogrel (Plavix) in preventing stroke recurrence after a first event. The difference between the agents was not statistically significant for the primary outcome of recurrent stroke.²⁷⁵ Fish oil (omega-3 fatty acids) lowers triglycerides and VLDLs and may reduce serum viscosity by lowering fibrinogen. Some studies suggest that fish oil consumption lowers the risk of ischemic stroke. The effect of fish oils on carotid atherosclerosis is unknown.²⁷⁶

ATHEROEMBOLISM

Atheromatous embolism refers to the dislodgment into the bloodstream of arterial plaque material, including cholesterol crystals (“cholesterol embolism”) from ulcerated vascular plaques. The cholesterol embolization syndrome involves systemic microembolism to the end arteries of almost any circulatory bed. Atheroembolism most characteristically originates from lesions in the abdominal aorta and iliofemoral arteries. Cholesterol emboli that lodge in an arteriole incite an acute inflammatory response, followed by a foreign-body reaction, intravascular thrombus formation, endothelial proliferation, and eventually fibrosis. These processes generally result in ischemia that sometimes leads to infarction and necrosis.²⁷⁷ Mortality rate of clinically diagnosed atheroembolism can be as high as 80 percent, depending on the anatomic location and size of the vascular beds involved.²⁷⁸

Patients with atheroembolism, including the cholesterol embolization syndrome, generally have advanced atherosclerosis, often complicated by a history of hypertension, diabetes mellitus, renal failure, or aortic aneurysms. Atherosclerotic plaques can disrupt and embolize spontaneously; however, the clinical syndrome typically is triggered by vascular intervention, including vascular surgery, catheterization, angioplasty, endarterectomy, or angiography. Anticoagulation or thrombolytic therapy may be risk factors with atheroembolism.²⁷⁸ Clinical presentation depends on the sites of embolization. When these sites involve the distal extremity microcirculation, the “blue toe syndrome” may develop. The syndrome presents with the acute appearance of painful and tender discoloration or mottled blue and patchy appearance of one or more toes that may progress to ulceration and gangrene. Other common cutaneous manifestations are livedo reticularis involving the legs, buttocks, or abdomen, painful nodules, and purpura. Cerebrovascular embolism can cause transient neurologic abnormalities. Cholesterol emboli lodged in retinal arterial bifurcations can be visualized by ophthalmoscopy as bright, refractile, yellow rectangular crystals. Visceral organs most commonly affected by atheroembolism include the kidneys, sometimes causing renal failure, and the gastrointestinal tract, where abdominal pain, ischemic colitis, and bleeding may ensue.

Diagnosis is based on clinical presentation associated with imaging evidence of atherosclerosis of the arterial supply of affected organs.²⁷⁸ Transient eosinophilia occurs in most cases.²⁷⁹ Treatment of atheroembolism should include surgical removal or bypass of the source of emboli. No medical treatment modalities have been established to be effective. Anticoagulation or fibrinolytic therapy may increase the risk of further atheroembolism.

CHAPTER 135

FIBRINOLYSIS AND THROMBOLYSIS

Katherine A. Hajjar and Jia Ruan

SUMMARY

Improved understanding of the molecular mechanisms of fibrinolysis has led to major advances in fibrinolytic and antifibrinolytic therapy. Characterization of the genes for all the major fibrinolytic proteins has revealed the structure of the relevant serine proteases, their inhibitors, and their receptors. The development of genetically engineered animals deficient in one or more fibrinolytic protein(s) has revealed both expected and unexpected functions. In addition, we now have a catalog of acquired and inherited disorders reflective of either fibrinolytic deficiency with thrombosis or fibrinolytic excess with hemorrhage. These advances have led to development of more effective and safer protocols for both pro- and antifibrinolytic therapy in a variety of circumstances.

BASIC CONCEPTS OF FIBRINOLYSIS

In response to vascular injury, fibrin, the insoluble end product of the action of thrombin on fibrinogen, is deposited in blood vessels, thus stemming the flow of blood. Once the vessel has healed, the fibrinolytic system is activated, converting fibrin to its soluble degradation products through the action of the serine protease, plasmin (Fig. 135-1A). Fibrinolysis is subject to precise control because of the actions of multiple activators, inhibitors, and cofactors.¹ In addition, receptors expressed by endothelial, monocytoïd, and myeloid cells provide specialized, protected environments where plasmin can be generated without compromise by circulating inhibitors (Fig. 135-1B).^{2,3} Beyond its more traditional role in fibrin degradation, the fibrinolytic system also supports a variety of tissue remodeling mechanisms. This chapter reviews the fundamental features of plasmin generation, considers the major clinical syndromes resulting from abnormalities in fibrinolysis, and discusses approaches to fibrinolytic and antifibrinolytic therapy.

COMPONENTS OF THE FIBRINOLYTIC SYSTEM

PLASMINOGEN

Synthesized primarily in the liver,^{4,5} plasminogen is a Mr approximately 92,000 single-chain proenzyme that circulates in plasma at a concentration of approximately 1.5 μM ⁶ (Table 135-1). The plasma half-life of

Acronyms and Abbreviations: α_2 -PI, alpha-2 plasmin inhibitor; APL, acute promyelocytic leukemia; IL, interleukin; MMP, matrix metalloproteinase; Plg, plasminogen; PAI, plasminogen activator inhibitor; TAFI, thrombin-activatable fibrinolysis inhibitor; TGF- β , transforming growth factor beta; t-PA, tissue-type plasminogen activator; u-PA, urokinase-type plasminogen activator; uPAR, urokinase-type plasminogen activator receptor.

plasminogen in adults is approximately 2 days.⁷ Its 791 amino acids are crosslinked by 24 disulfide bridges, 16 of which give rise to five homologous triple loop structures called “kringles” (Fig. 135-2).⁸ The first (K1) and fourth (K4) of these 80-amino-acid, Mr approximately 10,000 structures impart high- and low-affinity lysine binding, respectively.⁹ The lysine-binding domains of plasminogen appear to mediate its specific interactions with fibrin, cell surface receptors, and other proteins, including its circulating inhibitor α_2 -plasmin inhibitor (α_2 -PI).¹⁰⁻¹⁴

Posttranslational modification of plasminogen results in two glycosylation variants (forms 1 and 2; see Table 135-1).¹⁵⁻¹⁷ *O*-linked oligosaccharide, consisting of sialic acid, galactose, and galactosamine resident on Thr345, is common to both forms. Only form 2, however, contains *N*-linked oligosaccharide on Asn 288 that is comprised of sialic acid, galactose, glucosamine, and mannose. The carbohydrate portion of plasminogen appears to regulate its affinity for cellular receptors, and may also specify its physiologic degradation pathway.

Activation of plasminogen results from cleavage of a single Arg-Val peptide bond at position 560-561,⁶ giving rise to the active protease, plasmin (see Table 135-1). Plasmin contains a typical serine protease catalytic triad (His 602, Asp 645, and Ser 740), but exhibits broad substrate specificity when compared to other proteases of this class.¹⁸ The circulating form of plasminogen, aminoterminal glutamic acid plasminogen (Glu-Plg), can be converted by limited proteolysis to several modified forms known collectively as Lys-Plg.^{19,20} Hydrolysis of the Lys77-Lys78 peptide bond gives rise to a conformationally modified form of the zymogen that more readily binds fibrin, displays two- to threefold higher avidity for cellular receptors, and is activated 10 to 20 times more rapidly than Glu-Plg.^{11,21,22} Lys-Plg does not normally circulate in plasma,²¹ but has been identified on cell surfaces.^{23,24}

Spanning 52.5 kb of DNA on chromosome 6q26-27, the Plg gene consists of 19 exons^{25,26} and directs expression of a 2.7-kb mRNA⁸ (see Fig. 135-2). The 5' upstream region of the Plg gene contains two regulatory elements common to genes for acute-phase reactants (CTGGGA) and six interleukin (IL)-6 response elements.²⁶ Plg gene activity, moreover, is stimulated by the acute-phase-mediator IL-6 both *in vitro* and *in vivo*.²⁷ The gene is closely linked and structurally related to that of apolipoprotein(a), an apoprotein associated with the highly atherogenic low density lipoprotein-like particle lipoprotein(a),²⁸ and more distantly related to other kringle-containing proteins such as tissue-type plasminogen activator (t-PA), urokinase-type plasminogen activator (u-PA), macrophage-stimulating protein, and hepatocyte growth factor.²⁹⁻³⁴

The Physiologic Functions of Plasmin(ogen)

Mice made completely deficient in Plg through gene targeting undergo normal embryogenesis and development, are fertile, and survive to adulthood (Table 135-2).^{35,36} These animals display runting and liginous conjunctivitis,³⁷ and harbor spontaneous thrombi in the liver, stomach, colon, rectum, lung, and pancreas, as well as fibrin deposition in the liver and ulcerative lesions in the gastrointestinal tract and rectum. These results suggested that Plg is not strictly required for normal development, but does play a central role in fibrin homeostasis. In humans, Plg deficiency presents most often with liginous mucositis as a result of fibrin deposition, and is rarely a cause of macrovascular thrombosis (see Fibrinolytic Deficiency and Thrombosis below).

PLASMINOGEN ACTIVATORS

Tissue-Type Plasminogen Activator

One of two major endogenous Plg activators, t-PA consists of 527 amino acids comprising a glycoprotein of Mr approximately 72,000 (see Table 135-1).³⁸ t-PA contains five structural domains including a fibronectin-like “finger,” an epidermal growth factor-like domain, two

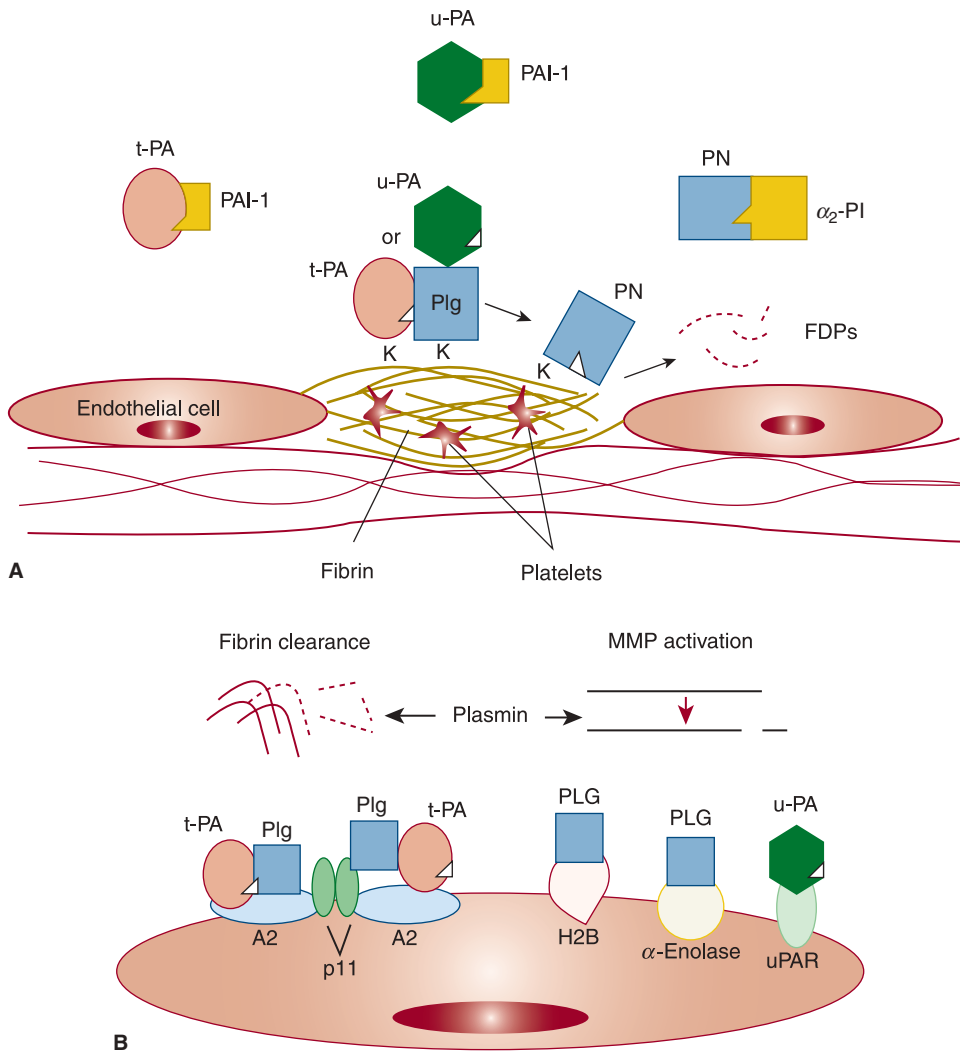

Figure 135-1. Overview of the fibrinolytic system. **A.** Fibrin-based plasminogen activation. The zymogen plasminogen (Plg) is converted to the active serine protease, plasmin (PN), through the action of tissue plasminogen activator (t-PA) or urokinase (u-PA). The activity of t-PA is greatly enhanced by its assembly with Plg through lysine residues (K) on a fibrin-containing thrombus. u-PA acts independently of fibrin. Both t-PA and u-PA can be inhibited by plasminogen activator inhibitor-1 (PAI-1), the main physiologic regulator of plasminogen activator activity. By binding to fibrin, PN is protected from its major inhibitor, α_2 -plasmin inhibitor (α_2 -PI). Fibrin-bound plasmin degrades crosslinked fibrin, giving rise to soluble fibrin degradation products (FDPs). **B.** Cell surface plasminogen activation. Although many cell types express receptors for Plg, urokinase, and t-PA, only the endothelial cell is depicted here. The annexin A2 heterotetramer, consisting of two copies each of annexin A2 (A2) and protein p11 (p11), binds both t-PA and Plg, thereby augmenting the efficiency of plasmin generation on endothelial cells. Plg may also bind to other endothelial cell receptors, including histone H2B (H2B), α -enolase, and may be activated by u-PA bound to its receptor, uPAR, to effect plasmin generation.

TABLE 135-1. Fibrinolytic Proteins

A. MAJOR PROTEASES

Property	Plasminogen	t-PA	u-PA
Molecular mass	92,000	72,000	54,000
Amino acids	791	527	411
Chromosome	6	8	10
Site of synthesis	Liver	Endothelium	Endothelium, kidney
Plasma concentration			
nM	1500	0.075	0.150
mcg/mL	140	0.005	0.008
Plasma half-life	48 h	5 min	8 min
N-glycosylation (%)	2	13	7
Form 1	–	Asn117, Asn184, Asn448	Asn302
Form 2	Asn288	Asn117, –, Asn448	–
O-Glycosylation			
α -Fucose	–	Thr61	Thr18
Complex	Thr345	–	–

α_2 -PI, α_2 -plasmin inhibitor; ND, not determined; PAI-1, plasminogen activator inhibitor type 1; PAI-2, plasminogen activator inhibitor type 2; Plg, plasminogen; Plg-R_{KT}, plasminogen receptor with terminal lysine; PN, plasmin; t-PA, tissue-type plasminogen activator; u-PA, urokinase plasminogen activator; uPAR, urokinase plasminogen activator receptor.

“kringle” structures homologous to those of Plg, and a serine protease domain (see Fig. 135-2). Cleavage of the Arg275–Ile276 peptide bond by plasmin converts t-PA to a disulfide-linked, two-chain form.³⁸ Although single-chain t-PA is less active than two-chain t-PA in the fluid phase, both forms demonstrate equivalent activity when fibrin-bound.³⁹

The two glycosylation forms of t-PA are distinguishable by the presence (type 1) or absence (type 2) of a complex *N*-linked oligosaccharide moiety on Asn184 (see Table 135-1).^{40,41} Both types, however, contain high mannose carbohydrate on Asn 117, complex oligosaccharide on

Asn448, and an *O*-linked α -fucose residue on Thr61.⁴² The carbohydrate moieties of t-PA may modulate its functional activity, regulate its binding to cell surface receptors, and specify its degradation pathways.

Located on chromosome 8p12–q11.2, the gene for human t-PA is encoded by 14 exons spanning a total of 36.6 kb (see Fig. 135-2).^{43–45} Although exon 1 encodes a 58-nucleotide mRNA leader sequence, each of the structural domains of t-PA is encoded by one or two of the remaining 13 exons. This arrangement suggests that the t-PA gene arose by an evolutionary process called “exon shuffling,” whereby functionally

Figure 135-2. Alignment of the intron–exon structure of plasminogen, tissue plasminogen activator, and urokinase genes showing functional protein domains. Protein domains are labeled signal peptide (SP), preactivation peptide (PAP), “kringle” domains (K), fibronectin–like “finger” (F), epidermal growth factor–like domain (EGF), and protease (P). The position of catalytic triad amino acids histidine (H), aspartic acid (D), and serine (S) are shown within individual protease domains. The positions of individual introns relative to amino acid encoding exons are indicated with inverted triangles.

related genes evolved through rearrangement of exons encoding autonomous domains. Consistent with this hypothesis, deletion of exons encoding the fibronectin–like finger or kringle 2, but not kringle 1, domains of t-PA results in expression of mutants resistant to the cofactor activity of fibrin, while catalytic activity in the absence of fibrin remains intact.⁴⁶

The proximal promoter of the human t-PA gene contains binding sequences for potentially important transcriptional factors including AP1, NF1, SP1, and AP2,^{47,48} as well as a potential cyclic adenosine monophosphate (cAMP)–responsive element (CRE).⁴⁹ *In vitro*, many agents have been shown to exert small effects on the expression of t-PA mRNA, but relatively few enhance t-PA synthesis without augmenting plasminogen activator inhibitor (PAI)–1 synthesis as well. Agents that regulate t-PA gene expression independently of PAI–1 include histamine, butyrate, retinoids, arterial levels of shear stress, and dexamethasone.^{50–55} Forskolin, which increases intracellular cAMP levels, has been reported to decrease synthesis of both t-PA and PAI–1.^{48,56}

In the vascular system, t-PA is synthesized and secreted primarily by endothelial cells belonging to a restricted set of blood vessels. In rodents, t-PA expression appears in 7- to 30- μ m diameter precapillary arterioles in the lung, postcapillary venules, and vasa vasorum; much less expression is seen in endothelial cells of the femoral artery, femoral vein, carotid artery, or aorta.⁵⁷ In the mouse lung, bronchial arteriolar endothelial cells express t-PA antigen, especially at branch points, while pulmonary blood vessels are uniformly negative.^{51,58–60} t-PA has

also been detected in sympathetic neurons associated with the blood vessel wall.⁶¹ Release of t-PA is governed by a variety of stimuli such as thrombin, histamine, bradykinin, epinephrine, acetylcholine, arginine vasopressin, gonadotropins, exercise, venous occlusion, and shear stress.^{50,51,62,63} Its circulating half-life is exceedingly short (~5 minutes). Alone, t-PA is actually a poor activator of Plg, but, in the presence of fibrin, the catalytic efficiency of t-PA–dependent plasmin generation (k_{cat}/K_m) increases by at least two orders of magnitude.²² This is the result of a dramatic increase in affinity (decreased K_m) between t-PA and its substrate Plg in the presence of fibrin. Although it is also expressed by extravascular cells, t-PA appears to represent the major intravascular activator of Plg.¹⁸

Urokinase

The second endogenous Plg activator, single-chain u-PA or prourokinase, is a Mr approximately 54,000 glycoprotein consisting of 411 amino acids (see Table 135–1). u-PA possesses an epidermal growth factor–like domain, a single Plg–like “kringle,” and a classical catalytic triad (His204, Asp255, Ser356) within its serine protease domain (see Fig. 135–2).⁶⁴ Cleavage of the Lys158–Ile159 peptide bond by plasmin or kallikrein converts single-chain u-PA to a disulfide–linked two-chain derivative.⁶⁵ Located on chromosome 10, the human u-PA gene is encoded by 11 exons spanning 6.4 kb, and expressed by activated endothelial cells, macrophages, renal epithelial cells, and some tumor cells.^{66,67} Its intron–exon structure is closely related to that of the t-PA

TABLE 135-2. Mouse Gene Deletion Models Relevant to Fibrinolysis

Genotype	Some Phenotypic Features	References
Plasminogen		
Plg ^{-/-}	Spontaneous thrombosis, runting, premature death	35, 36
	Fibrin in liver, lungs, stomach; gastric ulcers	35, 36
	Impaired wound healing	243, 244
	Ligneous mucositis	37
	Impaired monocyte recruitment	245
	Impaired neointima formation after electrical injury	246
	Impaired dissemination of <i>Borrelia burgdorferi</i>	247
Plasminogen Activators		
t-PA ^{-/-}	Reduced lysis of fibrin clot	84
	Increased endotoxin-induced thrombosis	84
u-PA ^{-/-}	Occasional fibrin in liver/intestine	84
	Rectal prolapse, ulcers of eyelids, face, ears	84
	Reduced macrophage degradation of fibrin	84
	Increased endotoxin-induced thrombosis	84
u-PA ^{-/-} t-PA ^{-/-}	Reduced growth, fertility, and life span; cachexia	84
	Fibrin deposits in liver, gonads, lungs	84
	Ulcers in intestine, skin, ears; rectal prolapse	84
	Impaired clot lysis	84
Inhibitors		
α_2 PI ^{-/-}	Reduced fibrin deposition following endotoxin	90
	Enhanced lysis of injected plasma clots	90
PAI-1 ^{-/-}	Mildly increased lysis of fibrin clot	123
	Resistance to endotoxin-induced thrombosis	124
TAFI ^{-/-}	Increased clot lysis	140, 142
	Reduced injury-related venous thrombosis	141
Receptors		
uPAR ^{-/-}	Normal development and fertility	163
	Normal clot lysis	164
Annexin A2 ^{-/-}	Fibrin deposition in microvasculature	205
	Impaired clearance of arterial thrombi	205
	Impaired postnatal neoangiogenesis	198, 205, 270
S100A10 ^{-/-}	Reduced baseline fibrin deposition	199

gene. u-PA expression appears to be induced during neoplastic transformation, possibly through the action of transcription factors AP1 and AP2.⁶⁸ Other *in vitro* u-PA inducers include hormones, angiogenic growth factors, and cAMP,⁵⁵ as well as tumor necrosis factor and transforming growth factor- β (TGF- β).⁶⁹⁻⁷¹

Two-chain u-PA occurs in both high- (Mr 54,000) and low-molecular-weight (Mr 33,000) forms that differ by the presence or absence, respectively, of a 135-residue aminoterminal fragment released by plasmin cleavage between Lys135 and Lys136.^{72,73} Although both forms are capable of activating Plg, only the high-molecular-weight form binds to the u-PA receptor (see Urokinase Plasminogen Activator Receptors below). u-PA has much lower affinity for fibrin than t-PA, and is an effective Plg activator both in the presence and in the absence of fibrin.^{74,75}

Accessory Plasminogen Activators and Fibrinolysis

Under certain conditions, proteases traditionally classified within the intrinsic arm of the coagulation cascade have been shown to be capable of activating Plg directly. These include kallikrein, factor XIa, and factor XIIa.⁷⁶⁻⁷⁸ These proteases, however, normally account for no more than 15 percent of total plasmin generating activity in plasma.⁷⁹ In addition, the membrane type 1 matrix metalloproteinase (MT1- MMP) appears to exert fibrinolytic activity in the absence of Plg, and may explain the unexpectedly mild phenotype observed in Plg-deficient mice.⁸⁰

Physiologic Function of the Plasminogen Activators

Because there are no clinical examples of complete deficiency of t-PA or u-PA in humans, except for patients with deficient release in the setting of chronic renal disease and hypertension,⁸¹⁻⁸³ the most compelling data regarding the physiologic functions of t-PA and u-PA come from gene disruption analysis in mice.⁸⁴ Both u-PA and t-PA null deletion mice exhibit normal fertility and embryonic development. However, u-PA^{-/-} mice develop rectal prolapse, nonhealing ulcerations of the face and eyelids, and occasional fibrin deposition in tissues. Although they show normal lysis rates of pulmonary clots injected via the jugular vein, endotoxin-induced microvascular thrombus formation is significantly enhanced. t-PA-deficient mice also display a normal spontaneous phenotype, but have a decreased rate of lysis of artificially induced pulmonary thrombi, as well as enhanced thrombus formation, in response to injection of endotoxin. Like Plg^{-/-} mice, mice doubly deficient in t-PA and u-PA (t-PA^{-/-}; u-PA^{-/-}) exhibit rectal prolapse, nonhealing ulceration, runting, and cachexia, with extensive fibrin deposition in liver, intestine, gonads, and lung. Not surprisingly, clot lysis is also markedly impaired.

INHIBITORS OF FIBRINOLYSIS

Plasmin Inhibitors

The action of plasmin is negatively modulated by a family of serine protease inhibitors, called serpins (see Table 135-1).⁸⁵ Serpins form an irreversible complex with the active site serine of their target protease following proteolytic cleavage of the inhibitor by the target protease. Within such a complex, both protease and inhibitor lose their activity.

A single-chain glycoprotein of Mr approximately 70,000, α_2 -PI is synthesized primarily in the liver, circulates in plasma at relatively high concentrations (~0.9 μ M), and enjoys a plasma half-life of 2.4 days (see Table 135-1).⁸⁶ This serpin contains approximately 13 percent carbohydrate by mass and consists of 452 amino acids with two disulfide bridges.⁸⁷ In humans, the gene is located on chromosome 18 and contains 10 exons distributed over 16 kb of DNA.⁸⁸ The promoter region of the α_2 -PI gene contains a hepatitis B-like enhancer element that directs tissue-specific expression in the liver.⁸⁷ α_2 -PI is also a constituent

of platelet α granules.⁸⁹ Plasmin released into flowing blood or in the vicinity of a platelet-rich thrombus, is immediately neutralized upon forming an irreversible 1:1 stoichiometric, lysine-binding site-dependent complex with α_2 -PI. Interaction with plasmin is accompanied by cleavage of the Arg364–Met365 peptide bond, and the resulting covalent complexes are cleared in the liver. Mice globally deficient in α_2 -PI display reduced fibrin deposition, following treatment with endotoxin and enhanced lysis of injected plasma clots, but no spontaneous bleeding (see Table 35–2).⁹⁰

Several additional proteins can act as plasmin inhibitors (see Table 135–1). α_2 -Macroglobulin is a Mr 725,000 dimeric protein synthesized by endothelial cells and macrophages, and found in platelet α granules. This nonserpin inhibits plasmin with approximately 10 percent of the efficiency exhibited by α_2 -PI by forming noncovalent complexes with several distinct serine proteases.⁹¹ C₁-esterase inhibitor can inhibit t-PA in plasma⁹² and protease nexin may function as a noncirculating cell surface inhibitor of trypsin, thrombin, factor Xa, urokinase, or plasmin, resulting in protease-inhibitor complexes that are endocytosed via a specific nexin receptor.^{93,94} The purpose of these multiple plasmin inhibitors is to guard against premature plasmin activation and subsequent degradation of fibrinogen, until intravascular fibrin begins to appear/.

Plasminogen Activator Inhibitors

Plasminogen Activator Inhibitor-1 Of the two major Plg activator inhibitors, PAI-1 is the most ubiquitous (see Table 135–1).⁹⁵ This Mr approximately 52,000 single-chain, cysteine-less glycoprotein is released by endothelial cells, monocytes, macrophages, hepatocytes, adipocytes, and platelets.^{96–98} Release of PAI-1 is stimulated by many cytokines, growth factors, and lipoproteins common to the global inflammatory response.^{69,70,99,100,101} The PAI-1 gene consists of nine exons, spanning 12.2 kb on chromosome 7q21.3–q22.¹⁰² The serpin-reactive site is located at Arg346–Met347, and activity of this labile serpin is stabilized upon complex formation with vitronectin, a component of plasma and pericellular matrix.^{103–105}

Regulation of PAI-1 gene expression is complex.^{106,107} The upstream regulatory region of the human PAI-1 gene contains a strong endothelial cell/fibroblast-specific element^{108,109} a glucocorticoid-responsive enhancer,¹⁰⁹ and TGF- β responsive elements.¹¹⁰ TGF- β is known to stimulate fos and jun, the two components of the AP1 complex, and an AP1 binding site (GGAGTCA) is located upstream of the PAI-1 cap site.¹¹¹ Agents shown to enhance expression of PAI-1 at the message level, the protein level, or both, without affecting t-PA synthesis, include the inflammatory cytokines lipopolysaccharide, IL-1, tumor necrosis factor- α ,^{69,70,99,112,113} TGF- β and basic fibroblast growth factor,^{71,99,110,114} very-low-density lipoprotein and lipoprotein(a),^{115,116} angiotensin II,¹¹⁷ thrombin,^{118,119} and phorbol esters.¹²⁰ In addition, endothelial cell PAI-1 is downregulated by forskolin⁵⁶ and by endothelial cell growth factor in the presence of heparin.¹²¹

PAI-1 is the most important and rapidly acting physiologic inhibitor of both t-PA and u-PA. Transgenic mice that overexpress PAI-1 exhibit thrombotic occlusion of tail veins and swelling of hind limbs within 2 weeks of birth.¹²² Mice deficient in PAI-1, on the other hand, exhibit normal fertility, viability, tissue histology, and development, and are resistant to endotoxin-induced thrombosis, but show no evidence of overt hemorrhage (see Table 135–2).^{123,124} These observations contrast with the moderately severe bleeding disorder observed in a human patient with complete PAI-1 deficiency.¹²⁵

Plasminogen Activator Inhibitor-2 Originally purified from human placenta, PAI-2 is a 393-amino-acid member of the serpin family whose reactive site is the Arg358–Thr359 peptide bond¹²⁶ (see Table 135–1). The gene encoding PAI-2 is located on chromosome 18q21–23, spans 16.5 kb, and contains eight exons.¹²⁷ PAI-2 exists as

both a Mr 47,000 nonglycosylated intracellular form and an Mr 60,000 glycosylated form secreted by leukocytes and fibrosarcoma cells. Functionally, PAI-2 inhibits both two-chain t-PA and two-chain u-PA with comparable efficiency (second order rate constants 10^5 M⁻¹s⁻¹). However, it is less effective toward single-chain t-PA (second order rate constant 10^3 M⁻¹s⁻¹), and does not inhibit prourokinase.

Significant levels of PAI-2 are found in human plasma primarily during pregnancy. The gene's 5'-untranslated region contains a potent silencer, the PAUSE-1 element, which may be responsible for its low level of expression in nonpregnant individuals.^{127,128} The 3'-downstream sequences include the TTATTAT motif which has been identified with inflammatory mediators.^{129,130} In macrophages *in vitro*, secretion of PAI-2 is enhanced by endotoxin and phorbol esters^{130,131} and dexamethasone decreases PAI-2 expression in HT-1080 cells.⁵⁵

Thrombin-Activatable Fibrinolysis Inhibitor

Thrombin-activatable fibrinolysis inhibitor (TAFI) is a plasma carboxypeptidase with specificity for carboxy terminal arginine and lysine residues.¹³² The action of TAFI eliminates binding sites for Plg and t-PA on fibrin.¹³³ This single-chain Mr 60,000 polypeptide circulates in plasma at concentrations of approximately 75 nM, and undergoes limited proteolysis in the presence of thrombin, which leads to its activation.^{134–136} The profibrinolytic effect of activated protein C in plasma is a result of its ability to inactivate coagulation factors Va and VIIIa, which reduces activation of thrombin, the primary activator of TAFI.¹³² The profibrinolytic effect of activated protein C in an *in vitro* plasma-based system was TAFI-dependent,¹³⁷ and, in a system of purified components, TAFI has been shown to downregulate t-PA-induced fibrinolysis half-maximally at a concentration of approximately 1 nM, which is 2 percent of its concentration in plasma.¹³⁸ Inhibition of either the intrinsic pathway of coagulation or TAFI itself results in a doubling of endogenous clot lysis in an *in vivo* rabbit jugular vein model of thrombolysis.^{139,140} TAFI-deficient mice display increased lysis of plasma clots and reduced injury-induced venous thrombosis (see Table 135–2).^{141,142} In plasma, TAFI may regulate Plg binding to both cell surface receptors and to fibrin.¹⁴³

CELLULAR RECEPTORS

A large number of structurally diverse fibrinolytic “activation” and “clearance” receptors have been described. Here, we focus on endothelial cell activation receptors that are likely to contribute to homeostatic control of plasmin activity (see Table 135–1).² Clearance receptors eliminate plasmin and Plg activators from the blood or focal microenvironments.

Activation Receptors

Plasminogen Receptors Proposed Plg receptors include α -enolase, glycoprotein IIb/IIIa complex, the Heymann nephritis antigen, amphoterin, the annexin A2/S100A10 complex, histone H2B, and plasminogen receptor-KT (Plg-R_{KT})^{2,3}; these are expressed on a wide spectrum of cells, including monocytoïd cells, platelets, renal epithelial cells, neuroblastoma cells, endothelial cells, and tumor cells.^{144–151} Typically, Plg receptors interact with the kringle structures of Plg through carboxyl-terminal lysine residues that are either present on the native protein, or generated by limited proteolysis.¹⁴⁴

Urokinase Plasminogen Activator Receptor The u-PA receptor (uPAR) is expressed on monocytes, macrophages, fibroblasts, endothelial cells, and many tumor cells (see Table 135–1).^{152,153} uPAR complementary DNA (cDNA) was cloned and sequenced from a human fibroblast cDNA library¹⁵⁴ and encodes a protein of 313 amino acids with a 21-residue signal peptide. The gene consists of seven exons distributed over 23 kb of genomic DNA, and places this glycoprotein within the Ly-1/elapid venom toxin superfamily of cysteine rich proteins.^{155,156}

uPAR is anchored to the plasma membrane through glycosylphosphatidylinositol linkages.¹⁵⁷ u-PA bound to its receptor maintains its activity and susceptibility to the physiologic inhibitor, PAI-1.¹⁵⁸ Formation of u-PA-PAI-1 complexes hastens clearance of u-PA by hepatic or monocyte cells.¹⁵⁸⁻¹⁶¹

Although originally thought to function only as a means of localizing Plg activation to the cell surface, uPAR now appears to play a central role in cellular signaling and adhesion events.^{152,162} The uPAR-deficient mouse has normal development and fertility, and unimpaired fibrin clot lysis (see Table 135-2).^{163,164} uPAR binds the adhesive glycoprotein vitronectin at a site distinct from the u-PA binding domain^{165,166} and u-PA transfected renal epithelial cells acquire enhanced adhesion to vitronectin while they lose their adhesion to fibronectin.¹⁶⁷ uPAR, furthermore, colocalizes with integrins in focal contacts and at the leading edge of migrating cells,¹⁶⁸ and also associates with caveolin, a major component of caveolae, structures abundant in endothelial cells and thought to participate in signaling events.¹⁶⁹⁻¹⁷¹ In addition, cleaved and soluble forms of uPAR have recently been detected in the sera of patients with cancer, and these modified forms are thought to regulate the activity of several receptors involved in inflammatory and angiogenic responses.¹⁵³

The Annexin A2-S100a10 System Annexin A2, a Mr 36,000, 339-amino-acid member of the annexin superfamily of calcium-dependent, phospholipid-binding proteins, forms a heterotetramer with the S100 family protein, S100A10 (see Table 135-1).¹⁷²⁻¹⁷⁴ It is highly conserved, and abundantly expressed on endothelial cells,¹⁷⁵⁻¹⁷⁸ monocyte/macrophages,^{179,180} early myeloid cells,¹⁸¹ developing neuronal cells,¹⁸² and some tumor cells.¹⁸³⁻¹⁸⁵ All of the more than 60 annexin family members have in common a conserved membrane-binding C-terminal “core” region and a more variable N-terminal “tail.”¹⁸⁶ The human annexin A2 gene consists of 13 exons distributed over 40 kb of genomic DNA on chromosome 15 (15q21).¹⁸⁷

Annexin A2 is unique among fibrinolytic receptors in that it possesses binding affinity for both Plg (Kd 114 nM)¹⁴⁸ and t-PA (Kd 30 nM), but not u-PA.¹⁴⁹ In a fluid phase system of purified proteins, native human annexin A2 stimulates the catalytic efficiency of t-PA-dependent Plg activation by 60-fold.¹⁸⁸ This effect is completely inhibited in the presence of lysine analogues or upon treatment of annexin A2 with carboxypeptidase B, an agent that removes basic carboxyl-terminal amino acids. Although it lacks a classical signal peptide, annexin A2 is constitutively translocated to the endothelial cell surface within 16 hours of its biosynthesis. This translocation event can be stimulated either by thrombin or by heat stress, in a process that requires phosphorylation of annexin A2 at Tyr23, the action of a Src family kinase, and the presence of the annexin A2 binding protein p11 (S100A10).¹⁸⁹

At the cell surface, A2 binds phospholipid via core repeat 2, which contains the linear amino acid sequence KGLGT and downstream aspartate residue (Asp 161); together these moieties constitute a classical “annexin” motif.¹⁹⁰ The annexin A2 heterotetramer, which consists of two A2 monomers and two protein p11 subunits and constitutes the cell surface form of A2, appears to have even greater stimulatory effects on t-PA-dependent plasmin generation.¹⁷⁷ Interestingly, A2 regulates endogenous levels of protein p11 in the endothelial cell by masking a polyubiquitination site on p11, which otherwise directs p11 to the proteasome where it is rapidly degraded.¹⁹¹

Plg and t-PA appear to bind to distinct domains. Lys307 appears to be crucial for the effective interaction of Plg with annexin A2, and may be revealed upon limited proteolysis of the parent protein.¹⁸⁸ The atherogenic low-density lipoprotein (LDL)-like particle, lipoprotein(a), competes with Plg for binding to annexin A2 *in vitro*,¹⁹² thereby reducing cell surface plasmin generation. t-PA binding to annexin A2 requires a domain consisting of residues 8 to 13 (LCKLSL) within the receptor’s amino terminal “tail” domain.¹⁹³ This region is a target for homocysteine

(HC), a thiol-containing amino acid that accumulates in association with nutritional deficiencies of vitamin B₆, vitamin B₁₂, or folic acid, or in inherited abnormalities of cystathionine β -synthase, methylenetetrahydrofolate reductase, or methionine synthase,¹⁹⁴ and is associated with atherothrombotic disease.^{195,196} *In vitro*, HC impairs t-PA-dependent plasmin generation at the endothelial cell surface by approximately 50 percent¹⁹⁷ by forming a covalent derivative with Cys,¹⁹⁷ and mice with diet-induced hyperhomocysteinemia have deficient annexin A2 function¹⁹⁸ The half-maximal dose of HC for inhibition of t-PA binding to annexin A2 is approximately 11 μ M HC, a value close to the upper limit of normal for HC in plasma (12 μ M).

The important role of S100A10 in fibrin balance has recently been underscored. S100A10^{-/-} mice display increased deposition of fibrin in the vasculature and reduced clearance of batroxobin-induced vascular thrombi, and S100A10-deficient endothelial cells demonstrate a 40 percent reduction in Plg binding and plasmin generation *in vitro* (see Table 135-2).¹⁹⁹ S100A10 also appears to contribute to Plg-dependent macrophage invasion *in vitro* by enhancing plasmin-dependent activation of matrix metalloproteinase-9.²⁰⁰

Several studies suggest a physiologic role for the annexin A2 system in fibrin homeostasis. First, blast cells from human patients with acute promyelocytic leukemia overexpress annexin A2 in proportion to their degree of hyperfibrinolytic coagulopathy¹⁸¹; S100A10 also appears to be upregulated by the PML-RAR- α oncoprotein,²⁰¹ and both annexin A2 and S100A10 are downregulated by treatment with all-*trans*-retinoic acid. Second, in rats, arterial thrombosis can be significantly attenuated by pretreatment with intravenous annexin A2.²⁰² Third, the prevalence of high-titer anti-annexin A2 antibodies correlates with a history of severe thrombosis in humans with antiphospholipid syndrome and in a cohort of individuals with cerebral venous thrombosis.^{203,204} Finally, mice with total deficiency of annexin A2 display impaired clearance of artificial arterial thrombi, fibrin deposition in the microvasculature, and angiogenic defects in a variety of tissues (see Table 135-2).²⁰⁵

Clearance Receptors

Clearance of serpin-enzyme complexes, such as t-PA-PAI-1 and u-PA-PAI-1, occurs mainly in the liver, and is mediated by a large two-chain receptor called the LDL receptor-related protein 1 (LRP1).^{206,207} LRP1 binds a large number of serpin-protease complexes and other ligands, indicating a multifunctional role in mammalian physiology. An additional Mr 39,000 “receptor associated protein” copurifies with LRP1 and appears to regulate the binding and uptake of LRP1 ligands.²⁰⁸ Interestingly, LRP1 “knockout” embryos undergo developmental arrest by 13.5 days after conception, suggesting that regulation of serine protease activity may be crucial for early embryogenesis.^{209,210} Although PAI-1-independent clearance pathways for t-PA have been proposed involving the mannose receptor,²¹¹ or an α -fucose-specific receptor,²¹² *in vivo* studies in mice suggest that LRP1 and the mannose receptor play a dominant role in t-PA clearance.²¹³

● THE FIBRINOLYTIC ACTIONS OF PLASMIN

DEGRADATION OF FIBRINOGEN AND FIBRIN

Fibrinogen

Plasmin releases carboxyl-terminal A α and N-terminal fibrinopeptide B moieties from fibrinogen (Fig. 135-3). This reaction is distinct from the proteolytic cleavage of fibrinogen by thrombin, which releases fibrinopeptide A, exposing the Gly-Pro-Arg tripeptide sequence and allowing fibrinogen to polymerize and form insoluble fibrin.²¹⁴ Plasmin cleavage of fibrinogen (Mr 340,000) initially produces

Figure 135-3. Degradation of fibrinogen and crosslinked fibrin by plasmin. **Top panel:** On fibrinogen, plasmin initially cleaves the C-terminal regions of the α and β chains within the D domain, releasing the $A\alpha$ and $B\beta$ fragments. In addition, a fragment containing fibrinopeptide B (FPB) from the N-terminal region of the β chain is released giving rise to the intermediate fragment known as "fragment X." Subsequently, plasmin cleaves the three connecting polypeptide chains connecting D and E domains, giving rise to fragments D, E, and Y. **Bottom panel:** Upon polymerization by thrombin, fibrinogen forms fibrin. When degrading crosslinked fibrin, plasmin initially cleaves the C-terminal region of the α and β chains within the D domain. Subsequently, some of the connecting regions between the D and E domains are severed. Fibrin is ultimately solubilized upon hydrolysis of additional peptide bonds within the central portions of the coiled-coil connectors, giving rise to fibrin degradation products such as D-dimer. (Reproduced with permission Nathan DG, Orkin SH, Ginsburg D, et al: Hematology of Infancy and Childhood. 6th edition. Philadelphia, PA: WB Saunders; 2003.)

carboxyl-terminal fragments from the α chain within the D domain of fibrinogen ($A\alpha$ fragment).^{205-208,215-218} Simultaneously, but more slowly, the N-terminal segments of the β chains are cleaved, releasing a peptide containing fibrinopeptide B. The resulting Mr approximately 250,000 molecule is termed fragment X and represents a clottable form of fibrinogen. Additional cleavage events may release the $B\beta$ fragment from the β chain's carboxyl-terminus, and, in a series of subsequent reactions, plasmin cleaves the three polypeptide chains that connect the D and E domains giving rise to free D domain (Mr ~100,000) plus the binodular D-E fragment known as fragment Y (Mr ~150,000). Finally, domains D and E are separated from each other, and some of the N-terminal fibrinopeptide A sites on domain E are also modified. Although fragment X can be converted to fibrin by thrombin, the fragments Y, D, and E are all nonclottable, and, in fact, may inhibit polymerization of fibrinogen.²¹⁹

Fibrin

Plasmin degradation of fibrin leads to a distinct set of molecular products (see Fig. 135-3).²²⁰ Species similar to fragments Y, D, and E, but lacking fibrinopeptide sites, are released from noncrosslinked fibrin. If fibrin has been extensively crosslinked by factor XIII, however, the resulting D fragments are crosslinked to an E domain fragment. Assay of crosslinked D-dimer fragments is employed clinically to identify disseminated intravascular coagulation-like states associated with excessive plasmin-mediated fibrinolysis. Several biologic activities, including inhibition of platelet function,²²¹ potentiation of the hypotensive effects

of bradykinin,²²² chemotaxis,²²³ and immune modulation,²²⁴ have been ascribed to fibrin breakdown products.

