

A microscopic view of red blood cells, showing their characteristic biconcave disc shape. The cells are illuminated from the side, creating a strong red glow and highlighting their surface texture and the central indentation. The background is dark, making the red cells stand out prominently.

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Williams Hematology

Ninth Edition

Kenneth Kaushansky, MD, MACP

Senior Vice President for Health Sciences
Dean, School of Medicine
SUNY Distinguished Professor
Stony Brook University
Stony Brook, New York

Josef T. Prchal, MD

Professor of Medicine, Pathology, and Genetics
Hematology Division
University of Utah
Salt Lake City, Utah
Department of Pathophysiology
First Faculty of Medicine
Charles University in Prague
Prague, Czech Republic

Oliver W. Press, MD, PhD

Acting Director, Clinical Research Division
Dr. Penny E. Peterson Memorial Chair for Lymphoma
Research
Fred Hutchinson Cancer Research Center
Professor of Medicine and Bioengineering
University of Washington
Seattle, Washington

Marshall A. Lichtman, MD

Professor of Medicine and of Biochemistry and Biophysics
University of Rochester Medical Center
Rochester, New York

Marcel Levi, MD, PhD

Professor of Medicine
Dean, Faculty of Medicine
Academic Medical Center
University of Amsterdam
Amsterdam, The Netherlands

Linda J. Burns, MD

Professor of Medicine
Division of Hematology, Oncology and Transplantation
University of Minnesota
Minneapolis, Minnesota

Michael A. Caligiuri, MD

Director, Comprehensive Cancer Center
CEO, James Cancer Hospital and Solove Research Institute
Professor of Medicine
The Ohio State University
Columbus, Ohio

New York Chicago San Francisco Athens London Madrid Mexico City
Milan New Delhi Singapore Sydney Toronto

CONTENTS

Contributors	ix
Preface	xxi

PART I

Clinical Evaluation of the Patient

1. Initial Approach to the Patient: History and Physical Examination..... 3
Marshall A. Lichtman and Linda J. Burns
2. Examination of Blood Cells..... 11
Daniel H. Ryan
3. Examination of The Marrow..... 27
Daniel H. Ryan
4. Consultative Hematology..... 41
Rondeep S. Brar and Stanley L. Schrier

PART II

The Organization of the Lymphohematopoietic Tissues

5. Structure of the Marrow and the Hematopoietic Microenvironment..... 53
Utpal P. Davé and Mark J. Koury
6. The Organization and Structure of Lymphoid Tissues..... 85
Aharon G. Freud and Michael A. Caligiuri

PART III

Epochal Hematology

7. Hematology of the Fetus and Newborn..... 99
James Palis and George B. Segel
8. Hematology during Pregnancy..... 119
Martha P. Mims
9. Hematology in Older Persons..... 129
William B. Ershler, Andrew S. Artz, and Bindu Kanapuru

PART IV

Molecular and Cellular Hematology

10. Genetic Principles and Molecular Biology..... 145
Lynn B. Jorde
11. Genomics..... 155
Lukas D. Wartman and Elaine R. Mardis
12. Epigenetics..... 165
Bradley R. Cairns
13. Cytogenetics and Genetic Abnormalities..... 173
Lucy A. Godley, Madina Sukhanova, Gordana Raca, and Michelle M. Le Beau
14. Metabolism of Hematologic Neoplastic Cells..... 191
Zandra E. Walton, Annie L. Hsieh, and Chi V. Dang
15. Apoptosis Mechanisms: Relevance to the Hematopoietic System..... 203
John C. Reed

16. Cell-Cycle Regulation and Hematologic Disorders..... 213
Yun Dai, Prithviraj Bose, and Steven Grant
17. Signal Transduction Pathways..... 247
Kenneth Kaushansky
18. Hematopoietic Stem Cells, Progenitors, and Cytokines..... 257
Kenneth Kaushansky
19. The Inflammatory Response..... 279
Jeffrey S. Warren and Peter A. Ward
20. Innate Immunity..... 293
Bruce Beutler
21. Dendritic Cells and Adaptive Immunity..... 307
Madhav Dhodapkar, Crystal L. Mackall, and Ralph M. Steinman

PART V

Therapeutic Principles

22. Pharmacology and Toxicity of Antineoplastic Drugs..... 315
Benjamin Izar, Dustin Dzube, James M. Cleary, Constantine S. Mitsiades, Paul G. Richardson, Jeffrey A. Barnes, and Bruce A. Chabner
23. Hematopoietic Cell Transplantation..... 353
Andrew R. Rezvani, Robert Lowsky, and Robert S. Negrin
24. Treatment of Infections in The Immunocompromised Host..... 383
Lisa Beutler and Jennifer Babik
25. Antithrombotic Therapy..... 393
Gregory C. Connolly and Charles W. Francis
26. Immune Cell Therapy..... 409
Carolina Berger and Stanley R. Riddell
27. Vaccine Therapy..... 421
Katayoun Rezvani and Jeffrey J. Mollndrem
28. Therapeutic Apheresis: Indications, Efficacy, and Complications..... 427
Robert Weinstein
29. Gene Therapy for Hematologic Diseases..... 437
Hua Fung and Stanton Gerson
30. Regenerative Medicine: Multipotential Cell Therapy for Tissue Repair..... 447
Jakub Tolar, Mark J Osborn, Randy Daughters, Anannya Banga, and John Wagner

PART VI

The Erythrocyte

31. Structure and Composition of the Erythrocyte..... 461
Narla Mohandas
32. Erythropoiesis..... 479
Josef T. Prchal and Perumal Thiagarajan
33. Erythrocyte Turnover..... 495
Perumal Thiagarajan and Josef Prchal
34. Clinical Manifestations and Classification of Erythrocyte Disorders..... 503
Josef T. Prchal

35. Aplastic Anemia: Acquired and Inherited	513
<i>George B. Segel and Marshall A. Lichtman</i>	
36. Pure Red Cell Aplasia	539
<i>Neal S. Young</i>	
37. Anemia of Chronic Disease	549
<i>Tomas Ganz</i>	
38. Erythropoietic Effects of Endocrine Disorders	559
<i>Xylina T. Gregg</i>	
39. The Congenital Dyserythropoietic Anemias	563
<i>Achille Iolascon</i>	
40. Paroxysmal Nocturnal Hemoglobinuria	571
<i>Charles J. Parker</i>	
41. Folate, Cobalamin, and Megaloblastic Anemias	583
<i>Ralph Green</i>	
42. Iron Metabolism	617
<i>Tomas Ganz</i>	
43. Iron Deficiency and Overload	627
<i>Tomas Ganz</i>	
44. Anemia Resulting from Other Nutritional Deficiencies	651
<i>Ralph Green</i>	
45. Anemia Associated with Marrow Infiltration	657
<i>Vishnu VB Reddy and Josef T. Prchal</i>	
46. Erythrocyte Membrane Disorders	661
<i>Theresa L Coetzer</i>	
47. Erythrocyte Enzyme Disorders	689
<i>Wouter W. van Solinge and Richard van Wijk</i>	
48. The Thalassemias: Disorders of Globin Synthesis	725
<i>David J. Weatherall</i>	
49. Disorders of Hemoglobin Structure: Sickle Cell Anemia and Related Abnormalities	759
<i>Kavita Natrajan and Abdullah Kutlar</i>	
50. Methemoglobinemia and Other Dyshemoglobinemias	789
<i>Archana M. Agarwal and Josef T. Prchal</i>	
51. Fragmentation Hemolytic Anemia	801
<i>Kelty R. Baker and Joel Moake</i>	
52. Erythrocyte Disorders as a Result of Chemical and Physical Agents	809
<i>Paul C. Herrmann</i>	
53. Hemolytic Anemia Resulting from Infections with Microorganisms	815
<i>Marshall A. Lichtman</i>	
54. Hemolytic Anemia Resulting from Immune Injury	823
<i>Charles H. Packman</i>	
55. Alloimmune Hemolytic Disease of the Fetus and Newborn	847
<i>Ross M. Fasano, Jeanne E. Hendrickson, and Naomi L. C. Luban</i>	
56. Hypersplenism and Hyposplenism	863
<i>Jaime Caro and Srikanth Nagalla</i>	
57. Primary and Secondary Erythrocytoses	871
<i>Josef T. Prchal</i>	
58. The Porphyrias	889
<i>John D. Phillips and Karl E. Anderson</i>	
59. Polyclonal and Hereditary Sideroblastic Anemias	915
<i>Prem Ponka and Josef T. Prchal</i>	

PART VII**Neutrophils, Eosinophils, Basophils, and Mast Cells**

60. Structure and Composition of Neutrophils, Eosinophils, and Basophils	925
<i>C. Wayne Smith</i>	
61. Production, Distribution, and Fate of Neutrophils	939
<i>C. Wayne Smith</i>	
62. Eosinophils and Related Disorders	947
<i>Andrew J. Wardlaw</i>	
63. Basophils, Mast Cells, and Related Disorders	965
<i>Stephen J. Galli, Dean D. Metcalfe, Daniel A. Arber, and Ann M. Dvorak</i>	
64. Classification and Clinical Manifestations of Neutrophil Disorders	983
<i>Marshall A. Lichtman</i>	
65. Neutropenia and Neutrophilia	991
<i>David C. Dale and Karl Welte</i>	
66. Disorders of Neutrophil Function	1005
<i>Niels Borregaard</i>	

PART VIII**Monocytes and Macrophages**

67. Structure, Receptors, and Functions of Monocytes and Macrophages	1045
<i>Steven D. Douglas and Anne G. Douglas</i>	
68. Production, Distribution, and Activation of Monocytes and Macrophages	1075
<i>Steven D. Douglas and Anne G. Douglas</i>	
69. Classification and Clinical Manifestations of Disorders of Monocytes and Macrophages	1089
<i>Marshall A. Lichtman</i>	
70. Monocytosis and Monocytopenia	1095
<i>Marshall A. Lichtman</i>	
71. Inflammatory and Malignant Histiocytosis	1101
<i>Kenneth L. McClain and Carl E. Allen</i>	
72. Gaucher Disease and Related Lysosomal Storage Diseases	1121
<i>Ari Zimran and Deborah Elstein</i>	

PART IX**Lymphocytes and Plasma Cells**

73. The Structure of Lymphocytes and Plasma Cells	1137
<i>Natarajan Muthusamy and Michael A. Caligiuri</i>	
74. Lymphopoiesis	1149
<i>Christopher S. Seet and Gay M. Crooks</i>	
75. Functions of B Lymphocytes and Plasma Cells in Immunoglobulin Production	1159
<i>Thomas J. Kipps</i>	
76. Functions of T Lymphocytes: T-Cell Receptors for Antigen	1175
<i>Fabienne McClanahan and John Gribben</i>	
77. Functions of Natural Killer Cells	1189
<i>Giorgio Trinchieri, Richard W. Childs, and Lewis L. Lanier</i>	
78. Classification and Clinical Manifestations of Lymphocyte and Plasma Cell Disorders	1195
<i>Yvonne A. Efebera and Michael A. Caligiuri</i>	

- 79.** Lymphocytosis and Lymphocytopenia 1199
Sumithira Vasu and Michael A. Caligiuri
- 80.** Immunodeficiency Diseases 1211
Hans D. Ochs and Luigi D. Notarangelo
- 81.** Hematologic Manifestations of Acquired Immunodeficiency Syndrome 1239
Virginia C. Broudy, Robert D. Harrington
- 82.** Mononucleosis Syndromes 1261
Robert F. Betts

PART X**Malignant Myeloid Diseases**

- 83.** Classification and Clinical Manifestations of the Clonal Myeloid Disorders 1275
Marshall A. Lichtman
- 84.** Polycythemia Vera 1291
Jaroslav F. Prchal and Josef T. Prchal
- 85.** Essential Thrombocythemia 1307
Philip A. Beer and Anthony R. Green
- 86.** Primary Myelofibrosis 1319
Marshall A. Lichtman and Josef T. Prchal
- 87.** Myelodysplastic Syndromes 1341
Rafael Bejar and David P. Steensma
- 88.** Acute Myelogenous Leukemia 1373
Jane L. Liesveld and Marshall A. Lichtman
- 89.** Chronic Myelogenous Leukemia and Related Disorders ... 1437
Jane L. Liesveld and Marshall A. Lichtman

PART XI**Malignant Lymphoid Diseases**

- 90.** Classification of Malignant Lymphoid Disorders 1493
Robert A. Baiocchi
- 91.** Acute Lymphoblastic Leukemia 1505
Richard A. Larson
- 92.** Chronic Lymphocytic Leukemia 1527
Farrukh T. Awan and John C. Byrd
- 93.** Hairy Cell Leukemia 1553
Michael R. Grever and Gerard Lozanski
- 94.** Large Granular Lymphocytic Leukemia 1563
Pierluigi Porcu and Aharon G. Freud
- 95.** General Considerations for Lymphomas: Epidemiology, Etiology, Heterogeneity, and Primary Extranodal Disease .. 1569
Oliver W. Press and Marshall A. Lichtman
- 96.** Pathology of Lymphomas 1587
Randy D. Gascoyne and Brian F. Skinnider
- 97.** Hodgkin Lymphoma 1603
Oliver W. Press
- 98.** Diffuse Large B-Cell Lymphoma and Related Diseases 1625
Stephen D. Smith and Oliver W. Press
- 99.** Follicular Lymphoma 1641
Oliver W. Press
- 100.** Mantle Cell Lymphoma 1653
Martin Dreyling

- 101.** Marginal Zone B-Cell Lymphomas 1663
Pier Luigi Zinzani and Alessandro Broccoli
- 102.** Burkitt Lymphoma 1671
Andrew G. Evans and Jonathan W. Friedberg
- 103.** Cutaneous T-Cell Lymphoma (Mycosis Fungoides and Sézary Syndrome) 1679
Larisa J. Geskin
- 104.** Mature T-Cell and Natural Killer Cell Lymphomas 1693
Neha Mehta, Alison Moskowitz, and Steven Horwitz
- 105.** Plasma Cell Neoplasms: General Considerations 1707
Guido Tricot, Siegfried Janz, Kalyan Nadiminti, Erik Wendlandt, and Fenghuang Zhan
- 106.** Essential Monoclonal Gammopathy 1721
Marshall A. Lichtman
- 107.** Myeloma 1733
Elizabeth O'Donnell, Francesca Cottini, Noopur Raje, and Kenneth Anderson
- 108.** Immunoglobulin Light-Chain Amyloidosis 1773
Morie A. Gertz, Taimur Sher, Angela Dispenzieri, and Francis K. Buadi
- 109.** Macroglobulinemia 1785
Steven P. Treon, Jorge J. Castillo, Zachary R. Hunter, and Giampaolo Merlini
- 110.** Heavy-Chain Disease 1803
Dietlind L. Wahner-Roedler and Robert A. Kyle

PART XII**Hemostasis and Thrombosis**

- 111.** Megakaryopoiesis and Thrombopoiesis 1815
Kenneth Kaushansky
- 112.** Platelet Morphology, Biochemistry, and Function 1829
Susan S. Smyth, Sidney Whiteheart, Joseph E. Italiano Jr., Paul Bray, and Barry S. Collier
- 113.** Molecular Biology and Biochemistry of the Coagulation Factors and Pathways of Hemostasis 1915
Mettine H. A. Bos, Cornelis van 't Veer, and Pieter H. Reitsma
- 114.** Control of Coagulation Reactions 1949
Laurent O. Mosnier and John H. Griffin
- 115.** Vascular Function in Hemostasis 1967
Katherine A. Hajjar, Aaron J. Marcus, and William Muller
- 116.** Classification, Clinical Manifestations, and Evaluation of Disorders of Hemostasis 1985
Marcel Levi, Uri Seligsohn, and Kenneth Kaushansky
- 117.** Thrombocytopenia 1993
Reyhan Diz-Küçükaya and José A. López
- 118.** Heparin-Induced Thrombocytopenia 2025
Adam Cuker and Mortimer Poncz
- 119.** Reactive Thrombocytosis 2035
Kenneth Kaushansky
- 120.** Hereditary Qualitative Platelet Disorders 2039
A. Koneti Rao and Barry S. Collier
- 121.** Acquired Qualitative Platelet Disorders 2073
Charles S. Abrams, Sanford J. Shattil, and Joel S. Bennett
- 122.** The Vascular Purpuras 2097
Doru T. Alexandrescu and Marcel Levi

- 123.** Hemophilia A and Hemophilia B 2113
Miguel A. Escobar and Nigel S. Key
- 124.** Inherited Deficiencies of Coagulation Factors II, V, V+VIII, VII, X, XI, and XIII 2133
Flora Peyvandi and Marzia Menegatti
- 125.** Hereditary Fibrinogen Abnormalities 2151
Marguerite Neerman-Arbez and Philippe de Moerloose
- 126.** von Willebrand Disease 2163
Jill Johnsen and David Ginsburg
- 127.** Antibody-Mediated Coagulation Factor Deficiencies 2183
Sean R. Stowell, John S. (Pete) Lollar, and Shannon L. Meeks
- 128.** Hemostatic Alterations in Liver Disease and Liver Transplantation 2191
Frank W.G. Leebeek and Ton Lisman
- 129.** Disseminated Intravascular Coagulation 2199
Marcel Levi and Uri Seligsohn
- 130.** Hereditary Thrombophilia 2221
Saskia Middeldorp and Michiel Coppens
- 131.** The Antiphospholipid Syndrome 2233
Jacob H. Rand and Lucia Wolgast
- 132.** Thrombotic Microangiopathies 2253
J. Evan Sadler
- 133.** Venous Thrombosis 2267
Gary E. Raskob, Russell D. Hull, and Harry R. Buller
- 134.** Atherothrombosis: Disease Initiation, Progression, and Treatment 2281
Emile R. Mohler III and Andrew I. Schafer
- 135.** Fibrinolysis and Thrombolysis 2303
Katherine A. Hajjar and Jia Ruan

PART XIII**Transfusion Medicine**

- 136.** Erythrocyte Antigens and Antibodies 2329
Marion E. Reid and Christine Lomas-Francis
- 137.** Human Leukocyte and Platelet Antigens 2353
Myra Coppage, David Stroncek, Janice McFarland, and Neil Blumberg
- 138.** Blood Procurement and Red Cell Transfusion 2365
Jeffrey McCullough, Majed A. Refaai, and Claudia S. Cohn
- 139.** Preservation and Clinical Use of Platelets 2381
Terry Gernsheimer and Sherrill Slichter
- Index* 2393

CONTRIBUTORS

Charles S. Abrams, MD [121]

Professor of Medicine, Pathology and Laboratory Medicine
Vice Chair for Research & Chief Scientific Officer
Department of Medicine
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Archana M. Agarwal, MD [50]

Department of Pathology
University of Utah/ARUP Laboratories
Salt Lake City, Utah

Doru T. Alexandrescu, MD [122]

Department of Medicine
Division of Dermatology
University of California, San Diego
VA San Diego Health Care System
San Diego, California

Carl E. Allen, MD, PhD [71]

Associate Professor of Pediatrics
Texas Children's Cancer Center/Hematology
Baylor College of Medicine
Houston, Texas

Karl E. Anderson, MD, FACP [58]

Professor, Departments of Preventative Medicine and Community Health, Internal Medicine, and Pharmacology and Toxicology
University of Texas Medical Branch
Galveston, Texas

Kenneth Anderson, MD [107]

Dana-Farber Cancer Institute
Boston, Massachusetts

Daniel A. Arber, MD [63]

Ronald F. Dorfman, MBBch, FRCPath Professor in Hematopathology
Professor of Pathology
Stanford University School of Medicine
Stanford University Medical Center
Stanford, California

Andrew S. Artz, MD, MS [9]

Associate Professor of Medicine
University of Chicago
Chicago, Illinois

Farrukh T. Awan, MD [92]

Associate Professor of Internal Medicine
Division of Hematology
Department of Internal Medicine
The Ohio State University Comprehensive Cancer Center
Columbus, Ohio

Jennifer Babik, MD, PhD [24]

Division of Infectious Diseases
Department of Medicine
University of California
San Francisco, California

Robert A. Baiocchi, MD, PhD [90]

Associate Professor of Medicine
Division of Hematology
Department of Internal Medicine
The Ohio State University
Columbus, Ohio

Kelty R. Baker, MD [51]

Clinical Assistant Professor
Baylor College of Medicine
Houston, Texas

Anannya Banga, PhD, [30]

Assistant Professor
Department of Genetics
Cell Biology, and Development, Stem Cell Institute
University of Minnesota
Minneapolis, Minnesota

Jeffrey A. Barnes [22]

Instructor in Medicine
Dana-Farber Cancer Institute
Harvard Medical School
Boston, Massachusetts

Philip A. Beer, MRCP, FRCPath, PhD [85]

Wellcome Trust Sanger Institute
Wellcome Trust Genome Campus, Hinxton
Cambridge, United Kingdom

Rafael Bejar, MD, PhD [87]

Division of Hematology and Oncology
Moores Cancer Center
University of California San Diego
La Jolla, California

Joel S. Bennett, MD [121]

Professor of Medicine
Division of Hematology-Oncology
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Carolina Berger, MD [26]

Fred Hutchinson Cancer Research Center
Seattle, Washington

Robert F. Betts, MD [82]

Professor of Medicine, Emeritus
Division of Infectious Diseases
University of Rochester Medical Center
Rochester, New York

Bruce Beutler, MD [20]

Regental Professor and Director
Center for the Genetics of Host Defense
Raymond and Ellen Willie Distinguished Chair in Cancer Research in
Honor of Laverne and Raymond Willie Sr.
University of Texas Southwestern Medical Center
Dallas, Texas

Lisa Beutler, MD, PhD [24]

Department of Medicine
UCSF School of Medicine
San Francisco, California

Neil Blumberg, MD [137]

Professor and Director, Clinical Laboratories and Transfusion
Medicine
Department of Pathology and Laboratory Medicine
University of Rochester
Rochester, New York

Niels Borregaard, MD, PhD [66]

Professor of Hematology
Department of Hematology
University of Copenhagen
Copenhagen, Denmark

Prithviraj Bose, MD [16]

Assistant Professor
Department of Leukemia
University of Texas MD Anderson Cancer Center
Houston, Texas

Rondeep S. Brar, MD [4]

Clinical Assistant Professor of Medicine (Hematology and Oncology)
Stanford University School of Medicine
Stanford, California

Paul Bray, MD [112]

Professor
Director, Division of Hematology
Jefferson University
Philadelphia, Pennsylvania

Alessandro Broccoli, MD [101]

Institute of Hematology "L. e A. Seràgnoli"
University of Bologna
Bologna, Italy

Virginia C. Broudy, MD [81]

Professor of Medicine
Scripps Professor of Hematology
University of Washington
Seattle, Washington

Francis K. Buadi, MD [108]

Division of Hematology
Mayo Clinic
Rochester, Minnesota

Harry R. Buller, MD [133]

Professor of Medicine,
Department of Vascular Medicine
Academic Medical Center
Amsterdam, The Netherlands

Linda J. Burns, MD [1]

National Marrow Donor Program/Be The Match
Vice President and Medical Director
Health Services Research
Minneapolis, Minnesota

John C. Byrd, MD [92]

D. Warren Brown Chair of Leukemia Research
Professor of Medicine, Medicinal Chemistry, and Veterinary
Biosciences
Director, Division of Hematology
Department of Medicine
The Ohio State University
Columbus, Ohio

Bradley R. Cairns, PhD [12]

Howard Hughes Medical Institute
Professor and Chair
Department of Oncological Sciences
Huntsman Cancer Institute
University of Utah School of Medicine
Salt Lake City, Utah

Michael A. Caligiuri, MD [6, 73, 78, 79]

Professor and Director, The Ohio State University Comprehensive
Cancer Center
CEO, James Cancer Hospital and Solove Research Institute
The Ohio State University
Columbus, Ohio

Jaime Caro, MD [56]

Professor of Medicine
Department of Medicine
Thomas Jefferson University
Cardeza Foundation for Hematologic Research
Philadelphia, Pennsylvania

Jorge J. Castillo, MD [109]

Assistant Professor of Medicine
Dana-Farber Cancer Institute
Harvard Medical School
Boston, Massachusetts

Bruce A. Chabner, MD [22]

Professor of Medicine
Massachusetts General Hospital Cancer Center
Harvard Medical School
Boston, Massachusetts

Richard W. Childs, MD [77]

Clinical Director, NHLBI
 Chief, Section of Transplantation Immunotherapy
 National Heart, Lung, and Blood Institute, NIH
 Bethesda, Maryland

James M. Cleary, MD, PhD [22]

Instructor in Medicine
 Dana-Farber Cancer Institute
 Harvard Medical School
 Boston, Massachusetts

Theresa L Coetzer, MD [46]

Head: Red Cell Membrane Unit
 Department of Molecular Medicine and Haematology
 National Health Laboratory Service
 University of the Witwatersrand
 Wits Medical School
 Johannesburg, South Africa

Claudia S. Cohn, MD [138]

Assistant Professor, Laboratory Medicine and Pathology
 University of Minnesota
 Minneapolis, Minnesota

Barry S. Collier, MD [112, 120]

Head
 Allen and Frances Adler Laboratory of Blood and Vascular Biology
 Physician-in-Chief
 Vice President for Medical Affairs
 The Rockefeller University
 New York, New York

Gregory C. Connolly, MD [25]

Department of Medicine
 Lipson Cancer Center
 Rochester Regional Health System
 Rochester, New York

Myra Coppage [137]

Associate Professor of Laboratory Medicine
 Department of Pathology and Laboratory Medicine
 University of Rochester
 Rochester, New York

Michiel Coppens, MD, PhD [130]

Department of Vascular Medicine
 Academic Medical Center
 Amsterdam, The Netherlands

Francesca Cottini, MD [107]

Dana-Farber Cancer Institute
 Boston, Massachusetts

Gay M. Crooks, MB, BS, FRACP [74]

Professor
 Departments of Pathology & Laboratory Medicine and Pediatrics
 David Geffen School of Medicine
 University of California, Los Angeles
 Los Angeles, California

Adam Cuker, MD, MS [118]

Assistant Professor of Medicine & of Pathology and Laboratory
 Medicine
 Perelman School of Medicine at the University of Pennsylvania
 Philadelphia, Pennsylvania

Yun Dai, MD [16]

Associate Professor of Medicine
 Department of Medicine
 Massey Cancer Center
 Virginia Commonwealth University
 Richmond, Virginia

David C. Dale, MD [65]

Professor of Medicine
 Department of Medicine
 University of Washington
 Seattle, Washington

Chi V. Dang, MD, PhD [14]

Professor and Director
 Abramson Cancer Center
 University of Pennsylvania
 Philadelphia, Pennsylvania

Utpal P. Davé, MD [5]

Division of Hematology/Oncology
 Department of Medicine
 Vanderbilt University Medical Center
 Nashville, Tennessee

Randy Daughters, PhD [30]

Assistant Professor
 Department of Genetics
 Cell Biology, and Development, Stem Cell Institute
 University of Minnesota
 Minneapolis, Minnesota

Philippe de Moerloose, MD [125]

Professor
 Division of Angiology and Haemostasis
 University of Geneva Faculty of Medicine
 Geneva, Switzerland

Madhav Dhodapkar, MBBS [21]

Arthur H. and Isabel Bunker Professor of Medicine (Hematology) and
 Professor of Immunobiology
 Chief, Section of Hematology, Department of Internal Medicine
 Clinical Research Program Leader, Hematology Program
 Yale Cancer Center
 New Haven, Connecticut

Angela Dispenzieri, MD [108]

Division of Hematology
 Mayo Clinic
 Rochester, Minnesota

Reyhan Diz-Küçükaya, MD [117]

Associate Professor
Department of Internal Medicine
Division of Hematology
Istanbul University
Istanbul Faculty of Medicine
Istanbul, Turkey

Anne G. Douglas, BA [67, 68]

Student, Perelman School of Medicine
University of Pennsylvania (Class of 2017)
Philadelphia, Pennsylvania

Steven D. Douglas, MD [67, 68]

Professor and Associate Chair
Department of Pediatrics
Perelman School of Medicine
University of Pennsylvania
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Martin Dreyling, MD [100]

Department of Internal Medicine III
Medical Center of the University of Munich
Munich, Germany

Ann M. Dvorak, MD [63]

Senior Pathologist, Professor of Pathology
Department of Pathology
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, Massachusetts

Dustin Dzube, MD [22]

Resident Physician
Massachusetts General Hospital
Harvard Medical School
Boston, Massachusetts

Yvonne A. Efebera, MD, MPH [78]

Associate Professor of Internal Medicine
Division of Hematology
Department of Internal Medicine
The Ohio State University
Columbus, Ohio

Deborah Elstein, PhD [72]

Gaucher Clinic
Shaare Zedek Medical Center
Jerusalem, Israel

William B. Ershler, MD [9]

Scientific Director
Institute for Advanced Studies in Aging and Geriatrics
Falls Church, Virginia

Miguel A. Escobar, MD [123]

Professor of Medicine and Pediatrics
Division of Hematology
University of Texas Health Science Center at Houston
Director, Gulf States Hemophilia and Thrombophilia Center
Houston, Texas

Andrew G. Evans, MD, PhD [102]

Assistant Professor
Department of Pathology and Laboratory Medicine
University of Rochester Medical Center
Rochester, New York

Ross M. Fasano, MD [55]

Assistant Professor
Emory University School of Medicine
Departments of Pathology and Pediatric Hematology
Assistant Director, Children's Healthcare of Atlanta Transfusion
Services
Associate Director, Grady Health System Transfusion Service
Atlanta, Georgia

Charles W. Francis, MD [25]

Hematology/Oncology Division
University of Rochester Medical Center
Rochester, New York

Aharon G. Freud, MD, PhD [6, 94]

Assistant Professor
Department of Pathology
The Ohio State University
Columbus, Ohio

Jonathan W. Friedberg, MD [102]

Samuel Durand Professor of Medicine
Director, Wilmot Cancer Institute
University of Rochester Medical Center
Rochester, New York

Hua Fung, MD [29]

Case Western Reserve University
University Hospital of Cleveland
Cleveland, Ohio

Stephen J. Galli, MD [63]

Mary Hewitt Loveless, MD, Professor
Professor of Pathology and of Microbiology and Immunology
Chair, Department of Pathology
Stanford University School of Medicine
Stanford University Medical Center
Stanford, California

Tomas Ganz, MD, PhD [37, 42, 43]

Departments of Medicine and Pathology, David Geffen School of
Medicine
University of California, Los Angeles
Los Angeles, California

Randy D. Gascoyne, MD, FRCPC [96]

Clinical Professor of Pathology
Research Director, Centre for Lymphoid Cancers
Departments of Pathology and Advanced Therapeutics British
Columbia Cancer Agency, the BC Centre Research Center and
University of British Columbia
Vancouver, British Columbia, Canada

Terry B. Gernsheimer, MD [139]

Professor of Medicine
Department of Medicine, Division of Hematology
University of Washington School of Medicine
Seattle Cancer Care Alliance
Seattle, Washington

Stanton Gerson, MD [29]

Director, Case Comprehensive Cancer, Seidman Cancer Center
& National Center for Regenerative Medicine
Distinguished University Professor
Case Western Reserve University
University Hospital of Cleveland
Cleveland, Ohio

Morie A. Gertz, MD, MACP [108]

Division of Hematology
Mayo Clinic
Rochester, Minnesota

Larisa J. Geskin, MD, FAAD [103, 105]

Associate Professor of Dermatology and Medicine
Director, Division of Cutaneous Oncology and Comprehensive Skin
Cancer Center
Department of Dermatology
Columbia University
New York, New York

David Ginsburg, MD [126]

Professor, Department of Internal Medicine, Human Genetics and
Pediatrics
Investigator, Howard Hughes Medical Institute
Life Sciences Institute
University of Michigan
Ann Arbor, Michigan

Lucy A. Godley, MD, PhD [13]

Section of Hematology/Oncology
Department of Medicine and The University of Chicago
Comprehensive Cancer Center
The University of Chicago
Chicago, Illinois

Steven Grant, MD [16]

Professor of Medicine and Biochemistry
Shirley and Sture Gordon Olsson Professor of Oncology
Associate Director
Translational Research, Massey Cancer Center
Virginia Commonwealth University Health Sciences Center
Richmond, Virginia

Anthony R. Green, PhD, FRCP, FRCPath, FMedSci [85]

Professor of Haematology
Cambridge Institute for Medical Research and Stem Cell Institute
University of Cambridge
Cambridge, United Kingdom

Ralph Green, MD, PhD, FRCPath [41, 44]

Professor of Pathology and Medicine
University of California Davis Medical Center
Sacramento, California

Xylina T. Gregg, MD [38]

Director of Laboratory Services
Utah Cancer Specialists
Salt Lake City, Utah

Michael R. Grever, MD [93]

Chair and Professor
Department of Internal Medicine
Bertha Bouroncle MD and Andrew Pereny Chair in Medicine
The Ohio State University
Columbus, Ohio

John Gribben, MD, DSc, FRCP, FRCPath, FMedSci [76]

Chair of Medical Oncology
Barts Cancer Institute
Centre for Haemato-Oncology
Queen Mary University of London
London, United Kingdom

John H. Griffin, PhD [114]

Professor
Department of Molecular and Experimental Medicine
The Scripps Research Institute
La Jolla, California

Katherine A. Hajjar, MD [115, 135]

Professor of Pediatrics
Brine Family Professor, Department of Cell and Developmental
Biology
Professor of Medicine
Well Cornell Medical College
Attending Pediatrician
New York Presbyterian Hospital
New York, New York

Robert D. Harrington, MD [81]

Professor of Medicine
University of Washington
Seattle, Washington

Jeanne E. Hendrickson, MD [55]

Associate Professor
Departments of Laboratory Medicine and Pediatrics
Yale University School of Medicine
New Haven, Connecticut

Paul C. Herrmann, MD, PhD [52]

Associate Professor and Chair
Department of Pathology and Human Anatomy
Loma Linda University School of Medicine
Loma Linda, California

Steven Horwitz, MD [104]

Department of Medicine
Memorial Sloan Kettering Cancer Center
New York, New York

Annie L. Hsieh, MD [14]

Department of Pathology
Johns Hopkins University, School of Medicine
Baltimore, Maryland

Zachary R. Hunter, PhD [109]

Bing Center for Waldenström's Macroglobulinemia
Dana-Farber Cancer Institute
Instructor of Medicine, Harvard Medical School
Boston, Massachusetts

Russell D. Hull, MD [133]

Professor
Department of Medicine
University of Calgary
Active Staff
Department of Internal Medicine
Foothills Hospital
Calgary, Alberta, Canada

Achille Iolascon, MD, PhD [39]

Professor of Medical Genetics
Dept. of Molecular Medicine and Medical Biotechnologies
University Federico II of Naples
Naples, Italy

Joseph E. Italiano Jr., PhD [112]

Associate Professor of Medicine
Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts

Benjamin Izar, MD, PhD [22]

Post-doctoral Scientist
Dana-Farber Cancer Institute and Broad Institute
Associate Physician, Brigham and Women's Hospital
Harvard Medical School
Boston, Massachusetts

Siegfried Janz, MD, DSc [105]

Division of Hematology/Oncology & Blood and Marrow Transplantation
Department of Pathology, Carver College of Medicine
University of Iowa Health Care
Iowa City, Iowa

Jill M. Johnsen, MD [126]

Assistant Member, Research Institute
Bloodworks Northwest
Puget Sound Blood Center
Assistant Professor, Division of Hematology
Department of Medicine
University of Washington
Seattle, Washington

Lynn B. Jorde, PhD [10]

H. A. and Edna Benning Presidential Professor
Department of Human Genetics
University of Utah School of Medicine
Salt Lake City, Utah

Bindu Kanapuru, MD [9]

Institute for Advanced Studies in Aging and Geriatrics
Falls Church, Virginia

Kenneth Kaushansky, MD, MACP [17, 18, 111, 116, 119]

Senior Vice President, Health Sciences
Dean, School of Medicine
SUNY Distinguished Professor
Stony Brook Medicine
State University of New York
Stony Brook, New York

Nigel S. Key, MB, ChB, FRCP [123]

Harold R. Roberts Distinguished Professor of Medicine
Director, University of North Carolina Hemophilia and Thrombosis
Center
Chapel Hill, North Carolina

Thomas J. Kipps, MD, PhD [75]

Evelyn and Edwin Tasch Chair in Cancer Research
Professor of Medicine
Division of Hematology/Oncology
Deputy Director for Research Operations
Moore's UCSD Cancer Center
University of California, San Diego
La Jolla, California

Mark J. Koury, MD [5]

Division of Hematology/Oncology
Department of Medicine
Vanderbilt University Medical Center
Nashville, Tennessee

Abdullah Kutlar, MD [49]

Professor of Medicine
Georgia Sickle Cell Center
Medical College of Georgia
Sickle Cell Center
Augusta, Georgia

Robert A. Kyle, MD [110,]

Professor of Medicine
Laboratory Medicine and Pathology
Mayo Clinic
Rochester, Minnesota

Lewis L. Lanier, PhD [77]

Professor
Department of Microbiology and Immunology
University of California, San Francisco
San Francisco, California

Richard A. Larson, MD [91]

Section of Hematology/Oncology
Department of Medicine and the Comprehensive Cancer Center
University of Chicago
Chicago, Illinois

Michelle M. Le Beau, PhD [13]

Section of Hematology/Oncology
Department of Medicine and the Center Research Center
University of Chicago
Chicago, Illinois

Frank W.G. Leebeek, MD, PhD [128]

Professor of Hematology
Department of Hematology
Erasmus University Medical Center
Rotterdam, The Netherlands

Marcel Levi, MD, PhD [116, 122, 129]

Department of Medicine/Vascular Medicine
Academic Medical Center
University of Amsterdam
Amsterdam, The Netherlands

Marshall A. Lichtman, MD [1, 35, 53, 64, 69, 70, 83, 86, 88, 89, 95, 106]

Professor of Medicine and of Biochemistry and Biophysics
University of Rochester Medical Center
Rochester, New York

Jane L. Liesveld, MD [88, 89]

Professor of Medicine (Hematology-Oncology)
James P. Wilmot Cancer Institute
University of Rochester Medical Center
Rochester, New York

Ton Lisman, PhD [128]

Professor of Experimental Surgery
Surgical Research Laboratory and Section of Hepatobiliary Surgery
and Liver Transplantation
Department of Surgery
University Medical Center, Groningen
Groningen, The Netherlands

John S. (Pete) Lollar III, MD [127]

Aflac Cancer Center and Blood Disorders Services
Department of Pediatrics
Emory University
Atlanta, Georgia

Christine Lomas-Francis, MSc, FIBMS [136]

Technical Director
Laboratory of Immunohematology and Genomics
New York Blood center
New York, New York

José A. López, MD [117]

Chief Scientific Officer
Bloodworks Northwest
Professor of Medicine and Biochemistry
University of Washington
Seattle, Washington

Robert Lowsky, MD [23]

Division of Blood and Marrow Transplantation
Stanford University
Stanford, California

Gerard Lozanski, MD [93]

Director, Hematopathology
Medical Director
Flow Cytometry Laboratory
Associate Professor—Clinical
Department of Pathology
The Ohio State University
Columbus, Ohio

Naomi L. C. Luban, MD [55]

Professor, Pediatrics and Pathology
George Washington University Medical Center
Division Chief, Laboratory Medicine
Director, Transfusion Medicine/Donor Center
Children's National Medical Center
Washington, D.C.

Crystal L. Mackall, MH [21]

Head, Immunology Section and
Chief, Pediatric Oncology Branch
National Cancer Institute
Bethesda, Maryland

Aaron J. Marcus, MD* [115]

Professor of Medicine
Weill Cornell Medical College
Attending Physician
New York Harbor Healthcare System
New York, New York

Elaine R. Mardis, PhD [11]

Robert E. and Louise F. Dunn Distinguished Professor of Medicine
Co-director, The Genome Institute, Division of Genomics and
Bioinformatics, Department of Medicine, Washington University
School of Medicine
Siteman Cancer Center, Washington University School of Medicine
Saint Louis, Missouri

Fabienne McClanahan, MD, PhD [76]

Barts Cancer Institute
Centre for Haemato-Oncology
Queen Mary University of London
London, United Kingdom

Kenneth L. McClain, MD, PhD [71]

Professor of Pediatrics
Texas Children's Cancer Center/Hematology
Baylor College of Medicine
Houston, Texas

Jeffrey McCullough, MD [138]

Professor
Department of Laboratory Medicine and Pathology
American Red Cross Professor, Transfusion Medicine
University of Minnesota Medical School
Minneapolis, Minnesota

Janice McFarland, MD [137]

Blood Center of Southeast Wisconsin
Milwaukee, Wisconsin

Shannon L. Meeks, MD [127]

Aflac Cancer Center and Blood Disorders Services
Department of Pediatrics
Emory University
Atlanta, Georgia

*Deceased

PREFACE

The first edition of *Williams Hematology* (né *Hematology*) was published in 1972. This, our 9th edition, will represent our continued efforts over nearly one-half century to provide the most current concepts of the pathophysiology and treatment of hematologic diseases.

The rate of growth in our understanding of diseases of blood cells and coagulation pathways provides a challenge for editors of a comprehensive textbook of hematology. The sequencing of individual genomes, analysis of the “dark DNA” and noncoding RNAs, advances in knowledge in proteomics, metabolomics, and other “-omics” fields, as applied to hematologic disorders, have accelerated the understanding of the pathogenesis of the diseases of our interest. The rate at which basic knowledge in molecular and cellular biology and immunology has been translated into improved diagnostic and therapeutic methods is equally impressive. Specific molecular targets for therapy in several hematologic disorders have become reality, and it is not hyperbole to state that hematology is the poster child for the rational design of therapeutics applicable to other fields of medicine.

This edition of *Williams Hematology* includes changes designed to facilitate ease of access to information, both within the book and its associated links, and has been modestly reorganized to reflect our greater understanding of the origins of hematologic disorders. Each chapter has been revised or rewritten to provide current information. Four new chapters have been added and other notable changes have been made. Chapter 4 “Consultative Hematology” is new to this edition. The chapter “Epigenetics and Genomics” has been divided into separate chapters to reflect the growth of knowledge in those disciplines. Chapter 14, “Metabolism of Hematologic Neoplastic Cells” is new, as this topic has become the basis of multiple potential drug targets for hematologic disease. A section on “Autophagy” has been added to Chap 15 “Apoptosis Mechanisms: Relevance to the Hematopoietic System,” as the topic is becoming increasingly important for understanding of the physiology of blood cell development; and an independent chapter “Heparin-Induced Thrombocytopenia” (Chap 118) has been created to reflect both its pathophysiologic and clinical importance. Recognizing that at the heart of diagnostic hematology is blood and marrow cell morphology, we have continued our incorporation of informative color images of the relevant disease topics in each chapter, allowing easy access to illustrations of cell morphology important to diagnosis.

The 9th edition of *Williams Hematology* is also available online, as part of the excellent www.accessmedicine.com website. With direct links to a comprehensive drug therapy database and to other important medical texts, including *Harrison's Principles of Internal Medicine* and *Goodman and Gilman's The Pharmacological Basis of Therapeutics*, *Williams Hematology Online* is part of a powerful resource covering all disciplines within medical education and practice. The online edition

of *Williams Hematology* also includes PubMed links to journal articles cited in the references.

In addition, *Williams Manual of Hematology* will be revised to reflect the diagnostic and therapeutic advances incorporated in the 9th edition of *Williams Hematology*. The convenient *Manual* features the most clinically salient content from the parent text, and is useful in time-restricted clinical situations. The *Manual* will be available for iPhone™ and other mobile formats.

The readers of the 9th edition of *Williams Hematology* will note a “changing of (some of) the guard” of our editorial group; Drs. Marcel Levi (a member of the 8th edition of *Williams Manual of Hematology* editorial group), Oliver Press, Linda Burns, and Michael Caligiuri have joined continuing editors Drs. Kenneth Kaushansky, Marshall Lichtman, and Josef Prchal in the 9th edition.

The production of this book required the timely cooperation of 101 contributors for the production of 139 chapters. We are grateful for their work in providing this comprehensive and up-to-date text. Despite the growth of both basic and clinical knowledge and the passion that each of our contributors brings to the topic of their chapter, we have been able to maintain the text in a single volume through scrupulous attention to chapter length.

Each editor has had expert administrative assistance in the management of the manuscripts for which they were primarily responsible. We thank Susan Madden in Salt Lake City, Utah; Nancy Press and Deborah Lemon in Seattle, Washington; and Annie Thompson, Rebecca Posey, and Kimberly Morley in Columbus, Ohio for their very helpful participation in the production of the book. Special thanks go to Susan Daley in Rochester, New York, and Marie Brito in Stony Brook, New York, who were responsible for coordinating the management of 139 chapters, including many new figures and tables, and managing other administrative matters, a challenging task that Ms. Daley and Ms. Brito performed with skill and good humor. The editors also acknowledge the interest and support of our colleagues at McGraw-Hill, including James F. Shanahan, Publisher, Medical Publishing; Karen Edmonson, Senior Editor for *Williams Hematology*; and Harriet Lebowitz, Senior Project Development Editor for *Williams Hematology*.

CHAPTER 1

INITIAL APPROACH TO THE PATIENT: HISTORY AND PHYSICAL EXAMINATION

Marshall A. Lichtman and Linda J. Burns

SUMMARY

The care of a patient with a suspected hematologic abnormality begins with a systematic attempt to determine the nature of the illness by eliciting an in-depth medical history and performing a thorough physical examination. The physician should identify the patient's symptoms systematically and obtain as much relevant information as possible about their origin and evolution and about the general health of the patient by appropriate questions designed to explore the patient's recent and remote experience. Reviewing previous records may add important data for understanding the onset or progression of illness. Hereditary and environmental factors should be carefully sought and evaluated. The use of drugs and medications, nutritional patterns, and sexual behavior should be considered. The physician follows the medical history with a physical examination to obtain evidence for tissue and organ abnormalities that can be assessed through bedside observation to permit a careful search for signs of the illnesses suggested by the history. Skin changes and hepatic, splenic, or lymph nodal enlargement are a few findings that may be of considerable help in pointing toward a diagnosis. Additional history is obtained during the physical examination, as findings suggest an additional or alternative consideration. Thus, the history and physical examination should be considered as a unit, providing the basic information with which further diagnostic information is integrated: blood and marrow studies, imaging studies, and biopsies.

Primary hematologic diseases are common in the aggregate, but hematologic manifestations secondary to other diseases occur even more frequently. For example, the signs and symptoms of anemia and the presence of enlarged lymph nodes are common clinical findings that may be related to a hematologic disease but occur frequently as secondary manifestations of disorders not considered primarily hematologic. A wide variety of diseases may produce signs or symptoms of hematologic illness. Thus, in patients with a connective tissue disease, all the signs and symptoms of anemia may be elicited and lymphadenopathy may be notable, but additional findings are usually present that indicate primary involvement of some system besides the hematopoietic (marrow) or lymphopoietic (lymph nodes or other lymphatic sites). In this discussion, emphasis is placed on the clinical findings resulting from either primary hematologic disease or the complications of hematologic disorders so as to avoid presenting an extensive catalog of signs and symptoms encountered in general clinical medicine.

Acronyms and Abbreviations: Ig, immunoglobulin; IL, interleukin; POEMS, polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes; PS, performance status.

In each discussion of specific diseases in subsequent chapters, the signs and symptoms that accompany the particular disorder are presented, and the clinical findings are covered in detail. In this chapter, a more general systematic approach is taken.

THE HEMATOLOGY CONSULTATION

Table 1-1 lists the major abnormalities that result in the evaluation of the patient by the hematologist. The signs indicated in Table 1-1 may reflect a primary or secondary hematologic problem. For example, immature granulocytes in the blood may be signs of myeloid diseases such as myelogenous leukemia, or, depending on the frequency of these cells and the level of immaturity, the dislodgment of cells resulting from marrow metastases of a carcinoma. Nucleated red cells in the blood may reflect the breakdown in the marrow-blood interface seen in primary myelofibrosis or the hypoxia of congestive heart failure. Certain disorders have a propensity for secondary hematologic abnormalities; renal, liver, and connective tissue diseases are prominent among such abnormalities. Chronic alcoholism, nutritional fetishes, and the use of certain medications may be causal factors in blood cell or coagulation protein disorders. Pregnant women and persons of older age are prone to certain hematologic disorders: anemia, thrombocytopenia, or intravascular coagulation in the former case, and hematologic malignancies, pernicious anemia and the anemia of aging in the latter. The history and physical examination can provide vital clues to the possible diagnosis and also to the rationale choice of laboratory tests.

THE HISTORY

In today's technology- and procedure-driven medical environment, the importance of carefully gathering information from patient inquiry and examination is at risk of losing its primacy. The history (and physical examination) remains the vital starting point for the evaluation of any clinical problem.¹⁻³

GENERAL SYMPTOMS AND SIGNS

Performance status (PS) is used to establish semiquantitatively the extent of a patient's disability. This status is important in evaluating patient comparability in clinical trials, in determining the likely tolerance to cytotoxic therapy, and in evaluating the effects of therapy. Table 1-2 presents a well-founded set of criteria for measuring PS.⁴ An abbreviated version sometimes is used, as proposed by the Eastern Cooperative Oncology Group (Table 1-3).⁵

Weight loss is a frequent accompaniment of many serious diseases, including primary hematologic malignancies, but it is not a prominent accompaniment of most hematologic diseases. Many "wasting" diseases, such as disseminated carcinoma and tuberculosis, cause anemia, and pronounced emaciation should suggest one of these diseases rather than anemia as the primary disorder.

Fever is a common early manifestation of the aggressive lymphomas or acute leukemias as a result of pyrogenic cytokines (e.g., interleukin [IL]-1, IL-6, and IL-8) released as a reflection of the disease itself. After chemotherapy-induced cytopenias or in the face of accompanying immunodeficiency, infection is usually the cause of fever. In patients with "fever of unknown origin," lymphoma, particularly Hodgkin lymphoma, should be considered. Occasionally, primary myelofibrosis, acute leukemia, advanced myelodysplastic syndrome, and other lymphomas may also cause fever. In rare patients with severe pernicious

TABLE 1-1. Findings That May Lead to a Hematology Consultation

Decreased hemoglobin concentration (anemia)
Increased hemoglobin concentration (polycythemia)
Elevated serum ferritin level
Leukopenia or neutropenia
Immature granulocytes or nucleated red cells in the blood
Pancytopenia
Granulocytosis: neutrophilia, eosinophilia, basophilia, or mastocytosis
Monocytosis
Lymphocytosis
Lymphadenopathy
Splenomegaly
Hypergammaglobulinemia: monoclonal or polyclonal
Purpura
Thrombocytopenia
Thrombocytosis
Exaggerated bleeding: spontaneous or trauma related
Prolonged partial thromboplastin or prothrombin coagulation times
Venous thromboembolism
Thrombophilia
Obstetrical adverse events (e.g., recurrent fetal loss, stillbirth, and HELLP syndrome)

HELLP, *h*emolytic anemia, *e*levated *l*iver enzymes, and *l*ow *p*latelet count.

TABLE 1-2. Criteria of Performance Status (Karnofsky Scale)⁴

Able to carry on normal activity; no special care is needed.	
100%	Normal; no complaints, no evidence of disease
90%	Able to carry on normal activity; minor signs or symptoms of disease
80%	Normal activity with effort; some signs or symptoms of disease
Unable to work; able to live at home, care for most personal needs; a varying amount of assistance is needed.	
70%	Cares for self; unable to carry on normal activity or to do active work
60%	Requires occasional assistance but is able to care for most personal needs
50%	Requires considerable assistance and frequent medical care
Unable to care for self; requires equivalent of institutional or hospital care; disease may be progressing rapidly.	
40%	Disabled; requires special care and assistance
30%	Severely disabled; hospitalization is indicated though death not imminent
20%	Very sick; hospitalization necessary; active supportive treatment necessary
10%	Moribund; fatal processes progressing rapidly
0%	Dead

Adapted with permission from Mor V, Laliberte L, Morris JN, Wiemann M: The Karnofsky performance status scale: An examination of its reliability and validity in a research setting *Cancer* 1984 May 1; 53(9):2002–2007.

TABLE 1-3. Eastern Cooperative Oncology Group Performance Status⁵

Grade	Activity
0	Fully active, able to carry on all predisease performance without restriction
1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light housework, office work
2	Ambulatory and capable of all self-care but unable to carry out any work activities; up and about more than 50% of waking hours
3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours
4	Completely disabled; cannot carry on any self-care; totally confined to bed or chair
5	Dead

Oken MM, Creech RH, Tormey DC, et al: Toxicity and response criteria of the Eastern Cooperative Oncology Group. *Am J Clin Oncol*.

anemia or hemolytic anemia, fever may be present. *Chills* may accompany severe hemolytic processes and the bacteremia that may complicate the immunocompromised or neutropenic patient. *Night sweats* suggest the presence of low-grade fever and may occur in patients with lymphoma or leukemia.