TISSUE-TYPE PLASMINOGEN ACTIVATOR – MEDIATED PLASMINOGEN ACTIVATION

With or without fibrin, t-PA-mediated activation of Plg follows Michaelis-Menten kinetics.²² In the absence of fibrin, t-PA is a weak activator of Plg. However, in the presence of fibrin, the catalytic efficiency (k_{cat}/K_m) of t-PA-dependent Plg activation is enhanced by approximately 500-fold. This is the basis for its specificity as a lytic agent in the treatment of thrombosis. The affinity between t-PA and Plg in the absence of fibrin is low (K_m 65 μ M), but increases significantly in its presence (K_m 0.16 μ M), even though the catalytic rate constant remains essentially unchanged (k_{cat} ~0.05 sec^{-1}). When plasmin forms on the fibrin surface, both its lysine binding sites and its active site are occupied. Thus, it is relatively protected from its physiologic inhibitor, α_2 -PI.²²⁵

The interaction of t-PA with fibrin is probably initiated by its "finger" domain. However, once fibrin is modified by plasmin, carboxy-terminal lysine residues are generated, and these become binding sites for "kringle" 2 of t-PA and "kringles" 1 and 4 of Plg.²²⁶ Therefore, fibrin accelerates its own destruction by (1) enhancing the catalytic efficiency of plasmin formation by t-PA, (2) protecting plasmin from its physiologic inhibitor, α_2 -PI, and (3) providing new binding sites for Plg and t-PA once its degradation has begun.

UROKINASE-TYPE PLASMINOGEN ACTIVATOR-MEDIATED PLASMIN GENERATION

For the activation of Glu-Plg by u-PA in a fibrin-free system, reported Michaelis constants (K_m) vary from 1.4 to 200 μM , while catalytic rate constants (kcat) range from 0.26 to 1.48 sec^{-1} .¹ Interestingly, activation of Glu-Plg by two-chain u-PA is increased in the presence of fibrin by approximately 10-fold even though u-PA does not bind to fibrin.²²⁷ In contrast, single-chain u-PA has considerable fibrin-specificity. This may reflect neutralization by fibrin of components in plasma that impair Plg⁷⁴ also reflect a conformational change in Plg upon binding to fibrin.²²⁸ It is important to recognize, however, that the intrinsic Plg activating potential of single-chain u-PA is less than 1 percent of that of two-chain u-PA. Two-chain u-PA has been used effectively as a thrombolytic agent for many years.²²⁹

THE NONFIBRINOLYTIC ACTIONS OF PLASMIN

PLASMIN AS A TISSUE REMODELER

A large number of *in vitro* studies suggest a role for plasmin in tissue remodeling. Basement membrane proteins such as thrombospondin,²³⁰ laminin,²³¹ fibronectin,²³² and fibrinogen,²³³ are readily degraded by plasmin *in vitro*, suggesting possible roles in inflammation,²³⁴ tumor cell invasion,²³⁵ embryogenesis,²³⁶ ovulation,²³⁷ neurodevelopment,^{238,239} and prohormone activation.^{240,241} Plasmin also activates MMPs 3 and 13 in the mouse, thereby facilitating the degradation of matrix proteins such as the collagens, laminin, fibronectin, vitronectin, elastin, aggrecan, and tenascin C.²⁴² On the other hand, activation of other MMPs apparently proceeds in the absence of Plg, possibly providing the basis for the mild phenotype observed in Plg-null homozygote animals.⁸⁰

Roles for plasmin in tissue remodeling and host defense mechanisms are further supported by *in vivo* observations in Plg-deficient mice (see Table 135-2). Impaired wound healing is observed in the Plg “knockout,”²⁴³ and is reversed upon simultaneous deletion of fibrinogen.²⁴⁴ Plg-deficient mice also display diminished recruitment of monocytes in response to intraperitoneal thioglycolate,²⁴⁵ and impaired neointima formation following electrical injury to blood vessels.²⁴⁶ In studies involving *Borrelia burgdorferi*, the agent of Lyme disease, dissemination of the spirochete within its arthropod vector *Ixodes dammini* is absolutely dependent upon host Plg even though the deer tick contains no fibrin.²⁴⁷ Furthermore, kainate-induced excitotoxicity and attendant neuronal cell dropout in the hippocampus is not observed in Plg knockout mice but does occur in fibrinogen-deficient animals.²⁴⁸ The latter two studies may define new roles for plasmin, which appear to be unrelated to degradation of fibrin.

In the lung, the fibrinolytic system mediates lung matrix remodeling, through mechanisms that appear to be independent of fibrin degradation.²⁴⁹ In mice, deficiency of fibrinogen has no effect on the development of bleomycin-induced pulmonary fibrosis.²⁵⁰ Mice lacking either PAI-1 or TAFI are protected from lung fibrosis in the same model,²⁵¹⁻²⁵³ whereas inducible expression of u-PA within alveoli abrogates the fibrotic response.²⁵⁴

Plasmin may play a role in the activation of growth factors. TGF- β is a Mr 25,000 homodimeric polypeptide that regulates vascular cell responses and epithelial-mesenchymal transformation in development and in tissue fibrosis.^{255,256} In culture, cell-associated plasmin appears to convert latent TGF- β to its physiologically relevant active state. Inhibition of wound healing in this system was dependent upon active TGF- β , and activation of this agent could be blocked in the presence of plasmin inhibitors such as aprotinin or α_2 -PI. Activation of TGF- β by plasmin

may reflect alteration of its tertiary structure upon cleavage of an aminoterminal glycopeptide.²⁵⁷ Once activated by plasmin, TGF- β can stimulate production of PAI-1, thus impairing further activation of Plg.

The role of the fibrinolytic system in vascular remodeling during atherosclerosis appears to be complex.²⁵⁸ In the evolution of an injury to the endothelial cell lining of blood vessels, deposition of intravascular fibrin and organization of a thrombus occurs.²⁵⁹ As the injury resolves, fibrin participates in plaque growth and luminal narrowing. Evidence of the importance of fibrinolytic balance in this process is that, in the absence of PAI-1, there is less neointima formation and reduced luminal stenosis, possibly because of more rapid resolution of fibrin.²⁶⁰ In areas of the vasculature where injury is not associated with fibrin deposition, however, absence of PAI-1 may lead to enhanced lesion formation, as cells that invade the developing plaque may require plasmin activity for their directed migration.²⁶¹

FIBRINOLYSIS AND ANGIOGENESIS

Although the fibrinolytic system has generally been assumed to be proangiogenic by virtue of its ability to promote “tunneling” of endothelial cells through fibrin-containing matrices, its effect, in actuality, appears to be context specific.^{262,263} PAI-1 deficiency in mice, for example, seems to prevent tumor vascularization in a malignant keratinocyte model.²⁶⁴ The same mice are also resistant to laser-induced neovascularization of the choroid.^{265,266} The paradoxical proangiogenic effect of PAI-1 in some settings may relate to its ability to protect endothelial cells from apoptosis mediated by FasL, which is activated by plasmin.²⁶⁷

In the mouse cornea, absence of t-PA, u-PA, or TAFI, had no effect on neovascularization, whereas loss of Plg, PAI-1, or annexin A2 significantly diminished this response.^{205,268} Within the atherosclerotic plaque, moreover, expression of a truncated form of PAI-1 (rPAI-1₂₃) was antiangiogenic, inhibiting the proliferation of vasa vasorum, and reducing overall plaque area and plaque cholesterol in the descending aorta.²⁶⁹ As a gene product that is transcriptionally upregulated by hypoxia, annexin A2 is required for the normal corneal angiogenic response to growth factor stimulation, and also for hypoxia-induced retinal angiogenesis.^{198,205,270}

DISORDERS OF PLASMIN GENERATION

FIBRINOLYTIC DEFICIENCY AND THROMBOSIS

Although partial human Plg deficiency was first described in a young man with a history of venous thrombosis and pulmonary embolism,²⁷¹ there is currently little evidence that hypoplasminogenemia alone is a significant cause of deep venous thrombosis.²⁷² In a study of 23 consecutive patients with thrombophilia, the prevalence of Plg deficiency was only 1.9 percent.²⁷³ Approximately half of these individuals had other risk factors such as deficiency of antithrombin, protein C, or protein S, or resistance to activated protein C. Among 93 patients with type I Plg deficiency, the prevalence of thrombosis was 24 percent, or 9 percent when the propositi were excluded.²⁷⁴ Two additional epidemiologic studies concluded, moreover, that isolated hypoplasminogenemia is not a risk factor for thrombosis.^{275,276}

Although there are no reported cases of complete absence of Plg in humans, a large number of Plg polymorphisms and dysplasminogenemias have been reported.²⁷² Congenital Plg deficiency has been classified into two types: in type I the concentration of immunoreactive Plg is reduced in parallel with functional activity,²⁷⁷ whereas in type II (dysplasminogenemia), immunoreactive protein is normal while functional activity is reduced.²⁷⁸ Patients with type I Plg deficiency are most likely to present with ligneous conjunctivitis, which resolves completely

upon infusion of Lys-Plg.^{279,280} In a study of a Japanese cohort, approximately 27 percent of individuals with type II deficiency had a clinical history of thrombosis, but it is not clear whether there were other explanations for thrombophilia in these individuals.²⁸¹ Acquired Plg deficiency may occur in liver disease, sepsis, and Argentine hemorrhagic fever due to decreased synthesis and/or increased catabolism,²⁸² but associated thrombosis may be due to abnormalities in other hemostatic factors in these very ill patients. Similarly, there are no reported cases of complete t-PA or u-PA deficiency in humans, and no mutations or polymorphisms in these genes have so far been clinically linked to thrombophilia. Defects in Plg activator release, as well as increased inhibition of t-PA by PAI-1, have been reported in association with thrombosis,^{283,284} and with chronic renal disease and hypertension.^{81,83}

Global deficiency in fibrinolytic function, moreover, is associated with increased risk for venous thrombosis, as well as first myocardial infarction in young men.^{285,286} Increased circulating PAI-1 appears to represent an independent risk factor for vascular reocclusion in young survivors of myocardial infarction.²⁸⁷ In addition, increased levels of PAI-1 have been associated with deep vein thrombosis in patients undergoing hip replacement surgery²⁸⁸ and in individuals with insulin resistance.²⁸⁹ Although a 4G versus 5G polymorphism in the PAI-1 promoter has been reported, the 4G form being associated with higher PAI-1 plasma levels, it is not yet established as to whether this allele correlates with elevated thrombotic risk.^{290,291} With regard to such studies, one should bear in mind that PAI-1 is itself an acute phase reactant, and thus may not be directly responsible for the observed prothrombotic tendency.²⁹²

ENHANCED FIBRINOLYSIS AND BLEEDING

Enhanced fibrinolysis resulting from congenital or acquired loss of fibrinolytic inhibitor activity may be associated with a bleeding diathesis.²⁹³ Patients with congenital deficiency of α_2 -PI may present with a severe hemorrhagic disorder as a result of impaired inactivation of plasmin and premature lysis of the hemostatic plug.²⁹⁴ Acquired α_2 -PI deficiency may be seen in patients with severe liver disease from decreased synthesis, disseminated intravascular coagulation from consumption, nephrotic syndrome from urinary losses, or during thrombolytic therapy, which induces excessive utilization of the inhibitor.²⁹⁴ TAFI levels are markedly reduced in liver cirrhosis, correlating with enhanced plasma fibrinolysis, and serving as an independent predictor of mortality.²⁹⁵

Patients with acute promyelocytic leukemia demonstrate excessive expression of annexin A2 on their developmentally arrested promyelocytes. Bleeding in this disorder is accompanied by evidence of high levels of plasmin generation and depletion of α_2 -PI. Bleeding resolves upon initiation of all-*trans*-retinoic acid therapy, which eliminates expression of promyelocyte annexin A2, probably through a transcriptional mechanism.¹⁸¹ In this setting, A2 acts most likely in concert with S100A10, which is also upregulated in an acute promyelocytic leukemia (APL) cell line.^{201,296}

Complete loss of PAI-1 expression resulting in hemorrhage in a 9-year-old child was associated with severe hemorrhage in the setting of trauma or surgery.²⁹⁷ This autosomal recessive trait reflected a frameshift mutation within exon 4 that induced a premature stop codon. This case demonstrates that PAI-1 is a central regulator of fibrinolysis in humans.

DEVELOPMENTAL REGULATION OF THE FIBRINOLYTIC SYSTEM

In the resting, nonstressed state, the plasmin-generating potential in the newborn is significantly less than that of the adult.^{298,299} Although

the amino acid composition and apparent molecular mass of neonatal Plg are indistinguishable from those of the adult protein,^{300,301} plasma concentrations of Plg in the neonate are approximately 50 to 75 percent of those observed in adults.^{300,302,303} On the other hand, levels of histidine-rich glycoprotein, a carrier protein that may limit Plg's interaction with fibrin, are also reduced by 50 to 80 percent in healthy, term newborns.³⁰⁴ Neonatal Plg is heavily glycosylated, less readily activated by t-PA, and only weakly bound to the endothelial cell surface.³⁰¹ Throughout childhood, global plasma fibrinolytic activity and plasmin generation are decreased in comparison to adults, and this relative deficiency may contribute to the high frequency of thrombosis associated with central venous line placement, Kawasaki disease, and Henoch-Schönlein purpura in this age group.³⁰⁵

Although t-PA antigen and activity levels are reduced by 50 to 75 percent compared with adult values throughout childhood,³⁰³ stressed infants, such as those with severe congenital heart disease or respiratory distress syndrome, may have t-PA antigen levels that are increased by up to eightfold because of the t-PA release response.^{306,307} In contrast, the principal plasmin inhibitors undergo only minimal change from birth to adulthood.^{302,308–310} Thus, reduced fibrinolytic activity may contribute to the thrombogenic state commonly observed in the newborn,³¹¹ but this predilection may be reversed under conditions of physiologic stress.

FIBRINOLYTIC ACTIVITY DURING PREGNANCY AND PUERPERIUM

Pregnancy is a hypofibrinolytic state.^{312–314} Both Plg and fibrinogen levels in plasma increase by 50 to 60 percent in the third trimester. However, overall fibrinolytic activity, as reflected in euglobulin lysis activity, is reduced, and increased fibrin deposition is suggested by increasing D-dimer levels throughout pregnancy.³¹⁵ Between the 20th week of pregnancy and term, PAI-1 levels increase to three times their normal level, while PAI-2 levels rise to 25 times their level in early pregnancy.³¹² Less dramatic increases in both u-PA and t-PA levels are also observed. Within 1 hour of delivery, however, concentrations of both PAI-1 and PAI-2 begin to decrease, and return to normal within 3 to 5 days.³¹²

In preeclampsia, the hemostatic and fibrinolytic imbalances seen in pregnancy are further exaggerated.³¹⁶ Circulating PAI-1 levels exceed those in normal pregnancy, and fibrin deposition is seen in the glomerular capillaries and spiral arteries of the placenta. Interestingly, levels of PAI-2, a marker of placental function, are reduced during preeclampsia compared with normal pregnancy, and this decrease correlates with intrauterine growth retardation of the fetus. Elevated TAFI levels may be a cause of fibrin deposition and occlusion of placental vessels in preeclampsia.³¹⁷

FIBRINOLYTIC THERAPY

The goal of thrombolytic therapy is rapid restoration of flow to an occluded vessel achieved by accelerating fibrinolytic proteolysis of the thrombus.³¹⁸ The fibrinolytic system functions physiologically to remove fibrin deposits through the action of plasmin, but this is often too slow to prevent tissue injury following acute vascular occlusion. Because arterial thrombosis immediately renders distal tissue ischemic with rapid onset of dysfunction and necrosis, a critical problem is minimizing time to restoration of flow. Thrombolytic therapy should be viewed as one part of an overall antithrombotic plan that frequently includes anticoagulants, antiplatelet agents, and mechanical approaches, all designed to rapidly restore flow, prevent reocclusion, and promote healing. Here we review thrombolytic approaches to stroke and peripheral vascular disease. Thrombolytic therapy for deep vein thrombosis, pulmonary embolism, and myocardial infarction are discussed elsewhere.

PRINCIPLES OF THERAPY

The basic principle of all fibrinolytic therapy is administration of sufficient Plg activator to achieve a high local concentration at the site of the thrombus, thereby accelerating conversion of Plg to plasmin, and increasing the rate of fibrin dissolution. However, if large amounts of Plg activator overwhelm the natural regulatory systems, plasmin may be formed in the blood, resulting in degradation of susceptible proteins, the “lytic state.”³¹⁹ In addition, if high concentrations of activator reach fibrin deposits at sites of injury, bleeding, often exacerbated by plasmic proteolysis of other proteins in the blood may ensue.

Several therapeutic agents, from both recombinant and natural sources, are available and approved for thrombolytic use (Table 135-3). The degree of “fibrin specificity,” is critical in determining the intensity of action at the site of a thrombus. The plasma half-life of most agents is short, ranging, for example, from 5 to 70 minutes for t-PA and anistreplase, respectively. Decisions to administer by bolus versus continuous infusion, as well as the duration of therapy, are determined by the agent’s half-life and the condition being treated. Regarding site of delivery, systemic therapy via peripheral vein is simpler and does not require specialized facilities, but results in greater systemic complications. Regional delivery with a catheter placed close to the proximal end of the thrombus can provide a high local concentration with a smaller total dose, thereby increasing the local effect and limiting systemic exposure. Fibrinolytic therapy is often administered in combination with an anticoagulant to block fibrin formation and with an antiplatelet agent to limit continued platelet deposition. Anticoagulant therapy is routinely continued after completion of fibrinolytic therapy to prevent reocclusion. In addition, mechanical approaches such as percutaneous coronary intervention often play a vital role in removing the underlying cause of thrombosis.

The activation of plasmin has effects beyond the thrombus, including a reduction in fibrinogen, increase in fibrinogen degradation products, and depletion of Plg and α_2 -plasmin inhibitor. Screening coagulation tests, including the activated partial thromboplastin time (aPTT), prothrombin time (PT), and thrombin clotting time, will be

TABLE 135-3. Comparison of Plasminogen Activators

Agent (Regimen)	Source (Approved)	Antigenic	Half-Life (min)
Streptokinase (infusion)	Streptococcus (Y)	Yes	20
Urokinase (infusion)	Cell culture; recombinant (Y)	No	15
Alteplase (t-PA) (infusion)	Recombinant (Y)	No	5

prolonged depending on the intensity of the lytic state. Tests reflecting Plg activation, such as the euglobulin clot lysis time, will be abnormal. Platelet membrane proteins may also be degraded, resulting in abnormal platelet function.³²⁰⁻³²² Overall, these effects contribute to a hypocoagulable lytic state that may be beneficial for vessel patency, but may also exacerbate a bleeding complication. High doses of a nonspecific activator, such as streptokinase, will cause a more marked lytic state, compared to that seen with a fibrin-specific agent such as reteplase.

Patient selection for fibrinolytic therapy depends on careful consideration of risks and benefits (Table 135-4). For patients with acute myocardial infarction or stroke there is a higher tolerance of bleeding complications, because lytic therapy can be lifesaving and limit disability. Timing of treatment is also critical, with greater benefit achieved with earlier administration. Whereas fibrinolytic therapy for acute pulmonary embolism may be lifesaving, the potential benefits for venous disease are less clear and more likely to be associated with bleeding problems.

THROMBOLYTIC THERAPY FOR STROKE

Stroke is the third leading cause of death, and the leading cause of serious disability in the United States.³²³ Its incidence has been declining in

TABLE 135-4. Selection of Patients for Thrombolytic Therapy

Treat those most likely to respond and benefit
Acute MI: Within 12 hours of onset; consider percutaneous intervention
Stroke: Ischemic stroke within 4.5 hours of symptom onset
Peripheral arterial obstruction
Acute occlusions
Distal obstruction not correctable by surgery
Deep vein thrombosis
Large proximal thrombi with symptoms for less than 7 days (Chap. 134)
Pulmonary embolism
Massive or submassive embolism, especially with hemodynamic compromise
Avoid bleeding complications
Major contraindications
Risk of intracranial bleeding
Recent head trauma or central nervous system surgery
History of stroke or subarachnoid bleed
Intracranial metastatic disease
Risk of major bleeding
Active gastrointestinal or genitourinary bleeding
Major surgery or trauma within 7 days
Dissecting aneurysm
Relative contraindications
Remote history of gastrointestinal bleeding
Remote history of genitourinary bleeding
Remote history of peptic ulcer
Other lesion with potential for bleeding
Recent minor surgery or trauma
Severe, uncontrolled hypertension
Coexisting hemostatic abnormalities
Pregnancy

recent years due to control of risk factors, but total numbers are increasing as a consequence of aging of the population. Although aspirin and anticoagulants may be useful in prevention, thrombolytic therapy is the only available intervention during the acute stage.

The appropriate use of thrombolytic therapy for stroke is based on an understanding of its pathogenesis. Ischemic stroke is most commonly caused by rupture of an atherosclerotic plaque within a large or medium-sized artery in the neck or cranium. In addition, transient ischemic attacks (TIAs) and strokes involving small arteries can result from embolization of platelet-fibrin thrombi that form on atherosclerotic vessels in the neck and ascending aorta, or from embolization of thrombi that form in the heart in association with atrial fibrillation, valve dysfunction, artificial valves, or endocardial thrombi. Up to 30 percent of strokes have no defined etiology.

Current approaches to thrombolytic therapy for stroke are based on imaging to define the etiology, results of clinical trials, and the experience with thrombolysis for acute myocardial infarction. Modern computed tomography (CT) imaging and magnetic resonance imaging (MRI) can identify ischemic areas and localize areas of hemorrhage quite early. Additionally, arteriography can identify obstructed vessels and follow the course of recanalization during thrombolytic therapy. Clinical studies have generally followed the successful designs used for myocardial infarction that demonstrated the critical pathologic role of the occluded vessel, the importance of early recanalization in preserving myocardium, and the impressive decrease in morbidity and mortality resulting from early reperfusion. They have also characterized the bleeding risk.

The experience with thrombolytic treatment for stroke also highlights important differences from myocardial infarction. The arterial anatomy of the brain is more complex, the time from onset of ischemia to

irreversible necrosis is shorter, the risk and consequences of bleeding are greater, and there is more variability in the thrombo(embolic) occluding lesion. Further, the occlusive platelet-fibrin thrombus that precipitates a myocardial infarction is quite small, whereas the occlusive lesion causing ischemic stroke may be a large *in situ* thrombus, small platelet-fibrin embolus, or large embolus of varying age and composition originating from the left atrium. Thrombolysis has had a smaller impact for stroke than it has for myocardial infarction, based largely on these differences.

Early Thrombolytic Studies

The current therapeutic approach began with small, open-label studies that used intravenous or intraarterial streptokinase, urokinase, and t-PA to determine dose, recanalization rate, hemorrhagic potential, and clinical predictors of response.^{324–339} These studies demonstrated that recanalization could be achieved, that early treatment was essential, and that the rate of intracranial hemorrhage and hemorrhagic transformation within the ischemic area was high. Phase II studies defined the optimum dosage and time window for intravenous t-PA and served as the basis for larger phase III trials that led to the current t-PA-based approach to thrombolytic therapy for stroke (Table 135–5). At present, the only FDA-approved therapy for acute stroke is intravenous alteplase (recombinant t-PA) given within 3 hours of symptom onset.

Tissue Plasminogen Activator Therapy

The National Institute of Neurological Disorders and Stroke (NINDS) Study was a two-part randomized, double-blind, placebo-controlled study³⁴⁰ to test whether t-PA improved clinical outcome at 24 hours and 3 months. All patients were treated within 3 hours of symptom onset with a total dose of 0.9 mg/kg of t-PA. The combined results showed a

TABLE 135–5. Major Fibrinolytic Therapy Trials in Stroke

Study	No. of Patients	Time	Drug	Thrombolytic Dose*†	Main Efficacy Result
NINDS	624	≤3 h	t-PA, IV	0.9 mg/kg	Reduced disability at 3 months
ECASS I	620	≤6 h	t-PA, IV	1.1 mg/kg	No significant difference
ECASS II	800	≤6 h	t-PA, IV	0.9 mg/kg	No significant difference
ECASS III	821	3–4.5 h	t-PA, IV	0.9 mg/kg	Improved outcome at 3 months
ATLANTIS	613	≤6 h‡	t-PA, IV	0.9 mg/kg	No significant difference
SITS-ISTR‡	11,865 vs. 664	≤3 vs. 3–4.5 h	t-PA, IV	0.9 mg/kg	No significant difference
ASK	340	≤4 h	SK, IV	1.5 million units	Increased morbidity and mortality
MAST-I	622	≤6 h	SK, IV¶	1.5 million units	Increased mortality
MAST-II	310	≤6 h	SK, IV¶	1.5 million units	Increased mortality
PROACT II	180	≤6 h	pro-UK, IA	9 mg	Improved 3-month outcome
MELT	114	≤6 h	u-PA, IA	variable<	No significant difference in favorable outcome; significant difference in excellent functional outcome

<Mean doses of u-PA in patients with good and poor outcome were 555,000 IU and 789,000 IU.

30 percent improvement in clinical outcomes at 3 months and the benefit persisted at 12 months, despite a 10-fold increase in early symptomatic intracranial hemorrhage. At 3 months, there was no difference in mortality between the groups. This study formed the basis of the approval by the FDA of intravenous t-PA for stroke in 1996.

Early randomized trials of IV t-PA did not show clear benefit for patients treated beyond 3 hours after stroke onset. In the European Cooperative Acute Stroke Study (ECASS) Study, subjects with moderate to severe symptoms were randomized to placebo or t-PA within 6 hours of symptom onset³⁴¹; results showed no significant difference in either the primary end point of functional status at 90 days or in 30-day mortality. In the ECASS II, in which patients were randomized and stratified for presentation up to 3 hours after symptom onset or between 3 and 6 hours, there was no significant benefit of thrombolytic therapy using the primary end point of functional capacity of 90 days.³⁴² The Alteplase Thrombolysis for Acute Noninterventional Therapy in Ischemic Stroke (ATLANTIS) Study evaluated the safety of recombinant t-PA (rt-PA) in a double-blind, placebo controlled study with administration of drug between 3 and 5 hours after symptom onset,³⁴³ and the primary end point of excellent neurological recovery was observed in 32 percent of placebo and 34 percent of rt-PA-treated patients. Early symptomatic intracranial hemorrhage occurred in 1.1 percent of control and 7.0 percent of rt-PA-treated patients. There was a nonsignificant trend toward increased mortality with rt-PA treatment at 90 days (6.9 percent vs. 11.0 percent, $p = 0.09$). A meta-analysis pooling data from NINDS, ATLANTIS, and ECASS II patients who received either alteplase or placebo within 6 hours showed that the odds of a favorable 3-month outcome decreased as the interval from stroke onset to the start of alteplase treatment increased. Furthermore, the study alluded to the potential benefit of extending the treatment window to 4.5 hours with favorable but decreasing odds ratio for alteplase treatment beyond 3 hours.³⁴⁴

The benefit of IV t-PA for treatment beyond the 3-hour window was established by the ECASS III trial.³⁴⁵ This study showed that IV t-PA treatment initiated at 3 to 4.5 hours after ischemic stroke onset led to a modest improvement in the 3-month outcome. More patients had a favorable outcome with t-PA than with placebo (52.4 percent vs. 45.2 percent; odds ratio: 1.34; 95 percent CI 1.02 to 1.76). While the incidence of intracranial hemorrhage was higher with t-PA treatment (2.4 percent vs. 0.2 percent; $p = 0.008$), there was no difference in mortality between the two groups.

The effect of alteplase given beyond 3 hours after stroke on infarct growth and reperfusion was studied in the Echoplanar Imaging Thrombolytic Evaluation Trial (EPITHET) trial.³⁴⁶ Alteplase was shown to be significantly associated with increased reperfusion in patients who had mismatch at baseline ($p = 0.001$), better neurologic outcome ($p < 0.0001$), and better functional outcome ($p = 0.010$). The observational Safe Implementation of Treatment in Stroke International Stroke Thrombolysis Register (SITS-ISTR) study further supported the safety of administering IV t-PA between 3 and 4.5 hours after acute ischemic stroke.^{347,348} Compared to patients treated within less than 3 hours ($n = 11,865$), those treated at 3 to 4.5 hours ($n = 664$) had similar rates of independence, symptomatic intracranial hemorrhage, and mortality. An updated pooled analysis of ECASS, ATLANTIS, NINDS, and EPITHET trials continues to demonstrate that patients with ischemic stroke, selected by clinical symptoms and CT, benefit from intravenous alteplase when treated no later than 4.5 hours.³⁴⁹

Streptokinase Therapy

Streptokinase has been evaluated in three large stroke trials. The Australian Streptokinase (ASK) study showed an increase in death rate at 90 days in streptokinase-treated patients, and the study was prematurely terminated.³⁵⁰ The Multicentre Acute Stroke Trial–Italy (MAST-I) study

examined benefits and risks of streptokinase treatment with or without aspirin in patients with acute ischemic stroke who presented within 6 hours of symptom onset.³⁵¹ An interim analysis resulted in early termination because streptokinase treatment was associated with a 2.7-fold increase in fatality at 10 days among patients receiving both streptokinase and aspirin. In the Multicenter Acute Stroke Trial–Europe (MAST-E) trial, the mortality rate at 10 days was higher in patients who received streptokinase (34.0 percent) compared with placebo (18.2 percent, $p < 0.02$) primarily because of hemorrhagic transformation of infarcts.³⁵²

Tenecteplase Therapy

Tenecteplase is a genetically modified and genetically engineered recombinant t-PA; it has a higher fibrin specificity and greater resistance to inactivation by its endogenous inhibitor (PAI-1) compared to native t-PA. In a phase IIB study, there were no significant differences in intracranial bleeding or other serious adverse events in patients receiving alteplase versus tenecteplase.³⁵³ However, the two tenecteplase groups had greater reperfusion ($p = 0.004$) and clinical improvement ($p < 0.001$) at 24 hours compared with the alteplase group. The study outcome supports ongoing phase II–III trials of tenecteplase versus alteplase in the time window that is currently approved for stroke thrombolysis (NCT01472926 and NCT01949948).

Intraarterial Thrombolysis

Intraarterial administration allows delivery of a high concentration of a Plg activator in proximity to the thrombus, more accurate anatomic diagnosis, the ability to observe the course of recanalization, and lower total doses of drug that might reduce intracranial hemorrhage. On the other hand, this approach requires specialized facilities and experienced personnel to perform arteriography and selective catheterization, which may delay treatment. Several small open-label trials observed a high rate of recanalization and apparent clinical benefit with intraarterial therapy using urokinase, streptokinase or t-PA, but hemorrhagic transformation was a frequent problem.^{327,331,334,337,354–360}

The Prolyse in Acute Cerebral Thromboembolism (PROACT) and PROACT II trials evaluated recombinant human prourokinase by catheter-directed intraarterial administration.^{361,362} In the PROACT trial, a significantly higher recanalization rate was observed with prourokinase treatment with no increase in intracranial hemorrhage. This led to the larger PROACT II trial, which revealed a significantly higher recanalization rate with prourokinase (66 percent vs. 18 percent, $p < 0.001$), and superior functional improvement at 90 days.^{363,364} Symptomatic intracranial hemorrhage occurred in 10 percent of patients treated with prourokinase and 2 percent of controls. Although promising, these results did not lead to FDA approval of intraarterial prourokinase for treatment of stroke.

A third study, the Middle Cerebral Artery Embolism Local Fibrinolytic Intervention Trial (MELT), was underpowered because of premature study closure.³⁶⁵ A favorable, but not statistically significant, outcome at 90 days was more likely with intraarterial urokinase compared with placebo. The proportion of patients with an excellent functional outcome was significantly better in the intraarterial urokinase group (42 percent vs. 23 percent, $p = 0.045$). Intracerebral hemorrhage within 24 hours of treatment occurred in 9 percent and 2 percent, respectively ($p = 0.206$). This study suggested that intraarterial fibrinolysis has the potential to increase the likelihood of excellent functional outcome in appropriate clinical settings.

Overall, these studies show that treatment of acute stroke with thrombolytic therapy can lead to recanalization of the occluded artery and improvement in clinical outcomes. The need for early treatment, which improves outcome, is currently the single largest limitation to greater application of thrombolytic therapy for stroke, and less

than 5 percent of stroke patients currently receive t-PA treatment, indicating the need for focused community educational efforts.^{366–368} Randomized studies with rt-PA have shown that intravenous thrombolytic therapy can be safely extended to 4.5 hours after symptom onset in selected patients, whereas streptokinase was associated with an unacceptably high rate of intracranial hemorrhage.^{344,345,347} In addition, intracranial hemorrhage can be reduced by identifying patients at greatest risk using MRI diffusion–perfusion mismatch to identify reversible ischemia.^{346,369–371} The combination of potent antiplatelet therapy using a glycoprotein IIb/IIIa antagonist with a lower dose of a thrombolytic agent may improve results.^{372–377}

In summary, current recommendations limit thrombolytic therapy for stroke to patients presenting within 3 hours of symptom onset.^{378–380} The approved therapy is with 0.9 mg/kg (maximum: 90 mg) of t-PA administered intravenously with 10 percent as an initial bolus and the remainder infused over 60 minutes. The best results are obtained in patients who meet strict eligibility requirements (Table 135–6). Patients should be closely monitored for bleeding complications, especially intracranial hemorrhage, and careful attention should be paid to blood pressure and other comorbidities.

PERIPHERAL VASCULAR DISEASE

Acute peripheral arterial occlusion presents with the sudden onset of new, severe leg symptoms or acute worsening of chronic ischemia, and often involves embolic or thrombotic occlusion of leg arteries. The goals of treatment are to preserve limb function through restoration of flow.

TABLE 135–6. Guidelines for Tissue-Type Plasminogen Activator Therapy in Stroke

Eligibility

- Time from symptom onset to therapy ≤ 3 hours
- Results from European Cooperative Acute Stroke Study (ECASS) III trial suggest treatment within 4.5 h of onset is beneficial

Exclusions

- Prior intracranial hemorrhage
- Major surgery within 14 days
- Gastrointestinal or urinary tract bleeding with 21 days
- Arterial puncture in noncompressible site
- Recent lumbar puncture
- Intracranial surgery, serious head trauma, or prior stroke within 3 months
- Minor neurologic deficit
- Seizure at time of stroke onset
- Clinical findings of subarachnoid hemorrhage
- Active bleeding
- Persistent systolic blood pressure (BP) >185 and/or diastolic BP >110 or requiring aggressive treatment
- Arteriovenous malformation or aneurysm
- Evidence of hemorrhage on computed tomography scan
- Platelets $<100,000/\mu\text{L}$
- International normalized ratio >1.5 on warfarin
- Elevated partial thromboplastin time on heparin
- Blood glucose <40 or >400 mg/dL
- ECASS III additionally excluded patients >80 years old, patients with a combination of previous stroke and diabetes mellitus, and patients with an National Institutes of Health Stroke Scale score of >25 .

Anticoagulation is useful to prevent thrombus extension, while thrombolytic therapy or surgery can restore perfusion.

Early approaches to acute peripheral arterial occlusion involved streptokinase. Several small studies demonstrated reperfusion in approximately 40 percent of patients, with greatest success when occlusions were recent; bleeding complications occurred in up to one-third of subjects.³⁸¹ Following the report in 1974 by Dotter³⁸² of successful thrombolysis in peripheral arterial occlusion using locally administered thrombolysis, practice moved progressively to the nearly exclusive use of local intraarterially administered treatment. Advantages include delivery of a high concentration of drug directly to the site of thrombosis, the ability to follow the course of treatment using the treatment catheter, and identification of local vascular lesions requiring endovascular or surgical treatment after recanalization.

Treatment involves arterial access from a remote site followed by fluoroscopic guidance of the catheter to administer drug directly into the thrombus. Therapy is delivered by continuous infusion over hours to days and requires close monitoring and a large dose of thrombolytic agent. Successful reperfusion occurs in approximately three-quarters of cases.³⁸³ Ouriel and colleagues³⁸⁴ reported that thrombolytic therapy resulted in a 70 percent recanalization rate, and a frequency of limb salvage that mirrored that of operative intervention. There was, however, a survival advantage in patients receiving primary thrombolytic therapy resulting primarily from a decrease in the occurrence of in-hospital complications. The Surgery versus Thrombolysis for Ischemia of the Lower Extremity (STILE) trial, which compared the optimal surgical procedure to catheter directed thrombolysis with either t-PA or urokinase, was terminated prematurely because of ongoing or recurrent ischemia at 30 days in surgically treated patients.³⁸⁵ More than half of patients receiving thrombolysis had a decrease in the magnitude of the surgical procedure eventually required, with significant reductions in the 1-year rate of major amputation. In addition, there was no difference in outcome with t-PA versus urokinase.

The Thrombolysis or Peripheral Arterial Surgery (TOPAS) I study compared recombinant urokinase or surgery for initial therapy of acute lower-extremity ischemia of less than 14 days duration.³⁸⁶ The 1-year mortality and amputation-free survival were similar in the urokinase and surgery groups. There was a significant reduction in the frequency and magnitude of surgical interventions eventually required in patients randomized to initial thrombolysis. The larger TOPAS II study showed recanalization in 80 percent of patients who received urokinase.³⁸⁷ Amputation-free survival at 1 year was not significantly different between the surgical and thrombolysis groups, 70 percent and 65 percent, respectively. Major hemorrhagic complications were significantly more frequent with urokinase (13 percent) compared to 6 percent with surgery ($p = 0.005$).

In other studies, reteplase appears to be equally effective as t-PA or urokinase with comparable recanalization rates, and clinical outcomes and bleeding complications.^{388,389} Prourokinase also gave similar overall results to urokinase in a phase II study.³⁹⁰ In an open-label trial, staphylokinase, a highly fibrin-specific Plg activator, resulted in revascularization in 83 percent of subjects with occluded arteries.³⁹¹ Occasional allergic reactions occurred, and severe bleeding complications were comparable to those with other agents. The addition of abciximab, a glycoprotein IIb/IIIa, inhibitor, to urokinase resulted in more rapid clot lysis in a randomized study,³⁹² and good results were also reported with reteplase and abciximab.³⁹³ Intraoperative thrombolysis during thromboembolectomy has been used successfully to improve clearance of distal thromboemboli with or without adjunctive mechanical thrombectomy.^{394–398}

Thrombolysis should be viewed as one part of a combined, comprehensive management approach to peripheral arterial occlusion.

Key points include early, accurate angiographic diagnosis, appropriate intrathrombotic catheter positioning, and, in some cases, definitive endovascular or surgical procedures.^{399–402} Evidence favors mechanical thromboembolectomy as adjunctive therapy for acute limb ischemia resulting from peripheral arterial occlusion.⁴⁰³

OTHER INDICATIONS

Thrombolytic therapy has been useful in treating acute venous and arterial occlusions in a wide variety of sites. Reports document successful treatment of intraabdominal thrombosis including Budd-Chiari Syndrome,⁴⁰⁴ portal vein thrombosis,^{405–407} and mesenteric vein thrombosis.^{407–409} Thrombolytic agents are frequently used to open thrombosed central venous catheters,^{410–413} as well as access devices for hemodialysis.^{414–418}

MANAGEMENT OF BLEEDING COMPLICATIONS

Bleeding complications are more frequent with fibrinolytic than with anticoagulant therapy and require rapid diagnosis and management. The most serious complication, intracranial hemorrhage, occurs in approximately 1 percent of patients and is associated with a high mortality and serious disability in survivors. Risk factors for intracranial hemorrhage, including prior stroke, serious head trauma, intracranial surgery, tumor or vascular disease such as aneurysms or arteriovenous malformation and uncontrolled hypertension, are strong contraindications to fibrinolytic therapy.⁴¹⁹ Bleeding is most common at sites of invasive vascular procedures or preexisting gastrointestinal or genitourinary lesions, and should not interrupt therapy if it can be managed with local pressure or other simple measures.

Treatment of bleeding involves local measures as well as correction of the systemic hypocoagulable state resulting from proteolysis of plasma proteins and platelets (Table 135–7).⁴²⁰ The fibrinolytic agent should be discontinued, and most will be cleared rapidly, because of the short half-life. For serious bleeding, an antifibrinolytic agent such as epsilon aminocaproic acid can be administered, but will be effective only if the fibrinolytic agent remains in the blood. Replacement of fibrinogen and other hemostatic proteins can be accomplished with cryoprecipitate and fresh frozen plasma, respectively; treatment should be monitored with repeated coagulation tests. Administration of platelet concentrates may also be useful because fibrinolytic therapy results in

TABLE 135–7. Treatment of Fibrinolytic Bleeding

If intracranial bleeding is suspected, obtain imaging, consult neurosurgery, and correct hemostasis as below.

For major bleeding:

Send diagnostic test: activated partial thromboplastin time (aPTT), platelet count, and fibrinogen.

Attend to local hemostatic problems. Apply pressure if bleeding related to arterial puncture. Proceed with general supportive measures, including intravenous fluid hydration and transfusion of packed red cells if indicated. Proceed with diagnostic evaluation for gastrointestinal or genitourinary tract bleeding.

Correct abnormal hemostasis:

Prevent further fibrinolysis: stop fibrinolytic therapy; consider ϵ -aminocaproic acid or tranexamic acid.

Replacement therapy to repair hemostasis defect induced by fibrinolytic therapy: give cryoprecipitate 5–10 U and 2 U fresh-frozen plasma; consider platelet transfusion.

Correct other hemostatic defects: stop anticoagulant and antiplatelet agents; consider protamine to reverse heparin.

TABLE 135–8. Principal Uses of Antifibrinolytic Agents

Condition	Comment
SYSTEMIC FIBRINOLYSIS	
α_2 -Plasmin inhibitor or plasminogen activating inhibitor (PAI)-1 deficiency	Rare inherited disorders
Acute promyelocytic leukemia	Must distinguish fibrinolysis from disseminated intravascular coagulation (DIC)
Cirrhosis and liver transplantation	Occasional cases of cirrhosis; common in anhepatic phase of liver transplantation
Malignancy	Occasional cases of prostate and other carcinomas
DIC	Must be used with caution; thrombosis can result
Cardiopulmonary bypass	Decreases blood loss and transfusion needs
Fibrinolytic therapy	Can be used in treating bleeding complications
Localized fibrinolysis	
Hemophilia and von Willebrand disease	Decreases bleeding after dental extractions and possibly other procedures
Prostatectomy	Can decrease postoperative bleeding
Kasabach-Merritt syndrome	May shrink hemangioma
Menorrhagia	Often decreases bleeding

platelet dysfunction from proteolysis of surface proteins. Heparin can be reversed by administration of protamine sulfate, and 1-deamino-8-D-arginine vasopressin (DDAVP) may have some value in reversing platelet dysfunction.

ANTIFIBRINOLYTIC THERAPY

Pharmacologic agents can be used to inhibit fibrinolytic bleeding, but care must be exercised given the risk of thrombosis (Table 135–8). For example, in patients with consumption coagulopathies there may be excessive activation of both the coagulation and fibrinolytic systems, resulting in clinical manifestations of both bleeding and thrombosis. In this situation, inhibiting fibrinolysis to treat bleeding can precipitate or worsen thrombosis.

ANTIFIBRINOLYTIC AGENTS

Both ϵ -aminocaproic acid and tranexamic acid are synthetic lysine analogues. These agents inhibit fibrinolysis by competitively blocking binding of Plg to lysine residues on fibrin.^{421–424} Both can be administered orally or intravenously, have rapid absorption after oral administration and are excreted primarily through the kidneys. Only ϵ -aminocaproic acid is approved for use in the United States, with the exception that tranexamic acid can be used for treatment of menorrhagia. Pharmacologically, tranexamic acid is approximately 10-fold more potent than ϵ -aminocaproic acid because of its higher binding affinity. Both drugs have a short half-life of 2 to 4 hours and must, therefore, be administered frequently. ϵ -Aminocaproic acid can be administered intravenously with a loading dose of approximately 100 mg/kg over 30 to

60 minutes followed by a continuous infusion of up to 1 g/h, or the dose can be divided for intermittent administration. For oral treatment, the same loading dose can be administered followed by a maximum dose of 24 g/day in divided doses given every 1 to 6 hours as indicated. The use of tranexamic acid follows similar principles. The intravenous dose is 10 mg/kg followed by 10 mg/kg every 2 to 6 hours as needed. It can also be administered orally in a dose of 25 mg/kg given three or four times daily. Both ϵ -aminocaproic acid and tranexamic acid are generally well tolerated, but patients must be observed for possible thrombotic complications. Additionally, thrombotic ureteral obstruction can occur in patients with upper urinary tract bleeding, and such patients should be treated only after careful consideration. The risks of ureteral obstruction can be decreased by insuring high urine flow. Thrombotic complications can occur in patients with hypercoagulability, and thrombotic events can be precipitated or worsened in patients with disseminated intravascular coagulation (DIC). Myonecrosis is a rare complication. Minor complications, including rash, abdominal discomfort, nausea, and vomiting, are reported.

Aprotinin is a naturally occurring, broad-spectrum, proteinase inhibitor derived from bovine lung.⁴²⁵⁻⁴²⁷ It has both antiinflammatory and antifibrinolytic properties. Until recently, aprotinin was used in the United States for reducing perioperative blood loss and blood transfusions in patients undergoing cardiopulmonary bypass. However, its use is associated with an increased risk of postoperative renal dysfunction, cardiac and cerebral events,^{428,429} and of increased short- and long-term mortality in patients who received aprotinin compared to ϵ -aminocaproic acid, tranexamic acid, or placebo. In a retrospective analysis of electronic records from 33,517 aprotinin recipients and 44,682 ϵ -aminocaproic acid recipients, the unadjusted risk of death within the first 7 days after coronary artery bypass graft was 4.5 percent for aprotinin recipients compared to 2.5 percent for ϵ -aminocaproic acid recipients. The relative risk of death was significantly increased in the aprotinin group (relative risk: 1.64; 95 percent CI 1.50 to 1.78).⁴³⁰ Another retrospective study found that use of aprotinin was associated with both a significantly increased mortality risk at 1 year, and a larger risk-adjusted increase in serum creatinine ($p < 0.001$).⁴³¹ The prospective Blood Conservation Using Antifibrinolytics in a Randomized Controlled Trial (BART), which was designed to randomize a total of 3000 patients to either aprotinin, aminocaproic acid or tranexamic acid to further assess the safety of aprotinin, was terminated early because of a significantly higher death rate from any cause at 30 days in the aprotinin recipients.⁴³² Based on these studies, aprotinin was removed from U.S. market in May 2008, and its access is limited to investigational use.

Excessive systemic fibrinolytic activation can lead to bleeding and may result in a shortened euglobulin clot lysis time, decreased Plg, decreased α_2 -plasmin inhibitor, increased plasmin-antiplasmin complexes, decreased fibrinogen and increased fibrinogen degradation products. Screening tests including the PT and aPTT may be prolonged. It may be difficult to distinguish between abnormal hemostasis caused by DIC versus systemic fibrinolysis. Useful features include a more prominent decrease in fibrinogen and increase in fibrinogen degradation products and relatively less thrombocytopenia, and elevation of D-dimer with primary fibrinolysis. Homozygous deficiencies of either α_2 -plasmin inhibitor or of PAI-1 can cause a lifelong bleeding disorder and have been treated effectively with antifibrinolytic agents.^{297,433-436}

APL is often associated with a severe bleeding disorder that may have elements of both DIC and systemic fibrinolysis in addition to thrombocytopenia. Administration of ϵ -aminocaproic acid to inhibit fibrinolysis can be useful, but must be given with care to avoid thrombosis.⁴³⁷⁻⁴⁴⁰ In severe liver disease, fibrinolysis caused by reduced inhibitor synthesis can contribute to bleeding and may occasionally be the primary abnormality.⁴⁴¹⁻⁴⁴³ During orthotopic liver transplantation,

accelerated fibrinolysis often contributes to bleeding, particularly during the anhepatic phase. Treatment with antifibrinolytic agents can improve bleeding complications and decrease blood loss.⁴⁴⁴⁻⁴⁴⁷

Primary fibrinolysis with bleeding may rarely occur with some malignant tumors including prostatic carcinoma,⁴⁴⁴⁻⁴⁵³ and also with heat stroke.⁴⁵⁴ Fibrinolytic activation routinely occurs as a compensatory mechanism in consumption coagulopathy. If fibrinolytic activation is prominent in DIC and other measures do not control bleeding, use of antifibrinolytic therapy can be helpful, but must be used with caution, to avoid exacerbation of underlying thrombotic events.

The contact system is activated during cardiopulmonary bypass, resulting in alterations in the coagulation, fibrinolytic and complement systems^{455,456} and both postoperative bleeding and the need for large transfusion volumes can be a major problems. Several trials of antifibrinolytic therapy have established that total blood loss and transfusion requirements can be reduced, with aminocaproic acid and tranexamic acid often used for this purpose.^{450,451,457-460} Antifibrinolytic therapy can also be useful in treating bleeding associated with some snakebites and following administration of fibrinolytic therapy.

In hemophilia or von Willebrand disease, bleeding associated with a local lesion such as dental extraction may also respond to antifibrinolytic therapy. Both the oral and urinary mucosae are rich in fibrinolytic activity, and inhibition of normal fibrinolysis can prevent local bleeding, such as after prostatectomy.⁴⁶¹⁻⁴⁶³ Similarly, endometrial fibrinolysis contributes to menstrual bleeding, and antifibrinolytic therapy can be useful in treating menorrhagia.^{464,465} Antifibrinolytic therapy may also be useful in rare cases of Kasabach-Merritt syndrome in which a giant hemangioma is associated with consumption coagulopathy.^{466,467} Antifibrinolytic therapy has been used in treating gastrointestinal or genitourinary bleeding in patients with severe thrombocytopenia, ulcerative colitis, hereditary hemorrhagic telangiectasia, traumatic hyphema, following tonsillectomy, and with subarachnoid hemorrhage. However, caution is advised in the latter condition, as rebleeding may be decreased with antifibrinolytic therapy, but vasospasm and distal ischemia may worsen.⁴⁶⁷

CHAPTER 136

ERYTHROCYTE ANTIGENS AND ANTIBODIES

Marion E. Reid and Christine Lomas-Francis

SUMMARY

Blood group antigens are structures on the outer surface of human red blood cells (RBCs) that can be recognized by the immune system of individuals who lack that particular structure. Identification of RBC antigens and antibodies has been the basis of pretransfusion compatibility testing and the safe transfusion practices used today and also can provide insights into understanding the etiology of hemolytic disease of the fetus and the newborn. Biochemical and molecular studies have led to definition of the biologic functions of molecules expressing blood group antigens. These molecules play a critical role in susceptibility to infection by malarial parasites, some viruses, and bacteria. Alteration of RBC antigen expression is associated with many molecular backgrounds and some play a role in the clinical manifestations of certain diseases. Erythrocytes, far from being inert containers of hemoglobin, are active in a variety of physiologic processes.

DEFINITIONS AND HISTORY

A *blood group system* consists of a group of antigens encoded by alleles at a single gene locus or at gene loci so closely linked that crossing over does not occur or is very rare. An *antigen collection* consists of antigens that are phenotypically, biochemically, or genetically related, but the genes encoding them have not been identified.¹ Placement of a blood group antigen into a system or collection begins with the discovery of an antibody, usually in the serum of a multiparous woman or a multiply transfused recipient, with a unique pattern of reactivity. The antibody can be used to study basic biochemical properties of the corresponding antigen, to enable recognition of the pattern of inheritance of the antigen in families and in populations, to identify red blood cells (RBCs) that lack the antigen, and to search for an antithetical antigen. Identified characteristics, such as prevalence of positive reactions or sensitivity or resistance to specific enzymes, are compared to antigens in known systems and collections. A newly recognized antigen is also evaluated

Acronyms and Abbreviations: AET, 2-aminoethylisothiouonium bromide; CD, cluster of differentiation; DTT, dithiothreitol; GPA, glycophorin A; GPB, glycophorin B; GPC, glycophorin C; GPD, glycophorin D; GPI, glycosylphosphatidylinositol; HDFN, hemolytic disease of the fetus and newborn; HEM-PAS, hereditary erythroblastic multinuclearity with a positive acidified serum test; Ig, immunoglobulin; ISBT, International Society of Blood Transfusion; LAD, leukocyte adhesion deficiency; 2-ME, 2-mercaptoethanol; PNH, paroxysmal nocturnal hemoglobinuria; RBC, red blood cell.

using biochemical and molecular genetic methods. Orphan antigens of low or high prevalence are placed in “holding tanks” until the gene that encodes them is established.

The majority of genes encoding blood group antigens have been cloned and sequenced,² and the molecular bases of most blood group antigens have been determined.^{3–6} Details on the alleles associated with blood group antigens and phenotypes can be obtained from the National Center for Biotechnology Information (NCBI) “dbRBC” website: <http://www.ncbi.nlm.nih.gov/gv/mhc/xslcgi.cgi?cmd=bgmut/home> and from the International Society of Blood Transfusion (ISBT) website: www.isbt-web.org.

RBC antigens are inherited carbohydrate or protein structures located on the outside surface of the RBC membrane (Fig. 136–1). Although most of the protein blood group antigens are carried on integral transmembrane proteins (either single-pass type I or type II, or multipass; Fig. 136–1), a few are carried on glycosylphosphatidylinositol (GPI)-linked proteins or adsorbed from plasma. Some carbohydrate antigens are attached to proteins or lipids and some require a combination of a specific portion of protein and carbohydrate. Blood group antigens have revealed that certain transmembrane proteins interact with other transmembrane proteins (e.g., band 3 and glycophorin A [GPA]; Kell and Kx; Rh and RhAG), with lipids (e.g., Rh), or with proteins in the membrane skeleton (e.g., band 3 and ankyrin, glycophorin C [GPC], and protein 4.1 and p55). Many of the proteins carrying blood group antigens reside in the erythrocyte membrane as complexes.^{7–10} Many components carrying blood group antigens have been assigned cluster of differentiation (CD) numbers (Table 136–1). In human blood grouping, agglutination of RBCs usually serves as the detectable end point, but it can also be hemolysis.¹¹ Our ability to detect and identify blood group antigens and antibodies has contributed significantly to current safe blood transfusion practice, reducing death from hemolytic disease of the fetus and newborn (HDFN) from 40 percent to less than 2 percent, and supporting patients receiving chemotherapy or organ transplantation.

The naming of blood group antigens usually does not follow the classic convention wherein dominant traits are given capital letters and recessive traits are designated with lowercase letters. For example, in the ABO blood group system, A and B are codominant and the recessive O phenotype is encoded by a gene designated O, whereas in the MNS system the genes S and s are codominant. To standardize terminology used to describe RBC blood groups, the ISBT Working Party for Terminology for Red Cell Surface Antigens recommended using the traditional name for an antigen for verbal communication and a numerical system in computer databases (see Blood Group Terminology website at www.isbt-web.org). The working party has placed blood group antigens into four categories: (1) genetically discrete blood group systems; (2) serologically, biochemically, or genetically related antigens in blood group collections; (3) series of low-incidence antigens; and (4) series of high-incidence antigens. Each system and collection has been given a number and letter designation, and each antigen within the system is numbered sequentially in order of discovery. At the time of going to press (2015), 35 blood group systems and 6 antigen collections are defined (see Table 136–1; www.isbt-web.org).^{1,5,6,12–14} Over time, notations devised to describe blood group antigens have changed. A single letter (e.g., A, D, K), a symbol with a superscript (e.g., Fy^a, Jk^b, Lu^a), a symbol with a number (e.g., Fy3, Lu4, K12), and three to four letters (e.g., Vel, JMH, ELO, FPPT) are all used, sometimes within the same blood group system. The ISBT Working Party name has changed to ISBT Working Party on Red Cell Immunogenetics and Blood Group Terminology, which reflects that DNA testing is now often used to predict a blood group.

Figure 136-1. Membrane structures carrying blood group activity.

BLOOD GROUP SYSTEMS

Tables 136-1 and 136-2 summarize the characteristics of common blood group antigens. The following sources provide more detail: Issitt and Anstee,⁵ Reid, Lomas-Francis and Olsson,⁶ Reid and Lomas-Francis,¹⁵ Mollison and colleagues,¹⁶ Daniels,⁴ and Fung and associates.¹¹ In the interest of space, reviews or books are referenced in place of original reports.

ABO BLOOD GROUP SYSTEM

The ABO blood group system was the first system described and remains the most significant in transfusion medicine. A mismatch of ABO may be fatal, whereas a mismatch of other blood groups initially mostly is harmless. This situation occurs because anti-A and anti-B antibodies usually are present in the blood of adults lacking the corresponding antigen. These antibodies are stimulated by the ubiquitous distribution of the antigen that forms part of the membrane structure of many bacteria, plants, and animals. For this reason, all donor blood for transfusion is tested and labeled with the ABO group. The four main phenotypes are A, B, AB, and O, the latter indicating a lack of A and B antigens. The sugars defining A and B antigens are added to carbohydrate chains carrying the H antigen (fucose), which is "hidden" by the A (GalNAc) or B (Gal) sugar. Thus, group A or B erythrocytes appear to have less H antigen than group O cells. Nonetheless, H is found on all human erythrocytes except those from rare individuals of the O_h (Bombay) phenotype.

Anti-A or anti-B immunoglobulins can cause intravascular hemolysis when ABO-incompatible RBCs are transfused. Because A and B antigens also are expressed on most tissue cells, ABO compatibility is a significant consideration in solid-organ transplantation. However, ABO incompatibility only rarely causes severe HDFN because antibodies directed against A and B antigens are predominantly immunoglobulin (Ig) M, which do not cross the placenta, in addition, A and B antigens are not fully developed on RBCs from a fetus (Chap. 55).

Although the ABO blood group system has only four phenotypes, hundreds of alleles have been identified by DNA analyses. The ABO gene was cloned in 1990 following purification of A transferase.^{17,18} A and B transferases have only four amino acid differences in the catalytic domain, two of which (Leu266Met and Gly268Ala) are primarily responsible for substrate specificity.¹⁹ The group O phenotype results from nucleotide changes in A and/or B alleles that cause loss of glycosyltransferase activity. The most common group O (O_i) results from a single nucleotide deletion near the 5' end of the gene that causes a frameshift and early termination with no active enzyme production.²⁰ The ABO gene has seven exons, and A or B subgroups (with only few exceptions) result from a variety of nucleotide changes in exon 7 that cause alterations in the catalytic domain of the glycosyltransferase (reviewed by Chester and Olsson²¹). The rare B(A), A(B), and *cis*-AB phenotypes expressing both A and B antigens result from variant glycosyltransferases that have a combination of A- and B-specific residues.²¹ Numerous common and rare ABO alleles have been reported, and current information is available on websites: <http://www.ncbi.nlm.nih.gov/gv/mhc/xslcgi.cgi?cmd=bgmut/home> and www.isbt-web.org. In addition to nucleotide changes, recombinations and gene rearrangements can result in hybrid alleles that encode for unexpected transferase activity. This situation makes typing of ABO by DNA analysis difficult to interpret.²² The function of the ABO system is not known, although several disease associations are well established.²³

Rh BLOOD GROUP SYSTEM

The Rh (*not* Rhesus) system is the second most important blood group system in transfusion medicine because antigen-positive RBCs frequently immunize antigen-negative individuals through transfusion and pregnancy.

Inheritance of Rh antigens is determined by a complex of two closely linked genes: one encodes the protein carrying D antigen (RhD); the other encodes the protein carrying C or c and E or e antigens (RhCE).

TABLE 136-1. Characteristics of International Society of Blood Transfusion Defined Blood Group Systems and Antigen Collections

Conventional Name	ISBT Symbol (No.)	Chromosome Location	ISBT Gene Name (ISGN If Different)	Associated Antigens [Null Phenotype]	Function of RBC Membrane Component (CD No.)	Disease Association
BLOOD GROUP SYSTEMS						
ABO	ABO (001)	9q34.2	<i>ABO</i>	A, B, A, B, A1 [group O]	Glycocalyx	Altered expression in some hematologic disorders
MNS	MNS (002)	4q31.21	<i>MNS (GYPA, GYPB)</i>	M, N, S, s, U, and 43 more [En(a-); U-; M ^k M ^k]	Binds microbe glycocalyx, complement regulation, chaperone for band 3 (CD235)	Decreased <i>Plasmodium falciparum</i> invasion, may be receptor for <i>Escherichia coli</i>
P1PK	P1PK (003)	22q13.2	<i>P1 (A4GALT)</i>	P1, P ^k , NOR	Glycocalyx	
Rh	RH (004)	1p36.11	<i>RHD, RHCE (RH)</i>	D, C, E, c, e, and 49 more [Rh _{null}]	Possibly transports CO ₂ or NH ₃ (CD240)	Hemolytic anemia, hereditary stomatocytosis, hematologic malignancies
Lutheran	LU (005)	19q13.32	<i>LU</i>	Lu ^a , Lu ^b , Lu ³ , and 18 more [recessive Lu(a-b-)]	Binds laminin (CD239)	Increased expressions possibly involved in vasocclusion in sickle cell disease
Kell	KEL (006)	7q34	<i>KEL</i>	K, k, Kp ^a , Kp ^b , Js ^a , Js ^b , and 29 more [K ₀ or K _{null}]	Cleaves big endothelin-3 to ET-3, a potent vasoconstrictor (CD238)	
Lewis	LE (007)	19p13.3	<i>LE (FUT3)</i>	Le ^a , Le ^b , and 4 more [Le(a-b-)]	Glycocalyx, Le ^b is receptor for <i>Helicobacter pylori</i>	Increased expression in fucosidosis, Lewis antibodies may be important in graft rejection
Duffy	FY (008)	1q23.2	<i>FY (DARC)</i>	Fy ^a , Fy ^b , Fy ³ , Fy ⁵ , Fy ⁶ [Fy(a-b-)]	Chemokine, <i>Plasmodium vivax</i> receptor (CD234)	Resistance to <i>P. vivax</i> invasion
Kidd	JK (009)	18q12.3	<i>JK (HUT11, SLC14A1)</i>	Jk ^a , Jk ^b , Jk ³ [Jk(a-b-)]	Urea transporter	Impaired urea transport, urine-concentrating defect
Diego	DI (010)	17q21.31	<i>DI (SLC4A1; AE1)</i>	Di ^a , Di ^b , Wr ^a , Wr ^b , and 18 more	Anion exchanger (CD233), Band 3 cytoskeletal protein	Southeast Asian ovalocytosis, hereditary spherocytosis, renal tubular acidosis
Yt	YT(011)	7q22.1	<i>Yt (ACHE)</i>	Yt ^a , Yt ^b	Acetylcholinesterase	Absent from PNH III RBCs
Xg	XG (012)	Xp22.33	<i>XG (XG, MIC2)</i>	Xg ^a , CD99	Adhesion molecules (CD99)	
Scianna	SC (013)	1p34.2	<i>SC (ERMAP)</i>	Sc1, Sc2, Sc3, and 4 more [SC: -1, -2, -3]	Possible adhesion	
Dombrock	DO (014)	12p12.3	<i>DO (ART4)</i>	Do ^a , Do ^b , Gy ^a , Hy, Jo ^a and 3 more [Gy(a-)]	Enzymatic (CD297)	Absent from PNH III RBCs
Colton	CO (015)	7p14.3	<i>CO (AQP1)</i>	Co ^a , Co ^b , Co ³ , Co ⁴ [Co(a-b-)]	Water transport	Monosomy 7, inability to maximally concentrate urine, congenital dyserythropoietic anemia
Landsteiner-Wiener	LW (016)	19p13.2	<i>LW (ICAM4)</i>	LW ^a , LW ^{ab} , LW ^b [LW(a-b-)]	Binds CD11/CD18, ligand for integrins (CD242)	Depressed in pregnancy and some malignant diseases
Chido/Rogers	CH/RG (017)	6p21.32	<i>C4A, C4B</i>	CH1, RGI, and 7 more	Complement components	Certain phenotypes have increased susceptibility to certain autoimmune conditions and infections

aa, amino acids; B-CAM, B-cell adhesion molecule; DHTR, delayed hemolytic transfusion reactions; GPA, glycophorin A; GPB, glycophorin B; granulos, granulocytes; Ig, immunoglobulin; ISBT, International Society of Blood Transfusion; lymphs, lymphocytes; monos, monocytes; plts, platelets; RBC, red blood cell.

RBCs from Rh-positive people have both RhD and RhCE, whereas Rh-negative RBCs have only RhCE. In the Rh system, eight common antigen combinations or haplotypes are possible: Dce (R_0 , Rh_0), DCE (R_1 , Rh_1), DcE (R_2 , Rh_2), DCE (R_3 , Rh_3), ce (r , rh), Ce (r' , rh'), cE (r'' , rh''), and CE (r^y , rh^y). The letter “d” is commonly used to designate the lack of D, but there is no d antigen or anti-d.

Several nomenclatures can be used to describe Rh genes and antigens. The Fisher-Race nomenclature, which uses CDE terminology, is more commonly used for antigens; the Wiener nomenclature, which uses Rh/rh (or R/r) designations, is favored for haplotypes and gene complexes; and the Rosenfield and Rubinstein nomenclature, which uses numerical designations, was introduced to allow interpretation without bias.²⁴

The Rh blood group system has over 50 antigens (the ABO system has 4). By far the most important and immunogenic antigen is D (Rh_0 in Wiener terminology, referring to Wiener's discovery that a rhesus monkey injected with human RBCs would produce antibody that agglutinated the RBCs of 85 percent of white New Yorkers). For most clinical purposes, testing individuals for the D antigen and classifying them as D+ (or Rh-positive), or D- (or Rh-negative) is sufficient. Approximately 85 percent of the white population is Rh-positive, and 15 percent is Rh-negative. Most Rh-negative recipients produce anti-D if they receive Rh-positive blood. Anti-D can cause hemolysis in adults following an Rh-mismatched transfusion and in the newborn (HDFN) if antibodies were made by the mother from a prior transfusion or pregnancy. Thus, donors and recipients are routinely typed and matched for D. The risk of anti-D sensitization by transfusion is essentially eliminated by matching. The risk of anti-D sensitization in pregnancy is minimized by passive immunization of mothers at risk against D.

The antigens C, c, E, and e are less immunogenic and become important in patient care only after the corresponding antibody develops or when the basic Rh haplotype must be determined. The remaining 45+ antigens are other Rh protein epitopes whose corresponding antibodies are seldom encountered. Some are encoded by variant Rh alleles and appear as antithetical antigens to C, c, E, or e, or as related “extra” antigens. Others are referred to as *compound* antigens or *cis* gene products. For example, the protein produced by *RHCE*ce* encodes c and e antigens, and the compound f (or ce) antigen. Other compound antigens include Ce (rh_1), cE and CE. Still other Rh antigens are related to the complex “mosaic” nature of D and e, and less commonly C, c and E antigens. If immunized, individuals who lack a part of an antigen and who make antibody to the portion they lack, can present with a challenging serologic picture. For example, the D+ person who lacks part of the D antigen and makes an antibody to the missing portion appears to make alloanti-D because normal D+ RBCs carry all D epitopes.²⁵

Some, but not all, individuals who lack part of the D antigen (partial D) have weak expression of D on their red cells that is detected only by the antiglobulin test. Having a *RHCE*C* gene in trans position to a *RHD* gene (e.g., *Dce/Ce* or *DCE/Ce* genotypes) also can weaken expression of D in some individuals. A third type of weak D expression results from inheriting a *RHD* gene that encodes all epitopes of D, but in less-than-normal quantity.

DNA analyses have revealed the molecular basis underlying antigens and phenotypes. A list of the alleles that have been described to date is available at: <http://www.ncbi.nlm.nih.gov/gv/mhc/xslcgi.cgi?cmd=bgmut/home> and www.isbt-web.org. Rh blood group orthologs are present in nonhuman primates and other species on the evolutionary tree.²⁶ The RhD and RhCE proteins complex with the Rh-associated glycoprotein (RhAG) in the membrane. RhAG acts as a transporter of gases, most likely for ammonium, nitrous oxide, CO₂ and/or O₂ but confirmation is needed as to which it is.

OTHER BLOOD GROUP SYSTEMS

In terms of transfusion and HDFN, the other blood group systems and their antigens become clinically relevant only when antibody develops. Transfusion service laboratories identify (*antibody identification*) the specificity and characterize the reactivity of antibodies detected in routine testing (*antibody screening*). Once this information is known, the blood bank assesses the clinical significance of the antibody and selects the most appropriate blood for transfusion. Tables 136–1 and 136–2 summarize the number of antigens in each blood group system and other relevant information. A detailed description of all the blood group antigens is beyond the scope of this chapter. Because the molecular bases of most blood group antigens and phenotypes are known,⁶ DNA analysis can be used to predict the type of transfused patients and to identify the fetus at risk for HDFN.²⁷

● GENERAL IMMUNOLOGY OF BLOOD GROUP ANTIGENS

An *antigen* is a substance that can evoke an immune response when introduced into an immunocompetent host and react with the antibody produced from that immune response. An antigen can have several *epitopes*, which together are called an *antigenic determinant*, each of which is capable of eliciting an antibody response.

The ability of an antigen to stimulate an immune response is called *immunogenicity*, and its ability to react with an antibody is called *antigenicity*. These primary characteristics are affected by antigen size, shape, rigidity, and the number and location of the determinants on the red cell membrane.

IMMUNOGENICITY

Immunogenicity depends on many antigen characteristics, not just the number of antigen sites. Relative immunogenicity is estimated by comparing the actual observed incidence of an antibody to the calculated likelihood of a possible immunizing event. After A and B, the D antigen is most immunogenic (early work suggested that approximately 80 percent of Rh-negative individuals produce anti-D after receiving a single Rh-positive RBC component but more recent studies indicate it is more like 20 to 30 percent⁴), followed by K, which stimulates anti-K in approximately 10 percent of cases.¹⁶ The antigens c and E are one-third as immunogenic; Fy^a is one-twenty-fifth as potent; and Jk^a is one-fiftieth to one-one hundredth times as potent as K.²⁸ It should be noted that immunogenicity does not always correlate with the hemolytic potential of an antibody specificity; for example, K is more immunogenic than Jk^a but anti-Jk^a is more likely to cause hemolysis.

● ANTIGEN EXPRESSION

NUMBER OF ANTIGEN SITES

The number of antigen sites per RBC has been estimated by measuring the uptake of ¹²⁵I-labeled antibody or of ferritin-conjugated anti-IgG. Numbers vary widely among blood group systems from a few hundred to over a million (see Table 136–2). Also, estimates for any given antigen can vary greatly.

ANTIGEN DEVELOPMENT ON FETAL ERYTHROCYTES

Most RBC antigens can be detected early in fetal development (A, B, and H antigens can be detected at 5 to 6 weeks' gestation), but not all are fully developed at birth. A, B, H, I, P1, Lu^a, Lu^b, Yt^a, Xg^a, Vel, Bg,

Do^a, Do^b, and Kn^a antigen expression is considerably weaker on cord RBCs than on RBCs from adults. Le^a, sometimes Le^b, Ch/Rg, AnWj, and Sd^a, are not readily detectable, although 50 percent of cord samples type Le(a+) with more sensitive test methods. Full expression of A, B, H, I, and Lewis antigens usually is present by age 3 years, whereas full expression of P1 and Lutheran antigens may not occur until age 7 years.

VARIATION IN ANTIGEN EXPRESSION

RBCs from individuals who are homozygous for an allele typically have a greater number of antigen sites than do RBCs from individuals who are heterozygous. Consequently, their RBCs can react more strongly with antibody. This difference in expression and antigen-antibody reactivity because of zygosity is known as *dosage*. For example, RBCs from a homozygous *MM* individual carry a double dose of M antigen and react more strongly with anti-M than do RBCs from a *MN* heterozygous individual carrying only a single dose of M. Antithetical antigens C/c, E/e, M/N, S/s, and Jk^a/Jk^b commonly show dosage effect. Dosage is less obvious with D, K/k, and Lu^a/Lu^b antigens. It typically is more apparent within a family than between families. Dosage within the Duffy system also may not be serologically obvious because Fy(a+b-) or Fy(a-b+) phenotypes are seen in either homozygous (Fy^aFy^a or Fy^bFy^b) or hemizygous (Fy^aFy or Fy^bFy) individuals.

Some blood group antigens are inherited as closely linked genes or haplotypes. Haplotype pairings and gene interaction (either *cis* or *trans*) also can affect phenotypic expression. For example, the pairing of *RHCE**C in *trans* position to *RHD* can result in weak expression of D (see “Rh Blood Group System” above), whereas *RHCE**E in *cis* position with *RHD* is associated with strong expression of D. Among the common phenotypes, R₂R₂ RBCs carry the strongest expression of D. In the Kell system, Kp^a is associated with weakened expression of *in cis* k and J^b antigens.

Still other antigens are affected by regulator genes.²⁹ The dominant type of the Lu(a-b-) phenotype [In(Lu)] results from heterozygosity for an allele of the *KLF1* gene, the gene that encodes erythroid Krüppel-like factor (EKLF). The dominant inhibitor gene *KLF1* suppresses expression of Lutheran, P1, i, and many other antigens.³⁰ The dominant inhibitor *In(Jk)* suppresses expression of Jk^c and Jk^b antigens.³¹ Rare variants of the *RHAG* gene depress or prevent expression of the Rh antigens (see “Rh_{null} Syndrome” below).

BIOCHEMISTRY OF ERYTHROCYTE ANTIGENS

An antibody typically recognizes an epitope consisting of four to five amino acids on linear proteins or one to seven sugars. Alternatively, the antibody-binding site may encompass a more complex three-dimensional structure with branches or folds, and recognition may depend on both amino acids and sugars. Tables 136-2 and 136-3 and Fig. 136-1 summarize blood group biochemistry and antigen structure.^{4,6,16}

CARBOHYDRATE ANTIGENS

Polysaccharides with blood group activity are made by sequential addition of specific sugars (or sugar derivatives) to specific precursors in specific linkages by specific transferases. Sugars commonly involved are galactose (Gal), *N*-acetyl-D-galactosamine (GalNAc), *N*-acetylglucosamine (GlcNAc), fucose (Fuc), and *N*-acetylneuraminic acid (NeuAc).

Antigens in ABO, LE, P1PK, and GLOB blood group systems depend on an immunodominant sugar, usually terminally located, the polysaccharide to which the sugar is attached, and the type of linkage involved. I/i specificity is defined by a series of sugars on the inner portion of ABH saccharide chains. The presence of at least two repeating Gal(β1-4)GlcNAc(β1-3)Gal units in a linear structure defines i activity. I activity involves these same sugars in branched form (see Table 136-3). The gene for I (*GCNT2*) encodes the transferase responsible for branching (β(1-6) glucosaminyltransferase). During the first years of a child's life, linear chains are modified into branched chains, resulting in the appearance of I antigens.³² The I antigen is reduced on RBCs from fetuses and infants. A rare i phenotype occurs in adults (see “I-Negative Phenotype [i Adult]” below).

Polysaccharide chains are attached to glycoproteins in secretions (on type 2 chains), to glycolipids in plasma (on type 1 chains), and to both on the RBC membrane. Approximately 70 percent of A, B, H, and I antigens on the RBC membrane are carried on glycoproteins, primarily on the anion transporter, but also on the glucose transporter, the RhAG, and others. Approximately 10 percent of these antigens are on NeuAc-rich glycoproteins, 5 percent on simple glycolipids, and the remainder on polyglycosylceramide.¹⁶ P1, P^k, and P antigens are found on glycolipids both on the membrane and in plasma.³³

Lewis antigens are unique because they occur only on type 1 polysaccharide chains, which are found in plasma and secretions but not made by RBCs. Hence, they exist on RBCs only by adsorption of Lewis substance from plasma. The Le (or *FUT3*) gene encodes an α(1-4)fucosyltransferase. Whether the resulting antigen is Le^a or Le^b depends on the secretor gene Se (or *FUT2*), which encodes an α(1-2) fucosyltransferase.

PROTEIN ANTIGENS

Protein structures that carry blood group antigens can be grouped into three categories: (1) those that make a single pass through the erythrocyte membrane, (2) those that make multiple passes through the membrane, and (3) those that are attached to the membrane through a covalent linkage to lipid (GPI-linked; see Fig. 136-1).

Single-pass proteins include GPA with M and N antigens, glycophorin B (GPB) with S, s, and U antigens, GPC and glycophorin D (GPD) with Gerbich antigens, and the Lutheran, LW, Indian, Knops, Xg, Ok, and Scianna proteins (see Fig. 136-1). These proteins have an extracellular amino-terminus and an intracellular carboxyl-terminus (referred to as *type I*). In contrast, the Kell glycoprotein has an extracellular carboxyl-terminus and an intracellular amino-terminus (referred to as *type II*).

Most proteins that carry blood group antigens and make multiple passes through the erythrocyte membrane have both carboxyl- and amino-terminal ends that are intracellular, are hydrophobic, and have a transport function. Rh, RhAG, Diego, Colton, Kidd, Kx, GIL, and Raph proteins are included in this category. Duffy and Lan are multipass proteins, but they have an extracellular amino-terminus. Duffy has homology with a family of cytokine receptors and the Lan protein belongs to the family of ATP-binding cassettes.^{4,6,34}

Lipid-linked proteins have their carboxyl-terminus attached to the lipid GPI and are said to be GPI-linked or anchored. Cromer, Yt, Dombrock, and JMH proteins belong to this category. GPI-linked proteins are of special interest to hematologists because defective synthesis of the GPI anchor is responsible for paroxysmal nocturnal hemoglobinuria (PNH).³⁵ Thus, PNH-III RBCs lack all proteins attached by a GPI anchor, including those carrying blood groups (Chap. 40).

TABLE 136-3. Biochemistry of Common Carbohydrates and Antigens on Glycophorin A and Glycophorin B

Specificity	Structure	Gene for Bolded Determinant
i	Gal (β1→4) GlcNAc (β1→3) Gal (β1→4) GlcNAc (β1→3)Gal-R

*Proposed gene.

● EFFECT OF ENZYMES AND OTHER CHEMICALS ON ERYTHROCYTE ANTIGENS

Expression of an RBC antigen is determined by its exposure as a result of its position on the cell surface and its biochemical structure. Expression can be modified with treatment of RBCs by enzymes and other chemicals. These reagents are used to help identify complex mixtures of antibodies and to help characterize antibody specificity when identity is not readily apparent.

Proteolytic enzymes, such as ficin, papain, bromelain, trypsin, and α -chymotrypsin, cleave proteins from the erythrocyte membrane at specific amino acids. Enzyme treatment of RBCs cleaves certain protein antigens and allows carbohydrate and other resistant protein antigens to react more strongly with their antibody. The reactivity of antibodies with antigens in ABO, I, P1PK, LE, RH, and JK systems is enhanced after enzyme treatment of the RBCs, whereas reactivity of antibodies to M, N, Fy^a, Fy^b, and many minor antigens (Xg^a, Ch, Rg, JMH, In^b, Ge2, Ge4, Pr, Tn, and some examples of Yt^a) is reduced or eliminated. S and s are variably affected by enzyme treatment, and Kell and Scianna antigens are relatively unaffected.⁴⁻⁶

Reagents that reduce disulfide bonds, such as 2-mercaptoethanol (2-ME), dithiothreitol (DTT), and 2-aminoethylisothiuronium bromide (AET), denature Kell blood group antigens but enhance Kx. Reducing reagents also denature antigens in LW, SC, IN, JMH, and YT systems and weaken antigens in LU, DO, CROM, KN, and RAPH systems and the AnWj antigen.⁴⁻⁶

Acid treatment of RBCs (ethylenediaminetetraacetic acid [EDTA]/glycine/acid reagent), which is frequently used to remove IgG from RBCs, can weaken or completely denature antigens in the KEL blood group system. Chloroquine treatment of erythrocytes (also sometimes used to remove IgG from RBCs) at room temperature has little effect on most antigens. However, treatment for 30 minutes at 37°C can weaken expression of many antigens, including Fy^b, Lu^b, Yt^a, JMH, and those in the RH, DO, and KN systems.

● GENETICS OF ERYTHROCYTE ANTIGENS

Protein antigens are direct gene products: The gene encodes a protein that expresses one or more antigens. Carbohydrate antigens, made by transferase action, are indirect gene products. Most blood group genes are located on autosomes; only two, Xg and XK, are located on the X chromosome (see Table 136-1 for locations of genes on chromosomes).

Most genes that encode blood groups have two or more alleles. Individuals who inherit two identical alleles are homozygous and make a double dose of a single gene product, whereas those who inherit two different alleles are heterozygous and make single dose of each of two gene products. Males are hemizygous for the genes located on their single X chromosome and make a single gene product. In contrast, females produce a double dose of the Xg and XK gene products, as X-chromosome inactivation does not involve Xg^a or Kx antigens.³⁶

ALLELES

Alleles encoding blood group antigens commonly arise from only a single or a few nucleotide changes. For example, A and B alleles differ by only seven DNA base substitutions, which result in four amino acid substitutions in their respective transferases.⁴⁻⁶ The common O allele is similar to A except for a single base deletion at nucleotide 261 that shifts

the reading frame during RNA translation. The resulting protein is truncated and has no transferase activity. Another variant O allele encodes a transferase identical to that of B except it has arginine instead of alanine at amino acid position 268, which blocks the enzyme activity. A comprehensive listing of blood group alleles is available at the following websites: <http://www.ncbi.nlm.nih.gov/gv/mhc/xslcgi.cgi?cmd=bgmut/home> and www.isbt-web.org.

GENE COMPLEXES

Some blood group genes are complexes of several closely linked genes or loci that evolved through duplication of an ancestral gene. The antigens they encode are inherited as a haplotype with no or few crossovers. Blood group examples include the Rh system with genes *RHD* and *RHCE*, and the MNS system with genes *GYP A*, *GYP B*, and *GYPE*.

RHD and *RHCE* show remarkable homology between them and with *RHAG*, which encodes the RhAG. *GYP A* and *GYP B* probably arose by duplication of an ancestral *GYP A* gene encoding the N antigen.³⁷ The most common MNS complex is Ns, followed by Ms, MS, and NS.

In both RH and MNS systems, other antigens arose by further nucleotide changes, deletions, or rearrangements within the gene complex. Unequal pairing of *GYP A* and *GYP B* during meiosis, with subsequent recombination, resulted in several hybrids, such as *GYP(A-B)* (called Lepore type, by analogy with a similar hemoglobin hybrid), which encodes a protein with the amino-terminal end of GPA but the carboxyl-terminal end of GPB. Anti-Lepore-type hybrids, *GYP(B-A)* (amino-terminal end of GPB and carboxyl-terminal end of GPA), and other rearrangements (e.g., *GYP[B-A-B]* and *GYP[A-B-A]*) are known. Within the Rh complex, numerous hybrids of *RH(D-CE-D)* and *RH(CE-D-CE)* have been identified. Such hybrids can result in altered antigen expression and new antigens.⁴⁻⁶

Kell and Lutheran proteins are single-gene products that carry multiple antigens. The most common alleles in humans are *kKp^bJ^sK¹* and *Lu^aLu^aLu^aAu^a*. Antigens of lower prevalence (K, Kp^a/Kp^r, or Js^a, and Lu^a, Lu9, Lu14, or Au^b) arise from separate nucleotide changes.

SILENT ALLELES

Some blood group alleles are amorphs, or silent; that is, they do not produce a recognizable antigen, although they may encode a product that is simply not detected with standard test methods. As discussed with regard to the ABO system, A and B genes produce transferases that add GalNAc or Gal, respectively, to the same precursors, but O produces no active enzyme. AB individuals express both A and B antigen, but AA and AO individuals express A, and BB and BO individuals express B. Amorphic alleles are recognized only in a homozygous state, and the result is a “null” phenotype. Null phenotypes exist in most blood group systems (see Table 136-1). Group O is the most common, followed by Fy(a-b-) and Le(a-b-) in Africans. Other null phenotypes are rare.

The Fy(a-b-) phenotype is especially interesting. Fy(a-b-) Africans have Fy^b genes that express normal Fy^b glycoprotein on tissue cells but not on RBCs. A nucleotide change that disrupts the GATA-1 binding site for RBC transcription is present in these individuals,³⁸ which helps explain why many Fy(a-b-) Africans do not make anti-Fy^b despite exposure to antigen-positive RBCs from transfusion.

GENE FREQUENCIES

Gene and phenotype frequencies vary widely with race and geographical boundaries.^{6,11,16,39} This information is useful when estimating the availability of compatible blood and the probability of HDFN.

● RED CELL ANTIGENS IN HEALTH AND DISEASE

EXPRESSION OF RED CELL ANTIGENS IN OTHER BODY TISSUES AND FLUIDS

Antigens in the RH and JK blood group systems are present only on RBCs and have not been detected on platelets, lymphocytes, or granulocytes or in plasma, other body tissues, or secretions (saliva, milk, amniotic fluid).^{4-6,16} Antigens in MNS, LU, KEL, and FY systems are found on RBCs and other body tissues (see Table 136-2).

ABH antigens have broad tissue distribution. In embryos, A, B, and H antigens are detectable on all endothelial cells and all epithelial cells except those of the central nervous system. Antigens in ABO, P1PK, LE, H, and I systems are in plasma and on platelets and lymphocytes. Granulocytes carry I antigen but no ABH. ABH on platelets and lymphocytes may be acquired at least in part by adsorption from plasma. Lewis antigen is acquired by RBCs by adsorption. Secretions (saliva, milk, sweat, semen, and urine, but not cerebral spinal fluid) contain soluble A, B, H, I, and Le^a and Le^b antigens but no P1PK or GLOB system antigens. Sd^a antigen is found in most body secretions, with the greatest concentration in urine.^{5,16}

● ASSOCIATIONS OF RED CELL ANTIGENS WITH DISEASE

ANTIGENS ASSOCIATED WITH POSSIBLE SUSCEPTIBILITY TO DISEASE

Some blood groups are statistically associated with medical conditions or disease (Table 136-4).^{4-6,16} For example, blood group A is more common in persons with cancer of the salivary glands, stomach, colon, or ovary and with thrombosis (because of higher levels of coagulation factors VIII, V, and IX). Blood group O is more common in patients with duodenal and gastric ulcers, rheumatoid arthritis, and von Willebrand disease.

Associations with infection arise when microorganisms carry structures homologous with blood group activity. The presence of blood group antibody and/or soluble blood group antigen in secretions may help confer protection. Having anti-B may offer protection against *Salmonella*, *Shigella*, *Neisseria gonorrhoeae*, and some *Escherichia coli* infections. An association exists between nonsecretion of ABH antigen and susceptibility to *Candida albicans*, *Neisseria meningitidis*, *Streptococcus pneumoniae*, and *Haemophilus influenzae*.⁶

A number of disease associations with globoside have been identified. *Streptococcus suis*, which can cause meningitis and septicemia in humans, binds exclusively to P^k antigen. A class of toxins secreted by *Shigella dysenteriae*, *Vibrio cholerae*, and *Vibrio parahaemolyticus* have binding specificity for Gal(α 1-4)-Gal(β 1-4). In addition, globoside is the receptor of human parvovirus B19. Some strains of *E. coli* use the disaccharide receptor Gal(α 1-4)-Gal β on uroepithelial cells to gain entry to the urinary tract receptors associated with P1, P^k, and P antigens.^{5,33} People with the rare p phenotype lack this disaccharide and are not susceptible to acute pyelonephritis from such *E. coli* strains nor to infection by human parvovirus B19.

PHENOTYPES ASSOCIATED WITH DISEASE RESISTANCE

Erythrocytes lacking Fy^a and Fy^b antigens are not infected by the malarial parasite *Plasmodium vivax* or by the simian malarial parasite

Plasmodium knowlesi. These parasites attach to the Fy(a-b-) RBC membrane, but penetration does not take place. The Fy6 antigen is the critical receptor for *P. vivax* attachment.⁵ *Plasmodium falciparum* attaches to RBC glycoporphins and their O-linked oligosaccharides (carrying NeuAc). RBCs with the following phenotypes have a decreased rate of infection: M-N- (GPA-deficient), S-s-U- (GPB-deficient), Ge- (Leach type or GPC/GPD-deficient), and Cad-positive and Tn-positive RBCs (which have abnormal O-linked sugars).