Fatigue, *malaise*, and *lassitude* are such common accompaniments of both physical and emotional disorders that their evaluation is complex and often difficult. In patients with serious disease, these symptoms may be readily explained by fever, muscle wasting, or other associated findings. Patients with moderate or severe anemia frequently complain of fatigue, malaise, or lassitude and these symptoms may accompany the hematologic malignancies. Fatigue or lassitude may occur also with iron deficiency even in the absence of sufficient anemia to account for the symptom. In slowly developing chronic anemias, the patient may not recognize reduced exercise tolerance, or other loss of physical capabilities except in retrospect, after a remission or a cure has been induced by appropriate therapy. Anemia may be responsible for more symptoms than has been traditionally recognized, as suggested by the remarkable improvement in quality of life of most uremic patients treated with erythropoietin.

Weakness may accompany anemia or the wasting of malignant processes, in which cases it is manifest as a general loss of strength or reduced capacity for exercise. The weakness may be localized as a result of neurologic complications of hematologic disease. In vitamin B₁₂ deficiency (e.g., pernicious anemia), there may be weakness of the lower extremities, accompanied by numbness, tingling, and unsteadiness of gait. Peripheral neuropathy also occurs with monoclonal immunoglobulinemias. Weakness of one or more extremities in patients with leukemia, myeloma, or lymphoma may signify central or peripheral nervous system invasion or compression as a result of vertebral collapse, a paraneoplastic syndrome (e.g., encephalitis), or brain or meningeal involvement. Myopathy secondary to malignancy occurs with the hematologic malignancies and is usually manifest as weakness of proximal muscle groups. Foot drop or wrist drop may occur in lead poisoning, amyloidosis, systemic autoimmune diseases, or as a complication of vincristine therapy. Paralysis may occur in acute intermittent porphyria.

SPECIFIC SYMPTOMS OR SIGNS

Nervous System

Headache may be the result of a number of causes related to hematologic diseases. Anemia or polycythemia may cause mild to severe headache.

Invasion or compression of the brain by leukemia or lymphoma, or opportunistic infection of the central nervous system by *Cryptococcus* or *Mycobacterium* species, may also cause headache in patients with hematologic malignancies. Hemorrhage into the brain or subarachnoid space in patients with thrombocytopenia or other bleeding disorders may cause sudden, severe headache.

Paresthesias may occur because of peripheral neuropathy in pernicious anemia or secondary to hematologic malignancy or amyloidosis. They may also result from therapy with vincristine.

Confusion may accompany malignant or infectious processes involving the brain, sometimes as a result of the accompanying fever. Confusion may also occur with severe anemia, hypercalcemia (e.g., myeloma), thrombotic thrombocytopenic purpura, or high-dose glucocorticoid therapy. Confusion or apparent senility may be a manifestation of pernicious anemia. Frank psychosis may develop in acute intermittent porphyria or with high-dose glucocorticoid therapy.

Impairment of consciousness may be a result of increased intracranial pressure secondary to hemorrhage or leukemia or lymphoma in the central nervous system. It may also accompany severe anemia, polycythemia, hyperviscosity secondary, usually, to an immunoglobulin (Ig) M monoclonal protein (uncommonly IgA or IgG) in the plasma, or a leukemic hyperleukocytosis syndrome, especially in chronic myelogenous leukemia.

Eyes

Conjunctival plethora is a feature of polycythemia and pallor a result of anemia. Occasionally blindness may result from retinal hemorrhages secondary to severe anemia and thrombocytopenia or blurred vision resulting from severe hyperviscosity resulting from macroglobulinemia or extreme hyperleukocytosis of leukemia. Partial or complete visual loss can stem from retinal vein or artery thrombosis. Diplopia or disturbances of ocular movement may occur with orbital tumors or paralysis of the third, fourth, or sixth cranial nerves because of compression by tumor, especially extranodal lymphoma, extramedullary myeloma, or myeloid (granulocytic) sarcoma.

Ears

Vertigo, tinnitus, and “roaring” in the ears may occur with marked anemia, polycythemia, hyperleukocytic leukemia, or macroglobulinemia-induced hyperviscosity. Ménière disease was first described in a patient with acute leukemia and inner ear hemorrhage.

Nasopharynx, Oropharynx, and Oral Cavity

Epistaxis may occur in patients with thrombocytopenia, acquired or inherited platelet function disorders, and von Willebrand disease. *Anosmia* or *olfactory hallucinations* occur in pernicious anemia. The nasopharynx may be invaded by a granulocytic sarcoma or extranodal lymphoma; the symptoms are dependent on the structures invaded. The paranasal sinuses may be involved by opportunistic organisms, such as fungus in patients with severe, prolonged neutropenia. *Pain or tingling in the tongue* occurs in pernicious anemia and may accompany severe iron deficiency or vitamin deficiencies. *Macroglossia* occurs in amyloidosis. *Bleeding gums* may occur with bleeding disorders. Infiltration of the gingiva with leukemic cells occurs notably in acute monocytic leukemia. *Ulceration* of the tongue or oral mucosa may be severe in the acute leukemias or in patients with severe neutropenia. *Dryness of the mouth* may be caused by hypercalcemia, secondary, for example, to myeloma. *Dysphagia* may be seen in patients with severe mucous membrane atrophy associated with chronic iron-deficiency anemia.

Neck

Painless swelling in the neck is characteristic of lymphoma but may be caused by a number of other diseases as well. Occasionally, the enlarged

lymph nodes of lymphomas may be tender or painful because of secondary infection or rapid growth. Painful or tender lymphadenopathy is usually associated with inflammatory reactions, such as infectious mononucleosis or suppurative adenitis. *Diffuse swelling* of the neck and face may occur with obstruction of the superior vena cava due to lymphomatous compression.

Chest and Heart

Both *dyspnea* and *palpitations*, usually on effort but occasionally at rest, may occur because of anemia or pulmonary embolism. *Congestive heart failure* may supervene, and *angina pectoris* may become manifest in anemic patients. The impact of anemia on the circulatory system depends in part on the rapidity with which it develops, and chronic anemia may become severe without producing major symptoms; with severe acute blood loss, the patient may develop shock with a nearly normal hemoglobin level, prior to compensatory hemodilution. *Cough* may result from enlarged mediastinal nodes compressing the trachea or bronchi. *Chest pain* may arise from involvement of the ribs or sternum with lymphoma or multiple myeloma, nerve-root invasion or compression, or herpes zoster; the pain of herpes zoster usually precedes the skin lesions by several days. Chest pain with inspiration suggests a pulmonary infarct, as does *hemoptysis*. *Tenderness of the sternum* may be quite pronounced in chronic myelogenous or acute leukemia, and occasionally in primary myelofibrosis, or if intramedullary lymphoma or myeloma proliferation is rapidly progressive.

Gastrointestinal System

Dysphagia has already been mentioned under “Nasopharynx, Oropharynx, and Oral Cavity” above. *Anorexia* frequently occurs but usually has no specific diagnostic significance. Hypercalcemia and azotemia cause anorexia, nausea, and vomiting. A variety of ill-defined gastrointestinal complaints grouped under the heading “indigestion” may occur with hematologic diseases. *Abdominal fullness*, *premature satiety*, *belching*, or *discomfort* may occur because of a greatly enlarged spleen, but such splenomegaly may also be entirely asymptomatic. *Abdominal pain* may arise from intestinal obstruction by lymphoma, retroperitoneal bleeding, lead poisoning, ileus secondary to therapy with the *vinca* alkaloids, acute hemolysis, allergic purpura, the abdominal crises of sickle cell disease, or acute intermittent porphyria. *Diarrhea* may occur in pernicious anemia. It also may be prominent in the various forms of intestinal malabsorption, although significant malabsorption may occur without diarrhea. In small-bowel malabsorption, steatorrhea may be a notable feature. Malabsorption may be a manifestation of small-bowel lymphoma. *Gastrointestinal bleeding* related to thrombocytopenia or other bleeding disorder may be occult but often is manifest as *hematemesis* or *melenas*. *Hematochezia* can occur if a bleeding disorder is associated with a colonic lesion. *Constipation* may occur in the patient with hypercalcemia or in one receiving treatment with the *vinca* alkaloids.

Genitourinary and Reproductive Systems

Impotence or *bladder dysfunction* may occur with spinal cord or peripheral nerve damage caused by one of the hematologic malignancies or with pernicious anemia. Priapism may occur in hyperleukocytic leukemia, essential thrombocythemia, or sickle cell disease. *Hematuria* may be a manifestation of hemophilia A or B. *Red urine* may also occur with intravascular hemolysis (hemoglobinuria), myoglobinuria, or porphyria. Injection of antihypertensive drugs or ingestion of drugs such as phenazopyridine (Pyridium) regularly causes the urine to turn red. The use of deferoxamine mesylate (Desferal) may result in rust-colored urine. *Amenorrhea* may also be induced by certain drugs, such as antimetabolites or alkylating agents. *Menorrhagia* is a common cause of iron deficiency, and care must be taken to obtain a history of the

number of prior pregnancies and an accurate assessment of the extent of menstrual blood loss. Semiquantification can be obtained from estimates of the number of days of heavy bleeding (usually <3), the number of days of any bleeding (usually <7), number of tampons or pads used (requirement for double pads suggests excessive bleeding), degree of blood soaking, and clots formed, and inquiries such as, “Have you experienced a gush of blood when a tampon is removed?” However, an objective distinction between menorrhagia (loss of more than 80 mL blood per period) and normal blood loss can best be made by a visual assessment technique using pictorial charts of towels or tampons.⁶ Menorrhagia may occur in patients with bleeding disorders.

Back and Extremities

Back pain may accompany acute hemolytic reactions or be a result of involvement of bone or the nervous system in acute leukemia or aggressive lymphoma. It is one of the most common manifestations of myeloma.

Arthritis or *arthralgia* may occur with gout secondary to increased uric acid production in patients with hematologic malignancies, especially acute lymphocytic leukemia in childhood, myelofibrosis, myelodysplastic syndrome, and hemolytic anemia. They also occur in the plasma cell dyscrasias, acute leukemias, and sickle cell disease without evidence of gout, and in allergic purpura. Arthritis may accompany hemochromatosis, although the association has not been carefully established. In the latter case the arthritis starts typically in the small joints of the hand (second and third metacarpal joints), and episodes of acute synovitis may be related to deposition of calcium pyrophosphate dehydrate crystals. Hemarthroses in patients with severe bleeding disorders cause marked joint pain. Autoimmune diseases may present as anemia and/or thrombocytopenia, and arthritis appears as a later manifestation. *Shoulder pain* on the left may be a result of infarction of the spleen and on the right of gall bladder disease associated with chronic hemolytic anemia such as hereditary spherocytosis. *Bone pain* may occur with bone involvement by the hematologic malignancies; it is common in the congenital hemolytic anemias, such as sickle cell anemia, and may occur in myelofibrosis. In patients with Hodgkin lymphoma, ingestion of alcohol may induce pain at the site of any lesion, including those in bone. *Edema* of the lower extremities, sometimes unilateral, may occur because of obstruction to veins or lymphatics by lymphomatous masses or from deep venous thrombosis. The latter can also cause edema of the upper extremities.

Skin

Skin manifestations of hematologic disease may be of great importance; they include changes in texture or color, itching, and the presence of specific or nonspecific lesions. The skin in iron-deficient patients may become dry, the hair dry and fine, and the nails brittle. In hypothyroidism, which may cause anemia, the skin is dry, coarse, and scaly. *Jaundice* may be apparent with pernicious anemia or congenital or acquired hemolytic anemia. The skin of patients with pernicious anemia is said to be “lemon yellow” because of the simultaneous appearance of jaundice and pallor. Jaundice may also occur in patients with hematologic malignancies, especially lymphomas, as a result of liver involvement or biliary tract obstruction. *Pallor* is a common accompaniment of anemia, although some severely anemic patients may not appear pale. Erythromelalgia may be a troublesome complication of polycythemia vera. Patchy plaques or widespread *erythroderma* occur in cutaneous T-cell lymphoma (especially Sézary syndrome) and in some cases of chronic lymphocytic leukemia or lymphocytic lymphoma. The skin is often involved, sometimes severely, in graft-versus-host disease following hematopoietic cell transplantation. Patients with hemochromatosis may have bronze or grayish pigmentation of the skin. *Cyanosis* occurs

with methemoglobinemia, either hereditary or acquired; sulfhemoglobinemia; abnormal hemoglobins with low oxygen affinity; and primary and secondary polycythemia. Cyanosis of the ears or the fingertips may occur after exposure to cold in individuals with cryoglobulins or cold agglutinins.

Itching may occur in the absence of any visible skin lesions in Hodgkin lymphoma and may be extreme. Mycosis fungoides or other lymphomas with skin involvement may also present as itching. A significant number of patients with polycythemia vera will complain of itching after bathing.

Petechiae and *ecchymoses* are most often seen in the extremities in patients with thrombocytopenia, nonthrombocytopenic purpura, or acquired or inherited platelet function abnormalities and von Willebrand disease. Unless secondary to trauma, these lesions usually are painless; the lesions of psychogenic purpura and erythema nodosum are painful. *Easy bruising* is a common complaint, especially among women, and when no other hemorrhagic symptoms are present, usually no abnormalities are found after detailed study. This symptom may, however, indicate a mild hereditary bleeding disorder, such as von Willebrand disease or one of the platelet disorders. *Infiltrative lesions* may occur in the leukemias (leukemia cutis) and lymphomas (lymphoma cutis) and are sometimes the presenting complaint. Monocytic leukemia has a higher frequency of skin infiltration than other forms of leukemia. *Necrotic lesions* may occur with intravascular coagulation, purpura fulminans, and warfarin-induced skin necrosis, or rarely with exposure to cold in patients with circulating cryoproteins or cold agglutinins.

Leg ulcers are a common complaint in sickle cell anemia and occur rarely in other hereditary anemias.

DRUGS AND CHEMICALS

Drugs

Drug therapy, either self-prescribed or ordered by a physician, is extremely common in our society. Drugs often induce or aggravate hematologic disease, and it is therefore essential that a careful history of drug ingestion, including beneficial and adverse reactions, should be obtained from all patients. Drugs taken regularly, including nonprescription medications, often become a part of the patient’s way of life and are forgotten or are not recognized as “drugs.”

Agents such as aspirin, laxatives, tranquilizers, medicinal iron, vitamins, other nutritional supplements, and sedatives belong to this category. Furthermore, drugs may be ingested in unrecognized form, such as antibiotics in food or quinine in tonic water. Specific, persistent questioning, often on several occasions, may be necessary before a complete history of drug use is obtained. It is very important to obtain detailed information on alcohol consumption from every patient. The four “CAGE” questions—about needing to cut down, being annoyed by criticism, having guilt feelings, and requiring a drink as a morning eye-opener—provide an effective approach to the history of alcohol use. Patients should also be asked about the use of recreational drugs. The use of “alternative medicines” and herbal medicines is common, and many patients will not consider these medications or may actively withhold information about their use. Nonjudgmental questioning may be successful in identifying agents in this category that the patient is taking. Some patients equate the term “drugs,” as opposed to “medicines,” with illicit drugs. Establishing that the examiner is interested in all forms of ingestants—prescribed drugs, self-remedies, alternative remedies, etcetera—is important to ensure getting the information required.

Chemicals

In addition to drugs, most people are exposed regularly to a variety of chemicals in the environment, some of which may be potentially harmful

agents and result in a deleterious hematologic effect, such as anemia or leukopenia. An occupational history should explore exposure to potentially harmful chemicals. This information should be supplemented by inquiries about hobbies and other interests that result in work with chemicals, such as glues and solvents. When a toxin is suspected, the patient's daily activities and environment should be carefully reviewed, as significant exposure to toxic chemicals may occur incidentally.

VACCINATION

Vaccinations can be complicated by acute immune thrombocytopenia. In infants, this is most notable after measles, mumps, rubella (MMR) vaccine. This occurrence is approximately 1 in 25,000 children vaccinated, occurs within 6 weeks of vaccination, and in the majority of occurrences is self-limited. There is no evidence that children with antecedent immune thrombocytopenia are at risk of recurrence after MMR vaccination.⁷ Analysis, thus far, shows rare cases in following administration of other vaccines (hepatitis A, diphtheria-pertussis-tetanus, or varicella) administered to older children and adolescents and significant risk has not been ascertained.⁸

NUTRITION

Children who are breastfed without iron supplementation may develop iron-deficiency anemia. Nutritional information can be useful in deducing the possible role of dietary deficiency in anemia. The avoidance of certain food groups, as might be the case with vegetarians, or the ingestion of uncooked fish can be clues to the pathogenesis of megaloblastic anemia.

FAMILY HISTORY

A carefully obtained family history may be of great importance in the study of patients with hematologic disease (Chap. 10). In the case of hemolytic disorders, questions should be asked regarding jaundice, anemia, and gallstones in relatives. In patients with disorders of hemostasis or venous thrombosis, particular attention must be given to bleeding manifestations or venous thromboembolism in family members. In the case of autosomal recessive disorders such as pyruvate kinase deficiency, the parents are usually not affected, but a similar clinical syndrome may have occurred in siblings. It is particularly important to inquire about siblings who may have died in infancy, as these may be forgotten, especially by older patients. When sex-linked inheritance is suspected, it is necessary to inquire about symptoms in the maternal grandfather, maternal uncles, male siblings, and nephews. In patients with disorders with dominant inheritance, such as hereditary spherocytosis, one may expect to find that one parent and possibly siblings and children of the patient have stigmata of the disease. Ethnic background may be important in the consideration of certain diseases such as α - and β -thalassemia, sickle cell anemia, glucose-6-phosphate dehydrogenase deficiency, hemoglobin E, and other inherited disorders that are prevalent in specific geographic areas, such as the Mediterranean basin or Southeast Asia.

SEXUAL HISTORY

Because of the frequency of infections with the human immunodeficiency viruses, it is important to ascertain the sexual behavior of the patient, especially risk factors for transmission of HIV.

PREVENTIVE HEMATOLOGY

Ideally, the physician's goal is to prevent illness, and opportunities exist for hematologists to prevent the development of hematologic disorders. These opportunities include identification of individual genetic risk factors and avoidance of situations that may make a latent disorder

manifest. Prophylactic therapy, as for example in avoiding venous stasis in patients heterozygous for protein C deficiency or administering prophylactic heparin at the time of major surgery, is a more immediate aspect of prevention because it depends on the physician's intervention. Hematologists may also prevent disease by reinforcing community medicine efforts. Examples include fostering the elimination of sources of environmental lead that may result in childhood anemia. Prenatal diagnosis can provide information to families as to whether a fetus is affected with a hematologic disorder.

PHYSICAL EXAMINATION

A detailed physical examination should be performed on every patient, with sufficient attention paid to all systems so as to obtain a full evaluation of the general health of the individual. The skin, eyes, tongue, lymph nodes, skeleton, spleen and liver, and nervous system are especially pertinent to hematologic disease and therefore deserve special attention.

SKIN

Pallor and Flushing

The color of the skin is a result of the pigment contained therein and to the blood flowing through the skin capillaries. The component of skin color related to the blood may be a useful guide to anemia or polycythemia, as pallor may result when the hemoglobin level is reduced, and redness when the hemoglobin level is increased. The amount of pigment in the skin modifies skin color and can mislead the clinician, as in individuals with pallor resulting from decreased pigment, or make skin color useless as a guide because of the intense pigmentation present.

Alterations in blood flow and in hemoglobin content may change skin color; this, too, can mislead the clinician. Thus emotion may cause either pallor or blushing. Exposure of the skin to cold or heat may similarly cause pallor or blushing. Chronic exposure to wind or sun may lead to permanent redness of the skin, and chronic ingestion of alcohol to a flushed face. The degree of erythema of the skin can be evaluated by pressing the thumb firmly against the skin, as on the forehead, so that the capillaries are emptied, and then comparing the color of the compressed spot with the surrounding skin immediately after the thumb is removed.

The mucous membranes and nail beds are usually more reliable guides to anemia or polycythemia than the skin. The conjunctivae and gums may be inflamed, however, and therefore not reflect the hemoglobin level, or the gums may appear pale because of pressure from the lips. The gums and the nail beds may also be pigmented and the capillaries correspondingly obscured. In some individuals, the color of the capillaries does not become fully visible through the nails unless pressure is applied to the fingertip, either laterally or on the end of the nail.

The palmar creases are useful guides to the hemoglobin level and appear pink in the fully opened hand unless the hemoglobin is 7 g/dL or less. Liver disease may induce flushing of the thenar and hypothenar eminences of the palm, even in patients with anemia.

Cyanosis

The detection of cyanosis, like the detection of pallor, may be made difficult by skin pigmentation. Cyanosis is a function of the total amount of reduced hemoglobin, methemoglobin, or sulfhemoglobin present. The minimum amounts of these pigments that cause detectable cyanosis are approximately 5 g/dL blood of reduced hemoglobin, 1.5 to 2.0 g/dL of methemoglobin, and 0.5 g/dL of sulfhemoglobin.

Jaundice

Jaundice may be observed in the skin of individuals who are not otherwise deeply pigmented or in the sclerae or the mucous membranes.

The patient should be examined in daylight rather than under incandescent or fluorescent light, because the yellow color of the latter masks the yellow color of the patient. Jaundice is a result of actual staining of the skin by bile pigment, and bilirubin glucuronide (direct-reacting or conjugated bilirubin) stains the skin more readily than the unconjugated form. Jaundice of the skin may not be visible if the bilirubin level is below 2 to 3 mg/dL. Yellow pigmentation of the skin may also occur with carotenemia, especially in young children.

Petechiae and Ecchymoses

Petechiae are small (1 to 2 mm), round, red or brown lesions resulting from hemorrhage into the skin and are present primarily in areas with high venous pressure, such as the lower extremities. These lesions do not blanch on pressure, and this can be readily demonstrated by compressing the skin with a glass microscope slide or magnifying lens. Petechiae may occasionally be elevated slightly, that is, palpable; this finding suggests vasculitis. Ecchymoses may be of various sizes and shapes and may be red, purple, blue, or yellowish green, depending on the intensity of the skin hemorrhage and its age. They may be flat or elevated; some are painful and tender. The lesions of hereditary hemorrhagic telangiectasia are small, flat, nonpulsatile, and violaceous. They blanch with pressure.

Excoriation

Itching may be intense in some hematologic disorders, such as Hodgkin lymphoma, even in the absence of skin lesions. Excoriation of the skin from scratching is the only physical manifestation of this severe symptom.

Leg Ulcers

Open ulcers or scars from healed ulcers are often found in the region of the internal or external malleoli in patients with sickle cell anemia, and, rarely, in other hereditary anemias.

Nails

Detection of pallor or rubor by examining the nails was discussed earlier. The fingernails in chronic, severe iron-deficiency anemia may be ridged longitudinally and flattened or concave rather than convex. The latter change is referred to as *koilonychia* and is uncommon in present practice.

Eyes

Jaundice, *pallor*, or *plethora* may be detected from examination of the eyes. Jaundice is usually more readily detected in the sclerae than in the skin. Ophthalmoscopic examination is also essential in patients with hematologic disease. *Retinal hemorrhages* and *exudates* occur in patients with severe anemia and thrombocytopenia. These hemorrhages are usually the typical “flame-shaped” hemorrhages, but they may be quite large and elevate the retina so that they may appear as a darkly colored tumor. Round hemorrhages with white centers are also often seen. *Dilatation of the veins* may be seen in polycythemia; in patients with macroglobulinemia, the veins are engorged and segmented, resembling link sausages.

Mouth

Pallor of the mucosa has already been discussed (see “Pallor and Flushing” above). *Ulceration* of the oral mucosa occurs commonly in neutropenic patients. In leukemia there may also be infiltration of the gums with swelling, redness, and bleeding. *Bleeding* from the mucosa may occur with a hemorrhagic disease. A dark line of lead sulfide may be deposited in the gums at the base of the teeth in lead poisoning. The *tongue* may be completely smooth in pernicious anemia and iron-deficiency anemia. Patients with an upper dental prosthesis may also have

papillary atrophy, presumably on a mechanical basis. The tongue may be smooth and red in patients with nutritional deficiencies. This may be accompanied by fissuring at the corners of the mouth, but fissuring may also be caused by ill-fitting dentures. An enlarged tongue, abnormally firm to palpation, may indicate the presence of primary amyloidosis.

Lymph Nodes

Lymph nodes are widely distributed in the body, and in disease, any node or group of nodes may be involved. The major concern on physical examination is the detection of enlarged or tender nodes in the cervical, supraclavicular, axillary, epitrochlear, inguinal, or iliofemoral regions. Under normal conditions in adults, the only readily palpable lymph nodes are in the inguinal region, where several firm nodes 0.5 to 2.0 cm long are normally attached to the dense fascia below the inguinal ligament and in the femoral triangle. In children, multiple small (0.5 to 1.0 cm) nodes may be palpated in the cervical region as well. Supraclavicular nodes may sometimes be palpable only when the patient performs the Valsalva maneuver.

Enlarged lymph nodes are ordinarily detected in the superficial areas by palpation, although they are sometimes large enough to be seen. Palpation should be gentle and is best performed with a circular motion of the fingertips, using slowly increasing pressure. Tender lymph nodes usually indicate an inflammatory etiology, although rapidly proliferative lymphoma may be tender to palpation.

Nodes too deep to palpate may be detected by specific imaging procedures, including computerized tomography, magnetic resonance imaging, ultrasound studies, gallium scintigraphy, and positron emission tomography.^{9,10}

Chest

Increased rib or sternal tenderness is an important physical sign often ignored. Increased bone pain may be generalized, as in leukemia, or spotty, as in plasma cell myeloma or in metastatic tumors. The superficial surfaces of all bones should be examined thoroughly by applying intermittent firm pressure with the fingertips to locate potential areas of disease.

Spleen

The normal adult spleen is usually not palpable on physical examination, but occasionally the tip may be felt.¹¹ Palpability of the normal spleen may be related to body habitus, but there is disagreement on this point. Percussion, palpation, or a combination of these two methods may detect enlarged spleens.¹² Some enlarged spleens may be visible by protrusion of the abdominal wall.

The normal spleen weighs approximately 150 g and lies in the peritoneal cavity against the diaphragm and the posterolateral abdominal wall at the level of the lower three ribs. As it enlarges it remains close to the abdominal wall, while the lower pole moves downward, anteriorly, and to the right. Spleens enlarged only 40 percent above normal may be palpable, but significant splenic enlargement may occur and the organ still not be felt on physical examination. A good but imperfect correlation has been reported between spleen size estimated from radioisotope scanning or ultrasonography and spleen weight determined after splenectomy or at autopsy.¹³ Although it is common to fail to palpate an enlarged spleen on physical examination, palpation of a normal-sized spleen is unusual, and therefore a palpable spleen is usually a significant physical finding.

An enlarged spleen lies just beneath the abdominal wall and can be identified by its movement during respiration. The splenic notch may be evident if the organ is moderately enlarged. During the examination the patient lies in a relaxed, supine position. The examiner, standing on the patient's right, lightly palpates the left upper abdomen with the

right hand while exerting pressure forward with the palm of the left hand placed over the lower ribs posterolaterally. This action permits the spleen to descend and be felt by the examiner's fingers. If nothing is felt, the palpation should be performed repeatedly, moving the examining hand approximately 2 cm toward the inguinal ligament each time. It is often advantageous to carry out the examination initially with the patient lying on the right side with left knee flexed and to repeat it with the patient supine.

It is not always possible to be sure that a left upper quadrant mass is spleen; masses in the stomach, colon, kidney, or pancreas may mimic splenomegaly on physical examination. When there is uncertainty regarding the nature of a mass in the left upper quadrant, imaging procedures will usually permit accurate diagnosis.^{13–15}

Liver

Palpation of the edge of the liver in the right upper quadrant of the abdomen is commonly used to detect hepatic enlargement, although the inaccuracies of this method have been demonstrated. It is necessary to determine both the upper and lower borders of the liver by percussion in order to properly assess liver size.^{16,17} The normal liver may be palpable as much as 4 to 5 cm below the right costal margin but is usually not palpable in the epigastrium. The height of liver dullness is best measured in a specific line 8, 10, or 12 cm to the right of the midline. Techniques should be standardized so that serial measurements can be made. The vertical span of the normal liver determined in this manner will range approximately 10 cm in an average-size man and approximately 2 cm smaller in a woman. Because of variations introduced by technique, each physician should determine the normal area of liver dullness by the physician's own procedure. Correlation of radioisotope imaging data with results from routine physical examinations indicates that often a liver of normal size is considered enlarged on physical examination and an enlarged liver is considered normal. Ultrasonography and computed tomography measurements are useful in determining size and demonstrating localized infiltrative lesions.^{18–20}

Nervous System

A thorough evaluation of neurologic function is necessary in many patients with hematologic disease. Vitamin B₁₂ deficiency impairs cerebral, olfactory, spinal cord, and peripheral nerve function, and severe chronic deficiency may lead to irreversible neurologic degeneration. Leukemic meningitis is often manifested by headache, visual impairment, or cranial nerve dysfunction. Tumor growth in the brain or spinal cord compression may be caused by malignant lymphoma or plasma cell myeloma. A variety of neurologic abnormalities may develop in patients with leukemias, lymphomas, and myeloma as a consequence of tumor infiltration, bleeding, infection, or a paraneoplastic syndrome. Essential monoclonal gammopathy is associated with several types of sensory

and motor neuropathies. Polyneuropathy is a feature of POEMS, a syndrome marked by polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes.

Joints

Deformities of the knees, elbows, ankles, shoulders, wrists, or hips may be the result of repeated hemorrhage in patients with hemophilia A, hemophilia B, or severe factor VII deficiency. Often, a target joint is prominently affected.

CHAPTER 2

EXAMINATION OF BLOOD CELLS

Daniel H. Ryan

SUMMARY

Determining a patient's blood cell counts and examining the appearance of cells on a blood film is central to the diagnosis of blood cell diseases and can give important information about numerous other degenerative, inflammatory, and neoplastic diseases that are reflected in quantitative or qualitative changes of blood cells. The quantity and quality of blood cells reflects the aggregate function of the major blood forming tissue, the marrow, and is thus an essential component of diagnosis and followup of primary hematological disorders. The decision to perform a marrow examination, and the types of special studies required, follow from a careful analysis of blood cells. Currently available automated blood cell analyzers continue to evolve and are the mainstay of blood cell counting, providing an increasing array of novel quantitative parameters, and flagging of abnormal samples that need manual microscopic review. The blood provides a unique example of a tissue that can be readily analyzed with a degree of quantitative detail unavailable in any other organ system.

INTRODUCTION

The blood is examined so as to answer these questions: Is the marrow producing appropriate numbers of mature cells in the major hematopoietic lineages? Is the development of each hematopoietic lineage qualitatively normal? Are there abnormal (e.g., leukemia or lymphoma) cells in the blood? Quantitative measures available from automated cell counters are reliable and provide a rapid and cost-effective way to screen for primary or secondary disturbances of hematopoiesis. Light microscopic observation of the blood film is essential to confirm certain quantitative results and to investigate qualitatively abnormal differentiation of the hematopoietic lineages. Based on examination of the blood, the physician is directed toward a more focused assessment of marrow function or to systemic disorders that secondarily involve the hematopoietic system.

Acronyms and Abbreviations: Chr, reticulocyte-specific hemoglobin content; EDTA, ethylenediaminetetraacetic acid; fl, femtoliter; FRC, fragmented red cell counts; Hct, hematocrit; HYPO%, percentages of red cells falling below a cutoff for hemoglobin concentration; %HypoHe, percentages of red cells falling below a cutoff for hemoglobin content; Ig, immunoglobulin; MCH, mean cell hemoglobin; MCHC, mean cell hemoglobin concentration; MCV, mean cell volume; MPV, mean platelet volume; NHANES, National Health and Nutrition Examination Survey; NK, natural killer; PDW, platelet volume distribution width; RBC, red blood cell; RDW, red cell distribution width; RET-He, reticulocyte-specific hemoglobin content.

The complete blood count is a necessary part of the diagnostic evaluation in a broad variety of clinical conditions. Similarly, the leukocyte differential count and examination of the blood film, in spite of limitations as a screening test for occult disease, is important in initial consideration of the differential diagnosis in most ill patients. Although quantitative and qualitative (morphologic) examination of the cells of the blood are considered separately in this chapter, the distinction between these two is not absolute, and measures once considered "qualitative" become quantitative as technology advances.

QUANTITATIVE MEASURES OF CELLS IN THE BLOOD

PRINCIPLES OF AUTOMATED BLOOD CELL ANALYSIS

Automated blood cell analysis is the cornerstone of the modern hematology laboratory, allowing rapid, cost-effective, and accurate analysis of the cells of the blood, including new parameters with diagnostic utility. The morphologic and functional complexity of blood cells requires direct microscopic examination of a stained blood film by a trained observer. However, it is possible to use automated techniques to analyze and report on the majority of samples, using defined criteria ("flags") to select those that need further microscopic review. Automated hematology analyzers typically incorporate multiple proprietary software flags based on acceptability criteria related to pattern recognition in the multiparameter displays or comparison of different detection modes for the same cell type. These are frequently updated in software or when new models are introduced to improve sensitivity and specificity. In this way, instruments identify samples that contain cells or abnormalities the instrument cannot definitively identify, so that a skilled morphologist can visually evaluate that specimen. Some of these flags can be adjusted or suppressed by the user to achieve an appropriate balance that minimizes both false positives and false negatives. The optimum balance is dependent on the patient population examined. Guidelines for manual smear review based on comparative data have been published, based on instruments then in common use.¹ Protocols for evaluating and adjusting flagging criteria within an individual laboratory have been described.² Manual review may consist of a scan of the blood film, a more detailed blood film examination including leukocyte differential count, or a physician's review, based on laboratory defined criteria.³ The proportion of samples requiring manual blood film review differs among instruments and the type of patient population tested. Studies show a 10 to 30 percent manual review rate,⁴⁻⁶ with a false negative rate (i.e., abnormal samples that were not flagged for review) varying from approximately 3 percent¹ to 10-14 percent.⁴ Most of the false negatives with current instrumentation are related to red cell and platelet morphology with relatively limited diagnostic significance.⁴ Continued improvement in methodology and increased sophistication of data analysis will result in further reduction of unnecessary manual smear reviews. Depending on workload and space considerations, laboratories may choose to link automated hematology analyzers with automated blood film preparation and automated image analyzers to facilitate manual morphologic review of cells by traditional light microscopy or online review of digitized images.⁷ These instruments can provide a provisional differential count with good accuracy,⁸ although typically final classification of problematic cells is performed by a technologist or physician.

The characteristics of automated hematology analyzer systems have been reviewed.⁹ A detailed description of individual instruments is beyond the scope of this chapter, but the general principles employed by state-of-the-art instrumentation are summarized below. The major

analytical challenges are the frequency of the different cell types, which vary over many orders of magnitude, from red cells (millions per μL) to basophils (dozens per μL), and the complexity of the structure of normal and abnormal blood cells. Over the past several decades, instruments have become increasingly sophisticated with the use of multiple parameters to produce more precise results in the great majority of patient samples. In a typical automated hematology analyzer, the blood sample is aspirated and separated into different fluidic streams. The streams are mixed with various buffers that accomplish specific purposes in the analysis, for instance, using differential lysis to distinguish subsets of leukocytes, reagents to measure hemoglobin or detect myeloperoxidase containing leukocytes, and various fluorescent dyes. Measurements of each fluidic stream are made in flow as the sample passes through a series of detectors in what are essentially modified flow cytometers (Chap. 3). Commonly used principles include light scatter at various angles, electrical impedance and conductivity, and fluorescence or light absorption of cells stained in flow. Light scatter yields information about cell size (using scatter at low-incident angles), nuclear lobulation, and cytoplasmic granularity (using high-angle light scatter) and refractive index, with polarization of the scattered light as an additional parameter. If red cells are converted to spherocytes by the buffer solution to eliminate the variability of cell shape, light scatter at different angles can provide information about hemoglobin content, as well as size of individual red cells. Cell size is also estimated by measuring change in electrical resistance, which is proportional to cell size as cells enter a narrow orifice through which a direct current is maintained, the original Coulter principle, named for Wallace Coulter who developed the electronic particle counter.¹⁰ Radiofrequency capacitance measurement yields additional intracellular structural information that complements the direct current measurement. Differential lysis with detergents of varying strength or pH is used to separate certain leukocyte types, such

as basophils and immature granulocytic cells, from the major normal blood cell types. In addition, nucleic-acid-binding fluorescent dyes incorporated into the lysis buffer measure total RNA plus DNA in the cells and are used in some analyzers to help differentiate leukocyte types. Fluorescence measurements after staining with RNA binding dyes are commonly used to detect and subclassify reticulocytes and platelets. Light absorption is the principle used for hemoglobin measurement and in some instruments for identifying peroxidase-positive granulocytes. Instruments rely on a combination of techniques for accuracy and precision¹¹ (Fig. 2-1). Complex algorithms are invoked to determine whether the distribution of variables for a specific result or for the specimen as a whole fit sufficiently within an expected variable space so that the results can be reported with high confidence, or whether the specimen should be “flagged” for further analysis or manual blood film review (Fig. 2-2). There is significant overlap in methodology between automated hematology analyzers and flow cytometers (flow cytometers are discussed in Chap. 3). The latter are distinguished by extensive use of fluorochrome tagged antibodies to identify cell subtypes. These instruments have replaced laborious manual work, but also demand increasing interpretation skills on the part of laboratory technologists. Automated blood analyzers have been adapted to accurately count the smaller numbers of blood cells typically found in body fluids,¹² but accurate differential counts¹³ and detection of blast cells in fluids of patients¹⁴ remains a challenge.

Point of care “bedside” testing is far more challenging in hematology than for typical clinical chemistry analytes for many of the reasons described above. Instruments have been described for bedside measurement of hemoglobin, total leukocytes, three-part leukocyte differential count, malaria parasitemia, and CD4+ T-cell count, mainly targeting clinical settings with limited access to standard laboratory testing. More work remains to be done to demonstrate the reliability and clinical impact of such testing strategies.¹⁵

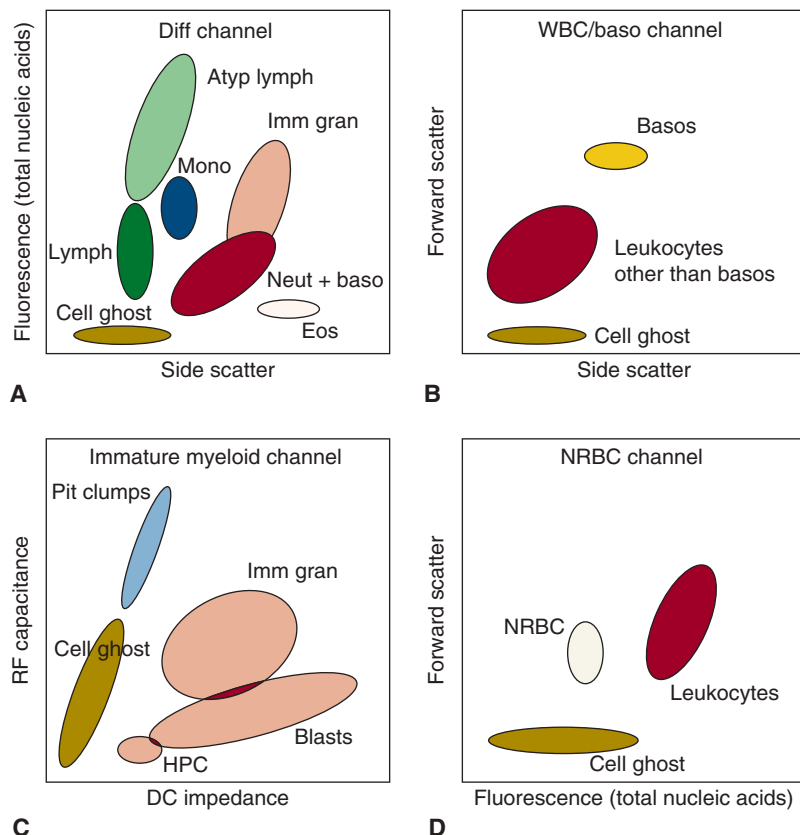

Figure 2-1. Schematic of multiparameter cell discrimination in an automated hematology analyzer. The Sysmex XE-2100 is used as an example, in which leukocytes are discriminated by (A) DNA/RNA fluorescence using a polymethine dye versus high-angle (side) light scatter in lysed blood; (B) side scatter versus low-angle (forward) light scatter after acidic lysis in a separate aliquot that preserves basophil structure; and (C) direct current (DC) impedance versus radio frequency (RF) capacitance of cells subjected to a lysis reagent that relatively preserves immature cells with lower membrane lipid content. Nucleated red blood cells (NRBC) are distinguished (D) in a lysed sample stained with nucleic acid dye where leukocyte nuclei have detectably higher DNA/RNA content than red cell nuclei. Atyp Lymph, atypical lymphocytes; Baso, basophils; Blasts, blast cells; Diff Channel, differential count channel; Eos, eosinophils; HPC, hematopoietic progenitor cells; Imm Gran, immature granulocytes; Lymph, lymphocytes; Mono, monocytes; Neut + Baso, neutrophils + basophils; Plt Clumps, platelet clumps; WBC, white blood cells.

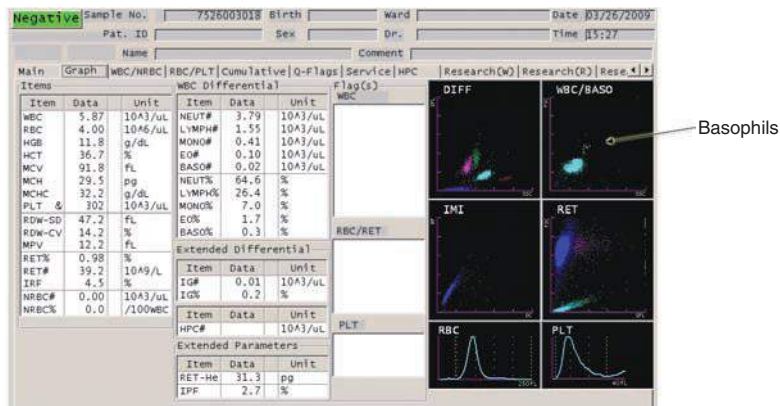

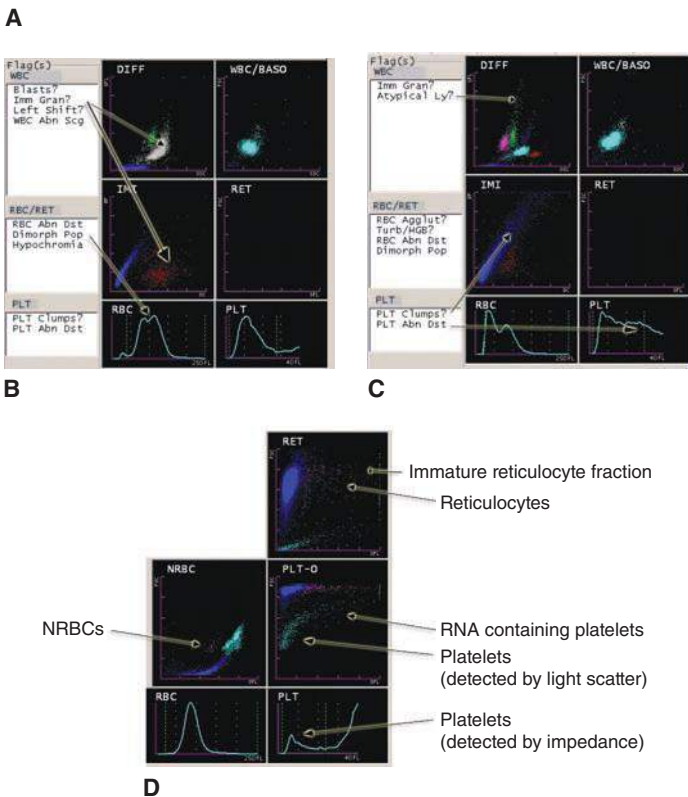

Figure 2-2. Examples of how samples containing various abnormal findings are flagged for manual review. **A.** Normal sample showing how the major variables and results are displayed. **B.** Immature granulocytes appearing on the DIFF (leukocyte differential count) and IMI (immature myeloid) histograms, as well as a dimorphic red cell population. **C.** Multiple flags, including cells in the area of atypical lymphocytes, and platelet clumps with abnormal platelet volume distribution. **D.** Appearance of nucleated red blood cells (NRBCs), reticulocytes, and reticulated platelets on a different set of parameters. This figure is not intended as a comprehensive illustration of the technical details, but serves to demonstrate that differential lysing reactions coupled with multiparameter light-scatter, impedance, capacitance, and fluorescence measurements are used to analyze blood cells in current high-throughput instruments.

AUTOMATED ANALYSIS OF RED CELLS

Some red cell parameters (for instance, mean cell volume [MCV], red cell number, hemoglobin concentration, red cell distribution width [RDW]) are directly measured, while others (for instance, hematocrit, mean cell hemoglobin [MCH], mean cell hemoglobin concentration [MCHC]) are derived from these primary measurements.

Measurement of the Red Cell Count and Hematocrit

In electronic instruments, the hematocrit (Hct; fractional volume of blood occupied by erythrocytes) is calculated from the product of direct measurements of the erythrocyte count and the MCV: $(\text{Hct } [\mu\text{L}/100 \mu\text{L}] = \text{RBC } [\times 10^{-6} / \mu\text{L}] \times \text{MCV } [\text{fL}]/10)$. Falsely elevated MCV and decreased red cell counts can be observed when red cell autoantibodies are present and retain binding capability at room temperature (cold agglutinins and some cases of autoimmune hemolytic anemia). This causes red cells to clump and affects the accuracy of both the red blood cell (RBC) count and MCV, as well as the resultant hematocrit.

The hematocrit may also be determined by subjecting the blood to sufficient centrifugal force to pack the cells while minimizing trapped extracellular fluid. This approach was traditionally done in capillary tubes filled with blood and centrifuged at very high speed in a small tabletop centrifuge, and the technique was referred to as the “microhematocrit” or informally as a “spun crit.” Before standardized methods for hemoglobin quantification were available, the hematocrit was the simplest and most accurate method for determining the fractional volume of red cells in blood and by inference the hemoglobin. However, this is a manual procedure not well adapted to routine processing in a high-volume clinical laboratory, and is affected by varying amounts of plasma trapped between red cells in the packed cell volume,¹⁶ typically about 2 to 3 percent of the packed volume.¹⁷ The hematocrit from polycythemic samples or blood containing abnormal erythrocytes (sickle cells, thalassemic red cells, iron-deficient red cells, spherocytes, macrocytes) is increased because of enhanced plasma trapping associated with increased red cell rigidity.¹⁷ Therefore, although automated hematocrit values are adjusted to be equivalent to spun hematocrit for normal

samples, in abnormal samples, the spun hematocrit may be spuriously elevated (up to 6 percent in microcytosis).¹⁸ The hemoglobin determination now is preferred to the hematocrit, because it is measured directly and is the best indicator of the oxygen-carrying capacity of the blood.

Measurement of Hemoglobin

Hemoglobin is intensely colored, and this property has been used in methods for estimating its concentration in blood. Erythrocytes contain a mixture of hemoglobin, oxyhemoglobin, carboxyhemoglobin, methemoglobin, and minor amounts of other forms of hemoglobin. To determine hemoglobin concentration in the blood, red cells are lysed and hemoglobin variants are converted to the stable compound cyanmethemoglobin for quantification by absorption at 540 nm. All forms of hemoglobin are readily converted to cyanmethemoglobin except sulfhemoglobin, which is rarely present in significant amounts. In automated blood cell counters, hemoglobin is usually measured by a modified cyanmethemoglobin or an alternate lauryl sulphate method. In practice, the major interference with this measurement is chylomicronemia, but newer instruments identify and minimize this interference. Noninvasive transcutaneous monitoring of total hemoglobin concentration, as well as methemoglobin and carboxyhemoglobin, using multiwavelength pulse oximetry has become available.¹⁹ Although these instruments offer the opportunity to track hemoglobin concentration trends in patients subject to blood loss and fluid shifts,²⁰ it is not yet clear that they have sufficient precision to guide transfusion decisions.^{21,22} Such hemoglobin measurements may be unreliable under conditions of peripheral circulatory hypoperfusion.

The hemoglobin level varies with age (Table 2-1). Chapter 7 discusses changes in hemoglobin in the neonatal period. After the first week or two of extrauterine life, the hemoglobin falls from levels of approximately 17 g/dL to levels of approximately 12 g/dL by 2 months of age. Thereafter, the levels remain relatively constant throughout the first year of life. Any child with a hemoglobin level below 11 g/dL should be considered anemic.²³ Chapter 8 discusses changes in hemoglobin concentration with pregnancy and Chap. 9 discusses changes in hemoglobin levels in older persons.

Standard Red Cell Indices

The size and hemoglobin content of erythrocytes (red cell indices), based on population averages, have traditionally been used to assist in the differential diagnosis of anemia.²⁴ A variety of newer indices based on size and hemoglobinization characteristics of red cell subpopulations are discussed in the section "Novel Red Cell and Reticulocyte Indices".

Mean Cell Volume Automated blood counters measure the MCV directly by either electrical impedance or light scatter measurements of individual red cells. The MCV has been used to guide the diagnostic workup in patients with anemia; for example, testing patients with microcytic anemia for iron deficiency or thalassemia, and those with macrocytic anemia for folate or vitamin B₁₂ deficiency. This approach has practical value, but also limitations²⁵; for instance, MCV may be normal in some older patients with pernicious anemia,²⁶ or in advanced pernicious anemia with severe red cell fragmentation,²⁷ while one-third of older patients have an elevated MCV without an evident cause.²⁸ Mathematical manipulations of various red cell indices take advantage of the trend toward relatively more severe microcytosis than hypochromia in thalassemia trait versus iron-deficiency anemia to assist in the differential diagnosis of these disorders,²⁹ particularly in high-prevalence populations where laboratory resources are limited,³⁰ but their usefulness has been questioned.³¹

Mean Cell Hemoglobin The MCH, the amount of hemoglobin per red cell, increases or decreases in parallel with the red cell volume (i.e., MCV) and generally provides similar diagnostic information,

although because this parameter is affected by both hypochromia and microcytosis, it is at least sensitive as the MCV in detecting iron-deficiency states.³² Another advantage of the MCH is the consistency across different analyzer types, as it is derived from two of the most accurately measured parameters: hemoglobin and red cell count.³³ The MCHC is not used much diagnostically, and is primarily useful for quality control purposes, such as detecting sample turbidity. These red cell indices are average quantities and, therefore, may not detect abnormalities in blood with mixed-cell populations. In situations such as sideroblastic anemia, recently transfused patients, patients with severe pernicious anemia with red cell fragmentation, and folate plus iron deficiency, both large and small red cells are present, diminishing the value of the MCV.

Red Cell Distribution Width The RDW is an estimate of the variance in volume within the population of red cells, expressed as 1 SD of red cell volume measurements divided by the MCV. Instrument manufacturers calculate RDW using different algorithms, so that reference ranges vary according to analyzer model. The RDW can be used in the laboratory as a flag to select those samples that should have manual review of blood films for red cell morphology. More significantly, a large literature has now developed around the evidence that the RDW is a biomarker predicting morbidity and mortality in a broad variety of clinical settings,³⁴ such as angina/myocardial infarction,³⁵ heart failure, trauma, pneumonia, sepsis, intensive care treatment, renal and liver disease, and in the general population.³⁶ Most of these studies are retrospective, observational, or cohort-based studies, often using databases of routinely collected data gathered for other purposes, but prospectively designed studies have arrived at similar conclusions.^{37,38} The RDW retains its association with poor clinical outcomes whether or not anemia is present,³⁹ and it adds predictive power to more established predictive risk models.⁴⁰ RDW may be a surrogate for systemic inflammation⁴¹ and/or oxidative stress, but the predictive value of RDW is independent of other inflammatory markers,⁴⁰ suggesting that this biomarker is tracking other mechanistic processes as well. Identification of physiologic mechanisms linking RDW to adverse clinical outcomes will be important in using this predictive biomarker to inform therapeutic decisions.³⁴

Reticulocyte Count and RNA Content

The reticulocyte is a newly released anucleate red cell that enters the blood with residual detectable amounts of RNA (Chaps. 31 and 32). The number of reticulocytes in a volume of blood permits an estimate of marrow erythrocyte production and is thus useful in evaluating the pathogenesis of anemia by distinguishing inadequate production from accelerated destruction (Chap. 32). The manual method for enumerating reticulocytes by placing a sample of blood in a tube containing new methylene blue and preparing a blood film to enumerate the proportion of cells that show blue beaded precipitates (residual ribosomes) has largely been replaced by automated methods, which are incorporated into high-volume hematology analyzers.⁴² Reticulocytes are identified by direct fluorescence measurement after staining with RNA-binding dyes or light scatter measurements to detect staining if nonfluorescent RNA-binding dyes are used. Various proprietary combinations of light scatter and other parameters are used to minimize interferences such as nucleated red cells, nuclear remnants (Howell-Jolly bodies), malaria parasites, or platelet clumps.

Automated reticulocyte counts are typically reported in absolute numbers (reticulocytes per μL or per L of blood), obviating the need to correct for a reduced red cell count (anemia), if present. However, one may still consider the effect of elevated erythropoietin levels secondary to severe anemia, which results in premature release of reticulocytes persisting in the circulation for more than the usual 1 day, correspondingly inflating estimates of daily marrow reticulocyte production based

TABLE 2-1. Reference Ranges for Leukocyte Count, Differential Count, and Hemoglobin Concentration in Children*

Age	Leukocytes Total ($\times 10^3/\mu\text{L}$)	Neutrophils			Eosinophils	Basophils	Lymphocytes	Monocytes	Hemoglobin g/dL Blood

*The means and ranges are in thousands of cells per mL. This table is provided as a guide. Normal ranges should be validated by the clinical laboratory for the specific methods in use. The number in *italic* is mean percentage of total leukocytes.

For leukocyte and differential count, see Altman PL, Dittmer DS (eds): *Blood and Other Body Fluids*. Federation of American Societies for Experimental Biology, Washington, DC, 1961.

For hemoglobin concentration, see Rudolph AM, Hoffman JI (eds): *Pediatrics*, 18th ed, pp 1011, 1012. Appleton and Lange, Norwalk, CT, 1987.

on the reticulocyte count (Chap. 32). The correlation between manual and automated methods of reticulocyte enumeration is good, but reference ranges differ slightly among the methods, given the different dyes and conditions used and the continuous nature of the variables separating reticulocytes from mature red cells.

Many hematology analyzers now report some quantitative measure of reticulocyte RNA content. Increase in the immature (highest RNA content) reticulocyte fraction is an early sign of marrow recovery from cytotoxic therapy⁴³ or treatment for nutritional anemias, usually preceding the rise in total reticulocyte count. A limitation at present is that the methods lack standardization and reference ranges for these parameters are instrument dependent.⁴⁴

Additional Red Cell and Reticulocyte Indices

Current high-end automated cell counters measure unique properties of mature red cells and reticulocytes on a cell-by-cell basis, not just as population averages. The result is a plethora of new indices that are in many cases specific to an instrument manufacturer, presenting new diagnostic opportunities but also a confusing nomenclature and a potential lack of comparability. Some examples of parameters that have been studied include %HypoHe, %MicroR, RET-He (available on Sysmex instruments), CHr, HYPO% (Siemens), RSf, LHD% (Beckman-Coulter), and FRC (fragmented red cells; Sysmex and Siemens).

New formulas for distinguishing causes of microcytosis based on several novel red cell indices function about as well⁴⁵ or somewhat better⁴⁶ than traditional formulas for differentiating iron deficiency from thalassemia trait. More sophisticated mathematical modeling of individual cell-based volume and hemoglobin content data available in current analyzers has been used in a systems biology approach to demonstrate latent iron deficiency and to distinguish causes of microcytosis.^{47,48} The ability of new automated analyzers to measure parameters specifically in reticulocytes on a cell-by-cell basis also opens up the possibility of reticulocyte-specific indices. The theoretical advantage is that acute changes in red cell function would be detected more rapidly and reliably in the reticulocyte fraction as opposed to the total red cell population.

Estimates of reticulocyte-specific hemoglobin content (CHr and RET-He, which are comparable) by light-scatter measurements of reticulocytes are closely related to adequacy of iron availability to erythroid precursors during the preceding 24 to 48 hours, and have been described as diagnostically useful in detecting functional iron deficiency in complex clinical settings, such as chronic inflammation⁴⁹ and chronic renal disease.⁵⁰ The increase in serum ferritin as an acute phase reactant combined with the physiologic variation of serum iron and iron-binding capacity limits the value of conventional parameters in these settings. The CHr may be a better predictor of depleted marrow iron stores than traditional serum iron parameters in nonmacrocytic patients,⁵¹ and is a more sensitive predictor of iron deficiency than hemoglobin for screening infants⁵² and adolescents for iron deficiency. Estimates of percentages of red cells falling below a cutoff for hemoglobin concentration (HYPO%) or hemoglobin content (%HypoHe) may provide greater sensitivity than the corresponding mean values averaged over all red cells, for instance with respect to iron deficiency in renal disease.⁵³ Four of the newer parameters (HYPO%, %HypoHe, CHr, RetHe) similarly outperformed transferrin saturation and ferritin in hemodialysis patients⁵⁴ for diagnosis of iron deficiency. However, both the CHr and RET-He are less effective than the MCH in screening elderly patients for iron-deficiency anemia.⁵⁵ The RSf (square root of MCV times MRV [mean reticulocyte volume]) and LHD% (a mathematical transformation of the MCHC) have similar diagnostic utility as RET-He.⁵⁶ Fragmented red cell (FRC) counts by automated analyzers, based on better methods of separating small red cells from platelets, appear to lack specificity and their clinical role is not yet defined.

These parameters have the advantage of ready access in the context of an automated blood count, but the availability of differently derived and calculated parameters from various instrument makers is a challenge to remember and compare across laboratories.

Other Red Cell Findings

Nucleated Red Cells Nucleated red cells are present in newborns, particularly if physiologically stressed, and in a variety of disorders, including hypoxic states (congestive heart failure), severe hemolytic anemia, primary myelofibrosis, and infiltrative disease of the marrow (Chap. 45). Most modern automated hematology analyzers are capable of detecting and quantitating nucleated red blood cells, which were a source of spuriously elevated leukocyte counts in earlier instruments, at a level of 1 to 2 nucleated red cells per 100 leukocytes.

Malarial Parasites Malarial parasites can also be detected by some current analyzers, based on detecting parasite infected red cells or neutrophils containing ingested hemozoin in regions of the multiparameter display that are not characteristically populated in normal blood (sometimes causing spurious eosinophilia⁵⁷). Some reports indicate high sensitivity and specificity with certain instrumentation,⁵⁸ a useful consideration in endemic areas where access to technologists with morphologic expertise may not be consistent. Careful attention to instrument characteristics and limitations as well as the relative prevalence of disorders causing instrument flags in the laboratory's patient population is essential in fine tuning instrument review criteria to provide reasonable sensitivity and specificity.

Other Abnormalities Not Detected by Automation Some disorders, such as immune and hereditary spherocytosis (Chaps. 46 and 54), hemoglobin C disease (Chap. 49), elliptocytosis (Chap. 46), inherited granule abnormalities (Chap. 66), and malaria and other parasitic diseases (Chap. 53), may not be reliably detected by the various flagging strategies on automated analyzers, and morphologic findings such as basophilic stippling (Chap. 31), toxic granulation (Chap. 60), siderocytes (Chap. 31), and pathologic rouleaux (Chap. 109) are only detectable by microscopic examination of the blood film.

AUTOMATED ANALYSIS OF LEUKOCYTES

Leukocyte Count

Leukocyte counts are performed by automated cell counters on blood samples appropriately diluted with a solution that lyses the erythrocytes (e.g., an acid or a detergent), but preserves leukocyte integrity. Manual counting of leukocytes is used only when the instrument reports a potential interference or the count is beyond instrument linearity limits. Manual counts are subject to much greater technical variation than automated counts because of technical and statistical factors, and with modern instrumentation, need to be done infrequently. Instruments that perform an automated 5-part differential can measure absolute neutrophil counts accurately down to 100/ μL .⁵⁹ Automated leukocyte counts may be falsely elevated as a result of cryoglobulins or cryofibrinogen, clumped platelets or fibrin from an inadequately anticoagulated or mixed sample, ethylenediaminetetraacetic acid (EDTA)-induced platelet aggregation, nucleated red blood cells, or nonlysed red cells, and falsely decreased because of EDTA-induced neutrophil aggregation. This potential interference is instrument dependent, and current analyzers use a variety of algorithms to minimize their effect and flag those rare samples on which accurate automated analysis cannot be performed.

Leukocyte Differential

Leukocytes in the blood serve different functions and arise from different hematopoietic lineages, so it is important to evaluate each of the major leukocyte types separately. Modern automated instruments use

multiple parameters to identify and enumerate the five major morphologic leukocyte types in blood: neutrophils, basophils, eosinophils, lymphocytes, and monocytes, as well as indicate the possible presence of immature or abnormal cell. Customarily, both absolute (cells per μL) and relative (percent of leukocytes) counts are reported in the leukocyte differential. It is the absolute values that relate to pathologic states, and percentages are sometimes misleading (e.g., absolute neutropenia appearing as a relative lymphocytosis) if the absolute values are not carefully examined. Some have proposed to eliminate the reporting of differential count percentages entirely for this reason.⁶⁰ “Band” neutrophils cannot be identified as such by automated analyzers, although they will usually trigger a manual review flag if present in increased numbers. Current high-throughput instruments can perform an accurate automated “five-part” differential count with a false-positive rate (i.e., unnecessarily flagged for review) of 2 to 15 percent in samples from a medical center patient population.⁶¹ Eosinophils are accurately counted by current state-of-the-art instruments, but automated basophil counts remain imprecise.¹¹ Small numbers of abnormal cells can escape detection by either automated or manual methods. The false-negative rate for detection of abnormal cells varies from 1 to 20 percent, depending on the instrument, type of abnormal cell examined, and the detection limit desired (1–5 percent abnormal cells).^{62–64} Careful attention to use of flagging criteria designed to prompt manual review, which are linked to instrument-specific methodology, is essential to insure that optimum workflow strategies are used to detect samples containing abnormal cells with a manageable rate of manual review. Many instruments have “blast” flags designed to pick up leukemic blasts, but the sensitivity of such flags alone varied from 65 to 94 percent in a recent study,¹¹ and is lower in leukopenic patients.⁶⁵ One must rely not only on the specifically designed “blast” flags, but also on other abnormalities identified in the automated blood count, including other flags, to select samples for manual morphologic smear review. Lymphoma cells and reactive lymphocytes are the most difficult for both automated instruments and the human observer to identify. If one needs to search for infrequent abnormal cells or evaluate leukocyte morphology, there is still no substitute for microscopic examination of a properly stained blood film by a trained observer. The variability of morphologic quantification of band neutrophils is so high that some have advocated ceasing quantitative reporting of band cells.⁶⁶ In spite of instrumentation that permits automated analysis of a majority of clinical samples, the leukocyte differential count is still labor intensive relative to other high-volume laboratory tests, and its value as a cause-finding tool in screening of asymptomatic patients has been questioned.⁶⁷

The normal differential leukocyte count varies with age. As described in Chap. 7, polymorphonuclear neutrophils are predominant in the first few days after birth, but thereafter lymphocytes account for the majority of leukocytes. This pattern persists up to approximately 4 to 5 years of age, when the polymorphonuclear leukocyte again becomes the predominant cell and remains so throughout the rest of childhood and adult life. Chapter 9 discusses the leukocyte count in older persons. The leukocyte count may decrease slightly in older subjects because of a fall in the lymphocyte count with age. Neutrophil counts are lower in individuals of African descent, and in some Middle Eastern populations than in persons of European descent.⁶⁸

AUTOMATED ANALYSIS OF PLATELETS

Platelet Count

Platelets are usually counted electronically by enumerating particles in the unlysed sample within a specified volume window (e.g., 2–20 fl), where volume may be measured by electrical impedance or light scatter.⁶⁹ The platelet count was more difficult to automate than the red cell

count because of the small size, tendency to aggregate, and potential overlap of platelets with more numerous smaller red cells and cellular debris. Current instruments typically construct a platelet volume histogram based on platelet size within a reliably measured platelet volume window and mathematically extrapolate this histogram to account for platelets whose size overlaps with debris (smaller) or small red cells (larger). This works because platelet volumes in health or disease follow a log-normal distribution. Some analyzers compare platelet counts determined by different methods (e.g., impedance, light scatter, or fluorescence staining) to improve accuracy, especially useful for low platelet counts. Based on analysis of volume-distribution histograms of platelets and red cells and comparison of optical and impedance-based platelet counts, suspect samples are flagged for microscopic review. Automated platelet counting by current instrumentation is accurate and far more precise than manual methods. At very low platelet counts (less than $20 \times 10^9/\text{L}$), results are less precise⁷⁰ and there is a method-dependent tendency to overestimate platelet counts.⁷¹ Conversely, platelet activation in disorders such as disseminated intravascular coagulation (DIC) and acute leukemia may result in systematic slight undercounting of platelets.⁷² Advances in instrumentation, such as fluorescent dyes to more specifically identify platelets in thrombocytopenic⁷³ and microcytic⁷⁴ samples, should improve accuracy. When reviewing the blood film, platelet count may be roughly estimated as 2000 times the number of platelets in 10 consecutive oil immersion (1000 \times) fields.⁷⁵

Falsely Decreased Platelet Counts Causes of falsely decreased platelet counts include incomplete anticoagulation of the sample (sometimes accompanied by small clots in the specimen or fibrin strands on the stained film) and platelet clumping (pseudothrombocytopenia) or “satellitism” (adherence of platelets to neutrophils), caused by aggregation induced by nonpathogenic antibodies recognizing platelet adhesion molecule epitopes exposed as a result of chelation of divalent cations in the anticoagulated sample.⁶⁹ Platelet clumping occurs in approximately 0.1 percent of hospitalized patients.⁷⁶ The same phenomenon may occur to a lesser degree in citrate, which is often used to obtain platelet count in such cases. Magnesium EDTA, as compared to sodium EDTA, anticoagulant is reported to more effectively inhibit platelet aggregation in these patients and provide an accurate platelet count.⁷⁷ Classical causes of falsely elevated platelet count include severe microcytosis, cryoglobulins, and leukocyte cytoplasmic fragmentation.⁶⁹ Infrequently, it may be necessary to confirm automated results by a microscopic (phase contrast) platelet count or platelet estimate from the blood film, bearing in mind that these methods are imprecise.

Mean Platelet Volume The mean platelet volume (MPV) has been proposed as a useful clinical tool in the differential diagnosis of thrombocytopenias, and is associated with cardiovascular risk, stroke, and metabolic disease. Increased MPV may be related in a complex way to thrombopoietic stimuli that affect megakaryocyte ploidy, and not platelet age per se. A platelet volume distribution width (PDW) can be calculated just as the RDW, and is correlated with platelet count and MPV.⁷⁸ However, platelet size parameters are difficult to accurately quantify and use diagnostically because of the wide physiologic variation of the MPV in normal subjects, lack of standardization of automated measurement techniques and instability of platelet size parameters in the presence of commonly used anticoagulants.⁷⁹

Newly Released (Reticulated) Platelets Newly released platelets contain RNA, as do newly released red cells, and are functionally more active, with enhanced expression of adhesion molecules and bound coagulation factors.⁸⁰ The number of platelets with high RNA content (sometimes termed *reticulated platelets* or *immature platelet fraction*, measured by flow cytometry with RNA-binding fluorescent dyes, or by certain automated analyzers⁸¹) is a marker of marrow megakaryocytopoiesis and is proposed as a way of differentiating decreased

production of platelets from circulatory destruction or removal as a cause of thrombocytopenia, in an analogous fashion to the use of the reticulocyte count. The percentage of reticulated platelets is increased in destructive thrombocytopenias, but remains within the reference range in hypoproliferative states.⁸² Reticulated platelet number or RNA content correlates with imminent platelet recovery after chemotherapy.⁸³ Reticulated platelet number is correlated with risk of death in patients with acute coronary syndrome⁸⁴ and DIC,⁸⁵ and with hyporesponsiveness to platelet function inhibitors⁸⁶ or aspirin.⁸⁷

REFERENCE RANGES

The use of reference ranges for quantitative hematology measurements deserves some additional comment. The physiologic variation of certain blood cell counts is notably higher than usually found in blood chemistry analytes. This is a reflection of the adaptive responsiveness of the marrow and other tissues to cytokine and hormonal signaling. For instance, the leukocyte and differential counts are affected by stress, diurnal variation, tobacco smoking, and ethnic origin. With increasing globalization of clinical research and therapy, ethnic characterization of populations used for reference ranges is critical to data interpretation of clinical studies.⁸⁸ Platelet count and MPV show substantial ethnic variation.⁸⁹

The platelet and absolute neutrophil counts are lower in individuals of African ethnic origin.⁶⁸ American men and women of African descent have lower hemoglobin concentrations than do men and women of European descent, a difference that is reduced by half, but still significant, when subjects with iron deficiency, thalassemia, sickle trait, and renal disease are excluded.⁹⁰ Important clinical consequences may result from these differences; for instance, reduced neutrophil counts in Americans of African descent result in lower-dose intensity of treatment in early stage breast cancer, which may be related to survival outcome disparities.⁹¹ Beutler and West⁹⁰ summarize the situation well: “The problem cannot be solved by simply establishing different ranges for different ethnic groups, especially since all represent some degree of admixture. Thus, it is basically information that the physician must possess that becomes one of the many factors that we designate as clinical judgment.” With these caveats in mind, reference ranges for children, and African American, Hispanic, and white adults are presented in Tables 2-1 and 2-2. As with all laboratory parameters, clinical interpretation of patient results should be based on laboratory specific reference ranges. Therefore, these tables are not presented to guide interpretation of specific laboratory results, but to indicate the challenges facing laboratories and physicians in constructing and interpreting reference ranges of even standard and traditional assays.

F, female; Hct, hematocrit; Hgb, hemoglobin; M, male; MCV, mean cell; NORIP, Nordic Reference Interval Project; U.K., United Kingdom; U.S., United States; WBC, white blood cell count; NA, measurement not available.

*Ranges calculated from adult (>18 years) data, assuming equal contribution of subjects from each of multiple adult age groups, derived from the National Health and Nutrition Examination Survey (NHANES) III.

This table is provided as a guide. Normal ranges should be validated by the clinical laboratory for the specific methods in use.

Figure 2-3. Absolute neutrophil count, hemoglobin, mean cell volume (MCV), and platelet count determined repeatedly by automated hematology analyzer on 24 healthy elderly subjects. Fasting (7–9 AM) blood samples were obtained 9 to 10 times at 14-day intervals from seated elderly subjects with minimal stasis by the same phlebotomist and performed in duplicate on the morning specimen collection. Subjects had no chronic medical conditions requiring therapy and were not taking drugs. The mean and range for each patient is shown separately for each assay. This is an illustration of the relatively narrow range within which most variables are maintained in an individual, whereas there are striking differences in both mean and variance between subjects. Reference ranges need to encompass at least 95% of values from all healthy individuals, placing limits on diagnostic sensitivity in detecting progressive change in a hematologic variable, previously maintained in a homeostatic range. (Adapted with permission from Fraser CG, Wilkinson SP, Neville RG, et al: *Biologic variation of common hematologic laboratory quantities in the elderly*. *Am J Clin Pathol* 92(4):465–470. 1989.)

Note the variation in reference ranges obtained from different studies. The major variability is likely population selection, especially the degree to which chronic illness or asymptomatic iron deficiency are excluded, and physiologic factors, such as diurnal variation, are considered. For example, the Wakeman study⁹² exclusively used early morning samples, hence the upper limit of leukocyte count is lower because of diurnal physiologic variation. The National Health and Nutritional Examination Surveys (NHANES) III national database has the advantage of being a very large broad nationwide sampling, which, as used by Cheng and colleagues,⁹³ excluded any subjects with history of smoking, alcohol consumption, contraceptive use, and a variety of chronic diseases (excluding 60 percent of the tested subjects). However, those with asymptomatic iron deficiency were not excluded, so hemoglobin tends to be lower than in studies that may have been weighted toward groups of individuals in which undiagnosed iron deficiency and other asymptomatic disorders are less common. α - and β -thalassemia traits are also quite common in healthy individuals of certain ethnic groups, and inclusion of subjects with these disorders will also affect reference ranges. Normal lower limits for hemoglobin have been determined in U.S. subjects of different ethnic backgrounds carefully screened for occult disease.⁹⁴ Such considerations also affect determination of the upper (97.5th percentile) limit of normal hematocrit and hemoglobin in relation to a possible diagnosis of polycythemia, where one has to carefully weigh the likelihood that a “normal-range” study has adequately excluded iron-deficient subjects.^{95,96} Biomedical parameters are also subject to historical trends, such as the observed improvement in hemoglobin levels in the post-folic-acid-fortification era.⁹⁷ Finally, when one observes significant changes in reference ranges based on age (e.g., glomerular filtration rate, lipid parameters, hemoglobin), there is the question of whether this is physiologic or a result of increased prevalence of undiagnosed occult disease.

Most hematologic variables show more stability within an individual than between individuals, illustrating one reason for the lack of sensitivity and specificity of any test “cutoff,” which is typically designed for a population rather than for an individual person. A study of repeated analyses of blood variables from older subjects⁹⁸ graphically demonstrates this phenomenon. Some normal subjects have a normal steady-state platelet count between $170 \times 10^9/L$ and $200 \times 10^9/L$, whereas others have one between $280 \times 10^9/L$ and $310 \times 10^9/L$ (Fig. 2-3). For the latter group, a progressive fall in platelet count because of marrow failure may not be detected as quickly as the former group. The same observations are shown for absolute neutrophil count, hemoglobin, and MCV, among others. In normal subjects, the ratio of between subject to within subject variation ranges from about two times for absolute neutrophil count⁹⁹ to four to six times for hemoglobin, platelet count, absolute reticulocyte count, and MCV.¹⁰⁰ Data from a large clinical trial’s central laboratory show similar findings for hemoglobin in study subjects with various disease states. In this report bayesian methods were used to construct a (narrower) personalized reference range using progressive accumulation of baseline measurements to achieve greater sensitivity to perturbations following treatment.¹⁰¹ Circadian variations in hematologic laboratory values, including hematocrit, total leukocyte count, serum iron, and serum folate have been described.¹⁰² Some have proposed to customize reference ranges for time of sample collection, so that reference ranges aren’t inflated by the need to accommodate circadian variation.¹⁰³ Genetic loci affect quantitative hematologic traits (such as hemoglobin, MCH, platelet count, leukocyte count, etc.) in normal subjects of European, African, and South Asian ancestry.^{104,105} The loci contain many candidate genes known to be involved in hematopoiesis, but known genetic influences identified in such studies only explain a small proportion (4–9 percent) of the observed phenotypic heterogeneity of these variables.

MORPHOLOGIC EXAMINATION OF THE BLOOD

Microscopic examination of the blood spread on a glass slide or coverslip yields useful information regarding all the cells of the blood. The process of preparing a thin blood film causes mechanical trauma to the cells, introducing artifacts that can be minimized by good technique. The optimal part of the stained blood film to use for morphologic examination of the blood cells should be sufficiently thin that a small proportion of erythrocytes in a $\times 1000$ magnification field touch each other, but not so thin that no red cells are touching. Figure 2-4 is a composite image taken from the optimal portion of the film showing the five major leukocyte types, normal red cells, and platelets. Selection of a portion of the blood film for analysis that is too thick or too thin for proper morphologic evaluation is the most common error in blood

film interpretation. For example, leukemic blasts may appear dense and rounded and lose their characteristic features when viewed in the thick part of the film. For specific purposes, the thick portion or side and “feathered” edges of the film are of interest (for instance, to detect microfilariae and malarial parasites or to search for large abnormal cells and platelet clumps).

The blood film is first scanned at low magnification ($\times 200$) to confirm reasonably even distribution of leukocytes and to check for abnormally large or immature cells in the side and feathered edges of the film. The feathered edge is examined for platelet clumps. Abnormal cells, red cell aggregation or rouleaux, background bluish staining consistent with paraproteinemia, and parasites are all findings that can be suggested by medium magnification examination ($\times 400$). The optimal portion of the film is then examined at high magnification ($\times 1000$, oil immersion) to systematically assess the size, shape, and morphology of the major cell lineages.

Figure 2-4. Images from a normal blood film showing major leukocyte types. The red cells are normocytic (normal size) and normochromic (normal hemoglobin content) with normal shape. The scattered platelets are normal in frequency and morphology. **A.** A platelet caught sitting in the biconcavity of the red cell in the preparation of the blood film. This normal finding should not be mistaken for a red cell inclusion. Images are taken from the optimal portion of the blood film for morphologic analysis. Image shows a **(A)** segmented (polymorphonuclear) neutrophil and in the inset a band neutrophil; **(B)** monocyte; **(C)** small lymphocyte; **(D)** large granular lymphocyte, note larger size than lymphocyte in **(C)** and increased amount of cytoplasm containing scattered eosinophilic granules; and **(E)** eosinophil. Virtually all normal blood eosinophils are bilobed and filled with relatively large (compared to the neutrophil) eosinophilic granules. The eosinophilic and basophilic granules are readily resolvable by light microscopy ($\times 1000$), whereas the neutrophilic granule is not resolvable but in the aggregate imparts a faint tan coloration to the neutrophil cytoplasm, quite distinctly different from the blue-gray cytoplasmic coloring of the monocyte and lymphocyte.

RED CELL MORPHOLOGY

Normal erythrocytes on dried films are nearly uniform in size, with a mean diameter of approximately $7.5\ \mu\text{m}$ (normal and abnormal red cells are described in more detail in Chap. 31). The normal-sized erythrocyte is about the diameter of the nucleus of a small lymphocyte. The MCV is a more sensitive measure of red cell volume than the red cell diameter; however, an experienced observer should be able to recognize abnormalities in average red cell size when the MCV is significantly elevated or decreased. *Anisocytosis* is the term that describes variation in erythrocyte size, and is the morphologic correlate of the RDW. *Macrocytes* and *microcytes* are red cells larger or smaller than normal, and their presence consistent with the measured MCV suggests certain diagnostic possibilities. Early (“shift” or “stress”) *reticulocytes* (i.e., those with the most residual RNA) appear in stained films as large, slightly bluish cells, referred to as *polychromatophilic* cells (Chap. 32). These cells are roughly the morphologic counterpart of the immature reticulocyte fraction identified by automated instruments.

The normal erythrocyte on a blood film is circular with central pallor. *Poikilocytosis* is a term used to describe variations in the shape of erythrocytes. The predominant appearance of a specific abnormality in red cell shape can be an important diagnostic clue in patients with anemia (Fig. 2–5). Erythrocytes with evenly spaced spikes (echinocytes or crenated cells) can be an artifact caused by prolonged storage, or may reflect metabolic erythrocyte abnormalities.

The normal erythrocyte appears as a disc with a rim of hemoglobin and a clear central area, which normally occupies less than one-half the cell diameter. Increased central pallor (*hypochromia*) is associated with disorders characterized by diminished hemoglobin synthesis, such as iron deficiency (Chap. 42). Evaluation of red cell hemoglobin content, as well as red cell size, is dependent on examining the proper part of the blood film. Cells at the far “feathered edge” will always be large and lack central pallor, whereas cells in the thick part of the film will look small and rounded and will also lack central pallor. A sharp refractile border demarcating the central area of pallor is an artifact secondary to inadequate drying of the film before staining (associated with high humidity, and more common in anemic samples). *Spherocytes* are more

densely stained and appear smaller because of their rounded shape, and show decreased or absent central pallor. A red cell with a spot or disc of hemoglobin within the central pale area is a *target cell*, in reality a cup-shaped cell that distorts as it is flattened on the glass slide. These cells are typically found in disorders of hemoglobin synthesis (e.g., thalassemia), liver disease, and postsplenectomy where the cell-surface-to-cell-volume ratio is high. Chapter 31 describes the inclusions that may be observed in erythrocytes on blood films.

Erythrocytes are usually distributed evenly throughout the blood film. In some cases the cells become aligned in overlapping stacks, referred to as *rouleaux* (Chap. 109), resembling overlapping rows of coins. *Rouleaux* are normal in the thick part of the film, but when found in the optimal viewing portion of the film, suggest a pathologic increase in immunoglobulin (Ig), particularly IgM-macroglobulinemia. Occasionally, high concentrations of IgA or IgG in patients with myeloma may also produce *rouleaux*.

The blood film is also useful to identify red cells with basophilic stippling (evidence of dyserythropoiesis), siderotic granules (evidence of sideroblastic erythropoiesis), Heinz bodies (evidence of unstable hemoglobins), and Howell-Jolly bodies (nuclear remnants). Microorganisms other than malaria parasites also may be found in or attached to red cells (Chap. 53).

PLATELET MORPHOLOGY

Platelets appear in normal stained blood film as small blue or colorless bodies with red or purple granules (see Fig. 2–4). Normal platelets average approximately 1 to $2\ \mu\text{m}$ in diameter, but show wide variation in shape, from round to elongated, cigar-shaped forms. In improperly prepared films, platelets may form large aggregates in some areas and appear to be diminished or absent in others. The frequent occurrence of giant platelets or platelet masses may indicate a myeloproliferative neoplasm or improper collection of the blood specimen. The latter circumstance can occur when venipuncture technique is faulty and platelets become activated before the blood sample is thoroughly mixed with anticoagulant. These platelet masses are apparent typically in the thin “feathered edge” of the film, with corresponding fewer platelets elsewhere.

	Name	Characteristic of	Also seen in
	Spherocyte (Chaps. 31, 46, 54)	Hereditary spherocytosis, immune hemolytic anemia	Clostridial perfringens septicemia, Wilson disease
	Elliptocyte (Chaps. 31, 46)	Hereditary elliptocytosis (HE)	Iron deficiency, megaloblastic anemia, thalassemia, myelofibrosis, MDS
	Dacryocyte (teardrop) (Chaps. 31, 86)	Myelofibrosis	Severe iron deficiency, megaloblastic anemia, thalassemia, MDS
	Schistocyte (Chaps. 31, 51, 129, 132)	Microangiopathic, mechanical hemolytic anemia	Occasional schistocytes are seen in many disorders affecting red cells.
	Echinocyte (Chaps. 31, 37)	Renal failure, malnutrition	Common <i>in vitro</i> artifact after storage
	Acanthocyte (Chaps. 31, 56)	Spur cell anemia, abetalipoproteinemia	Postsplenectomy
	Target cell (Chaps. 31, 48)	Cholestasis, Hgb C disease	Iron deficiency, thalassemia
	Stomatocyte (Chaps. 31, 46)	Hereditary stomatocytosis	Alcoholism

Figure 2–5. Disorders associated with certain red cell morphologic changes. *Poikilocytosis* is a general term used to indicate the presence of abnormally shaped red cells, such as dacryocytes (teardrop-shaped red cells), schistocytes (fragmented red cells), and elliptocytes, as is found in the most extreme form in hereditary pyropoikilocytosis (Chap. 46). MDS, myelodysplastic syndromes (Chap. 87).

Figure 2-6. Blood films. **A.** Toxic granules in neutrophils. In inflammatory states the neutrophil may develop overt purplish granules as shown in this example of reactive neutrophilia. **B.** Chédiak-Higashi disease. Note the giant eosinophilic granule in the monocyte and the numerous enlarged granules in the lymphocyte (Chap. 66). **C.** Hurler syndrome. Note characteristic prominent dense cytoplasmic inclusions in the mononuclear cell. These inclusions are accumulations of glycosaminoglycans resulting from a deficiency of α -L-iduronidase in leukocytes and other tissues. **D.** Examples of apoptosis of two neutrophils in normal anticoagulated blood during standing at room temperature. Nuclear condensation and fragmentation are evident. A normal neutrophil is also present. **E.** Döhle bodies. These RNA remnants of rough endoplasmic reticulum appear as blue rod-shaped structures (*arrow* points to one) in neutrophils involved in inflammatory reactions. **F.** May-Hegglin disease. The large blue-gray inclusions (*arrow*) represent precipitates of nonmuscle myosin heavy chain type IIA. Note also the two macrothrombocytes (the size of red cells) characteristic of this disorder (Chap. 120). The neutrophil inclusions stain with fluorescent antibodies to nonmuscle myosin heavy chain type IIA. **G.** Marrow film. A strand of endothelial cells derived from vascular tissue caught on the biopsy needle. Individual endothelial cells may be found, rarely in a blood film. **H.** Platelet satellitism. Three neutrophils surrounded by adherent platelets. This blood film was prepared from an EDTA-anticoagulated sample. (*Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.*)

Platelet clumping throughout the blood film, or platelet “satellitism” (adherence of platelets to neutrophils), may be a result of platelet agglutinins (Fig. 2-6). A platelet will occasionally overlie an erythrocyte, where it may be mistaken for an inclusion body or a parasite. The differentiation depends on the observation of a halo around the platelet, determination that it lies above the plane of the erythrocyte, and observation of the characteristics of a normal platelet in the “inclusion.”

LEUKOCYTE MORPHOLOGY

The cells normally found in blood are mature neutrophils, lymphocytes, and monocytes, with smaller numbers of eosinophils and basophils

(see Fig. 2-4). *Neutrophils* are round cells ranging from 10 to 14 μm in diameter on a blood film. The nucleus is lobulated, with two to four lobes connected by a thin chromatin thread. The defining feature of the mature neutrophil is the round lobes with condensed chromatin, because the chromatin thread may overlie the nucleus and not be visible. The chromatin stains purple and is coarse and arranged in clumps. The nucleus of 1 to 16 percent of the neutrophils from females may have an appendage that is shaped like a drumstick and is attached to one lobe by a strand of chromatin. It represents the inactive X chromosome of the pair. The cytoplasm is diffusely pale pink and contains many small, tan to pink granules distributed evenly throughout the cell. *Bands* are identical in appearance to mature neutrophils except that the nucleus

is not segmented but is sausage-shaped or U-shaped (see Fig. 2-4). Nuclear chromatin is slightly less condensed than the mature neutrophil (Chap. 60).

Eosinophils are on the average slightly larger than neutrophils (Chap. 62). The nucleus usually has two lobes (see Fig. 2-4). The chromatin pattern is the same as that of the neutrophil, but the nucleus tends to be more lightly stained. The differentiating characteristic of these cells is the presence of many refractile, orange-red granules that are distributed evenly throughout the cell and may be visible overlying the nucleus. These granules are larger than those in the neutrophil and are more uniform in size. Occasionally, some of the granules in eosinophils stain light blue rather than orange-red.

Basophils are similar to the other polymorphonuclear cells and are slightly smaller than neutrophils (Chap. 63). The nucleus may stain more faintly and usually is less segmented and has less distinct chromatin condensation than is the case in neutrophils. The large deeply basophilic granules of basophils are fewer in number and less regular in size and shape than in the eosinophil. The granules are visible overlying the nucleus and, in some cells, almost completely obscure the lightly stained nuclear chromatin. Because the granular constituents are water soluble, some granules may stain only faintly or not at all or may be lost from the cell during preparation (see Fig. 2-4).

Lymphocytes on blood films are usually smaller than other leukocytes, approximately 10 μm in diameter, but large lymphocytes up to 20 μm in diameter occasionally are seen (see Fig. 2-4). The small lymphocyte, the predominant type in normal blood, is round and contains a relatively large, round, densely stained nucleus (Chap. 73). The cytoplasm is scanty and stains pale to dark blue. In the large lymphocytes, the nuclear-to-cytoplasmic ratio is lower and the chromatin is slightly less condensed than in the small lymphocytes. The nucleus is usually round but may be oval or indented. The cytoplasm is abundant and may contain a few azurophilic granules. *Large granular lymphocytes* contain azurophilic granules and relatively abundant cytoplasm, and generally represent cytotoxic T or natural killer (NK) cells (Chap. 94). *Reactive lymphocytes*, as seen in viral infections caused by Epstein-Barr virus, cytomegalovirus, adenovirus, or other organisms, are large with indented nuclei and abundant blue cytoplasm (Chap. 82). Nuclear chromatin condensation is variable, and nucleoli may be evident. A low nuclear-to-cytoplasmic ratio and greater degree of chromatin condensation distinguishes them from neoplastic cells.

Monocytes are the largest normal cells in the blood, usually measuring from 15 to 22 μm in diameter (see Fig. 2-4). The nucleus is of various shapes—round, kidney-shape, oval, or lobular—and frequently appears to be folded (Chap. 67). The lacy chromatin is arranged in fine strands with sharply defined margins. The cytoplasm is light gray, contains variable numbers of fine lilac or purple granules, and is often vacuolated. The gray (as opposed to blue) color of monocyte cytoplasm is a result of fine granules (staining pink) seen on the background of RNA-containing cytoplasm (staining blue), and helps to distinguish between monocytes and reactive lymphocytes. The monocyte nuclear chromatin contains a fine, string-like structure as opposed to the smudgy-appearing clumps of the lymphoid chromatin. Nuclear shape and cytoplasmic vacuolization are less reliable for distinguishing features between monocytic and lymphoid cells.

LEUKOCYTE INCLUSIONS

Abnormal Granules

In a systemic inflammatory reaction, neutrophil granules may appear larger than normal and stain more darkly, often assuming a dark blue-black color. This has been called *toxic granulation* (see Fig. 2-6). These granules if unusually prominent can be confused with the larger

granules of basophils. In *mucopolysaccharidoses*, coarse, dark granules may be found in the neutrophils, and large azurophilic granules in some lymphocytes and monocytes (see Fig. 2-6). Huge misshapen granules are found in the neutrophils, and giant azurophilic granules are present in the lymphocytes of patients exhibiting the *Chédiak-Higashi* anomaly (see Fig. 2-6; Chap. 66). *Auer rods* are sharply outlined, red-staining rods found in the cytoplasm in blast cells, and occasionally in more mature leukemic cells, in the blood of some patients with acute myelogenous leukemia or myelodysplastic syndromes (Chap. 88).

Abnormal Neutrophil Inclusions

Light blue round or oval *Döhle bodies*, approximately 1 to 2 μm in diameter, may be seen in the cytoplasm of neutrophils of patients with infections, burns, and other inflammatory states (see Fig. 2-6). The blue staining is caused by RNA of the rough-surfaced endoplasmic reticulum contained in Döhle bodies. These bodies are thought to be a reflection of accelerated maturation of neutrophils with residual endoplasmic reticulum from the promyelocyte stage. They usually occur in circumstances in which toxic granulation may be present. *May-Hegglin* anomaly is one of several MYH9 disorders, autosomal dominant macrothrombocytopenias secondary to defective megakaryocyte maturation and fragmentation, with leukocyte inclusion bodies (also Fechtner, Sebastian, Epstein, and Alport-like syndromes; Chap. 112). The leukocytic inclusions, pale blue-stained, irregularly shaped inclusions are precipitates of nonmuscle myosin heavy chains (see Fig. 2-6). Neutrophil function is normal.

LEUKOCYTE ARTIFACTS

Damaged (“Smudge,” “Basket”) and Apoptotic Cells

During film preparation, leukocytes may be damaged, resulting in an enlarged nucleus with homogeneous, slightly reddish chromatin strands with a large blue nucleolus. There is no specific association with disease other than chronic lymphocytic leukemia (Chap. 92), where increased cell fragility commonly results in variable numbers of smudge cells, which connote a favorable prognosis. Eosinophils and basophils often are partially or largely degranulated in preparation film with the granules scattered beside the cell. Occasional neutrophils may be seen in stages of apoptosis after standing in anticoagulated blood at room temperature (see Fig. 2-6).

Radial Nuclear Segmentation

This refers to abnormal segmentation of the nuclei of leukocytes on the blood film, in which the lobes appear to radiate from a single point, giving a cloverleaf or cartwheel picture. This change is common in cyto-centrifuged preparations (i.e., from a body fluid), EDTA anticoagulated blood after excessive storage, and samples collected in oxalate.

Vacuolization

Vacuoles may develop in the nucleus and cytoplasm of leukocytes, especially monocytes and neutrophils, with prolonged storage in EDTA anticoagulated blood. Vacuoles may be associated with swelling of the nuclei and loss of granules from the cytoplasm. In blood films prepared without anticoagulation, vacuoles in neutrophils suggest sepsis.

Endothelial Cells

If the blood film is prepared from the first drop of blood issuing from fingerstick, endothelial cells may be present singly, in clumps, or as strings of attached cells (see Fig. 2-6). These cells en face may simulate the appearance of abnormal cells and may be misinterpreted as blasts or metastatic tumor cells.

CHAPTER 3

EXAMINATION OF THE MARROW

Daniel H. Ryan

SUMMARY

Microscopic examination of the marrow is a mainstay of hematologic diagnosis. Even with the advent of specialized biochemical and molecular assays that capitalize on advances in our understanding of the cell biology of hematopoiesis, the primary diagnosis of hematologic malignancies and many nonneoplastic hematologic disorders relies upon examination of the cells in the marrow. An aspirate and biopsy of the marrow can be obtained with minimal risk and only minor discomfort and are quickly and easily processed for examination. The marrow should be examined when the clinical history, blood cell counts, blood film, or laboratory test results suggest the possibility of a primary or secondary hematologic disorder for which morphologic analysis or special studies of the marrow would aid in the diagnosis. Leukopenia or thrombocytopenia may require a marrow examination for diagnosis. Nonhemolytic anemia that is not readily diagnosed by blood cell examination and supporting laboratory tests often requires a marrow examination. Abnormal cells in the blood, such as nucleated red cells, white cell precursors, abnormal lymphocytes not explained by concurrent infection, and blast cells, usually require a marrow examination. In addition to determining the cellularity and morphology of precursor cells, or infiltration by nonhematopoietic cells, the study provides marrow cells for immunophenotyping, cytogenetic, molecular and genomic studies, culture of infectious organisms, and storage of marrow cells for further analysis.

HISTORY OF THE MARROW EXAMINATION

The first recorded examinations of marrow in living patients occurred in the first decades of the 20th century, first using the tibia as the source of marrow and then surgical bone biopsies. Neither technique led to routine examination of the marrow, because in the former case the tibia was usually hypocellular in adults, and in the latter case, because of the invasiveness of an open procedure and the discomfort and risk of infection and bleeding. In 1923, Arinkin devised the marrow aspiration technique,¹ which was the prototype for our current aspiration procedure. Thirty years passed before the suggestion that the pelvis might

be preferable to the sternum gained hold, and another 10 years passed before a practical marrow biopsy instrument was put to use. Regular use of the posterior iliac crest for aspiration and biopsy and regular use of biopsy to complement aspiration did not occur until the 1970s, when staging of lymphoma made biopsy a frequent procedure and new simpler biopsy instruments became readily available.

INDICATIONS FOR MARROW ASPIRATE OR BIOPSY

The International Council for Standardization in Hematology has published guidelines for marrow aspirate and biopsy to promote consistency in performance and reporting.² Although marrow aspiration and biopsy techniques are safe, they should be performed with a clear idea as to how the results will help distinguish the differential diagnoses under consideration or provide followup of treatment.³⁻⁵ In many hematologic disorders, such as most cases of iron-deficiency anemia, thalassemia, and acquired and inherited hemolytic anemia, examination of the blood and specialized laboratory tests usually suffice to make the diagnosis without the need for a marrow examination.

When examination of the marrow is indicated, the decision as to whether an aspirate or an aspirate plus biopsy is desired should be made. Aspiration is always attempted because of the superior morphology offered by examination of the aspirate smear. However, a marrow biopsy is superior to the aspirate in quantifying marrow cellularity and diagnosing infiltrative diseases of the marrow and should be performed when these conditions are part of the differential diagnosis.^{6,7} Marrow biopsy is useful for diagnosing and following the course of disorders that are commonly associated with reticulin fibrosis, such as megakaryoblastic leukemia, hairy cell leukemia, and the chronic myeloproliferative neoplasms.⁸ In myelodysplastic syndromes, marrow biopsy is useful for evaluating abnormal localization of immature precursor cells and abnormal megakaryocytes. Marrow necrosis and gelatinous transformation are more readily detected in marrow sections than in aspirate films. Marrow aspirate alone may be appropriate in some clinical settings where the diagnostic question is very targeted, such as diagnosis of childhood immune thrombocytopenia purpura or surveillance followup of leukemia patients in apparent remission.

Depending on the diagnostic question, availability of material, and expected frequency of the abnormal cells, an appropriate selection of specialized diagnostic methods may be needed to support the clinical diagnosis. Morphology of marrow cells is still the gold standard for diagnosis of hematologic malignancy and allows construction of a good differential diagnosis for nonmalignant disorders. Immunocytochemistry provides excellent phenotype–morphology correlation on an individual cell basis, but is limited to epitopes that resist destruction by fixation, decalcification, and paraffin embedding. Flow cytometry allows study of almost any surface or intracellular protein, with the added ability to detect important quantitative changes in cellular proteins and simultaneous determination of multiple proteins within the same cell. However, flow cytometry requires that cells be viable and dissociated from tissue. Gene expression arrays allow analysis of complex patterns of RNA expression by sophisticated mathematical algorithms to discover diagnostic patterns based on gene expression. These studies may point the way to a smaller more practical set of proteins that can be studied by immunocytochemistry or immunofluorescence. Molecular assays target oncogenic DNA sequence alterations from the chromosome to the nucleotide, and include classic metaphase cytogenetics, fluorescence *in situ* hybridization (FISH), reverse transcriptase polymerase chain reaction (PCR), and targeted or whole-genome sequencing.

Acronyms and Abbreviations: CD, cluster of differentiation; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; DMSO, dimethylsulfoxide; EDTA, ethylenediaminetetraacetic acid; FISH, fluorescence *in situ* hybridization; GPI, glycosylphosphatidylinositol; MDS, myelodysplastic syndrome; M:E, myeloid-to-erythroid cell ratio; MRD, minimal residual disease; PCR, polymerase chain reaction.

MARROW ASPIRATION TECHNIQUE

At birth, all bones contain hematopoietic marrow. Fat cells begin to replace hemopoietic marrow in the extremities in the fifth to seventh year. By adulthood, the hemopoietic marrow is limited to the axial skeleton and the proximal portions of the extremities (Chaps. 5 and 9). Fatty marrow appears yellow, whereas hematopoietic marrow is red. Red marrow contains fat, however, and fat droplets are visible grossly in aspirated marrow specimens. Histologically, yellow marrow consists almost entirely of fat cells and supporting connective tissue. Red marrow contains an abundance of hematopoietic cells, fat cells, and connective tissue. The marrow fills the spaces between the trabeculae of bone in the marrow cavity. Marrow is soft and friable and can be readily aspirated or biopsied with a needle.

The posterior iliac crest (Fig. 3-1) is the preferred site for marrow aspiration and biopsy. In adults, the anterior iliac crest and rarely the sternum have been used (Fig. 3-2). The sternum should be used for aspiration only. The anterior iliac crest is less preferred than the posterior crest in adults because of its thick cortical bone. The anteromedial surface of the tibia is an option for infants younger than 1 year old (particularly newborns), but the posterior iliac crest is still the preferred site. Serious adverse outcomes after marrow aspiration or biopsy are rare, occurring in less than 0.05 percent. One direct fatality and three

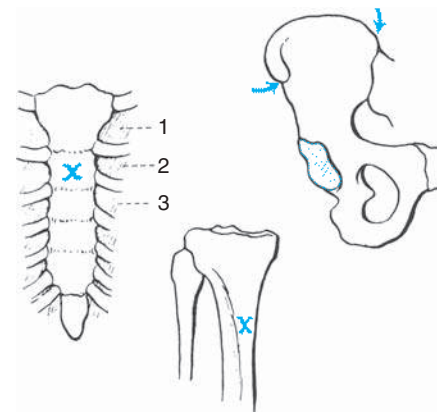

Figure 3-2. Sites used for marrow aspiration. (Modified with permission from Schwartz SO, Hartz WH Jr, Robbins JH: Hematology in Practice. New York, NY: McGraw-Hill; 1961.)

episodes of prolonged but not permanent disability were reported in nearly 55,000 marrow biopsies.⁹ Morbidity most frequently involved hemorrhage, which was associated more with platelet function impairment than thrombocytopenia or coagulation factor defects.⁹ Infection and reactions to anesthetic agents are other infrequent complications. Penetration of the bone with damage to the underlying structures is possible with all marrow aspirations, but the hazard is greatest in sternal aspirations because the sternum at the second interspace is only approximately 1 cm thick in adults, and the distance from posterior sternal cortex to the ascending aorta varies greatly and may be as little as 4 to 5 mm,¹⁰ giving rise to the rare but dramatic consequence of aortal wall tear. To prevent this, a guard should be in place on the needle if a sternal aspirate needs to be done.

For either a marrow biopsy or aspiration, sedation minimizes anxiety and pain,¹¹ particularly in children,¹² for whom propofol, with or without fentanyl, administered under carefully controlled conditions¹³ with monitoring of oxygen saturation, blood pressure, and vital signs, is frequently used. Midazolam (Versed) is a popular choice for conscious sedation of adult patients, although a variety of other premedications have been used. There is a relative lack of empirical research and consensus guidelines on the subject of pain reduction during adult marrow procedures.^{14,15} The experience of marrow procedures from the patient's point of view is worth reading.¹⁶ The only significant correlates with severe/unbearable pain (experienced by 4 percent of patients) during marrow examination were quality of the information about the procedure provided before the examination and previous painful experiences.¹⁷ Marrow biopsies and aspirations for lymphoma staging purposes often can be performed while the patient is under anesthesia for other procedures. Several different types of needles are available for marrow aspiration.³ For adults, a 16-gauge needle is sufficiently large to permit aspiration of adequate specimens; larger needles are unnecessary. The patient is prone or in the left or right lateral decubitus position. Sterile precautions must be observed. The skin over the puncture site is shaved if necessary and cleansed with a disinfectant solution. The skin, subcutaneous tissues, and periosteum are infiltrated with a local anesthetic solution, such as 1 percent lidocaine. Adequate infiltration of the anesthetic at the periosteal surface is important to minimize severe pain during the procedure, but no more than 20 mL of 1 percent lidocaine should be used in an adult.¹⁸ Adequate anesthesia can be achieved with much less lidocaine in virtually all cases. An air gun can be used to anesthetize the skin surface prior to application of anesthetic to the periosteal surface by injection. After the anesthesia has taken effect, usually in 3 to 5 minutes, the marrow needle is inserted through the skin, subcutaneous tissue, and cortex of the bone using a slight twisting motion. In

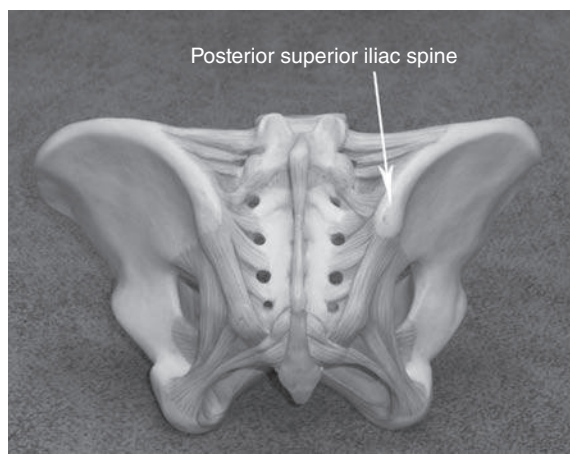

Figure 3-1. A. Jamshidi biopsy instrument. B. Site of marrow biopsy.⁹⁶ (A, reproduced with permission from Jamshidi K, Swaim WR: Bone marrow biopsy with unaltered architecture: A new biopsy device. J Lab Clin Med 77(2):335-342, 1971.)

obese patients, the length of the needle must be sufficient to reach the iliac crest. The stylet should be locked into place on the hub of the needle to prevent plugging of the needle with tissue prior to needle entry into the marrow cavity. Penetration of the cortex can be sensed by a slight, rapid forward movement accompanied by a sudden increase in the ease of advancing the needle. The stylet of the needle is removed promptly, the hub is attached to a 10- or 20-mL syringe, and approximately 0.5 to 1.5 mL of fluid is aspirated. The actual aspiration of the marrow causes a transient painful sensation for most patients. If additional specimen volume is required, another syringe is fitted on the marrow needle, the syringe and needle is rotated and an adjacent area is entered and marrow is aspirated. The stylet may be reinserted and the marrow needle slightly repositioned between aspirations. When aspiration is complete, the stylet is reinserted and the needle immediately removed from the bone. Pressure is applied to the skin over the aspiration site for at least 5 minutes to minimize bruising at the site. If platelet number or function is decreased, firm pressure should be applied for at least 10 to 15 minutes. The bloody fluid that is aspirated contains light-colored particles of marrow approximately 0.5 to 1 mm in diameter. They often are readily visible in the syringe, but may not be detected until the syringe contents are discharged on glass slides for film preparation.