DISEASES ASSOCIATED WITH ALTERED ANTIGEN EXPRESSION

Antigen expression can be altered with inherited or acquired disease. Inherited changes are fixed and consistent; acquired changes can disappear with remission or recovery. In some diseases, antigen expression weakens; in others, antigen expression increases or new antigens appear.

Weakened ABH expression on RBCs has been noted in acute myeloid leukemias and may result from reduced transferase activity.^{5,16} Normal antigen expression returns with disease remission. Transient weakened expression of target antigen also occurs in some cases of autoimmune hemolytic anemia. Weak Rh, Kell, Kidd, LW and AnWj blood group activity has been reported with concurrent autoantibody.^{5,16,40}

Increased expression of i on RBCs is associated with inherited disorders, such as thalassemia, sickle cell disease, Diamond-Blackfan syndrome, and hereditary erythroblastic multinuclearity with a positive acidified serum test (HEMPAS). Increased i expression also is noted with acquired conditions that decrease the red cell maturation time in the marrow, such as myeloblastic or sideroblastic myeloblastic erythropoiesis, refractory anemia, and excessive phlebotomy.^{16,23} Expression of the *de novo* antigen Tn is caused by a galactosyltransferase deficiency acquired by somatic mutation in a population of stem cells. The antigen is present on RBCs, platelets, and granulocytes arising from these stem cells. This condition (seen as persistent mixed-field agglutination because of the presence of both normal and abnormal cells) causes other RBC changes, such as depressed MN expression, enhanced H, and reduced NeuAc content. Tn antigen exposure is associated with myelodysplastic syndrome and acute myelomonocytic leukemia.¹⁶ Other antigens (T, Tk) occur as a result of infection when microbes produce enzymes that remove some sugars (NeuAc) and expose new ones. Group A individuals can appear to acquire a B antigen when bacterial deacetylase removes the acetyl group on GalNac.^{4,16} This phenomenon is associated with severe infection, gastrointestinal lesions, and malignancies.

RBCs may acquire blood group activity when they adsorb material from certain microorganisms. Group B activity has been associated with *E. coli*³⁶ and *Proteus vulgaris* infection, and K antigen with *Enterococcus faecium*. Acquired Jk^b-like activity has been associated with *E. faecium* and *Micrococcus* infections, although the mechanism is not clear.⁴¹

DISEASES ASSOCIATED WITH ABSENT ANTIGENS OR NULL PHENOTYPES

*Rh*_{null} Syndrome

The Rh_{null} phenotype is associated with hereditary stomatocytosis, hemolytic anemia (usually mild and well compensated), and a lack of proteins carrying Rh antigens. The Rh protein resides in the RBC membrane, interacts with other membrane proteins and possibly the membrane skeleton, and may help regulate or organize the lipids within the red cell membrane bilayer.^{9,10} Hence, it is an important determinant of membrane shape and expression of other antigens. Rh_{null} cells have depressed expression or absence of S, s, U, LW, and Fy5 antigens.

Most Rh_{null} red cells are stomatocytes or occasionally spherocytes and demonstrate increased osmotic fragility, increased potassium

TABLE 136-4. Blood Group Antigens and Antibodies Associated with Disease

PHENOTYPES ASSOCIATED WITH DISEASE SUSCEPTIBILITY	
Group A	Carcinoma of the salivary glands, stomach, colon, rectum, ovary, uterus, cervix, bladder (T1 and T2 tumors); idiopathic thrombocytopenic purpura, coronary thrombosis, thrombosis (oral contraceptives), pernicious anemia, giardiasis, meningococcal meningitis infections
Group B	<i>Escherichia coli</i> urinary tract infection, gonorrhea
Group O	Duodenal and gastric ulcers, rheumatoid arthritis, von Willebrand disease, typhoid, paratyphoid, cholera
ABH nonsecretors	Duodenal ulcers, spondyloarthropathies; increased susceptibility to <i>Candida albicans</i> , <i>Neisseria meningitidis</i> , <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i>
Le(a-b-)	Sjögren syndrome
Group O, Le(a-b+)	<i>Helicobacter pylori</i>
Globoside	Parvovirus
PHENOTYPES ASSOCIATED WITH DISEASE RESISTANCE	
p (PP1 P ^k -)	Pyelonephritogenic infections of <i>E. coli</i> , parvovirus B
Fy(a-b-)	<i>Plasmodium vivax</i> , <i>Plasmodium knowlesi</i>
Tn-, Cad-, En(a-), U-, Ge-	<i>Plasmodium falciparum</i>
DISEASES ASSOCIATED WITH ALTERED ANTIGEN EXPRESSION	
Weakened AB	Leukemia, myelodysplastic syndrome, Hodgkin lymphoma and non-Hodgkin lymphomas, aplastic anemia, bacterial infections
Weakened MN	Bacterial infections, myelodysplastic syndrome, leukemia (Tn, T, Tk activation)
Enhanced i	Thalassemia, sickle cell disease, HEMPAS, Diamond-Blackfan anemia, myeloblastic or sideroblastic erythropoiesis, refractory anemia
Acquired A (Tn)	Myelodysplastic syndrome, acute myelogenous leukemia
Acquired B	Bacterial infections, gastrointestinal lesions or malignancies
Acquired T, Tk	Bacterial infections
Acquired K antigens	<i>Enterococcus faecium</i>
Acquired Jk ^b antigen	<i>E. faecium</i> or <i>Micrococcus</i> infection
Absent Cromer, Yt, Dombrock, JMH, Emm antigens	Paroxysmal nocturnal hemoglobinuria
Weakened target antigens (Rh, Kell, Kidd, LW)	Autoimmune hemolytic anemia
LW	Hodgkin disease, lymphoma, leukemia, sarcoma
Weakened I, Rh, S, s, U, Kp ^b , Jk ^a , Xg ^a , or En ^a	Stomatocytic hereditary elliptocytosis
DISEASES ASSOCIATED WITH NULL PHENOTYPES	
Rh _{null} (D-C-E-c-e-)	Hereditary stomatocytosis, mild hemolytic anemia
McLeod phenotype (Kx-)	Hereditary acanthocytosis, mild hemolytic anemia, see text
GE _{null} (Leach type)	Hereditary elliptocytosis, mild hemolytic anemia
Bombay (O _n)	Leukocyte adhesion deficiency II (some)
I- (i Adult)	Congenital cataracts in Asians (some)
CO _{null}	Inability to maximally concentrate urine
RAPH _{null}	Kidney disease
DISEASES ASSOCIATED WITH ANTIBODY PRODUCTION	
Anti-I, -IH, -i, -H, -Pr	Cold agglutinin disease
Anti-"Rh," -"Kell," -U, -Wr ^b	Warm autoimmune hemolytic anemia
Anti-I	<i>Mycoplasma pneumoniae</i> , chronic lymphocytic leukemia, Hodgkin lymphoma and non-Hodgkin lymphomas
Anti-i	Infectious mononucleosis, reticuloendothelial diseases

(continued)

TABLE 136-4. Blood Group Antigens and Antibodies Associated with Disease (Continued)

Anti-I ^T	Hodgkin lymphoma and non-Hodgkin lymphomas
Anti-K	Enterocolitis, bacterial infections (<i>E. coli</i> 0125:B15, <i>Campylobacter jejuni</i> , <i>E. coli</i>)
Anti-P1	Parasitic infections: hydatid cyst disease, liver flukes
Anti-PP1P ^k	Early spontaneous abortions
Anti-P	Paroxysmal cold hemoglobinuria, early spontaneous abortions, lymphoma
Anti-NF	Renal dialysis (formaldehyde exposure)
Anti-Forssman	Neoplastic disorders
Anti-Rx	Virally induced hemolysis
Decreased anti-A or -B	Agammaglobulinemia or hypogammaglobulinemia
"NULL" PHENOTYPES ASSOCIATED WITH BIOLOGIC DIFFERENCES BUT NO OR MILD DISEASE	
Group O	Lack GalNAc or Gal on terminal Gal
Bombay	Lack Fuc on terminal Gal
Le(a-b-)	Lack Fuc on terminal GlcNAc
M-N- or En(a-)	Lack or have altered GPA
S-s-U-	Lack or have altered GPB
Wr(a-b-)	Lack or have altered GPA
M ^k phenotype	Lack GPA and GPB
K ₀	Lack Kell glycoprotein
Jk(a-b-)	Lack or have altered Jk protein, reduced ability to concentrate urine
Lu(a-b-)	Lack or have reduced or altered Lu glycoprotein; RBC may show poikilocytosis, potassium loss, increased hemolysis during storage
LW(a-b-)	Lack or have altered LW glycoprotein
Do(a-b-), Gy(a-)	Lack a GPI-linked protein (Do glycoprotein)
SC:-1,-2,-3	Lack or have altered Sc glycoprotein

Fuc, fucose; GlcNAc, *N*-acetylglucosamine; GPA, glycophorin A; GPB, glycophorin B; GPI, glycosylphosphatidylinositol; HEMPAS, hereditary erythroblastic multinuclearity with positive acidified serum lysis test.

Data from Issitt PD, Anstee DJ: *Applied Blood Group Serology*, 4th ed. Montgomery Scientific, Durham, NC, 1998; Daniels G: *Human Blood Groups*, 3rd. Blackwell Science, Oxford, 2013; Reid ME, Lomas-Francis C, Olsson ML: *Blood Group Antigen FactsBook*, 3rd. permeability, and higher potassium pump activity. They have reduced cation and water content and a relative deficiency of membrane cholesterol. Although these abnormalities are assumed to contribute to shortened *in vivo* survival, Rh_{null} RBCs survive normally in splenectomized patients, suggesting their removal is related more to splenic clearance because of shape rather than some other intrinsic factor.

Two genetic mechanisms account for the Rh_{null} phenotype. Persons with the amorphic type are homozygous for the silent *RHCE* gene on a deleted *RHD* background. Individuals with the more common regulator type of Rh_{null} have normal RH genes but an altered (silenced) *RHAG* gene. RhAG is required for expression of Rh antigens. Individuals with the Rh_{mod} phenotype have similar membrane and clinical anomalies associated with Rh_{null} syndrome but demonstrate some Rh antigen expression. The reduced expression of Rh antigens results from the presence of an altered form of RhAG.^{24,26,42}

McLeod Phenotype

Numerous males (but no females) with the McLeod phenotype have been identified. These individuals have acanthocytosis, decreased RBC survival, very weak expression of Kell blood group antigens, lack of Kx antigen on RBCs, and a well-compensated hemolytic anemia.⁴³

Kx antigen is carried on the Xk protein encoded by the XK gene on the X chromosome, which interacts with the RBC membrane skeleton and helps stabilize the membrane. The absence of Kx is associated with a lipid deficiency in the membrane bilayer that may be critical to the Kell glycoprotein and general RBC discoid shape. RBCs with the McLeod phenotype show a defect in water transport, increased mobility of phosphatidylcholine across the membrane, and increased phosphorylation of protein band 3 and β -spectrin.⁴³

After age 40 years, patients with the McLeod phenotype develop a slowly progressive form of muscular dystrophy that is associated with areflexia, choreiform movements, and cardiomegaly, leading to cardiomyopathy. They have elevated levels of serum creatine kinase and carbonic anhydrase III. Some patients with the McLeod phenotype and X-linked chronic granulomatous disease (CGD) have a deletion of both the XK and *Phox-91* genes (Chap. 66). The McLeod phenotype results from deletions or nucleotide changes in the XK gene.⁴⁴

Gerbich-Negative Phenotype

The *GYPC* on chromosome 2 encodes two proteins: GPC, with antigens Ge3 and Ge4 (the Ge2 portion is "hidden" by the Ge4-bearing terminal end), and its shorter partner GPD, with antigens Ge2 (now exposed) and Ge3. GPC and GPD interact with membrane skeleton proteins 4.1

and p55, which are involved in cell deformability and membrane stability. Gerbich-negative RBCs of the Leach type (Ge:–2, –3, –4) lack both GPC and GPD, have reduced protein 4.1, and elliptocytosis but exhibit normal survival *in vivo*.^{6,10}

Bombay (O_h) Phenotype

Rare people lack A, B, and H antigens and have naturally occurring anti-A, anti-B, and anti-H in their plasma. Such people are said to have the Bombay (O_h) phenotype. In rare people with the Le(a–b–) Bombay phenotype, the gene that encodes the Fuc transporter is silenced. As a consequence, all cells lack Fuc. Without Fuc, neutrophils lack sialyl Le^x and thus cannot roll and ingest bacteria. These patients have a high white blood cell count and severe recurrent infections. The condition is called *leukocyte adhesion deficiency II* (LADII) or congenital disorder of glycosylation II (CDG II).^{45,46}

I-Negative Phenotype (i Adult)

The gene encoding the I-branching β -1,6-*N*-acetylglucosaminyltransferase (*GCNT2*) has three alternative forms of exon 1, with common exons 2 and 3. Mutations in exon 2 or 3 silence *GCNT2* and give rise to the form of I-negative phenotype associated with congenital cataracts in Asians.^{47,48} Mutations in exon 1C (*IGNTC* or *IGNT3*) silence the gene in RBCs but not in other tissues, and lead to the I-negative phenotype (i adult) without cataracts.⁴⁹

CO_{null} Phenotype

Antigens of the Colton blood group system are carried on the water transporter (aquaporin [AQP1]). Although an absence of this protein from the RBC membrane was thought to be incompatible with life, in reality these rare individuals have been shown only to be unable to maximally concentrate urine.⁵⁰

RAPH_{null} Phenotype

The MER₂ antigen in the RAPH blood group system is carried on CD151. Rare individuals who lack CD151 have chronic renal failure, skin ulcers, and deafness.⁵¹

Other Null Phenotypes

Patients with null phenotypes can develop RBC antibodies that make it difficult to find compatible blood to avoid the otherwise serious hemolytic transfusion reactions. For example, people with the Bombay phenotype (O_h or H_{null}) demonstrate no red cell abnormality but make potent hemolytic anti-H as well as anti-A and anti-B. These antibodies are incompatible with all RBCs except those from other persons with the Bombay phenotype. Likewise, p individuals (PP1P^k-negative) or P^k individuals (P-negative) can make hemolytic antibodies to the antigens they lack. Anti-PP1P^k and anti-P also are associated with spontaneous abortions in the first trimester.¹⁶ Women with such antibodies (notably IgG anti-P), even those with a history of spontaneous abortions, have delivered viable infants after plasmapheresis.⁵²

Null phenotypes in the MNSs and Lutheran systems are interesting because several types of null phenotypes are known. Within the MNSs blood group system, people may lack GPA (En[a–] or MN-negative), GPB (SsU-negative), or both (M^kM^k phenotype). The rare Lu(a–b–) phenotype is caused by a dominant inhibitor called *In(Lu)*, by homozygous pairing of the silent allele *Lu*, or by a recessive sex-linked inhibitor *XS2*.^{5,16} Only the *LuLu*-type null (recessive Lu[a–b–]) is associated with antibody production because the inhibitor type nulls produce small amounts of Lutheran antigen. *In(Lu)* type, Lu(a–b–) RBCs have low expression of CD44 and AnWj, and have varying degrees of poikilocytosis and acanthocytosis. RBCs of this type tend to hemolyze more

quickly during storage, even though they demonstrate normal osmotic fragility.⁵³ Inactivating nucleotide changes in *KLFI*, which encodes an altered transcription factor, cause the InLu phenotype.³⁰

The Jk(a–b–) phenotype is caused by the silent alleles *Jk/jk* or the dominant inhibitor *In(Jk)*. RBCs having the Jk(a–b–) phenotype resist lysis in 2M urea,⁵⁴ a reagent commonly used in automated platelet counting systems; resulting in erroneously high platelet counts. No significant clinical abnormalities have been identified to date, although Jk(a–b–) individuals have reduced ability to concentrate urine.⁵⁵

The following diagnoses are made easily by simply typing the RBCs with appropriate antisera: Rh syndrome, McLeod syndrome, and LAD II.

ERYTHROCYTE ANTIBODIES

IMMUNOLOGY OF RED CELL ANTIBODIES

Blood group antibodies are classified as *alloantibodies* if they only react with antigens present on the RBCs of other people and as *autoantibodies* if they react with *self-antigens* present on the patient's own RBC. Alloantibodies also can be classified according to their mode of sensitization as *naturally occurring* (no apparent sensitization) or *immune* (following sensitization). Table 136–5 summarizes the common anti-erythrocyte antibodies.^{4,6,15,16}

IMMUNOGLOBULIN CLASSES ASSOCIATED WITH BLOOD GROUP ACTIVITY

Immunoglobulin G

IgG is the predominant antibody made in an immune response and constitutes approximately 80 percent of total serum Ig (Chap. 75). These antibodies, when specific for RBC antigens, can attach to or induce hemolysis of transfused antigen-positive RBCs. Receptors on macrophages in the liver and spleen allow the macrophages to remove IgG-coated RBCs from the circulation. IgG blood group antibodies also are capable of fixing complement, although some subclasses do so less efficiently than others: IgG₃ > IgG₁ > IgG₂ > IgG₄. How well an IgG erythrocyte antibody binds complement, depends on the surface density and location of the recognized antigen. This situation occurs because C1q, the initiator of the classic complement cascade, requires binding of at least two IgG molecules to the RBC within a span of 20 to 30 nm to initiate the complement cascade.¹⁶ For example, IgG anti-D rarely binds complement, presumably because most D sites are spaced too far apart.¹⁶ Most IgG blood group antibodies do not agglutinate saline-suspended RBCs, presumably because the IgG molecule is too small to span the distance between RBCs, although some exceptions are known (i.e., potent IgG examples of anti-A, anti-B, anti-M, and anti-K). Some IgG anti-D can directly agglutinate RBCs with the D-phenotype. Most IgG antibodies sensitize RBCs at 37°C and are detected with an anti-globulin reagent.¹¹

Immunoglobulin M

IgM is a pentamer of five basic units (having μ heavy chains plus a short J, or joining, chain) and makes up only approximately 4 percent of total serum Ig (Chap. 75). IgM is the first class of Ig produced by the fetus and is the predominant antibody in a primary immune response, but it does not cross the placenta. Because of their pentameric structure, even low-affinity IgM blood group antibodies can agglutinate RBCs and activate complement. Both hemolyzing and agglutinating abilities of IgM molecules are destroyed by reducing reagents, such as 2-ME and DTT. IgM antibodies of low affinity may agglutinate RBCs only at temperatures below 37°C. Such antibodies still may fix complement onto the

TABLE 136-5. Summary of Selected Erythrocyte Antibodies

RBC membrane *in vivo*, at the lower temperatures in the extremities, and activate the complement cascade in the core of the body. Because such IgM antibodies dissociate from RBCs at higher temperatures, their reactivity may be detected in routine antiglobulin tests (using polyspecific antiglobulin) by virtue of the complement components that remain bound to the red cell membrane.^{11,16}

Immunoglobulin A

IgA is the primary Ig in body secretions, where it exists predominantly as a dimer with a secretory component (Chap. 75). IgA does not cross the placenta or fix complement, but aggregated IgA can activate the alternative pathway of complement, and IgA can trigger cell-mediated events. Multimeric IgA antibodies in serum are seen as hemagglutinins in blood bank tests and most often are associated with anti-A or anti-B.

IMMUNOGLOBULIN IN THE FETUS AND NEWBORN

Initially, the fetus acquires low levels of maternal IgG, probably by diffusion across the placenta. These levels rise significantly between 20 and 33 weeks' gestation as a selective transport system matures and maternal IgG is actively transported across the placenta. Thus, almost all blood group antibodies detected in the fetus and newborn originate from the mother and disappear within the first few months of life.

Actual fetal antibody production begins shortly before birth with low levels of IgM, followed by IgG and IgA several weeks after birth. Anti-A and anti-B usually are readily detected by age 2 to 6 months.

Because of this late immune response in the newborn and because maternal antibody is so predominant at birth, blood bank standards permit abbreviated testing on neonates younger than 4 months.⁵⁶ If available, the mother's serum is used (and preferred) for identifying antibodies in a newborn and for crossmatching RBC components.

NATURALLY OCCURRING ANTIBODIES

Naturally Occurring Antibodies in Development

An antibody is said to be *naturally occurring* when it is found in the serum of an individual who has not been exposed to the antigen through transfusion or pregnancy. These antibodies most likely are heteroagglutinins produced in response to substances in the environment that are similar to those on RBC antigens.

Evidence supporting this concept has come from studies on the formation of anti-B in chickens.⁵⁷ Chicks raised in a normal environment made anti-B within the first 30 days of life, whereas chicks raised in a germ-free environment did not make anti-B by day 60. Naturally occurring anti-A and anti-B in humans, also called *isoagglutinins*, can increase in titer following ingestion or inhalation of suitable bacteria.⁵⁸

However, a great many antigens that likely are not present in the environment have been associated with naturally occurring antibodies, so the stimulus for naturally occurring antibodies is not clearly known.

Blood Group Associations and Presence of Naturally Occurring Antibodies

Naturally occurring alloantibodies are commonly associated with the carbohydrate antigens of the ABO, LE, and P1PK blood group systems. Anti-A and anti-B are expected in people who lack the corresponding antigens, as are antibodies specific for H, PP1P^k, or P antigens. Naturally occurring antibodies reactive with A1, Le^a, Le^b, or P1 determinants also are seen frequently. Carbohydrate antigens, especially those with repetitive epitopes, can stimulate B cells to make specific antibody without the aid of helper T cells. Such thymus-independent immune responses typically result in antigen-specific antibodies of the IgM class.

Within other systems,¹⁶ anti-Sd^a, anti-Vw, and anti-Wr^a are found in up to 2 percent of normal people. Other, less-common antibody specificities in approximate order of descending occurrence are anti-M, -S, -N, -Ge, -K, -Lu^a, -Di^a, and -Xg^a. Rh antigens are thought to reside only on RBCs, but apparent naturally occurring anti-D has been reported in 0.15 percent of Rh-negative donors and anti-E in more than 0.1 percent of Rh-positive donors when more sensitive enzyme detection methods are used. Examples of naturally occurring anti-C, anti-C^w, and anti-C^x also have been described.⁴⁻⁶

Some naturally occurring antibodies exist as autoagglutinins (e.g., anti-H and anti-I). Patients with autoimmune hemolytic anemia can produce many antibodies to low-prevalence antigens with no specific stimulus, in addition to autoantibody.^{5,6,16,40}

Characteristics of Naturally Occurring Alloantibodies

Most naturally occurring antibodies are IgM, but some have an IgG component and a few are predominantly IgG. Some anti-A or anti-B may even be of the IgA class. Antibodies that cause direct agglutination of saline-suspended RBCs most commonly are of the IgM class. However, even IgG antibodies may cause agglutination of RBCs when they bind antigens that are present at high density on the RBC membrane, such as the ABO or MN antigens. With the exception of anti-A and anti-B, most common naturally occurring antibodies do not react at body temperature and are considered clinically insignificant. However, if they are found to react at 37°C, providing crossmatch-compatible blood for transfusion is prudent.

ANTIBODIES GENERATED IN RESPONSE TO IMMUNIZATION: IMMUNE ANTIBODIES

Blood Group Associations and Occurrence of Immune Antibodies

Immune antibodies are produced following exposure to foreign RBC antigens through pregnancy or transfusion. The primary immune response is seen several weeks to several months after the first exposure to antigen. IgM usually is associated with early primary responses, but whether it is always the first antibody class made is unclear. In most individuals, IgG soon predominates. This process is characteristic of a thymus-dependent immune response, where T cells help induce B cells to undergo isotype switching from IgM to IgG.

In a secondary or anamnestic response, antibody concentration starts to increase several days to several weeks following exposure, and IgG may rise to very high levels. Some IgG antibodies remain detectable for decades after a stimulus. Others, especially Kidd antibodies, can disappear after several months and are more commonly associated with delayed hemolytic transfusion reactions.^{5,6,16}

Immune antibodies are found more commonly in individuals who have been multiply transfused than in multiparous women. This situation occurs because in pregnancy the immunizing dose of red cells often is too small to elicit a primary response and the foreign antigens are limited to those of the father.¹⁶

Anti-D used to be the most common immune antibody, but with the advent of Rh matching of donors and recipients in the late 1940s and use of RhIg prophylaxis since the 1970s, its incidence has sharply decreased. Anti-D is present in 0.27 to 0.56 percent of transfusion recipients, 0.10 to 0.20 percent of pregnant women, and 0.16 to 0.25 percent of healthy blood donors.¹⁶

In contrast, the occurrence of immune antibodies other than anti-D has increased. Specificities other than anti-D have been reported in approximately 0.6 percent of transfusion recipients, 0.14 percent of pregnant women, and 0.19 percent of healthy blood donors. Pooled data from three 5-year periods and approximately 300,000 patients

suggest the absolute occurrence of Rh antibodies other than anti-D is 0.22 percent, other than anti-K is 0.19 percent, other than anti-Fy^a is 0.05 percent, and other than anti-Jk^a is 0.04 percent.¹⁶ The rate of alloimmunization in patients with sickle cell anemia was 18.6 percent in one survey, and 55 percent of the immunized patients made more than one antibody. The most common specificities were anti-C, anti-E, and anti-K.¹⁶

Characteristics of Immune Antibodies

Immune antibodies most often are IgG but may be IgM and sometimes are IgA. Most immune antibodies react at body temperature and are considered clinically significant, except those directed against Bg, Knops, Cs^a, JMh, and sometimes Yt^a and Lutheran antigens.

CLINICAL SIGNIFICANCE OF ERYTHROCYTE ANTIBODIES

Information about the clinical significance of alloantibodies is available at www.nybloodcenter.org.^{59,60}

HEMOLYTIC TRANSFUSION REACTIONS

Clinically significant antibodies are capable of destroying transfused RBCs. The severity of the reaction varies with antigen density and antibody characteristics.

Antibodies commonly associated with intravascular hemolysis include anti-A, anti-B, anti-Jk^a, and anti-Jk^b. ABO incompatibility is the most potent cause of immediate hemolytic reactions because A and B antigens are strongly expressed on RBCs and the antibodies so efficiently bind complement. Kidd antibodies are associated more often with delayed hemolytic reactions because they typically are difficult to detect and can disappear quickly from the circulation. IgG anti-Jk^a appears to bind complement only when traces of IgM anti-Jk^a are present.¹⁶ Anti-PP1P^k, anti-Vel, and anti-Le^a have been associated with hemolysis, but such examples are rare.

Extravascular hemolysis occurs with IgG₁ and IgG₃ antibodies that react at body temperature; that is, immune antibodies reactive with Rh, Kidd, Kell, Duffy, or Ss antigens. These antibodies make up the bulk of clinically significant antibodies. Antibodies not expected to cause RBC destruction are those that react only at temperatures below 37°C and IgG antibodies of the IgG₂ or IgG₄ subclass.¹⁶

HEMOLYTIC DISEASE OF THE FETUS AND NEWBORN

HDFN is caused by blood group incompatibility between a sensitized mother and her antigen-positive fetus (Chap. 55). The antibodies most significant in HDFN are those that cross the placenta (IgG₁ and IgG₃), react at body temperature to cause red cell destruction, and are directed against well-developed RBC antigens. ABO incompatibility most commonly is seen, but ABO HDFN is clinically mild, presumably because the antigens are not fully expressed at birth. Antibodies directed against the D antigen can cause severe HDFN, and fetal health should be carefully monitored when anti-D titers are greater than 16. The severity of HDFN is less predictable with other blood group antibodies and can vary from mild to severe. For example, anti-K and anti-Ge3 not only causes red cell hemolysis but also may suppress erythropoiesis.^{4,6}

AUTOIMMUNE HEMOLYTIC ANEMIA

Autoimmune hemolytic anemia is caused by the production of “warm-” or “cold-” reactive autoantibodies directed against RBC

antigens (Chap. 54).⁴⁰ Production can be triggered by disease, viral infection, or drugs; from breakdown in immune system tolerance to self-antigens; or from exposure to foreign antigens that induce antibodies that crossreact with self-RBC antigens. Autologous specificity is not always obvious because antigen expression can be depressed when autoantibody is present.⁴⁰

Warm autoantibodies react best at 37°C and are primarily IgG (rarely IgM or IgA). Most are directed against the Rh protein, but Wr^b, Kell, Kidd, and U blood group specificities have been reported.⁴⁰

Cold-reactive autoantibodies are primarily IgM. They react best at temperatures below 25°C but can agglutinate RBCs or activate complement at or near 37°C, causing hemolysis or vascular occlusion upon exposure to cold.¹⁶ Patients with cold agglutinin disease often have C3d on their RBCs, which can provide some protection from hemolysis. Most cold-reactive autoantibodies have anti-I activity. Reactivity with i, H, Pr, P, or other antigenic specificities is much less common.

The biphasic cold-reactive IgG antibody associated with paroxysmal cold hemoglobinuria (“Donath-Landsteiner” antibody) typically reacts with the high-prevalence antigen P (GLOB). It attaches to RBCs in the cold and very efficiently activates complement before it dissociates at warmer temperatures.

DISEASES ASSOCIATED WITH ANTIBODY PRODUCTION

Table 136–4 lists diseases associated with specific antibody production. These antibodies cause autoimmune hemolytic anemia only if the patient carries the corresponding antigen.

SEROLOGIC DETECTION OF ERYTHROCYTE ANTIGENS AND ANTIBODIES

ABO

ABO grouping is the single most important test performed in the transfusion service because it is the fundamental basis for determining blood compatibility. ABO grouping is determined by testing RBCs with licensed antisera to identify the A or B antigens they carry (forward, or cell, grouping) and by testing the corresponding serum or plasma with known A and B cells to identify the antibodies present (reverse, or serum, grouping). Positive reactions are seen as hemagglutination or hemolysis, and the results of one test should confirm the results of the other.

If results are discrepant or reactions are weaker than expected, the cause must be investigated before the ABO group can be interpreted with confidence. Discrepancies can be related to RBC anomalies, serum anomalies, or both, and they may be associated with disease.^{5,11,16} Table 136–6 lists common causes, excluding clerical and technical error. If the ABO group of a patient cannot be determined, group O blood can be used for transfusion.

Rh

The D type is the next most important test performed for blood compatibility. Individuals whose RBCs type D+ are called *Rh-positive*, and those who type D– are called *Rh-negative*, provided controls are acceptable. Blood donors who type D– using standard typing sera are tested further for weak D expression using more sensitive methods, such as an indirect antiglobulin test. Donors with weak D antigen are considered

TABLE 136-6. Common Causes of Abo Discrepancies

RED CELLS MAY APPEAR TO HAVE	
Weak or missing antigens	Weak subgroup of A or B antigen Excess soluble A or B antigen in plasma Disease-associated loss (leukemia) ABO nonidentical marrow transplantation ABO nonidentical red blood cell (RBC) transfusions
Extra antigens	Positive direct antiglobulin test Antibody to reagent additive or dye Rouleaux or cold agglutinin on cells Disease-associated acquisition (polyagglutination)
SERUM MAY APPEAR TO HAVE	
Weak or missing antibody	Age related (newborns or the very elderly) Disease-associated immunosuppression Congenital hypogammaglobulinemia ABO nonidentical marrow transplantation
Extra antibody	Alloantibodies (A ₁ , Le ^a , Le ^b , P ₁ , M, N) Autoantibodies (I, i, H, Pr, P) Rouleaux Antibodies to additives in reagent RBCs Passive antibody acquisition from transfusion or from passenger lymphocytes in organ transplantation

Rh-positive. Testing for weak D is optional for transfusion recipients and pregnant women.⁵⁶

EXTENDED ANTIGEN PHENOTYPING

Reagent antisera to detect other common antigens (e.g., CcEe, MNSS, Kk, Fy^aFy^b, Jk^aJk^b) are available and used when identification of the red cell phenotype is essential to antibody identification, blood compatibility, determination of zygosity, or paternity or forensic issues. Extended phenotyping is especially important to patients who are at high risk for alloimmunization from chronic blood transfusion, for example, those with sickle cell anemia or thalassemia. Ideally, an extended RBC phenotype of patients who are likely to be chronically transfused should be determined prior to initiation of transfusion therapy. Prediction of a blood group antigen can be made by testing DNA of a patient, even in the presence of transfused RBCs.²⁷

ANTIBODY SCREEN

The antibody screen, or indirect antiglobulin test, detects “atypical” or “unexpected” antibodies in the serum (i.e., other than anti-A and anti-B) using group O reagent red cells that are known to carry various combinations of antigens. The methods used must be able to detect clinically significant antibodies. Typically, serum or plasma and screening cells are incubated at 37°C with an additive to potentiate antibody-antigen reactions, then an indirect antiglobulin test is performed. Hemagglutination or hemolysis at any point is a positive reaction, indicating the presence of naturally occurring or immune alloantibody or autoantibody. The antibody screen will not detect all atypical antibodies in serum, such as antibodies to low-prevalence antigens not present on

screening cells and antibodies that are not apparent at 37°C and in the antiglobulin phase.

DIRECT ANTIGLOBULIN TEST

The direct antiglobulin test (often referred to as the direct Coombs test, a term discouraged by Robin Coombs because he said that Race and Mourant were also key to the description of the test) detects antibody or complement bound to RBCs *in vivo*. Red cells are washed free of serum and then mixed with an antiglobulin reagent that agglutinates RBCs coated with IgG or the C3 component of complement.

Positive direct antiglobulin test results are associated with the following: (1) transfusion reactions, in which recipient alloantibody coats transfused donor RBCs or transfused donor antibody coats recipient RBCs; (2) HDFN, in which maternal antibody crosses the placenta and coats fetal RBCs; (3) autoimmune hemolytic anemias, in which autoantibody coats the patient's own RBCs; (4) drug or drug-antibody complex interactions with RBCs that sometimes lead to hemolysis; (5) passenger lymphocyte syndrome, in which transient antibody produced by passenger lymphocytes from a transplanted organ coats recipient RBCs; and (6) hypergammaglobulinemia, in which Ig nonspecifically adsorb onto circulating RBCs.

A positive direct antiglobulin test result does not always indicate decreased red cell survival. As many as 10 percent of hospital patients and 0.1 percent of blood donors have a positive direct antiglobulin test result with no clinical indication of hemolysis.¹¹

COMPATIBILITY TESTING

Compatibility testing refers to a set of donor and recipient tests that are performed prior to red cell transfusion. The collecting facility tests donors for ABO, Rh, and unexpected antibody. However, transfusing hospitals retest the ABO (and D on Rh-negative units) to verify the accuracy of the blood label.⁵⁶ Routine recipient testing includes an ABO, D, and antibody screening on a blood sample collected within 3 days of the intended transfusion. Results are checked against historical records to verify ABO, D, and antibody status.⁵⁶

If the recipient has a negative antibody screening test result and no history of clinically significant antibodies, a serologic immediate spin crossmatch between recipient serum and donor red cells or a “computer crossmatch” (wherein computer software compares the ABO test results of both donor and recipient) is required to confirm ABO compatibility.¹¹

If clinically significant antibodies are detected in a recipient's serum or previously were identified, red cell components should test negative for the corresponding antigens and be crossmatch compatible at 37°C by the antiglobulin test. The chance of finding compatible units usually reflects the antigen prevalence in the population, that is, 91 percent of units should be compatible with a patient making anti-K because 9 percent of the population is K⁺. This reasoning will not be valid if the local donor population varies significantly from the general population. When more than one antibody is present, the probability of finding compatible blood is the product of the prevalence (probability) of each independent antigen tested. For example, only 21 percent of units will be compatible for the recipient having both anti-K and anti-Jk^a: $(0.91 \text{ for } K^-) \times (0.23 \text{ for } Jk[a-]) = 0.21$.

When multiple clinically significant antibodies or an antibody directed against a high-prevalence antigen are present, finding compatible RBC components can be extremely difficult. Such antibody producers should be encouraged to give autologous donations prior to their elective blood needs. If the patient is not a candidate for autologous donation, compatible units may be found by testing the patient's siblings or by asking regional blood suppliers to check their rare donor inventories and files. Such procurement requires additional time.

TABLE 136-7. ABO-Rh Compatibility Guidelines

	Antigen on Red Cells	Antibody in Serum	Compatible Blood Groups	
			Donor Red Cells	Donor Plasma
If recipient blood group is				
A	A	Anti-B	A, O	A, AB
B	B	Anti-A	B, O	B, AB
O	O	Anti-A, anti-B	O	O, A, B, AB
AB	A, B	None	AB, A, B, O	AB
Rh-positive	D	None	Rh-positive, Rh-negative	Rh not considered
Rh-negative	None	Anti-D only if immunized	Rh-negative	Rh not considered

Whole blood must be identical to recipient's blood group. Red blood cell (RBC) products must be compatible with recipient's serum. Plasma products should be compatible with recipient's RBCs. Platelet and cryoprecipitate products should be compatible with recipient's RBCs, but any ABO group can be given if compatible products are not available.

Repeat donor testing and crossmatching are not performed for plasma and platelet components, but the recipient's ABO and Rh phenotypes must be known for appropriate selection of components. [Table 136-7](#) gives general ABO-D compatibility guidelines.

ANTIBODY IDENTIFICATION

All unexpected antibodies should be investigated. Those detected in serum or plasma as an ABO discrepancy, a positive antibody screening result, or an incompatible crossmatch are identified using a panel of eight to 16 different group O red cells that have been typed for antigens corresponding to clinically significant antibodies. Serum reactions with these RBCs are compared to their antigen typing to determine specificity.¹¹ For example, an antibody that reacts with all K+ RBCs but not with K- cells most likely is anti-K.

A control of autologous RBCs and serum is tested concurrently with panel RBCs. Absence of reactivity with autologous cells implies the antibody is an alloantibody, whereas a positive result suggests autoantibody or a positive direct antiglobulin test result. Once antibody specificity is identified, the patient's RBCs are tested for the corresponding antigen. If the alloantibody is anti-K, the cells should type K-. Such antigen typing helps to confirm serum findings.

When antibody is detected both on red cells (a positive direct antiglobulin test result) and in serum, only the antibody in serum is identified unless a review of the medical, pregnancy and transfusion history offers evidence that the antibodies might be different. When antibody is detected only on RBCs and *in vivo* hemolysis is suspected, the antibody can be eluted from the patient's RBCs and tested against panel RBCs to identify the specificity.

CHAPTER 137

HUMAN LEUKOCYTE AND PLATELET ANTIGENS

Myra Coppage, David Stroncek, Janice McFarland, and Neil Blumberg

SUMMARY

The human leukocyte antigens (HLAs) are highly polymorphic glycoproteins encoded by the major histocompatibility complex on chromosome 6. Their biologic function is presentation of antigenic peptides to T lymphocytes, and there are two major classes: class I (A, B, and C loci) and class II (DR, DQ, and DP loci). Class I antigens are present on almost all nucleated cells, whereas class II antigens are primarily expressed on B cells and other antigen-presenting cells such as dendritic cells, endothelial cells, and monocytes. These antigens play key roles in hematopoietic cell transplantation acceptance/rejection and allosensitization to nonleukoreduced blood transfusions leading to platelet transfusion refractoriness, with lesser, but distinct roles in solid-organ transplantation. Other clinically important lineage-specific white cell antigens include those on neutrophils, which are much less polymorphic and less commonly a cause of clinical problems than the HLA system. Antibody to neutrophil antigens plays a role in autoimmune neutropenia, and reactions such as transfusion-related acute lung injury. Platelets also possess a relatively limited number of polymorphic antigens that are involved in clinical problems such as posttransfusion purpura and platelet transfusion refractoriness, and neonatal problems such as alloimmune thrombocytopenia.

HUMAN LEUKOCYTE ANTIGENS (MAJOR HISTOCOMPATIBILITY COMPLEX)

DEFINITION

The human leukocyte antigens (HLAs) are highly polymorphic glycoproteins encoded by a region of genes known as the major histocompatibility complex (MHC) located on chromosome 6p21 and covering a region of approximately 7.6 Mbp.^{1,2} After ABO antigens, HLA antigens are the major barrier to transplantation. Their biologic function is to present antigenic peptides to T lymphocytes. The MHC codes for several groups of antigens. The best understood are the highly polymorphic, classical class I (HLA-A, HLA-B, and HLA-C) and class II (HLA-DR, HLA-DQ, and HLA-DP) antigens. Class I antigens are ubiquitous and present on most nucleated somatic cells. Class II antigens exhibit more

Acronyms and Abbreviations: CDC, complement-dependent cytotoxicity; ELISA, enzyme-linked immunosorbent assay; GP, glycoprotein; GVHD, graft-versus-host disease; HLA, human leukocyte antigen; HNA, human neutrophil antigen; HPA, human platelet antigen; MHC, major histocompatibility complex; NAIT, neonatal alloimmune thrombocytopenia; NMDP, National Marrow Donor Program; PCR, polymerase chain reaction; PRA, panel reactive antibody; PTP, posttransfusion purpura; SSO, sequence-specific oligonucleotide; SSP, sequence-specific primer; TRALI, transfusion-related acute lung injury; WHO, World Health Organization.

restricted distribution, with varying levels of expression on B cells, dendritic cells, monocytes, macrophages, and endothelial cells. However, class II antigens can be induced on many cell types through activation.³ The nonclassical class Ib antigens HLA-E, HLA-F, and HLA-G, and the MHC class I chain-related antigens are much less polymorphic, their function less understood, and their tissue expression more limited. In addition the MHC region codes for a number of pseudogenes. This chapter focuses on the classic class I and II molecules because of their importance in transfusion and transplantation.

The two major classes of HLA antigens are homologous. However, there are areas of high variability (polymorphism) that distinguish individual HLA molecules (alleles) and confer antigen specificity. HLA antigens are codominantly expressed so that each individual expresses two antigens at each locus (A, B, DR, etc.). As of July 2014, many thousands of HLA alleles had been characterized.⁵ Table 137-1 lists the number of known HLA alleles at each locus.

GENETICS OF THE MAJOR HISTOCOMPATIBILITY COMPLEX

The first sequence map of the MHC encompassed approximately 3.6 Mbp on chromosome 6p21 and was divided into three regions: class I, class II, and class III genes.² Newer analysis confirming high linkage disequilibrium and conserved synteny led to the concept of an extended MHC (xMHC), and a new map was produced in 2004.⁶ The xMHC occupies approximately 7.6 Mbp, and is composed of five subregions, which include the classical classes I, II, and III genes. Class II genes are the most centromeric and occupy approximately 1 Mbp of DNA. The genes are ordered sequentially beginning with HLA-DP genes followed by HLA-DM, TAP, HLA-DQ and lastly the HLA-DR genes. The class III genes occupy space between the class I and class II genes. The class III genes include genes that encode other proteins that participate in immune response such as complement, heat shock proteins, tumor necrosis factor, and other lymphocyte antigens. Telomeric are the class I genes sequentially as MICA, MICB, HLA-B, HLA-C, HLA-E, HLA-A, HLA-F, and HLA-G. Extended class I genes include histone clusters and zinc finger genes. Figure 137-1B is a representative map of the MHC.