If nothing enters the syringe when aspiration is performed, the needle may not be properly placed in the marrow cavity. The needle can be cautiously advanced 1 to 2 mm after reinsertion of the stylet and aspiration attempted again, or the needle can be removed from the bone and reinserted in a nearby site in the anesthetized area. The thickness of the bone must be considered when the needle is being adjusted in the bone. Occasionally the needle must be rotated on its longitudinal axis, or in a larger orbit, in order to loosen the marrow mechanically before the marrow can be aspirated. If a small amount of blood has been aspirated, a new needle should be used because of the probability of clotting the aspirate when it finally is obtained. Aspiration with a 50-mL syringe may succeed if use of a smaller syringe fails. Fibrotic or densely packed leukemic marrow may resist all attempts at aspiration, in which case a biopsy is necessary. The most common cause of failure to obtain marrow is faulty positioning of the needle, and a second attempt at aspiration usually succeeds. A specimen preparation checklist used at the time of procedure to verify presence of spicules, length of biopsy, and other protocol items has been found to increase biopsy specimen length and decrease frequency of non-diagnostic samples.¹⁹

● NEEDLE BIOPSY TECHNIQUE

Needle biopsy usually is performed with the Jamshidi needle, using the same preparation as described above. The Jamshidi instrument (see Fig. 3-1) consists of a cylindrical needle with constant bore, except for a concentrically tapered distal portion ending in a sharp, beveled cutting tip. The stylet fits precisely inside the opening at the tapered tip, interlocks at the hub of the needle, and extends 1 to 2 mm beyond the end of the needle. An 11-gauge needle is most commonly used in the United States. After the skin and the periosteum of the biopsy site are anesthetized, a 3-mm incision is made in the skin. The needle, with obturator in place, is inserted into the skin incision and through the subcutaneous tissue to the cortex of the bone. The needle is directed toward the posterior iliac spine and advanced with a twisting motion. Penetration of the cortex is sensed by a decreased resistance to forward movement of the needle. The obturator is removed, and the needle is slowly advanced with reciprocal clockwise-counter-clockwise twisting motions around the long axis. After sufficient penetration of the bone (up to approximately 3 cm), the needle is rotated several times on its axis and withdrawn approximately 2 to 3 mm. Some needles now come with a “trap” that snares the biopsy so that the needle can be directly

removed. The needle is reinserted to the original depth at a slightly different angle, taking care not to bend the needle, and rotated several times to free the specimen from attachments in the marrow cavity. The needle is slowly withdrawn, with the same twisting motion used during insertion. The core of marrow inside the needle is removed by inserting the probe through the cutting tip and extruding the specimen through the hub of the needle. The smaller size of the cutting aperture relative to the bore of the shaft of the Jamshidi instrument yields a specimen that fits loosely inside the needle and therefore is less subject to compression, distortion, or fragmentation. The technique reliably produces good quality biopsy specimens. Marrow biopsy should be performed before marrow aspiration is attempted (or in a slightly different site on the iliac crest) to avoid hemorrhage and distorted marrow architecture in the biopsy core. With the availability of the biopsy needles described in this section, open (surgical) biopsies rarely are necessary but may be performed, for example, for diagnosis of deeply situated bone lesions or at the time of a surgical procedure performed for a related indication (e.g., staging). An FDA-approved battery-powered drill that inserts a biopsy needle into the posterior iliac bone of adult patients provides more consistent and longer biopsy cores and shortens procedure time.²⁰

● PREPARATION OF MARROW SPECIMENS FOR STUDY

Several types of preparations can be made from the marrow aspirate to maximize use of the diagnostic material. Most important is the *direct film*, which is made immediately from a drop of marrow suspension from the unmanipulated aspirate. This preparation is the best for evaluating cellular morphology and differential counts of the marrow. The *particle film* is best for estimating marrow cellularity and megakaryocyte abundance, but morphology is obscured in the thicker parts of the film. A *concentrate film*, which is prepared from a concentrate of nucleated cells (marrow buffy coat) achieved by centrifugation of a small volume of anticoagulated marrow, is sometimes used for detecting low-abundance cells when the marrow is hypocellular. The relative proportions of cell lineages are not maintained in the concentrate film preparation (often erythroid precursors are relatively enriched). In addition, this preparation is subject to anticoagulant-induced changes in nuclear morphology or cytoplasmic vacuolization. The *touch imprint* from the biopsy is quite valuable and sometimes diagnostically necessary for evaluating cellular morphology when the aspirate is hypocellular.²¹

MARROW FILMS

After aspiration, approximately 0.5 mL of marrow is placed on a glass slide; the rest is mixed into a tube containing ethylenediaminetetraacetic acid (EDTA) solution. The marrow specimen is examined to ensure the presence of “spicules” or particles of marrow containing bony or fatty pieces, indicating successful aspiration of the marrow cavity. Direct marrow films are immediately prepared by transferring drops of the unanticoagulated marrow pool to fresh slides and making push films with coverslips. Sufficient films should be made for special stains. Heparinization of the aspirate is not necessary if the operator works rapidly and should be avoided because heparinization may introduce artifacts. Formalin vapor artifact that can distort morphology can be avoided by making sure formalin containers are not opened until aspirate smears are prepared and put away.

A useful technique is preparing a thick film of marrow by discharging a drop or two of the aspirate on a slide, covering the aspirate with a second slide, gently pressing the slides together to express most of the blood into a gauze sponge, and then pulling the slides apart

longitudinally. Such preparations may contain an increased number of broken cells if too much pressure is applied, but they provide a large number of particles from which marrow cellularity can be estimated and which are useful for estimating the amount of hemosiderin present. Broken cells may be minimized using a squash technique with cover-slips instead of glass slides, which compared favorably to push (wedge) films in achieving representative distribution of intact cells derived from marrow particles.²²

The EDTA-anticoagulated sample may be centrifuged (1500 g for 10 minutes) in a Wintrobe tube to concentrate the cellular elements of the marrow. After centrifugation, the fatty layer and plasma are removed, and the “buffy coat” is mixed with an equal amount of plasma. Multiple films of this preparation are made. All smears should be thoroughly air-dried, which can take longer in a humid environment, before staining to avoid artifacts.

TOUCH PREPARATIONS

After a biopsy specimen is obtained using the Jamshidi needle, the specimen should be extruded through the hub of the needle and then gently rolled across a glass slide (using an applicator stick to move the specimen) before it is placed in fixative, taking care to avoid crushing. The touch preparations are allowed to dry and are stained in the same manner as films.

SPECIAL STUDIES

It is essential to formulate the diagnostic question before performing a marrow aspiration to ensure an adequate sample is obtained for all the special studies that may be needed to make the correct diagnosis, while avoiding aspiration of more marrow than is needed, which can lead to dilution of the sample.²³ A sterile anticoagulated sample containing viable unfixed cells in single-cell suspension is the best substrate for nearly all special studies. Specifically, flow cytometry is best performed on EDTA- or heparin-anticoagulated aspirate specimens, which are stable for at least 24 hours at room temperature. For cytogenetic or cell culture analysis, preservative-free heparin-anticoagulated marrow should be added to tissue culture medium and analyzed as soon as possible to maintain optimal cell viability. Cytogenetic samples are generally not adversely affected by overnight incubation.²⁴ In cases where the marrow aspirate is dry, a duplicate biopsy specimen can be disaggregated to produce a cell suspension for morphology, flow cytometry, and cytogenetic studies.²⁵ FISH for detection of chromosomal deletions, duplications, and translocations can be performed in marrow biopsies when EDTA-based decalcification protocols are used.²⁶

For molecular analysis of fresh specimens, sample storage should be minimized, and storage at 4°C is preferable. EDTA is the preferred anticoagulant because heparin can interfere with some molecular assays. DNA is relatively stable, but RNA has a variable half-life in an intact cell and is degraded rapidly (on the order of seconds to minutes) in a cell lysate by ubiquitous ribonucleases. Sample storage prior to RNA isolation should be minimized.²⁷ Collection tubes have been designed for stabilization of RNA, but for maximal RNA recovery, samples should be transported to the laboratory immediately, where cell suspensions (typically buffy coat or mononuclear cell preparations) can be prepared and nucleic acids extracted under conditions that inhibit ribonucleases. DNA and messenger RNA can be extracted and analyzed from paraffin-embedded tissue sections²⁸ and dried stained films,²⁹ with variable degree of degradation dependent on the length of sequence required.

Archival storage of marrow specimens is important in light of advances in molecular diagnosis that may necessitate validation studies using samples of known origin or retrospective testing of diagnostic

material. Isolated DNA or RNA can be stored for long periods at -70°C , whereas viable, intact cells can be reliably preserved only by controlled rate freezing in dimethylsulfoxide (DMSO) and storage in liquid nitrogen.

HISTOLOGIC SECTIONS

A variety of techniques for preparing aspirated material for histologic study have been advocated. All of the techniques are designed to collect a sufficient number of marrow particles in a small volume so that adequate sections can be prepared. This goal can be accomplished by discharging the marrow aspirate onto a glass slide, allowing the particles to settle for a few seconds, and then gently tilting the slide so that the excess blood runs off. The particles then are pushed together with an applicator stick, and the remaining blood is allowed to clot. The clot is promptly fixed, typically in buffered formalin, for tissue processing and sectioning. An alternative method using filtration of the anticoagulated aspirate specimen has been described.³⁰

The core marrow biopsy specimen is processed for histologic examination typically by fixation in neutral buffered formalin, followed by decalcification and embedding in paraffin. Decalcification can be accomplished with acid reagents or EDTA, the latter of which is preferred as it provides better preservation of nucleic acid and protein antigens. Sections of high quality cut at $3\ \mu\text{m}$ and stained with hematoxylin and eosin are satisfactory for routine work. Refinements in fixation and embedding techniques have enabled use of many immunologic markers in decalcified paraffin-embedded marrow biopsy specimens. Fixation in neutral-buffered formalin and embedding without decalcification in plastic resin has the advantage of superior morphology,³¹ but is less frequently used as the potential for immunostaining and molecular assays is more restricted.

MORPHOLOGIC INTERPRETATION OF MARROW PREPARATIONS

OVERVIEW

The Wright-Giemsa–stained direct marrow aspirate film should be examined as quickly as possible to provide a preliminary assessment of the marrow morphology and allow setup of specialized testing based on this preliminary evaluation while the sample is fresh. Final interpretation of the marrow biopsy and aspirate should be integrated with results from the clinical history, blood film, cell counts, laboratory data, cell marker studies, and molecular or cytogenetic data. No other histologic specimen exists in which a state-of-the-art interpretation is dependent on such an array of supportive data. The challenge for the hematopathologist and hematologist is to understand the advantages and limitations of each diagnostic approach so that results can be reconciled and placed into perspective. Some common pitfalls in preparation and interpretation of marrow aspirates⁴ and biopsies⁵ have been reviewed.

ADEQUACY OF THE MARROW SAMPLE

The first question in interpreting the marrow is whether the sample is adequate for diagnosis. At the time of the procedure, the presence of marrow particles in the aspirate is the best indicator that the needle entered the medullary cavity and marrow was successfully withdrawn. Marrow particles are bony with a glistening appearance caused by fat in the particles. Specimens containing cortical bone, muscle, or other tissue with little or no medullary bone are inadequate for marrow interpretation. Samples with extensive crush artifact or hemorrhage are sub-optimal, underscoring the importance of proper technique in obtaining

a useful sample. An unspoken assumption is that the piece of marrow provided for diagnostic evaluation is representative of the marrow as a whole. Based on reproducibility of bilateral biopsies, this more likely is true in leukemia and myeloma than in lymphoma and metastatic tumor.³² A biopsy specimen should contain at least a 0.5-cm length of marrow cavity. However, for detection of lymphoma or metastatic tumor, current recommendations suggest a biopsy length of 1.6 to 2.0 cm.³³ A significant proportion of biopsies obtained in routine practice may fall short of this recommended length.³⁴

The marrow cavity was entered if the aspirate contains marrow particles or hematopoietic precursors (e.g., megakaryocytes, nucleated red cells) not found in the blood film. However, this finding does not ensure the specimen is adequate for diagnosis, because the amount of marrow actually aspirated can vary significantly in disease states. Also, some cell types, notably fibroblasts and metastatic tumor cells, are not as readily removed from the marrow space by aspiration as are normal precursors. Lack of particles or precursor cells does not prove the marrow cavity was not entered, because marrow packed with leukemic cells or infiltrated with fibroblasts may yield few cells (“dry tap”).³⁵ Marrow aspirations resulting in a dry tap usually are a consequence of significant pathology (only 7 percent show normal histology on biopsy³⁵) and indicate the need to examine a biopsy specimen, which should include a touch imprint.²¹

MARROW CELLULARITY

The “gold standard” for overall marrow cellularity is examination of an adequate marrow biopsy specimen.³⁶ The normal cellularity percentage of marrow space occupied by hematopoietic cells as opposed to fatty and nonhematopoietic tissue of iliac crest marrow decreases from a mean of 80 percent in early childhood to 50 percent by age 30 years, with further decreases after age 70 years.³⁷ Consequently, marrow cellularity should be evaluated with reference to normal individuals of the same age as the patient.³⁸ When evaluating cellularity, consider that the marrow spaces directly adjacent to cortical bone frequently are fatty and are not representative of the cellularity of the deeper marrow spaces. A grid can be used to estimate marrow cellularity of a biopsy.³⁹

Cellularity assessment by examination of the direct marrow aspirate film is more difficult because of loss of histologic structure and mixture with blood. The aspirate may suggest the marrow is more hypocellular than indicated by the biopsy.⁴⁰ Marrow particles (seen in the direct film or a particle preparation) are the best indicators of cellularity. These particles are like “mini-biopsies” and contain sufficient hematopoietic and fatty elements to give some idea of marrow cellularity. Cellularity estimates based on careful examination of particles in the aspirate preparation agree well with cellularity estimated from the marrow biopsy.³⁸

The degree of dilution of marrow aspirate specimens with blood during the aspiration is variable and may affect interpretation of marrow cellularity. Adult marrows with greater than 30 percent lymphocytes plus monocytes likely are substantially admixed with blood, as shown by cytokinetic studies of paired marrow aspirate and biopsy preparations.⁴¹ A higher-than-expected proportion of mature neutrophils in the marrow differential is another clue to a hemodilute marrow aspirate. In patients with hematologic disease, from 6 to 93 percent of the nucleated cells were derived from the blood.⁴² The greatest admixture was observed in patients with leukemia. Substantial dilution with blood may occur in difficult aspirates or when multiple draws were taken from the same puncture site. For instance, contamination of marrow aspirates with blood cells was only 8 percent in the first 1 mL, but 20 percent in subsequent draws.⁴³

Cellularity of individual lineages is best assessed by examination of the biopsy specimen. Erythroid cells typically are arranged in clusters, whereas megakaryocytes are scattered throughout the biopsy. Erythroid and megakaryocytic cellularity is best appreciated at low power. In the aspirate, a myeloid-to-erythroid (M:E) ratio frequently is calculated to give some impression of the relative cellularity of these two major lineages. As a rule of thumb, the M:E ratio normally should be between 2:1 and 4:1 (Table 3-1 lists the normal ranges in men and women). The relative proportions of cell types should be assessed only on the direct marrow film, biopsy imprint, or particle preparation, not a concentrate film, which has been manipulated by centrifugation. A decreased M:E ratio can be interpreted as either myeloid hypocellularity or erythroid hyperplasia, depending on the overall marrow cellularity. Megakaryocyte numbers can be assessed from the direct marrow aspirate film, where at least five megakaryocytes should be present in the optimal portion of the film. In the particle preparation, most large particles should contain one or more megakaryocytes. Megakaryocyte number varies markedly in direct marrow aspirate films of normal subjects and depends on the degree of admixture of the specimen with blood. Megakaryocytes are enriched at the feathered edge of concentrate films.

INFILTRATIVE DISEASES OF THE MARROW

Malignant Neoplasms

Metastatic nonhematopoietic tumor in the marrow biopsy is characterized by disruption of the marrow architecture with groups of cytologically abnormal cells. Assessment of the tissue of origin is primarily based on morphology, clinical history, and immunocytochemical staining. The tendency of carcinoma cells to form tightly adherent clusters frequently is helpful in recognizing these neoplasms (Chap. 45). The clumps can appear on the marrow aspirate, but the aspirate is less sensitive than the biopsy for detecting metastatic tumor. Tumor clumps may occur only on side or feathered edges of the film, or only in the concentrate preparation. These tumor clumps must be distinguished from clumps of damaged hematopoietic cells, which commonly appear in aspirate preparations, especially the concentrate film. The distinction is best accomplished by examining cells at the periphery of the clumps to determine if the cells show the morphology of hematopoietic precursors or are cytologically atypical cells. Isolated nonhematopoietic tumor cells are seen infrequently in aspirate preparations, even when tumor is obvious in the biopsy, because of the adherent nature of most nonhematopoietic tumors. Examination of multiple films may be necessary to find isolated tumor cell clumps.⁴⁴ Methods for identifying rare micrometastatic tumor cells (disseminated tumor cells) in marrow aspirates and blood have continued to evolve, but have not yet found an established role in guiding clinical prognosis or therapy.^{45,46}

Myeloma⁴⁷ and lymphomas⁴⁸ are nonhomogeneously distributed and more reliably detected on the biopsy preparation. Abnormal lymphoid aggregates should be distinguished from lymphoid aggregates found in reactive conditions or in older patients. Neoplastic aggregates show cytologic atypia and a monomorphous cellular population, and they often are adjacent to bony trabeculae, but the distinction can be difficult in some cases. The cellular morphology often can be better appreciated on the marrow aspirate, but the key histologic features are lost. Lymphoma cells do not form the tight clusters seen in nonhematopoietic tumors on the marrow aspirate film. In hairy cell leukemia (Chap. 93), the hematopoietic cells are sufficiently adherent to each other and the marrow matrix with variably increased collagen matrix that the aspirate specimen is often markedly hypocellular (dry tap), whereas biopsy specimens show extensive infiltration with hairy

cells. Immunohistochemistry is useful in the differential diagnosis of plasma cell myeloma and other lymphoproliferative disorders, as is flow cytometry when the abnormal cells are sufficiently represented in the aspirated material. Demonstration of immunoglobulin light-chain restriction in B-cell lymphoma is not possible by immunohistochemistry, but *in situ* hybridization for κ versus λ light-chain messenger RNA may be successful. Detection of clonal immunoglobulin gene rearrangements by PCR amplification of messenger RNA transcripts may be used for this purpose, but clinical interpretation of the results can be problematic, and morphology remains the standard in evaluating marrow involvement by lymphoma.⁴⁹ Positron emission tomography using

[¹⁸F]fluorodeoxyglucose (FDG-PET) has been recommended to replace staging marrow biopsy in Hodgkin lymphoma,^{50,51} and in many patients with diffuse large B-cell lymphoma.⁵²

Fibrosis

Marrow fibrosis typically is recognizable only on a marrow biopsy specimen; the aspirate merely shows reduced or absent recovery of hematopoietic cells. Early stages of fibrosis are characterized by increased stainable marrow reticulin fibers (Chap. 86). Fibrosis may accompany either primary hematopoietic disorders (e.g., myelofibrosis) or infiltrative diseases such as metastatic tumor.

Storage Diseases

Storage disorders, such as Gaucher and Niemann-Pick diseases (Chap. 72), are characterized by abnormal macrophages containing stored material in various forms seen in aspirate or biopsy.⁵³ Reactive cells, such as the histiocytes with “sea-blue” inclusion granules (Chap. 72) or pseudo-Gaucher cells associated with chronic myelogenous leukemia (CML) (Chap. 89),⁵³ can resemble the cells seen in storage disorders.

Amyloidosis

Amyloid refers to extracellular proteins that become insoluble as a result of alteration in secondary structure to form beta pleated sheets. Amyloid light-chain amyloidosis may result from a plasma cell neoplasm, and is associated with nephrotic syndrome, restrictive cardiomyopathy, neuropathy and other tissue involvement. Amyloid deposits can be identified in the marrow by characteristic birefringence or fluorescence of deposits when stained with Congo Red.⁵⁴

INFECTIONS

Infectious organisms with an intracellular location, such as *Leishmania*, *Histoplasma*, and *Toxoplasma*,⁵⁵ can be visualized in monocytic cells by morphologic examination of the marrow (Fig. 3–3). Identification of mycobacterial organisms in the marrow by acid-fast staining lacks sensitivity but allows early diagnosis in one-third of cases with HIV-related *Mycobacterium avium* complex infection.⁵⁶ Microscopic examination and culture of the marrow are the most sensitive diagnostic tests for disseminated leishmaniasis.⁵⁷ Mycobacteria, also, may be cultured from marrow. Marrow morphology also is a sensitive diagnostic tool for detecting disseminated histoplasmosis.⁵⁸ However, marrow culture has a low diagnostic yield in the workup of fever of unknown origin in nonimmunosuppressed patients.⁵⁹ Definitive diagnoses arising from marrow examination in this setting are usually hematologic malignancies.^{59,60} The presence of marrow granulomas, recognizable

only on biopsy specimens, necessitates examination by special stains for fungal and mycobacterial organisms, but the differential diagnosis is extensive.^{53,61}

NECROSIS AND GELATINOUS TRANSFORMATION

Marrow necrosis may occur in a variety of disorders, particularly sickle cell disease and neoplastic processes involving the marrow.⁶² Aspirates of necrotic marrow stained with polychrome stains contain cells with indistinct margins and smudged basophilic nuclei surrounded by acidophilic material. Marrow sections stained with hematoxylin and eosin show loss of normal marrow architecture, indistinct cellular margins, and a background of amorphous eosinophilic material. Patients with severe weight loss may develop gelatinous transformation of the marrow, characterized by amorphous extracellular material (proteoglycans), fat atrophy, and marrow hypoplasia.⁶³

MORPHOLOGIC DIFFERENTIATION OF HEMATOPOIETIC LINEAGES

OVERVIEW

Marrow aspirate films should be examined under low-power magnification to assess the cellularity of particles and estimate the number of megakaryocytes, plasma cells, and mast cells. Low-power examination may also permit detection of malignancy or abnormal storage cells. The entire film should be examined, including the particles, and higher magnification should be used to study any abnormalities discovered. Similarly, biopsy sections are examined at low power to assess adequacy, overall cellularity, presence of infiltrative disease, and cellularity of the major hematopoietic lineages.

Figure 3–3. Marrow findings. **A.** Two osteoblasts are in this field. Elongated ovoid cells with nucleus at extreme end, a morphology which characteristically looks like the nucleus is falling out of the cell. A clear area is apparent spaced at an interval from the nucleus. **B.** Osteoclast. Multinucleated giant cell. The nuclei are characteristically scattered throughout the cell, appearing separate. **C.** Macrophage (arrow), relatively large cell with circular nucleus and abundant cytoplasm. Ingested debris and few vacuoles. **D.** Macrophage (two). Prussian blue stain. Relatively large cell with circular nuclei. One binucleate. Each macrophage is full of iron as indicated by blue reaction product of stain. **E.** Macrophage engorged with *Histoplasma capsulatum*. **F.** Macrophage engorged with amastigote forms of *Leishmania donovani*. After the low-power survey, the films should be examined at higher power and under oil-immersion magnification to determine the various hemopoietic cell types present and assess adequacy of differentiation in each hematopoietic lineage. For most diagnostic questions, careful and systematic visual examination of the marrow is sufficient to assess differentiation, but a marrow differential cell count can be performed to quantify blasts or other abnormal cells. Based on the diagnostic question at issue, the marrow differential count may require examination of 300 to 500 nucleated cells. Table 3–1 lists the normal values for these determinations, including data for infants from birth to age 18 months.⁶⁴ Between birth and age 1 month, lymphocytes increase and erythroid and granulocytic precursors decrease. After 1 month, the marrow differential count varies little to age 18 months, the duration of the study.⁶⁴ The proportion of segmented neutrophils increases with large volumes of aspirate, probably because of dilution of marrow cells by mature granulocytes in the blood.⁶⁵ The range of normal for all cell types is broad, and differential counts and M:E ratios should be considered rough guides to the character of the marrow as a whole.

Progenitors of all lineages typically are unremarkable cells without distinctive morphologic attributes. Precursors and mature cells of the hematopoietic lineages show characteristic diagnostic morphologic changes as described below. Further details of the morphology of these cells are discussed in the relevant specific chapters of this book as referenced below.

GRANULOCYTES

Granulocytes are precursors or mature forms of leukocytes characterized by neutrophilic, eosinophilic, or basophilic granules in their cytoplasm in the more mature stages of development. This series sometimes is referred to as the *myeloid series* (Chap. 60). The overall trend is a gradual decrease in nuclear size and enhanced clumping of nuclear chromatin as cells lose proliferative capacity, while granules of varying types progressively appear in the cytoplasm.

The *myeloblast* is round and large, with a nucleus occupying most of the cell. The nuclear chromatin is very fine, and two to five nucleoli are present. The cytoplasm is basophilic, but less so than the cytoplasm of the erythroid series. Few azurophilic granules may be present.⁶⁶ The *promyelocyte* is larger than the myeloblast, with a coarser chromatin, but still containing nucleoli. The cytoplasm is basophilic with a clear Golgi area and a small number of prominent, large red granules—the primary, nonspecific, or azurophilic granules. The *myelocyte* is slightly smaller than the promyelocyte, and is the most mature mitotic cell in the myeloid lineage. Its nucleus is round or oval and often eccentrically located. The chromatin pattern is coarser than that of the promyelocyte, and nucleoli usually are not visible. The defining feature is the presence of specific granules in the perinuclear cytoplasm, which identify the cell lineage. The granules may be neutrophilic (fine, variable size, lilac color), eosinophilic (larger, round, orange–red), or basophilic (larger still, irregular in size, deep blue). The *metamyelocyte* is about the same size as the myelocyte and resembles it closely, except that the nucleus is indented, the chromatin is more coarse, and the cytoplasm is less basophilic. The *band cell* is characterized by a nucleus that is horseshoe shaped or lobular but is not narrowly segmented. The cytoplasm is yellowish–pink or nearly colorless with abundant lineage specific granules. *Segmented (polymorphonuclear) granulocytes* differ from band cells by the multilobed character of the nucleus. At least two separate lobes are defined by a complete rounded shape, whether or not the thin filament joining them is seen. Nuclear chromatin is very dense. The mature eosinophil typically has only two lobes, whereas the nuclei of most

neutrophils have two to four lobes. Basophil nuclei may be obscured by the abundant basophilic granules.

MONOCYTES

Monocytes in normal marrow are identical morphologically to those in the blood. Promonocytes (Chap. 67) have delicate lace-like chromatin similar to a monoblast, but with indented or convoluted nuclear outline.⁶⁷ These are important cells to identify as they are considered blast equivalents in the evaluation of myelodysplastic syndrome (MDS) and acute leukemia.

MACROPHAGES (HISTIOCYTES)

These cells are derived from monocytes but are larger, reaching 20 to 30 μm in the longest dimension (Chap. 67). The nucleus is oval with delicate reticular chromatin and one or two small nucleoli. The cytoplasm ranges from blue-gray to pale and colorless, and often contains phagocytosed cells, degenerating cell debris, and vacuoles. Normally, intact red cells are rarely visible inside marrow macrophages. Erythrophagocytic macrophages are a feature of autoimmune hemolytic anemia, hemophagocytic lymphohistiocytosis (HLH), a severe uncontrolled hyperinflammatory reaction that can occur in a variety of clinical settings, such as infection, neoplasia, and autoimmune disorders (where it is termed *macrophage activation syndrome*), in addition to certain rare genetic disorders of cytotoxic granule function or immunodeficiency states⁶⁸ (Chap. 71).

ERYTHROID CELLS

During erythroid differentiation, the nucleus progressively becomes smaller and nuclear chromatin more condensed, as the cell's proliferative capacity decreases. The cytoplasm gradually loses the bluish color imparted by RNA, which is replaced by the pink-staining hemoglobin. Cells in the erythroid series are termed *erythroblasts* (previously the term “normoblast” was used to distinguish the normal sequence from the sequence observed in megaloblastic anemia). These stages are arbitrary divisions within a continuum of differentiation. Chapter 31 provides more detailed descriptions of normal red cell precursors.

The *proerythroblast* is a large, round cell measuring from 15 to 20 μm in diameter. The nucleus occupies most of the cell and contains nucleoli. The chromatin is present in a fine reticular or stippled pattern but is usually more densely stained than the chromatin of the myeloblast. The cytoplasm typically is more basophilic than the myeloblast. The *basophilic*, *polychromatophilic*, and *orthochromatophilic erythroblasts* are characterized by cytoplasm gradually changing from blue to gray to pink in color as hemoglobin is produced and RNA reduced. The *erythrocyte* is the mature anucleate red cell. *Polychromatophilic erythrocytes* are mature anucleate red cells that are just released from the marrow (corresponding to early reticulocytes) and still have sufficient residual RNA to impart a slight grayish tinge to the cytoplasm (Chap. 32).

EVALUATION OF IRON STORES

Marrow examination often should include evaluation of the iron stores, especially if the patient is anemic. The examination is accomplished by staining a marrow film or section by the Prussian blue technique. Because decalcification of marrow biopsy specimens results in decreased recovery of stainable iron,⁶⁹ a nondecalcified specimen or aspirate should be stained when evaluating iron stores in the differential diagnosis of anemia. Marrow macrophages (seen best in the aspirate particle preparation) are evaluated for storage iron (see Fig. 3–3),

and erythroblasts (best evaluated in the direct film or concentrate) are examined for the presence of iron granules in the cytoplasm (sideroblasts). Late erythroblasts are readily identified by their small size and the size, shape, and chromatin pattern of the nucleus. The proportion of normal late erythroblasts that contain one to four small Prussian blue granules is extremely variable (3–69 percent) in normal subjects.⁷⁰ Pathologic ring sideroblasts are characterized by an increased number of iron granules arranged in a ring encircling at least 1/3 of the nucleus, reflecting accumulation of iron in mitochondria (Chap. 87).

MEGAKARYOCYTES

Chapter 111 discusses the megakaryocyte in detail. Megakaryocytes are large cells (30–150 μm) with darkly stained, irregularly lobed nuclei. The cytoplasm is blue “cotton candy” textured, and the more mature cells contain many azurophilic granules.

LYMPHOCYTES

In normal marrow, lymphocytes similar to those found in the blood occur in variable numbers, depending on the degree of blood contamination of the marrow (Chap. 73). Immature lymphoid cells with a high nuclear-to-cytoplasmic ratio and moderately dense, but finely distributed, chromatin (“hematogones”) often are seen in marrow aspirates of children, and mostly represent B-cell precursors.⁷¹ These cells may cause diagnostic difficulty in some clinical settings, such as the “rebound” lymphocytosis that occurs after cessation of maintenance chemotherapy for acute lymphoblastic leukemia.

PLASMA CELLS

Normal plasma cells vary in size but usually are 12 to 16 μm in diameter when spread on a slide. They are round or oval. The nucleus is small, round, eccentrically placed, and stained densely purple. The chromatin is coarse and clumped. Nucleoli are not visible. The cytoplasm is deep blue, often with a paranuclear clear zone (Chap. 73). Binucleate forms may be found in normal marrow.

OTHER CELL TYPES

Mast cells are readily recognized by their content of dark-blue granules, which usually completely fill the cytoplasm and may obscure the nucleus (Chap. 63). The cells are round or spindle-shaped and often are located deep in the particles, frequently lying along blood vessels. The nucleus often is not visible but when seen is round or oval with a vesicular chromatin pattern.

Osteoclasts and *osteoblasts* are uncommon, and are more likely seen in hypocellular marrow or marrow obtained from children and from adults with hyperparathyroidism or osteoblastic reactions to tumors. *Osteoclasts* are large cells and may be larger than 100 μm in diameter (see Fig. 3–3). They superficially resemble megakaryocytes but contain multiple separated nuclei that have a moderately fine chromatin pattern with nucleoli. The cytoplasm varies from slightly basophilic to intensely acidophilic because of the content of acidophilic granules. *Osteoclasts* may contain coarse basophilic debris. *Osteoblasts* usually are oval cells up to 30 μm in the longest diameter (see Fig. 3–3). They often occur in groups. The nucleus usually is quite eccentric and may seem to be spilling out of the cell. The chromatin pattern is uniform, and one to three nucleoli are present. The cytoplasm is light blue and may contain a few red granules. *Osteoblasts* may be mistaken for plasma cells. In *osteoblasts*, the pale centrosomal region of the cytoplasm is separated from the nucleus, in contrast to that of the plasma cell, in which the centrosomal region directly abuts the nucleus.

● PRINCIPLES OF FLOW CYTOMETRY INTERPRETATION

Immunophenotyping is complementary to morphology in the contemporary practice of marrow cell identification. Flow cytometers use similar principles to the automated hematology analyzers discussed in Chap. 2, with the notable difference that fluorescence-labeled monoclonal antibodies directed toward cluster of differentiation (CD) antigens are the primary diagnostic tool. As described in the World Health Organization classification of hematologic malignancies,⁷² immunophenotypic data (expression of cell surface, intracytoplasmic, and nuclear antigens) are key determinants of diagnosis and classification of hematopoietic malignancies. The principle of immunophenotyping is to diagnose and follow neoplastic cell populations by virtue of differential patterns of protein expression. Only the basic principles of flow cytometry analysis are described in this chapter, so that the reader has the basis for understanding the phenotypic characteristics associated with the hematopoietic disorders described in greater detail in other chapters of this book.

METHODOLOGY

Flow cytometers are automated hematology analyzers that use principles of light scatter and fluorescence to define cellular populations in which to analyze expression of proteins typically identified by fluorescent tagged antibodies. A single-cell suspension is aspirated into a laminar flow of isotonic diluent that passes in front of one or more laser beams. Light scatter and fluorescence data are collected using specific photomultiplier tubes with appropriate filtration to collect scattered light (same wavelength as the incident laser light) or fluorescence emitted light (at a longer wavelength determined by the dye used). Multiple detectors with different filtration coupled with single or multiple lasers are used to collect highly multiplexed data. As with automated hematology analyzers, light scatter information is collected at a low angle (correlates with cell size) and 90-degree angle (correlates with cellular granularity and nuclear complexity; Chap. 2, Fig. 2–1). The latter measurement is especially useful in separating developing myeloid progenitors, monocytes, and mature granulocytes from lymphoid cells and blasts.

Immunophenotyping can be achieved by using monoclonal antibodies specific to certain cell surface proteins, most of which have CD designations as defined by international workshops. A primary requirement for flow cytometry analysis is that cells must be viable and in single-cell suspension prior to staining, which is why this method is used largely for hematopoietic malignancies and immunologic disorders, and not for analysis of solid tumors. This consideration also explains differences in results between flow cytometry and morphologic or immunohistochemical observations when samples with highly adherent neoplastic cells are analyzed. For instance, in multiple myeloma or large cell lymphoma the proportion of malignant cells is typically lower (or absent) by flow cytometry compared with marrow biopsy. In a well-equipped and appropriately staffed clinical laboratory, preliminary information often can be provided within 3 to 4 hours after the initial sample collection, thereby facilitating institution of appropriate therapy (e.g., in the case of newly diagnosed acute leukemias).

Clinical laboratories typically use four- to six-color analysis, plus side and forward light scatter, for routine diagnostic panels. For research studies, simultaneous analysis of up to 20 simultaneous fluorochromes is possible, by excitation with up to 5 lasers and separate collection of the emitted light produced by interaction with each laser. At present, routine use of that many simultaneously measured markers is not necessary for clinical diagnosis. An important consideration is that analysis

with more simultaneous colors places greater demand on resources for development, maintenance and ongoing quality assurance. Most clinically important phenotypic markers are analyzed as cell surface proteins by directly adding conjugated antibodies to cell suspension, followed by washing and lysis of red cells.⁷³ Assessment of intracytoplasmic and nuclear-associated proteins is accomplished after staining for surface markers by then fixing cells in suspension and adding the relevant antibodies in conjunction with a membrane-permeabilizing agent. Some lineage-specific markers (CD3 in precursor T cells; CD79a and CD22 in B cells; myeloperoxidase in granulocyte lineage; cyclin D1 in mantle cell lymphoma) are expressed only in the cytoplasm at certain stages of development. Fluorescence and light scatter data are stored electronically as list mode data files that can be archived and later reanalyzed using appropriate software. As the number of parameters collected on individual cells increases, standard ways of looking at multiple two-parameter histograms of gated cell populations become more difficult. Data analysis techniques and automation appropriate to discovery and interpretation of multidimensional data sets such as those generated by various “-omics” analyses may become part of the multiparameter flow cytometry workflow.^{74,75} Computational methods for identifying cell populations in highly multidimensional data sets have been shown to be more effective in reliable and consistent identification of clinically relevant cell populations in multicolor flow cytometry than manual gating and analysis,⁷⁶ particularly in the context of a consensus approach using an ensemble of algorithms, as is commonly done today in weather forecasting.

GATING STRATEGIES

In heterogeneous specimens such as marrow, in which the relevant clinical population (such as blasts) may be a minor population overall, a strategy for specifically identifying the population(s) of interest is necessary. As discussed in Chap. 2, this is accomplished for blood cells by very complex cluster analysis using multiple physical parameters. Because the flow cytometer has a much more sophisticated analytical capability at the back end with the fluorescent markers, the front-end selection of cells is not intended to be definitive, but should include the cells of interest and exclude nonrelevant cells, particularly those that may create an interpretive problem if included in the analysis. This process, referred to as *gating*, is typically accomplished by a combination of CD45 (common leukocyte antigen) and 90-degree light scatter (side scatter). As shown in Figure 3-4, lymphocytes, monocytes, myeloid precursors, and blast cells can be reasonably distinguished in marrow using this method. It is important to exclude monocytes, if they are not the cells one wishes to phenotype, as they express high-affinity Fc receptors that nonspecifically bind antibodies and may cause false-positive fluorescence signals. Individual lineages, such as eosinophils, basophils, and neutrophils, or stages of neutrophilic maturation, are not distinguished as automated hematology analyzers do for blood, but this is not necessary for the diagnostic questions usually asked by flow cytometry. The “blast gate,” defined by dim CD45 expression and low to intermediate side scatter, is a helpful region within which to identify and phenotype blast cells using more specific markers (only a minority of cell in this gate may be blasts,⁷⁷ but many cells with confounding immunophenotypes are excluded). Care must be taken to look for cells with unusual light scatter patterns not fitting in the usual “gates” to make sure the abnormal cells are not “hiding” in these regions. In particularly complex clinical circumstances, several fluorescent markers can be used just to identify a rare or subtly defined neoplastic subset, which can then be more definitively phenotyped in additional tubes containing those “backbone” markers to define the cells of interest plus additional markers to phenotype them. This strategy benefits from the ability to simultaneously measure up to 8 fluorescent markers in currently available clinical

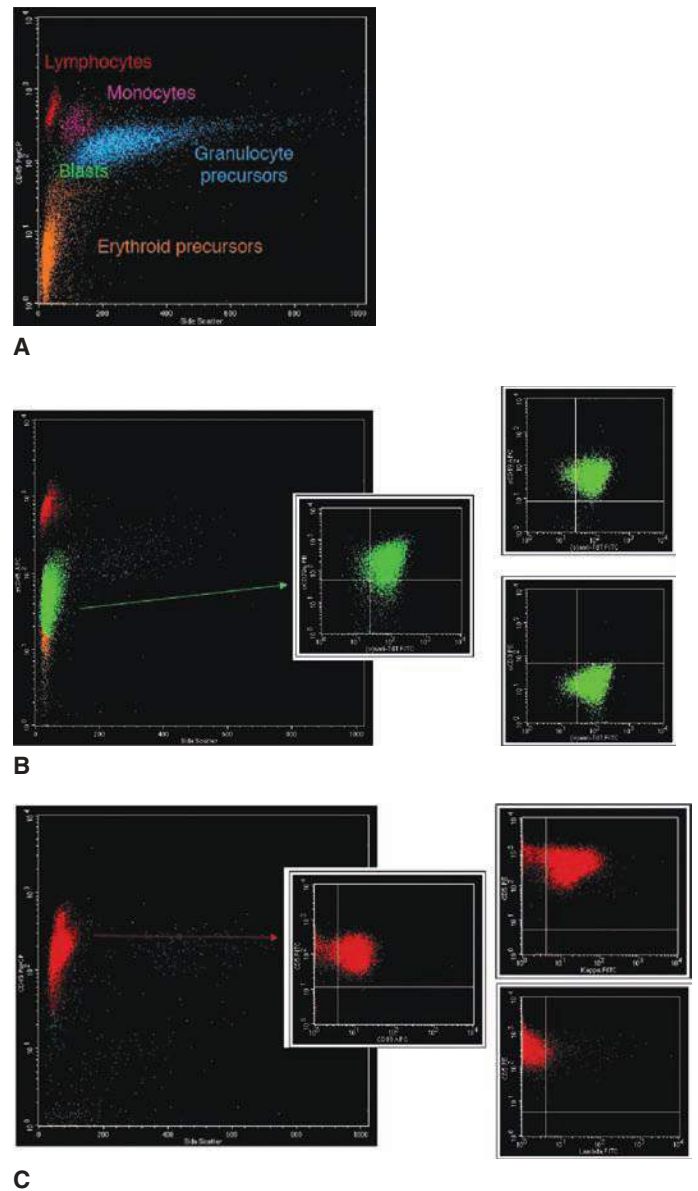

Figure 3-4. Flow cytometry examples: **A.** Normal marrow showing CD45 versus side scatter, which identifies major cell populations as indicated. **B.** Acute lymphoid leukemia, in which an expanded blast population is evident in the CD45 versus side scatter histogram (shown in green). Those cells with dim CD45 and negative side scatter (green) are then gated, so that expression of cell markers on this population only can be analyzed, as shown in the three histograms to the right, where the population is shown to be CD19+/CD79a+ (B cell), terminal deoxynucleotidyl transferase (TdT)+ (immature lymphoid), and CD3- (not T cell), hence B-precursor lymphoblastic leukemia. **C.** Chronic lymphocytic leukemia (CLL), in which an expanded lymphocyte population is evident on the CD45 versus side scatter histogram (shown in red), with coexpression of CD5 and CD19 (consistent with CLL), and expression of only surface immunoglobulin light-chain κ isotype on the CD5+ cells, showing that the population is monoclonal.

systems.⁷⁵ For samples with low cell viability, gating strategies based on light scatter and/or vital exclusion dyes, such as 7 α -actinomycin-D, to limit analysis to the viable cell population only, may be used.⁷³ Strategies are commonly used to exclude cell doublets, for instance, based on the relationship of the pulse width (duration of signal) to pulse height of the forward light scatter signal. Immunocytochemistry of a marrow biopsy

specimen is the preferred method for phenotyping solid tumors and is highly complementary to flow cytometry in diagnosis of lymphoid infiltrates.

COMMON FLOW CYTOMETRY APPLICATIONS IN HEMATOLOGY

Often the diagnostic question involves characterizing an expanded blast population or detection and analysis of a clonal lymphoid population (see Fig. 3–4). These determinations can be achieved by examining lineage-specific or maturation stage-specific markers. For instance, in marrow, immature cell populations can be identified by expression of antigens such as CD34 and CD117. In some instances, the stage of differentiation can be determined using combinations of markers that are expressed only during certain phases of differentiation (e.g., dual expression of CD4 and CD8 in an immature T-precursor population). Stage-specific phenotypes are sometimes valuable clues to clinically relevant diagnoses, such as the characteristic lack of human leukocyte antigen-D related (HLA-DR) expression in promyelocytic leukemia, a phenotype that mimics the normal loss of this antigen in promyelocytes. Among lymphoid leukemia/lymphomas, chronic lymphocytic leukemia (CLL)/small cell lymphoma, mantle cell lymphoma, hairy cell leukemia, and B- or T-precursor lymphoblastic leukemia, among others, have distinctive immunophenotypes. Methodologic advances such as multicolor analysis (6 or more simultaneous fluorescence colors) have allowed flow cytometers to detect and analyze diagnostically important rare subpopulations such as Reed-Sternberg cells in classical Hodgkin lymphoma.⁷⁸ Aberrant phenotype combinations suggestive of malignancy, such as coexpression of high levels of CD56 or CD117 on plasma cells in plasma cell myeloma, or loss of the T-cell markers CD7 or CD26 in a mature phenotype T cell in T-cell lymphoma, are diagnostically useful. Expression intensity is a frequent clue to diagnosis; for example, the weak surface immunoglobulin and weak CD20 expression in CLL. In reporting flow cytometry immunophenotyping results, the summary immunophenotype of the relevant population(s) should be described, rather than simply a listing of the percentage of cells positive for each marker, with subpopulations noted as observed.

Immunophenotyping of marrow by flow cytometry is a useful adjunct to established morphologic and cytogenetic criteria in diagnosing MDS,⁷⁹ and is predictive of later development of overt MDS in the diagnostically challenging group of cytopenic patients with initially morphologically equivocal marrow findings.⁸⁰ Abnormalities in MDS marrow include an increase in the percentages of CD34+ cells even when blasts are not morphologically increased; decreased CD34+ B progenitors; aberrant antigen expression by myeloid progenitors, mature granulocytic cells, or monocytes; and decreased side scatter of mature granulocytic cells. A simplified scoring system (so-called Ogata score) has been validated for use in an interlaboratory study,⁸¹ and international guidelines for a more extensive scoring panel have been published by the International/European Leukemia Net Working Group for Flow Cytometry in MDS.⁸² Immunophenotyping may provide therapeutically relevant prognostic information independent of existing risk factors incorporated in the commonly used (and recently revised) International Prognosis Scoring System (IPSS) score.⁸³

Clonality of immunoglobulin-expressing B-cell malignancies involving marrow (e.g., CLL and lymphoplasmacytic lymphoma) can be determined by simultaneous assessment of surface κ and λ immunoglobulin light-chain expression on the surface of B cells, often in combination with a characteristic neoplastic immunophenotype, such as CD5 expression in CLL B cells. Technical considerations are important to minimize nonspecific binding of serum monoclonal immunoglobulins to the surface of lymphocytes. Cytoplasmic κ and λ identification,

in conjunction with aberrant surface immunophenotype, can also be useful in establishing the clonality of plasma cell neoplasms in marrow. T-cell clonality is not as easily demonstrated, because there are dozens of V β specificities expressed by T cells, and antibodies exist only to identify approximately 70 percent of these. Analysis of V β repertoire of the $\alpha\beta$ T-cell antigen receptor in cells with an atypical immunophenotype, can identify clonal populations of T cells at diagnosis and posttherapy,⁸⁴ but this methodology is less-routinely used in clinical laboratories.

Presence of minimal residual disease (MRD) measured by either detection of a molecular target using PCR or aberrant immunophenotype using multicolor flow cytometry is increasingly used as a prognostic marker, often in the setting of clinical trials, in a variety of hematopoietic neoplasms, including acute leukemia, plasma cell myeloma, and CLL. In some settings, such as chronic phase CML, MRD monitoring by molecular assay is standard practice. In others, both flow cytometry and molecular methods for MRD detection are used successfully, each having their own advantages and limitations.⁸⁵ Flow cytometry assays for MRD are considerably more complex than standard diagnostic phenotyping and need to be designed for this specific purpose,⁸⁶ with collection of large numbers of events, multicolor strategies for detecting different types of subtle aberrant phenotypes, consistent data interpretation protocols, and confirmation of absence of “background” cells in noninvolved (but otherwise comparable; e.g., posttherapy) marrows expressing each aberrant phenotype to be tested. Immunophenotypic evidence of MRD can be sought by detection of specific leukemia associated immunophenotype, or by observation of a population in multidimensional space shifted significantly from any corresponding normal population (“different from normal” approach). Immunophenotypic shifts can occur during treatment, so identification of more than one aberrant phenotype to be tested is advisable when possible. Interpretation of MRD assays is dependent on type of neoplasia, timing of testing, treatment regimen, and standardization of assay methods. Standardization of flow cytometry MRD assays is a challenge that will need to be resolved as these assays move into more routine clinical practice. In acute leukemia, where MRD testing by flow cytometry has been most intensively studied, the assays provide post-treatment prognostic information, but the translation of this information into therapeutic decision making based on MRD risk stratification is further advanced in pediatric leukemia and acute promyelocytic than in adult acute myelogenous leukemia (AML).⁸⁷ MRD detection by either flow cytometry or PCR is standard clinical practice in pediatric acute lymphocytic leukemia (ALL),^{85,86} where nearly all patients have leukemia associated targets suitable for either molecular or flow cytometry MRD assays. Detection of MRD in AML is more challenging because half of patients lack a molecular target suitable for MRD testing, but the majority of AML patients have a leukemia-associated phenotype that can be detected at the 0.1 percent level or below by multicolor flow cytometry. MRD detection in chronic lymphocytic leukemia (CLL)^{88,89} and plasma cell myeloma⁹⁰ is also possible by flow cytometry and molecular techniques, and is becoming a relevant clinical issue now that therapeutic options in these malignancies are rapidly improving.

Flow cytometry is used to enumerate CD34+ progenitors when evaluating the adequacy of blood stem cell collections (Chaps. 23 and 28), with several routine assay kits available.⁹¹ Flow cytometry offers the potential to incorporate other markers defining clinically relevant progenitor and stem cell subpopulations.⁹² Lymphocyte subset quantitation is diagnostically important in acquired and congenital immunodeficiency states. Flow cytometry analysis of glycosylphosphatidylinositol (GPI) linked proteins in multiple blood cell types is the gold standard for diagnosis of paroxysmal nocturnal hemoglobinuria (Chap. 40).⁹³ Flow cytometry detection of paroxysmal nocturnal hemoglobinuria (PNH) clones is facilitated by using FLAER (fluorescently labeled inactive variant of the bacterial protein aerolysin), which binds to all (GPI) linked

structures thus sensitively detecting GPI-linked protein expression in multiple cell lineages. Guidelines for standardized PNH flow assays have been published⁹⁴ and these assays are readily set up in clinical laboratories.

CHAPTER 4

CONSULTATIVE HEMATOLOGY

Rondeep S. Brar and Stanley L. Schrier

SUMMARY

Hematology is a unique science in that its complexity is readily accessible via the examination of blood and marrow. The ease with which a complete blood count (CBC) may be obtained also leads to frequent observation of values which fall outside the reference range. Such perturbations may be the sign of something as ominous as acute leukemia, or as inconsequential as the common cold. That such changes might generate considerable anxiety, both for patients and providers, is not surprising given the plethora of life-threatening diseases that often manifest classic CBC findings.

This ever-increasing dependence on labs as screening tools generates a seemingly endless supply of “abnormal” results, often triggering hematologic consultation. Electronic medical records (EMRs), as repositories for this ever-growing data, serve as invaluable tools in evaluating the chronicity and trend of such findings.

Acronyms and Abbreviations: AC, anticoagulation; ACD, anemia of chronic disease; ADAMTS13, a disintegrin and metalloprotease with a thrombospondin type 1 motif member 13; ALC, absolute lymphocyte count; ALL, acute lymphoblastic leukemia; ANC, absolute neutrophil count; APS, antiphospholipid antibody syndrome; BCR-Abl, breakpoint cluster region-Abelson; CBC, complete blood count; CD, clonal designator; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CMML, chronic myelomonocytic leukemia; CNL, chronic neutrophilic leukemia; CRP, C-reactive protein; DIC, disseminated intravascular coagulation; DVT, deep venous thrombosis; EDTA, ethylenediaminetetraacetic acid; EMR, electronic medical record; EPO, erythropoietin; ER, emergency room; ESR, erythrocyte sedimentation rate; ET, essential thrombocythemia; HELLP, hemolysis, elevated liver enzymes, low platelet count; HHT, hereditary hemorrhagic telangiectasia; HIT, heparin-induced thrombocytopenia; HUS, hemolytic uremic syndrome; ITP, immune thrombocytopenia; JAK2, Janus kinase 2; LDH, lactate dehydrogenase; LGL, large granular lymphocytic; LMWH, low-molecular-weight heparin; MCH, mean corpuscular hemoglobin; MCV, mean corpuscular volume; MDS, myelodysplastic syndrome; MGUS, monoclonal gammopathy of undetermined significance; MPN, myeloproliferative neoplasm; MTHFR, methylenetetrahydrofolate reductase; nRBC, nucleated red blood cell; NSAID, nonsteroidal antiinflammatory drug; p50, partial pressure required to achieve 50 percent saturation; PCR, polymerase chain reaction; PE, pulmonary embolism; PFA, platelet function analysis; PMN, polymorphonuclear neutrophil; PNH, paroxysmal nocturnal hemoglobinuria; PT, prothrombin time; PTT, partial thromboplastin time; PV, polycythemia vera; RBC, red blood cell; RIPA, ristocetin-induced platelet aggregation; RT, reptilase time; SPEP, serum protein electrophoresis; TT, thrombin time; TTP, thrombotic thrombocytopenic purpura; UPEP, urine protein electrophoresis; VWD, von Willebrand disease; WBC, white blood cell.

In this chapter, we outline our approach to dealing with these common queries. The individual epidemiology, pathogenesis, and treatment of such disorders are covered comprehensively and with clarity within their corresponding chapters and are not repeated here. Rather, what we describe is our thought process in approaching such questions and narrowing the broad differential to that which is reasonable and probable.

● LEUKOPENIA

Detection of a low white blood cell (WBC) count is a common reason for hematologic consultation. Clinicians and patients are attentive to early signs of marrow pathology, such as myelodysplastic syndrome (MDS), although such diseases are found only in a minority of referrals. Nevertheless, the severity of potential pathology mandates leukopenia be taken seriously and approached thoughtfully.

One begins by determining if the predominant finding is neutropenia, lymphopenia, monocytopenia, or all of the above.