STRUCTURE AND FUNCTION

Class I Antigens

The HLA-A, -B, and -C molecules are transmembrane glycoproteins with an Mr 56,000.⁷ Each is a heterodimer composed of one α heavy chain (Mr 45,000) noncovalently bound to β_2 -microglobulin (Mr 11,000). The α heavy chain is the polymorphic glycoprotein encoded by the MHC genes. The extracellular region of the α chain consists of three domains (α_1 , α_2 , α_3) based on folding and disulfide bonding (see Fig. 137-1A). Antigenicity resides in the α_1 and α_2 domains, the areas of highest polymorphism. These two chains form a platform composed of a single β -pleated sheet “floor” topped by two α helices with a cleft or groove between them. The structure is supported by the third, α_3 , domain of the heavy chain in conjunction with β_2 -microglobulin, which stabilizes the molecule on the cell surface. Class I HLA molecules present peptide fragments from endogenously derived proteins (e.g., viral infection, intracellular bacteria, or transformation) to CD8+ T cells. The highly polymorphic groove permits presentation of highly variable peptides of nine amino acids average length. Class I HLA-A, -B, and -C antigens are found on most nucleated somatic cells.⁸ Platelets express HLA-A antigens, but lack some HLA-B and most HLA-C antigens.⁹

Class II Antigens

The class II antigens are also transmembrane glycoproteins formed by two noncovalently bound chains.¹² Both the α heavy chain (Mr 34,000)

and the light β chain (Mr 29,000) are encoded in the MHC region. Class II molecules, like class I, consist of an extracellular hydrophilic NH_2 -terminal region, a hydrophobic transmembrane region, and an intracellular COOH -terminus region. Unlike class I antigens, the extracellular regions of each chain contain only two domains. The two domains of the α chain are designated α_1 and α_2 , and the two domains of the β -chain are called β_1 and β_2 . The α chain of HLA-DR is constant for all HLA-DR molecules, whereas the β chain is polymorphic and determines specificity of the molecule. Both α and β chains of HLA-DQ and -DP are polymorphic, although the β chain is more so than the α chain. In all class II antigens the β_1 domain represents the most polymorphic region. The structure of HLA-DR is essentially similar to the structure of class I molecules. Class II antigens present peptides from exogenous sources, such as bacterial pathogens, to CD4+ cells. The binding groove is more open than that of class I, and peptides of longer length (11 to 18 amino

acids) are accommodated.^{13,14} Class II antigens have a more restricted tissue distribution, being found primarily on B lymphocytes and other antigen-presenting cells such as dendritic cells, monocytes, and macrophages. They may also be expressed on activated endothelial cells and T lymphocytes.¹²

The extraordinarily polymorphic nature of HLA has probably evolved because of the need to present a very large array of different antigenic peptides in host defense. Antigen processing and presentation is a tightly regulated process, especially among the professional antigen-presenting cells such as dendritic cells. A number of alternative mechanisms have been demonstrated *in vitro*, such as cross-presentation, whereby dendritic cells transfer antigen derived from endocytic sources to the class I pathway, but are poorly understood.¹⁵ One promising area of research is the ability of HLA molecules to present antigenic peptides derived from tumors. Such peptides could arise via point mutation, or reactivation of a normally silent gene that produces a peptide that can bind to HLA and induce a T-cell immune response. Several such peptides (melanoma-associated gene [MAGE] antigens) have been identified for melanoma.¹⁶

NOMENCLATURE

Distinguishing polymorphic variations among HLA antigens is clinically important in stem cell transplantation. Terminology used to describe accepted HLA alleles or antigens is standardized by the World Health Organization (WHO), Nomenclature Committee for Factors of the HLA System, which issues biannual reports and monthly updates.⁴ In addition, an HLA dictionary defining HLA antigens, their assigned nomenclature, and serologic equivalents is published periodically.⁵ The nomenclature committee approved major changes to the system that were implemented in 2010.¹⁷ The revisions were designed to accommodate the unexpected number of new sequenced alleles. Under this system, colons are used as delimiters to separate fields. The first field signifies the allele family that often corresponds to the serological antigen. The second field denotes the alleles, assigned in order of determination. The third field is used for defining synonymous nucleotide substitutions.

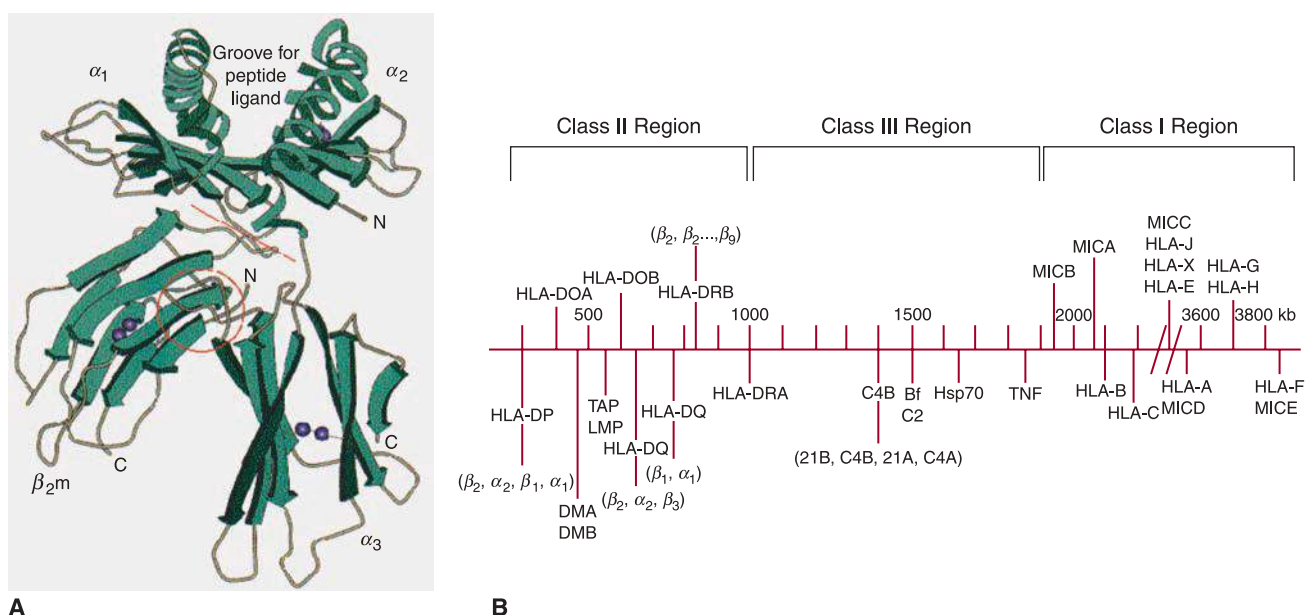

Figure 137-1. **A.** Schematic of the HLA-A2 molecule. The peptide groove is formed by the α helices and β -pleated sheet floor. The groove holds processed peptide antigen. The peptide and the polymorphic α helices interact with the T-cell receptor. **B.** Representative diagram of the genes of the MHC on chromosome 6. (A, reproduced with permission from Bjorkman PJ, Saper MA, Samraoui B, et al: *The foreign antigen binding site and T cell recognition regions of class I histocompatibility antigens*. *Nature* 329(6139):512–518, 1987. B, adapted with permission from Campbell RD, Trowsdale J: *Map of the human MHC*, *Immunol Today* 14(7):349–352, 1993.)

The last field defines alleles that differ by sequence polymorphisms in introns or in the 5' or 3' untranslated regions that flank the exons and introns. In addition, there are suffixes that are used to describe expression status. Null alleles (not expressed) are identified by the suffix "N." Low surface expression is represented by "L." Secreted molecules not present at the surface are assigned "S."

INHERITANCE OF MAJOR HISTOCOMPATIBILITY COMPLEX ANTIGENS

The genes of the MHC demonstrate more polymorphism than any other genetic system; that is, many alleles exist for each locus. Each individual, however, has one allele for each locus per chromosome, and therefore, encodes two HLA antigens per locus. The identification of each HLA antigen of an individual is called a *phenotype*. Because HLA genes are closely linked, recombination within the MHC is rare ($\leq 1\%$), and a complete set of HLA genes usually is inherited from each parent as a unit. The genes inherited from each parent are referred to as a *haplotype*. Maternal and paternal haplotypes can be identified through family studies. Identification of both haplotypes of an individual provides the *genotype*. Family studies consist of typing for the HLA-A, HLA-B, HLA-C, HLA-DR, and HLA-DQ antigens to identify haplotypes and to rule out genetic recombination within the MHC. Because HLA genes are inherited together on a single chromosome, four combinations of maternal and paternal haplotypes are possible provided no recombination occurs (Fig. 137–2).

Linkage Disequilibrium

Because the MHC is so highly polymorphic, the probability that any two unrelated individuals are HLA identical is extremely low. However, the system exhibits a phenomenon known as *linkage disequilibrium*. That is, HLA alleles are inherited together on the same chromosome

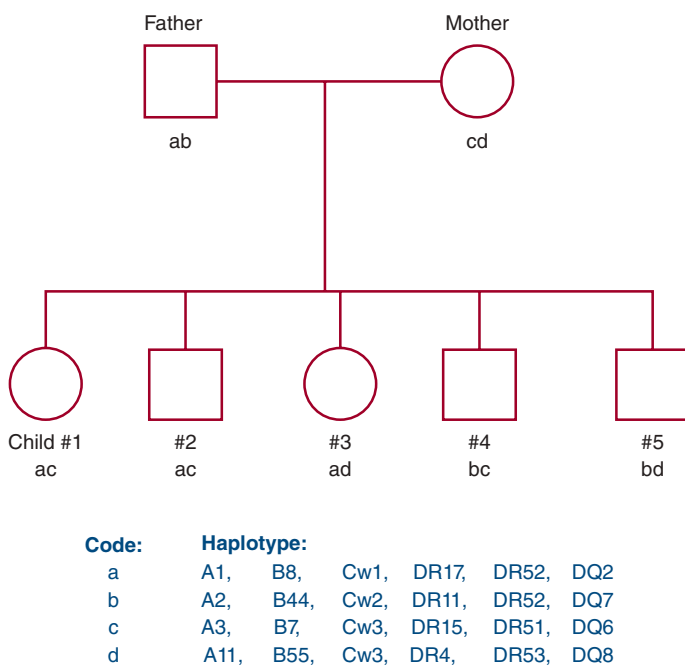

Figure 137–2. Pedigree representing inheritance of HLA antigens. Each of the four parental haplotypes is coded by a letter: *a* and *b* represent paternal haplotypes; *c* and *d* represent maternal haplotypes. Each child inherits one paternal and one maternal haplotype such that four combinations are possible.

more often than would be predicted if HLA loci were in equilibrium. At equilibrium, the frequency of an allele at one locus is independent of the frequencies of alleles at linked loci. For example, the gene frequency of HLA-A1 is 0.145 and that of HLA-B8 is 0.1 in North American whites. Given no preferential association between A1 and B8, then the haplotype frequency would be 0.0145 (0.145×0.1). However, population studies demonstrate that the actual frequency of the HLA-A1, B8 haplotype is 0.0726.¹⁸ The degree of linkage disequilibrium is defined as the observed frequency minus its expected frequency, 0.0581 in this example. Although particular alleles found in linkage disequilibria differ for various racial groups, all racial groups display significant disequilibria. Different races and ethnic groups can vary greatly in the frequency with which HLA antigens are found.¹⁹

HUMAN LEUKOCYTE ANTIGEN TYPING

Tissue typing for HLA antigens can be performed by various methods using serologic, cellular, and molecular technologies. The most frequent procedures used in the clinical setting are serologic and molecular. Cellular assays such as the mixed lymphocyte reaction and the primed lymphocyte test were common prior to the widespread adoption of DNA methods. Compared to DNA techniques, cellular methods are labor-intensive and require the use of radioisotopes; they are mainly used in research laboratories.

Serology

The microlymphocytotoxicity complement-dependent cytotoxicity (CDC) test has been a fundamental procedure for defining HLA antigens for more than 30 years,²⁰ although it has been supplanted by molecular typing methods. In this assay, a suspension of lymphocytes is incubated with human alloantisera or monoclonal antibody in a microtiter tray.²¹ Rabbit serum is added as a source of complement. Cell death is induced when antibody binds to antigen on the cell surface and the complement cascade activated. Death is visualized microscopically by the uptake of vital dye or by immunofluorescence. Panels used to determine a patient's HLA type consist of two to four antisera that recognize the same specificity, which requires approximately 150 different reagents for class I antigens and 80 to 150 for class II antigens. Antisera are usually obtained from multiparous women, multiply transfused patients, and from patients who have rejected allografts. Monoclonal antibodies are also commercially available for many HLA specificities. Serology for class II (DR and DQ) antigens requires enrichment for B lymphocytes, which can be accomplished with antibody or immunomagnetic bead reagents.

Molecular Human Leukocyte Antigen Typing

The development of the polymerase chain reaction (PCR)²² revolutionized the approach to HLA typing. Several DNA-based methods are commonly accepted for HLA typing. These include sequence-based typing, sequence-specific primer (SSP) amplification²³ and sequence-specific oligonucleotide (SSO) probe hybridization. All of these methods involve amplification of genomic DNA from selected portions of HLA genes with oligonucleotide primer pairs. Generally exons 2 and 3 of class I and exon 2 of class II genes are amplified. These exons encode most of the polymorphisms of the classes I and II molecules. Molecular HLA typing is primarily of clinical interest in marrow/blood stem cell transplantation.

The advent of "next-generation sequencing" (NGS) strategies has proven useful to high-throughput sequencing of HLA genes. NGS methods also overcome limitations of Sanger-based methods, including combination ambiguities that result from heterozygous samples in diploid genomes or between alleles where sequence varies outside the target region (i.e., exons 2 and 3). NGS methods are described as

massively parallel allowing for many overlapping reads of the same sequence area. Multiple platforms using different chemistries are available; bioinformatics expertise is required to analyze the extensive data provided by these methods.

Detection of Antibodies to Human Leukocyte Antigen Molecules

In addition to typing for HLA antigens, most laboratories also use technology to detect antibodies to HLA antigens. This is very important for solid-organ transplantation where the presence of anti-HLA antibodies can cause irreversible rejection upon transplantation. It is of less concern for marrow/stem cell transplantation where donors and recipients are generally matched for HLA antigens. The microcytotoxicity serologic test is still in use, but solid phase assays have become standard practice as they are more sensitive than the CDC method. These assays include enzyme-linked immunosorbent assay (ELISA) and microbead-based flow assays such as FlowPRA and Luminex assays. These tests require HLA antigen, in either recombinant or native form, bound to a solid surface such as a microsphere and used to capture alloantibody in patient serum. Analysis of the reaction patterns yields information about the breadth of alloimmunization, or PRA (panel reactive antibody), and the specificity of the reactions. Prior to most solid-organ transplants, a donor-specific crossmatch is also performed to ensure that the recipient does not have anti-HLA antibodies against donor HLA antigens. Crossmatches are performed by microlymphocytotoxicity (CDC), flow cytometry, and by solid-phase (ELISA and microbead) assays. Labs are now adopting the “virtual” crossmatch using data from the sensitive microbead assays to predict crossmatch outcome. For low-risk cases this allows a transplant to proceed without waiting for a physical crossmatch and shortens cold ischemic time for an organ.²⁴

CLINICAL APPLICATIONS

The HLA antigens coded by the MHC play a central role in transplantation, regulation of immune responses, and susceptibility to a variety of diseases. The most common application, however, is the field of transplantation. In renal and stem cell transplantation, allografts from HLA-identical sibling donors have significantly greater survival than grafts from nonmatched family or unrelated donors.

For solid-organ transplantation, a living donor is not always available or feasible (e.g., for heart transplantation). HLA typing for matching of kidneys and pancreas is performed at the HLA-A, HLA-B, and HLA-DR loci at low resolution (serologic or antigen level by DNA). In the early years of renal transplantation a high degree of match was sought between recipients and donors. However, as more potent immunotherapies have developed, the level and use of HLA matching has declined. HLA matching is not prospectively performed for hepatic or cardiac transplantation. Detection of alloantibody by screening techniques and the donor specific crossmatch is of prime importance for kidney and heart transplants where its existence could cause a hyperacute rejection and graft failure. The role of alloantibody is less clear in the immediate posttransplantation period, but may be detrimental to long-term survival.²⁵ In the last several years, several “paired donor exchanges” have arisen to assist recipients who have incompatible, but willing living donors. These programs, such as the National Kidney Registry allow donor-recipient pairs to swap within or between transplantation centers. Chains of up to 30 cross-country swaps in the United States have facilitated more than 1200 transplantations since its inception.

Marrow or stem cell transplantation entails problems other than allograft survival. In these therapies an immunocompetent graft is transplanted to an immunocompromised/immunoablated host.

The graft may recognize the host tissue as foreign and mount an immune response resulting graft-versus-host disease (GVHD). With HLA-identical sibling donors, disease-free survival of greater than 80 percent can be achieved for some hematopoietic malignancies.^{26,27} However, fewer than 30 percent of individuals have an HLA-identical sibling. For these patients, alternative donors, such as phenotypically matched unrelated volunteers and partially matched family members, may be considered. However, the risks and incidence of graft failure and GVHD are higher than seen with HLA-identical siblings, and increase with the level of HLA disparity. HLA typing for stem cell transplants is generally performed by molecular methods. For those with a family donor, low-resolution typing may be sufficient to identify a match. However for unrelated or haploidentical family donors, high-resolution (allele-level) typing for HLA-A, HLA-B, HLA-C, HLA-DR, and HLA-DQ should be performed, and is required by the national registry program (National Marrow Donor Program [NMDP]).²⁶ HLA alloantibody is becoming common, especially when incompletely matched donors are used.

Patients requiring platelet transfusions may be broadly sensitized to HLA-A, and -B (i.e., have high PRA) through prior transfusions (particularly nonleukoreduced) or pregnancies. HLA antibody screening to select nonreactive donors and/or HLA donor platelet matching may enable these refractory patients to achieve improved platelet transfusion count increments.

HLA typing at one or a few antigens or alleles may also be performed to support diagnosis of diseases associated with specific HLA antigens. The most common of these is the association between HLA-B27 and ankylosing spondylitis²⁸ and HLA-DQ2's association with narcolepsy.²⁹ HLA typing may also be performed to determine eligibility for vaccine trials that use peptides and HLA.^{30,31} HLA antigens also are implicated in drug hypersensitivity. For example, HLA-B*5701 is associated with hypersensitivity to the drug for treatment of the human immunodeficiency virus, abacavir.³²

HLA tetramers may be used to monitor the efficacy of HLA-based peptide vaccines. Recombinant HLA molecules are loaded with the peptide vaccine and linked via a fluoresceinated streptavidin molecule. They are incubated with patient blood lymphocytes. Effector T cells specific for the peptide-HLA will be bound by the tetramer and monitored by flow cytometry.

● NEUTROPHIL ANTIGENS AND ANTIBODIES

Clinically significant alloantigens expressed only or predominantly by neutrophils are known as human neutrophil antigens (HNAs).³³ In this nomenclature, the antigen systems are indicated by integers, and specific antigens within each system are designated alphabetically by date of publication (Table 137-2).

THE HNA-1 ANTIGEN SYSTEM

HNA-1 Antigen

The neutrophil-specific HNA-1 antigen system is made up of the four antigens alleles, HNA-1a, -1b, -1c and -1d (see Table 137-2).³⁴ HNA-1 antigens are located on the low-affinity Fcγ receptor IIIb (FcγRIIIb), CD16, and are expressed only on neutrophils.³⁵⁻³⁸ FcγRIIIb and HNA-1 antigens are expressed on all segmented neutrophils, on approximately one-half of neutrophilic metamyelocytes, and on approximately 10 percent of neutrophilic myelocytes.³⁹ Soluble FcγRIIIb is present in plasma and has the same HNA-1 polymorphisms found on neutrophils.⁴⁰

TABLE 137-2. Human Neutrophil Antigens

System	Alleles	Location of Antigens	Genes
HNA-1	HNA-1a, -1b, -1c, and 1d	FcγRIIIb	<i>FCGR3B*01</i> , <i>FCGR3B*02</i> , and <i>FCGR3B*03</i>
HNA-2	HNA-2	NB1gp	<i>CD177</i>
HNA-3	HNA-3a	Choline transporter-like protein-2 (CTL2)	<i>SLC44A2*01</i>
HNA-4	HNA-4a	α _M integrin, C3bi-receptor (CR3)(CD11b)	<i>ITGAM*01</i>
HNA-5	HNA-5a	αL integrin, LFA-1(CD11a)	<i>ITGAL*01</i>

Molecular Biology

FcγRIIIb and the HNA-1 antigens are encoded by the *FCGR3B* gene located on chromosome 1q23–24. *FCGR3B* is highly homologous to *FCGR3A*, which encodes FcγRIIIa. In addition to the polymorphic *FCGR3B* nucleotides only four others differ between *FCGR3B* and *FCGR3A*. The most important difference between the two genes is a C-to-T change at 733 in *FCGR3B* that creates a stop codon. As a result, *FCGR3A* has 21 more amino acids than *FCGR3B* and *FCGR3B* is a glycosylphosphatidylinositol (GPI)-anchored rather than a transmembrane glycoprotein (GP).

The four HNA-1 system antigens are encoded by three alleles. The *FCGR3B*01* allele differs from *FCGR3B*02* by only five nucleotides in the coding region, at positions 141, 147, 227, 277, and 349.^{35–38} Four of the nucleotide changes result in changes in amino acid sequence between the HNA-1a and HNA-1b forms of FcγRIIIb. The glycosylation pattern of FcγRIIIb differs between the two antigens because of two nucleotide changes at bases 227 and 277. The HNA-1b form of FcγRIIIb has six N-linked glycosylation sites and the HNA-1a form has four glycosylation sites.

The *FCGR3B*03* allele is identical to *FCGR3B*02* except for a C-to-A substitution at nucleotide 266 resulting in an alanine to aspartate change at amino acid 78 of FcγRIIIb.³⁴ In many cases, *FCGR3B*03* exists on the same chromosome with a second or duplicate *FCGR3B*

gene.^{41,42} *FCGR3B*03* encodes both HNA-1b and HNA-1c. *FCGR3B*02* also encodes HNA-1d which is characterized by the FcγRIIIb sequence Ala78–Asn82.⁴³

The antigen frequencies of three of the alleles vary widely among different racial groups. Among whites, HNA-1b is the most common antigen (Table 137-3),^{44–46,48–50} but in Japanese and Chinese populations HNA-1a is most common.^{44,46,48,49,51} The frequency of the gene encoding HNA-1c antigen also varies among racial groups. HNA-1c is expressed by neutrophils in 4 to 5 percent of whites, 25 to 38 percent of African Americans, and 10 percent of Brazilians.^{52,53} The antigen frequency of HNA-1d should be nearly the same as that of HNA-1b, but it has not yet been investigated.

Several other sequence variations in *FCGR3B* have been described.⁴⁶ Most of these chimeric alleles have single-base substitutions involving one of the five single nucleotide polymorphisms (SNPs) that distinguish *FCGR3B*1* and *FCGR3B*2*. *FCGR3B* alleles that most closely resembled *FCGR3B*2* were found more often in African Americans than in whites or Japanese.^{46,47}

Genetic deficiencies of neutrophil FcγRIIIb and HNA-1 antigens have also been reported. Among whites the incidence of individuals homozygous for *FCGR3B* deletion is approximately 0.1 percent.^{52,54,55} However, among Africans and African Americans the incidence is much higher. In one study, 3 of 126 Africans were found to be *FCGR3B* deficient,⁴⁸ and in another study, 1 of 53 were found to be *FCGR3B* deficient.⁴⁶

Function of HNA-1 Antigens

Polymorphisms in FcγRIIIb have some effect on neutrophil function. Neutrophils that are homozygous for HNA-1b have a lower affinity for immunoglobulin (Ig) G₃ than those homozygous for HNA-1a.⁵⁶ Neutrophils from those who are homozygous for HNA-1b phagocytize erythrocytes sensitized with IgG₁ and IgG₃ anti-Rh monoclonal antibodies and bacteria opsonized with IgG₁ at a lower level than neutrophils homozygous for HNA-1a.^{57,58}

THE HNA-2 ANTIGEN SYSTEM

The HNA-2 Antigen

HNA-2 is an isoantigen without allelic variation. HNA-2 is expressed only on neutrophils, neutrophilic metamyelocytes, and myelocytes.^{39,59} It's unique in that it is expressed on subpopulations of neutrophils. The mean size of the HNA-2-positive subpopulation of neutrophils is 45 to

TABLE 137-3. Human Neutrophil Antigen Frequencies

System	Alleles	Antigen Frequencies			
		Europeans/ North Americans	Africans and African Americans	Asians	Brazilians/ Argentineans
HNA-1	HNA-1a	58%	59–67%	91%	68%
	HNA-1b	88%	71–88%	54%	76%
	HNA-1c	5%	25–38%	<1%	5–10%
	HNA-1d	NA	NA	NA	NA
HNA-2	HNA-2	95–97%	95%	89–99%	NA
HNA-3	HNA-3a	89–92%	NA	NA	NA
HNA-4	HNA-4a	99%	NA	99%	97%
HNA-5	HNA-5a	85%	88%	81–96%	78–92%

NA, not available.

65 percent⁶⁰⁻⁶² and is dependent on gender. The size of the HNA-2 positive subpopulation of neutrophils from women is approximately 60 percent, compared with approximately 50 percent for men.^{62,63} Neutrophil expression of HNA-2 is greater in pregnant women than in healthy female blood donors.⁶⁴

HNA-2 Molecular Biology

The glycoprotein carrying HNA-2, NB1 glycoprotein, is located on neutrophil plasma membranes and secondary granules^{60,64} and is a GPI-anchored glycoprotein.⁶⁰ The gene encoding NB1 glycoprotein, *CD177*, is located on chromosome 19q13.31^{65,66} and belongs to the *Ly-6* snake toxin superfamily. Other genes in this family include urokinase-type plasminogen activator receptor (CD87) and decay accelerating factor (CD59).

HNA-2 is expressed on neutrophils by approximately 95 to 97 percent of whites, 95 percent of African Americans, and 89 to 99 percent of Japanese.^{62,67,68} SNPs have been identified in *CD177*. These SNPs have been associated with the size of the HNA-2-positive population of neutrophils, but not the HNA-2-negative phenotype.⁶⁹ The HNA-2-negative neutrophil phenotype is the result of a *CD177* transcription defect.⁷⁰

Role of NB1 Glycoprotein in Neutrophil Function

NB1 glycoprotein binds to platelet endothelial cell adhesion molecule-1 (PECAM-1, CD31) and functions as a cell adhesion molecule.⁷¹ PECAM-1 is expressed on both neutrophils and endothelial cells and PECAM-1-PECAM-1 interactions are important in the migration of neutrophils through endothelial cells. Interactions between NB1 glycoprotein and PECAM-1 are also involved with neutrophil-endothelial cell interactions, and mediate neutrophil transendothelial cell migration.⁷¹ However, women who produce HNA-2 specific alloantibodies and who lack NB1 glycoprotein are healthy.

CD177 mRNA is overexpressed by neutrophils from patients with polycythemia rubra vera and essential thrombocytosis, but the expression of HNA-2 is not.^{72,73} The increased expression of *CD177* mRNA in neutrophils from these patients may be secondary to the constitutive activation of Janus kinase 2 (JAK2) by JAK2 V617F.

THE HNA-3 ANTIGEN SYSTEM

The HNA-3 antigen system has one antigen, HNA-3a, that was previously known as 5b. HNA-3a is expressed by neutrophils, lymphocytes, platelets, endothelial cells, kidney, spleen, and placental cells. HNA-3a has an antigen frequency of 89 to 92 percent and is located on a 70- to 95-kDa neutrophil glycoprotein.⁷⁴ HNA-3a is a result of a single nucleotide change in choline transporter-like protein-2 gene (*SLC44A2*) at nucleotide 455, which results in an amino acid change at position 152.^{75,76} Several cases of transfusion-related acute lung injury (TRALI) have been associated with transfusion of plasma containing anti-HNA-3a.⁷⁷⁻⁷⁹

THE HNA-4 AND HNA-5 ANTIGEN SYSTEMS

The HNA-4 and HNA-5 antigens are located on the β_2 integrins. Each antigen system contains only a single antigen, HNA-4a and HNA-5a, respectively. The HNA-4a antigen was previously known as Mart(a). HNA-4a was defined by an antibody in the sera of three nontransfused multiparous blood donors. This antigen has an autosomal dominant inheritance and an antigen frequency of 99 percent in whites⁸⁰ and Asians,⁸¹ and 97 percent in Brazilians.⁸² HNA-4a is located on the α_M chain (CD11b) of the C3bi receptor (CR3) and is caused by a single nucleotide substitution of G-to-A at position 302⁸³ that results in an Arg-to-His polymorphism at amino acid 61. The significance of the antibody is not known, and none of the infants of the three multiparous

women with anti-HNA-4a showed evidence of neonatal alloimmune neutropenia.

A second polymorphism of the β_2 integrins, HNA-5a, was first described as Ond(a). A chronically transfused man with aplastic anemia became alloimmunized to HNA-5a. HNA-5a was found to be expressed on the α_L integrin unit, leukocyte function antigen-1 (CD11a), and is a result of a G-to-C single nucleotide substitution at position 2446 that results in a change of Arg to Thr at amino acid 766.⁸⁷ The antigen frequency of HNA-5a is 78 to 96 percent.^{81,82,84}

ANTIBODIES TO NEUTROPHIL ANTIGENS

Alloimmune Neonatal Neutropenia

Neutrophil antibody tests are performed by agglutination or fluorescent techniques, and these are not widely available because clinical syndromes caused by these antibodies are uncommon. A commercial solid-phase assay that allows for the detection of antibodies directed to HNA-1, HNA-2, HNA-3, HNA-4, and HNA-5 antigens is now available.⁸⁵ During pregnancy, mothers can become alloimmunized to fetal neutrophil antigens. Maternal IgG directed to neutrophils can cross the placenta and destroy the neonate's neutrophils. Maternal alloimmunization to neutrophil antigens can affect the first child. Most neonates experience isolated neutropenia, but the cytopenias are self-limiting and resolve as the antibody is cleared. Antibodies to neutrophil-specific antigens HNA-1a, HNA-1b, and HNA-2 most commonly cause neonatal alloimmune neutropenia.^{74,86} Mothers with Fc γ RIIIb deficiency have also produced antibodies to Fc γ RIIIb, causing neonatal neutropenia.^{55,74,86}

Most often the neutropenia is detected in the first week of life when the neonate becomes febrile or develops an infection and a neutrophil count is done. Typically, the counts are 0.1 to 0.2 $\times 10^9/L$. Total white blood cell count, platelet count, and hemoglobin are usually normal, but eosinophilia or monocytosis may be present. The clinical course is quite variable. An occasional infant is asymptomatic, but almost all affected children have an infection. The duration of the neutropenia may be as short as a few days or as long as 28 weeks.⁸⁶ The mean duration of neutropenia is approximately 11 weeks.⁸⁶ Intravenous immunoglobulin (IVIG) and granulocyte colony-stimulating factor (G-CSF) have a limited role in the treatment of neonatal alloimmune neutropenia.⁸⁶

Autoimmune Neutropenia of Childhood

Autoimmune neutropenia is well described in children.⁸⁷⁻⁹⁰ Typically, the onset of the autoimmune neutropenia of children begins at 8 months of age, but children between 1 and 36 months of age can be affected. Most studies have found that neutrophil counts recover spontaneously by the age of 5 years, with a median duration of neutropenia of 13 to 20 months.⁸⁷⁻⁹⁰ In most cases, children presented with severe neutropenia, having neutrophil counts less than 0.5 $\times 10^9/L$. Monocytosis has been reported to occur in up to 38 percent of patients. Marrow biopsies in affected patients usually show normal to hypercellular marrow with a decreased number of mature neutrophils.

Antibodies to neutrophils can be detected in up to 98 percent of affected patients. If an antibody specificity is identified, the antibodies are almost always specific to epitopes located on Fc γ RIIIb. The antibodies are directed to HNA-1a in 10 to 46 percent of patients, to HNA-1b in 2 to 3 percent of patients, and rarely to Fc γ RIIIb epitopes expressed by neutrophils from all donors.⁸⁸⁻⁸⁹ Autoimmune neutropenia has been treated with glucocorticoids, IVIG, and G-CSF.⁸⁸

Transfusion Reactions

Antibodies to neutrophil and HLA antigens in transfused blood can cause febrile nonhemolytic reactions. Febrile nonhemolytic transfusion

reactions occur within a few hours of a transfusion and can be associated with chills and rigors. These reactions are a result of neutrophil antibodies in the transfusion recipient binding to leukocytes in the transfused blood component. Febrile transfusion reactions can be prevented in recipients of platelet and red blood cell component transfusions by the use of leukocyte-reduced blood components.

A more serious type of neutrophil antibody-mediated transfusion reaction is TRALI. TRALI is often caused by the transfusion of neutrophil antibodies in the plasma portion of a blood component. TRALI occurs within 6 hours of a transfusion when hypoxia and noncardiogenic pulmonary edema occur, as measured by a fall in hemoglobin oxygen saturation to less than 90 percent or a partial pressure of arterial oxygen (PaO_2)-to-fraction of inspired oxygen (FIO_2) ratio ($\text{PaO}_2:\text{FIO}_2$) of less than 300 torr.⁹¹

Many case reports have associated TRALI with the inadvertent transfusion of neutrophil antibodies. Investigations of transfusion recipients of blood components from donors with neutrophil antibodies who have been implicated in cases of TRALI suggest that a large proportion of neutrophil antibodies can cause TRALI and less-severe pulmonary transfusion reactions.^{78,92-94} A prospective case study with controls and a prospective nested case-control study have confirmed that the transfusion of blood products containing antibodies directed to neutrophil antigen are an important cause of TRALI.^{95,96}

Antibodies to HNA-2 and -3a have most frequently been implicated in lung injury. Animal models also show that the transfusion of anti-HNA-2 and anti-HNA-3a can cause acute lung injury.⁹⁷⁻⁹⁹

● HUMAN PLATELET ANTIGENS

Platelets express a variety of immunogenic markers on the cell surface. Some of these antigens are shared with other cell types as in the case of HLAs or blood group (ABO) antigens, whereas others are specific to platelets. Some of these platelet-specific markers can be recognized by autoantibodies¹⁰⁰⁻¹⁰³ or by antibodies induced by certain drugs,¹⁰⁴⁻¹⁰⁶ and still others by antibodies made by pregnant women or recipients of blood transfusions.

PLATELET ALLOANTIGENS

Platelet alloantigens are associated with polymorphisms of platelet surface GPs and can induce production of alloantibodies when individuals lacking a particular polymorphism are exposed via pregnancy or transfusion.¹⁰⁷ Immune responses to platelet alloantigens are involved in the pathogenesis of several clinical syndromes, including fetal or neonatal alloimmune thrombocytopenia (FNAIT), posttransfusion purpura (PTP), and occasionally in unresponsiveness to platelet transfusion.¹⁰⁸ Alloimmune thrombocytopenia can also be an unusual complication of solid-organ transplantation in which donor lymphocytes make alloantibodies specific for the platelets produced by the recipient of an organ allograft.¹⁰⁹

PLATELET ISOANTIGENS

A condition similar to alloimmune platelet destruction occurs in patients who lack part or all of a particular platelet GP because of defective alleles of the GP-encoding genes. Such patients can make isoantibodies against platelets of virtually all donors that bear the platelet GP. For example, patients with Bernard-Soulier syndrome, who lack platelet GPIb-V-IX (CD 42a-c), or patients with Glanzmann thrombasthenia, who lack expression of GPIIb (CD41) and GPIIIa (CD61), can be induced to make broadly reactive antiplatelet isoantibodies.¹¹⁰⁻¹¹³

Platelet GPIV (CD36) is expressed on various human cells including platelets, macrophages, capillary endothelium, erythroblasts, and adipocytes.^{114,115} Some apparently normal individuals lack CD36 on their platelets (type II deficiency) or platelets and monocytes (type I deficiency).¹¹⁶ CD36 deficiency is common in Asians (3 to 11 percent)¹¹⁷ and Africans (3 to 6 percent),¹¹⁸ but is rare in white populations (0.1 percent).¹¹⁸ CD36 deficiency may confer protection from malaria and has been shown to be a receptor for red cells infected with *Plasmodium falciparum*. However, one report suggests CD36 deficiency may actually increase the risk for more severe forms of malarial infection.¹¹⁹ The role of CD36 deficiency as either a protective or aggravating factor in malarial infection remains controversial.^{120,121} Type I CD36-deficient individuals can become immunized via transfusion or pregnancy and make isoantibodies against CD36 that have been implicated in cases of FNAIT, PTP, and platelet transfusion refractoriness.^{117,122-125}

PLATELET ANTIGENS: GENETICS AND STRUCTURE

Platelet-specific alloantigens result from genetic polymorphism in genes encoding platelet surface proteins.¹²⁶ These alloantigens were first defined by antiplatelet antibodies discovered in the sera of multiparous females who gave birth to thrombocytopenic infants (FNAIT) or in patients who developed PTP. Many of these alloantibodies were subsequently found to recognize allotypic determinants of platelet-associated membrane GPs, such as GPIIb/IIIa (CD41/CD61). Almost all of these determinants are generated by single-amino-acid substitutions encoded by SNPs in the GP genes (Table 137-4).¹²⁷ In some cases, differential glycosylation may contribute to or influence the expression of certain human platelet antigen (HPA) epitopes, such as those associated with HPA-3.^{128,129} In any case, these amino acid substitutions generally do not appear to affect platelet function *in vitro*. However, the genetic polymorphism in platelet GPs may be associated with more subtle differences in platelet physiology that can contribute to the relative risk for thrombosis and/or atherosclerosis.¹³⁰⁻¹³⁵

To date, 33 HPA expressed on six different platelet GPs: GPIIb (CD41), GPIIIa (CD61), GPIb α (CD42b), GPIb β (CD42c), GPIa (CD49b), and CD109 have been described including localization to platelet surface GPs, quantification of their density on the platelet surface, and determination of DNA polymorphisms in genes encoding for them (see Table 137-4).^{127,136} For a current list see <http://www.ebi.ac.uk/ipd/hpa/table1.html> and <http://www.ebi.ac.uk/ipd/hpa/table2.html>.¹²⁷ Thirteen antigens are clustered into one triallelic¹³⁷ (HPA-1) and five biallelic groups (HPA-2, HPA-3, HPA-4, HPA-5, HPA-15). HPA for which antibodies against only one of the alleles have been detected are labeled with a "w" for workshop, for example, HPA-8bw. To date, 20 such low-frequency single-allele HPAs have been discovered, essentially all involved in FNAIT cases.¹³⁸

Although the frequencies of HPAs have been most extensively studied in white populations, it should be noted that they have been determined for other racial and ethnic groups as well and in some cases vary significantly from white frequencies. For example, HPA-1b is expressed on the platelets of approximately 15 percent of persons of European ancestry but of less than 1 percent of persons of Asian ancestry. For more information re HPA frequencies in different populations, readers are directed to: http://www.ebi.ac.uk/ipd/hpa/freqs_1.html¹²⁷

NOMENCLATURE

A nomenclature for human platelet alloantigens has been adopted to replace the old complex "classic" nomenclatures that previously were developed independently in laboratories throughout the world (see

TABLE 137-4. Human Platelet Alloantigens^{127,136,163*}

Alloantigens	Other Names	Phenotypic Frequency (Whites)	Glycoprotein Location/ Amino Acid Substitution	Encoding Gene/ Nucleotide Change

[†]Sensitization to CD36 (GPIV) is an example of isoimmunization. Anti-CD36 antibodies have been implicated in cases of neonatal alloimmune thrombocytopenia (NAIT) and posttransfusion purpura (PTP) and thus are included in the list of platelet alloantigens that are associated with these disorders.

Table 137-4). In most cases, an HPA site has two alleles, designated by the suffix *a* or *b*. These alleles are expressed by platelets codominantly. The *a* allele represents the more prevalent form of the protein, while the *b* allele represents the less-common form. There is one example of a triallelic HPA system, HPA-1, with the *c* allele being least prevalent.¹³⁷ A number of HPA alleles, for example, HPA-6b, HPA-7b, HPA-8b, and HPA-10b, are present at gene frequencies of less than 0.1 percent and were recognized in the sera of mothers of thrombocytopenic babies (FNAIT) in a single or only a very few families. Their putative high-frequency alternative alleles or the *a* form of the HPAs have not yet been identified serologically, probably because of the extremely low frequency of individuals who are homozygous for the rare alleles and who could therefore be sensitized to the high-frequency alternative allele. When such low-frequency markers are detected in only one family, they are referred to as *private* alleles. When more than one family is discovered to have such low-frequency markers and the families are unrelated, the alleles are then designated as *rare*. Such extremely rare or private alleles are unlikely to be present in the blood donor population. For this reason, these markers are unlikely to account for cases of PTP, but can be found in isolated cases of FNAIT in selected families. Alleles present at gene frequencies greater than 2 percent within the population are designated as *public* alleles. These alleles are more likely to encode alloantigens involved in PTP. Similarly, sensitization to HPA alleles with frequencies less than 50 percent are unlikely to account for platelet

transfusion refractoriness by themselves, as it would be expected that randomly selected platelet products would have been collected from a donor population with a similar frequency of these more common antigens.

TESTING FOR PLATELET-SPECIFIC ANTIGENS AND ANTIBODIES

Three types of platelet antibody detection methods have been developed. The earliest were phase I assays that involved mixing of patient serum with normal platelets and used platelet function-dependent end points such as α -granule release, aggregation, or agglutination. The serotonin release assay, used for the laboratory diagnosis of heparin-induced thrombocytopenia, and in which radiolabeled serotonin, a dense-granule constituent, is measured, is the only major phase I assay remaining in wide use today.¹³⁹ Other phase I assays were largely succeeded by phase II tests that detect either surface or total platelet-associated immunoglobulin on patient platelets or on normal platelets after sensitization with patient serum. An example of a phase II assay in wide use today is the solid-phase red cell adherence test, used for platelet cross-matching.¹⁴⁰ Phase III assays have been developed in which the binding of antibodies to isolated platelet surface GPs is detected. These assays are used to detect alloantibodies in the evaluation of suspected FNAIT and PTP cases as well as autoantibodies in some cases of idiopathic

thrombocytopenic purpura.¹⁴¹ Phase III assays have an advantage over both phase I and phase II tests in that they detect antibodies that bind to platelet GPs, and not to non-platelet-specific epitopes, such as class I HLA. Examples of phase III assays are the monoclonal antibody immobilization of platelet antigens assay (MAIPA)¹⁴² and the modified antigen capture ELISA (MACE).¹⁴³

Although most of the platelet antibody detection methods can be employed to determine platelet alloantigen types of individuals, because of limited access to rare typing sera and the need to establish platelet typing in patients with very few platelets, they have been largely supplanted by molecular typing using methods based on PCR. Molecular typing is now available for all of the platelet alloantigens that have been elucidated at the gene level.^{144–150}

CLINICAL IMPORTANCE

Antibodies recognizing platelet-specific alloantigens have been discovered in three clinical situations: mothers who give birth to infants with FNAIT; patients who develop dramatic thrombocytopenia after blood transfusion (PTP); and patients who have received multiple transfusions. Chapter 117 discusses the clinical syndromes of FNAIT.

Although antibodies to class I HLA antigens are the principal cause of immunologic platelet transfusion refractoriness (discussed in Chap. 139), occasionally patients receiving multiple platelet transfusions will develop antibodies to platelet specific alloantigens. Many of the best-documented platelet-specific antibodies detected in such patients are directed against platelet antigens whose phenotypic frequencies are less than 30 percent in the blood-donor population.^{151–154} Therefore, it is difficult to attribute refractory responses in random-donor and/or HLA-matched platelet transfusions to these antibodies alone. Indeed, the majority of refractory patients with platelet-specific antibodies also have HLA antibodies. Alloimmunization to high-frequency platelet-specific antigens would be expected to present a major challenge in finding compatible platelets to support a patient requiring multiple platelet transfusions. Fortunately, these cases are extremely rare.^{152,154} If platelet transfusion refractoriness does develop because of platelet-specific antibodies, compatible platelet products may be identified by using either platelet crossmatching or by accessing family member or other HPA-typed donors who are compatible with the patient's antibodies.^{155,156} Platelet GP reactivity in transfusion recipients that lacks specificity usually does not influence transfusion responses.^{151,157–159}

Antibodies against some HPA-allelic determinants can inhibit platelet function. Anti-HPA-1 alloantibodies, for example, can inhibit clot retraction and platelet aggregation, presumably because they block the binding of GPIIb/IIIa ($\alpha_{IIb}\beta_3$) (CD41/CD61) to fibrinogen. Moreover, anti-HPA-4 alloantibodies can completely inhibit aggregation of HPA-4 platelets that are homozygous for the allele recognized by the alloantibodies because the epitope is in close proximity to the RGD (arginine-glycine-aspartic acid peptide sequence)-binding domain of the $\alpha_{IIb}\beta_3$ integrin.^{160,161} On the other hand, other anti-HPA-alloantibodies, such as those specific for HPA-3, may not significantly interfere with platelet function but nonetheless can cause Fc-mediated platelet destruction and immune thrombocytopenia.¹⁶²

CHAPTER 138

BLOOD PROCUREMENT AND RED CELL TRANSFUSION

Jeffrey McCullough, Majed A. Refaai, and Claudia S. Cohn

SUMMARY

Blood procurement is a vital national priority that is met in the United States by volunteer donors and a pluralistic blood collection program that includes the American Red Cross, independent community blood centers, and hospitals. More than 15 million units of whole blood are collected from approximately 10 million donors annually. Recruitment of donors is preceded by a medical history and limited physical examination. The donated blood is subjected to tests of blood type, red cell antibodies, and infectious agents that may be transmitted by blood transfusion. In some cases, collection of red cells, platelets, leukocytes, or plasma is achieved by hemapheresis. Plasma for the subsequent manufacture of derivatives such as albumin and intravenous immunoglobulin is obtained from paid donors by for-profit organizations different from those that collect whole blood and prepare blood components. The meticulous attention to donor risk characteristics and the use of sensitive assays to detect infectious agents that may be transmitted by blood have greatly improved the safety of blood.