NEUTROPENIA

The potential causes of neutropenia are diverse and include congenital disorders, autoimmune disorders, infections, nutritional deficiencies, medications, and, of course, hematolymphoid neoplasias. These are discussed in detail in Chap. 65.

Degrees of neutropenia may be broadly classified as mild (absolute neutrophil count [ANC] 1000–1500 cells/ μ L), moderate (ANC 500–1000 cells/ μ L), or severe (ANC <500 cells/ μ L).

The three most important historical details are the degree of neutropenia, acuity of onset, and presence or absence of associated symptoms. Each is considered individually and within the context of other findings.

The degree of neutropenia is informative. There is no specific ANC threshold that mandates evaluation. In general, mild neutropenia with preservation of other lineages in the asymptomatic patient may be observed, whereas moderate or severe neutropenia increases the risk of infection and probability of underlying pathology. The degree of neutropenia is not *a priori* a measure of its potential consequences. For example, patients with chronic idiopathic neutropenia may have blood neutrophil counts approaching zero with no symptoms or increased risk of infection.

The acuity of neutropenia is quite helpful, and the advent of the electronic medical record (EMR) allows for the rapid evaluation of such trends. In acute onset neutropenia, it is useful to inquire about recent infections and new medications. The latter is often an important clue. The number of medications that might cause neutropenia is vast, and some representative agents are shown in Chap. 65, Table 65–1. The temporal association of new medications with cytopenias is often the strongest evidence of causality. If there is suspicion for drug-induced neutropenia, the offending medication should be discontinued. If this is not possible, switching to a congener with a different chemical structure would be strongly considered.

In cases of chronic neutropenia, one should explore possibilities such as congenital neutropenia, chronic idiopathic neutropenia, infection particularly hepatitis and HIV, and autoimmune disorders. With respect to the latter, systemic lupus erythematosus is important to be cognizant of, as nearly half of such patients will be leukopenic. Thus

symptoms of photosensitivity, arthralgia, and recurrent pregnancy morbidity should trigger rheumatologic consultation.

Hematolymphoid neoplasias may present with either acute or chronic cytopenias. When considering the presence of malignancy, one should attempt to identify other concerning findings, such as other cytopenias, adenopathy, fever, organomegaly, or unintentional weight loss, in addition to isolated neutropenia.

LYMPHOPENIA

Lymphopenia, defined as an absolute lymphocyte count (ALC) less than 1500 cells/ μ L, may be seen in a variety of settings. One should begin by assessing the chronicity and severity of lymphopenia, along with a thorough physical examination. The latter should focus on any evidence of splenomegaly, adenopathy, or evidence of fungal infection, such as oral candidiasis. The numerous inherited and acquired causes of lymphopenia are noted in Chap. 79.

Notably HIV infection should be excluded in the lymphopenic patient. Similarly, a concomitant infection with a number of viral or bacterial pathogens may result in lymphopenia. One of the most common iatrogenic causes of lymphopenia is the use of glucocorticoids. Alcoholism may also result in lymphopenia.

MONOCYTOPENIA

Although monocytopenia is described in a number of settings (Chap. 70), the most notable entity to exclude is hairy cell leukemia. Although rare, this B-cell lymphoproliferative disorder presents with constitutional symptoms, splenomegaly, and the majority of patients are monocytopenic as well as neutropenic (Chap. 93). Thus, in a patient with compatible symptoms and monocytopenia, even without classic hairy cells on the blood film, it is worthwhile performing flow cytometry with attention to hairy cell markers, including clonal designator (CD) 11c and CD103.

Severe monocytopenia may rarely be seen in the MonoMAC (monocytopenia and mycobacterial infection) syndrome. Described in 2010, it is associated with extreme monocytopenia or a monocytosis, may be associated with mycobacterial and viral infections and results from a mutation in the *GATA-2* gene. It has a high risk of progressing to MDS or acute myelogenous leukemia (Chap. 70).

ANEMIA

The underlying pathophysiology of the anemia must be identified. We use three interacting analytic tools:

1. Standard hematologic indices, particularly mean corpuscular volume (MCV) and mean corpuscular hemoglobin (MCH).
2. Kinetic analysis (Chaps. 32 and 33) seeking to determine if the underlying cause is a defect in red blood cell (RBC) production, an increase in RBC destruction (hemolysis), or blood loss. Humans replace 1 percent of their RBCs per day (Chap. 32). Any decrease in hemoglobin greater than 1 percent/day implies the patient is bleeding, hemolyzing, or both.
3. An awareness of patient demographics. For example, a pediatric practice may place hemoglobinopathies high on the differential, whereas a geriatric internal medicine practice will commonly encounter anemia of chronic disease and iron deficiency.

The history and medical records are important tools in identifying the severity and duration of anemia. The timeline of development is crucial: if it has been lifelong, congenital causes are likely. If not, then the events

surrounding the development of anemia may also provide clues, as well as indicate if additional abnormalities in the other cell lines are present.

The physical should be a comprehensive exam with particular attention to lymphadenopathy, liver/spleen size, and assessment of cardiovascular status. Laboratory analysis requires a current complete blood count (CBC) and a blood film. Critically, one cannot rely on an isolated hemoglobin value without the remainder of the CBC. An absolute reticulocyte count, corrected for the degree of anemia, is also required. A comprehensive metabolic panel as well, including renal and liver function tests, is useful in narrowing the differential.

If the anemia is of recent origin with a normal MCV and a low corrected absolute reticulocyte count (meaning there is a production defect), then anemia of chronic disease (ACD) (Chap. 37) is likely. Additional labs evaluating inflammatory activity, such as ferritin, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP), may be helpful. If there is a RBC production defect, but no evidence of inflammatory disease, it is important to exclude renal dysfunction. In this setting, we evaluate serum creatinine and erythropoietin levels.

One must maintain a high suspicion for iron deficiency, even in the setting of a normal MCV and blood film (Chap. 43). Useful items include a ferritin, transferrin saturation, and clinical evaluation for blood loss. Conversely, consider a patient in which the hemoglobin is 10.5 g/dL, MCV 64 fL, MCH 19 pg, and absolute reticulocyte count is elevated to 180,000. The blood film shows microcytic, hypochromic RBCs with occasional target cells. Although iron levels should be determined, thalassemia will be much more likely (Chap. 48).

If the MCV is greater than 100 fL and the reticulocyte count suggests a production defect, examine both the WBC and platelet number and morphology. If either is abnormal, then primary marrow disorders such as MDS become more likely than nutritional deficiencies such as vitamin B₁₂ or folate. A marrow biopsy should be performed in this setting.

If the rate of hemoglobin fall is greater than 1 percent/day, and the corrected reticulocyte count is elevated, bleeding or hemolysis is occurring. One should search for specific RBC morphologic anomalies on the blood film. If spherocytes, fragmented cells, or Heinz bodies (Chaps. 2 and 31) are present, then hemolysis is likely. We obtain a haptoglobin, indirect bilirubin, lactate dehydrogenase (LDH), and a direct Coombs study. The history is informative. If the hemolysis is lifelong, then RBC intracorpuscular defects (either of hemoglobin, membrane, or enzymes [Chaps. 46, 47, and 49]) are likely. If the hemolysis is recent, then acquired extracorpuscular causes, such as autoimmune hemolysis, parasitic disease, renal/hepatic disease, or hypersplenism, are likely (Chaps. 51 to 54 and 56).

If the anemia is persistent, symptomatic, and the aforementioned workup has not provided a diagnosis, then marrow biopsy and aspiration are indicated.

THROMBOCYTOPENIA

Whereas the consultative approach to thrombocytosis is relatively straightforward, the opposite is true for thrombocytopenia. The clinical situation may be urgent and the differential diagnosis, upon which management is based, is huge (Chap. 117). It is helpful to think of the underlying cause(s) mechanistically:

- *Platelet production is low:* The marrow is replaced (leukemia, lymphoma), empty (aplastic anemia), or ineffective (MDS, vitamin B₁₂ deficiency).
- *Platelets are being rapidly removed from circulation:* Thrombotic microangiopathy (thrombotic thrombocytopenic purpura [TTP], hemolytic uremic syndrome [HUS], disseminated intravascular

coagulation [DIC], hemolysis, elevated liver enzymes, low platelet count [HELLP]) or autoimmune platelet removal (immune thrombocytopenia [ITP], drug-induced thrombocytopenia, heparin-induced thrombocytopenia [HIT]).

- *Platelets are being sequestered:* Massive splenomegaly or hemangiomas.

If one encounters a new finding of severe thrombocytopenia, one must immediately review the blood film for the presence of microangiopathy. If present, concern is raised for TTP, and immediate intervention is required (Chap. 132).

The history provides key information. Comorbid autoimmune and lymphoproliferative diseases may be associated with ITP. Culprit drugs, such as heparin or quinidine, must be explored. Hepatic disease is a common cause of thrombocytopenia and should be queried. The EMR should be used to explore the temporal nature of the thrombocytopenia and other associated CBC anomalies. The physical exam should pay special attention to petechiae, oral blood blisters, ecchymoses, adenopathy, and organomegaly. In reviewing the blood film, one should exclude *spurious thrombocytopenia* (Chap. 117) that may include ethylenediaminetetraacetic acid (EDTA)-induced platelet clumping (pseudothrombocytopenia), presence of megathrombocytes that are too large to be recognized as such by automatic cell counters, or adherence of platelets to neutrophils (platelet satellitism) which can be ameliorated by using sodium citrate as an anticoagulant. Next, one should check for the presence of microangiopathy which, if present, would lead to consideration for TTP, HUS, or DIC. Spherocytes and polychromasia would raise the possibility of combined ITP and autoimmune hemolytic anemia, otherwise known as Evans syndrome. Giant hypogranulated platelets raise consideration of MDS, and more than six lobed polymorphonuclear neutrophils (PMNs) associated with an MCV >115 suggest vitamin B₁₂ or folate deficiency (Chap. 41). In a patient with newly developed isolated thrombocytopenia, megathrombocytes, platelets greater in diameter than one-third of a red cell diameter ($>2.5 \mu\text{M}$), are the parallel of the reticulocyte count. More than 10 percent such platelets are suggestive of immune platelet destruction with a compensatory increase in thrombopoiesis.

In the case of isolated thrombocytopenia, the most common cause is autoimmune thrombocytopenia. ITP may also be drug-induced. An important feature of autoimmune thrombocytopenia is the absence of splenomegaly, thus an enlarged spleen points to other diagnoses such as lymphoproliferative disease, hypersplenism, or lupus. Approximately 25 percent of patients with the antiphospholipid antibody syndrome have mild thrombocytopenia (50 to $130 \times 10^9/\text{L}$). Bleeding is not a feature of this phenomenon and it may be confused with autoimmune thrombocytopenia. HIT is an event seen in hospitalized patients or those receiving heparin through home care (Chap. 118). The thrombocytopenia can be mild (e.g., 20 to $100 \times 10^9/\text{L}$) and bleeding is unusual. It usually occurs 5 to 10 days after exposure to heparin and is associated with both venous and arterial thrombosis. Often, the patient may be quite ill, postoperative, and have other plausible explanations for thrombosis, thus requiring a high index of suspicion. It is less frequent with low-molecular-weight heparin (LMWH) preparations, but still can occur in that setting. The specifics of diagnostic tests and management are discussed in Chap. 118.

With baseline data from history, exam, and routine labs, a preliminary analysis should be performed to focus subsequent specialized testing. For example, in a patient with CNS symptoms, microangiopathic hemolysis, and an elevated serum creatinine, a disintegrin and metalloprotease with a thrombospondin type 1 motif member 13 (ADAMTS13) activity level should be ordered in addition to instituting prompt plasmapheresis for the tentative diagnosis of TTP. In a patient who received heparin 5 days prior during cardiac surgery, HIT is considered and an immunoassay for antiplatelet factor 4 obtained.

● PANCYTOPENIA

The presentation of a patient with new-onset pancytopenia requires immediate medical attention. In formulating an approach to a patient who presents with a combination of anemia, thrombocytopenia, and leukopenia it is useful to think of the pathophysiology in mechanistic terms. It is also important in constructing a differential diagnosis to determine whether the leukopenia is balanced, neutropenia, or lymphopenia.

The blood counts may be low because the normal hematopoietic marrow has been replaced (fibrosis, infiltrative malignancy), is absent (aplastic anemia), or is ineffective (MDS, vitamin B₁₂ deficiency). Hypersplenism can also result in the rapid removal of cells from the blood, for example in the context of a malignant lymphoma.

The history provides several critical pieces of information: How severe is the pancytopenia? How long has it been present? Is it getting better or worse? What was going on when it began? Was there an infection at onset, or has the patient had any new medications or occupational exposures? Symptoms of anemia (fatigue, shortness of breath), thrombocytopenia (mucosal bleeding, bruising), and leukopenia (recurrent infections, stomatitis) are important to determine, as are risk factors for hepatic disease (as cirrhosis commonly results in pancytopenia).

The physical exam should be comprehensive with a particular focus on organomegaly and adenopathy.

If the MCV is greater than 100 fL, consider MDS. Chemistry panels are obtained to evaluate for evidence of renal or hepatic dysfunction. An increase in MCV of greater than 115 fL is more common in megaloblastic anemia than in MDS. Folate deficiency may be seen in settings of alcohol abuse or celiac sprue. Pernicious anemia is an important consideration for vitamin B₁₂ deficiency because it is treatable with cobalamin and, if unrecognized, may proceed to severe neurologic impairment. Uncommonly, the latter may be the presenting feature (in addition to the cognitive abnormalities known as megaloblastic madness; Chap. 41).

As always, a critical review of the blood film may suggest the diagnosis, including the presence of dysplasia (MDS), hypersegmented neutrophils (vitamin B₁₂ and folate deficiency), and myelophthistic features (leukoerythroblastic findings such as nucleated RBCs and teardrops) that might suggest primary myelofibrosis (Chap. 86) or a marrow-replacing process (Chap. 45). The presence of abnormal or neoplastic cells in the blood may be diagnostic, such as leukemic blasts, hairy cells, or circulating lymphoma cells.

With this information one can decide on a further diagnostic strategy. Occasionally one sees patients where the pancytopenia is mild and resolves spontaneously within 1 month, which may represent a viral infection with transient suppression of hematopoiesis.

If, in a patient with pancytopenia, the reticulocyte count is very low, aplastic anemia becomes a primary consideration. Other malignant causes of severe cytopenias, such as acute leukemia or MDS, are uncommonly associated with reticulocyte counts less than 0.4 percent. An enlarged spleen is not a feature of aplastic anemia, and its presence would argue against the diagnosis.

Nearly all patients with unexplained severe and persistent pancytopenia will require a diagnostic marrow aspirate and biopsy.

● LEUKOCYTOSIS

An elevated leukocyte count often raises concern for marrow pathology, but may be seen in nearly any systemic disorder. There is no numeric cutoff that reliably distinguishes between primary hemolymphoid and secondary causes of leukocytosis. Rather, a thorough history, physical, and focused laboratory evaluation is required.

Leukocytosis refers to an elevated total leukocyte count. When combined with an elevated ANC, the term *neutrophilic leukocytosis* is used. If an elevated ANC is present without leukocytosis, the term *neutrophilia* is applied. The same terminology holds for elevations of the lymphocyte, monocyte, eosinophil, and basophil compartments. In practice, however, these distinctions are rarely made, nor do they have a major impact on diagnostic evaluations, and thus we use them interchangeably.

NEUTROPHILIA

Neutrophilia may be seen in a variety of settings as outlined in Chap. 65. Primary marrow disorders include chronic myelogenous leukemia (CML), other myeloproliferative neoplasms, neutrophilic leukemia, and sickle cell disease. Secondary disorders include infection, inflammation, smoking, stress (both physical and emotional), asplenia, and medications. With respect to the latter, common offenders include corticosteroids, lithium, and exogenous growth factors such as granulocyte colony-stimulating factor. Rare cases of dramatic neutrophilia (usually accompanied by mild anemia) can be associated with granulocyte colony-stimulating factor–secreting tumors (e.g., bronchogenic carcinoma). In a patient with persistent neutrophilia of unclear etiology, it is generally advisable to exclude CML with a qualitative breakpoint cluster region-Abelson (BCR-Abl) polymerase chain reaction (PCR) analysis. The other classic myeloproliferative neoplasms (MPNs), such as polycythemia vera (PV), essential thrombocythemia (ET), and myelofibrosis, will typically have other manifestations suggesting the diagnosis, such as erythrocytosis, thrombocytosis, organomegaly, and/or a leukoerythroblastic blood film. Chronic neutrophilic leukemia (CNL), though often considered by clinicians, is a rare disorder. The WBC should be greater than 25,000/ μL of which greater than 80 percent are neutrophils to consider this entity.

Smokers commonly demonstrate a mild neutrophilia, and if this has been longstanding in an otherwise asymptomatic patient, further measures other than smoking cessation are typically unnecessary. Similarly, mild neutrophilic leukocytosis may be seen in obese patients, perhaps reflective of an underlying inflammatory state. It is rarely useful to perform a marrow examination for neutrophilia during times of systemic infection or critical illness in the intensive care unit, except for the rare instance in which neutrophilia is felt to be the proximate illness, as in CNL.

LYMPHOCYTOSIS

The diverse causes of lymphocytosis are listed in Chap. 79. Primary marrow disorders include chronic lymphocytic leukemia (CLL), acute lymphoblastic leukemia (ALL), and hairy cell leukemia. Reactive lymphocytosis may be seen in viral infection (classically infectious mononucleosis), HIV, bacterial infection, smokers, and autoimmune disorders (such as rheumatoid arthritis).

Lymphocyte morphology is generally more informative than is the case in neutrophilia. If the lymphocytes display coarse, clumped chromatin, suspicion is raised for CLL. Readily identifiable lymphoblasts suggest ALL. An excess of large granular lymphocytes, particularly in a patient with autoimmune disease such as rheumatoid arthritis, suggest large granular lymphocytic (LGL) leukemia. The presence of lymphocytes with villous projections might suggest splenic marginal zone lymphoma or hairy cell leukemia. Larger lymphocytes with cleaved nuclei may be seen in follicular lymphoma, and cells with cerebriform nuclei might represent the malignant T cells of Sézary syndrome. Hence, examination of the blood film is a critical component of the lymphocytosis evaluation. The laboratory evaluation might also include flow cytometric analysis, as the immunophenotype of atypical lymphocytes often leads to significant narrowing of the differential diagnosis.

EOSINOPHILIA

Eosinophilia has a daunting differential, as discussed in Chap. 62. On initial screen, we seek to identify patients with moderate (>1500 cells/ μL) or greater eosinophilia, or those with evidence of end organ damage, as these groups are more likely to have serious pathology. The history should include assessment of B symptoms, rash, diarrhea, allergic symptoms, travel history, and food intake. Ingestion of raw or undercooked meat, especially pork, increases the chance of parasitic infection with *Trichinella spiralis*, which may be accompanied by significant eosinophilia, periorbital edema, myositis, and fever. This infestation usually occurs at festivities where a pig is roasted and served. Pork from abattoirs involves mixing of meat from a large number of pigs, diluting the *Trichinella* organisms that might have infected a rare animal. The geographic location and lifestyle of the patient determines if consideration of another parasitic infestation is a high probability. In underdeveloped countries, helminthic infections are the most common cause of eosinophilia (see Chap. 62, Table 62–5 for causes of helminthic-induced eosinophilia). Signs of adrenal insufficiency (fatigue, hypotension, hyperpigmentation) a rare cause of eosinophilia, may be subtle. Rhinosinusitis, asthma, and eosinophilia should trigger screening for eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome). Mast cell disorders are also associated with eosinophilia, and should be kept in mind in patients with a rash suggestive of urticaria pigmentosa or symptoms of mediator release with identified triggers. Patients with extreme eosinophilia are often critically ill and nearly always require hospitalization because of the high probability of malignancy or infection, in addition to risks for life-threatening damage to the cardiac, respiratory, nervous, and gastrointestinal systems.

BASOPHILIA AND MONOCYTOSIS

Disorders associated with basophilia and monocytosis are more limited, and are listed in Chaps. 63 and 70, respectively. In the absence of an obvious infectious/inflammatory insult, basophilia should always trigger evaluation for CML and PV. Unexplained monocytosis, particularly in elderly patients with other cytopenias, should reflex concern for myeloid malignancies such as MDS and chronic myelomonocytic leukemia (CMML) and generally warrants examination of the marrow.

● ERYTHROCYTOSIS/POLYCYTHEMIA

As opposed to hematologic consultation for the cytopenias, evaluation for polycythemia generally has a more limited differential diagnosis (Chaps. 57 and 84). Technically, “polycythemia” refers to increases in RBC, WBC, and platelets, while “erythrocytosis” more specifically refers to increases in RBCs alone. We are aware, however, that in common hematologic parlance the term *polycythemia* is frequently used to indicate erythrocytosis and here we use them interchangeably. The disorders that may cause polycythemia are diverse and have widely varying treatments. Attention to detail is critical.

First, the distinction between absolute and relative polycythemia should be made. The former refers to a true elevation of the red cell mass, whereas the latter refers to an apparent increase in hemoglobin caused by a contracted plasma volume. Reduced plasma volumes might be seen in patients who are dehydrated and are also reported in chronic smokers. However, smokers are more often polycythemic by virtue of their cardiopulmonary disease, so this distinction is difficult to make.

When evaluating a referral for elevated RBC, hemoglobin, or hematocrit, one begins by determining which measure is elevated. Although definitions vary, one may assume polycythemia is present if the hemoglobin is greater than 18.5 g/dL in men or greater than 16.5 g/dL in women.

If a referral is received for an elevated RBC count in the absence of true erythrocytosis, a major consideration is thalassemic trait. Additional clues for this would include a normal or low hemoglobin in addition to severe microcytosis, and a blood film showing targets, as well as hypochromia and microcytosis.

The history is critical in evaluation of erythrocytosis (Chap. 57). Key items after determining if the abnormality is acquired or congenital include:

- History of pulmonary disease or chronic hypoxia
- Risk factors for renal, hepatic, or CNS tumors
- History of obstructive sleep apnea
- Family history of polycythemia
- Use of androgens or anabolic steroids
- Surreptitious erythropoietin (EPO) injection (particularly in competitive athletes)
- Presence of symptoms related to polycythemia

Primary polycythemia refers to autonomous marrow production of erythrocytes, as in PV, whereas secondary polycythemia refers to increased erythrocyte production from stimulation by EPO (Chap. 57). Elevated EPO levels may be a compensatory response to hypoxia or produced in excess by malignancy. Secondary causes of polycythemia are discussed at length in Chap. 57.

Historical symptoms related to polycythemia should also be elicited, including headache, fatigue, visual changes, and shortness of breath. Symptoms of pruritus, erythromelalgia, or intolerance of hot water might be more suggestive of PV.

Clues during the physical exam include:

1. Digital clubbing, which might suggest pulmonary disease
2. Splenomegaly, which might suggest PV
3. Hepatomegaly, which might suggest PV or a hepatic tumor
4. Facial plethora, which is often seen in PV, although can be seen in erythrocytosis of any cause

The laboratory evaluation should include a CBC, EPO level, and venous blood gas measurement. The latter is useful in that it allows indirect calculation of the partial pressure required to achieve 50 percent saturation (p50) (reduced in high-affinity hemoglobinopathies, which should be considered in cases of familial polycythemia) and also provides information regarding carboxyhemoglobin (elevated in smokers or in carbon monoxide poisoning) and methemoglobin levels.

The combination of polycythemia and a low EPO level is highly suggestive of PV. This should trigger reflex mutational testing for *JAK2*^{V617F} (exon 14), and, if negative, Janus kinase 2 (*JAK2*) exon 12 mutation. These two mutations capture nearly all cases of PV, and if negative, should trigger the diagnosis to be reconsidered and/or tertiary referral.

More commonly, the EPO level is found to be normal or elevated. This makes PV less likely, although certainly not exclusionary. If the patient has symptoms suggestive of PV or otherwise unexplained polycythemia, *JAK2* mutational testing should still be obtained.

If the EPO level is high normal/elevated and there are no PV-related symptoms, a thorough evaluation for secondary polycythemia should be performed. In the absence of cardiopulmonary disease or obvious offending medications, polycythemia with a significantly elevated EPO level should trigger evaluation for malignancy.

Although rare, familial polycythemia should always be in the differential, particularly if the family history is suggestive. The various mutations in regulators of erythropoiesis and hypoxia-sensing, and are discussed in detail in Chap. 57.

A diagnostic algorithm for erythrocytosis is shown in Chap. 57, Fig. 57-6.

● THROMBOCYTOSIS

When evaluating thrombocytosis, one must generally determine whether it is reactive or the manifestation of a MPN (Chaps. 84 to 86).

Historical details should include: When were the platelets first elevated? Is the elevation intermittent or constant? Have the platelets ever exceeded 1,000,000/ μ L? Has there been any thrombosis? Has there been paradoxical bleeding suggestive of acquired von Willebrand disease (VWD)? Causes of reactive thrombocytosis (Chap. 119), such as inflammatory disease, infection, recent splenectomy, iron deficiency, and malignancy, should be explored.

The physical exam should include evaluation for organomegaly, given this may be seen in a variety of MPNs.

In reviewing the CBC, a concomitant elevation of the hemoglobin and platelets might suggest PV. Neutrophilia, myeloid immaturity, or basophilia might suggest CML or myelofibrosis.

If there is significant suspicion for a MPN, such as organomegaly, persistent thrombocytosis, polycythemia, or neutrophilia, additional evaluation might include molecular testing for *BCR-Abl*, *JAK2*, and/or calreticulin mutations (Chaps. 84-86).

● PREGNANCY

Hematologic issues arising during pregnancy are a common cause for consultation. In contrast to the nonpregnant patient, the consultant must consider both the patient and the fetus (Chaps. 7 and 8). In this section we will not consider hematologic disorders of the fetus such as hemolytic disease of the newborn and neonatal alloimmune thrombocytopenia (Chaps. 8 and 55).

During the transition from the second to third trimester, the plasma volume increases by approximately 1.0 L while the RBC mass increases by approximately 0.25 L. This partial hemodilution can cause a drop in hemoglobin values below the normal 12 g/dL for women. There are further complicating issues. The growing fetus requires approximately 500 mg of iron from the mother, and if the mother is already iron deficient and/or not taking adequate iron supplements, iron-deficiency anemia will develop. In mothers with thalassemia intermedia, the marrow is already stressed and providing close to maximum compensatory erythropoiesis at baseline. The marrow cannot provide the additional 0.25 L of RBC mass during pregnancy, causing hemoglobin levels to fall where both the patient and fetus may be stressed. Supportive transfusions are often necessary in this case.

One is often asked to consult because of a neutrophilic leukocytosis occurring during the second and third trimesters. This is typically physiologic and the film may show myeloid immaturity with bands, metamyelocytes, and even myelocytes. Observation is recommended.

Other than the variations noted above, the approach to anemia and WBC abnormalities is essentially identical to the nonpregnant patient.

Thrombocytopenia as low as 50,000 to 70,000/ μ L may be seen as a normal consequence of pregnancy and is termed *gestational thrombocytopenia*. It requires no specific management. Nongestational thrombocytopenia, however, requires particular care because the differential is broader in pregnancy and because of the risk of both maternal and fetal hemorrhage. For example, when treating patients with ITP, there is concern that the causative antiplatelet antibody will cross the placenta and cause fetal thrombocytopenia. The distortion of the fetus, particularly of the cranium during delivery, raises concern about intracranial hemorrhage if the neonate is thrombocytopenic. Newborns of mothers with ITP should generally have serial platelet counts over the first week of life as thrombocytopenia may be delayed as splenic function develops.

The appearance of low platelets along with hypertension in the third trimester raises concern for preeclampsia. Perhaps a more-severe

variant of preeclampsia is the HELLP syndrome (Chaps. 8 and 51), an emergency where low platelets are accompanied by microangiopathic hemolysis and hepatic dysfunction. The blood film and liver function tests are essential in making this diagnosis.

Disorders of hemostasis/coagulation include placental abruption and retained products of conception. These two conditions are unique to pregnancy and release large amounts of necrotic tissue into the circulation, leading to DIC (Chap. 129). The consultant is often called because of severe bleeding from many sites, including the vagina, vascular access sites, and surgical incisions. Laboratory findings often demonstrate profound anemia and thrombocytopenia, and the blood film shows microangiopathy. The coagulation panel demonstrates a prolonged prothrombin time (PT) and partial thromboplastin time (PTT), low fibrinogen, and significantly elevated D-dimer. If assayed, virtually all coagulation factors will be low. The key to management is prompt recognition, establishment of adequate IV access, and massive replacement of RBCs, platelets, and coagulation factors, along with removal of the uterine contents.

Two disorders have a specific predilection for the immediate postpartum period: appearance of a factor VIII inhibitor and postpartum TTP. Patients with a factor VIII inhibitor will show a long PTT and mixing studies will identify and quantify the inhibitor. Patients with postpartum TTP will have a clinical presentation like other TTP patients: microangiopathic hemolysis, thrombocytopenia, and potentially CNS and renal involvement.

● BLEEDING

Clinical bleeding is a common request for hematologic consultation. The setting and context provide important clues about the diagnosis. Requests arising from the ICU or emergency room (ER) usually relate to a specific event like trauma or surgery. These requests may involve hemodynamic compromise and often mandate a rapid response. Conversely, complaints about “easy bruising” can be equally ominous, but often don't rise to the same level of acuity.

The conventional wisdom is that mucosal and skin bleeding is likely to be caused by platelet abnormalities (qualitative or quantitative), vascular disorders, or VWD, whereas deep tissue or joint bleeding is caused by coagulation factor deficiencies. This is generally accurate, although there is substantial overlap caused by factors like age and comorbid medications (including aspirin, nonsteroidal antiinflammatory drugs [NSAIDs], and anticoagulants).

As expected, the history is critical. One must inquire about bleeding length, duration, and context. A long duration and early onset suggest a hereditary disorder. Bleedings that occur after dental extractions or surgery are clues for mild hemophilia or VWD. If the bleeding always occurs at one site, there may well be a local issue, whereas bleeding at multiple sites points to a systemic disorder. Drug history is critical, not only for anticoagulant drugs, but also for the many agents that cause drug-induced platelet functional abnormalities (Chap. 121). A history of alcohol abuse, hepatic disease, or renal disease is relevant.

The exam should be used to identify petechiae, oral blood blisters, ecchymoses, hematomas, giant hemangiomas, hemarthroses, and liver/spleen size.

Laboratory analysis should include a blood film, CBC, and chemistry panel. A basic coagulation panel containing a PT, PTT, fibrinogen, D-dimer, thrombin time (TT), and reptilase time (RT) is also important (Chaps. 114 and 116). The PT and PTT screen both the intrinsic and extrinsic pathways. The fibrinogen and D-dimer provide useful information about DIC and fibrinolysis, while a discrepancy between the RT and TT can determine whether there is *in vivo* presence of heparin.

Before deciding that a prolonged PT or PTT is because of a factor deficiency, consider the possibility of an inhibitor by ordering a mixing study. If an inhibitor is ruled out, then one can determine whether specific factor assays are warranted. A prolonged PTT might also be the result of a lupus anticoagulant, which generally poses a risk for thrombosis rather than hemorrhage.

If there is recurrent mucosal bleeding and a family history of bleeding, we generally obtain screening for VWD. A platelet function analysis (PFA) is a highly sensitive test for VWD. Additional tests, such as a von Willebrand antigen, ristocetin cofactor activity, and factor VIII levels can be used to confirm the diagnosis. More expensive studies, such as multimer analysis and ristocetin-induced platelet aggregation (RIPA) are generally not needed if screening studies are negative. A variety of disorders are associated with acquired VWD, including cardiac valvular disorders, extreme thrombocytosis, paraproteinemias, and autoimmune disorders (Chap. 126).

Mucosal or posttraumatic bleeding might also suggest a platelet functional defect. Screening with a PFA is often useful before launching into more detailed studies, such as formal platelet aggregometry.

A low fibrinogen and markedly elevated D-dimer points to DIC, which can be seen in a variety of systemic illnesses and is associated with both bleeding and thrombosis.

Of course, not all bleeding is related to disorders of coagulation factors and platelets. One should not forget vasculitis or other vascular defects, such as hereditary hemorrhagic telangiectasia (HHT), when evaluating a patient with recurrent mucosal bleeding and epistaxis. Vitamin C deficiency (scurvy) can rarely be encountered in alcoholics or severely malnourished individuals and results in bruising and gingival bleeding because of defective collagen synthesis.

Pathologic fibrinolysis may also result in bleeding and is not easily assessed by standard coagulation panels (Chap. 135).

We have used thromboelastography to evaluate global hemostasis on an individualized basis, although this study lacks broad clinical utility.

Finally, preoperative consultations for bleeding can be frustrating because there are no generally accepted guidelines. The most important tool is the history including family and personal history of bleeding. The type, site, and timing of prior episodes of bleeding, whether postoperative, traumatic, or spontaneous, provide the requisite information upon which to base further testing as discussed above.

● THROMBOSIS

VENOUS THROMBOSIS

Consultations regarding deep venous thrombosis (DVT) may be daunting. The decision to commit a young patient to indefinite anticoagulation (AC), or to cease AC in an older patient at increased risk for recurrence often gives the physician pause.

Here we discuss some of the highlights of our approach to venous thromboembolism. The individual components are discussed at length in other chapters, including principles of AC (Chap. 25), DVT (Chap. 133), hereditary thrombophilia (Chap. 130), and the antiphospholipid antibody syndrome (APS; Chap. 131).

Patients often have significant anxiety after a thrombotic event. Although considerable progress has been made in the safety and convenience of AC, the process still poses serious risk and may impair the patient's quality of life. It is important to communicate that AC management is inherently complex, therapeutic approaches must be individualized, and, ultimately, no approach is without risk, including life-threatening bleeding and/or thrombosis.

One should begin the evaluation of a new DVT by defining the context of the event. Critical questions include:

1. Were there any risk factors, such as surgery, immobility, trauma, indwelling catheters, cirrhosis, nephrotic syndrome, inflammatory disorders, or systemic estrogen therapy (Chap. 133)?
2. If present, are those risk factors modifiable and might they have reasonably provoked the event?
3. If dealing with a reoccurrence while on AC, had the patient been compliant with therapy?
4. Are there historical or physical clues that might suggest malignancy, APS, or a hereditary thrombophilia?

When probing hard enough, one is often able to identify a “risk factor” for thrombosis. This alone is insufficient to label an event “provoked”; rather, that risk factor must be thought to have reasonably caused the event. Attribution of causality is arduous and ultimately subjective.

When dealing with recurrent events in patients on AC, compliance must be probed at length. Labeling a patient as having “failed” therapy has significant consequences. First, this might suggest an underlying thrombophilia, such as malignancy or APS. Second, the lack of clear superiority data of one agent over another makes management decisions murky.

The physical exam must of necessity focus on the affected extremity. However, a comprehensive exam may provide valuable clues. Adenopathy or temporal wasting might suggest malignancy. Arthritis and malar rash might suggest an autoimmune diathesis such as lupus. Organomegaly and erythromelalgia should trigger concern for an MPN such as PV or ET. Spontaneous upper-extremity events might suggest thoracic outlet syndrome whereas unprovoked left iliofemoral DVT, particularly in young women, may represent May-Thurner syndrome.

Screening for underlying hereditary thrombophilias is often pursued although the general utility of this approach is not clear. This is discussed at length in Chap. 130. In general, such screening rarely changes management and has the potential for error if performed at the incorrect time. For example, levels of antithrombin III, protein C, and protein S may be falsely low in the acute setting. Functional protein S levels might be reduced when the factor V Leiden mutation is present, leading to erroneous diagnosis. Anticardiolipin antibodies require sustained elevation over 12 weeks to satisfy criteria for APS. Pregnancy and hepatic disease can also affect the serum levels of various pro- and anticoagulants and confound diagnosis.

The decision regarding the duration of therapy is complex (Chap. 133). These decisions must incorporate the risk of recurrence, risk of bleeding, and patient preferences. Generally, patients with either a provoked or distal DVT may be treated for a finite course, generally three months. Patients with unprovoked DVT/pulmonary embolism (PE), APS, recurrent thromboses, or active malignancy are often considered for indefinite therapy should the bleeding risk be acceptable.

In patients with unprovoked events who discontinue AC after a finite course, efforts aimed at risk stratification via D-dimer assays appear to be useful. Thromboprophylaxis with aspirin, has shown promise. However these approaches are not standardized. The American College of Chest Physicians publishes evidence-based antithrombotic guidelines that provide specific recommendations for a variety of scenarios and are a useful resource.

The availability of new, oral anticoagulants has dramatically changed AC management from both the patient and physician perspectives. Dabigatran, a direct thrombin inhibitor, and rivaroxaban, a factor Xa inhibitor, are FDA approved for the treatment of venous thromboembolism, with the former requiring an initial 5 to 10 days of parenteral

AC. Both agents are oral, require adequate renal function, and produce a reliable anticoagulant effect that need not be monitored or titrated. They lack reliable antidotes in the event of bleeding, although such products are in development. It should be noted that patients with poor warfarin compliance are equally poor candidates for these agents. Because of their short half-life, skipped doses will result in a prompt loss of AC and increased risk of recurrent thrombosis.

In general, there is insufficient information regarding the superiority of one anticoagulant over another. There is abundant experience with warfarin (Coumadin) and LMWH. The latter is often preferred in patients with malignancy, although high-quality evidence in its support is lacking. Dabigatran and rivaroxaban lack specific data in hereditary thrombophilias, malignancy, and APS, and therefore caution should be exercised in these settings. Dabigatran showed an excess risk of bleeding and thrombosis when compared to Coumadin in patients with mechanical heart valves, exemplifying the potential peril in assuming anticoagulants are of equal efficacy in different settings.

Decisions regarding AC touch upon every aspect of a patient's life and are not taken lightly. They are not as black and white as standardized chemotherapy regimens and require an understanding of the patient's lifestyle, values, and risk of recurrence. Such assessment is difficult in the modern time-constrained environment. Furthermore, such decisions should not be made in a single-instance and then followed indefinitely. Rather, the decision to continue (or withdraw) AC is dynamic and should be revisited serially depending on the tolerance of therapy and other medical comorbidities.

ARTERIAL THROMBOSIS

Consultation is often requested in patients with arterial thrombosis, such as myocardial infarction, cerebrovascular accident, or acute limb ischemia. In the vast majority of cases, however, this is related to underlying atherosclerosis with local inflammation rather than a primary hypercoagulable state. Risk factors, mechanisms, and treatment of atherothrombosis are discussed in Chap. 134.

In rare cases where underlying risk factors for atherothrombosis are absent or there is a strong family history of thrombosis, particularly at young ages, we perform a limited hypercoagulable evaluation, including studies for the APS. Paroxysmal nocturnal hemoglobinuria (PNH) and MPNs may rarely result in arterial thromboses. We rarely find it helpful to obtain studies for protein C, protein S, or antithrombin III deficiency, and do not obtain studies for factor V Leiden or prothrombin 20210A mutations as these do not have a meaningful effect on management. Furthermore, routine screening for the thermolabile variant of the methylenetetrahydrofolate reductase (MTHFR) should be discouraged as there is no evidence of benefit in reducing plasma homocysteine levels.

Hence, broad hypercoagulable evaluations are not useful in isolated arterial thrombosis, as most findings are likely incidental rather than causal, and do not have a direct impact on patient management.

● IMMATURE CELLS ON THE BLOOD FILM

Consultations may arise from the discovery of incidental abnormalities on the blood film. Nucleated RBCs (nRBCs) and immature myeloid cells are relatively common.

NUCLEATED RED BLOOD CELLS

The clinical lab may report the finding of nRBCs, which is often reported in the differential as #nRBC/100 WBC.

Although there are several causes for the appearance of nRBCs, two predominate: stress erythropoiesis and extramedullary hematopoiesis.

Stress erythropoiesis occurs as a response to severe anemia. The marrow attempts to compensate by increasing erythropoiesis (Chaps. 32 and 33) and discharges reticulocytes of increasingly younger age to the blood. If the anemic stress is not ameliorated or deepens further, nRBCs, usually late normoblasts, leave the marrow. The blood film often shows abundant polychromasia, skip macrocytes, and late normoblasts.

Extramedullary hematopoiesis can occur if the normal marrow is replaced by fibrosis or cancer or if somatic mutation such as seen in primary myelofibrosis decreases stem cell adherence (Chap. 86). The hematopoietic stem cells travel through the blood to find suitable alternative sites for growth, often settling in the spleen. However, the sinusoidal structure there is not identical to that of the marrow. Hence, blood cells, particularly nRBCs, are released in an uncoordinated manner.

A leukoerythroblastic smear (nRBCs, teardrop RBCs, myeloid immaturity, giant platelets) is a significant clue. If clinically indicated, biopsy of the marrow will usually confirm the diagnosis.

IMMATURE MYELOID CELLS

The clinical lab may report the presence of metamyelocytes, myelocytes, promyelocytes, or blasts on the blood film. The differential is enormous, ranging from normal pregnancy to myeloid malignancies (Chaps. 61–63). One begins with a thorough history, CBC, and blood film. We inquire about recent stressors and the use of glucocorticoids. In patients with normal blood counts and rare metamyelocytes, observation is generally appropriate. The presence of peripheral blasts, particularly in association with cytopenias, is never normal and mandates examination of the marrow. A full spectrum of myeloid maturity, particularly in association with basophilia, should raise concern for CML.

LYMPHADENOPATHY

On occasion, consultation is requested for lymphadenopathy without a tissue diagnosis. The differential diagnosis is vast, including benign adenopathy, viral infections, autoimmune disorders, and malignant lymphomas. A thorough history is critical (Chap. 1). Laboratory studies should include a CBC and blood film.

Generally with this information, the diagnostic studies can be focused and lymph node biopsy is not always required. For example, in adolescents with fever, pharyngitis, and cervical adenopathy, tests for infectious mononucleosis are pursued. If there is an accompanying lymphocytosis, the diagnosis might be established via flow cytometry of the blood, as in CLL. If the patient is well appearing, asymptomatic, and the nodes are minimally enlarged, a short period of observation is often prudent.

In patients with cytopenias, B symptoms, and organomegaly without obvious infections, lymph node biopsy is nearly always indicated. Fine-needle aspirates, although often more convenient, are discouraged because the lack of lymph node architecture impairs pathologic analysis. If a diagnosis of malignant lymphoma is suspected, treatment with glucocorticoids prior to tissue diagnosis is also discouraged as it may impair diagnostic sensitivity.

SPLENOMEGALY

Referrals for splenomegaly open up an immense differential, including hemoglobinopathies, infection, liver disease, heart failure, autoimmune disorders, and malignant leukemia or lymphoma (Chap. 56).

Critical diagnostic elements include personal history, family history, CBC, and the blood film. Has the diagnosis been made on physical exam or was it detected incidentally on an imaging procedure? If prior studies are available for comparison, one may be able to use the EMR to determine how long the spleen has been enlarged. On exam, is the spleen tip barely palpable or does it extend into the pelvis and cross the midline as might be the case with primary myelofibrosis (Chap. 86)?

Evidence of cirrhosis or heart failure might suggest congestive splenomegaly. Erythrocytosis and pruritus would raise concern for PV.

A blood film showing basophilia and myeloid immaturity might indicate CML. If risk factors are present, HIV testing is appropriate. Thalassemia can readily be identified via the blood film. Because the diagnostic possibilities are innumerable, it is critical to avoid a shotgun approach, identify the likely diagnostic possibilities, and focus the workup accordingly. It is almost never necessary to do a diagnostic splenectomy.

MONOCLONAL GAMMOPATHY

Monoclonal gammopathies are increasingly detected given the wide availability of comprehensive metabolic panels and the subsequent use of serum protein electrophoresis (SPEP) as a screening tool. Referring physicians often have already requested a SPEP in cases of suspected myeloma, anemia, unexplained renal failure, or neuropathy. The finding of elevated serum protein or globulin fractions, or the report of extensive rouleaux formation on blood film may also trigger a request for SPEP. The SPEP can demonstrate the presence of a monoclonal protein whereas immunofixation defines the heavy-chain isotype and light-chain restriction.

Rouleaux formation reported on a CBC is not synonymous with a monoclonal protein. Rouleaux simply describes visible stacked red cells, either as a result of poor smear preparation, inappropriate viewing in the “thick” area of the slide, or as a consequence of increased plasma proteins, such as immunoglobulins and fibrinogen. Although rouleaux may result from a monoclonal gammopathy, it may also be seen in chronic infections, autoimmune disorders, and liver disease.

When seeing referrals for monoclonal gammopathies, one should obtain a CBC, renal and liver function studies, blood film, immunoglobulin panel, free light-chain ratio, urine protein electrophoresis (UPEP) with immunofixation, and skeletal survey. This analysis seeks to identify any evidence of end organ damage attributable to the monoclonal population, such as hypercalcemia, anemia, renal dysfunction, or lytic bone disease. The physical exam focuses on the presence of adenopathy or organomegaly that might suggest a lymphoproliferative disorder.

If there is no clear evidence of end organ damage, the term *monoclonal gammopathy of undetermined significance* (MGUS) is often applied, and observation is pursued. The natural history, risk stratification, and prognosis of such patients is discussed in Chaps. 106 and 107. Monoclonal proteins may also be seen in association with several disorders, including plasma cell dyscrasias, lymphoproliferative disorders, infections, and various autoimmune diseases. Notably, it is important to identify patients with signs concerning for immunoglobulin light-chain amyloidosis (nephrotic range proteinuria, macroglossia, neuropathy). In cases of immunoglobulin (Ig) M paraproteins, look for evidence of Waldenström macroglobulinemia (adenopathy, constitutional symptoms, organomegaly, bleeding). Although rare, in patients with anemia and IgM κ paraproteins, one should inquire about cold sensitivity and seek to exclude cold agglutinin hemolysis.

One is often faced with an elderly patient with multiple comorbidities, such as chronic renal dysfunction, peripheral neuropathy, diabetes mellitus, and osteoporosis in conjunction with a systemic paraprotein.

In most cases, if these findings have been chronic and longstanding, they are thought to be unrelated to the paraprotein, and ongoing observation is appropriate rather than cytotoxic chemotherapy. In some cases, particularly those in which historical labs are unavailable, this distinction is more difficult to make, and marrow exam may be useful to assess the degree of marrow effacement. In younger patients with monoclonal proteins greater than 1.5 g/dL, non-IgG isotypes, or abnormal free light-chain ratios, we often obtain marrow biopsies given the higher likelihood of progression and potential intervention for patients with high-risk smoldering myeloma.

● **ADVICE TO REFERRING PHYSICIANS**

A good relationship and open line of communication between hematologists and referring physicians are imperative. A few points to keep in mind:

- The clinical history is invaluable. If there is lack of clarity, we recommend a quick phone call to the referring physician focusing on the salient features of the patient's medical history and the reason for consultation. Much like pathologists, this information helps us place the labs and blood film in appropriate context and aids the diagnostic evaluation, particularly in cases with broad differentials such as anemia or leukopenia. The importance of the history and physical exam also reinforces the need for the attending hematologist to personally review the blood film, rather than relying solely on hematopathologists or laboratory technicians.
- Avoid the laboratory "shotgun" approach. For example, exhaustive hypercoagulable studies in patients with provoked thromboses are not particularly useful and can create patient anxiety. Patients have concerns about their "genetic disease," and hematologists have a hard time explaining the implications of tests they would not typically order. The consulting hematologist should direct the laboratory evaluation to avoid unnecessary, duplicate, and/or costly tests.
- The increasing variety of molecular and genetic diagnostics, in addition to the evolving complexity of hematopathology, mandates one be aware of the resources of their local hematologist. For example, rare disorders such as systemic mastocytosis, CNL, severe eosinophilia, and atypical CML are often best evaluated in a tertiary center. Once the diagnosis is made and a treatment plan established, care should then be transitioned to local physicians, with intermittent input from an academic center if required. Value should always be placed on avoiding repeat marrow examinations.
- With rare exception, diagnoses should not be made off scant marrow specimens. Terms such as "aspiculate aspirate" and "subcortical biopsy" should trigger concern for an inadequate specimen. In such cases, a repeat biopsy should be obtained by an experienced provider rather than making diagnostic assumptions from a poor specimen.
- A referral to a hematologist, "cancer center," or hematologist/oncologist often generates considerable patient anxiety, even if not verbalized. The waiting period of several days to weeks to see such a provider can cause significant distress. Unless the diagnosis is clear, it is useful to counsel patients that such a referral does not imply the presence of "cancer" or "leukemia" but rather a request for more information.

6. The Organization and Structure of Lymphoid Tissues 85

CHAPTER 5

STRUCTURE OF THE MARROW AND THE HEMATOPOIETIC MICROENVIRONMENT

Utpal P. Davé and Mark J. Koury*

SUMMARY

The marrow, located in the medullary cavity of bone, is the site of hematopoiesis in humans. The marrow produces approximately 6 billion cells per kilogram of body weight per day. Hematopoietically active (red) marrow regresses after birth until late adolescence, after which it is focused in the lower skull, vertebrae, shoulder and pelvic girdles, ribs, and sternum. Fat cells (yellow marrow) replace hematopoietic cells in the bones of the hands, feet, legs, and arms. Fat comprises approximately 50 percent of red marrow in the adult. Further fatty replacement of the red marrow continues slowly with aging, but hematopoiesis can be expanded when demand for blood cells is increased.

Acronyms and Abbreviations: AGM, aorta-gonad-mesonephros; ALCAM, activated leukocyte adhesion molecule; bFGF, basic fibroblast growth factor; BFU-E, burst-forming unit—erythroid; BMP, bone morphogenetic protein; CAR, CXCL 12—abundant reticular cells; CD, cluster of differentiation; C/EBP, CCAAT/enhancer-binding protein; CFU-E, colony forming unit—erythroid; CFC-G, colony-forming cell-granulocyte; CXCL12/SDF1, stromal cell-derived factor; dpc, days postcoitum; EBI, erythroblastic island; ECM, extracellular matrix; ELAM, endothelial leukocyte adhesion molecule; EPO, erythropoietin; FN, fibronectin; GAG, glycosaminoglycan; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; GMP, granulocyte-macrophage progenitor; HGF, hepatocyte growth factor; HIF, hypoxia-inducible factor; HSC, pluripotent hematopoietic stem cell; ICAM, intercellular adhesion molecule; IHH, Indian hedgehog family of proteins; IL, interleukin; LFA, lymphocyte function antigen; MAdCAM, mucosal addressin cell adhesion molecule; M-CSF, macrophage colony-stimulating factor; MEP, megakaryocytic-erythroid progenitor; MIP, macrophage inflammatory protein; MMP, matrix metalloproteinase; MPP, multipotential pluripotential progenitor; MSC, mesenchymal stem cell; NFAT, nuclear factor of activated T cells; NK, natural killer; OPG, osteoprotegerin; PDGF, platelet-derived growth factor; PECAM, platelet endothelial cell adhesion molecule; PPAR, peroxisome proliferator-activated receptor; ProEBs, proerythroblasts; PSGL, P-selectin glycoprotein ligand; RANK, receptor activator of nuclear factor- κ B; Rb, retinoblastoma tumor-suppressor protein; SCF, stem cell factor; Siglecs, sialic acid-binding immunoglobulin (Ig)-like lectins; SP, side population; TGF- β , transforming growth factor- β ; TLR, toll-like receptor; TNF- α , tumor necrosis factor- α ; TPO, thrombopoietin; TRAP, tartrate-resistant acid phosphatase; TSP, thrombospondin; VCAM, vascular cell adhesion molecule; VEGF, vascular endothelial growth factor; VLA, very-late antigen.

The marrow stroma consists principally of a network of sinuses that originate at the endosteum from cortical capillaries and terminate in collecting vessels that enter the systemic venous circulation. The trilaminar sinus wall is composed of endothelial cells; a thin basement membrane; and adventitial reticular cells that are progenitors of chondrocytes, osteoblasts and adipocytes. Stem cells can leave and reenter marrow as part of their normal circulation.

Hematopoiesis, the proliferation and differentiation of stem cells and their progeny in the intersinus spaces, is controlled by a complex array of stimulatory and inhibitory cytokines, cell–cell contacts, and interactions with the extracellular matrix. In this unique environment, lymphohematopoietic stem cells differentiate into all the blood cell lineages. Mature cells are produced and released to maintain steady-state blood cell levels. The hematopoietic system also can respond to meet increased demands for additional cells as a result of blood loss, hemolysis, inflammation, immune cytopenias, and other causes.

HISTORY AND GENERAL CONSIDERATIONS

The marrow, one of the largest organs in the human body, is the principal site for blood cell formation. In the normal adult, daily marrow production amounts to approximately 2.5 billion red cells, 2.5 billion platelets, and 1 billion granulocytes per kilogram of body weight. The rate of production adjusts to actual needs and can vary from a basal rate to several times normal. Until the late 19th century, blood cell formation was thought to be the prerogative of the lymph nodes or the liver and spleen. In 1868, Neuman¹ and Bizzozero² independently observed nucleated blood cells in material squeezed from the ribs of human cadavers and proposed that the marrow is the major source of blood cells.³ The first *in vivo* marrow biopsy probably was done in 1876 by Mosler,⁴ who used a wood drill to obtain marrow particles from a patient with leukemia. Studies by Arinkin⁵ in 1929 established marrow aspiration as a safe, easy, and useful technique (Chap. 3).