It is widely accepted that red blood cell (RBC) transfusions save lives and prevent ischemia-related morbidity in severely hemorrhaging patients and those with acute anemia (hemoglobin [Hgb] less than 6 g/dL). When a

patient's Hgb level exceeds 10 g/dL, oxygen delivery and consumption do not necessarily increase with RBC transfusions. For patients in the 6 to 10 g/dL Hgb "gray zone," the benefit of a transfusion depends upon a patient's clinical status and should be weighed against the inherent risks of allogeneic blood.

These risks include adverse reactions, which occur in up to 3 percent of transfusions. Transfusion-related acute lung injury is the number one cause of transfusion-related fatalities, and new pathogens causing transfusion-transmitted infections continue to pose a threat to the blood supply. Transfusion-associated circulatory overload is often not recognized, but is associated with increased morbidity and prolonged lengths of stay.

As the aging population grows in the United States, the demand for blood will increase, even as the donor population declines. Patient blood management efforts are growing in popularity as hospitals grapple with the risks and costs associated with transfusion. The implementation of evidence-based practice is the best way to benefit patients and minimize the risks of transfusion.

OVERVIEW OF THE BLOOD BANKING SYSTEM IN THE UNITED STATES

The United States has a pluralistic system of blood collection rather than the single national system that exists in other developed countries. In the United States during 2011, approximately 15,721,000 units of blood were available for use (Table 138-1). This was a 9 percent decrease from 2008. Approximately 94 percent of the blood was collected in regional blood centers and hospitals collected 7 percent.¹ Less than 1 percent of the units donated in the United States were autologous donations or directed donations, that is, blood given by family or friends for a specific patient. Both autologous and directed donations decreased substantially from 2008.¹ Of red cells collected, 97.7 percent of allogeneic, 59.0 percent of autologous, and 72.0 percent of directed donor red cells were transfused to the intended recipient.

All whole blood for transfusion in the United States is donated by unpaid volunteers; however, costs are incurred in the collection, testing, production, and distribution of blood components. Blood banks pass on these costs to hospitals. Some areas of the United States are able to collect more blood than is needed locally and other areas are unable to collect enough blood to meet their local needs. Several inventory-sharing systems are used to move blood around the United States so as to alleviate the shortages.

Blood is considered a drug and all aspects of the selection of donors, collection, processing, testing, preservation, and dispensing are regulated by the FDA. The FDA requirements define the procedures, record-keeping, staff proficiency, specific testing, and donor medical requirements that blood banks must follow. Blood banks meet these requirements using the FDA-defined good manufacturing practices that are similar to those used by pharmaceutical manufacturers.² Additional standards are formulated by the American Association of Blood Banks (AABB), a voluntary organization that accredits blood banks.

INTERNATIONAL PRACTICES

Approximately 107 million units of blood are collected annually worldwide. Considerable differences in the availability of blood and blood components throughout the world are related to the extent of development in the country and the country's healthcare system.³ The amount of blood collected in relation to the population ranges from 50 donations per 1000 population in industrialized countries to five to 15 per 1000 population in developing countries and one to five per 1000

population in the least-developed countries.³ Thus, industrialized countries utilize transfused blood products far more commonly. In developed countries, especially Western Europe and parts of Asia, a governmental agency usually oversees the blood collection activities, although the extent to which the government sets requirements and monitors or inspects the blood collection system varies. In developed countries, the basic processes of donor medical screening, blood collection, laboratory testing, and preparation of blood components are similar to the system found in the United States. In virtually all developed countries, blood is donated by volunteers because paid donors are associated with a higher risk of disease transmission.⁴ The basic blood components—red cells, platelets, and plasma—usually are available and apheresis instruments are used to collect platelets. Plasma derivatives such as albumin, coagulation factor VIII, other plasma protein concentrates (coagulation factors or inhibitors, or complement factor-1 inhibitor) and immune globulins are available.

However, in the developing world the blood supply is very limited and components are often not available. Patients may be required to arrange for the blood they need so donors may be friends or family members of patients or even individuals who have been paid by the patient's family to donate the blood needed. Donor screening may not be as extensive, transmissible disease testing may be lacking, and equipment may be reused. These difficulties may be compounded by the presence of endemic transfusion-transmissible diseases for which screening is difficult or expensive and thus not performed as extensively as in more developed countries. Great strides have been made during the last decade primarily from the U.S.-funded President's Emergency Plan for AIDS Relief (PEPFAR) program.⁵ Thus, the availability of blood and its components around the world varies widely, from inadequate supplies

and uncertain safety to sophisticated supply systems and component availability equal to or surpassing those of the United States.

● PROCUREMENT OF PLASMA DERIVATIVES

The plasma industry is separate from the blood banking system described above. Plasma can be subjected to a fractionation process to produce several medically valuable products referred to as *plasma derivatives*. Plasma fractionation is performed in manufacturing plants in batches of up to 10,000 L involving the pooling of plasma from a large number of donors. Plasma for manufacture or fractionation into derivatives can be obtained from units of whole blood, but this amount of plasma is inadequate to meet the needs for plasma derivatives. Consequently, large amounts of plasma are obtained by plasmapheresis in which only the plasma and not red cells or platelets are retained from the donor. Individuals can donate plasma up to two times per week and usually are paid because of the more extensive time commitment. This plasma collection system usually is operated by for-profit organizations and functions separately from the system for whole-blood donation.

Approximately 29 million liters of plasma were collected in the United States in 2013. Twenty-six plasma derivatives are approved for licensure by the FDA. Disruption in the sources of plasma or in one manufacturer's plant can have serious consequences and create shortages of certain derivatives.

The remainder of this chapter describes the blood collection system operated by voluntary community organizations to provide cellular and whole-blood-derived components.

● RECRUITMENT OF BLOOD DONORS

Although most Americans will require a blood transfusion at some time in their lives, only about one-third of the U.S. population is eligible to donate blood,⁶ and only a small portion of those actually donate. Blood donors are more likely than the general population to be male, age 30 to 50 years, white, employed, and have more education and higher income.⁷ It is generally believed that the most effective way to get someone to donate blood is to ask him or her personally. Factors such as the convenience of donation, peer pressure, receipt of blood by a family member, and perceived community needs are important factors that are superimposed onto the individual's basic social commitments.

● WHOLE-BLOOD DONOR SCREENING

The approach to the selection of blood donors is designed to (1) ensure the safety of the donor and (2) obtain a high-quality blood component that is as safe as possible for the recipient. Some specific steps that are taken to ensure that blood is as safe as possible are the use of only volunteer blood donors; questioning of donors about their general health before their donation is scheduled; obtaining a medical history, including specific risk factors, before donation; conducting a brief physical examination before donation; laboratory testing of donated blood; checking the donor's identity against a donor deferral registry; and providing a method by which the donor can confidentially designate the unit as unsuitable for transfusion after the donation is completed.

HEALTH HISTORY, PHYSICAL EXAMINATION, AND LABORATORY EXAMINATION OF THE BLOOD

The health history is usually done by a computer-assisted self-interview. The questions designed to protect the safety of the donor include

TABLE 138-1. United States Blood Supply System in 2011*

	Number	Percent
Total units whole blood	15,721,000	100
Blood centers	14,686,000	93
Hospitals	1,036,000	7
Red blood cell transfusions	13,785,000	100
Allogeneic	13,785,000	99
Autologous	65,000	<1
Directed	37,000	<1
Platelets—total dose	1,738,000	100
SDP collected	2,516,000	92
WB platelet concentrates	1,110,000	8
Total platelets transfused*	9,875,000	
Fresh-frozen plasma	5,926,000	—
Fresh-frozen plasma transfused	4,089,000	—
Cryoprecipitate	1,690,000	
Cryoprecipitate transfused	890,000	

SDP, single-donor platelet concentrate prepared by plateletpheresis. One SDP is equivalent to five platelet concentrates; WB, whole-blood derived platelet concentrate. Usually five units are pooled to obtain a therapeutic dose.

Data from Whitaker BI, Henry, RA, World Health Organization: National blood transfusion services [on the Internet]. www.who.int/bloodsafety/transfusion_services/en/. Accessed September 1, 2009.

whether the donor is under the care of a physician or has a history of cardiovascular or lung disease, seizures, present or recent pregnancy, recent donation of blood or plasma, recent major illness or surgery, unexplained weight loss, unusual bleeding, or is taking medication(s). Some medications may make the donor unsuitable because of the condition requiring the medication, whereas other medications may be potentially harmful to the recipient. Questions designed to protect the safety of the recipient include those related to the donor's general health, history of receipt of growth hormone, and occurrence of or exposure to patients with hepatitis or other liver disease, or a previous diagnosis of HIV or AIDS (or symptoms of AIDS), Chagas disease, or babesiosis. A history also is obtained regarding the injection of drugs; receipt of coagulation factor concentrates; blood transfusion; tattoos; acupuncture; body piercing; receipt of an organ or tissue transplant; recent travel to areas endemic for malaria; recent immunizations; ingestion of medications (especially aspirin); presence of a major illness or surgery; and previous notice of a positive test for a transmissible disease. In addition, several questions are related to AIDS risk behavior, including whether the potential donor has had sex with anyone with AIDS, given or received money or drugs for sex, (for males) had sex with another male, or (for females) had sex with a male who has had sex with another male.

The physical examination includes determination of the temperature, pulse, blood pressure, weight, and blood hemoglobin (Hgb) concentration. The donor's general appearance is assessed for any signs of illness or the influence of drugs or alcohol. The skin at the venipuncture site is examined for signs of intravenous drug abuse, and local lesions that would make disinfecting the skin difficult and thus lead to contamination of the blood unit during venipuncture.

● COLLECTION OF WHOLE BLOOD

BLOOD CONTAINERS

Blood must be collected into single-use, sterile, FDA-licensed containers. The containers are made of plasticized material that is biocompatible with blood cells and allows diffusion of gases so as to provide optimal cell preservation. These blood containers are combinations of bags and integral tubing that allow separation of the whole blood into its components in a closed system, thus minimizing the chance of bacterial contamination while making storage of the components for days or weeks possible. Plasticizers from the bags accumulate in red cell components during storage and can be found in tissues of multitransfused patients but also in healthy nontransfused individuals. Although no evidence indicates that transfusion of this material causes clinical problems, containers without plasticizers are now used in some countries.

VENIPUNCTURE AND BLOOD COLLECTION

The blood should be drawn from an area free of skin lesions and the phlebotomy site should be decontaminated. The site is scrubbed with a soap solution, followed by the application of tincture of iodine or iodophor complex solution. The venipuncture is done with a needle that should be used only once in order to prevent contamination. The blood must flow freely and be mixed with anticoagulant frequently as the blood fills the container to prevent the development of small clots. The actual time for collection of 450 to 500 mL usually is approximately 7 minutes and almost always is less than 10 minutes. During blood donation, cardiac output falls slightly but heart rate changes little. A slight decrease in systolic pressure results with a rise in peripheral resistance and diastolic blood pressure.

Usually 500 mL is collected. The blood is mixed with 63 to 70 mL of anticoagulant composed of citrate, phosphate, and dextrose (CPD).

The amount of blood withdrawn must be within prescribed limits so as to maintain the proper ratio with the anticoagulant; otherwise, the blood cells may be damaged and/or anticoagulation may be unsatisfactory.

An untoward reaction occurs after approximately 2 to 5 percent of blood donations, but, fortunately, most of the reactions are not serious. Donors who have reactions are more likely to be younger, unmarried, have a higher predonation heart rate and lower diastolic blood pressure, lower weight, female, and first-time or infrequent donors. Donors who experience a reaction are less likely to donate in the future.

The most common reactions to blood donation are weakness, cool skin, and diaphoresis.⁸ More extensive, but still moderate, reactions are dizziness, pallor, hypertension, and bradycardia.⁹ Bradycardia usually is considered a sign of a vasovagal reaction rather than hypotensive or cardiovascular shock, where tachycardia would be expected. In a more severe form, a vasovagal reaction may progress to loss of consciousness, convulsions, and involuntary passage of urine or stool. Other reactions include nausea and vomiting; hyperventilation, sometimes leading to twitching or muscle spasms; hematoma at the venipuncture site; convulsions; and serious cardiac difficulties. Such serious reactions are rare. Injury of the brachial nerve and resulting pain and/or paresthesia may occur as a result of needle puncture of the nerve or compression from a hematoma.

Donors are advised to drink extra fluids to replace lost blood volume and to avoid strenuous exercise for the remainder of the day of donation. The latter advice is given to prevent fainting and to minimize the possibility of hematoma development at the venipuncture site. Some donors are subject to lightheadedness or even fainting if they change position quickly. Therefore, donors are advised not to return to work for the remainder of the day if they have an occupation where fainting would be hazardous to themselves or others.

● SPECIAL BLOOD DONATIONS

AUTOLOGOUS DONOR BLOOD

Autologous blood for transfusion can be obtained by preoperative donation, acute normovolemic hemodilution, intraoperative salvage, and postoperative salvage, but only preoperative donation is discussed here. Most commonly, this situation occurs with elective surgery. Autologous blood accounts for a very low level (<1 percent) of the United States' blood supply.¹

If patient candidates for autologous blood donation meet the usual FDA criteria for blood donation, their blood can be used for other patients if the original autologous donor has no need for the blood. However, this practice is not allowed by AABB standards and is usually not relevant because most patients do not meet the FDA donation criteria. If the autologous donor does not meet the FDA criteria for blood donation, the blood must be specially labeled, segregated during storage, and discarded if it is not used by that specific patient. Thus, the autologous blood donation should be collected only for procedures with a substantial likelihood that the blood will be used. Without this type of planning, a very high rate of wastage of autologous blood is observed, estimated at 59 percent in 2011.¹ Thus, the cost of autologous blood is high.

No age or weight restrictions exist for autologous donation. Pregnant women can donate, but this practice is not recommended routinely because these patients rarely require transfusion. The autologous donor's Hgb may be lower (11 g/dL) than that required for routine donors (12.5 g/dL), although usually only 2 to 4 units of blood can be obtained before the Hgb falls below 11 g/dL. Autologous blood donors can be given erythropoietin and iron to increase the number of units of blood they can donate,^{10,11} although this strategy has not been shown to reduce

the need for allogeneic donor blood. Reactions in autologous donors are similar to allogeneic donors and are related to first-time donation, female gender, lower age, and lower weight.

Autologous blood must be typed for ABO and Rh antigens. If the unit is to be shipped to another facility for transfusion, it must be tested for transmissible diseases similar to allogeneic blood. If any of the transmissible disease tests are positive, the unit must be labeled with a biohazard label.

DIRECTED DONOR BLOOD

Directed donors are friends or relatives who wish to give blood for a specific patient because the patient hopes those donors will be safer than the regular blood supply. However, directed donors do not have a lower incidence of transmissible disease markers¹² and thus do not support a realistic rationale for these donations. Because the blood becomes part of the community's general blood supply if it is not used for the originally intended patient, directed donors must meet all the usual FDA requirements for routine blood donation.

PATIENT-SPECIFIC DONATION

In a few situations, appropriate transfusion therapy involves collecting blood from a particular donor for a particular patient. Examples are donor-specific transfusions prior to kidney transplantation, maternal platelets for a fetus projected to have neonatal alloimmune thrombocytopenic purpura (NATP), or family members of a patient with a rare blood type. Usually, these donors must meet all the usual FDA requirements, except that they may donate as often as every 3 days so long as the Hgb remains above the normal donor minimum of 12.5 g/dL. An exception is donation of maternal platelets for a neonate with NATP. Patient-specific donated units must undergo all routine laboratory testing.

THERAPEUTIC BLEEDING

Blood can be collected as part of the therapy of diseases such as polycythemia vera or primary hemochromatosis. Usually such blood is not used for transfusion because the donors do not meet the FDA standards for donor health. As the genetic basis of hemochromatosis has become better understood, blood removed from these patients appears to be safe and red cells from patients with hemochromatosis are normal during blood bank storage,¹³ and although a blood collection program can operate successfully, this has not gained general acceptance.

● COLLECTION AND PRODUCTION OF BLOOD COMPONENTS BY APHERESIS

Blood components can be obtained by apheresis rather than prepared from whole blood. In apheresis, the donor's anticoagulated whole blood is passed through an instrument in which they use centrifugation to separate the blood components. Red cells, platelets, granulocytes, blood stem cells, mononuclear cells, and plasma can be obtained by apheresis.

PLATELETPHERESIS

In the United States, approximately 92 percent of platelet concentrates are produced by plateletpheresis (see Table 138-1). Plateletpheresis requires approximately 90 minutes, during which approximately 4000 to 5000 mL of the donor's blood is processed through the blood cell separator. The process results in a platelet concentrate with a volume of approximately 200 mL and containing approximately 4.0×10^{11} platelets and less than 0.5 mL red cells. Currently manufactured blood cell separators produce a platelet concentrate that contains less than 5×10^6

leukocytes and thus can be considered leukocyte reduced. Following plateletpheresis, the donor's platelet count declines by approximately 30 percent but returns to preplateletpheresis levels in approximately 4 days.

COLLECTION OF RED CELLS BY APHERESIS

Chronic shortages of group O red cells stimulated interest in the use of apheresis for collecting the equivalent of 2 units of red cells from some donors, especially group O.¹⁴ In 2011, 1,978,000 units of red cells were collected by apheresis.¹ The collection procedure is similar to other apheresis procedures, except that red cells are retained rather than returned to the donor. The red cells usually have a very high hematocrit (Hct) as they are removed from the instrument, but an additive solution is incorporated and the red cells can be stored for the usual 42 days. Red cells obtained by apheresis have the same characteristics as those produced from whole blood. Because 2 U of red cells are removed, donors may donate only every 4 months.

LEUKAPHERESIS

Leukapheresis has been used to produce a granulocyte concentrate for transfusion therapy of infections unresponsive to antibiotics. Because the efficiency of granulocyte extraction from whole blood is less than for platelets, the leukapheresis procedure involves processing 6500 to 8000 mL of donor blood for approximately 3 hours. To increase the separation of granulocytes from other blood components, hydroxyethyl starch is added to the blood-cell-separator flow system. In addition, glucocorticoids and granulocyte colony-stimulating factor (G-CSF) have been administered to granulocyte donors to increase the granulocyte count and the granulocyte yield.¹⁵

PLASMAPHERESIS

Plasmapheresis is used to obtain plasma for manufacture of derivatives but not plasma for transfusion. Plasmapheresis usually can be performed in approximately 30 minutes and produces up to 750 mL of plasma. Because few red cells are removed, the procedure can be repeated up to two times per week, so theoretically a donor could provide a large amount of plasma. Because of the nature and possible frequency of plasma donation, special donor criteria apply.

● SELECTION OF APHERESIS DONORS

The selection of donors for apheresis uses the same criteria as for whole-blood donation with some additional donor requirements. No more than 15 percent of the donor's blood should be extracorporeal during apheresis; thus, the donor's size is considered when making decisions about specific apheresis procedures or instruments to be used. The platelet count must be monitored for frequent donors. Because a plateletpheresis concentrate would be the sole source of platelets for the transfusion, the donor must not have taken aspirin for at least 3 days.

The amount of blood components removed from apheresis donors must be monitored. Not more than 200 mL of red cells per 2 months or approximately 1500 mL of plasma per week can be removed. The laboratory testing of donors and apheresis components for transmissible diseases is the same as for whole-blood donation. Thus, the likelihood of disease transmission from apheresis components is the same as from whole blood.

● REACTIONS IN APHERESIS DONORS

Apheresis donors can experience the same kind of reactions as whole-blood donors. In addition, apheresis donors experience a higher incidence of paresthesias, probably because of the infusion of citrate (that may

affect calcium levels) used to anticoagulate the donor's blood while it is in the cell separator. This type of reaction is managed by slowing the blood flow rate through the instrument, which slows the rate of citrate infusion. In leukapheresis, donors can be given glucocorticoid and/or G-CSF to increase the granulocyte count, and the sedimenting agent hydroxyethyl starch is used in the cell separator to improve the granulocyte yield. When G-CSF and glucocorticoids are used, approximately 60 percent of donors experience side effects, usually myalgia, arthralgia, headache, or flu-like symptoms.¹⁵ The major side effect of hydroxyethyl starch is blood volume expansion manifested by headache and/or hypertension.

LABORATORY TESTING OF DONATED BLOOD

Each unit of whole blood or each apheresis component undergoes a standard battery of tests, including those for blood type, red cell antibodies (including ABO, Rh, minor antigens), and transmissible diseases (Table 138-2). Additional tests, such as those for cytomegalovirus (CMV) antibodies, may be done. During the last few years, testing for West Nile virus and *Trypanosoma cruzi* have been added. Babesia is another transfusion transmissible disease¹⁶ for which a donor screening test has been developed. It is not clear whether routine testing will be introduced.

SAFETY OF THE BLOOD SUPPLY

Ironically, the improvements in blood safety have occurred at a time of the public's increased fear of transfusion and the more cautious use of blood components by physicians. Each step in the overall process of

donor evaluation and testing adds to blood safety in important ways, and the medical history is important as illustrated by the 90 percent reduction in HIV infectivity from the use of donor-selection criteria identifying HIV risk behavior.¹⁷ Tests for transmissible diseases further reduce the proportion of infectious donors.¹⁸ Donor deferral registries detect individuals who previously were deferred as blood donors but who for various reasons attempt to donate again. Currently, the risk of acquiring a transfusion-transmitted disease ranges from one per 150,000/unit for hepatitis B to one per 2,135,000/unit for HIV (Table 138-3). Thus, although the blood supply is safer than ever, transfusion is not risk free and should be undertaken only after careful consideration of the patient's clinical situation and specific blood component needs.

RED CELL TRANSFUSIONS

Red blood cell (RBC) transfusions are indicated to increase oxygen carrying capacity in anemic patients. While oxygen extraction and delivery may be measured using invasive procedures, these methods are not available in most clinical settings. As a result, the decision to transfuse RBCs is often based on Hgb or Hct value(s).

Transfusing RBCs to a critically anemic patient will increase the oxygen-carrying capacity; however, the utility of RBC transfusions in an asymptomatic patient with a Hgb between 6 and 10 g/dL is less clear. Most of the large, prospective, randomized controlled studies looking at RBC usage and transfusion triggers did not specifically address the question of increased oxygen-carrying capacity at various Hgb/Hct levels. Instead they used the more practical markers of mortality, end-organ dysfunction, or adverse events to determine the efficacy and safety of restrictive (low Hgb threshold) versus liberal (higher Hgb threshold) transfusion strategies.

TABLE 138-2. Laboratory Tests for Transmissible Agents of Donated Blood

Agent	Disease

[‡]Of use for immunodeficient recipients.

RED BLOOD CELL TRANSFUSION THRESHOLDS

The Transfusion Requirements in Critical Care (TRICC) trial was the first adequately powered study to compare a restrictive and liberal strategy for RBC transfusions in critically ill patients.¹⁹ A total of 838 ICU patients were randomized into two groups: a liberal arm, which maintained Hgb concentrations between 10 and 12 g/dL and gave transfusions when the Hgb concentration fell below 10 g/dL; and a restrictive arm, which maintained Hgb levels between 7 and 9 g/dL and used a Hgb value of 7 g/dL as the trigger for transfusion. The exclusion criteria included age younger than 16 years; active blood loss at the time of enrollment; admission after a routine cardiac procedure; chronic anemia; imminent death; and others. Thirty-day mortality from all causes was the primary outcome measure. Secondary outcomes included 60-day mortality, death during hospitalization, and multiple-organ dysfunction (MOD). The severity of a patient's illness was classified using the Acute Physiology and Chronic Health Evaluation II (APACHE II) scores. This and other patient characteristics were statistically similar in the two study arms. This study was designed as an equivalency trial, and overall found similar results in the two groups for 30-day mortality (18.7 vs. 23.3 percent; $p = 0.11$), as well as for the secondary outcomes. Thirty-day mortality rates among patients in the restrictive transfusion arm who were less acutely ill (APACHE II ≤ 20) (8.7 vs. 16.1 percent; $p = 0.03$), or were younger than 55 years old (5.7 vs. 13.0 percent; $p = 0.02$). The restrictive group also received fewer transfusions (54 percent) than the liberal group. The authors concluded that "a restrictive strategy is at least as effective as and possibly superior to a liberal transfusion strategy in critically ill patients...."

Studies conducted after the TRICC trial have used various categories of high-risk patients to better define RBC transfusion thresholds in these populations (Table 138-4). Studies have focused on patients

TABLE 138-3. Incidence of Transfusion-Transmitted Diseases

	Data from Strong and Katz (2002) ⁷⁵	Data from Dodd, Notari, and Stramer (2002) ¹⁸	Data from Tabor (2002) ⁷⁷	Total U.S. Cases*

with upper gastrointestinal bleeding, cardiovascular risk factors, orthopedic surgery patients and other populations that usually require a large number of RBC transfusions. All studies followed the basic structure of the TRICC trial, randomizing patients into a restrictive versus liberal arm. Most studies also used mortality or end-organ dysfunction as end points.

A total of 899 patients with an upper gastrointestinal bleed were randomized so that the restrictive arm had a transfusion threshold of 7 g/dL versus a Hgb level of 9 g/dL for the liberal arm.²⁰ Death from any cause within the first 45 days was the primary outcome, and the rate of further bleeding and in-hospital complications were used as secondary outcomes. The two patient groups had similar characteristics, including equivalent numbers and grades of cirrhosis. The results of this study also favored a restrictive transfusion strategy. The probability of survival at 6 weeks was higher in the restrictive strategy group ($p = 0.02$) and the risk of further bleeding was lower ($p = 0.01$). Overall adverse events were also lower in the restrictive group when compared to the liberal transfusion arm ($p = 0.02$). The rate of survival was slightly higher in the restrictive group compared to the liberal group for patients with peptic ulcers (hazard ratio, 0.70; 95 percent confidence interval [CI], 0.26 to 1.25); and was significantly higher in patients with cirrhosis and Child-Pugh class A or B disease (hazard ratio, 0.30; 95 percent CI, 0.11 to 0.85). No difference was found for cirrhosis patients and Child-Pugh class C disease (hazard ratio 1.04; 95 percent CI, 0.45 to 2.37). As with the TRICC study, a highly significant difference in transfusion rates was reported. In the restrictive arm, 51 percent of patients did not receive a transfusion, compared to 15 percent of patients in the liberal arm who

did not receive RBC transfusions ($p < 0.001$). These two major trials demonstrated that a 7 g/dL Hgb threshold was safe for a variety of critically ill patients.

RED BLOOD CELL TRANSFUSIONS FOR CARDIOVASCULAR PATIENTS

Moderate anemia may lead to increased rates of myocardial ischemia and infarction in patients with cardiovascular risk factors. Several studies were designed to test whether lower transfusion thresholds were deleterious in this patient population. A subgroup analysis of the TRICC trial found that patients with cardiovascular disease had similar outcomes in the restrictive and liberal cohorts; however, the rate of patients suffering from acute pulmonary edema was significantly higher in the liberal transfusion arm.²¹

The Transfusion Trigger Trial for Functional Outcomes in Cardiovascular Patients Undergoing Surgical Hip Fracture Repair (FOCUS trial) compared the transfusion thresholds of 10 g/dL versus less than 8 g/dL in patients who were status post-hip fracture repair and had cardiovascular risk factors.²² The trial enrolled 2016 patients older than 50 years of age who were randomized into the restrictive or liberal transfusion threshold group. The primary outcome was death or an inability to walk across a room without human assistance on 60-day followup. Secondary outcomes included in-hospital myocardial infarction, unstable angina, or death for any reason. The liberal transfusion strategy, when compared with the restrictive strategy, did not reduce rates of death or inability to walk independently at 60-day followup or reduce in-hospital

TABLE 138-4. Major Randomized Controlled Trials for Safe Hemoglobin Thresholds in Adults

Trial	Patient Population	Number Enrolled	Hgb/Hct Thresholds (Rest/Lib)	Primary End Point	Conclusions
TRICC ⁹³	ICU	838	7/10 g/dL	30-Day all-cause mortality	Restrictive strategy as effective and possibly superior to liberal strategy
FOCUS ⁹⁷	History or risk factor for CV disease following hip fracture surgery	2016	8/10 g/dL	60-Day all-cause mortality or inability to walk 10 ft	Liberal strategy did not reduce death rates or inability to walk
TRACS ⁹⁸	Cardiac surgery	502	24/30 percent	30-Day all-cause mortality and severe morbidity	Restrictive strategy was noninferior to liberal strategy
Upper GI bleed ⁹⁴	Severe acute upper GI bleed	921	7/9 g/dL	45-Day all-cause mortality	Restrictive strategy improved outcomes compared with liberal

morbidity in elderly patients at high cardiovascular risk. The rates of in-hospital complications were similar in the two groups.

The Transfusion Requirements After Cardiac Surgery (TRACS) trial randomized patients who underwent cardiac surgery with cardiopulmonary bypass into a liberal (Hct ≥ 30 percent) or restrictive (Hct ≥ 24 percent) strategy for RBC transfusions.²³ This noninferiority study found similar rates of 30-day all-cause mortality and severe morbidity. The number of transfused RBC units was found to be an independent risk factor for complications or death at 30 days.

Taken together, the evidence points to a Hgb threshold of 8 g/dL as a safe level to maintain most patients with a history of cardiovascular disease. Patients with acute coronary syndrome continue to be an important exception for which current data is insufficient to support any guidance.

RED BLOOD CELL TRANSFUSIONS FOR ORTHOPEDIC PATIENTS

The FOCUS trial, discussed above (see “Red Blood Cell Transfusions for Cardiovascular Patients”), specifically identified patients with cardiovascular risk factors undergoing hip repair.²² Other studies with orthopedic patients looked at more general outcome measures such as ability to ambulate after hip surgery. One prospective study found a significant association between anemia and a decreased ability to walk independently before the anemia was corrected.²⁴ However, a second prospective study found no differences in postoperative functional mobility or length of stay when comparing patients maintained on restrictive (8 g/dL) or liberal (10 g/dL) transfusion strategies.²⁵ However, the liberal transfusion group had few cardiovascular complications and lower mortality when compared to the restrictive group. The authors concluded that a liberal transfusion strategy does not increase ambulation scores but that a restrictive strategy should be treated with caution in elderly high-risk hip fracture patients.

The population in the FOCUS trial was elderly, high-risk cardiovascular patients; the finding of an 8 g/dL Hgb threshold for RBC transfusions may not be generalizable to the remaining lower-risk orthopedic patient population. However, until adequately powered studies are conducted in these populations, applying the 8 g/dL trigger is the safest approach for lower risk patients. While a Hgb of 8 g/dL is safe for orthopedic patients, the quality-of-life studies indicate that a higher Hgb allows for faster recovery.

RED BLOOD CELL TRANSFUSIONS FOR NEUROLOGICALLY IMPAIRED PATIENTS

No large scale, prospective randomized trial has been done regarding the safety and efficacy of transfusion practice in neurocritically ill patients. The lack of large studies led to a systematic review of six studies that had a combined total of 537 patients.²⁶ The Hgb triggers in these studies ranged from 7 to 10 g/dL in restrictive groups, to 9.3 to 11.5 g/dL in higher Hgb groups. While some studies reported shorter lengths of stay in the lower Hgb groups, the systematic review found insufficient evidence to guide transfusion practice in neurocritically ill patients.

RED BLOOD CELL TRANSFUSIONS FOR PEDIATRIC PATIENTS

Clinical trials of transfusion triggers for pediatric patients fall into two basic categories: general studies of critically ill pediatric patients and studies focused on high-risk neonates. The Transfusion Strategies for Patients in Pediatric Intensive Care Units (TRIPICU) trial and its affiliated subanalyses represent the major data set covering the pediatric

population ranging from 3 days old to 14 years of age.²⁷ The trial enrolled 626 patients who had Hgb less than or equal to 9.5 during their first 7 days in the pediatric ICU. The restrictive arm used a Hgb threshold of 7 g/dL, versus the liberal threshold of 9.5 g/dL. The restrictive group received significantly fewer transfusions yet multiple-organ dysfunction syndrome (MODS) and mortality were almost identified in the two arms of the study. Thus, for critically ill children, a Hgb threshold of 7 g/dL could decrease transfusion requirements without increasing adverse outcomes.

Three subgroup analyses were conducted with the TRIPICU data. One study analyzed postoperative patients,²⁸ the second looked at pediatric patients after cardiac surgery,²⁹ and the third examined patients with sepsis.³⁰ All three found no significant differences between new or progressive MODS or 28-day mortality in the restrictive and liberal groups. However, all three studies suffered from small sample size and could not draw strong conclusions because of insufficient power.

Trials in the neonate population have focused on premature babies and infants of very low birth weight. Unlike the clinical trials in adults, where the results of all studies found that a restrictive transfusion approach was as good as, or possibly superior to a liberal transfusion strategy, the results from clinical trials in neonates were mixed. One trial enrolled 100 preterm infants with birth weights between 500 and 1300 g.³¹ The transfusion thresholds in the restrictive and liberal arms were dependent upon the infant's age and respiratory status and varied from 22 to 34 percent in the low group to 30 to 46 percent in the high group. In each age group the transfusion threshold levels decreased with improving clinical status, as indicated by the level of respiratory support required. In either arm of the study, additional RBC transfusions could be given at the discretion of the attending neonatologist based on a set of predetermined circumstances. Infants in the restrictive arm of the study were more likely to have intraparenchymal brain hemorrhage or periventricular leukomalacia and also had more frequent episodes of mild and severe apnea. The liberal arm received more RBC transfusions; however, donor exposure was similar in both groups. The authors concluded that a restrictive transfusion practice may be harmful to preterm infants.

The largest trial of transfusion practice in preterm infants was the Premature Infants in Need of Transfusion (PINT) study.³² This randomized trial asked whether extremely-low-birth-weight infants transfused at different Hgb thresholds had different rates of survival or morbidity at discharge. A total of 451 infants, each weighing less than 1000 g at birth, were randomized into a low or high Hgb threshold group. The thresholds ranged from 6.8 g/dL to 11.5 g/dL in the low group and 7.7 g/dL to 13.5 g/dL in the high group. The actual threshold was determined by a combination of age and presence or absence of respiratory support. There was no statistically significant difference between the two groups in terms of death before home discharge or survival with severe morbidity. In addition, fewer infants received one or more transfusions in the low threshold group. The authors concluded that maintaining extremely-low-birth-weight infants at a higher Hgb threshold conferred no benefit.

A Cochrane review of transfusion in neonates concluded that a restrictive approach resulted in a modest reduction in exposure to transfusion, but did not appear to have a significant impact on death or major morbidities (Table 138-5).³³

HEMOGLOBINOPATHIES

SICKLE CELL DISEASE

Transfusion therapy is indicated for sickle cell patients suffering from stroke, acute chest syndrome, acute exacerbations of anemia, and other complications. Regular transfusions also significantly reduce

TABLE 138-5. Major Randomized Controlled Trials for Safe Hemoglobin Thresholds in Children

Trial	Patient Population	Number Enrolled	Hgb/Hct	Primary End Point	Conclusions
TRIPICU ²⁷	PICU (age from 3 days old to 14 years of age)	626	7/9.5	New or progressive multiple-organ dysfunction syndrome	In stable, critically ill children, a Hgb threshold of 7 g/dL can decrease transfusions without increasing adverse outcomes
PINT ³²	ELBW	451	6.8–11.5 g/dL (low) 7.7–13.5 g/dL (high)	Death before home discharge or survival with severe retinopathy, bronchopulmonary dysplasia or brain injury	In ELBW, maintaining a higher Hgb results in more transfusions but confers little evidence of benefit

the recurrence of cerebral infarcts in children with sickle cell disease (SCD).³⁴ Transfusions are usually not necessary to correct baseline anemia or alleviate vasoocclusive crises. Because transfusion also creates complications, such as iron overload, transfusion reactions, alloimmunization, and delayed hemolytic transfusion reactions, clinicians should take particular care when considering transfusions for sickle cell patients.

Chronic transfusion can lead to a high rate of RBC alloimmunization in patients with SCD. Rates ranged from 18 to 47 percent, which is significantly higher than found in the general U.S. population (0.5 to 1.5 percent),³⁵ or the highly transfused hematology-oncology population (9 to 15 percent). The reasons for this high rate include number of transfusions, age at first transfusion, the inflammatory milieu created by SCD,³⁶ and the different RBC antigens present in donors of mostly European descent versus sickle cell patients of African ancestry.

The multiple antibodies specific for RBC antigens can cause delayed hemolytic transfusion reactions (DHTRs).³⁷ DHTRs may be difficult to recognize, because some occur without any detectable antibody present, and with a negative direct antiglobulin test (DAT).³⁸ In addition, some DHTRs occur without obvious clinical signs of hemolysis.³⁷ Severe cases of DHTR result in the hyperhemolysis syndrome, defined by a drop in the patient's Hgb to a level lower than the pretransfusion value. This steep decline in Hgb suggests hemolysis of autologous cells, as well as the transfused allogeneic RBCs.

Transfusion services may attempt to ameliorate the alloimmunization rate by prophylactically matching donor and patient for Rh (antigens D, C, c, E, e) and Kell antigens. A few will also provide an extended phenotype match for the common Kidd, Duffy and S antigens. Both strategies reduce alloimmunization, yet even with matched transfusions, SCD patients continue to form RBC antibodies at rates up to 58 percent of chronically transfused and 15 percent of episodically transfused SCD patients.³⁷ Most of these antibodies were made against Rh antigens, and more than half occurred in patients who received RBCs phenotypically matched for the corresponding Rh antigen. The likely explanation for this seeming paradox is that SCD patients have variant *RH* genes. In fact, high resolution *RH* genotyping showed variant alleles in 87 percent of the subjects.^{37,39}

THALASSEMIA

Thalassemia major patients are chronically transfusion dependent. Over time, this will lead to iron overload, and can result in RBC alloimmunization. No clinical trial has been staged to find the optimal transfusion threshold for patients with thalassemia; however, the consequences of anemia can be severe and must be balanced with the risks of

transfusion. Transfusing to maintain a Hgb of 10 g/dL is considered sufficient to suppress erythropoiesis, thereby averting the bone deformities and other sequelae of this disease; however, some transfusion regimens call for a pretransfusion minimum of greater than 10 g/dL, with a post-transfusion goal of more than 15 g/dL. Thalassemia intermedia patients have more varied transfusion requirements, in keeping with the wide clinical presentation of this disease. If transfusion therapy is clinically indicated, the transfusion recommendations are similar to those for thalassemia major (Chap. 48).

HEMATOPOIETIC STEM CELL TRANSPLANT

TRANSFUSION SUPPORT

The duration and specificity of transfusion support for hematopoietic stem cell transplantation (HSCT) patients depends upon the disease, the source of the stem cells, the preparative regimen applied prior to transplant, and patient factors during the post-transplant recovery period. Human leukocyte antigen (HLA) matching remains an important predictor of success with HSCT. As a result, the ABO barrier is often crossed when searching for the best HLA match between donor and patient. Crossing the ABO barrier has little or no effect upon overall outcomes; however, transfusion difficulties can arise due to antigen incompatibility between the transplanted cells and the patient.

Transfusion support can be divided into the pre- and posttransplantation periods. Prior to an HSCT, an immunocompetent patient (e.g., aplastic anemia, hemoglobinopathies) is capable of mounting an immune response to transfusions, leading to alloimmunization against HLA antigens present on the surface of leukocytes. Leukoreduction reduces alloimmunization rates, but sufficient white blood cells remain in the unit for alloimmunization to occur. Antibodies against HLA contribute to delayed engraftment and graft rejection in some patient populations.⁴⁰ As a result, pretransplantation transfusions in immunocompetent patients should be avoided, as they are associated with increased graft failure rates.^{41,42} RBC transfusions can be minimized by using a Hgb trigger of 8 g/dL for stable patients.⁴³

Patients who are immunocompromised, either because of their disease, or from chemotherapy, are less likely to become immunized to foreign antigens. Nonetheless, using leukoreduced products to minimize the risk of alloimmunization is still recommended. Extra care must also be taken if the stem cell donation comes from a blood relative. In this situation family members should not give directed blood donations prior to transplantation, as this may lead to alloimmunization against major

and/or minor HLA antigens that are present in the transplant organ. In addition, all RBC and platelet transfusions should be irradiated as the risk for transfusion-associated graft-versus-host disease (TA-GVHD) is high in HSCT patients (see section Transfusion-Associated-Graft-versus-Host Disease below for more in-depth discussion of TA-GVHD).

RBC engraftment is difficult to assess, but may be defined by the appearance of 1 percent reticulocytes in the peripheral blood, or as the day of the last RBC transfusion, with no transfusion given in the following 30 days. In general, engraftment time is shortest when hematopoietic progenitor cells are obtained by apheresis (HPC-A), and greatest when hematopoietic progenitor cells are obtained from umbilical cords (HPC-C) are used; however, considerable patient-to-patient variability exists. Prolonged engraftment directly translates into higher transfusion rates for RBCs and platelets.

When an ABO incompatible transplant is used, group O red cells are used to avoid incompatibility issues. The ABO type of plasma products may be different from the red cell type (Table 138–6). Once the patient begins to produce “donor-type” erythrocytes, their blood type should be reassessed. The decision to switch a patient’s blood type is highly variable across institutions. In our hospital, when a patient is RBC transfusion independent for 100 days, and no incompatible isohemagglutinins against the new RBC phenotype can be detected in two consecutive blood samples, the patient’s native blood type is switched to the donor type for future transfusions.

TRANSFUSION-RELATED COMPLICATIONS

There are transfusion-related complications that are specific to, or more frequently seen, in the HSCT population. Some of these complications arise when lymphocytes within the transplant are activated against the

recipient; these include TA-GVHD and passenger lymphocyte syndrome (PLS). Another complication, pure red cell aplasia (PRCA), occurs when the patient’s residual antibodies attack the transplanted red cells. Standard transfusion reactions, such as allergic or febrile nonhemolytic reactions, are frequently seen in this heavily transfused patient population; however, these “standard” transfusion reactions are discussed more fully later in this chapter in the section Adverse Effects of Red Cell Transfusions.

Major and Minor ABO Mismatches

Complications from ABO incompatibility depend upon whether a major or minor ABO mismatch is present (see Table 138–6). A major mismatch occurs when the transplant contains RBCs that are incompatible with the recipient’s plasma. Conversely, a minor mismatch is present when the donor plasma contains isohemagglutinins against the recipient’s RBCs. Bidirectional transplants (e.g., group A transplant into group B recipient) carry both major and minor mismatches.

Major ABO Mismatch When a major ABO mismatched transplant is given, immediate hemolysis may occur during the infusion. This complication is more commonly seen when the HSCT is derived from marrow, because more red cells are present; however, RBC depletion techniques have effectively eliminated this complication. Because HPC-A units contain a minimal volume of RBCs (8 to 15 mL), clinically significant cases of immediate hemolysis have not been identified.⁴⁴ Most HPC-C units are RBC-depleted prior to cryopreservation, and the residual erythrocytes lyse during cryopreservation, therefore immediate hemolysis is not a problem with cord blood transplants.