Kinetic studies of marrow cells, using radioisotopes and *in vitro* cultures, have shown that cell lineages consist mainly of maturing cells with a finite functional life span. On the other hand, sustained cellular production depends on pools of primordial cells capable of both differentiation and self-replication.⁶ The most primitive pool consists of pluripotential lymphohematopoietic stem cells with the capacity for continuous self-renewal, that is, hematopoietic stem cells (HSCs). The more mature pools consist of differentiating progenitor cells, with their maturation restricted to single or limited numbers of cell lineages and more restricted capacities for self-renewal (Chap. 18). The proliferative activity of these pools involves humoral feedback from peripheral target tissues⁷ and cell–cell and cell–matrix interactions within the microenvironment of the marrow.⁸ The marrow stroma and nearby hematopoietic cells provide unique structural and chemical environments (niches) that support the survival, differentiation, and proliferation of pluripotential HSCs. HSC interactive niches⁹ have been identified at the structural and molecular¹⁰ levels and are dynamically controlled by bone morphogenetic proteins (BMPs)¹¹ and factors regulating intramedullary osteoblastic cells and their progenitors.¹² Early stem cells can be identified and isolated using a unique array of surface antigen-receptor expressions (CD34+/-, Thy1,¹⁰ KIT+, CD38-, CD33-, vascular endothelial [VE]-cadherin+, KDR/FLK1+, FLK2-/FLT3-, CD133+/-)¹³⁻¹⁸ and have a unique molecular signature.^{19,20} The ability to efflux specific chemical dyes has also been used to provide enriched populations of HSC.²¹⁻²⁴ Isolated cell populations enriched in HSC can be quantified

*Marshall A. Lichtman was an author of this chapter in the previous six editions, and some material from those editions, including all illustrations, has been retained.

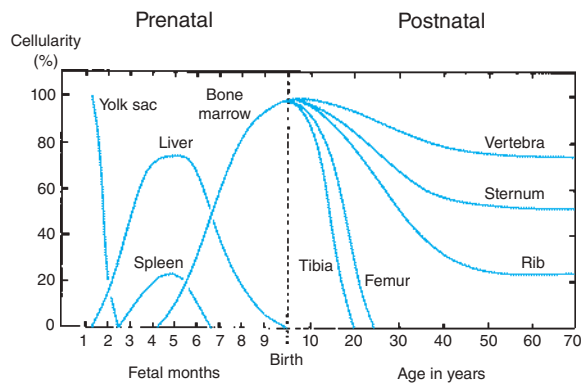

Figure 5-1. Expansion and recession of hematopoietic activity in extramedullary and medullary sites. For details regarding the nature of yolk sac and hepatic hematopoiesis, see “Sites of Hematopoiesis: Embryogenesis and Early Stem Cell Development.” Chapter 7 provides a more comprehensive treatment of this topic (see Fig. 7-1 in Chap. 7).

using *in vitro* long-term progenitor assays and surrogate *in vivo* repopulating assays in severely immunodeficient mice and xenogeneic animal models (Chap. 18).

● SITES OF HEMATOPOIESIS

EMBRYOGENESIS AND EARLY STEM CELL DEVELOPMENT

As shown in Fig. 5-1, the marrow is the last in a series of anatomical sites of hematopoiesis that change several times during embryonic and fetal development.²⁵⁻²⁸ The earliest hematopoietic cells develop in the blood islands of the extraembryonic yolk sac during late gastrulation and form the primitive hematopoietic system. This primitive hematopoiesis is transient, lasting from the appearance of the blood islands at embryonic days 7.5 days postcoitum (dpc) in mice and 19 dpc in humans through the final cellular divisions in the circulating embryonic blood at 13.5 dpc in mice and week 6 in humans.^{28,29} The large majority of primitive blood cells produced are erythrocytes that enucleate after release into the circulation, and their hemoglobin contains the embryonic α - and β -globin chains. Primitive hematopoietic cells also give rise to macrophages and megakaryocytes. Overlapping with this transient primitive hematopoiesis is definitive hematopoiesis that gives rise to all of the blood cell types found in the adult (Chap. 7).

Transplantation experiments in hematopoietically ablated mice have demonstrated that definitive hematopoietic cells arise on 8.5 to 11.5 dpc in mice and weeks 4 to 6 in humans in three different embryonic locations: the yolk sac blood islands, the anterior portion of the aorta-gonad-mesonephros (AGM) region, and the allantoic portion of the developing placenta.²⁶⁻²⁸ The definitive murine erythroid cells circulating on 8.5 to 11.5 dpc appear to be descendent from a transient population of erythroid/myeloid progenitors derived from the yolk sac, rather than being derived from HSCs that arise in the placenta and AGM as occurs at later times in the fetus and adult.³⁰ Serial transplantation in irradiated mice demonstrated that the earliest appearance of the intraembryonic human HSCs is in the AGM at week 5.³¹ HSCs migrate through the blood to the fetal liver where they seed and mature into all of the cellular elements of the blood.²⁵⁻²⁸ Erythrocytes, the predominant cell produced by definitive hematopoiesis during prenatal development, are smaller than the primitive erythrocytes, and their hemoglobin contains the fetal and adult globin chains. In mid-gestation, the HSCs that have migrated to the fetal liver undergo an exponential expansion and

display a specific integrin (Mac-1) that is not found in marrow HSCs.³² In the last third of gestation, the HSCs and early hematopoietic progenitor cells migrate from the fetal liver through the circulation seeding the spleen and marrow. Fetal liver hematopoiesis declines steadily as the spleen and marrow become the major hematopoietic sites. At birth, the marrow is the major hematopoietic site in humans, while the spleen remains a prominent but decreasing site in the mouse (Chap. 7).

Visceral endoderm is in close proximity to the mesoderm formed by gastrulation in those sites where HSCs are generated in the embryo. This proximity is important in that the endoderm appears to induce both endothelial and blood cell development in the adjacent mesoderm through secretion of Indian hedgehog (IHH), a member of the hedgehog family of proteins.³³ IHH, in turn, upregulates the expression of BMP4 in the developing mesodermal cells.³³ BMP4 upregulation is important for the development of both the endothelial cells that form blood vessels and the HSCs located within these vessels.^{33,34} Developing endothelial cells and hematopoietic cells in the vessels formed by these endothelial cells are found in each site of primitive and definitive hematopoiesis. The close association of these two cell types in the developing embryo has led to the proposal for their having a common precursor, the hemangioblast.^{35,36} Important proteins involved in the development of the hemangioblasts are BMP4, VE growth factor receptor KDR/Flk-1, transcription factor TAL1, and TAL1's binding partner LMO2.^{35,36}

Marked endothelial cells in mice give rise to the HSCs.³⁷ Imaging studies in zebrafish^{38,39} and mice⁴⁰ indicate that specialized hemogenic endothelial cells in the ventral part of the aorta can transform without mitosis into HSCs. The differentiation of HSCs from hemangioblasts and/or hemogenic endothelium requires the signaling protein Notch1 and the transcription factors GATA-2, MYB, and Runx1.^{35,36,41,42} The mechanism driving this earliest expansion of HSC is not well-defined, but two factors that also play roles later, KIT ligand/stem cell factor (SCF) and interleukin (IL)-3, are important in the embryo. BMP4, in addition to its role in the induction of hematopoietic and endothelial differentiation, increases proliferative and self-renewal of HSCs^{33,34} as it differentially upregulates KIT (SCF receptor) in the HSCs, but not in adjacent endothelial cells.⁴³ Expansion of the earliest definitive HSC is also mediated by Notch signaling as it induces the Runx1 transcription factor^{41,42} and one of its targets, the IL-3 gene.⁴⁴

STEM CELL AND MESENCHYMAL CELL PLASTICITY

Primitive stem cells from human fetal liver or marrow reconstitute all lymphohematopoietic-derived cells and part of the stromal microenvironment in *in vivo* repopulation assays.⁴⁵ These observations are consistent with the early derivation of hematopoietic, vascular, and stromal cells from a CD34⁻, KDR/Flk-1⁺, multipotential mesenchymal stem cell.^{14-16,46} Identification of AC133⁺, CD34⁻, CD7⁻ HSCs⁴⁷ and demonstration of endothelial precursors in AC133⁺ progenitor cells⁴⁸ underscore the crosstalk between hematopoiesis and angiogenesis signaling pathways and establish the functional role of hemangioblasts in ontogeny.⁴⁹⁻⁵¹ As early fetal hematopoiesis is established, the yolk sac vascular networks remain active sites of progenitor production and hematopoiesis.²⁸ Long-term reconstituting HSCs express two members of the ATP-binding cassette genes (ABCG-2 and P-glycoprotein), allowing the efflux of mitochondrial vital dyes such as Hoechst 33342 and rhodamine 123 and their isolation by multiparameter flow cytometry based on their low side scatter (side population [SP] cells).²¹⁻²⁴ Enrichment of the SP population for HSC has been achieved in both adult marrow⁵² and fetal liver⁵³ populations by using the signaling lymphocyte and activation markers (SLAMs) to select cells with the specific phenotype

(CD150+, CD244-, CD48-). Nearly half of the individual cells in the CD150+, CD244-, CD48- population provide long-term hematopoietic reconstitution in irradiated mice.⁵²

Derivation of hematopoietic cells from adult tissue (muscle, liver) is attributed to resident marrow-derived stem cells in these tissues.^{54,55} A role for adult marrow-derived mesenchymal stem cells in the repair and regeneration of nonmarrow organs has been described, including cardiac and smooth muscle, liver, and brain.^{56,57} However, these marrow-derived mesenchymal stem cells function mainly by providing a microenvironment through various cytokines that induce cell growth and stimulate vascularization or by fusing with local cells, rather than by transdifferentiation into specific differentiated cells of the organ undergoing repair (Chap. 18).^{56,57}

HISTOGENESIS

Stroma and Hematopoietic Tissue

The formation of the marrow in the third trimester of mammalian prenatal development involves the circulation and chemotaxis of HSCs, which have greatly expanded their numbers in the fetal liver, to the newly developed marrow niche (see “Marrow Structure” below). The release of HSC from the murine fetal liver coincides with the progressive loss of two adhesion proteins, CD144 (VE-cadherin) and CD41 (integrin α_{IIb}).^{58,59} In mice, the seeding of the marrow with HSCs is first detected at 17.5 dpc,⁶⁰ but the formation of the marrow niches for the HSCs and their progeny occurs in the preceding 3 days in sites of endochondral bone formation.⁶¹ Differentiation of a clonal skeletal progenitor stem cell results in cell populations that form cartilage, bone, or marrow niches that either support HSCs or the differentiating progeny of HSCs.⁶² The specific cells supported by a niche depend upon the expressions of endoglin, Thy1, and aminopeptidase A by the mesenchymal descendants of the skeletal progenitor stem cell. The migration of the circulating HSCs to their supporting marrow niches, which are formed by cells expressing aminopeptidase A but not endoglin or Thy1,⁶² is directed by the synergistic action of the chemokines CXCL12 and SCF for which the HSCs display the respective receptors, CXCR4 and KIT.⁶⁰ Other chemotactic factors and adhesion molecules contribute to HSC migration from the fetal liver to the developing bone where their seeding and differentiation initiates marrow hematopoietic function in mammals.⁵⁸⁻⁶⁰

Cavities within bone occur in the human being at about the fifth fetal month and soon become the exclusive site for granulocytic and megakaryocytic proliferation. Erythropoietic activity at the time is confined to the liver. The microenvironment in the marrow becomes supportive of erythroblasts only toward the end of the last trimester (see Fig. 5-1). The formation of the marrow cavities in the developing mouse bones appear at a relatively later time in the prenatal life of mice than humans, and it involves an IHH-regulated⁶³ synchronized maturation of osteoblast progenitors arising from mesenchymal stem cells and osteoclast progenitors arising from HSCs in the areas of mineralized cartilage of the fetal bones.⁶⁴ Most of the marrow spaces form in the endochondral bones but some marrow develops in the intramembranous bones of the cranium and scapulae. As these respective progenitors differentiate *in situ* they acquire the phenotype of osteoblasts with expression of osteopontin, osteonectin, bone sialoprotein, and macrophage colony-stimulating factor (M-CSF), and of osteoclasts with expression of tartrate-resistant acid phosphatase (TRAP), calcitonin receptors, and c-FMS (M-CSF receptor).⁶⁴ In the human, marrow hematopoiesis begins at the 11th week of gestation in specialized mesodermal structures termed *primary logettes*.⁶⁵ The logettes are composed of mesenchymal cells and fibers that surround a central artery and protrude into the venous sinuses of the developing marrow cavities. The myeloid and

erythroid hematopoietic cells that populate the logettes are derived not from HSCs but rather from later-committed progenitors.⁶⁵ Just after birth the HSCs are found in the marrow, and hematopoiesis is evident throughout the marrow cavity.

Adipose Tissue

By the fourth year of life, a significant number of fat cells have appeared in the diaphysis of the human long bones.⁶⁶ These cells slowly replace hematopoietic elements and expand centripetally until, at approximately 18 years of age, hematopoietic marrow is found only in the vertebrae, ribs, skull, pelvis, and proximal epiphyses of the femora and humeri. Direct measurements of the volume of bone cavities reveal increases from 1.4 percent of body weight at birth to 4.8 percent in the adult,⁶⁶ whereas blood volume decreases from 8 percent of body weight in the newborn to approximately 7 percent in the adult.⁶⁷ Expansion of marrow space continues throughout life, resulting in a further gradual increase in the amount of fatty tissue in all bone cavities, especially in the long bones.^{68,69} Although the quantity of adipose tissue in the head and trochanteric parts of the femur varies in individuals, the fat content of this area of hematopoietic marrow progressively increases as adult humans age.⁷⁰ The preference of hematopoietic tissue for centrally located bones has been ascribed to higher central tissue temperature with greater vascularity.⁷¹ In mice, an increased prevalence of adipose tissue in tail vertebrae as opposed to the more central thoracic vertebrae is associated with fewer HSCs and hematopoietic progenitors.⁷² Genetic absence of adipose tissue or chemical inhibition of adipocyte generation was associated with improved posttransplant hematopoietic regeneration, suggesting that marrow adipocytes are negative regulators in the hematopoietic microenvironment.⁷²

MARROW STRUCTURE

VASCULATURE

The blood supply to the marrow comes from two major sources. The nutrient artery, the principal source, penetrates the cortex through the nutrient canal. In the marrow cavity, the nutrient artery bifurcates into ascending and descending central or medullary arteries from which radial branches travel to the inner face of the cortex. After reentering the endosteum, the radial vessels diminish in caliber to structures of capillary size that course within the canalicular system of the cortex. In the canalicular system, arterial blood from the nutrient artery mixes with blood that enters the cortical capillary system from the periosteal capillaries derived from muscular arteries.⁷³ After reentering the marrow cavity, the cortical capillaries form a sinusoidal network (Fig. 5-2). Hematopoietic cells are located in the intersinusoidal tissue spaces. Some arteries have specialized, thin-walled segments that arise abruptly as continuations of arteries with walls of normal thickness.⁷⁴ These vessels give off nearly perpendicular branches analogous to the arterial branching observed in the spleen and kidney, permitting volume compensation for changes in intramedullary pressure. In the marrow cavity, blood flows through a highly branching network of medullary sinuses. These sinuses collect into a large central sinus from which the blood enters the systemic venous circulation through emissary veins. Histomorphologic studies of normal murine marrow demonstrate that all hematopoietic cells are within 18 μm or less than 3 cell diameters of a blood vessel.⁷⁵

Vascular networks consisting of cells expressing CD31, CD34, and CD105 (endoglin) but lacking intercellular adhesion molecule (ICAM)-1, ICAM-2, ICAM-3, or endothelial leukocyte adhesion molecule (ELAM)-1 (E-selectin) can form within the stroma of long-term marrow cultures. These findings underscore the intimate relationship of

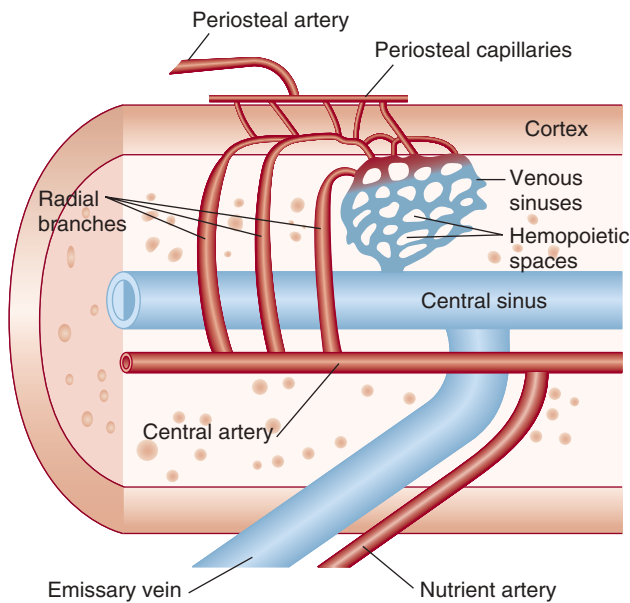

Figure 5-2. Schematic of the marrow circulation (see “Marrow Structure” for further explanation). (Used with permission of Lichtman MA, University of Rochester.)

blood vessels to hematopoietic activity.⁷⁶ A study of early hematopoiesis of human marrow from long bones (ages 6–28 weeks) has shown an absence of CD34+ hematopoietic progenitors before onset of hematopoiesis, a predominance of CD68+ cells mediating chondrolysis, and CD34+ endothelial cells developing into specific vascular structures organized by endothelial cells and myoid cells.⁷⁷ Vascular endothelial growth factor (VEGF) receptors found on CD34+ cells¹⁶ and AGM primitive stem cells underscore the common ontogeny.⁷⁸ Subsets of CD34+ cells expressing the AC133 antigen and the human VEGF receptor-2 (KDR/FLK1) define the functional endothelial precursor phenotype.⁷⁹ Endothelial progenitors residing in the CD34+, CD11b+ subsets are capable of producing and binding angiopoietins,⁸⁰ and fibronectin (FN) enhances VEGF-induced CD34 cell differentiation into endothelial cells.⁸¹ Growth and remodeling of bone, marrow space, and the vasculature that supplies them with nutrients and oxygen are closely linked by the relative hypoxia of the marrow and surrounding bone.⁸² The transcription factors, hypoxia-inducible factor (HIF)-1 α and -2 α , are stabilized by hypoxia and increase VEGF expression in osteoblasts, and lead to regulated, coupled growth by endothelial cells and osteoblasts, both of which have VEGF receptors.⁸² The expansion of erythropoiesis in response to erythropoietin (EPO) in mice is associated with a reciprocal decrease in the vasculature.⁸³

INNERVATION

Myelinated and nonmyelinated nerve fibers are present in periarterial sheaths in the marrow,⁸⁴ where they are believed to regulate arterial vessel tone. Nerve terminals are distributed between layers of periarterial adventitial cells or localize next to arterial smooth muscle cells.⁸⁵ Nonmyelinated fibers terminate in the hematopoietic spaces, implying that neurohumors elaborated from free-nerve terminals affect hematopoiesis. Intimate cell–cell communication between sympathetic nerve cells and structural elements within the marrow sinuses occurs at less than 5 percent of nerve terminals that terminate within the hematopoietic parenchyma or on sinus walls. This anatomical unit, termed a *neuroreticular complex*, consists of efferent (autonomic) nerves and marrow stromal cells connected by gap junctions.⁸⁵ The marrow is

highly innervated along the arterioles and less frequently along capillaries, where neurologic control of blood flow and angiogenesis appear to be mediated via neurokinin A and substance P.⁸⁶

SINUS ARCHITECTURE, NONHEMATOPOIETIC CELL ORGANIZATION AND NICHE FORMATION

In mammals, hematopoiesis occurs in the extravascular spaces between marrow sinuses. The marrow sinus wall is composed of a luminal layer of endothelial cells and an abluminal coat of adventitial reticular cells, which forms an incomplete outer lining (Fig. 5-3). A thin, interrupted basement lamina is present between the cell layers. Circulating HSCs move across the sinus endothelium into the extravascular space where they proliferate and differentiate into mature cells, which move across the sinus endothelium and circulate in the blood. Nonhematopoietic cells and extracellular matrix in the extravascular space form the marrow stroma. Stromal cells obtained from animal or human marrow can be studied in cultures,⁸⁷ are derived from fibroblasts, and have unique phenotypic and functional characteristics that allow them to nurture hematopoietic development in highly specialized microenvironmental niches.⁸⁸ However, newer studies with mutant mice and mice with specific cells that can be identified by direct fluorescence microscopy⁸⁹ have led to an understanding of the spatial orientation of the stroma and the localization of hematopoietic niches that they form in the marrow.

The hematopoietic niche concept was originally described for an operationally defined murine multipotential pluripotential progenitor (MPP) in the spleen,⁹⁰ but it has been extended to various marrow hematopoietic subpopulations, including physically demonstrated niches of HSCs,⁹¹ lymphoid cells,^{92,93} and erythroid cells.^{93,94} The cellular components of these hematopoietic areas of the marrow include several types of nonhematopoietic cells including: (1) the sinus endothelial cells, (2) mesenchymal stem cells (MSCs) that form the skeletal elements of bone and marrow space such as chondrocytes, osteoblasts, osteocytes, fibroblasts, and adipocytes, and (3) terminally differentiated cells of hematopoietic origin such as macrophages, lymphocytes, and plasma cells. Experiments in both mice⁶¹ and humans⁹⁵ have demonstrated by heterotopic bone formation that host marrow sinusoidal endothelial cells and hematopoietic cells will infiltrate and develop within microenvironment provided by a transplanted MSCs and its progeny. In mice, these MSCs are identified by a CD105+, Thy1–, 6C3– phenotype, which can support specific hematopoietic populations as their progeny develop Thy1 and 6C3 expression.⁶² In humans, these MSCs are identified as CD45–, CD146+ adventitial reticular cells with fibroblast colony forming capacity that can interconvert between this MSC status and CD146– chondrocytes.⁹⁶

Studies localizing marrow areas that support murine HSCs and their early progeny the hematopoietic progenitor cells (HPCs) have led to the concept of two niches for these hematopoietic cells: an endosteal niche that promotes HSC quiescence and a vascular/perivascular niche that is associated with self-replicating HSCs.⁹⁷ Studies combining vascular and endosteal imaging demonstrate that HSC/HPCs localized in the endosteal areas were also within a few cell diameters of VE cells.^{75,98} The hypoxic status of HSC/HPCs, in terms of HIF expression, is unrelated to their proximity to blood vessels,⁹⁸ the flow rate of blood in the marrow vessels in the vicinity of HSCs appears to be very low,⁹⁹ and the lowest oxygen tension directly measured in the marrow is in the perivascular areas of microvessels.¹⁰⁰ These results suggest that the functional status of microvessels has a larger role in HSC niche activity than the proximity of the potential niche to its vascular supply.

Endothelial Cells

Endothelial cells are broad flat cells that completely cover the inner surface of the sinus.¹⁰¹ They form a major barrier and control the system

Figure 5-3. Transmission electron micrograph of a mouse marrow sinus. The *small arrow* in the sinus lumen (L) indicates the perikaryon of an endothelial cell. Several endothelial cell junctions are present along the circumference of the sinus endothelial wall. Thus, the wall is composed of the cytoplasm of endothelial cells that overlap or interdigitate. Two adventitial reticular cell bodies are identified by *arrows* at the top and upper left of the sinus. The cytoplasm of the adventitial reticular cells is discontinuous as it is followed around the sinus. Three cytoplasmic processes of adventitial reticular cells are indicated by *arrows*. Other, smaller processes of reticular cell cytoplasm are found upon close inspection of the sinus periphery and the hematopoietic spaces. The scattered rough endoplasmic reticulum and dense bodies are characteristic of the reticular cell cytoplasm. (Reproduced with permission from Lichtman MA: *The ultrastructure of the hematopoietic environment of the marrow: A review*. Exp Hematol 9:391, 1981.)

for chemicals and particles entering and leaving the hematopoietic spaces, with overlapping or interdigitating unions permitting volume expansion.¹⁰² The endothelium of marrow sinusoids is actively endocytic and contains clathrin-coated pits, clathrin-coated vesicles, lysosomes, phagosomes, transfer tubules, and diaphragmed fenestrae.^{103,104} Marrow endothelial cells express von Willebrand factor protein,¹⁰⁵ type IV collagen, and laminin.¹⁰⁶ They also constitutively express adhesion molecules: ICAM-3,¹⁰⁷ vascular cell adhesion molecule (VCAM)-1, and E-selectin,¹⁰⁸ all of which regulate HSC proliferation.¹⁰⁹ The distribution of sialic acid and other carbohydrates on the luminal surface of marrow sinus endothelium is discontinued at diaphragmed fenestrae and coated pits, suggesting such glycosylation plays a role in endothelial membrane function and cellular interactions.¹¹⁰ *In vivo*, the conditional deletion in endothelial cells of gp130, the common receptor component for several cytokines, including IL-6, leads to a hypocellular marrow as mice age.¹¹¹ The loss of gp130 from marrow endothelial cells affects the progenitor cell populations rather than the HSC leading to a lethal anemia, a leukocytosis, but normal platelets.¹⁰⁸

Marrow endothelial cells via direct cell–cell contacts and secreted peptides uniquely influence osteoprogenitor cell differentiation¹¹² and regulate hematopoiesis.¹¹³ Marrow microvascular endothelium has major roles in osteogenesis through its physiologic production of the

VEGF164 isoform as well as multiple cytokines that are usually associated with inflammation.¹¹⁴ Other marrow endothelial cell cytokines that affect hematopoiesis include SCF,¹¹⁵ angiopoietin-like protein 3,¹¹⁶ IL-5,¹¹⁷ thymosin β_4 , AcSDKP,¹¹⁸ and B-type natriuretic peptide.¹¹⁹ Endothelial cells also regulate cellular trafficking into and out of the marrow sinusoidal spaces by altering their permeability and reorganizing their cytoskeleton by ICAM-3, by VE-cadherin-mediated cell–cell contacts,^{107,120} and via specialized heparin sulfate proteoglycans,¹²¹ CXCL12 bound to surface proteoglycans,¹²² and other chemokines/chemokine receptors,^{123,124} such as fractalkine, a membrane-bound chemokine with a mucin stalk expressed in activated vascular beds.¹²⁵ Marrow sinusoidal endothelium specifically expresses hyaluron and sialylated CD22 ligands, which are homing receptors for recirculating HSCs⁷⁵ and B lymphocytes,¹²⁶ respectively.

Adventitial Reticular Cells

The abluminal or adventitial surface of the vascular sinus is composed of reticular cells.^{101,127,128} The reticular cell bodies are contiguous with the sinus, forming part of its adventitial coat (see Fig. 5-3). Their extensive branching cytoplasmic processes envelop the outer wall of the sinus to form an adventitial sheath. The sheath is interrupted and is estimated to cover approximately two-thirds of the abluminal surface area of sinuses.

Figure 5-4. Scanning electron micrograph of rat marrow sinus. The floor of the lumen (L) is indicated. The *arrow on the left* indicates the cell body of an adventitial reticular cell, which is just beneath the endothelial cell layer. Reticular cell processes can be seen coursing between the sinus wall and the hematopoietic compartment (*small arrows*). (Reproduced with permission from Lichtman MA: *The ultrastructure of the hemopoietic environment of the marrow: A review*. Exp Hematol 9:391, 1981.)

The reticular cells synthesize reticular (argentophilic) fibers that, with their cytoplasmic processes, extend into the hematopoietic compartments and form a meshwork on which hematopoietic cells rest (Figs. 5-4 and 5-5). The cell bodies, their broad processes, and their fibers constitute the reticulum of the marrow.

Adventitial reticular cells can differentiate along the smooth muscle pathway and contain α smooth-muscle actin, vimentin, laminin, FN, and collagens I, III, and IV.^{129,130} More specialized contractile reticular “barrier cells” have been described in mouse marrow after hematopoietic stress.¹³¹ Barrier cells increase in number and seem to enclose small

vessels and extend the venous sinuses so that release of precursors is restrained while accommodating an increased entry of mature cells into the circulation.¹³¹

Studies in both mice and humans have identified subsets of adventitial reticular cells as MSCs with adipocytic-osteogenic potential that in mice appear to have significant overlap: (1) CXCL12-abundant reticular (CAR) cells,¹³² (2) adventitial reticular cells expressing the intermediate filament protein Nestin and displaying the surface proteins platelet-derived growth factor (PDGF) receptor- α and CD51 (Nestin+, PDGFR α +, CD51+),¹³³ and (3) adventitial reticular cells

Figure 5-5. Scanning electron micrograph of rat femoral marrow sinus. The lumen (L) of an exposed sinus that has been cut open is indicated. The *single asterisk* indicates the process of an adventitial reticular cell and the intimate contact it makes with a hematopoietic cell. To the left of this process are adventitial reticular cell fibers, which form a scaffold for hematopoietic cells. The *double asterisk* identifies a portion of a reticular cell. The hole in the sinus floor is an artifact of preparation or a migration channel bereft of the emigrating cell. Empty spaces between the cells and fibers are artifacts of preparation. The *arrow to the left* points to thin-walled fenestrae in the endothelial cytoplasm. The *arrow to the right* identifies the portion of a reticulocyte that may be penetrating the sinus wall, early in egress (see Fig. 5-8A). (Used Lichtman MA, University of Rochester.)

expressing leptin receptors.^{115,134} The human equivalents are a population of CD45⁻, CD146⁺ adventitial reticular cells that have smaller subsets that express Nestin, PDGFR α , and CD51.¹³³ A major proportion of these subsets are restricted to the perivascular area, but have some cells scattered throughout the hematopoietic marrow. However, because these adventitial reticular subsets are also the major sources of CXCL12 and SCF in the marrow, they have important roles in establishing the HSC niche near the marrow microvasculature while their progeny establish the endosteum and its associated hematopoietic niche in the marrow.

The majority of CAR cells are in close association with the sinusoidal endothelial cells but some are also associated with the endosteum. Like the Nestin⁺ MSCs, CAR cells appear to be progenitors of osteoblasts and adipocytes while producing major amounts of CXCL12 and SCF.¹³⁵ Development of CAR cells and their production of CXCL12 and SCF is associated with the expression of the transcription factor Fox1c.¹³⁶ CAR cells and the niches that they create in the marrow are required for the normal development of HSC, various differentiation stages of B-lymphocytes, natural killer cells, and the plasmacytoid dendritic cells that are all found in close physical association with CAR cells.¹³⁷

Autonomic neurons innervate the perivascular Nestin⁺, PDGFR α ⁺, CD51⁺ adventitial reticular cells which maintain the HSC niche by several surface-displayed and/or secreted products including IL-7 and VCAM-1, in addition to SCF and CXCL12.¹³⁸ β -Adrenergic neurotransmission inhibits the expression of these proteins so that mice with specific denervation have decreased marrow cellularity and increased circulating hematopoietic progenitors.¹³⁹ The sympathetic nervous system controls circadian fluctuations in circulating HSC numbers through its effect on MSC expression of the chemokine CXCL12 in the marrow.¹⁴⁰ Studies in mice with defective myelination and mice treated with adrenergic antagonists or agonists indicate that the adrenergic nervous system in the marrow also regulates mobilization of HSCs by granulocyte colony-stimulating factor (G-CSF).¹⁴¹ However, the non-myelinating Schwann cells associated with the autonomic nerves of the marrow secrete transforming growth factor- β (TGF- β) and thereby maintain the HSC quiescence.¹⁴²

Adipocytes

Adipocytes in the marrow develop by lipogenesis in fibroblast-like cells (Fig. 5-6). Reticular cells in mouse and human marrow can undergo transformation to fat cells *in vitro* and can revert into fibroblasts in culture by lipolysis,^{101,143} and the Nestin⁺ MSCs¹³⁸ and CAR MSCs can differentiate into adipocytes. A reciprocal relationship between adipocyte and osteoblast differentiation of MSCs appears to be controlled by multiple transcription factors, with both peroxisome proliferator-activated receptor- γ 2 (PPAR γ 2)¹⁴⁴ and CCAAT/enhancer binding protein (C/EBP)¹⁴⁵ promoting adipocyte differentiation. Marrow fat cells are relatively resistant to lipolysis during starvation, and their phenotype is consistent with both white and brown fat.^{146,147} Although the proportion of saturated fatty acids is lower than in other fat deposits, marrow fat composition depends on whether it is located in the red, hematopoietically active, or the yellow, hematopoietically inactive, marrow. Human marrow adipocytes support the differentiation of late-stage, committed, myeloid and lymphoid hematopoietic cells, but they are unable to support earlier progenitor stages.¹⁴⁸ Quantification of immature hematopoietic cells including HSCs shows reduced numbers in human marrows with increased fat,⁷⁰ and *in vivo* studies in mice confirm that marrow adipocytes create a negative hematopoietic microenvironment that reduces development of HSCs and early-stage common hematopoietic progenitors.⁷²

Bone Cells

Osteoblasts, osteoclasts, and elongated flat cells with a spindle-shaped nucleus form the marrow endosteal lining.¹⁴⁹ These endosteal cells and the closely associated microvascular cells participate in a dynamic process in which endochondral bone formation proceeds with removal of calcified cartilage and connective tissues by macrophages while new bone is formed by osteoblasts and remodeled by specialized osteoclasts.^{114,150} Osteoblasts that become embedded in the bone matrix proteins are termed *osteocytes*, a terminally differentiated cell that has secretory capacity and influences the activities of osteoblasts, osteoclasts, and hematopoietic cells. Resting endosteal cells express vimentin, tenascin, α smooth-muscle actin, osteocalcin, CD51, and CD56. They

Figure 5-6. Scanning electron micrograph of rat femoral marrow. Several sinuses and the intervening hematopoietic cords are evident. The exposed lumen (L) of one branching sinus is indicated. The sinus, just above the L, contains a bean-shaped proplatelet with an attenuated strand connected to a separating smaller proplatelet fragment. Smaller proplatelet fragments are below the L. The short horizontal arrow points to the cytoplasm of a transected megakaryocyte. The lower arrow points to a fat cell. The rat femoral marrow contains a modest number of fat cells. Spaces in the hematopoietic cords are artifacts resulting from transecting the femur. (Reproduced with permission from Lichtman MA: *The ultrastructure of the hemopoietic environment of the marrow: A review*. Exp Hematol 9:391, 1981.)

do not react with antibodies to CD3, CD15, CD20, CD34, CD45, CD68, or CD117.¹⁵¹ Enriched CD56+, CD45-, CD34- endosteal cells grown in the presence of cytokines (insulin growth factor I, basic fibroblast growth factor [bFGF], SCF, IL-3, granulocyte-macrophage colony-stimulating factor [GM-CSF]) do not give rise to hematopoietic cells, which suggests they are not totipotent MSCs.¹⁵¹ In the next sections, the two major types of cells responsible for endosteal activity, osteoblasts and osteoclasts, are considered in terms of their potential roles in maintaining the hematopoietic niche.

Osteoblasts

Osteoblasts have three major functions: formation of new bone by regulating the secretion of the bone matrix proteins, regulation of bone resorption via osteoclast activity, and regulation of the hematopoietic environment mainly by secretion of cytokines. Bone-forming osteoblast progenitor cells, like stromal precursors, reside in the CD34-, STRO-1+ nonadherent marrow cell population.^{152,153} The differentiation of mesenchymal cells into either osteoblasts or adipocytes is related to the relative activities of Runx2 and PPAR γ , respectively.¹⁵⁴ With aging, the sensitivity to PPAR γ appears to increase, contributing to the increase in adipose tissue in the marrow found with older age.¹⁵⁴ BMP2,¹⁵⁵ bFGF,¹⁵⁶ hepatocyte growth factor (HGF),¹⁵⁷ parathyroid hormone¹² and endothelin-1¹⁵⁸ promote osteoblast growth, whereas the cytokine TGF- β ¹⁵⁹ and the transcription factor osterix¹⁶⁰ promote differentiation. Osteoblasts increase early hematopoietic progenitor survival in long-term cultures and secrete hematopoietic growth factors such as M-CSF, G-CSF, GM-CSF, IL-1, and IL-6.^{161,162} Osteoblasts also produce various cytokines such as hematopoietic cell-cycle inhibitory factors TGF- β ,¹⁶³ osteopontin,¹⁶⁴ and CXCL12,¹² as well as cell-cycle stimulatory factor Dickkopf-1,¹⁶⁵ all of which contribute to stem cell regulation within the marrow microenvironment. Direct cell-cell communication has been shown in the marrow and in osteoblastic cell networks,¹⁶⁶ indicating a potential regulatory role for anatomical gap junctions in hematopoiesis.^{167,168} The size of stem cell niches increases after osteoblastic expansion and Notch activation in transgenic models.^{11,12} In another model, intramedullary hematopoiesis and stem cell numbers are severely diminished following *in vivo* ablation of osteoblasts,¹⁶⁹ underscoring the importance of this cell type to the marrow hematopoietic inductive microenvironment. The lymphoid niches for early lymphoid progenitors and differentiating B cells are located adjacent to the endosteal surface.^{92,93} Osteocytes, which are terminally differentiated osteoblasts trapped in the bony matrix, secrete cytokines into the marrow space that act in a negative feedback manner on new bone formation. Specifically, the osteoblast and stromal cell surface protein receptor activator of nuclear factor- κ B ligand (RANKL) activates osteoclasts,¹⁷⁰ while the cytokine sclerostin suppresses osteoblast activity.¹⁷¹ Disruption of the signaling mechanism of G-protein receptors in osteocytes leads to an expansion of myelopoiesis that is mediated by secreted myelopoietic cytokines, most likely G-CSF.¹⁷²

Osteoclasts

Mature osteoclasts are multinucleated giant cells derived from fusion of progenitor cells of the monocyte/macrophage lineage of the HSC.¹⁷³ The mature osteoclasts resorb and remodel bone, regulate osteoblast activity, and help control the HSC entry into and exit from the marrow.^{174,175} The osteoclasts have motile and resorptive phases. They require the Wiskott-Aldrich syndrome protein during clustering and fusion of actin-based adhesion structures named *podosomes*.¹⁷⁶ Podosomes are involved in the formation of specific structures termed *sealing zones* in which actin rings surround an area of ruffled plasma membrane at the face of the endosteal bone. Within these sealing zones, osteoclasts secrete hydrochloric acid and digestive enzymes that resorb bone.

Osteoclasts also can be derived from pro-B cells, as shown by Pax-5 knockout mice, which have increased osteoclasts and severe osteopenia.¹⁷⁷ When osteoclast activity or number are reduced or eliminated in mice through null mutations or homologous recombination, the marrow cavities fail to form resulting in osteopetrosis. Based on studies of osteopetrotic mice, proteins required for osteoclast differentiation include the macrophage transcription factor PU.1; the secreted and surface displayed cytokine M-CSF of stromal cells and its receptor c-FMS on osteoclasts; the transcription factor c-FOS; the cytokine RANKL; its osteoclast receptor RANK, the signaling transducer tumor necrosis factor- α (TNF- α) receptor-associated factor 6 (TRAF 6); the downstream transcription factor nuclear factor (NF)- κ B, and nuclear factor of activated T cells (NFAT).^{175,178,179} Other osteopetrotic mice strains have deficiency of proteins required for the bone resorption function of osteoclasts. These proteins include the β_3 component of the $\alpha_v\beta_3$ integrin (vitronectin receptor) required for binding of the osteoclast sealing zone to bone; c-Src signaling protein; the proton transporting H+ adenosine triphosphatase (ATPase) and chloride channel protein required for HCl secretion; and the secreted osteoclast proteins cathepsin K, matrix metalloproteinases, and TRAP that digest the bone matrix.^{174,175,179}

Osteoblast/stromal cells regulate differentiation of osteoclasts through intimate cell-cell contacts. They are found in direct apposition to osteoclasts with coated pit formation, suggesting accumulation of receptor-ligand complexes in endocytic vesicles.^{180,181} The recruitment of the osteoblasts and osteoclasts appears to be through capillaries associated with the remodeling compartment.¹⁸² A major regulatory mechanism by which osteoblasts and osteoclasts interact is the RANK/RANKL/osteoprotegerin (OPG) system of signaling.¹⁸² Osteoclast differentiation and maturation require the signaling cascade from RANK on the cell surface through TRAF 6, NF- κ B, and NFAT.¹⁸⁰ Osteoblasts and their progenitor cells display RANKL on their surfaces, and binding of RANKL to the RANK on the osteoclasts and their progenitors promotes differentiation and activation of the osteoclasts. Osteoblasts also secrete OPG, a decoy receptor for RANKL, which inactivates RANKL by binding to the active site of RANKL, thereby preventing its binding to RANK. As a result, osteoclastic activity is decreased when OPG concentrations are high and increased when they are low.¹⁸³ Another signaling mechanism by which osteoclasts and osteoblasts reciprocally regulate the differentiation and activities of each other is the ephrin-B2-EphB4 signaling system.¹⁸⁴ Osteoclasts express ephrinB2 on their surfaces while the osteoblasts express EphB4, a member of the receptor tyrosine kinase (RTK) family, which is the receptor for ephrinB2. Binding of ephrinB2-EphB4 results in bidirectional signaling in which osteoclast differentiation is decreased though suppression of the c-FOS-NFATc1 activity, whereas osteoblast differentiation is increased by EphB4 signaling.¹⁸⁴

Osteoclasts produce HGF and express c-Met, the HGF receptor, implying a paracrine and autocrine regulatory pathway between them and adjoining osteoblasts.^{157,185} Similarly, blocking expression of cadherin-6 interferes with heterotypic interactions between osteoclasts and stromal cells, impairing their ability to support osteoclast formation.¹⁸⁶ CD9, a tetraspanin transmembrane adhesion protein on stromal cells,¹⁸⁷ influences myelopoiesis in long-term marrow cultures.¹⁸⁸ Inhibition of stromal cell CD9-mediated signaling by a blocking antibody reduces osteoclast differentiation factor transcription, leading to reduced osteoclastogenesis.¹⁸⁹ Macrophage-stimulating protein, a HGF-like protein, signals through the stem cell-derived tyrosine kinase, a member of the HGF receptor family. It also stimulates osteoclast bone-resorbing activity by enhanced cytoskeletal reorganization without affecting proliferation of osteoclast precursors.^{190,191} Osteoclast differentiation is influenced by monocytes expressing ADAM-8 (CD156), a protein of the disintegrin and metalloproteinase family,¹⁹² and eosinophil chemotactic

factor-L (ECFL),¹⁹³ characterizing complex cell–cell, cell adhesion protein, stromal cell cytokine, and chemokine signals within the marrow microenvironment.

LYMPHOCYTES

Lymphocytes, including T, natural killer (NK), B, and plasma cells, and macrophages, including monocyte-derived, antigen-presenting dendritic cells, arise from the HSCs and undergo part of their differentiation in the marrow. They then circulate and, in the case of the lymphoid cells, reside and further differentiate in other organs such as the thymus, spleen or lymph nodes, before returning to the marrow, where they terminally differentiate and form part of the marrow microenvironment by producing growth factors (IL-3, CCL3) and participating in cell–cell interactions with developing progenitors.^{84,101,194} Monocytic/macrophage progenitor cells can enter the circulation and later enter many different tissues where they differentiate into macrophages. In the marrow, the monocytic/macrophage progenitors can differentiate into macrophages or fuse and become osteoclasts. Lymphocytes and macrophages concentrate around arterial vessels, near the center of the hematopoietic cords. B cells also cluster near the osteal surface.^{92,93} Mature B and T lymphocytes in the marrow are in contact with a specific set of monocyte-derived, antigen-presenting dendritic cells that are clustered around the blood vessels.¹⁹⁵

Lymphocytic differentiation begins as HSCs that have committed to differentiation as multipotent HPCs (MPPs) lose their potential to become megakaryocytic-erythroid progenitors (MEPs) and granulocyte-macrophage (GM) progenitors; this change in differentiation potential is detectable as the upregulation of lymphoid-specific transcripts, that is, they are lymphoid-primed multipotent progenitors (LMPPs). The commitment of LMPPs to lymphoid differentiation in these early-stage HPCs is reinforced by progressive expression of FMS-like tyrosine kinase 3 (Flt-3), IL-7 receptors (IL-7R), and recombination activating genes-1/2 (Rag-1/2) proteins.^{196,197} These early lymphoid progenitors (ELPs) require a microenvironment provided by MSCs and their osteogenic progeny which supplies VCAM-1, CXCL12, Flt-3 ligand, and IL-7.^{198,199} The ELPs enter the blood with transit to the thymus where they undergo differentiation into T cells. In addition, to its role as site of early T-lymphocyte development, the marrow acts a secondary organ for the proliferation of mature CD8 and CD4 memory T lymphocytes. Although no specific organized structure or niche has been found for these T lymphocytes, they can represent up to 4 percent of nucleated cells in the marrow that they reenter by migrating through the sinusoidal endothelium from the blood.²⁰⁰ Alternatively, LMPPs can remain in the marrow and differentiate into common lymphocyte progenitors (CLPs) that give rise to NK progenitor cells, which differentiate in the marrow, or prepro-B cells that mature to the pro-B cells, which migrate from the marrow to the lymph nodes or spleen where they differentiate further.^{196,197}

Marrow stromal cells facilitate the maturation of NK cells,²⁰¹ an effect likely mediated by stromal-derived Flt-3 ligand and IL-15.²⁰² Within the marrow, both NK cells and CD8+ memory T cells require the coordinated expression of secreted IL-15 and surface IL-15 receptors by other marrow cells for their survival and development.²⁰³ The marrow MSCs and their osteogenic progeny also create a microenvironment for proliferation and differentiation of ELPs through the later sequential lymphoid stages of CLPs, prepro-B cells, pro-B cells, and pre-B cells via the provision of osterix and galectin-1.¹⁹⁸

The differentiation stages subsequent to the pro-B cells occur after the cells enter the blood and seed the lymphoid follicles of the secondary lymphoid organs, mainly spleen and lymph nodes. From these lymphoid organs, the cells then reenter the blood as B lymphocytes

or immature plasma cells. The immature plasma cells that have differentiated in the spleen and will become the long-lived plasma cells return home to the marrow, where they are located in contact with CXCL12-producing stromal cells. A negative feedback is completed as the mature plasma cells either compete with the prepro-B cells for sites on the CXCL12-producing stromal cells or directly induce apoptosis of the prepro-B cells.²⁰⁴ Marrow blood vessel-associated dendritic cells produce macrophage migration-inhibition factor, a cytokine required for survival of mature B lymphocytes that have matured in secondary lymphoid organs and recirculated to the marrow.¹⁹⁵

MACROPHAGES

Hematopoietic progenitors restricted to monocyte/macrophage differentiation are characterized by expression of M-CSF receptors (FMS), membrane-activating complex-1 (CD11b), and F4/80 antigen, and give rise to monocytes that enter the blood.²⁰⁵ These nondividing monocytes can then enter various organs, including a subset with high Ly6C that reenter the marrow where they become macrophages and antigen-presenting dendritic cells.^{205,206} Although they are both descendants of similar M-CSF-dependent monocytic progenitors, macrophages differ from osteoclasts by their single nucleus and, in mice, expression of F4/80 antigen as well as lack of TRAP and calcitonin receptors.²⁰⁶ Marrow macrophage phenotype²⁰⁷ is regulated by adjoining stromal cell–accessory cell–derived colony-stimulating factors and cytokines,²⁰⁸ such as M-CSF–induced upregulation of $\alpha_4\beta_1$ - and $\alpha_5\beta_1$ -integrin expression²⁰⁹ and Flt-3 ligand-promoting macrophage outgrowth with B-cell-associated antigens.²¹⁰ Macrophages are an integral component of the local microenvironment and regulate hematopoiesis via a complex array of dual-acting stem cell stimulatory and inhibitory factors, such as IL-1, CCL3, TNF- α , and TGF- β .^{211–213} Macrophages respond to PDGF by upregulating IL-1 secretion and thereby activating primitive hematopoietic cells.²¹⁴ Macrophages also modulate the structure and composition of the extracellular matrix (ECM) and its FN content.²¹⁵

Specialized macrophages termed *osteomacs* form a canopy over the active osteoblasts and osteoclasts on the endosteal surface, where the macrophages coordinate the bone-forming activity of osteoblasts and bone-resorbing activity of osteoclasts.²⁰⁶ Another subset of macrophages, which are identified by CD169 (sialoadhesin/Siglec-1 [sialic acid-binding immunoglobulin-like lectin-1]), act to retain in the marrow those HSCs and early progenitor cells that are capable of circulation in the blood.²¹⁶ CD169-expressing macrophages also comprise the central macrophages of erythroblastic islands that interact directly with erythroid cells,²¹⁷ enhancing their proliferation and differentiation. Similarly, mature B and T lymphocytes in the marrow are supported in the specific microenvironment provided by monocyte-derived, antigen-presenting dendritic cells that are clustered around the blood vessels.¹⁹⁵

EXTRACELLULAR MATRIX

Mesenchymal cells forming the cellular stroma in the marrow create a network of ECM proteins, such as proteoglycans or glycosaminoglycans (GAGs), FN, tenascin, collagen, laminin, and thrombospondin (TSP).^{218–221} Localizing signals are provided by stromal-ECM and hematopoietic cell adhesive interactions^{222,223} in concert with chemokines²²⁴ and cytokines bound to heparin-like structures in the GAGs.²²⁵ The binding of specific cytokines may enhance the activity of a cytokine if the GAG-binding site does not interfere with the site that binds the cytokine receptor, whereas GAG-binding sites that overlap or interfere with a cytokine receptor-binding site can inhibit the cytokine function.²²⁵ Table 5–1 lists the cytokines that are presented on the surface of stromal cells and matrix-binding chemokines and cytokines.^{225–238}

TABLE 5-1. Cell Membrane Presentation and Matrix Association of Cytokines and Chemokines

Cell Membrane	Matrix Association
<i>Chemokine</i>	<i>Chemokine</i>
Fractalkine	RANTES, PF-4, IP-10, IL-8 Macrophage inflammatory proteins (MIP-1 α , MIP-1 β) CXCL12/stromal cell-derived growth factor-1 (SDF-1 α , SDF-1 β) Monocyte chemoattractant protein-1 (MCP-1)
<i>Cytokine</i>	<i>Cytokine</i>
c-KIT ligand	Granulocyte-macrophage colony-stimulating factor
Tumor necrosis factor- α (TNF- α)	Interferon- γ (IFN- γ)
Interleukin-1 (IL-1)	Leukemia inhibitory factor (LIF)
Macrophage colony-stimulating factor (M-CSF)	Interleukins (IL-1 α , IL-1 β , IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, IL-12) Basic fibroblast growth factor (bFGF)
Transforming growth factor- α (TGF- α)	Hepatocyte growth factor (HGF) Transforming growth factor- β (TGF- β); binding to endoglin and heparan sulfate)

IP-10, interferon-inducible protein 10; PF-4, platelet factor 4; RANTES, regulated upon activation normal T-cell expressed and secreted.