Preformed antibodies against non-ABO RBC antigens can remain in a recipient’s peripheral circulation for many weeks after transplantation. These antibodies may cause lysis when engrafted cells begin to produce new RBC. Also chimeric patients may develop antibodies against ABO or non-ABO RBC antigens, resulting in delayed hemolysis. When recipients have isohemagglutinins specific for the ABO type of the transplant, delayed erythrocyte engraftment and PRCA may ensue. This is seen most frequently when group O patients receive a group A transplant, or with bidirectional mismatches. PRCA develops when anti-ABO antibodies destroy erythrocyte progenitor cells in the marrow.

Minor Mismatches When lymphocytes within the HSCT recognize the recipient RBCs as foreign, antibodies may be produced that are specific for ABO or minor RBC antigens. This PLS usually presents 7 to 14 days after the transplant with the abrupt onset of hemolysis. The hemolysis ranges from mild to severe, and may be intra- or extravascular, depending upon the nature of the antibody involved. These “passenger lymphocytes” are reported most frequently in transplants that use a group O donor with a group A recipient.⁴⁵ Antibodies against minor RBC antigens are less frequently reported, and cause less-severe hemolysis.⁴⁵

In cases involving the ABO system, the Hgb level may drop precipitously. The laboratory signs of intravascular hemolysis, that is, hemoglobinemia, hemoglobinuria and an elevated lactate dehydrogenase (LDH) should be used to follow the course of disease. In most cases a DAT will be positive, unless all antibody bound cells have already been lysed. The hemolysis can persist as long as incompatible RBCs are present, but usually subsides within 5 to 10 days.⁴⁵

Nonmyeloablative conditioning regimens carry a greater risk for PLS than when full ablation is used. Because HPC-A preparations carry a greater lymphocyte load when compared to hematopoietic cell concentrate-marrow (HPC-M) and hematopoietic cell concentrate-cord (HPC-C) collections, recipients of peripheral blood stem cells are at an increased risk of developing PLS. The authors are not aware of a case of PLS that has been reported with an umbilical cord stem cell transplant.

TABLE 138–6. Component Type Selection for Hematopoietic Stem Cell Transplantations That Cross the ABO Barrier

Mismatch	Transplant		Transfuse	
	Donor Type	Recipient Type	Red Blood Cell	Platelets*/Plasma
Major mismatch	A	O	O	A, AB
	B	O	O	B, AB
	AB	O	O	AB
	AB	A	A, O	AB
	AB	B	B, O	AB
Minor mismatch	O	A	O	A, AB
	O	B	O	B, AB
	O	AB	O	AB
	A	AB	A, O	AB
	B	AB	B, O	AB
Bidirectional mismatch	A	B	O	AB
	B	A	O	AB

*Platelets stored in additive solution reduce the volume of incompatible plasma transfused.

Modified with permission from Cohn CS: Transfusion support issues in hematopoietic stem cell transplantation. *Cancer Control* 22(1): 52–59, 2015.

Maintaining graft-versus-host disease (GVHD) prophylaxis with only a T-cell inhibitor, such as cyclosporine, without an accompanying B-cell inhibitor, is also considered a risk factor.

Transfusion-Transmitted Cytomegalovirus

CMV infection continues to be a serious complication following HSCTs. Most CMV infections are likely the result of reactivation of virus from a previous infection rather than acquisition of a new strain. However, in CMV-antibody-negative patients there is a risk of developing a transfusion-transmitted *de novo* CMV infection. To reduce this risk, one may use CMV-antibody-negative blood, or leukocyte-reduced components. A large controlled trial and a meta-analysis from 2007 showed that leukocyte-reduced components are as effective as antibody-negative components in preventing transfusion-transmitted CMV.^{46,47} Two additional studies support the safety of using only leukoreduced blood in preventing transfusion transmission of CMV.^{48,49} Both studies found 0 percent risk of transfusion-transmitted CMV infection. Nonetheless, the overall risk of transfusion transmission of CMV in leukoreduced components is not zero. CMV DNA was found in 44 percent of newly seropositive blood donors, and the overall prevalence of CMV DNA was 0.13 percent in nearly 32,000 donations.⁵⁰ While blood products could be obtained from donors with a longstanding history of CMV-positive serology, a more practical approach is to screen donated blood for CMV DNA or immunoglobulin (Ig) M antibodies, although we believe that the use of leukoreduced blood components is adequate.

Transfusion-Associated Graft-Versus-Host Disease

All HSCT patients should receive irradiated components from the time of initiation of conditioning chemotherapy, and for at least 1 year following transplantation to prevent TA-GVHD. However, many centers continue to provide irradiated products for the life of the patient. The British Committee for Standards in Haematology (BCSH) recommends that allogeneic transplant recipients should receive irradiated components for 6 months posttransplantation, or until the patient's lymphocyte count is greater than $1 \times 10^9/L$; however, if chronic GVHD is present, then irradiated products should be given indefinitely.⁵¹ Autologous transplant patients should begin receiving irradiated components from the time of initiation of conditioning chemotherapy, but can revert to nonirradiated components 3 months after the transplantation. If autologous transplant patients received total-body irradiation, then the BCSH recommends extending the use of irradiated products for 6 months after the transplantation.

SOLID-ORGAN TRANSPLANT

Patients awaiting a solid-organ transplant should have minimal exposure to allogeneic blood products to reduce the risk of alloimmunization. Leukoreduced components contain sufficient white blood cells to immunize a patient against class I and class II HLA molecules. The risk of sensitization from a blood transfusion ranges from 2 to 21 percent.⁵² Sensitization may increase the extent of alloimmunization, which contributes to delays in finding a compatible organ for transplantation. In fact, patients who have been transfused have an 11 percent reduction in the likelihood of ever receiving a renal transplant.⁵² Attempts to reduce alloimmunization by matching blood donors and patients⁵³ or matching for the DR locus have shown no consistent reduction.⁵⁴ Using a Hgb of 7 g/dL as a safe threshold for transfusions can minimize exposure. In some patients the use of erythropoiesis-stimulating agents (ESA) may help decrease the number of RBC transfusions; however, ESAs are contraindicated in patients with a history of malignancy or stroke.

ADVERSE EFFECTS OF RED CELL TRANSFUSIONS

The precise risk of an adverse reaction is difficult to estimate; many reactions may be wrongly attributed to the patient's underlying illness, and approximately half of all transfusions are given to anesthetized patients in the operating rooms where reactions may be blunted or more difficult to recognize. The incidence of some adverse reactions has fallen in the past decade due to changes in component handling. Adverse reactions may occur soon after a transfusion begins, as seen with acute hemolytic reactions or acute lung injury, or within days to weeks of a transfusion, as seen with delayed hemolytic reactions.⁵⁵ Fortunately, the majority of acute transfusion reactions are mild and manageable. Many of the reported transfusion-related fatalities involve human errors which may be as much as 1:18,000 transfusions.

IMMEDIATE TRANSFUSION REACTIONS

In general, immediate transfusion reactions are more dangerous than delayed reactions. Severe complications, including death, can on rare occasions develop within a few minutes of initiating transfusion. Close attention and early vital sign assessments are recommended at the beginning and within 15 minutes of starting a transfusion.

Acute Hemolytic Transfusion Reactions

Acute hemolytic transfusion reactions (AHTRs) are almost always caused by the immune-mediated destruction of ABO-incompatible transfused blood. ABO incompatible transfusions are estimated to occur in one in 38,000 to one in 70,000 RBC transfusions.⁵⁶ Isohemagglutinins can activate the complement and coagulation systems. C3a and C5a can activate white blood cells to release inflammatory cytokines (interleukin [IL]-1, IL-6, IL-8, and tumor necrosis factor-alpha [TNF- α]), contributing to fever, hypotension, wheezing, chest pain, nausea, and vomiting.⁵⁷ The presence of antigen-antibody complexes and activated complement on donor RBCs may lead to bradykinin generation. This can increase capillary permeability and arteriolar dilatation causing a fall in systemic blood pressure. Activation of factor XII may initiate the coagulation cascade with formation of thrombin and lead to disseminated intravascular coagulation. Renal failure may also develop as a result of ischemia, hypotension, antigen-antibody complex deposition, and thrombosis. Although rare, AHTRs can also be seen because of other blood group antibodies, particularly those in the Kidd blood group system.

Clinical Presentation The most common presenting symptom is fever with or without chills or rigors. In mild cases, this may be accompanied with abdominal, chest, flank, or back pain, whereas dyspnea, hypotension, hemoglobinuria, and eventually shock can be seen in severe cases. Bleeding, caused by the consumptive coagulopathy, can occur. Hematuria can be the first sign of intravascular hemolysis, particularly in anesthetized or unconscious patients. The severity of AHTR is extremely variable and usually depends on the rate and total volume of blood administered. Approximately 47 percent of the recipients of ABO incompatible blood show no effects, even after receiving a whole unit, 41 percent show symptoms of AHTR, and mortality is approximately 2 percent.^{55,56}

Laboratory Evaluation Laboratory evaluation involves checking for technical and identification errors, examine a posttransfusion specimen for hemolysis, and perform a DAT to detect antibody-coated red cells. If AHTR is strongly suspected, repeat ABO and Rh typing of the patient and the transfused blood and repeat antibody screen and cross-match may be helpful. A negative DAT occurs in rare cases when all transfused RBCs are lysed.

Management Immediate discontinuation of transfusion should always be the first step in any transfusion reaction. Maintaining vascular

access with slow infusion of normal saline, monitoring vital signs, and assessing urine output are key early steps. A blood specimen should be collected immediately for laboratory evaluation. The component bag should be returned to the blood bank. If severe hemolysis has occurred, therapy focuses on management of hypotension, coagulation disorders, and renal function. A urine output of approximately 100 mL/h for 24 hours should be maintained in adults without contraindications. In simple cases, normal saline infusion may be sufficient; however, diuretics may be necessary in some cases. Intravenous administration of furosemide (40 to 80 mg) promotes diuresis and improves blood flow to the renal cortex. In severe cases of hypotension, intravenous dopamine, which dilates renal vasculature and increases cardiac output, can be used. Patients with coagulopathy and active bleeding may require administration of platelets, fresh-frozen plasma, or cryoprecipitate.

Prevention The most common basis for AHTRs is a clerical error resulting from mistakes in identifying the patient, labeling the pretransfusions sample, or identifying the correct red cell unit for the patient.⁵⁶⁻⁵⁸

Febrile Nonhemolytic Transfusion Reactions

A febrile nonhemolytic transfusion reaction (FNHTR) is defined, arbitrarily, as a temperature increase of 1°C or more during or up to 4 hours after transfusion. Other possible symptoms include increases in respiratory rate, anxiety, and, more unusually, nausea or vomiting.

FNHTRs are one of the most commonly encountered transfusion reactions occurring in approximately 0.12 to 0.5 percent of RBC units transfused, and are more likely to occur following transfusion of platelets than RBCs. Leukocyte reduction decreases the incidence of FNHTRs with both whole-blood derived and apheresis platelets.

Clinical Presentation Fever is triggered by the action of cytokines (e.g., IL-1, IL-6, TNF- α). This may be the result of activation of donor leukocytes by anti-HLA or other antibodies in the recipient, activation of recipient leukocyte and endothelial cells by transfused donor leukocytes or plasma constituents, or by the passive transfer of cytokines or CD40 ligand (CD154) that accumulated in the unit during storage.

Fever should not be solely attributed to FNHTR until other potential life-threatening transfusion reactions or patient-related factors have been excluded. Past transfusion reaction history should be reviewed to determine if additional measures should be implemented for future transfusions.

Laboratory Evaluation The laboratory investigation should concentrate on ruling out a septic transfusion reaction. A Gram stain is not a highly sensitive technique in this setting, but may be used to rule-in bacterial contamination. Rapid qualitative immunoassay tests (e.g., Verax or BacTx) are highly sensitive for most commonly encountered bacterial contaminants and may be used in lieu of Gram stain to screen implicated platelet units. In cases with a high index of suspicion, the unit should be cultured. If all results are negative and the patient's presentation is consistent with a mild FNHTR, no additional testing is required.

Management FNHTRs are typically benign, and usually resolve completely within 1 to 2 hours after the transfusion is discontinued. The remainder of the transfused unit and a posttransfusion blood sample from the patient should be sent to the laboratory for investigation. Antipyretics may be administered to shorten the duration of the fever and provide analgesia. Acetaminophen 325 to 650 mg orally for adults or 10 to 15 mg/kg/dose orally for children is effective for this purpose.

Transfusing leukoreduced RBCs and/or platelets stored in additive solution will significantly reduce the risk of FNHTRs.⁵⁹ Premedication with antipyretics (acetaminophen) is not helpful.^{60,61}

Allergic Transfusion Reactions

These are a common adverse reaction of transfusion therapy, ranging from mild forms characterized by localized pruritus and/or urticaria, to severe anaphylactic or anaphylactoid reactions. The mild forms of

allergic transfusion reaction (ATR) occur in 1 to 3 percent of transfusions of plasma-rich components (i.e., platelets/fresh-frozen plasma) and in 0.1 to 0.3 percent for red cells. Severe anaphylactic reactions are much less frequent and estimated at one in 20,000 to 50,000 transfusions.⁷

The majority of ATRs are immediate (type 1) hypersensitivity reactions, mediated by preformed IgE antibodies binding to soluble proteins present within donor plasma.⁶² Severe anaphylactic reactions may occur after transfusion of blood products to IgA-deficient patients who have anti-IgA antibodies. Most patients labeled as IgA deficient still have low levels of the immunoglobulin (2 to 4 mg/dL) and will not produce anti-IgA antibodies. The rare patient with complete IgA deficiency (<0.05 mg/dL) may develop anti-IgA antibodies and thus might experience anaphylaxis with transfusion. Anaphylactoid reactions are similar to anaphylaxis but clinically less severe and caused by non-IgE-mediated activation of mast cells.

Clinical Presentation ATRs usually begin during or within an hour of starting a transfusion, but may not become evident until several hours later. Common findings include urticaria, rash, pruritus, and flushing. More severe reactions occur sooner and may include angioedema, chest tightness, dyspnea, cyanosis, hoarseness, stridor, or wheezing. In addition, gastrointestinal symptoms such as abdominal pain, nausea, vomiting, and diarrhea may also occur. Unlike other acute transfusion reactions, fever is usually absent. Anaphylaxis occurs immediately after starting the transfusion. Symptoms can include bronchospasm, angioedema, respiratory distress, nausea, vomiting, abdominal cramps, diarrhea, shock, and loss of consciousness.

Laboratory Evaluation There is no need for laboratory investigation with simple urticarial and/or localized pruritus. However, the incident should be reported to the blood bank to update the patient's record for any future transfusions. In anaphylactic reactions, the patient should be tested for complete IgA deficiency; however, a history of anaphylactic reactions mandate use of washed red cells and platelets and avoidance of plasma transfusions regardless of the results of these tests.

Management Most ATRs are mild, self-limited and respond well to transfusion discontinuation and, if indicated, administration of antihistamine (diphenhydramine hydrochloride, usually orally). In cases limited to urticaria, the transfusion may be resumed immediately after symptoms resolve. However, transfusion should never be resumed when there is a severe reaction. In acute anaphylaxis, fluid resuscitation may be needed to maintain blood pressure followed by administration of subcutaneous or intramuscular epinephrine (0.3 mL of 1:1000 dilution), as well as airway management and intensive care. In case of shock, a higher concentration of intravenous epinephrine (3 to 5 mL of a 1:10,000 dilution) can be administered. Steroids are usually not helpful in acute crises.

Prevention Patients with a history of mild ATRs should not be premedicated with an antihistamine, as this does not reduce the overall risk of ATRs.⁶¹ Platelets stored in additive solution may be used to reduce the risk of a reaction. In IgA-deficient patients with a history of anaphylaxis to transfusion, components from IgA-deficient donors are sometimes available.⁵⁹

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is a syndrome of acute hypoxia attributable to noncardiogenic pulmonary edema that occurs within 6 hours of a transfusion.^{63,64} TRALI has been the leading cause of transfusion-related fatalities for several years.

There are two main hypotheses regarding the capillary leak seen in TRALI. The two-hit hypothesis states that underlying patient factors act as a necessary first hit, leading to adherence of primed neutrophils to the pulmonary endothelium. The second hit is caused by

mediators within the transfused component, which activate pulmonary neutrophils, which, in turn, damage the endothelium.⁶⁴ The mediators are often antibodies specific for either class II HLA or for human neutrophil antigens (HNAs). There are also cases in which no antibody was detected, which are thought to be a result of proinflammatory mediators, bioactive lipids, and CD40 ligand that accumulate in the blood product during storage.⁶⁵ Despite reports of a direct correlation between storage time of cellular blood components and TRALI, this mechanism remains controversial.

Specific patient factors (first hits) that are associated with a greater risk of TRALI include patients on mechanical ventilation, sepsis, chronic alcohol abuse, severe liver disease, hematologic malignancy, and others. It is not known whether the risk is determined by the patient's condition, or by a greater transfusion requirement. The two-hit hypothesis accounts for critically ill patients who develop TRALI; however, there are reports of TRALI in reasonably healthy patients. This observation led to the threshold model of TRALI.⁶⁶ In this paradigm, a threshold, or tipping point, must be surpassed to induce TRALI. A healthy patient may develop TRALI when transfused with a high titer of antibody. Conversely, a critically ill patient with primed neutrophils can be tipped into TRALI with a lower titer of antibody.

Clinical Presentation and Differential Diagnosis It is often impossible to fully distinguish TRALI from other causes of respiratory distress. The typical presentation of TRALI is the sudden development of dyspnea, severe hypoxemia (O_2 saturation <90 percent in room air) hypotension, and fever that develop within 6 hours of transfusion and usually resolves with supportive care within 48 to 96 hours. Although hypotension is considered one of the important signs in diagnosing TRALI, hypertension can occur in some cases.

In addition to new or worsening oxygen desaturation, TRALI is characterized by chest x-ray findings of bilateral diffuse patchy pulmonary densities without cardiac enlargement. TRALI can be ruled out as the sole cause of pulmonary failure by the presence of rales and jugular venous distention on physical exam and/or dilated pulmonary arteries on chest x-ray, which are evidence of congestive heart failure with or without transfusion-associated circulatory overload (TACO). Transient leukopenia, which follows the reaction within few hours, can also distinguish TRALI from TACO.

Management Supportive care is the mainstay of therapy in TRALI, including oxygen supplementation and aggressive respiratory support plus intravenous fluid and vasopressors for hypotension, if indicated. It has been suggested that diuretics, which are indicated in TACO management, are not efficacious and should be avoided in TRALI. Glucocorticoids may provide benefit.

Prevention HLA alloimmunization has been directly correlated with the number of times a woman is pregnant and plasma from multiparous women has been implicated as a risk factor in TRALI. To reduce this risk, blood banks attempt to collect plasma from males, nulliparous females, and/or females tested and found to be negative for HLA antibodies. After blood collection centers implemented TRALI mitigation strategies, the incidence of TRALI dropped from an estimate of one in 4000 transfusions, to approximately one in 12,000.⁶⁷ Nonetheless, TRALI continues to be the leading cause of transfusion-related fatalities.

Pooled plasma may also be used for TRALI mitigation because antibody titers drop due to dilution. No cases of TRALI resulting from transfusion of pooled solvent detergent treated plasma have been reported.^{68,69}

Transfusion-Associated Circulatory Overload

TACO occurs when patients are unable to effectively process the expansion in intravascular volume from a blood transfusion. Circulatory overload may be the consequence of the infusions rates, the volume of

infused blood product, and/or an underlying cardiac, renal, and/or pulmonary pathology. The fluid volume transfused may be less important than the infusion flow rate and the patient's ability to process the fluid.

The incidence of TACO is difficult to ascertain, as there are inconsistent case definitions, passive reporting systems and poor clinical recognition. Approximately 1 percent of orthopedic patients developed TACO postoperatively, compared to 6 percent of patients in an ICU setting.⁷⁰ Reports of TACO have surged as awareness has increased. Active surveillance also increases the number of cases. In one institution the historical prevalence rate from 6 years of passive reporting was one in 1566 from plasma transfusions. After 1 month of active surveillance the prevalence rate jumped to one in 68.⁷¹

TACO is seen more in younger and advanced age patients.⁷² Additional risk factors include female sex, a history of congestive heart failure, hemodialysis, mechanical ventilation, recent vasopressors, and positive fluid balance.⁷³

Clinical Presentation Symptoms of TACO may include dyspnea, orthopnea, cough, headache, and hypoxemia, which are not specific. However, signs such as rales, hypertension, and jugular vein distention may differentiate TACO from TRALI. These signs and symptoms usually present within 2 hours of the onset of transfusion, but may be up to 6 hours or even 24 hours after the onset of transfusion.

Laboratory Evaluation Oxygen saturation may decrease along with the partial pressure of oxygen in the arterial blood. New bilateral infiltrates on chest x-ray is characteristic for TACO; however, it is also seen in TRALI. Elevated levels of B-type natriuretic peptide (BNP) and N-terminal pro-BNP (NT-proBNP) are both useful markers for TACO, but NT-proBNP may be more useful as it has a longer *in vivo* and *in vitro* half-life. Unfortunately neither peptide was found to be useful in distinguishing TACO from TRALI in critically ill patients.⁷⁴

Management Once TACO is suspected, intravenous fluids should be restricted, followed by the administration of supplemental oxygen and a diuretic, if not contraindicated. Placing the patient in a sitting position can also be helpful. In severe cases, mechanical ventilation may be required.

If a patient is at risk for TACO and blood transfusion is imperative, blood should be administered slowly at a rate of 1 to 4 mL/kg/h. Most blood banks can also reduce the transfusion volume by splitting the blood product into smaller volumes if the transfusion is going to last longer than 4 hours. Close monitoring of the patient's vital signs throughout the transfusion may also help in decreasing the development of TACO.

Transfusion-Related Sepsis

Transfusion-related sepsis when it occurs is usually from platelet units that are stored at room temperature. Red cells, stored at refrigerator temperatures, are very rarely contaminated by unusual cold-growing organisms (e.g., *Yersinia*, *Serratia*, *Pseudomonas*). The rate of fatal transfusion-transmitted bacteremia from red cells has been estimated to be 0.13 per million units transfused in the United States.⁷⁵

Clinical Presentation The infusion of large numbers of Gram-negative microorganisms may lead to fever (>38.5°C), rigors, marked hypotension, abdominal pain, vomiting, diarrhea, and the development of profound shock. Gram-positive contaminants may cause fever and rigors, but are not associated with the severe symptoms produced by Gram-negative toxins.

Laboratory Evaluation Rapid diagnosis usually may be made via Gram stain of the residual donor blood; however, a culture of the transfused component is necessary.

Management Septic shock from transfusion of contaminated blood should be managed as for septic shock from other causes and is not discussed further here.

DELAYED TRANSFUSION REACTIONS

Delayed Hemolytic Transfusion Reactions

DHTRs occur when a previously immunized patient receives red cells containing the corresponding antigen but are compatible in the cross-match because of a low titer of circulating alloantibody. DHTRs occur in 0.2 to 2.6 percent of patients. It is vanishingly rare in infants younger than 4 months of age, and more common in chronically transfused patients.

Approximately 30 to 40 percent of alloantibodies become undetectable months to years after their initial identification. However, a patient previously immunized by transfusion or pregnancy may develop a secondary immune response after reexposure to a blood group antigen. Decreasing Hct or failure to see the typical 1 g/dL Hgb/3 percent Hct increment following transfusion may be noted within several days to weeks of a blood transfusion, as well as an unexplained fever. Hemolysis from DHTR is typically extravascular, without dramatic clinical symptoms and signs, although some classes of IgG bind complement and will cause intravascular hemolysis. Hemolysis in DHTRs is usually mild and gradual, however, when antibodies are produced against antigens in the Kidd blood system, the hemolysis may be rapid, intravascular, and may be severe.

The usual evidence of hemolysis is seen. The appearance of spherocytes and reticulocytes on peripheral blood film, increases in total and unconjugated bilirubin, and increased LDH. The DAT is usually positive but may be negative if all the transfused RBCs have been eliminated from the circulation. The antibody screen is usually positive and the antibody can be identified. No specific management is usually needed as these reactions are usually subtle and clinically silent. In cases of intravascular hemolysis, clinical support measures are similar to those described for an acute hemolytic transfusion reaction. If transfusion is necessary donor red cells negative for the offending antigen may be selected.

Posttransfusion Purpura

Posttransfusion purpura is a rare immune-mediated disorder that is discussed in greater detail in Chap. 139.

IRON OVERLOAD

One of the most common complications of chronic RBCs transfusion is iron overload, which is further discussed in the chapters on congenital hemoglobinopathies (Chaps. 48 and 49).

TRANSFUSION-ASSOCIATED GRAFT-VERSUS-HOST DISEASE

Most cases of TA-GVHD are associated with HSCT. TA-GVHD is a very rare complication that occurs when a susceptible patient is exposed to viable lymphocytes introduced in a blood transfusion. This can occur when transfusions from close relatives or other unintentionally genetically matched donors are administered to severely immunocompromised recipients. The immunocompromised recipient is incapable of “rejecting” or mounting an attack against the lymphocytes in the transfused blood. In addition, cases of TA-GVHD have been reported in recipients with an intact immune system.^{76,77}

TA-GVHD may present with maculopapular rash, fever, watery diarrhea, liver dysfunction, and marrow failure within 8 to 10 days of transfusion. The mortality rate is approximately 90 percent and the downhill course often rapid.

RBC, platelet, and granulocyte units all contain some lymphocytes and therefore carry a risk of TA-GVHD; plasma and cryoprecipitate are acellular and therefore pose no risk. To prevent TA-GVHD, lymphocytes within a blood component must be eliminated or disabled. Leukoreduction is not sufficient, as it reduces, but does not completely eliminate white blood cells. Frozen units may also carry a risk, as the lymphocytes may survive. Gamma and X-ray irradiation of components are effective prophylaxis for TA-GVHD.⁷⁸ A dose of at least 2500 centigray to the center of a cellular blood component and 1500 centigray throughout the unit leaves lymphocytes intact but unable to proliferate. This simple precaution prevents TA-GVHD.

Irradiation at the indicated dose appears to damage the red cell membrane. The damage does not affect the oxygen carrying capacity of the erythrocyte, but does allow potassium to leak from the cell. The level of extracellular potassium has been shown to increase with storage time. As a result, red cells may be stored for only 28 days after irradiation.

POTENTIAL EFFECT OF AGE OF RED CELLS ON TRANSFUSION OUTCOME

In the United States, RBC may be stored in additive solution for up to 42 days. The criteria used to determine storage limits are based on *in vivo* recovery and *in vitro* hemolysis data. During storage, RBC units develop a progressive “storage lesion.” Some of these changes include an increase in free Hgb which acts as a nitric oxide scavenger; a reduction in 2,3-bisphosphoglyceric acid (2,3-BPG), which leads to increased oxygen affinity/decreased oxygen delivery; an increase in hydrogen ions in the supernatant causing a drop in the pH; an increase in microvesicles in the supernatant, creating a procoagulant effect and reduced RBC membrane deformability. Each of these changes is a dynamic process, with some occurring on the first day of blood storage, and others taking days or weeks to be evident. Aspects of the storage lesion have been demonstrated *in vivo* using healthy volunteers who are transfused with autologous units that are stored for widely divergent time periods. In three of these controlled experiments, no differences were found in pulmonary function,⁷⁹ nitric oxide-mediated hyperemic response to ischemia,⁸⁰ or cognitive function.⁸¹ A fourth volunteer study found significant differences with *in vivo* iron-related parameters and signs of hemolysis when fresh and older units were compared.⁸²

The clinical relevance of these *in vitro* and *in vivo* studies is not clear. Some of the *in vitro* findings are reversed within 24 to 48 hours of transfusion, and no adverse effects were reported in the volunteers used for the *in vivo* studies; however, they were healthy and may be more able to withstand insults to their system. Multiple retrospective and prospective studies have looked for an association between the storage age of a RBC unit and clinical outcomes. In one study,⁸³ in more than 5000 cardiac surgery patients receiving more than 18,000 units of RBCs, patients receiving blood that was stored for longer than 2 weeks were at a significantly higher risk of postoperative complications as well as short-term and long-term survival. Subsequently, a large number of retrospective studies and a smaller number of prospective studies were performed. A recent review summarizing the findings of 32 studies reported that 18 found a detrimental effect from prolonged RBC storage, while 14 studies did not.^{84,85} It is notable that the four prospective randomized trials included in the review found no significant ill effect. A meta-analysis of 21 studies, either observational studies or randomized controlled trials, found that use of older stored blood is associated with a significantly increased risk of death.⁸⁵

The question of higher risk from transfusion of older units continues to be studied in multiple, large prospective clinical trials. These studies are being conducted with ICU and cardiac surgery patients,

among others. Until the results of these studies are available, no changes to practice should be made based on the available data.

PATIENT BLOOD MANAGEMENT

Patient blood management (PBM) is an evidence-based, systematic and multifaceted approach to optimizing the care of patients who might need transfusion. The risks associated with unnecessary transfusions, coupled with the rising cost of blood have helped fuel the growth of PBM efforts. PBM was recently adopted by the World Health Organization as the new standard of care, and the AABB has issued guidelines and other tools designed to help hospitals implement a PBM program. A comprehensive PBM program includes (1) hospital-wide guidelines for evidence-based use of blood components, (2) early assessment and correction of preoperative anemia, and (3) application of a variety of techniques to minimize perioperative blood loss.

Guidelines for transfusion have been published by multiple medical professional societies, and can serve as a useful starting point for hospitals; however, the evidence for Hgb thresholds was developed in selected patient populations and does not always apply in all clinical situations. Combining evidence with a clinical assessment is necessary when deciding if a transfusion is indicated. Adding decision support tools into computerized physician order entry systems can remind clinicians of guidelines and safety considerations when ordering blood.⁸⁶ These systems have been shown to reduce blood use and decrease costs associated with transfusions.⁸⁷ Auditing transfusion orders may reveal patterns of blood utilization that can be corrected with education.

Preoperative anemia is associated with adverse outcomes in surgery.⁸⁸⁻⁹⁰ Anemia levels act as an inverted sliding scale, with higher mortality seen in patients with lower preoperative Hgb. The effect of blood loss on mortality was also more pronounced in patients with lower versus higher preoperative Hgb values. When preexisting comorbidities and other confounders were considered, preoperative anemia continued to be independently associated with adverse outcomes after cardiac and noncardiac surgery. Even relatively mild preoperative anemia was shown to be an independent risk factor for higher early mortality in cardiac surgeries,⁸⁹ and for 30-day morbidity and mortality in patients undergoing major noncardiac surgery.⁹⁰

Given the risks of preoperative anemia, both patients and hospitals may benefit from a preoperative anemia assessment program for all surgical patients. When possible, this assessment should be undertaken 28 days before surgery, to correct anemia with oral iron when possible, and IV iron or erythropoietin when necessary and not contraindicated. Hematologists should be consulted for cases of refractory anemia.

Perioperative blood management is the third pillar of a strong PBM program. Blood sparing surgical techniques and anesthesiology-based blood conservation tools should be used whenever possible. Minimizing perioperative blood loss reduces the need for RBC transfusion and the length of hospital stay.⁹¹ Together the combination of a restrictive transfusion strategy, preoperative anemia correction and perioperative blood management has been shown to reduce RBC transfusions, decrease adverse events and reduce hospital costs.⁹¹

CHAPTER 139

PRESERVATION AND CLINICAL USE OF PLATELETS

Terry Gernsheimer and Sherrill Slichter

SUMMARY

The numbers of platelet transfusions administered in the United States increased dramatically during the 1980s, and has continued to grow as increasingly aggressive medical and surgical treatments have been developed and become more widely available. In particular, the growth of more intensive treatments for hematologic and other malignancies has spurred demands for platelet transfusion support and put pressure on platelet inventories nationwide.

The response to a platelet transfusion is affected by platelet recovery and platelet survival and includes the random loss of platelets in maintaining endothelial integrity. In a normal individual, weighing 70 kg, approximately 4.8×10^{10} platelets per day will be consumed maintaining the endothelium, less than the number of platelets in a single concentrate. However, many clinical conditions can adversely affect platelet recovery and platelet survival in the circulation. Prophylactic platelet transfusion is an important part of supportive care of patients with hypoproliferative thrombocytopenia because of hematologic malignancy and the effects of its treatment with cytotoxic drugs. A morning blood platelet count of less than $10 \times 10^9/L$ appears to be an appropriate threshold for prophylactic transfusion. Although higher thresholds may be indicated for patients at high risk or who have active bleeding, little or no data support specific platelet count goals and a transfusion plan should be guided by the clinical setting. Larger doses of platelets do not confer additional protection against bleeding in this patient population, although they do result in higher increments and a longer interval until the next platelet transfusion, a potential benefit in the outpatient setting. The platelet count at which an invasive procedure or major surgery can be safely performed is not supported by randomized control studies and practice has been governed by retrospective data and case reports. Most minor invasive procedures and even major surgery can be safely performed at platelet counts of 20 to $50 \times 10^9/L$ whereas high-risk procedures or severe bleeding may require platelet counts

Acronyms and Abbreviations: AML, acute myeloid leukemia; AP, apheresis platelet; BC, buffy coat; CCI, corrected count increment; GVHD, graft-versus-host disease; HIT, heparin-induced thrombocytopenia; HLA, human leukocyte antigen; HSCT, hematopoietic stem cell transplant; ITP, immune thrombocytopenia; LP, lumbar puncture; PLADO, Platelet Dose study; PRP, platelet-rich plasma; PROPPR, Pragmatic Randomized Optimal Platelet and Plasma Ratios study; rdWBP, random-donor whole-blood platelet; TOPPS, Therapeutic or Prophylactic Platelet Transfusion Study; TPO, thrombopoietin; TTP, thrombotic thrombocytopenic purpura; TRAP, Trial to Reduce Alloimmunization to Platelets; WHO, World Health Organization.

above $100 \times 10^9/L$. Patients may become refractory to platelet transfusion and fail to respond for many reasons. Patients alloimmunized to platelets may respond to platelet transfusions from class I human leukocyte antigen (HLA)-matched donors.

Platelets can be collected by apheresis or obtained from whole blood and pooled for transfusion. Both preparations have comparable effectiveness in the prevention of bleeding in patients with hematologic malignancy. Platelets should remain at room temperature and so are approved for only 5 days of storage because of risks of bacterial contamination and may lose viability within days after that. Leukocyte reduction of platelet components, either upon apheresis collection or by filtration, reduces HLA alloimmunization, prevents cytomegalovirus transmission by transfusion, and reduces febrile transfusion reactions. Pathogen reduction of platelets prevents replication of RNA and DNA in contaminating organisms and leukocytes and may prevent alloimmunization and decrease transfusion reactions. Prospective clinical trials are needed to better define indications for platelet transfusion and improve upon the effectiveness of transfusion therapy.

CLINICAL PLATELET TRANSFUSION THERAPY

The number of platelet units transfused in the United States increased by 33 percent between the years 1997 and 2008 (data available at the time of this writing).¹ Of more than 2,000,000 doses of platelets transfused in the United States in 2008, hematology-oncology patients used 32 percent, compared to the next highest usage of 15 percent in general medicine and 12 percent in cardiac surgery patients. Platelet transfusion therapy is associated with multiple adverse effects, including transfusion reactions, infection, alloimmunization, and immune modulation. The cost of platelets, their short storage time, and inventory pressures have made appropriate use of platelet transfusions a high priority for the management of thrombocytopenic patients to either prevent or control bleeding. Improved methods of collecting, processing, and storing platelets will be paramount in maintaining platelet inventories in the coming decade.

EXPECTED RESPONSE TO A PROPHYLACTIC PLATELET TRANSFUSION

The expected response to a prophylactic platelet transfusion in non-refractory thrombocytopenic patients is assessed by two parameters: (1) the number of platelets that circulate immediately after transfusion, as measured by platelet recovery; and (2) the survival time of the transfused platelet as measured by days-to-next-transfusion. Platelets circulate for a shorter time in thrombocytopenic patients (≤ 5 days) compared with normal subjects (8 to 10 days).² This can be explained by the two mechanisms by which platelets are lost from circulation: (1) senescence, whereby platelets are removed by the mononuclear phagocyte system, and (2) random, whereby platelets are consumed during hemostasis to provide endothelial support.³ The random loss has been estimated to be 7.1×10^9 platelets/L per day. Thus, the more thrombocytopenic a patient is, the higher the percentage of their circulating platelets that will be removed randomly versus lost by senescence (Fig. 139-1A). At a platelet count of $300 \times 10^9/L$, approximately 15 percent of the platelets will be randomly removed—a fraction too small to influence the overall platelet survival. However, in a patient with a platelet count of $50 \times 10^9/L$, approximately 60 percent of the platelets will be

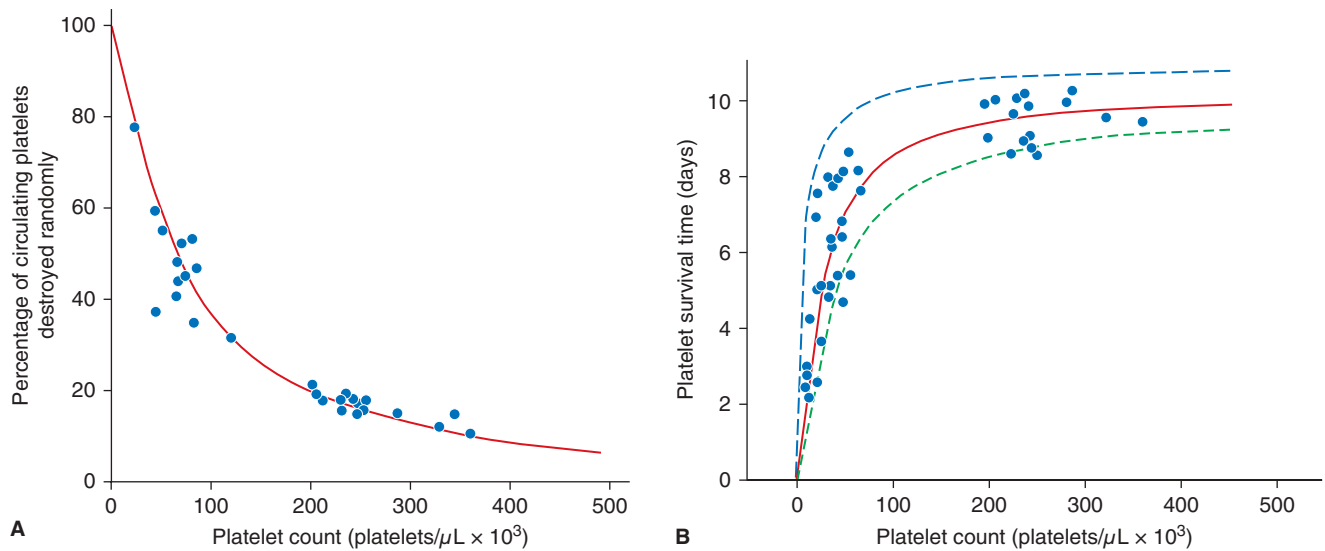

Figure 139-1. **A.** Relationship between platelet count and random platelet destruction. Studies were performed on healthy volunteers receiving autologous radiolabeled platelets as well as on patients receiving allogeneic platelet transfusions. Data points were obtained by dividing the fixed number of platelets lost per day by the number of circulating platelets lost from turnover.³ **B.** Relationship between platelet count and radiolabeled platelet survival measurements in healthy and thrombocytopenic patients. The curve (solid line) was obtained from an equation predicting the dependence of platelet life span on platelet count, assuming a fixed platelet requirement. The data show a high correlation of a finite rate of random platelet destruction per day with a fixed life span of the platelets.³

used for endothelial support, and this will have a significant impact on reducing platelet survival time. This random platelet loss at low platelet counts results in a direct relationship between platelet count and platelet survival at platelet counts of less than $100 \times 10^9/\text{L}$ (Fig. 139-1B).

The number of platelets needed daily to support the random loss of platelets in maintaining endothelial integrity can be calculated. For example, a man weighing 70 kg with an estimated blood volume of 5 L would need 7.1×10^9 platelets/L per day, thus 3.6×10^{10} platelets per day. To account for the platelets pooled in the spleen, an additional 30 percent should be added giving a daily requirement of 4.8×10^{10} platelets for endothelial support. As one random donor platelet concentrate contains on average 8.3×10^{10} platelets, the daily requirement for endothelial support should be easily maintained with the transfusion of only one platelet concentrate per day. A somewhat higher number of platelet concentrates may be needed for patients who are also consuming transfused platelets based on clinical conditions such as sepsis, extensive tumor burden, and others.

PATIENTS WITH HEMATOLOGIC MALIGNANCY

Bleeding Risks

Prior to the availability of platelets for transfusion, observational studies found the incidence of spontaneous bleeding increases at platelet counts of $100 \times 10^9/\text{L}$ or less in children with acute leukemia,⁴ but minor and major bleeding began to increase (>1 percent chance of observable bleeding per patient-day) when the platelet count fell below $50 \times 10^9/\text{L}$. Major bleeding was only observed below $20 \times 10^9/\text{L}$, and on only 3 percent of days. Major bleeding was much more common below a platelet count of $5 \times 10^9/\text{L}$, as high as 33 percent as the count fell toward zero. Notably, many of the patients observed in this study were treated with aspirin for pain and fever resulting in some degree of platelet dysfunction that likely increased their bleeding risk. More recent observations suggest that the amount of bleeding is not dependent on the platelet count as long as it is above $5 \times 10^9/\text{L}$.^{2,5} Life-threatening bleeding rarely

occurs above platelet counts of $5 \times 10^9/\text{L}$ to $10 \times 10^9/\text{L}$ without disruption of the vessel wall. In the Platelet Dose (PLADO) study, bleeding occurred on 17 percent of the study days at platelet counts between $6 \times 10^9/\text{L}$ and $85 \times 10^9/\text{L}$ and increased to 25 percent when counts fell below $6 \times 10^9/\text{L}$.⁶ These data are remarkably consistent with the increase in bleeding time when platelet counts fall below $100 \times 10^9/\text{L}$,⁷ although the bleeding time is not an accurate enough test to be relied upon clinically. There was also a marked increase in bleeding at platelet counts below $5 \times 10^9/\text{L}$ as determined by stool blood loss measurements.²

Most recent large platelet transfusion trials have used the World Health Organization (WHO) bleeding scale or some modification of this scale to standardize the incidence and severity of bleeding in thrombocytopenic patients (Table 139-1).⁸ Grade 1 bleeding is noticeable but without clinical significance. Grade 2 bleeding, which requires some minor intervention to control bleeding, is an observable and reliable measurement for monitoring bleeding risk in platelet transfusion trials. It occurs frequently enough to be a useful end point for comparison of bleeding incidence and severity with different platelet transfusion strategies. In two large platelet transfusion trials, the incidence of Grade 2 bleeding in patients being treated for hematologic malignancies with chemotherapy was between 38 and 73 percent.^{6,9} In patients undergoing autologous hematopoietic stem cell transplantation (HSCT), bleeding rates were 45 percent and 57 percent; however, it was much higher (79 percent) in patients undergoing allogeneic HSCT. The 79 percent bleeding rate in allogeneic HSCT patients is likely because of their intensive conditioning therapies and the occurrence of graft-versus-host disease (GVHD).

In a study of 1244 hematology-oncology patients, the 198 pediatric patients had a significantly higher overall risk of Grade 2 or higher bleeding than did adults (86 percent, 88 percent, and 77 percent for patients ages 0 to 5 years, 6 to 12 years, and 13 to 18 years, respectively, vs. 67 percent for adults).¹⁰ Children also experienced more days with Grade 2 or higher bleeding (median: 3 days in each pediatric group vs. 1 day in adults; $p < 0.001$). The pediatric patients were at higher risk of

TABLE 139-1. General Criteria for World Health Organization Bleeding Grade Categories Including Grade 2a Modification

Grade 1	Grade 2	Grade 3	Grade 4
Minor bleeding	Bleeding requires intervention or treatment, e.g., nasal packing, bladder irrigation, platelet transfusion or medications, to treat bleeding Grade 2a: Grade 2 bleeding excluding skin manifestations	Bleeding requires red cell transfusion related to treatment of bleeding or Significant intervention to treat bleeding, e.g., endoscopy or surgery	Bleeding that is fatal or life-threatening

bleeding over a wide range of platelet counts, indicating that their excess bleeding risk may be a result of factors other than just platelets.