In addition to its supply of hematopoietic growth factors, the ECM provides noncellular binding partners for surface adhesion molecules of the hematopoietic and mesenchymal cells. The marrow microelasticity, which is a function of cellular density and ECM composition, varies more than 100-fold from the soft central areas to the much stiffer endosteal areas.²³⁹ This microelasticity determines the differentiation of MSCs,²⁴⁰ and the fate of HSCs and committed hematopoietic cells.²⁴¹ In HSCs and HPCs, the activities of two nonmuscle myosin isozymes are regulated in response to the elasticity of the ECM. The increased relative activity of nonmuscle myosin II B that mediates asymmetric cell division and self-renewal is greatest in the stiffer ECM of endosteal areas, whereas increased relative activity of non-muscle myosin IIA in the areas of softer ECM mediates symmetric cell division and differentiation.²³⁹

Proteoglycans

Proteoglycans are polyanionic macromolecules (heparan sulfate, dermatan, chondroitin sulfate, hyaluronic acid) that are distributed on the surface of adventitial reticular cells and within the ECM.^{218,242} Heparan sulfate is the main cell-surface GAG in long-term marrow cultures, and chondroitin sulfate is the major secreted species.²⁴³ D-xylosides, which stimulate artificial sulfated GAG synthesis, increase chondroitin sulfate synthesis and hematopoietic cell production.²⁴³ Hyaluronic acid and chondroitin sulfate-containing proteoglycans are prominent in the adherent and nonadherent compartments of long-term marrow cultures.²⁴² Heparin-containing and heparan sulfate-containing proteoglycans interact with laminin and type IV collagen²⁴⁴ and may play a role in cell-cell interactions, cytokine presentation, and cell

differentiation.²⁴⁵⁻²⁴⁷ They also mediate progenitor cell binding to other ECM molecules such as FN.²⁴⁸⁻²⁵⁰

Agrin, a proteoglycan associated with neuromuscular junctions, is produced in the marrow by MSCs, osteoblasts and monocytes, and interacts through α -dystroglycan receptors on HSCs²⁵¹ and their progeny as they differentiate along the monocyte/macrophage lineage.²⁵² Agrin-deficient mice have hypocellular marrows as a result of decrease in all marrow hematopoietic cell lineages²⁵¹ as well as specific inhibition of numbers and phagocytic function of monocytes and macrophages.²⁵² An important hematopoietic cell proteoglycan, CD44, has hyaluronate as a major matrix ligand. The CD44-hyaluronate interaction is greatly enhanced by various cytokines, and it promotes other matrix and cellular interactions by hematopoietic cells.²⁵³ Cytokines (GM-CSF, IL-3, SCF) rapidly induce CD44 expression and increase CD44-mediated adhesion of CD34+ hematopoietic progenitors to hyaluronan.²⁵⁴ Lymphocyte CD44 has a binding site on the carboxy-terminal heparin-binding domain of FN,²⁵⁵ and neutralizing antibodies to CD44 inhibit hematopoiesis in long-term marrow cultures.²⁵⁶ Chondroitin sulfates A and B mediate monocyte and B-cell activation via a CD44-dependent pathway.²⁵⁷ Hyaluronate binding enhances hematopoiesis by releasing IL-1 in a CD44-dependent manner and IL-6 by a CD44-independent pathway.²⁵⁸ In humans, a specific CD44 isoform displayed on hematopoietic cells is a ligand for E- and L-selectins and plays a role in HSC homing and integrin-mediated transendothelial migration in the marrow.²⁵⁹

Heparan sulfate mediates IL-7-dependent lymphopoiesis²⁵⁵ and modulates hematopoiesis and stromal cell-matrix remodeling²⁶⁰ by anchoring HGF^{236,261} and bFGF.^{260,262,263} On the surface of marrow stromal cells, the main heparan sulfate-containing proteoglycans are syndecan-3, syndecan-4, and glypican-1. In the ECM, the most prevalent form is perlecan.²⁶⁴ Syndecan-3 is expressed by marrow stromal cells as a variant form with a core protein of 50 to 55 kDa, suggesting syndecan-3 plays a role in hematopoiesis.²⁶⁴ Perlecan promotes bFGF receptor binding and mitogenesis, and can bind GM-CSF.^{257,265} Heparan sulfate expression is induced on the cell surface in early erythroid differentiation of multipotential HSC.²⁶⁶ Glypican-4, another member of this family, is found on marrow stromal cells and progenitor cells.²⁶⁷ Syndecan-1 expression in B lymphoid cells is reduced by IL-6, which implies similar regulatory pathways in other cell types.²⁶⁸ Biglycan, a matrix glycoprotein, with homology to osteonectin, and the molecule SIM, a transmembrane protein, selectively increase IL-7-dependent proliferation of B cells.²⁶⁹ Interactions of B cells with other components of the immune system are mediated by syndecan-4, which facilitates the formation of dendritic processes²⁷⁰ and regulates focal adhesion, stress fiber formation, and cell migration.²⁷¹

Fibronectin

FN localizes at sites of attachment of hematopoietic cells and marrow stromal cells *in vitro*^{219,272} and at sites of interaction between these cells and developing granulocytes or monocytes.²⁷³ Early erythroid progenitors bind FN through their integrin receptors $\alpha_5\beta_1$ and $\alpha_4\beta_1$.^{274,275} Adhesion of HPCs to stroma is partly mediated by FN.^{248,276} The alternatively spliced form of FN (type III connecting segment [IIICS]), which is expressed uniquely within the marrow microenvironment, associates with the $\alpha_5\beta_1$ -integrin receptor on HSC.²⁷⁷ Additional IIICS FN variants have been detected in marrow stroma, providing for finely controlled progenitor-stem cell interactions based on messenger RNA splicing.²⁷⁸ FN adhesion to peptide domains, such as the CS1 domain (which activates α_5 integrins) or stromal cells, can have dual effects of stimulation and inhibition of hematopoietic progenitor growth.²⁷⁹⁻²⁸²

The very-late antigens (VLA)-4 and VLA-5 ($\alpha_4\beta_1$ and $\alpha_5\beta_1$) and CD44 cooperate to promote FN adhesive interactions.^{279,282-284} Cytokines

such as IL-3, SCF, and thrombopoietin (TPO) augment the magnitude of FN-mediated HPC adhesion and migration.^{285–288} Functional effects of FN within the marrow ECM include decreased erythroblast FN adhesion as differentiation progresses^{274,283} with modulation of erythroid cell differentiation dependent upon competing binding of $\alpha_4\beta_1$ integrin with FN in the ECM and with central macrophages in erythroblastic islands.²⁸⁹ Binding of collagen I in the marrow ECM by megakaryocytes leads to their spreading and inhibition of proplatelet formation by a mechanism involving FN induction and secretion with polymerization via cosecreted factor XIII-A.²⁹⁰ FN is required for expression of gelatinase in macrophages²⁹¹ and regulates cytokine release by M-CSF-activated macrophages²⁹² and chondrocytes.²⁹³

Tenascin

The fibrillar glycoprotein tenascin-C is found in the microenvironment surrounding maturing hematopoietic cells.^{218,294} Tenascin-C has distinct functional domains that promote hematopoietic cell adhesion to ECM proteins or mediate a strong mitogenic signal to marrow mononuclear cells.²⁹⁵ Although tenascin-C-deficient mutant mice appear to have normal steady-state hematopoiesis, colony-forming capacity of marrow is markedly decreased,²⁹⁶ marrow regeneration capacity after cytoreductive agents is decreased,²⁹⁷ and retention of T-lymphocyte progenitors is impaired.²⁹⁷ This last effect is mediated through the $\alpha_4\beta_1$ integrin on T-lymphocytes progenitors, but effects on HSCs and early hematopoietic progenitors is mediated by a different mechanism.²⁹⁷ Mutant tenascin-C-deficient animals also display decreased FN in their marrow, suggesting a possible mechanistic interaction between tenascin-C and FN in the marrow microenvironment.²⁹⁸

Collagen

Collagen types I and III are associated with microvascular walls, whereas collagen type IV is confined to basal lamina beneath endothelial cells.^{160,299} Marrow-derived capillary networks grow in collagen gel cultures,³⁰⁰ inhibition of collagen synthesis reduces hematopoiesis *in vitro*,³⁰¹ and collagen-based scaffolds are most effective for *in vitro* three-dimensional models of the hematopoietic microenvironment.³⁰² Marrow-derived fibroblasts and stromal cells synthesize collagens I, III, IV, V, and VI.³⁰³ Collagen VI binds von Willebrand factor and is a strong cytoadhesive component of the marrow microenvironment.³⁰⁴ Erythroid and granulocytic progenitors adhere to collagen type I *in vitro*.³⁰⁵ Collagen type XIV, another fibril-associated collagen, promotes hematopoietic cell adhesion of myeloid and lymphoid cell lines.³⁰⁶ *In situ* immunolocalization of ECM proteins in murine marrow shows that collagen types I and IV and FN localize to the endosteum.³⁰⁷ Megakaryocyte binding to collagen I that induces FN secretion and polymerization²⁹⁰ enhances the $\alpha_4\beta_1$ -mediated collagen binding by megakaryocytes, permitting increased megakaryocyte adhesion and migration,³⁰⁸ which are also mediated by other megakaryocytic collagen receptors including glycoprotein VI and discoid domain receptor 1 (DDR1).³⁰⁹

Laminin

Laminins, multidomain glycoproteins with mitogenic and adhesive sites, are major components of the ECM and basement membranes.³¹⁰ Laminin interactions with collagen type IV and basement membrane components such as proteoglycans and entactin³¹¹ regulate leukocyte chemotaxis.^{312,313} CD34+ granulocytic progenitors,³¹⁴ mature monocytes,³¹⁵ and neutrophils³¹⁶ adhere to laminins. The role of laminins within the cytomatrix may be to strengthen adhesive interactions with $\alpha_5\beta_1$ (VLA-5) and $\alpha_6\beta_1$ (VLA-6) on hematopoietic cells.³¹⁶ In combination with FN *in vitro*, laminins can expand both HSCs and several more differentiated progenitors.³¹⁷ Laminins are composed of α , β , and γ polypeptides with expression of laminin-2 ($\alpha_2\beta_1\gamma_1$), laminin-8 ($\alpha_4\beta_1\gamma_1$),

and laminin-10 ($\alpha_5\beta_1\gamma_1$) in the marrow.³¹⁸ Stromal cells in cultures and cytokine-expanded CD34+ cells also express laminin β_2 , which is found in the pericellular space in marrow and intracellularly in megakaryocytes.³¹⁹ Laminin- γ_2 chain expression, which is unique to marrow-derived stromal cells, colocalizes with α smooth-muscle actin in marrow and is not expressed in endothelial cells or megakaryocytes.³²⁰

Integrins $\alpha\beta_1$ and $\alpha\beta_4$ are receptors for laminin-10/11 and laminin-8.³¹⁴ Laminin-10/11 ($\alpha_5\beta_1\gamma_1/\gamma_5\beta_2\gamma_1$) and FN bind CD34+ and CD34+ CD38–progenitors, whereas laminin-8 ($\alpha_4\beta_1\gamma_1$) and laminin-10/11 facilitate CXCL12-mediated transmigration of CD34+ cells.³¹⁴ In mouse repopulation studies, antibodies that block the α_6 components of laminin receptors decreased the homing of HSCs and colony-forming units–granulocyte-macrophage (CFU-GM).³²¹ When combined with antibodies to the α_4 component of integrins, antibodies that block the α_6 components synergistically decreased marrow homing of the short-term, multipotent repopulating cells. In contrast to this role of these integrin receptors in the homing of HSCs, a 67-kDa, nonintegrin laminin receptor is upregulated in HSCs following G-CSF stimulation and plays a significant role in their mobilization.³²² This 67-kDa nonintegrin receptor for laminin also has a role in the marrow homing of burst-forming units–erythroid (BFU-Es), early-stage erythroid progenitors that circulate in the blood.³²³ On the other hand, the Lutheran blood group glycoproteins serve as receptors for the α_5 integrin component of laminins on the late-stage erythroid cells.³²⁴ Laminin promotes the M-CSF-dependent proliferation of marrow-derived macrophages via the α_6 -integrin subunit,³²⁵ and $\alpha_6\beta_1$ mediates mast cell adhesion to laminin.³²⁶

Thrombospondin

The TSPs are secreted matrix glycoproteins that modulate cell function by altering cell–matrix interactions.³²⁷ TSP1, a multifunctional ECM protein initially identified in platelet α granules, has domains that interact with collagen and FN and may participate in HSC lodgment.³²⁸ TSP activates TGF- β ³²⁹ which results in a stimulatory effect on NK cells.³³⁰ TSP binds to matrix heparan sulfates¹⁷⁸ and inhibits osteogenic differentiation.^{331,332} Receptors on hematopoietic and nonhematopoietic cells can interact with TSP, including CD36³³³ and the cutaneous lymphocyte antigen-1 protein of the CD36/LIMP II gene family.³³⁴ CD36 is expressed during erythroid and megakaryocytic maturation.³³⁵ TSP stimulates matrix metalloproteinase-9 activity in endothelial cells³³⁶ and is chemotactic to monocytes.³³⁷ A 140-kDa fragment of TSP1 binds bFGF, and TSP1 acts as a scavenger for matrix-associated angiogenic factors (fibroblast growth factor 2, VEGF, HGF), underscoring its antiangiogenic properties.^{338,339} Mice deficient in TSP2 demonstrate that TSP2 is taken up in an integrin-dependent manner within the marrow and is necessary for the release of functionally competent platelets by megakaryocytes.³⁴⁰ The 21-amino acid, C-terminal peptide of TSP4 stimulates proliferation of multiple types of early hematopoietic progenitors through the regulator of differentiation 1 (ROD1) nuclear receptor and increases erythropoiesis in mice.³⁴¹

Vitronectin

Vitronectin, a major cytoadhesive glycoprotein, is present in plasma and the interstitial matrix of tissues. It interacts with a vast number of ECM components, cytokines, growth factors and proteolytic enzymes *in vitro* and *in vivo*.³⁴² Vitronectin also binds to several α_v -containing integrins,³⁴² including the integrin $\alpha_v\beta_3$ receptor (CD51) on fibroblasts, endothelial cells, osteoclasts,^{343,344} and mature hematopoietic cells, including megakaryocytes, platelets,³⁴⁵ and mast cells.³⁴⁶ The integrin $\alpha_v\beta_3$ is expressed on monocyte-macrophages and neutrophils and mediates their transendothelial migration.^{347,348} The vitronectin receptor cooperates with TSP and CD36 in the recognition and phagocytosis of

apoptotic cells by neutrophils, macrophages, and dendritic cells.^{349–351} Vitronectin-deficient mice have normal blood cell counts,³⁵² but thrombogenesis, new microvessel formation and tissue repair capacity are impaired,³⁵³ most likely due to failure of inflammatory and thrombotic mechanisms. Thus, in the marrow ECM, vitronectin functions mainly in the coordination of apoptotic cell clearance, cellular migration, bone remodeling, and angiogenesis.

Other Matrix Proteins

Osteopontin, a glycoprotein produced by osteoblasts and hematopoietic cells in the marrow, binds to FN and collagen.^{354,355} The predominant form of osteopontin in the marrow is thrombin-cleaved, and its N-terminal peptide is the active ligand for the $\alpha_5\beta_1$ and $\alpha_4\beta_1$ integrins on HSCs and circulating hematopoietic progenitors that plays a role in their attraction to and binding in the marrow.³⁵⁶ Osteopontin can bind numerous integrins and CD44, and its binding through β_1 -integrin results in suppression of proliferation and maintenance of quiescence in HSCs.^{354,355} Conversely, the same osteopontin- β_1 -integrin pathway induces proliferation in erythroblasts.³⁵⁷ Osteopontin also plays a role in the development of NK cells^{358,359} and T lymphocytes.³⁵⁵ The fibulins are proteins secreted by the stromal cells of marrow, including osteoblasts and endothelial cells.^{360,361} The metalloproteinase-resistant fibulin-1 accumulates in the ECM where it binds to a specific site on FN,^{360,361} thereby disrupting HSC binding to FN with resultant decreases in HSC proliferation and differentiation.³⁶¹ Thus, fibulin-1 can act as a negative regulator that can maintain the quiescence of HSCs in the marrow.

HEMATOPOIETIC CELL ORGANIZATION

Erythroblasts

Erythroid progenitor cells arise from MPPs via the activity of the transcription factor GATA-1, which promotes differentiation toward the bipotent MEP that can subsequently differentiate into either erythroblasts or megakaryocytes (Chap. 32).³⁶² MEP fate is determined by the relative activities of two competing transcription factors, KLF-1, which directs differentiation toward the erythroid lineage, and Fli-1, which directs differentiation toward the megakaryocytic lineage.^{362,363} The earliest progenitor cells committed solely to erythroid differentiation, BFU-Es,³⁶⁴ which are defined by production of large colonies or bursts of erythroblasts after weeks in tissue culture, can circulate in the blood and reenter the marrow. When a BFU-E or one of its progeny, the colony-forming units–erythroid (CFU-Es),³⁶⁴ associates with a marrow macrophage, they form the precursor of the basic unit of terminal erythropoiesis, the erythroblastic island (EBI).⁹⁴ Under the influence of the KLF-1 in both the macrophage and the erythroid cells,^{365,366} an EBI develops as a central macrophage surrounded by as many as 30 adherent erythroblasts at various stages of differentiation from CFU-E through enucleating orthochromatic erythroblast. At least five cell-surface protein pairs contribute to adherence between macrophages and erythroblasts in EBIs⁹⁴: (1) VCAM-1 on macrophages and $\alpha_4\beta_1$ integrin (VLA-4) on erythroblasts; (2) α_v component of integrins on macrophages and ICAM-4 on erythroblasts; (3) erythroblast-macrophage protein (EMP), on both erythroblasts and macrophages via a homophilic reaction; (4) CD169/Siglec-1 on macrophages and sialylated glycoproteins on erythroblasts; and (5) hemoglobin-haptoglobin receptor (CD163) on macrophages and an unknown binding partner on erythroblasts.

Differentiating erythroblasts are defined as basophilic, polychromatophilic, and orthochromatic erythroblasts by their morphologic appearances in Giemsa-stained films of aspirated marrows. However, CFU-Es and their immediate progeny, the proerythroblasts (ProEBs), as well as the morphologically defined, later erythroblast stages can be purified and defined by flow cytometry. Murine erythroid cells from

CFU-Es through ProEBs, are identified by flow cytometric expression patterns of transferrin receptor (CD71) and the erythroid-specific membrane glycoprotein Ter119,³⁶⁷ or of CD44 and forward light scatter.³⁶⁸ Likewise, expression patterns of glycophorin A, Band 3, and the α_4 component of integrin permit identification of the same stages in human erythroid differentiation.³⁶⁹

In EBIs, CFU-Es lose SCF dependence that had been present throughout their differentiation from HSCs, and CFU-Es, ProEBs, and early basophilic erythroblasts develop a dependence upon EPO to prevent apoptosis.³⁷⁰ The level of EPO, the principal regulator of erythropoiesis, is regulated by tissue oxygen delivery in the kidney, and is dependent on both blood oxygen levels and red cell numbers.³⁷⁰ However, during hypoxic stress, CFU-Es and ProEBs can be increased without differentiation in response to circulating glucocorticoid hormones^{371,372} and BMP4 from central macrophages of EBIs.³⁷³ EPO prevents apoptosis by decreasing expression of Fas, a membrane protein of the TNF- α receptor family that is prominently expressed on CFU-E, ProEBs and early basophilic stage erythroblasts. Fas activation triggers a series of caspases, a family of intracellular proteases that cleave other caspase members in sequential fashion, ultimately inducing apoptosis.³⁷⁴ Fas-ligand, which binds and activates Fas, is produced mainly by immature erythroblasts in mice³⁷⁵ and by mature erythroblasts in humans.³⁷⁶ EPO also suppresses apoptosis in late-stage erythroblasts by inducing the antiapoptotic protein Bcl-X_L, which stabilizes mitochondria, preventing the activation of caspases other than those activated by Fas.³⁷⁷ As a result of the Fas/Fas-ligand negative feedback within the EBI, differentiating erythroblasts can modulate the rate of CFU-E/ProEB apoptosis and provide regulated control rates of erythrocyte production commensurate with erythropoietic demand.

In EBIs, differentiation events include: (1) hemoglobin production in differentiating erythroblasts, (2) formation of the erythrocyte plasma membrane and underlying membrane skeleton, (3) cell size decrease associated with the terminal 4 to 5 cell divisions being a result of decreased duration of the G₁ phase of erythroblasts attached to central macrophages,³⁷⁸ and (4) nuclear condensation,³⁷⁹ stiffening,³⁸⁰ and extrusion.³⁸¹ Erythroblast enucleation requires nonmuscle myosin IIB³⁸² and filamentous actin³⁸¹ to produce a membrane-enveloped nucleus and a nascent reticulocyte. The central macrophage sends out extensive slender membranous processes that envelop each erythroblast and phagocytize defective erythroblasts and extruded nuclei.³⁸³ The extruded nuclei display phosphatidylserine on their plasma membranes that leads to rapid phagocytosis by the central macrophage.³⁸⁴ Phagocytosis of extruded nuclei with recycling of the DNA components is essential in that deoxyribonuclease II-deficient mice die from an underproduction anemia with fetal liver macrophages filled with extruded erythroid nuclei.³⁸⁵ The irregularly shaped, maturing reticulocytes can interact directly with the central macrophages before entering the blood through the venous sinuses.⁹⁴

Megakaryocytes

During thrombopoiesis, HSC in the subcortical regions of the hematopoietic cords generate megakaryocytes by sequential, overlapping expressions of specific transcription factors. First HSCs differentiate to common myeloid progenitors (CMPs) via the influence of PU.1 and GATA-1, next to MEPs via GATA-1/FOG, then to megakaryocytic progenitors via Fli-1, and finally to megakaryocytes via NF-E2 (Chap. 11).^{362,386} The microenvironmental factors that control survival and differentiation of megakaryocytes and their progenitors include a similar pattern of dependence to that of erythroid progenitors, with an overlapping decrease in dependence on SCF and an increasing dependence upon a physiologically regulated cytokine, TPO in the case of megakaryocytes, which ceases before the completion of differentiation.^{386,387}

TPO concentrations are reciprocally related to the circulating platelet mass, which is the major site of metabolism of the hormone.³⁸⁸ As the major regulator of megakaryocyte development, TPO acts in concert with several synergistic cytokines, including IL-11, IL-3, and IL-6.^{386,387} TPO induces endomitosis in terminally differentiating megakaryocytes by inhibiting cytokinesis through reduced function of the contractile ring of filamentous actin and suppression of nonmuscle myosin expression.^{389,390} However, DNA replication and accumulation of cytoplasmic proteins continues during six to seven of these endomitotic cell cycles. The resultant polyploid nucleus and abundant cytoplasm characterize the mature megakaryocyte which can account for 2 percent of marrow hematopoietic cell volume.⁹³

Mature megakaryocytes lie directly outside the marrow vascular sinus wall³⁹¹ because of their translocation during differentiation under the influence of platelet endothelial cell adhesion molecule (PECAM)-1 (CD31) expressed on endothelial cells^{392,393} and an autocrine pathway of VEGF-A and its receptor Flt-1 stimulating CXCR4 (receptor for CXCL12) expression on megakaryocytes.³⁹⁴ This migration of maturing megakaryocytes is associated with the development of podosomes, actin-based extensions that bind to and remodel the local ECM.³⁹⁵ The podosomes not only direct the megakaryocytes through the marrow to the sinus wall, but they also extend through the sinus basement membrane into the circulation.³⁹⁵ Terminal differentiation of megakaryocytes involves the development of branching cytoplasmic protrusions, the proplatelets. Proplatelets are formed around a microtubular core that both provides a sliding mechanism that elongates and extends them into the vascular sinus lumen, but also provides a conduit for the redistribution of cytoplasmic granules from the megakaryocytes to bulbous formations at the distal ends of the proplatelets.³⁸⁹

Granulocytes

Granulocytes are mature myeloid cells comprised of neutrophils, eosinophils, and basophils originating from stem cells and myeloid progenitor cells concentrated in the subcortical regions of the hematopoietic cords (Chap. 18).³⁹⁶ Granulocytes are terminally differentiated from common granulocyte-macrophage progenitor (GMP) cells which arise from MPPs through the expression of multiple transcription factors (Chap. 61). The transcription factor PU.1 promotes the development of the GMP phenotype and antagonizes the activity of GATA-1, which promotes MEP differentiation.^{397,398} The myeloid commitment of GMPs is reinforced by C/EBP α , which promotes myeloid differentiation while suppressing the B-lymphoid transcription factor Pax5.^{398,399} The further activity of C/EBP α is associated with granulocytic differentiation, whereas increased PU.1 activity is associated with monocytic differentiation.⁴⁰⁰ The progression of myeloid differentiation beyond the promyelocyte stage, including the formation of secondary and tertiary granules, requires both C/EBP and the GFI-1 transcription factors.^{400,401} GFI-1 also antagonizes the activity of the Egr-1 and Egr-2 transcription factors that are associated with monocytic differentiation.⁴⁰⁰ The timing of expression and relative ratios of C/EBP α and GATA-2 transcription factors regulate differentiation of the GMP into a mature neutrophil, eosinophil, basophil, or mast cell.³⁹⁹ Increased C/EBP α activity at this stage promotes a differentiation pathway toward neutrophils and eosinophils, whereas increased GATA-2 activity promotes differentiation toward basophils and mast cells.³⁹⁹ Cells differentiating along the neutrophil and/or eosinophil pathway will follow a terminal neutrophil path when only C/EBP α is expressed, and a terminal eosinophil path when both C/EBP α and GATA-2 are expressed. Those cells differentiating along the basophil/mast cell pathway will follow a terminal mast cell path when only GATA-2 is active and a terminal basophil path when both GATA-2 and C/EBP α are active.

A group of hematopoietic growth factors, including SCF, GM-CSF, G-CSF, IL-6, and IL-5, support granulocytic progenitor/precursor viability and proliferation. In some cases, these growth factors can mobilize of these progenitors/precursors and their mature progeny from the marrow. These growth factors are produced in sites of inflammation in peripheral tissues, although some such as SCF and M-CSF are normally produced in the marrow stroma. Two hematopoietic growth factors have lineage-specific late-stage granulocytic cells as targets: IL-5 for eosinophil progenitors and G-CSF for neutrophilic progenitors. IL-5 is produced mainly by the T-helper type 2 (Th2) lymphocytes in response to allergens (Chap. 62).^{402,403} Eosinophilic progenitor cells display an IL-5 α receptor protein that when associated with the common β receptor (CSF2RB), binds IL-5, leading to their survival and proliferation.⁴⁰² Mature eosinophils have survival and chemotactic responses to IL-5, which mediates their entry into the circulation and accumulation in sites of allergic inflammation. GM-CSF, G-CSF, IL-3, and IL-6 all stimulate granulopoiesis *in vivo*, but only the deficiency of G-CSF results in severe neutropenia, making it the likely regulator of normal circulating granulocyte numbers.⁴⁰⁴ Under normal steady-state conditions, 1 to 2 percent of neutrophils circulate transiently in the blood, while the majority remains in the marrow unless mobilized by inflammation in other areas of the body.

Models of G-CSF regulation of granulopoiesis and circulating neutrophils under normal conditions and during inflammatory states have been proposed.^{405,406} Newly formed neutrophils have low expression of CXCR4 and can exit the marrow by migration through sinusoidal endothelial cells. As they age in the circulation they express more CXCR4 and are attracted back to the marrow by stromal CXCL12, the CXCR4 ligand.⁴⁰⁵ After reentering the marrow, the senescent neutrophils undergo apoptosis and are phagocytosed by macrophages that, in turn, produce G-CSF stimulating more granulopoiesis.⁴⁰⁵ Cells at sites of inflammation produce both G-CSF and chemokines, including KC chemokine (CXCL1), and macrophage inhibitory protein (MIP)-2 (CXCL2). The secreted G-CSF acts on the marrow mobilizing neutrophils by its ability to reduce both marrow CXCL12 production and neutrophilic CXCR4 expression. G-CSF, however, does not recruit the neutrophils to sites of inflammation from the blood.⁴⁰⁵ By their chemotactic properties, CXCL1 and CXCL2 also induce rapid mobilization from the marrow into the blood and to sites of inflammation.⁴⁰⁵ Another model involves similar migration of neutrophils from the marrow that depends on G-CSF downregulating CXCL12 production and neutrophilic CXCR4 expression, but the feedback that decreases G-CSF occurs in the peripheral tissues.⁴⁰⁶ In this model, macrophages that phagocytose apoptotic neutrophils in the peripheral tissues decrease IL-23 production, which decreases IL-17 production by a subset of T-lymphocytes that, in turn, results in decreased G-CSF in the marrow.

CELL ADHESION AND HOMING

After their initial migration from the yolk sac, AGM, or placenta to the marrow, the HSCs are located in specific sites in the marrow through interactions with other types of cells and with matrix proteins. HSCs do not remain permanently in the marrow because a small percentage of them are continuously entering the blood through the venous sinusoids, circulating briefly, and then reentering the marrow.^{407,408} In addition to the HSCs, the more differentiated progenitor cells, such as the short-term repopulating cells and the primitive BFU-Es, can circulate in a similar manner. When circulating, the HSCs can either reenter the marrow or they can enter other organs. After entering the interstitium of a peripheral organ, the HSCs can give rise to myeloid progeny and/or they enter the lymphatic drainage of the organ and circulate through lymphatic vessels and thoracic duct before reentering

the blood.⁴⁰⁹ HSCs display multiple adhesion and cytokine receptors that allow them to attach to cellular and matrix components within the marrow sinusoidal spaces.^{275,277,410–412} Such attachments facilitate HSC homing and lodgment in the marrow and provide the cell–cell contacts required for HSC survival and steady-state proliferation,⁴¹³ as shown by membrane-bound SCF regulation of HSC lodgment in the endosteal marrow region.⁴¹⁴

In most lineages, differentiated cells are released from the marrow, circulate in the blood, and eventually home to the marrow. In some cell types, the circulating cells will differentiate further in peripheral organs such as B lymphocytes in the lymph nodes and spleen, monocytes in the tissues, and T lymphocytes in the thymus. After a period of residence in these secondary lymphoid organs, some lymphocytes travel through the lymph and blood, homing to the marrow, where they become functioning mature cells, such as plasma cells and CD4 and CD8 mature T lymphocytes.^{199,200,204} Mature and band forms of neutrophils exit the marrow, circulate in the blood and, if not recruited to a site of inflammation, home as senescent cells to the marrow by the CXCL12/CXCR4 mechanism described in the preceding “Granulocytes” section.⁴⁰⁵ Senescent erythrocytes are also removed from circulation through a mechanism that involves binding surface ICAM-4 to integrin $\alpha_4\beta_2$ (lymphocyte function-associated antigen [LFA]-1) on macrophages in the spleen and marrow.⁴¹⁵ Mature leukocytes that participate in inflammatory reactions, such as the lymphocytes, monocytes/macrophages, and eosinophils, exit the circulation in areas of infection, allergic reactions, or injury. Table 5–2 lists the adhesive receptors and their ligands present on HSCs, progenitor cells, and components of the hematopoietic microenvironment, but receptor–ligand interactions that regulate the trafficking of mature leukocytes are not exhaustively listed.^{416,417}

INTEGRINS

Integrins mediate important cellular functions, including embryonic development, cell differentiation, and adhesive interactions between hematopoietic cells and inflammatory cells and surrounding vascular and stromal microenvironments.^{411,412,418} Integrins are divalent cation-requiring heterodimeric proteins (18 α subunits and 8 β subunits) subdivided by the β -chain component. Table 5–2 indicates that α -chains can associate with more than one β -chain subunit. The principal integrin receptors of the β_1 subgroup involved in HSC–endothelial and HSC–stromal interactions are $\alpha_4\beta_1$ (VLA-4), $\alpha_5\beta_1$ (VLA-5), and $\alpha_1\beta_2$ (LFA-1) of the β_2 subgroup. $\alpha_4\beta_1$ -based stromal adhesion events regulate erythropoiesis in the stages after EPO dependence.⁴¹⁹ Granulopoiesis is stimulated by $\alpha_4\beta_1$ activation by marrow stromal cells in cooperation with PECAM-1 (CD31), an immunoglobulin superfamily member.⁴²⁰ Antibodies against α_4 or small molecule antagonists can mobilize hematopoietic stem and progenitor cells into the peripheral circulation.⁴²¹ The high expression of $\alpha_4\beta_1$ in granulocytic precursor cells and newly formed granulocytes has an important role in their adherence to VCAM-1 in the marrow, whereas the downregulation of $\alpha_4\beta_1$ in the more mature neutrophils works in concert with CXCL12/CXCR4 for their release into the blood.⁴²² The $\alpha_4\beta_1$ integrin on B lymphocytes is important for interactions with the VCAM-1 on the stromal cells in the B-lymphocyte niche, both in early B-lymphocyte development prior to migration out of the marrow and in later development of plasma cell precursors that have reentered the marrow.¹⁹⁹ An acquired defect in stromal function, characterized by a deficiency in VCAM-1 and IL-7 expression,^{423–425} accounts for the delayed B-lymphoid reconstitution seen after marrow transplantation. During thrombopoiesis, CXCL12 induces VCAM-1 in the marrow sinusoid endothelial cells⁴²⁶ that mediates the binding of the megakaryocytes to the endothelium.⁴²⁷ Integrin $\alpha_4\beta_7$ and its receptor, mucosal addressin cell adhesion molecule

(MAdCAM)-1, like the integrin $\alpha_4\beta_1$ /VCAM-1 receptor pair, contribute equally to the homing of HSC to the marrow.^{428,429}

Integrins are signaling molecules.⁴³⁰ After engaging their ligands, or subsequent to activation by monoclonal antibodies, multiple events (tyrosine phosphorylation of focal adhesion kinase, paxillin, and ERK-2) are triggered (outside–in signaling), culminating with Ras activation.^{431,432} Integrin receptor crosstalk⁴³³ with other adhesive receptor members, such as the immunoglobulin superfamily (NK cell–T cell [$\alpha_4\beta_2$ /DYNAM-1], CD34+endothelial cell PECAM-1,^{434–436} or selectins,⁴³⁷ also results from outside–in signaling events that regulate receptor-binding affinity^{438,439} and mediates inhibitory signals for erythroid, myeloid, and lymphoid progenitor growth.^{440–443} Integrin binding of their respective receptors, such as $\alpha_4\beta_1$ /VCAM-1 or $\alpha_4\beta_1$ /FN, in early CD34+ progenitors enhances viability and preserves their long-term repopulating ability.⁴⁴⁴ In studies of isolated SP cells, high expression of the vitronectin receptor $\alpha_5\beta_3$ (CD51/CD61) is associated with quiescence and long-term repopulating ability.⁴⁴⁵ Conversely, expression of the α_2 integrin is associated with only short-term repopulating capacity.⁴⁴⁶

IMMUNOGLOBULIN SUPERFAMILY

The immunoglobulin superfamily designates a group of molecules containing one or more amino acid repeats also found in immunoglobulins and includes PECAM-1 (CD31), ICAM-3/R (CD50) and ICAM-1 (CD54), LFA-3 (CD58), ICAM-2 (CD102), VCAM-1 (CD106), KIT (CD117), and LW/ICAM-4 (CD242) (see Table 5–2).^{447–461} VCAM-1 is upregulated by inflammatory cytokines, IL-4 and IL-13.^{462,463} Immunoglobulin-like adhesion molecules also include NCAM, a neural cell-adhesion molecule that binds lymphocytes but not hematopoietic progenitors; Thy1, a stem cell antigen; major histocompatibility complex classes I and II; and CD2, CD4, and CD8 (see Table 5–2).²⁴⁷ LW/ICAM-4 on erythroblasts binds the α_5 component of integrins on macrophages in EBIs,⁹⁴ whereas the normal function of Lutheran red blood cell antigen, Lu/B-CAM (CD239), which binds the α_5 component of laminin and is expressed late in erythroblast differentiation, is uncertain.⁴⁶¹ The sialic acid-binding immunoglobulin-like lectins (Siglecs) are a family of surface proteins found on lymphocytes and myeloid cells that bind sialic acid residues of glycoproteins.⁴⁶⁴ Some Siglecs are evolutionarily conserved, such as Siglec-1 (sialoadhesin), which is highly expressed on macrophages, including the central macrophages of EBIs, and CD22, a coreceptor on B-lymphocytes. The remaining Siglecs, which are phylogenetically evolving rapidly, include CD33, which is expressed in lymphocytes and in all stages of myeloid cells where it is a commonly used marker for acute myeloid leukemia.

LECTINS (SELECTINS)

Homing of stem cells requires lectin receptors with galactosyl and mannosyl specificities.^{465,466} The selectins are a family of adhesion molecules, each containing type C lectin structures.⁴⁶⁷ The leukocyte selectin (L-selectin, CD62L) is expressed on hematopoietic stem and progenitor cells and mediates adhesive interactions with other receptors (addressins), such as the CD34 sialomucin present on specialized endothelium, using sialylated fucosyl-glucoconjugates (see Table 5–2).²⁵⁹ The CD34 receptor on stem cells, however, does not bind L-selectin,²⁵⁹ as a putative L-selectin ligand may exist on these cells but is yet to be defined. The selectin family also contains CD62E, an E-selectin constitutively expressed on the marrow sinusoidal endothelium that regulates transmigration of leukocytes and CD34+ stem cell homing. The third member of this family is P-selectin, which is found on platelets. P-selectin can bind HSCs using a mucin receptor, CD162 also known as

TABLE 5-2. Hematopoietic and Microenvironment Adhesion Receptors and Their Ligands

Receptor Subgroups	Receptor	Cellular Distribution	Ligand
INTEGRINS			
β_1 subgroup (CD29)	CD49d, $\alpha_4\beta_1$ (VLA-4)	CD34+ cells (erythroid, and lympho-myeloid progenitors)	VCAM-1 (CD106), FN, TSP
	CD49e, $\alpha_5\beta_1$ (VLA-5)	CD34+ cells, bone cells	FN, laminin
	CD49f, $\alpha_6\beta_1$ (VLA-6)	Rare CD34+ cells, monocytes	Collagen, laminin
β_2 subgroup (CD18)	CD11a/CD18, $\alpha_L\beta_2$ (LFA-1)	CD34+ cell subsets, not on repopulating stem cells	ICAM-1, ICAM-2, ICAM-3, DNAM-1
	CD11b/CD18, $\alpha_M\beta_2$ (Mac-1)	CD34+ subsets, monocytes	ICAM-1, ICAM-2, iC3b, fibrinogen
β_3 subgroup	$V\beta_3$ (VNR)	Megakaryocytes, osteoclast	FN, TSP, CD31
β_7 subgroup	$\alpha_4\beta_7$ (LPAM-1)	Lymphoid and myeloid progenitor cells, mature myeloid cells	MAdCAM-1, VCAM-1, FN
IMMUNOGLOBULINS			
	CD31 (PECAM-1)	ECs, CD34+ cells, monocytes	CD31 homophilic adhesion, $\alpha_V\beta_3$ (VNR), CD38
	CD50 (ICAM-3, ICAM-R)	CD34+ cells, monocytes	$\alpha_L\beta_2$ (LFA-1), CD11d/CD18 ($\alpha_V\beta_2$)
	CD54 (ICAM-1)	CD34+ cells, stroma, activated ECs	$\alpha_L\beta_2$ (LFA-1), $\alpha_M\beta_2$ (Mac-1)
	CD58 (LFA-3)	CD34+ progenitors, stroma, ECs	CD2
	CD102 (ICAM-2)	ECs, monocytes	$\alpha_L\beta_2$ (LFA-1)
	CD106 (VCAM-1)	Stroma, activated ECs	$\alpha_4\beta_1$ (VLA-4), $\alpha_4\beta_7$ (LPAM-1)
	CD117 (<i>c-KIT</i>)	CD34+ progenitors	Membrane KIT ligand
	CD242 (ICAM-4)	Erythroid cells	α_V -Integrins
	PRR2 (related to CD155, the poliovirus receptor)	CD34+, CD33+, CD41+, myelomonocytic cells, megakaryocytic cells, ECs	PRR2 homophilic adhesion
LECTINS			
	CD62L (L-selectin)	Stroma, CD34+ cells	GlyCAM-1, MAdCAM-1, CD162, CD34, sLe ^x , PCLP1
	CD62E (E-selectin)	Activated ECs, (marrow ECs express CD62E constitutively)	CD15, sLe ^a , CD162, CLA, sLe ^x
	CD62P (P-selectin)	Activated ECs	CD162, sLe ^x , CD24 (HSA)
SIALOMUCINS			
	CD34	CD34+ cells, ECs	Selectins, other ligands?
	CD43	CD34+, monocytes, NK cells	CD54 (ICAM-1)
	CD162 (PSGL-1)	CD34+ cells, ECs	CD62L, CD62E, CD62P
	CD164 (MGC-24v)	CD34+ cells, stroma, monocytes	Unknown
	CD166 (HCA, ALCAM)	CD34+ cells, stromal cells, ECs	CD6, CD166
HYALADHERIN			
	CD44	CD34+ cells, broad distribution	Hyaluronan, bFGF, HGF
OTHER			
	CD38	CD34+ subsets, early T and B cells, plasma cells, thymocytes	CD31, hyaluronan
	CD144 (VE-cadherin)	CFU-E, stromal cells, ECs	E-cadherin
	CD157 (BST-1)	Stroma, T and B cells, myeloid cells	Unknown

ALCAM, activated leukocyte adhesion molecule; bFGF, basic fibroblast growth factor; BST, bone marrow stroma; CD, cluster designation; CFU-E, colony forming unit–erythroid; CLA, cutaneous lymphocyte antigen; DNAM-1, DNAX accessory Molecule-1; EC, endothelial cell; FN, fibronectin; GlyCAM, glycosylation-dependent cell adhesion molecule; HCA, hematopoietic cell antigen; HGF, hepatocyte growth factor; HSA, heat-stable antigen; ICAM, intercellular adhesion molecule; iC3b, inactive complement 3b complex; KIT, tyrosine-protein kinase; LFA, lymphocyte function-associated antigen; LPAM, lymphocyte Peyer patch-specific adhesion molecule; MAdCAM, mucosal addressin cell adhesion molecule; MGC-24, multiglycosylated core of 24 kDa; NK, natural killer; PCLP, podocalyxin-like protein; PECAM, platelet/endothelial cell adhesion molecule; PRR2, poliovirus receptor-related protein 2; PSGL-P, selectin glycoprotein ligand; sLe, sialyl Lewis; TSP, thrombospondin; VCAM, vascular cell adhesion molecule; VE, vascular endothelial; VLA, very-late antigen; VNR, vitronectin receptor.

the P-selectin glycoprotein ligand (PSGL)-1, which binds to all three selectins (see Table 5–2). These proteins are responsible for leukocyte rolling over endothelial surfaces and tethering, thereby allowing integrin-mediated firm adhesion to the endothelium and mediating cellular homing events using specialized high endothelial venule lymphocyte homing sites.^{140,467,468} In addition to their role in HSC homing in the marrow, E-selectin and P-selectin can promote quiescence in HSC and induce apoptosis of late-stage myeloid progenitors while promoting the expansion (P-selectin) or differentiation (E-selectin) of short-term repopulating cells.⁴⁶⁹

SIALOMUCINS

Three members of the CD34 family—CD34, podocalyxin, and endoglycan—are expressed on vascular endothelium, HSCs, and various hematopoietic cell lineages.⁴⁷⁰ When expressed on lymphoid high endothelial venules, these sialomucins are receptors for L-selectin, but their differential glycosylation in hematopoietic cells prevents L-selectin binding and results in their reducing nonspecific adhesion and potentially enhancing mobility. Although its function has not been determined, endomucin is another CD34-like sialomucin expressed in endothelium and in HSCs.⁴⁷¹ In T lymphocytes, where it affects mobility, CD43 (leukosialin) acts in concert with PSGL-1 and binds both P-selectin and E-selectin.^{472,473} CD43 in neutrophils can foster adhesion when binding to E-selectin on endothelial cells, but it inhibits adhesion in most instances.⁴⁷³ CD43 can also regulate hematopoietic progenitor survival.⁴⁷⁴ CD162 (PSGL-1), a sialomucin that binds all three selectins, is important in leukocyte trafficking and stem cell homing.^{467,468,470} CD164 (endolyn), another sialomucin receptor displayed on HSCs, forms a complex with CXCR4, VLA-4, and VLA-5 on the leading edge of migrating HSCs after exposure to FN-bound CXCL12, indicating a role for CD164 in the homing of HSCs.⁴⁷⁵ CD166 (hematopoietic cell antigen [HCA], activated leukocyte adhesion molecule [ALCAM]) is expressed on HSCs and osteoblasts and is required for long-term engraftment potential of donor HSCs in murine transplantation models, probably through homophilic interaction.^{476–478} CD166's only other ligand is CD6.^{477,479}

HYALADHERINS

The fifth subgroup listed in Table 5–2 is the cartilage-related proteoglycan, CD44, also known as the *lymphocyte homing cell adhesion molecule* (HCAM). This adhesion receptor, which binds the hyaluronic acid in the marrow matrix and can be a receptor for E-selectin, is expressed on neutrophils, lymphocytes, erythroblasts, and HSC.^{467,468} CD44 displayed on HSCs facilitates their homing and adhesion to the marrow and plays a role in their mobilization in response to G-CSF.^{467,468,480} Studies with CD44-deficient mice show no defects in HSC homing and growth, and no decrease in hematopoiesis, suggesting that another hyaladherin receptor may compensate for the absence of CD44.⁴⁸¹ The other hyaladherin receptor on HSC is the receptor for hyaluron-mediated mobility (CD168/RHAMM),^{467,481} which does provide hyaluronic acid binding by neutrophils under inflammatory conditions in CD44 deficiency.⁴⁸² Thus, CD44 and CD168/RHAMM may provide redundant hyaluronic acid binding in HSC.

OTHER ADHESION MOLECULES

CD38 is an adhesion receptor that binds the CD31 receptor and matrix hyaluronan. It is expressed on early T and B cells and subsets of CD34+ hematopoietic progenitors.⁴⁸³ Similar to CD38, the stromal adhesion receptor BST-1 (CD157) is an adenosine diphosphate-ribosyl cyclase that is involved in regulation of intracellular calcium concentrations.

CD157 is expressed on marrow stroma, T and B cells, and myeloid cells. It promotes pre-B-cell adhesion and growth.⁴⁸³ Cadherins are large molecules involved in cell–cell junctions and vascular integrity. CD144 (VE-cadherin) is expressed on CD34+ hematopoietic and endothelial progenitor cells and is an important molecule for trafficking of HSCs in fetal tissues and for the maintenance of HSC self-renewal.^{115,484,485} Downregulation of VE-cadherin is associated with crosslinking of VCAM-1, resulting in enhanced transendothelial migration of CD34+ cells in response to CXCL12.¹²⁰ Although N-cadherin expression by both HSC and osteoblasts has been proposed to play a role in their interactions, experimental results in knockout mice do not support such a role.^{11,486}

CELLULAR HOMING

Leukocyte trafficking and migration have been central to understanding mechanisms of tissue homing. One of the best studied processes is lymphocyte homing to secondary lymphoid organs via specialized high endothelial venules (HEVs). Generally, leukocytes home to areas of inflammation by adhering to the endothelium and migrating between intercellular spaces by a sequence of specific events that begins with tethering of the leukocytes to the luminal surface of the endothelial cells.⁴⁸⁷ In the secondary lymphoid organs, tethering is mediated by L-selectin/CD62L receptor on the surface of naïve lymphocytes that binds a complex carbohydrate determinant, 6-sulfo-sialyl Lewis X, on glycoproteins called peripheral node addressins, such as CD34, podocalyxin, and endomucin.^{488,489} P-selectin and E-selectin are upregulated on the endothelial cell surface in response to various inflammatory cytokines, where they bind their respective receptors, PSGL-1 and CD44 on leukocytes.^{466,490} Tethering results in rolling of the leukocytes along the endothelial surface. Interactions of VLA-4 and $\alpha_4\beta_7$ integrin on the surface of lymphocytes with their respective ligands VCAM-1 and MAdCAM-1 on HEVs may also mediate rolling.⁴⁶⁷ Rolling of neutrophils is slowed further by PSGL-1 and L-selectin activation of other adhesion molecules that include the β_2 integrins $\alpha_1\beta_2$ (LFA-1) and $\alpha_M\beta_2$ (Mac-1).^{490–492} These β_2 integrins, in turn, bind ICAM-1 on endothelial cells. The rolling leukocytes also receive signals through surface G-protein-coupled receptors that bind chemokines in the heparan sulfate proteoglycans on the endothelial cells.^{490–492}

The interaction of PSGL-1, L-selectin, integrins, and G-protein-coupled receptors with their endothelial ligands leads to cytoskeletal changes with arrest of rolling and adhesion to the endothelium. The adherent leukocytes undergo a rapid diapedesis, with migration either through or between the endothelial cells into the abluminal interstitium. At the interface with the adherent leukocyte, ICAM-1 and VCAM-1 in the endothelial cell are concentrated in a cup-like, caveolin-rich structure that internalizes ICAM-1.^{492–494} This caveolin-rich structure is linked to the endothelial cell cytoskeleton through vimentin. The internalization of the ICAM caveolae leads to the formation of a channel through the cell to the abluminal surface. When leukocytes follow a paracellular route through the endothelium, they require the coordinated activity of multiple adhesion proteins. These include PECAM-1, CD99, JAM proteins, and VE-cadherin, each of which mediates homophilic interactions at intercellular junctions between endothelial cells, and ICAM-2.^{492–494} Although the roles of these proteins are uncertain, antibody inhibition and knockout mice demonstrate that they are necessary for the unidirectional migration of the leukocyte through the endothelium. PECAM-1, CD99, and JAM-C are expressed on leukocytes and may be involved in homophilic interactions between the migrating leukocyte and the endothelial junction. LFA-1 and Mac-1 on leukocytes can bind and interact with ICAM-2 and JAM-A on endothelium, whereas leukocyte VLA-4 can interact with endothelial JAM-B.

The driving force for the migration and homing of leukocytes is the expression of chemoattractants at the site of inflammation or areas of constitutive production, such as the secondary lymphoid organs or the marrow. Bacterial peptides, complement components, and cytokines are produced in inflammatory sites. More than 40 different, but structurally related, chemotactic cytokines (chemokines) can be produced by leukocytes in inflammatory sites.^{495,496} Chemokines accumulate on cell surfaces or in extracellular matrices through their binding to GAGs.^{495–497} Concentrations and chemotactic activities of each cytokine are related to production rate, binding affinities to GAGs, presence of decoy chemokines that can compete with chemotactic activity, and modulation by metalloproteinases that enhance or diminish activities of substrate chemokines.⁴⁹⁵

Based on the location of one or two cysteine residues in the amino terminus, chemokines are divided into four subfamilies.^{224,495,496} One large subfamily comprises the CXC ligand (CXCL) chemokines (e.g., platelet factor 4, IL-8, melanocyte growth-stimulating activity/GRO α , neutrophil activating protein-2, granulocyte chemotactic protein-2), which mediate neutrophil migration and activation. The other large subfamily comprises the CC ligand (CCL) chemokines (e.g., CCL3 [MIP-1 α], CCL4 [MIP-1 β], [CCL5] RANTES [regulated on activation, normal T-cell expressed, presumed secreted], MCP-1 through MCP-5), which mediate mostly monocyte, and in some cases lymphocyte, chemotaxis.⁴⁹⁷ A chemokine with CXXXCL structure is fractalkine, an endothelial transmembrane mucin–chemokine hybrid molecule that mediates the rapid capture, firm adhesion, and activation under physiologic flow of circulating monocytes, resting or IL-2–activated CD8 lymphocytes, and NK cells.⁴⁹⁸ The cytokines TNF- α and IL-1 upregulate fractalkine, in keeping with the need to rapidly recruit effector cells at sites of inflammation. The chemokine receptors on the surface of leukocytes are coupled to G proteins that initiate signaling for chemotaxis upon chemokine ligand binding.^{495,496} The chemokine receptors for the two large subfamilies bind those members such that CXCLs bind CXCRs and CCLs bind CCRs. However, within these two subfamilies is significant redundancy and promiscuity in chemokine-receptor binding. Table 5–3 gives a detailed listing of chemokine receptors and the cellular targets and ligands interacting with each receptor subgroup.

A major exception to this redundant and promiscuous chemokine-receptor interaction is the specific binding of CXCL12/stromal cell-derived factor (SDF)-1 α to its receptor CXCR4, which is associated with homeostatic maintenance of cell populations, including HSCs and their progeny in the marrow.^{496,499} CXCL12 can bind to one other chemokine receptor (CXCR7), but mouse knockout experiments show that CXCL12 null and CXCR4 null mice have embryonic lethal phenotypes that are markedly similar whereas CXCR7 null mice have postnatal lethality due to cardiovascular defects; CXCR7 may have a role in ligand sequestration but not in hematopoiesis.^{496,500–502} CXCL12 is produced by the bone, endothelial, perivascular reticular cells and some hematopoietic cells in the marrow, and its receptor CXCR4 is expressed on various hematopoietic and mature blood cells.^{468,499,503} The murine gene *Cxcl12* was floxed, allowing conditional deletion by various Cre transgenics expressed in mesenchymal progenitor cells. Conditional deletion of *Cxcl12* in mineralizing osteoblasts resulted in no obvious phenotype whereas deletion in Osterix-Cre–expressing reticular (CAR cells) and osteoblast cells resulted in constitutive HSC mobilization and loss of B-lymphoid progenitor cells.^{504,505} The Cre transgenics that delete floxed *Cxcl12* alleles have complicated patterns of expression and current evidence supports a more important role for the perivascular niche in the homing of HSCs.⁵⁰⁵ Hence, mouse genetics and pharmacologic inhibition show that CXCL12 and CXCR4 are involved in the trafficking of HSCs, committed progenitor cells, and mature cells,

including neutrophils, dendritic cells, NK cells, and T and B lymphocytes.^{404,405,421,499,503} The cellular specificity of the homing, localization, and mobilization that are driven by CXCL12 and CXCR4 are regulated by additional chemokines, adhesion proteins, and metalloproteinases associated with specific hematopoietic cell types and/or the organs to which they home, in which they reside, and from which they are mobilized.^{499,503} In the case of HSCs homing from the peripheral tissues through which they migrate, their initial entry into the lymphatic vessels is driven by the lipid chemoattractant sphingosine-1-phosphate (S-1-P).⁴⁰⁹ HSC display S-1-P receptors that respond to high levels in the lymph compared to the peripheral tissues where S-1-P is degraded.