Platelet Transfusion Therapy in the Patient with Hematologic Malignancy

Hematologic malignancies accounted for approximately 9 percent of all new cancers reported in the United States in 2012.¹¹ More aggressive therapies have led to increased 5-year survival rates, but also resulted in substantial increases in the demand for platelet transfusions to support extended periods of marrow failure. The disturbance of endothelial integrity that frequently occurs with these therapies¹² and the associated inflammation can induce hemorrhage in periods of thrombocytopenia.¹³ Mucositis, GVHD, infection, and organ dysfunction can all increase daily platelet consumption and negatively affect posttransfusion platelet increments and life span. Multiple strategies have been evaluated for maximizing the hemostatic effect of platelets while minimizing platelet use. Prospective randomized controlled trials have evaluated the relative safety of different platelet count thresholds for transfusion, whether platelets should be transfused prophylactically or can be administered therapeutically at the first sign of bleeding, and optimal platelet dose for platelet transfusion.

Platelet Transfusion Threshold

Prophylactic platelet transfusions were shown to decrease the incidence of bleeding into vital organs noted at autopsy of leukemia patients as early as 1966,¹⁴ and have become an integral part of treatment regimens for hematologic malignancy. However, maintaining platelet counts may be difficult owing to very short platelet survivals in severely thrombocytopenic patients.^{2,6,15} Several prospective randomized platelet transfusion trials have shown no differences in spontaneous bleeding events when patients are transfused at platelet counts below $10 \times 10^9/L$ versus $20 \times 10^9/L$ ¹⁶⁻¹⁸ or even versus $30 \times 10^9/L$,¹⁹ and a threshold for transfusion as low as $5 \times 10^9/L$ may be safe.²⁰ In one study, 85 patients with acute leukemia were randomized to receive prophylactic platelet transfusions when their platelet count fell to $20 \times 10^9/L$, $10 \times 10^9/L$, or $5 \times 10^9/L$.²⁰ An aliquot of each patient's red cells were labeled with radioactive ⁵¹chromium and daily stool collections were performed to quantify the amount of gastrointestinal mucosal bleeding. There were no differences in stool blood loss, red blood cell transfusion rates, or incidence of bleeding events among the three study arms. However, there was a significant decrease in both the frequency and number of platelet transfusions required among patients randomized to the lower

transfusion threshold compared to the higher transfusion thresholds. A platelet transfusion threshold of less than $10 \times 10^9/L$ in stable patients has been recommended by both the American Association of Blood Banks (AABB)²¹ and Sanquin Blood Supply in 2014.²² Patients with active infection, fever, or who are bleeding may require higher transfusion thresholds.²³

Prophylactic Versus Therapeutic Platelet Transfusions

WHO Grade 4 bleeding that causes life threatening hemorrhage or death is a rare occurrence.^{6,9} Several prospective trials have evaluated the potential bleeding risk of withholding platelet transfusions until WHO Grade 2 bleeding occurs with the assumption that Grade 4 bleeding would very rarely take place before Grade 2 bleeding was observed. A trial comparing a therapeutic-only transfusion strategy versus prophylactic platelet transfusion given routinely for a morning platelet count of less than $10 \times 10^9/L$ in 396 patients who were undergoing intensive chemotherapy for acute myeloid leukemia (AML) (n = 190) or autologous HSCT patients (n = 201) monitored patients for bleeding according to the WHO bleeding scale.²⁴ Despite randomization to the therapeutic-only transfusion arm, 30 percent of patients were transfused with platelets prophylactically and 22 percent for extended petechiae or bruising. The primary end point (number of platelet transfusions) was 33.5 percent higher in the prophylactic transfusion group. However, Grade 4 bleeding occurred in 14 patients with AML in the therapeutic-only transfusion arm, two of which were fatal cerebral hemorrhages. No Grade 4 bleeding occurred in patients undergoing autologous HSCT. In the Therapeutic or Prophylactic Platelet Study (TOPPS), 600 patients with acute leukemia, lymphoma, or myeloma undergoing chemotherapy alone (n = 98), autologous HSCT (n = 411) or reduced-intensity allogeneic HSCT (n = 74) were randomized to a therapeutic-only or prophylactic transfusion strategy.⁹ Patients in the therapeutic-only transfusion arm had a significantly shorter time to their first Grade 2 or greater bleeding event, and they also experienced more bleeding overall. Although both of these studies showed a decrease in the number of platelet transfusions administered in the therapeutic-only arms compared to the prophylactic transfusion arms, and there were no differences in the number of red cell transfusions, this strategy cannot be considered safe in the majority of patients undergoing HSCT or induction chemotherapy for acute leukemia.

Platelet Dose

It has been estimated that 4.8×10^{10} platelets are used daily to maintain endothelial integrity in an individual weighing 70 kg with an estimated blood volume of 5 L.³ As long as this minimal number of platelets is provided, higher platelet doses do not appear to decrease the incidence of bleeding in patients with hematologic malignancy. The PLADO trial studied more than 1200 patients with hematologic malignancies who were receiving prophylactic platelet transfusions at a threshold of less than $10 \times 10^9/L$ during chemotherapy or HSCT.⁶ Patients were randomized to one of three platelet doses; the accepted current standard dose of 2.2×10^{11} platelets/m² (expected to be equivalent to four to six pooled platelet concentrates or one apheresis platelet [AP] collection in most adults), a low dose of $1.1 \times 10^{11}/m^2$ (half of standard), or a high dose of $4.4 \times 10^{11}/m^2$ (twice standard). WHO Grade 2 bleeding was common in all patients and similar at all doses. Seventy percent of patients had at least one episode of Grade 2 or greater bleeding with no significant differences among the dose groups (71 percent, 69 percent, and 70 percent, respectively). Grade 3 bleeding occurred in 8 percent of patients and Grade 4 in only 2 percent with no differences among the groups. Only one hemorrhagic death occurred, in a patient in the high-dose group. By treatment category, 79 percent of patients

undergoing allogeneic HSCT had at least one episode of Grade 2 or greater bleeding compared to 73 percent of patients undergoing chemotherapy for hematologic malignancy, and 57 percent of autologous or syngeneic HSCT patients. There were no differences in bleeding risk based on transfused platelet dose among any of these patient categories. Lower platelet doses required fewer number of platelets overall, but more frequent transfusions to maintain a platelet threshold of $10 \times 10^9/L$. However, as the cost of platelet therapy is predominantly related to the number of transfused platelets rather than the frequency of administration, low-dose therapy may be the most cost-effective strategy, at least during hospitalization.²⁵ Platelet transfusion intervals were significantly longer in the higher-dose groups, resulting in fewer transfusion events, which may make higher-dose transfusions the preferred strategy for outpatients.

EFFECT OF THROMBOPOIETIN MIMETICS ON PLATELET TRANSFUSION REQUIREMENTS

Only mild shortening of the period of thrombocytopenia in patients undergoing chemotherapy for hematologic malignancy has been observed with the use of thrombopoietin mimetic agents. Treatment with romiplostim, a thrombopoietin (TPO) receptor agonist, in patients with low-risk/intermediate-1-risk myelodysplastic syndrome increased platelet counts and decreased the number of bleeding events and platelet transfusions. Although the study drug was discontinued because of an initial concern of risk of progression to AML, survival and AML rates were similar in patients receiving romiplostim and a placebo.²⁶ At this time, TPO receptor agonists cannot be routinely recommended as an adjunct to or replacement for platelet transfusions in patients with hypoproliferative thrombocytopenia, but clinical trials are ongoing.

PLATELET TRANSFUSION THRESHOLDS FOR INVASIVE PROCEDURES

Little data exist to guide platelet transfusions in patients who are undergoing invasive procedures.²⁷ Most recommendations are based on reports of “no harm” observed in groups of patients undergoing planned procedures. Some implications can be drawn from bleeding time measurements performed at various platelet counts (Fig. 139-2).⁷ At platelet

Figure 139-2. The relationship between platelet count and bleeding time. With normal platelet function, bleeding time above a platelet count of greater than $100 \times 10^9/L$ is maintained at approximately 5 minutes. Bleeding time has an inverse relationship with platelet count below a platelet count of $100 \times 10^9/L$, prolonging as the platelet count decreases. (Reproduced with permission from Harker LA, Slichter SJ: The bleeding time as a screening test for evaluation of platelet function. *N Engl J Med* 27;287(4):155–159. 1972.)

counts of $100 \times 10^9/L$ or greater, the bleeding time averages approximately 5 minutes. At platelet counts of less than $100 \times 10^9/L$, there is an inverse relationship between platelet count and bleeding time; that is, as the platelet count decreases, the bleeding time increases.⁷ Figure 139-2 provides a graphical comparison of bleeding times at different platelet counts but does not predict the risk of bleeding at surgery. Neither platelet counts nor bleeding times are exact measurements, and small differences in platelet counts are unlikely to make a significant difference in the time it takes for bleeding to cease. The need for a prophylactic platelet transfusion for an invasive procedure must consider platelet count, platelet function, and endothelial integrity, as well as the consequences of prolonged bleeding. Procedures that would result in significant harm with even small amounts of bleeding (e.g., neurosurgical procedures) should probably be performed at higher platelet counts ($\geq 100 \times 10^9/L$), although most procedures can safely be performed at lower platelet levels. Abnormal coagulation parameters, drugs or diseases (e.g., uremia) that inhibit platelet function should be corrected as much as possible before any procedure. Although international guidelines exist for platelet counts at which a procedure can be safely performed, evidence for these recommendations are generally weak and of low quality.^{22,27}

Platelet Transfusion for Minor Invasive Procedures

Central Venous Catheter Placement Observational studies of central venous catheter placement have reported low bleeding rates of 0 to 9 percent. The largest study included the placement of 604 nontunneled catheters in 193 consecutive patients and found only patients with pre-procedure platelet counts below $20 \times 10^9/L$ were at increased risk of bleeding compared to those with counts above $100 \times 10^9/L$.²⁸ Ninety-six percent of bleeding events were Grade 1, and the remaining were Grade 2, requiring only local compression for bleeding cessation. A study of 3170 tunneled catheter placements under ultrasound guidance reported no bleeding complications in 344 patients with platelet counts less than $50 \times 10^9/L$, nor in the 42 patients with even lower platelet counts of $25 \times 10^9/L$ or less.²⁹

Lumbar Puncture Lumbar puncture (LP) can often be safely performed at platelet counts below $20 \times 10^9/L$. A study of 5223 LPs performed in 956 pediatric leukemic patients reported that 941 procedures were done at or below $50 \times 10^9/L$, with 199 done below $21 \times 10^9/L$, with no bleeding complications.³⁰ Even in those patients who had a traumatic LP (>500 red blood cells/high power field), which occurred in 10.5 percent of the patients, there were no adverse clinical outcomes. In a study in 66 adults with acute leukemia undergoing 195 LPs, there were no bleeding complications in the 40 LPs performed at platelet counts of 31 to $50 \times 10^9/L$ nor in the 35 LPs performed at platelet counts of 20 to $30 \times 10^9/L$.³¹

Major Invasive Procedures

High-level evidence is again lacking for determining a safe platelet count for major invasive procedures. At this time there are no data to support increased perioperative bleeding risk in patients with platelet counts below $50 \times 10^9/L$ who are undergoing major surgery.³² However, the presence of other hemostatic abnormalities, especially platelet dysfunction, should be considered. Although there is no evidence to support platelet transfusion in the nonbleeding cardiac surgery patient, a bleeding patient post-cardiopulmonary bypass may benefit from platelet transfusion, even in the setting of a normal platelet count as a result of the detrimental effect of bypass on platelet function.³³ The patient undergoing major neuraxial surgery may require higher platelet counts perioperatively to minimize increased accumulation of blood in an enclosed space. Although no specific evidence supports the practice other than normalization of the bleeding time, a platelet count of $100 \times 10^9/L$ is generally accepted as appropriate for major neurosurgical procedures.^{21,22}

The Thrombocytopenic Patient on Anticoagulation Therapy

Anticoagulation itself does not slow the formation of the primary platelet plug, although a decrease in thrombin generation would slow activation of more platelets and clot stabilization. It is not known whether higher counts are more appropriate for patients on anticoagulation, and if so what the appropriate level would be. Although platelet counts of 40 to $50 \times 10^9/L$ are often considered to be a safe level for patients anticoagulated with warfarin or heparin therapy,²² there have been no trials to evaluate whether lower counts would be as safe.

Platelet Transfusion Thresholds for Bleeding A paucity of evidence exists on the target platelet count in bleeding patients. The site of bleeding and other hemostatic abnormalities or drugs that might result in a bleeding tendency should be considered and corrected as needed. A target platelet count of $100 \times 10^9/L$ should be used in life threatening bleeding such as intracerebral bleeding or diffuse alveolar hemorrhage to minimize compromise of healthy tissue. For diffuse microvascular bleeding, a platelet count of $100 \times 10^9/L$ is also usually recommended,^{22,34} but difficulties of obtaining timely results during massive hemorrhage make the feasibility of this approach unrealistic in the field and in many trauma centers. Retrospective analysis of combat casualties requiring massive transfusion (>10 units in 24 hours) found a transfusion ratio of one AP platelet component to every 8 units of red blood cells to be associated with significantly improved survival at 24 hours and 30 days in combat casualties requiring a massive transfusion (MT) within 24 hours of injury.³⁵ Equal ratios of plasma, platelets, and red blood cells, is an essential element of the United States Department of Defense “Damage Control Resuscitation” clinical practice guideline for control of massive hemorrhage adopted in 2006.³⁶ In the Pragmatic Randomized Optimal Platelet and Plasma Ratios (PROPPR) study,³⁷ 680 patients at level 1 trauma centers requiring massive transfusion were randomized to one of two standard transfusion ratio interventions: 1:1:1 or 1:1:2 (plasma: platelets: red cells), the equivalent of one AP platelet to every 6 or 12 units of red blood cells. Both 24-hour and 30-day mortality were significantly improved when the numbers of platelets and plasma transfusions were increased to a 1:1 ratio with red blood cell transfusions.³⁸

The Bleeding Patient on Platelet Inhibitor Therapy

Although aspirin inhibits the production of thromboxane A_2 , an effect that lasts for days after ingestion, the drug itself has a relatively short half-life of 2 to 3 hours, whereas other nonsteroidal antiplatelet agents have effects that last less than 24 hours.³⁹ Thienopyridine-class antiplatelet agents such as clopidogrel have much longer half-lives, as do the active metabolites of these drugs, and may continue to affect platelets for more than a week. Although it is common practice to transfuse platelets to patients treated with these drugs if they suffer serious or life-threatening bleeding, there are no data that have established the effectiveness of platelet transfusions in these patients.

MANAGEMENT OF PATIENTS REFRACTORY TO PLATELET TRANSFUSIONS

The incremental increase in platelet count following a platelet transfusion is dependent upon the platelet dose (number) and the patient's blood volume (which is, in turn, dependent on their body size). The corrected count increment (CCI), generally measured 30 minutes to 1 hour following a platelet transfusion, takes into account both patient size and the dose of platelets transfused and can be calculated by the formula:

$$CCI = \frac{(\text{Posttransfusion Platelet Count} - \text{Pretransfusion Platelet Count})}{(\text{Body Surface Area in Meters}^2)} \times \frac{\text{Number of Platelets Transfused} (\times 10^{11})}{\text{Number of Platelets Transfused} (\times 10^{11})}$$

Patients who have a CCI of less than $5 \times 10^9/L$ on at least two consecutive occasions are considered to be “refractory” to platelet transfusions. As the platelet count of the product is not usually available to the clinician, two sequential 1-hour platelet increments of $11 \times 10^9/L$ or less may also be used to indicate refractoriness.⁴⁰ Platelet refractoriness can be classified as immune or nonimmunologically mediated with the latter being the most common cause of platelet refractoriness.⁴¹ Unfortunately, many patients concurrently experience both types of platelet refractoriness. In the Trial to Reduce Alloimmunization to Platelets (TRAP)⁴² that involved 533 patients given 6379 transfusions, the factors that most likely resulted in platelet refractoriness, in order of frequency, were: developing lymphocytotoxic antibodies; being female with two or more pregnancies or male; heparin administration; fever; bleeding; transfusion of γ -irradiated platelets; and receiving an increasing number of platelet transfusions. In addition, platelets express ABO antigen on their surface and occasionally patients with high anti-A agglutinin titers may benefit from ABO-matched platelets.⁴³ Similar factors are associated with poor platelet responses in many other platelet transfusion studies.^{23,44,45}

Active bleeding or denuded endothelium may cause increased platelet consumption so that the incremental increase in platelet count is decreased. Patients with reduced responses to transfused platelets due to increased platelet consumption may benefit from more frequent transfusions. The use of very frequent or continuous (“drip”) platelet transfusions in patients with life-threatening bleeding is sometimes undertaken,⁴⁶ although no trials of this mode of therapy have been performed.

Patients who have been previously transfused or pregnant may fail to increase their platelet count following transfusion as a consequence of human leukocyte antigen (HLA) antibodies directed against the class I HLA antigens on the platelet surface. Transfusion of leukocyte reduced cellular blood components can reduce the rate of formation of these antibodies.⁴² A minority of patients will develop or recall these antibodies and have only minimal or no increase in the platelet count following transfusion. There are a number of methods for HLA antibody testing, either by cell-based or solid-phase assays. Testing can be used to screen for antibodies and to identify antibody specificity to aid in donor selection.⁴⁷ The results of these assays are expressed as a percentage of the test cells or beads that bind patient antibodies. Patients with poor responses to platelet transfusions because of HLA antibodies may benefit from HLA-matched platelets, identifying the specificity of the patient's antibodies and avoiding any incompatible antigens or using platelet crossmatching assays to select compatible donors.^{43,48,49}

In patients with marked splenomegaly, large doses of platelets may increase the total body platelet mass and increase the platelet count. Platelets are released from the spleen upon injection of epinephrine,⁵⁰ suggesting that under times of stress these sequestered platelets may become available for hemostasis. Homologous platelets transfused to patients with immune thrombocytopenia survive only a few hours in the majority of patients studied.⁵¹ Therefore, transfusion of platelets to patients with immune thrombocytopenia is appropriate only for life- or organ-threatening bleeding.⁴⁷ Platelet transfusion was associated with an increased risk of arterial thrombosis in patients with thrombotic thrombocytopenic purpura (TTP) and heparin-induced thrombocytopenia (HIT), but not in patients with immune thrombocytopenia (ITP).⁵²

Use of Antifibrinolytic Therapy

Tranexamic acid and aminocaproic acid improve bleeding and decrease platelet use in patients with thrombocytopenia associated with hematologic malignancy.⁵³ The use of antifibrinolytic therapy with tranexamic acid or ϵ -aminocaproic acid has been suggested to augment other measures to decrease or prevent bleeding in patients who continue to bleed in spite of platelet transfusions.

● PLATELET PRODUCTS AVAILABLE FOR TRANSFUSION

Platelets are obtained by two different methods: platelet concentrates from whole blood or apheresis platelets. The FDA requires at least 5.5×10^{10} platelets/concentrate and 3.0×10^{11} platelets/apheresis collection.

PLATELET CONCENTRATES FROM WHOLE BLOOD

Platelet concentrates can be prepared from units of whole blood using two different methods as outlined in Fig. 139–3. These are referred to as the platelet-rich plasma (PRP) method, which is used exclusively in the United States,⁵⁴ and the buffy coat (BC) method,⁵⁵ which is predominantly used in Europe and Canada. Comparative studies show no difference in the quality of these platelet concentrates when they are stored for up to 7 days.^{56,57} That there are no differences in these products was confirmed in a controlled trial in which the same normal subjects donated whole blood on two occasions.⁵⁸ A buffy-coat platelet concentrate or a PRP platelet concentrate was randomly assigned to be prepared from either the first or second whole-blood donation. After storage for 7 days, the platelets were radiolabeled and transfused back into their normal donor. Recovery differences averaged 3.7 ± 2.4 percent (\pm SE, $p = 0.15$) and survival differences 0.48 ± 0.56 days ($p = 0.41$).

APHERESIS PLATELETS

The major advantage of AP platelets is that enough platelets can be collected from a single donor to constitute a transfusion dose. In contrast, to obtain an equivalent number of platelets requires pooling four or five whole-blood–derived platelet concentrates.

The reduction in donor exposures by using AP platelets has the potential advantages of reducing transfusion-transmitted infections and the incidence of platelet alloimmunization. However, the current tests for detecting viral transmission by transfusion have reduced

the infectious risk/donor exposure to very low levels.⁵⁹ The bacterial risk associated with platelet transfusions is high because platelets are stored at 22°C. Some studies suggest a reduction in bacterial transmission by transfusion with the use of single-donor platelets.⁶⁰ However, both the American College of Pathologists and the AABB mandate testing of all platelet products for bacteria,⁶¹ which should reduce this potential advantage of single-donor platelets. Currently, the requirement for bacterial testing has increased the use of APs because the costs for culture-based testing of an apheresis unit versus testing each platelet concentrate that would be used in a pool has provided a significant cost advantage for APs. As platelet concentrates are less expensive to produce, this current cost advantage of APs will likely shift to pooled random donor platelets with more widespread use of prestorage pooling of platelet concentrates allowing bacterial testing of the pool.⁶² Certainly, there were no differences in post-transfusion platelet responses between patients given either pre- or poststorage pooled platelet concentrates.⁶³ Although transfusion reactions may occur less frequently with APs, leukoreduction appears to mitigate this advantage over pooled platelets.⁶⁴ In addition, the use of leukoreduced pooled random donor platelets does not appear to lead to increased alloimmunization rates or broaden the specificity of any preexisting or developing antibodies compared to leukoreduced single-donor platelets.⁴²

COMPARATIVE EFFECTIVENESS OF PLATELET-RICH PLASMA PLATELET CONCENTRATES VERSUS APHERESIS PLATELETS, ABO MATCHING, STORAGE DURATION, AND ADVERSE EVENTS

Transfusion Responses

Many clinicians consider that platelets obtained by AP give superior posttransfusion platelet responses compared to PRP pooled random-donor whole-blood platelets (rdWBPs). The large

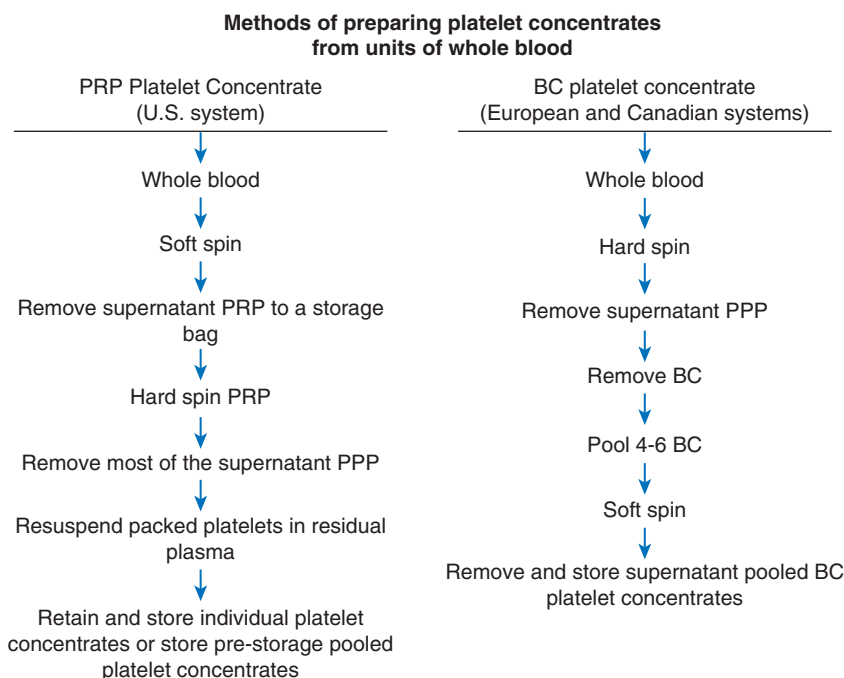

Figure 139–3. Preparation of platelet concentrates from whole blood. Two methods of preparing platelet concentrates from whole blood have been developed. The main differences are related to the centrifugation steps that are used when proceeding from whole blood to a platelet concentrate. Specific details of the methods are described in Slichter and Harker⁵⁴ for platelet-rich plasma (PRP) method platelet concentrates and Pietersz, Loos, and Reesink⁵⁵ for buffy coat (BC) method platelet concentrates. PPP, platelet-poor plasma.

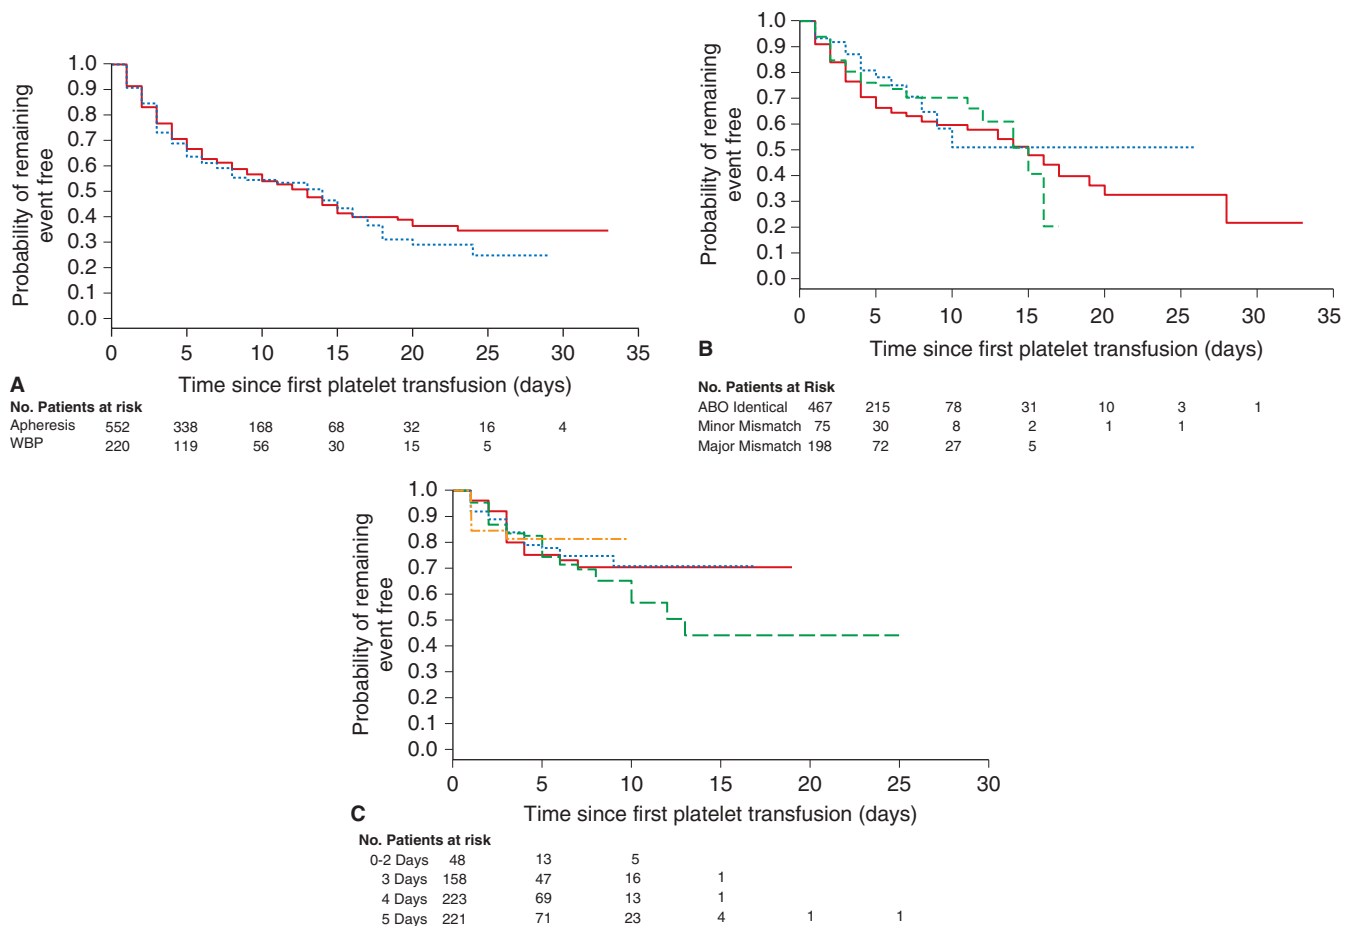

Figure 139-4. Kaplan-Meier plots of time from platelet transfusion to first Grade 2 or higher bleeding for each platelet characteristic. **A.** Time from first platelet transfusion to first Grade 2 or higher bleeding by source of platelets. Time to bleeding was censored at the first date that any of the following occurred: transfusion of a platelet unit with a different source from the patient's initial platelet transfusion; missing data on whether Grade 2 or higher bleeding occurred; or end of study. Platelet source was not a significant predictor of time to Grade 2 or higher bleeding ($p = 0.44$). Apheresis platelets (—) and random-donor whole-blood platelets (rdWBPs) (---). **B.** Time from first platelet transfusion to first Grade 2 or higher bleeding by ABO matching status from the patient's initial platelet transfusion or missing data on ABO matching status; missing data on whether Grade 2 or higher bleeding occurred; or end of study. Divergence of the curves after 15 days is probably the result of the small number of patients still at risk by that time. ABO matching status was not a significant predictor of time to Grade 2 or higher bleeding ($p = 0.33$). ABO identical platelets (—), ABO minor mismatched platelets (---), and major ABO mismatched platelets (---). **C.** Time from first platelet transfusion to first Grade 2 or higher bleeding, by platelet storage duration, among patients whose first platelet transfusion was stored for 0 to 5 days. Time to bleeding was censored at the first date that any of the following occurred: transfusion of a platelet unit with a different storage duration from the patient's initial platelet transfusion; transfusion of a platelet unit with missing data on storage duration; transfusion of pooled rdWBPs of different storage durations; missing data on whether Grade 2 or higher bleeding occurred; or end of study. Divergence of the curves after 10 days is probably the result of the small number of patients still at risk by that time. Duration of platelet storage was not a significant predictor of time to Grade 2 or higher bleeding ($p = 0.87$). Platelet storage times: 0 to 2 days (—), 3 days (---), 4 days (---), and 5 days (---). (Reproduced with permission from Triulzi DJ, Assmann SF, Strauss RG, et al: *The impact of platelet transfusion characteristics on posttransfusion platelet increments and clinical bleeding in patients with hypo-proliferative thrombocytopenia*. *Blood* 7;119(23):5553–5562, 2012.)

multiinstitutional PLADO trial provides new information on the relative merits of the two products.⁶ The PLADO trial involved 1272 platelet-transfused patients who received 8994 platelet transfusions of which 6031 were given prophylactically. The patients were observed for 24,309 days. Subsets of this database were used to analyze bleeding outcomes, posttransfusion increments, and CCI within 4 and 24 hours posttransfusion, and transfusion intervals based on blood product transfused, ABO matching between donor and recipient, and duration of platelet storage.⁶⁵

Time to Bleeding

Importantly, in the PLADO trial neither differences in platelet product, ABO matching, nor in storage duration affected time to bleeding (Fig. 139-4).⁶⁵

PLATELET INCREMENTS, CORRECTED COUNT INCREMENTS, AND TRANSFUSION INTERVAL

In the PLADO trial, the absolute increments for rdWBPs at 4 hours posttransfusion were on average $3.5 \times 10^9/L$ lower than APs ($p = 0.002$), and CCIs were 1400 less ($p = 0.01$), with no differences for these parameters at 24 hours.⁶⁵ Major ABO-incompatible (donor red cell A or B antigens incompatible with recipient's anti-A or anti-B antibodies), but not ABO-minor (donor's anti-A or anti-B antibodies incompatible with recipient's red cell A or B antigens), transfusions were associated with lower increments of $2.2 \times 10^9/L$ ($p = 0.0001$) and lower CCIs of $1.4 \times 10^9/L$ ($p < 0.0001$) at 4 hours posttransfusion, respectively, compared to ABO-identical transfusions. Similarly, at 24 hours posttransfusion, major ABO-mismatched transfusions had lower platelet

increments of $2.6 \times 10^9/L$ ($p < 0.001$) and CCIs were less by $1.8 \times 10^9/L$ ($p < 0.0001$), but there was no effect of minor ABO incompatibility on these measurements at any time point. Platelet storage duration did show a progressive decline in platelet increments and CCIs, but the effect was very modest. Importantly, transfusion intervals showed only trivial effects based on transfusion type (AP or rdWBP) and only for low-dose platelet transfusions (1.1×10^{11} platelets/ m^2) ($p = 0.02$), the interval was 3.9 hours less for ABO-major-mismatched transfusions ($p < 0.001$), and there was no effect of storage duration. Because of the large number of transfusions, some of the differences between platelet products, ABO matching, and storage duration were highly statistically significant. However, for the two most important parameters for clinicians (e.g., bleeding risk and interval between transfusions), there were no important differences based on product transfused, ABO matching, and storage duration of 5 or fewer days.⁶⁵ Even differences in platelet increments and CCIs were modest, as confirmed by previous meta-analysis.⁶⁶⁻⁶⁸

ADVERSE EVENTS

Additional analysis of the PLADO data base showed no differences in any adverse event based on platelet source, ABO matching, or storage duration.⁶⁹

MODIFICATIONS TO TRANSFUSED PLATELETS

LEUKOREDUCTION

There are clear indications for providing leukoreduced platelet products: (1) reduction of platelet alloimmunization,⁴² (2) prevention of cytomegalovirus transmission by transfusion,⁷⁰ and (3) reduction in febrile transfusion reactions.⁷¹ In addition, some studies suggest that white cells that contaminate platelet and red cell transfusions may contribute to immunomodulatory effects of transfusion, such as an increased incidence of postoperative infections and metastasis formation in cancer patients.⁷² However, controversy still surrounds whether transfusions have immunomodulatory effects.⁷³

γ-IRRADIATION

γ-Irradiation of platelets is indicated to prevent transfusion-related GVHD, which is uniformly fatal.⁷⁴ γ-Irradiation with the usual dose of 25 Gy in one study did not affect either posttransfusion platelet survival or function.⁷⁵ However, in a transfusion study in thrombocytopenic patients, γ-irradiation decreased 1-hour posttransfusion increments by $2.8 \times 10^9/L$ and showed an increased hazard ratio of 1.45 for the development of platelet refractoriness.⁷⁶ Furthermore, additional observations from the TRAP demonstrated that γ-irradiation prolonged the duration of HLA alloantibodies in patients who developed these antibodies during the course of their transfusions.⁷⁷ Therefore, indiscriminate use of γ-irradiation should be avoided. Situations in which γ-irradiation should be performed are: (1) patients receiving allogeneic HSCT and (2) patients who are severely immunocompromised, usually because of their disease or its treatment (e.g., patients who have Hodgkin or other lymphomas).⁷³

VOLUME REDUCTION

For some patients who are receiving large volumes of fluids where consideration of intravenous line availability is an issue, who are volume

overloaded, or for infants/young children where an adult volume may be excessive, volume reduction of platelets before transfusion is a consideration. For most children, volume reduction is often unnecessary.⁷⁸ Whenever platelets are concentrated by centrifugation, there is likely to be some damage to the platelets, re-suspension is often incomplete, and, therefore, this extra processing should only be done if necessary for patient care.⁷⁹

FUTURE ADVANCES IN PLATELET PRODUCTS FOR TRANSFUSION

PATHOGEN REDUCTION

Two methods of pathogen reduction^{80,81} have been evaluated in clinical trials. Both systems involve adding an agent—either amotosalen (Intercept system)⁸⁰ or riboflavin (Mirasol system)⁸¹—to the platelets prior to exposure to ultraviolet (UV) light. After UV exposure, these agents prevent replication of RNA and DNA in pathogenic organisms, as well as eliminating the function of contaminating leukocytes.^{82,83} Both the Mirasol and Intercept methods produce a reduction in posttransfusion autologous radiolabeled platelet recoveries and survivals^{84,85} that is related to the dose of UV used in the pathogen-reduction process.⁸⁶ Recoveries and survivals of 5-day stored pathogen-treated platelets were reduced by approximately 15 to 25 percent, compared to similarly stored nontreated platelets from the same subjects ($p < 0.05$ to < 0.01). The Intercept system has been evaluated in a 645-patient U.S. randomized trial comparing treated to control platelets.⁸⁷ This technology was approved by the FDA for pathogen reduction of platelet components on December 19, 2014. A limited randomized trial in France involving 110 thrombocytopenic patients documented hemostatic efficacy of Mirasol-treated platelets and similar rates of red cell and platelet utilization but lower CCIs for patients who received treated compared to control platelets.⁸⁸ However, there were no adverse events following transfusion of the treated platelets, and more studies will likely be needed for FDA approval. Both technologies have received regulatory approval for their use in Europe.

Several centers in Europe that have incorporated pathogen reduction technology have eliminated γ-irradiation of platelets to prevent transfusion-associated GVHD. Inactivating leukocytes may also decrease transfusion-related adverse events such as fever, chills, and allergic reactions associated with cytokine release from residual white cells during platelet storage, and it may also reduce rates of platelet alloimmunization. All of these benefits will mean safer, more cost-effective platelets for transfusion.

EXTENDED PLATELET STORAGE

The major risk of extended platelet storage at 22°C is bacterial overgrowth usually as a consequence of inadequate sterilization of the venipuncture site. Most bacteria have been demonstrated to grow to confluence by 3 to 5 days.⁸⁹ Therefore, once platelets have been stored beyond 5 days, there is little increased risk from bacterial overgrowth. The only remaining issue to allow extended platelet storage will likely be having either a sensitive and specific point of release bacterial assay or incorporating a prestorage pathogen reduction process.

The FDA has suggested a hierarchical system for evaluating stored platelets prior to licensing⁹⁰ proceeding from a variety of *in vitro* assays, to radiolabeled autologous platelet recovery and survival measurements in normal subjects, and, finally, depending on the magnitude of the differences in the new product compared to products that are currently licensed, to transfusion trials in thrombocytopenic patients

TABLE 139-2. Extended Platelet Storage in Plasma

Platelet Product	N	Storage Time (Days)	PLATELET						Reference
			Recovery (%)			Survival (Days)			
			Fresh	Stored	% of Fresh	Fresh	Stored	% of Fresh

to document efficacy (predominantly hemostatic) and safety. Previously, most platelets have not been stored beyond 7 days.^{57,91} We have completed a series of studies based on autologous radiolabeled platelet recovery and survival measurements in normal subjects to determine how long PRP or BC platelet concentrates or AP platelets can be stored in either plasma or a platelet additive solution (Plasmalyte) while still meeting FDA poststorage platelet viability guidelines; that is, the 95 percent lower confidence limits for each donor's stored radiolabeled autologous platelet recoveries should be 66 percent of the same donor's fresh radiolabeled recoveries, and survivals should be 58 percent of fresh. As shown in [Table 139-2](#), both plasma-stored PRP and BC platelet concentrates met FDA recoveries and survivals for 6 days of storage but only recoveries for 7 days of storage with no differences between the two types of platelet concentrates.^{92,93} In contrast, Haemonetics plasma stored AP could meet both FDA's platelet recovery and survival criteria for 8 days of storage, but, by 9 days, low pH values resulted in loss of platelet viability.⁹⁴ Although concurrent data with the same donor's

fresh platelets were not obtained, AP had poststorage platelet viability that was not significantly different than Haemonetics platelets when both products were stored for 1 to 9 days.⁹⁵

When platelets are stored in a platelet additive solution (Plasmalyte), the longest storage times that were achieved were the same as in plasma; that is, 6 days ([Table 139-3](#)).⁹³ However, Haemonetics platelets could be stored for 13 days. The significance of these data are (1) the life span of the platelet is not intrinsic to the cell as after 13 days of storage platelet survivals still averaged 4.6 ± 0.3 days, and (2) platelet viability is better maintained *in vitro* than *in vivo* as normal subjects *in vivo* fresh autologous platelet survivals are only 8 to 10 days.⁹⁶ This may be because platelets *in vivo* have a work-related function that shortens their life span compared to *in vitro* storage. In addition, our studies may suggest much longer storage times are possible in platelet additive solution than plasma, the same bags that are acceptable for storing platelets in plasma may not allow long-term platelet storage in this solution, and the method of platelet collection significantly affects storage duration.⁹⁶

lymphomas and, 1575*t*
macrophages in, 1059
neutropenia in, 993
pathogenesis, 2059
treatment, 2059
- Wiskott-Aldrich syndrome protein (WASp/WASP), 60, 439, 1063*f*, 1224, 1841, **2059–2060**
- WM. *See* Waldenström macroglobulinemia (WM)
- Wnt pathway, 232*t*, 237
- Wnt proteins, **266**
- Women. *See also* Pregnancy
iron deficiency in, 630
menorrhagia in, 5–6, 1987, 2007, 2135, 2139
rare bleeding disorders in, 2135
- Woringer-Kolopp disease, 1683
- Work performance, iron deficiency and, 632
- WT1, 227*t*, 863, 1378*t*, 1379, 1465
- WT1 vaccine, 423, 1404
- WT syndrome, 530*t*
- X**
- X-chromosome-based polymorphism assays, 883
- Xerocytosis, hereditary, 682*t*, **683**
- Xg blood group/antigens, 104, 2331*t*, 2337, 2345*t*
- XIAP, 204*f*, 207, 210, 218
- ξ-globin chain, 728
- X inactivation, 150, 150*f*
- XIST, 150
- XK protein, 681. *See also* McLeod phenotype
- X-linked adrenoleukodystrophy, 439
- X-linked agammaglobulinemia (XLA), 993, **1212–1213**, 1214*t*
- X-linked anhydrotic ectodermal dysplasia with immunodeficiency caused by NEMO mutations, 1215
- X-linked chronic granulomatous disease, 1029, 1030–1031, 1031*t*
- X-linked hyperimmunoglobulin M syndromes. *See* Hyperimmunoglobulin M syndromes
- X-linked inheritance, 149–151
- X-linked lymphoproliferative disease, **1228–1229**, 1266, 1575*t*
- X-linked protoporphyria (XLP), 889, 890*t*, 891*t*, 896
- X-linked severe combined immune deficiency, 437, 439, 1217. *See also* Severe combined immunodeficiency (SCID)
- X-linked sideroblastic anemia (XLSA), 894, 916–917, 920
- X-linked sideroblastic anemia with ataxia (XLSA/A), 918
- X-linked thrombocytopenia, 1224–1225, 2059
- XPO1, 231*t*, 1529
- X-ray repair complementing defective repair in Chinese hamster cells 4 (XRCC4), 1167
- Y**
- Yellow marrow, 28
- Yersinia enterocolitica*, 742
- ⁹⁰Y-ibritumomab tiuxetan, **346**
adverse effects, 343*t*
for diffuse large B-cell lymphoma, 1632
for follicular lymphoma, 1647
in hematopoietic cell transplantation, 360
for MALT lymphoma, 1666
for mantle cell lymphoma, 1657*t*
mechanism of action, 343*t*
- Yolk sac, hematopoiesis in, 54, 99–100, 100*f*, 257–258
- Yt blood group/antigens, 2331*t*, 2337, 2345*t*
- ⁹⁰Yttrium, 360

Z

- Zanamivir, 386
- ZAP-70 (zeta-associated protein of 70 kDa), 1178, 1214*t*, 1220, 1531–1532
- Zellweger syndrome, 1840
- Zero-mode waveguides (ZMWs), 158
- Zeta-associated protein of 70 kDa (ZAP-70), 1178, 1531–1532
- Zidovudine (AZT)
- chemotherapy drugs and, 1249
- for HIV infection, 1242
- macrocytic anemia and, 1252
- megaloblastic anemia and, 605, 606*t*
- Zieve syndrome, 655
- Zinc, 652*t*
- Zinc deficiency, **653**
- lymphocytopenia in, 1206
- senile purpura and, 2107
- Zinc finger nucleases (ZFNs), 440, 443–444, 443*f*, 453
- Zoledronic acid, 1756
- Zollinger-Ellison syndrome, 601, 629
- ZPI (protein Z-dependent protease inhibitor), 1916*t*, 1938, 1952*t*, **1960**
- ZRSR2, 1346*t*
- ZU5-ANK, 666