For the HSCs and the marrow, multiple experiments using inhibitors and antibodies with stem cell transplantation in mice and humans, parabiotic experiments with mice, and transplantation of human HSCs into immunocompromised mice (e.g., nonobese diabetic [NOD]/severe combined immunodeficiency [SCID] strains) have contributed to an understanding of some interactions of these multiple factors that influence HSCs within the marrow.⁵⁰⁶ Two adhesion mechanisms that play major roles in CXCL12-mediated HSCs homing to the marrow are the binding and activation of $\alpha_4\beta_1$ integrin and selectin ligands, particularly PSGL-1,^{140,468,507} on HSCs to their respective receptors, VCAM-1, and P- and E-selectins on the marrow sinusoidal endothelium.^{428,508} Although $\alpha_4\beta_1$ integrin appears to be the major integrin on HSCs involved in the first step of homing, other integrins have been implicated as having supporting roles, including $\alpha_3\beta_1$, $\alpha_5\beta_1$, and $\alpha_6\beta_1$ or $\alpha_6\beta_4$ integrin that bind to FN, MAdCAM-1, and laminins in the marrow.^{321,421} Similarly, a coordinated action between CXCR4 that has bound CXCL12 and the CD44 isoform on HSCs,⁵⁰⁹ or another hyaladherin such as RHAMM,⁴⁸¹ may provide a source of adhesion for HSCs to hyaluronic acid on marrow endothelial cells in the homing process. In cord blood cells enriched for HSCs, the colocalization and cooperative activity of the endolyn with CXCR4, $\alpha_4\beta_1$, and $\alpha_5\beta_1$ integrin appears to enhance HSCs homing to the marrow in response to CXCL12.⁴⁷⁵ CXCR4 has also been colocalized in lipid rafts on HSCs with Rac-1, a member of the receptor-associated RhoGTPases.⁵¹⁰ The RhoGTPases have two members, Rac-2 and RhoH, that are hematopoietic specific and, with other more widely expressed members such as Rac-1, Cdc42, and Rho A, are downstream effectors of CXCR4, β_1 -integrin, and KIT signaling in HSCs.⁵¹¹ The various RhoGTPases modulate actin polymerization and lead to cytoskeletal changes that are required for survival, proliferation, homing, and mobilization of HSCs and their progeny. In the homing of HSCs, the RhoGTPase-mediated signaling provided by the coordinated action of CXCR4, β_1 integrins, and CD44 leads to the rolling, arrest, and transmigration of the marrow sinusoidal endothelial cells.

Once the HSCs have migrated across the sinusoidal endothelial cells, they migrate further within the marrow in response to CXCL12. Using fluorescent SLAM-labeled markers for the identification of HSC in murine transplantation experiments, the homing of HSCs in the marrow cavity is associated with reticular cells that harbor the highest numbers of CAR cells in the marrow.¹³² The majority of CAR cells are in the perivascular areas to which the HSCs home.⁵² Another factor that may contribute to perivascular homing, especially following stress, such as lethal irradiation, is the ability of the marrow sinusoidal endothelial cells that express CXCR4 that binds circulating CXCL12 and transports it into the perivascular areas of the marrow.^{503,512} A second area in the marrow to which HSC home is the endosteal niche because of the proximity of these endosteal areas to perivascular areas,⁵¹² as well as the abundant CXCL12 production by osteoblasts and osteoclasts.^{134,165} Thus, two HSC niches are recognized in the marrow—perivascular and endosteal—with HSCs in the perivascular areas more likely to proliferate, differentiate, and mobilize into the blood than HSCs in the endosteal areas.^{75,150,512}

TABLE 5-3. Chemokine Receptors, Interacting Chemokine Ligands, and Cellular Specificity

Receptors	Receptor Expression	Chemokine Ligands
CXCR1	Neutrophils, monocytes	CXCL2 (GRO β), CXCL3 (GRO γ), CXCL5 (ENA78), CXCL6 (GCP-2), CXCL8 (IL-8)
CXCR2	Neutrophils, IL-5–primed Eos, monocytes	CXCL1,2,3 (GRO $\alpha/\beta/\gamma$), CXCL5 (ENA78), CXCL6, CXCL7 (NAP-2), CXCL8(IL-8),
CXCR3	Activated memory and naïve T cells, NK cells; T (preferentially Th1) cells, B cells	CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC)
CXCR4	Neutrophils, monocytes, megakaryocytes, CD34+ and pre-B-cell precursors, resting and activated T cells, DCs	CXCL12 (SDF-1 α , SDF-1 β)
CXCR5	B lymphocytes, T lymphocytes	CXCL13 (BCA-1/BLC)
CXCR6	T lymphocytes	CXCL16 (SR-PSOX)
CXCR7	B lymphocyte, T lymphocytes, Basos, monocytes, NK cells	CXCL11 (I-TAC), CXCL12 (SDF-1 α)
CX3CR1	Monocytes, DCs, CD34+ cells, NK cells; in nodal tissues activated T-helper lymphocytes, activated B cells, and follicular DCs	CX3CL1 (fractalkine/neurotactin)
XCR1	Resting T cells, NK cells	XCL1 (lymphotactin/SCM-1 α /ATAC), XCL2 (SCM-1 β)
CCR1	Monocytes, EOS, basophils, activated Neu and T cells, CD34+ cells, immature DCs	CCL3 (MIP-1 α), CCL5 (RANTES), CCL7 (MCP-3), CCL8 (MCP-2), CCL13 (MCP-4), CCL22 (MDC), CCL23 (MPIF-1)
	Monocytes, T cells (not Neu, EOS, or B cells)	CCL14 (HCC-1), CCL15 (HCC-2/MIP-5), CCL16 (HCC-4/LEC)
CCR2	Monocytes, basophils, DCs, T cells, activated memory CD4 T cells, NK cells	CCL2(MCP-1), CCL7 (MCP-3), CCL8 (MCP-2), CCL13 (MCP-4)
CCR3	Eos, thymocytes, basophils, DCs, activated memory CD4 T cells	CCL5 (RANTES), CCL7 (MCP-3), CCL8 (MCP-2), CCL11 (Eotaxin-1), CCL13 (MCP-4), CCL15 (HCC-2/MIP-5), CCL24 (Eotaxin-2/MPIF-2), CCL26 (Eotaxin-3)
CCR4	Activated T cells, immature DCs	CCL17 (TARC)
	Monocyte-derived DCs, activated NK cells	CCL22 (MDC)
	Thymocytes (CD3+, CD4+, CD8 ^{low})	CCL22 (MDC)
CCR5	Monocytes, activated memory CD4 T cells	CCL5 (RANTES), CCL8 (MCP-2), CCL13 (MCP-4), CCL14 (HCC-1)
	Immature DCs, CD34+ cells, NK cells	CCL3 (MIP-1 α), CCL4 (MIP-1 β)
	Human thymocytes	CCL4 (MIP-1 β)
CCR6	T cells, CD34+–derived dendritic cells	CCL20 (MIP-3 α /LARC/exodus-1)
CCR7	Activated T (naïve and memory T cells) > B lymphocytes, NK cells subsets, CD34+ macrophage progenitors, mature DCs	CCL19 (MIP-3 β /ELC/exodus-3), CCL21 (SLC/exodus-2/6Ckine) (6Ckine inactive on B cells)
CCR8	Monocytes, T (Th2) cells, NK cells	CCL1 (I309), CCL17 (TARC)
CCR9	Thymocytes (CD4+/CD8+, CD4+/CD8–), activated macrophages	CCL25 (TECK)
CCR10	Skin-homing memory T cells, CD4/CD8 cells	CCL26 (Eotaxin-3), CCL27 (CTACK/ILC/ESkine), CCL28 (MEC)
CCR1 and CCR3	Neutrophils, monocytes, lymphocytes	CCL15 (HCC-2/MIP-5)
Not known	Resting T cells	CCL18 (DC-CK1/PARC)
CCR3/CCR10	Memory lymphocytes, Eos, IgA plasmablasts	CCL28 (MEC)

6Ckine, chemokine with 6 cysteines; ATAC, activation-induced, chemokine-related molecule; Baso, basophil; BCA, B-cell attracting chemokine; BLC, B-cell homing chemokine that activates Burkitt lymphoma receptor 1 (BLR1); CTACK, cutaneous T-cell–attracting chemokine; DC, dendritic cell; ELC, EBI1-ligand chemokine; ENA, epithelial neutrophil-activating protein; EOS, eosinophil; ESkin, embryonal stem cell chemokine; GCP, granulocyte chemotactic protein; GRO, growth-related oncogene; HCC, human C-C chemokine; IgA, immunoglobulin A; IL-8 is also chemotactic for a specific subset of (CD3+, CD8+, CD56+, CD26–) T cells; IP, interferon-inducible protein; I-TAC, interferon-inducible T-cell α chemoattractant; LARC, liver and activation-regulated chemokine; LEC, liver-expressed chemokine; MCP, monocyte chemoattractant protein; MDC, macrophage-derived chemokine, MDC is chemotactic to eosinophils, in a CCR3- and CCR4-independent manner; MEC, mucosae-associated epithelial chemokine; MIG, monokine induced by interferon- γ ; MIP, macrophage inflammatory protein; MPIF, myeloid progenitor inhibitory factor; NAP, neutrophil-activating peptide; NK, natural killer; PARC, pulmonary and activation-regulated chemokine; RANTES, regulated on activation, normal T-cell expressed and secreted; SCM, single-C motif; SDF, stromal cell-derived factor; SLC, secondary lymphoid tissue chemokine, also known as exodus-2 and 6Ckine; SR-PSOX, scavenger receptor for phosphatidylserine and oxidized lipoprotein; TARC, thymus and activation-regulated chemokine; TECK, thymus-expressed chemokine; Th2, T-helper cell type 2.

In the marrow, multiple mechanisms act to stabilize and reinforce the lodgment of HSC, that is, to maintain the HSC in niches. One prominent mechanism is the binding of SCF, either secreted in and adherent to the marrow matrix or displayed on stromal cells. The absence of either KIT or SCF results in embryonic failure of hematopoiesis as a result of impaired homing of HSCs to the fetal liver where SCF acts cooperatively with CXCL12 as a chemoattractant, and to impaired retention of HSCs in the marrow⁵¹³ where KIT upregulates HSC expression of integrins $\alpha\beta_1$ and $\alpha\beta_1$.⁵¹⁴ The β_1 integrins of the HSCs also bind osteopontin, which, in turn, is bound to other matrix proteins, such as FN and collagen. Similarly, CD44 on HSCs binds to hyaluronic acid, FN, and collagen the marrow matrix.¹⁶⁴ Two receptors on HSCs that contribute specifically to endosteal niche retention are the calcium-sensing receptor,⁵¹⁵ which is needed for effective binding to collagen, and the Tie family receptor kinases, specifically Tie-2 receptor, which mediates HSC integrin binding to FN after engaging its ligand, angiopoietin-1, that is expressed by osteoblasts.^{516,517} Marrow SP cells enriched with long-term repopulating quiescent HSCs display high expression of β_3 -integrin, most likely as the vitronectin receptor $\alpha\beta_3$, suggesting another integrin–matrix protein interaction that supports HSC retention.^{445,518} One mechanism of retention in the endosteal niche is the long-term maintenance of HSCs by TPO produced by adjacent osteoblasts.^{519,520} The binding of TPO by its receptor induces HSC quiescence, whereas the absence of TPO leads to active cell cycling and to a protracted and progressive depletion of HSCs.^{519,520}

● CELLULAR RELEASE

Cell migration from the marrow occurs between adventitial cells and through endothelial cell channels that develop at the time of cell transit. Electron micrographs of leukocytes partially translocated across endothelium indicate that marked deformation of these cells occurs as

they penetrate the cytoplasm of the endothelial cell and enter the sinus lumen (Fig. 5–7).³⁹¹ As with reticulocytes, egress occurs adjacent to junctions of endothelial cells.³⁸³ The nucleus of the granulocyte, usually segmented, does not require as marked a deformation to traverse the migration pore as do the nuclei of monocytes and lymphocytes.³⁹¹ This transendothelial migration is likely to be related to leukocyte migration from the blood and into areas of inflammation described in the section on adhesion and homing because the marrow sinusoidal endothelial cells constitutively express adhesion proteins that are upregulated in inflammation, including VCAM-1, ICAM-1, and E- and P-selectin.⁴⁰⁵ Immature granulocytes in the marrow are anchored to adventitial reticular cells through lectin-like adhesion molecules. Gradual loss of these molecules (e.g., shedding of L-selectin) during maturation or after activation could permit movement toward the sinus wall.⁵²¹ Transient changes in surface glycoproteins (upregulation of α -2,6-sialylation of CD11b and CD18) of maturing marrow myeloid cells lead to decreased stromal and FN adhesion and may favor contact with endothelium and cell egress.⁵²² The complement component C5a and G-CSF administration recruit neutrophils by altering integrins (low CD11a with G-CSF) and decreased L-selectin expression (with both agents).^{523,524} Similar findings obtained in mice lacking two or all three selectins underscore the essential role of selectins in neutrophil recruitment.⁵²⁵ Mature leukocytes retain their nuclei as they enter the marrow venous sinuses and circulate in the blood, but erythroid and megakaryocytic cells release anucleate cells and their residual nuclei are rapidly phagocytosed by marrow macrophages.^{94,384,526} Occasional immature granulocytes and megakaryocyte nuclei or whole megakaryocytes are present in cell concentrates of normal blood.⁵²⁷ Restrictions on the release of immature myeloid cells, erythroblasts, and megakaryocytes are associated with the relative stiffness of their nuclei because of the ratio of nuclear lamin isotopes in erythroid and immature myeloid precursors and increased total lamins in megakaryocytes.³⁸⁰

Figure 5–7. Transmission electron micrograph of mouse femoral marrow. The lumen (L) of a sinus is indicated. Endothelial cell cytoplasm separates the sinus lumen from the hematopoietic spaces (arrow). Two neutrophils are evident traversing the sinus wall. Note deformation of the cell producing a narrow waist where the cell passes through endothelium. The luminal portion of the migrating cells is granule-poor. The remainder of the cytoplasm is granule-rich, possibly reflecting gel-sol transformation during pseudopod formation. (Used with permission of Lichtman MA, University of Rochester.)

A number of releasing factors are implicated in the initiation of marrow granulocyte egress, including G-CSF,^{528,529} GM-CSF,⁵³⁰ the C3e component of complement,⁵³¹ zymosan-activated plasma-containing complement fragments,⁵³² glucocorticoid hormones,⁵³³ androgenic steroids,⁵³⁴ and endotoxin.⁵³⁵ Neutrophils residing in the marrow venous sinusoids are rapidly released into the circulation by IL-8.⁵³⁶ In a rat model in which releasing factors can be given through the femoral artery and neutrophils collected from the femoral vein, chemokines CXCL2 (MIP-2) and CXCL1 (KC) that are produced at sites of inflammation induce rapid, selective neutrophil migration from the marrow compartment into the blood.^{537,538} Blocking or inhibiting the α_4 -integrin component, β_2 -integrin component, or the sheddase that catalyzes the proteolysis of L-selectin on migrating HSCs indicates that the interaction of the highly expressed VLA-4 on neutrophils with VCAM-1 on the sinusoidal endothelial cells is required for transendothelial migration, whereas shedding of L-selectin has no effect, and β_2 -integrin binding helps retain the neutrophils in the marrow.⁵³⁷ Blocking the neutrophil enzyme matrix metalloproteinase-9 (MMP-9) had no effect on the chemokine-induced neutrophil migration.⁵³⁸ CXCL2- and CXCL1-induced migration is synergistic with the rapid, selective neutrophil migration from the marrow induced by G-CSF,⁵³⁹ which is mediated by interrupting the interaction of CXCL12 in the marrow and CXCR4 on neutrophils.⁵⁴⁰ In a similar hind-leg model in guinea pigs, IL-5 and eotaxin, both of which are produced in sites of allergic inflammation, induce the rapid, selective migration of eosinophils from the marrow to blood with a synergistic effect when both are administered.⁵⁴¹ CCL11 (eotaxin) alone induces the migration of both eosinophil progenitor cells and mature eosinophils.⁵⁴¹ The route of migration is transendothelial, and blocking experiments demonstrate that β_2 -integrin binding enhances eosinophil migration from the marrow to the blood, whereas α_4 -integrin binding helps retain eosinophils in the marrow.⁵⁴² Prostaglandin D₂ (PGD₂) is produced by mast cells in sites of allergic inflammation, and it induces rapid, selective migration of eosinophils from the marrow to the blood in the guinea pig model.⁵⁴³ The eosinophils respond via two PGD₂ receptors, chemoattractant receptor-homologous molecule on Th2 (CRH2) and D-type prostanoid (DP) receptors.⁵⁴³

Releasing factors for reticulocytes have been difficult to identify. Adventitial reticular cell cytoplasm is a barrier to the reticulocytes on the abluminal surface of the endothelium.⁵⁴⁴ Phlebotomy, phenylhydrazine-induced hemolytic anemia, and EPO result in marked reduction of the adventitial cell cover of the sinus, a process that is thought to facilitate cell egress through the endothelium.⁵⁴⁵ Immature reticulocytes have much less deformability than more mature ones,⁵⁴⁶ suggesting that active migration by nascent reticulocytes through the endothelial cells is relatively unlikely, and release is via a passive mechanism. Thus, reticulocytes appear to require a pressure gradient to cross the venous endothelium and enter the blood as shown in Fig. 5–8.^{544,545} The pressures within the marrow sinuses are pulsatile, and pressures sufficient to cause egress may be transient.⁵⁴⁷ Another force that may contribute to reticulocyte egress is provided by the increasing numbers of erythroblasts proliferating in the EBIs that displace the more mature reticulocytes peripherally toward the venous sinuses.⁵⁴⁸

Platelet release by the megakaryocyte requires both actin-based podosomes and microtubulin-based proplatelets that extend through of the marrow sinus endothelium into the blood as described in the “Megakaryocytes” section of this chapter. The proplatelets can be separated from the megakaryocyte in the marrow, but the fate of these separated proplatelets is not certain, and they may not give rise to platelets.⁵⁴⁹ In normal thrombopoiesis, increased concentrations of S-1-P in the circulating blood activate the S-1-P receptor on the megakaryocytes, thereby, promoting proplatelet extension into the vascular sinus.⁵⁵⁰ The proplatelets extend through the endothelium (Fig. 5–9) and into the lumen of the venous sinus (see Figs. 5–6 and 5–10) producing elongated bean-shaped proplatelets.^{389,391} The formation of platelets also requires S-1-P and its receptor⁵⁵⁰ combined with the shear force of the blood flow,⁵⁴⁹ which releases both individual platelets or proplatelets themselves that later fragment in the circulation.

Under homeostatic conditions, the migration of HSCs from the marrow into the blood is a rare but steady process.^{408,409,551} With the stress of chemotherapeutic agents or pharmacologic doses of G-CSF administration, many HSCs are recruited into active cell cycle,⁵⁵¹ and they migrate into the blood before homing again to the marrow.⁴⁰⁸ The

Figure 5–8. Transmission electron micrograph of mouse femoral marrow. Composite of reticulocytes in egress. **A.** Small protrusion of marrow reticulocyte into sinus lumen (L). **B.** Reticulocyte in egress, with approximately half the cell in the sinus lumen. **C.** Reticulocyte virtually in the sinus. Egress occurs through a migration pore that is parajunctional in position (arrows point to endothelial cell junctions).

Figure 5-9. Transmission electron micrograph of mouse femoral marrow. **A.** The lumen (*L*) of a marrow sinus is indicated. The *arrow* points to the thin endothelial cytoplasmic lining of the sinus. The nucleus of a megakaryocyte (*N*) is indicated, with the cytoplasm of the megakaryocyte invaginating the endothelial cell cytoplasm in three places below the lumen. **B.** The *arrow* indicates the thin endothelial cell cytoplasmic lining of the sinus. The endothelium is attenuated to a double membrane in two places. A small process of megakaryocyte cytoplasm has formed a pore in the endothelial cell and has entered the sinus lumen (*L*). Cytoplasm flows through such pores and delivers proplatelets to the sinus lumen. (Used with permission of MA Lichtman, University of Rochester.)

stress of moderate blood loss also increases the cell cycling of the HSCs, but those cycling HSCs cannot be detected in the blood,⁵⁵² indicating that the migration of HSCs in response to stress is very likely related to the inflammatory/injury component of the stress. This relationship between inflammation/injury and HSC migration has been used experimentally to understand the mechanisms of HSC migration into the blood and clinically to mobilize the HSCs into the blood for collection for use in stem cell transplantation. Not surprisingly, these studies demonstrate that much of the regulation of HSC migration involves the reversal or inhibition of the mechanisms by which the HSCs home to the marrow and develop quiescence.

Many hematopoietic growth factors can mobilize HSCs from the marrow to the blood, but the best understood and most used clinically is G-CSF.^{480,506,553} Similar to other growth factors, the G-CSF mobilization of HSCs requires several days for maximal effect. A major determinant in both the homing to and migration from the marrow is the interaction of CXCR4 on HSCs with its ligand CXCL12 in the marrow. G-CSF induces stem cell mobilization by decreasing CXCL12 signaling.⁵⁵⁴ CXCR4 knockout mice do not mobilize HSCs with G-CSF, but they mobilize HSCs in response to VLA-4 ($\alpha\beta_1$ integrin) antagonists.⁵⁵⁵ Inhibitor studies originally identified the mobilization mechanism as

the degradation of CXCL12 by neutrophil-associated enzymes such as neutrophil elastase, cathepsin G, and MMP-9 or the HSC enzyme CD26/dipeptidylpeptidase, but mice genetically null for the proteases or treated with other protease inhibitors still show the G-CSF-induced decrease of CXCL12 mRNA and protein.^{480,553,556,557} Multiple mechanisms for CXCL12 modulation have been proposed, including the adrenergic nervous system suppressing MSC production of CXCL12 and direct G-CSF suppression of osteoblast lineage cells in the marrow.^{140,141,557,558} The successful development of small antagonists of CXCR4, such as plerixafor (formerly AMD3100), has provided a rapid means to mobilize HSCs and is used clinically for those patients that fail to mobilize with G-CSF.⁴²¹ Similarly, blocking α_4 -integrin binding or genetic deletion of the α_4 -integrin component leads to HSC mobilization within 1 or 2 days under both homeostatic or G-CSF-induced conditions.⁴²¹ This mobilization appears to be mainly mediated through disruption of VLA-4 activity and is further enhanced by blocking other adhesion mediators such as the β_2 -integrins or E-selectin, neither of which has an effect when used alone.^{421,559} Some of β_2 -integrin's synergistic effects may be indirect through the action on other cells.⁵⁶⁰ HSC mobilization with antibodies against the α_4 component of integrin⁵⁶¹ is replicated by potent and selective small molecule antagonists.⁵⁶² The results of interfering

Figure 5-10. Transmission electron micrograph of mouse femoral marrow. The marrow sinus lumen (*L*) and a megakaryocyte nucleus (*N*) virtually denuded of cytoplasm are indicated. The megakaryocyte nucleus abuts the nucleus of an adventitial reticular cell; the latter is separated from the lumen by the very thin endothelial cell cytoplasm. A portion of residual megakaryocyte cytoplasm (proplatelet) can be seen streaming into the lumen (*arrow*). The lumen contains several proplatelets (*asterisks*). Compare the size of the proplatelets to that of lymphocyte in the sinus. The bean-shaped, three-dimensional appearance of the proplatelets can be seen in the scanning micrograph shown in Fig. 5-6. (Used with permission of MA Lichtman, University of Rochester.)

with two other adhesion mediators of HSC homing, CD44 and SCF, are unclear in that antibodies to CD44 or administration of SCF induced HSC mobilization while genetic deficiencies of CD44 or KIT resulted in decreased G-CSF mobilization.⁴⁸⁰ Two chemokine ligands of the CXCR2 receptor, IL-8 and GRO- β (KC in mice), induce HSC mobilization within minutes to hours and can synergize with G-CSF, but their action is more complex in that it is mediated through neutrophils and their enzymes including MMP-9.^{480,563}

● CELL PROLIFERATION, APOPTOSIS, AND MATURATION

Irrespective of their location during the postnatal period, HSCs undergo continued self-renewal divisions, but at 3 to 4 weeks of age in mice (corresponding to 2 to 4 years in humans), they switch to their characteristic cell-cycle quiescence found in adult HSCs.^{564,565} This switch appears to be an intrinsic event that also decreases the myeloid differentiation potential of the HSCs.⁵⁶⁴ In the marrow endosteal niche, HSCs have multiple stimuli that induce cell-cycle quiescence. These stimuli include high concentrations of CXCL12 binding CXCR4^{499,503}; low concentrations of CD34, podocalyxin, and endoglycan; TPO binding by MPL^{519,520}; variable binding to matrix proteins such as osteopontin, FN, and fibulin, that depend upon angiopoietin-1/Tie-2, and SCF/KIT activities.^{355,514,516} Compared to HSCs located outside the endosteal niche, HSCs that are closely associated with to the endosteum have greater quiescence, marrow homing, and long-term reconstitution capacity.⁵⁶⁶

In murine transplantation studies, cell-cycle status significantly impacts the rate of engraftment and donor hematopoiesis with HSCs in G₀ phase providing maximal long-term reconstitution, whereas HSCs in G₁, S, G₂, or M phases provide minimal engraftment or long-term reconstitution.^{551,564,567} In long-term *in vivo* labeling with bromodeoxyuridine (BrdU), murine HSC immunophenotypically defined as Lin⁻, Sca-1+, KIT+, CD150+, CD48-, and CD34- have the greatest reconstitution capacity and are located in both endosteal and central areas of the marrow.⁵⁵¹ These HSCs are extremely quiescent, dormant, with an estimated division rate of only four or five times over the life of the adult mouse. However, the large majority of them are able to enter cell cycle and are mobilized within a day or two of stressful stimuli, including G-CSF or 5-fluorouracil (5-FU) administration.⁵⁵¹ Dormancy or quiescence is resumed upon homing and reestablishing marrow residence, indicating that the long-term reconstituting HSCs provide a large reserve that is able to respond, but only under situations of stress.⁵⁵¹

Dormant or quiescent HSCs are determined to be in G₀ based on lower RNA content and diploid genomic DNA content.^{567,568} Entry into the cell cycle induces cells into the G₁ phase where a restriction (R) point is encountered beyond which further progression to S phase and subsequent transit through G₂ to M phases is irreversible. The sequence of events and in particular transit through the R point is tightly regulated by the retinoblastoma tumor-suppressor protein (Rb) and its paralogs (p107, and p130).^{569,570} Rb is regulated by phosphorylation that is catalyzed by cyclin-dependent kinases, Cdk2, Cdk4, and Cdk6. Cdk4 and Cdk6 are regulated by D-type cyclins (D1, D2, D3), and Cdk2 is regulated by E-type cyclins (E1 and E2), at early and late stages, respectively, of the G₁ phase. Hyperphosphorylated Rb releases E2F transcription factors that promote entry into S phase by transcription of multiple genes required for replication.^{571,572} MPPs, the short-term repopulating cells and the colony-forming unit-granulocyte-erythroid-monocyte-macrophage (CFU-GEMM), have relatively low rates of proliferation, but they are greatly increased compared to the very infrequent cell divisions of HSC. The D cyclins and Cdk4 and Cdk6 kinases are important in these early progenitor cells because knockout mice that

lack all three D cyclins⁵⁷³ or lack both Cdk4 and Cdk6 kinases⁵⁷⁴ have specific, lethal hematopoietic failures at the fetal liver stage of definitive hematopoiesis.⁵⁷² In both of these knockout models, the HSC populations have little or no loss of numbers, but the multipotent progenitors are severely reduced, indicating these cell cycle regulators are required for the process that commits the HSC to increased proliferation during differentiation.^{573,574}

As they divide, MPPs have progressively restricted lineage potential, which is regulated by various transcription factors as described above in the sections on the individual cell types in the marrow. The single-lineage progenitors further increase the percentages of their populations in active cell cycle so that by the later stages of CFU-E, CFC-G, and more mature hematopoietic precursor cell development, the majority are in the S, G₂, and M phases.⁵⁷⁵ The two potential sources of extracellular stimuli that increase hematopoietic cell division are soluble hematopoietic cytokines and local interactions of the progenitors with other cells and matrix in the marrow. Hematopoietic cytokines include those produced either in remote organs, such as EPO, or those produced in a wide variety of organs, including the marrow, such as TPO, GM-CSF, and G-CSF.⁵⁷⁶ These latter hematopoietic cytokines have multiple effects on their target progenitor cells, including the promotion of survival, maturation, and migration, that are important for the increased production and recruitment of the mature cells to sites of inflammation.⁵⁷⁶ Among the cytokines, M-CSF is mitogenic, that is, it promotes progression from G₁ to S phase, in macrophages and their precursors.⁵⁷⁷ The signaling from FMS (CSF1R), the M-CSF receptor, which leads to S-phase progression, is mediated by both cyclin D1 and the transcription factor MYC.⁵⁷⁸ Among the various cellular interactions of late progenitors and precursors, attachment to central macrophages of EBIs promotes the G₁ to S phase transition in erythroid progenitors/precursors.³⁷⁸ This mitogenic effect of macrophage-erythroid cell interaction is unrelated to the antiapoptotic effect of EPO on the erythroid cells during these stages of erythroid differentiation.³⁷⁸

Mature hematopoietic cells cease cell division prior to their release from the marrow, but the mechanisms that signal cell cycle arrest in hematopoietic cells as they mature are uncertain. Among the potential mediators of this cell-cycle arrest are Rb and several intracellular inhibitors of the cyclin-dependent kinases, specifically the INK4 proteins (p15, p16, p18, p19) that inhibit Cdk4 and Cdk6 and the CIP/KIP family of Cdk2 inhibitors (p21, p27, and p57).⁵⁷⁵ Rb knockout mice have a lethal anemia during fetal liver hematopoiesis that is associated with persistent progression through cell cycle, but the erythroblast apoptosis appears to be related to failure of mitochondrial biogenesis.⁵⁷⁰ Understanding the activity of p16^{INK4a} in regulating cell cycle is complicated by its potential role in senescence and apoptosis of HSC.⁵⁷⁹ Although p21 and p27 proteins are proposed as having roles in the TGF- β -induced HSC quiescence and in the increased proliferation of later progenitor stages, Cdk2 knockout mice do not have impaired hematopoiesis,⁵⁸⁰ indicating that other cell-cycle mediators are required for the cessation of proliferation that accompanies terminal differentiation.

Apoptosis is the major regulator of cellular populations in the marrow. Because of the exponential expansion of cells in a proliferating population, cell death has a dramatic effect on the numbers of cells in subsequent generations.⁵⁸¹ Thus, the regulation of hematopoietic cell populations by apoptosis provides a mechanism for dramatic and prompt changes in blood cell production. During various stages of differentiation, hematopoietic cells depend upon specific cytokines to prevent apoptosis.^{576,581} A wide range of sensitivities to the hematopoietic cytokines among the dependent cells, as has been demonstrated for erythroid cells and EPO,⁵⁸² results in differential survival that allows for a graded response. Experiments in knockout mice have identified specific proteins in the Bcl-2 family as principal regulators of the intrinsic or

mitochondrial apoptosis pathway in the homeostasis of the hematopoietic cells populations in the marrow.^{583,584} Antiapoptotic members of the Bcl-2 family (Bcl-2, Bcl-X_L, Mcl-1, and A1) stabilize the mitochondrial membranes by preventing mitochondrial depolarization by the pore-forming family members, Bax and Bak.⁵⁸⁵ The antiapoptotic members are also opposed by the proapoptotic, regulatory family members that consist of the BH3-only domain, such as Bim, Bid, Nix, and Puma.

In HSC and multipotent progenitors, Mcl-1 is required to prevent apoptosis, and SCF stimulation increases the Mcl-1 expression.^{586,587} In the later stages of single-lineage progenitors, Mcl-1 continues to be required for survival of neutrophil and B and T lymphocytes, but it is antagonized by the expression of Bim and Puma in these progenitors, providing a means to eliminate specific cells, such as autoreactive B and T lymphocytes.^{583,584} A1 is required for normal neutrophil survival.⁵⁸⁸ In the erythroid lineage, Bcl-X_L is required to prevent apoptosis at the late erythroblast stage,⁵⁸⁹ and the proapoptotic Nix protein is also expressed.⁵⁹⁰ The sequential proapoptotic and antiapoptotic stimuli that regulate erythropoiesis demonstrate overlapping and cooperative interactions that affect erythroid cell homeostasis by both survival and differentiation. Following moderate blood loss, an increased percentage of HSC enter cell cycle and self-renewal.⁵⁵² In the BFU-E through CFU-E stages, SCF and glucocorticoids act in concert to upregulate proliferation according to the erythropoietic requirements.⁵⁹¹ However, because CFU-E depends upon EPO, SCF and EPO act together, enhancing the proliferation and survival, respectively, of CFU-E.⁵⁹² EPO prevents apoptosis of CFU-E through basophilic erythroblast stages by decreasing Fas expression,^{374,375} but its upregulation of Bcl-X_L prevents the apoptosis of the late-stage hemoglobin-producing erythroblasts.⁵⁸⁹ Expression of proapoptotic Nix in very late erythroblasts and reticulocytes plays a major role in targeting mitochondria for nontoxic elimination by autophagy.^{593,594}

Various mathematical models have been constructed to explain the production rates for each cell type during homeostasis and during periods of increased and decreased production. A model of homeostatic human marrow has been based upon marrow films and sections relating differential counts of marrow samples to their content of injected radioactive iron. A number of assumptions and approximations are made,⁵⁹⁵ but the summary data (Table 5-4) agree well with many other observations on the cellular content and kinetics of normal marrows. Under pathologic conditions such as infection, inflammation, or hematopoietic dysplasia, the proliferation and differentiation of hematopoietic progenitors may be affected by microbial products, cytokines, and cellular interactions that do not have a role in normal hematopoietic development. Infections, for example, can lead to increased myelopoiesis

without the involvement of the hematopoietic cytokines. HSC and their myeloid and lymphoid progeny have multiple toll-like receptors (TLRs) which bind specific bacterial or viral molecules.^{596,597} The activation of TLRs leads to increased myelopoietic proliferation and differentiation, especially of the monocyte/macrophage lineage, and differentiation of lymphoid cells toward the dendritic cell phenotype.^{596,598} Although increased hematopoietic cytokines are produced by TLR activation, a direct response to TLR activation in hematopoietic cells changes the prevalent myeloid transcription factor from C/EBP α , which mediates homeostasis by hematopoietic cytokines, to C/EBP β , which mediates the emergency responses to TLR activation.⁵⁹⁹ In response to the activation of TLRs, mature neutrophils have decreased apoptosis as a result of increased Mcl-1 and decreased Bad activity.⁶⁰⁰ This may be a result of direct ligation of TLR receptors on LT-HSC, ST-HSC, and MPP that are then stimulated to secrete cytokines such as IL-6, GM-CSF, and TNF- α .^{601,602} An alternative path to apoptosis in hematopoietic cells is the activation of specific death-domain receptors for the ligands such as FAS ligand, TNF- α , and TRAIL (tumor necrosis factor-related apoptosis-inducing ligand). Although these ligands are most commonly associated with pathologic states where they may play a role in the anemias of chronic disease, they have also been proposed to have a regulatory role in normal erythropoiesis.⁶⁰³

CHAPTER 6

THE ORGANIZATION AND STRUCTURE OF LYMPHOID TISSUES

Aharon G. Freud and Michael A. Caligiuri*

SUMMARY

The lymphoid tissues can be divided into primary and secondary lymphoid organs. Primary lymphoid tissues are sites where lymphocytes develop from progenitor cells into functional and mature lymphocytes. The major primary lymphoid tissue is the marrow, the site where all lymphocyte progenitor cells reside and initially differentiate. This organ is discussed in Chap. 5. The other primary lymphoid tissue is the thymus, the site where progenitor cells derived from the marrow differentiate into mature thymus-derived (T) cells. Secondary lymphoid tissues are sites where lymphocytes undergo additional maturation and also interact with each other and with nonlymphoid cells to generate immune responses to antigens. These tissues include the spleen, lymph nodes, and mucosa-associated lymphoid tissues such as tonsils. The structure of these tissues provides insight into how the immune system discriminates between self-antigens and foreign antigens and develops the capacity to orchestrate a variety of specific and nonspecific defenses against invading pathogens.

THE THYMUS

The thymus is the site for development of thymic-derived lymphocytes, or T cells. In this organ, developing T cells, called *thymocytes*, differentiate from lymphoid stem cells derived from the marrow into functional, mature T cells.¹ It is here that T cells acquire their repertoire of specific antigen receptors to cope with the antigenic challenges received throughout one's life span. Once they have completed their maturation, the T cells leave the thymus and circulate in the blood and through secondary lymphoid tissues.

Acronyms and Abbreviations: *AIRE*, autoimmune regulatory gene; *APECED*, autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy; *CT*, computed tomography; *GALT*, gastrointestinal-associated lymphoid tissue; *Ig*, immunoglobulin; *IL*, interleukin; *IILC*, innate lymphoid cell; *MALT*, mucosa-associated lymphoid tissue; *MHC*, major histocompatibility complex; *NK*, natural killer; *PALS*, periarteriolar lymphoid sheath; *PGA syndrome*, polyglandular autoimmune syndrome; *r*, correlation coefficient; *T*, thymus-derived; *TCR*, T-cell receptor.

*This chapter was prepared by Thomas J. Kipps in the 8th edition and much of the text has been retained.

THYMIC ANATOMY

The thymus is located in the superior mediastinum, overlying, in order, the left brachiocephalic (or innominate) vein, the innominate artery, the left common carotid artery, and the trachea. It overlaps the upper limit of the pericardial sac below and extends into the neck beneath the upper anterior ribs. It receives its blood supply from the internal thoracic arteries. Venous blood from the thymus drains into the brachiocephalic and internal thoracic veins, which communicate above with the inferior thyroid veins.

Arising from the third and fourth branchial pouches as an epithelial organ populated by lymphoid cells and endoderm-derived thymic epithelial cells, the thymus develops at about the eighth week of gestation.² The thymus increases in size through fetal and postnatal life and remains ample into puberty,³ when it weighs approximately 40 g. Thereafter, the size progressively decreases with aging as a consequence of thymic involution.⁴ The cause of thymic involution is likely in part a result of the influence of glucocorticoid hormones.⁵ Nonetheless, there is evidence that T lymphocytes continue to develop throughout life, potentially including in some extrathymic sites.⁶

The volume of the thymus can be estimated by sonography. In one study of 149 healthy term infants within 1 week of birth, there was a significant correlation between the estimated thymic volume and the weight of the infant.^{3,7} However, no correlation was apparent between the estimated thymic volume and the infant's sex, length, or gestational age. Also, there was no apparent correlation between estimated volume and the proportions of CD4+ T cells or CD8+ T cells found in the blood. The estimated thymic volume of healthy infants increases from birth to 4 and 8 months of age and then decreases.³ Most of the individual variation at 4 and 10 months of age appears to correlate with breastfeeding status, body size, and, to a lesser extent, illness. Breastfed infants at 4 months of age have significantly larger estimated thymic volumes than do age-matched formula-fed infants with similar thymic volumes at birth.⁸

THYMIC ARCHITECTURE

A longitudinal fissure divides the thymus into two asymmetrical lobes, a larger right and a smaller left, that are derived from the right and left branchial pouches, respectively. These two developmentally separate parts of the thymus are easily separated from each other by blunt dissection.

Each lobe of the thymus is divided into multiple lobules by fibrous septa that extend inward from an outer capsule. Each lobule consists of an outer cortex and an inner medulla (Fig. 6-1). The cortex contains dense collections of thymocytes (developing immature T cells) that cytologically appear as lymphocytes of slightly variable size with scattered, rare mitoses. The lighter-staining medulla is loosely arranged and more sparsely populated by mature thymocytes and characteristic tightly packed whorls of squamous-appearing epithelial cells, called *thymic* or *Hassall corpuscles* (Fig. 6-2). These appear to be remnants of degenerating cells and are rich in high-molecular-weight cytokeratins. Hassall's corpuscles are thought to serve a critical role in the development of regulatory T cells.⁹

The thymus contains several important cell types that serve a variety of functions including supporting the maturation of thymocytes into mature T cells. There are several types of specialized epithelial cells within the thymus.¹⁰ The three main categories of thymic epithelial cells are the medullary epithelial cells, which are organized into clusters; the cortical epithelial cells, which form an epithelial network; and the epithelial cells of the outer cortex. The epithelial cells in the cortex and medulla often have a stellate shape, display desmosomal intercellular connections, and likely function as support cells to developing thymocytes by providing important growth factors such

Figure 6-1. Normal human infant thymus. The thymus is surrounded by dense connective tissue capsule (*Cap*). It is organized into adjacent lobules separated by capsular connective tissue extensions or trabeculae. The lobules each have a dense cortex (*C*) and a lighter staining medulla (*M*). The medulla is a continuous tissue surrounded by the cortex that extends throughout the thymus, and it cannot be appreciated in a single section. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

as interleukin (IL)-7.¹¹ In addition, at primarily the corticomedullary junction, the thymus contains marrow-derived antigen-presenting cells, mostly interdigitating dendritic cells and macrophages. Scattered B cells are also present in the thymus, and these interact with maturing thymocytes and potentially regulate T-cell development.^{12,13}

After puberty, thymic involution begins within the cortex. This region may disappear completely with aging, while medullary remnants persist throughout life. Glucocorticoids also may induce atrophy of the cortex secondary to glucocorticoid-induced apoptosis of cortical

thymocytes.⁵ This also may be seen in conditions that are associated with increases in circulating glucocorticoid hormones, for example, pregnancy or stress.^{14,15}

THYMIC IMMUNE FUNCTION

The thymus is the site of T-cell development. The importance of the thymus is underscored by patients with DiGeorge syndrome, or chromosome 22q11.2 deletion syndrome, who lack the genes required for

Figure 6-2. Normal human infant thymus. Higher magnification. Medulla. The arrows indicate thymic corpuscles (synonymous with Hassall corpuscles). They are composed of tightly packed, concentrically arranged, type IV endothelioreticular cells with flattened nuclei. The central mass is composed of keratinized cells. In addition to thymic corpuscles and the mass of small densely stained T lymphocytes, the medulla contains scattered, larger, type V epithelioreticular cells with their light nuclei, dark nucleolus, and eosinophilic cytoplasm, evident on this section. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

Figure 6-3. Structure of the thymus. The top half of the figure provides a cross section of a thymic lobule, indicating the outer cortex (left), inner medulla (center), and periphery (far right). The arrows indicate various structures and cell types. As thymocytes mature, they migrate from the cortex toward the medullary region and acquire phenotypic features that are outlined at the bottom of the figure, as described in the text (Chap. 74).

thymic development.¹⁶ These patients do not develop T cells and hence have profound immune deficiency.

Prothymocytes originate in the marrow and migrate to the thymus, where they mature into T cells (Chap. 76). Maturation of T cells is accompanied by the sequential acquisition of various T-cell markers including CD2, CD3, CD4 or CD8, CD5, and the T-cell receptor (TCR) (Fig. 6-3).¹⁷ Terminal deoxynucleotidyl transferase (TdT) is found in prothymocytes and immature thymocytes but is absent in mature T cells. TdT facilitates the successful rearrangement of TCR genes in immature thymocytes.¹⁸

T-cell precursors can be found in distinct microenvironments within the thymus. Marrow-derived CD34⁺ pre-T cells enter the cortex via small blood vessels and are double-negative for CD4 and CD8 antigens.¹ One of the earliest identifiable T-cell membrane antigens is CD2. As the thymocytes proliferate and differentiate in the cortex, they acquire CD4 and CD8 antigens. They subsequently acquire the CD3 antigen and the TCR for antigen as they migrate toward the medulla. In the cortex, the thymocytes are induced to express the chemokine receptor, CCR7, which directs their migration to CCL19- and CCL21-producing cells in the thymic medulla where they undergo further maturation.¹⁹

Positive and negative selection of maturing T cells takes place in the thymus.²⁰ Double-positive (CD4⁺ and CD8⁺) thymocytes undergo an initial positive selection step that is mediated exclusively by thymic cortical epithelium to ensure that developing T cells can recognize peptides in the context of self major histocompatibility complex (MHC) molecules.²¹ Thymocytes that have TCRs capable of interacting with self MHC molecules expressed by thymic cortical epithelial cells undergo expansion, whereas thymocytes with defective TCR undergo apoptosis.²²⁻²⁴ As these positively selected cells migrate toward the medulla, they experience negative selection through their interaction with thymic medullary epithelial cells in order to ensure that any T cells that react too strongly to self MHC molecules are deleted. These thymic medullary epithelial cells uniquely express the autoimmune regulatory

gene (*AIRE*). *AIRE* encodes a transcriptional regulator that promotes ectopic expression of a large repertoire of transcripts encoding proteins that ordinarily are restricted to differentiated organs residing in the periphery.²⁵ This allows the thymic medullary epithelial cells to express many different self-antigens, which are presented to developing thymocytes. Those thymocytes that have TCR that react too vigorously with the MHC molecules of the medullary epithelium will undergo apoptosis.²³ Most of the developing thymocytes are destroyed. In this way, only those T cells that have the appropriate level of affinity for self-MHC molecules yet are not reactive against self antigens will reach the medulla to undergo the final maturation stages and eventually exit the thymus via efferent lymphatics as functionally competent naïve CD4⁺ and CD8⁺ single-positive T cells.

Patients with the rare disease *autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy* (APECED) or *polyglandular autoimmune syndrome type I* (PGA I) underscore the importance of negative selection of thymocytes by thymic medullary epithelial cells. APECED, or PGA I, is characterized by chronic mucocutaneous candidiasis, hypoparathyroidism, and adrenal insufficiency. In addition, most patients also have a number of other autoimmune manifestations, including thyroiditis, type 1 diabetes, ovarian failure, alopecia, and/or hepatitis.²⁶ These patients have genetic defects in *AIRE*,²⁷ which precludes their thymic epithelial cells from expressing the large variety of tissue differentiation self-antigens required for the negative selection of self-reactive thymocytes and the generation of central T-cell tolerance.^{25,28}

● THE SPLEEN

The spleen is a specialized abdominal organ serving multiple functions in erythrocyte clearance, innate and adaptive immunity, and the regulation of blood volume. In general the spleen contains two structurally and functionally distinct components: white and red pulp. The white pulp of the spleen consists of secondary lymphoid tissue that provides

an environment in which the cells of the immune system can interact with one another to mount adaptive immune responses to bloodborne antigens. The splenic red pulp contains macrophages that are responsible for clearing the blood of unwanted foreign substances and senescent erythrocytes, even in the absence of specific immunity. Thus, it acts as a filter for the blood.

SPLENIC ANATOMY

The spleen is located within the peritoneum in the left upper quadrant of the abdomen between the fundus of the stomach and the diaphragm. It receives its blood supply from the systemic circulation via the splenic artery, which branches off the celiac trunk, and the left gastroepiploic artery.²⁹ The blood returning from the spleen drains into the portal circulation via the splenic vein. Therefore, the spleen can become congested with blood and increase in size when there is portal vein hypertension (Chap. 56).

Approximately 10 percent of individuals have one or more accessory spleens. Accessory spleens are usually 1 cm in diameter and resemble lymph nodes. However, they usually are covered with peritoneum, as is the spleen itself. Accessory spleens typically lie along the course of the splenic artery or its gastroepiploic branch, but they may be elsewhere.³⁰ The commonest location is near the hilus of the spleen, but approximately 1 in 6 accessory spleens can be found embedded in the tail of the pancreas, where they may be occasionally mistaken for a pancreatic mass lesion.³¹

The average weight of the spleen in the adult human is 135 g (range: 100 to 250 g). However, when emptied of blood it weighs only approximately 80 g. On autopsy of 539 subjects with normal spleens, there was a positive correlation between the spleen weight and both the degree of acute splenic congestion and the subject's height and weight, but not with the subject's sex or age.³²

The splenic volume can be estimated by computed tomography (CT) of the abdomen.³³ In one study, the splenic volume was calculated from the linear and the maximal cross-sectional area measurements of the spleen, using the following formula: splenic volume = $30 \text{ cm}^3 + 0.58$ (the product of the width, length, and thickness of the spleen measured in centimeters).³⁴ Using this formula, the mean value of the calculated splenic volume for 47 normal subjects was 214.6 cm^3 , with a range of 107.2 to 314.5 cm^3 . The calculated splenic volume did not appear to vary significantly with the subject's age, gender, height, weight, body mass index, or the diameter of the first lumbar vertebra, the latter being considered representative of body habitus on CT.

The splenic volume also can be estimated by sonography, which provides good correlation with volumes measured by helical abdominal CT or actual volume displaced by the excised organ. In one study of 50 patients, the linear measurement by sonography that correlated most closely with CT volume was the spleen width measured on a longitudinal section with the patient in the right lateral decubitus position (correlation coefficient [r] = 0.89, $p < 0.001$). There was also good correlation between splenic length measured in the right lateral decubitus position and CT volume ($r = 0.86$, $p < 0.001$). In another post-mortem analysis of 32 normal adult spleens, the ultrasonogram measurements of maximal height, width, and breadth of the spleen were compared with the actual volume displaced by the excised organ.³⁵ The mean actual splenic volume was approximately 148 cm^3 ($\pm 81 \text{ cm}^3$ SD), whereas mean splenic volume estimated from ultrasonography was 284 cm^3 ($\pm 168 \text{ cm}^3$ SD). Despite the differences between the actual and estimated volumes, these investigators did find a roughly linear correlation between actual splenic volume and the estimated splenic volume measured by ultrasound. However, there may be operator-to-operator variation in measurement of the estimated splenic volume, making the use of sonography in longitudinal studies technically demanding.

SPLENIC ARCHITECTURE

The spleen has an open circulation, which lacks endothelial continuity from artery to vein. When isolated spleens are perfused in washout studies, erythrocytes that appear in the splenic vein appear to be flushed out from three compartments. The red cells that are flushed out first come from a compartment that presumably is formed by the splenic vessels. The erythrocytes that are flushed out next come from a second compartment, where they presumably are loosely held within the filtration beds. The erythrocytes that are flushed out last presumably were adherent to cells of the filtration beds. Although 90 percent of the blood flow passes through the splenic vessels, only approximately 10 percent of the total splenic red cells are found within this first compartment. The second compartment is perfused by 9 percent of the total inflow yet contains 70 percent of the splenic red cells. The last compartment is perfused by only 1 percent of the inflow but contains 20 percent of the splenic red cells.

These compartments reflect the anatomy of the spleen and its stroma. The stroma is composed of branched, fibroblast-like cells called reticular cells. These cells produce slender collagen fibers, the reticular fibers, which are rich in type III collagen. The reticular cells and fibers form a meshwork, or reticulum, which filters the blood. Three major types of filtration beds can be distinguished by their structure and content: the white pulp, the marginal zone, and the red pulp.

White Pulp

The white pulp contains the lymphocytes and other mononuclear cells that surround the arterioles branching off the splenic artery. After the splenic artery pierces the splenic capsule at the hilum, it divides into progressively smaller branches. Each branch is called a central artery because it runs through the central longitudinal axis of a distinctive filtration bed that surrounds each central artery (Fig. 6-4). This is composed of a cuff of lymphocytes called the periarteriolar lymphoid sheath (PALS). The PALS is composed mostly of T lymphocytes, about two-thirds of which are CD4+ T cells. The PALS around white pulp arterioles of the human spleen is not continuous.³⁶ Indeed, segments of the central arterioles might not be surrounded by T cells in areas where they run through lymphoid follicles containing pale areas of activated B lymphocytes interspersed with large, pale macrophages and dendritic cells.¹ The migration of T cells to the PALS is governed by stromal cell production of chemokines, primarily CCL19 and CCL21, which interact with the chemokine receptor CCR7 that is expressed by naïve T cells.³⁷ Stromal production of these chemokines can be stimulated by certain cytokines, such as lymphotoxin.³⁸

On gross inspection of the surface of a freshly cut spleen, these follicles appear as white dots referred to as malpighian corpuscles (Fig. 6-5). These corpuscles contain a germinal center and have the same anatomic features and functions as secondary follicles in the lymph node. Branches coming off the central artery deliver disproportionate amounts of plasma and lymphocytes to the rim of the PALS (Fig. 6-6). These branches tend to run at acute angles, leading to a selective loss of plasma from the blood, a phenomenon referred to as "skimming." After becoming relatively depleted of plasma, the arterioles then carry plasma-reduced blood into the filtration beds of the red pulp and marginal zone. As a result, the red pulp and marginal zone beds contain relatively high concentrations of red cells.

The Marginal Zone

The marginal zone surrounds the PALS and follicles. It is composed of a reticulum, which forms a finely meshed filtration bed, serving as a vestibule for much of the blood that flows through the spleen. The marginal zone surrounds the white pulp and merges with the red pulp. It contains more lymphocytes than the red pulp. These are primarily B cells and

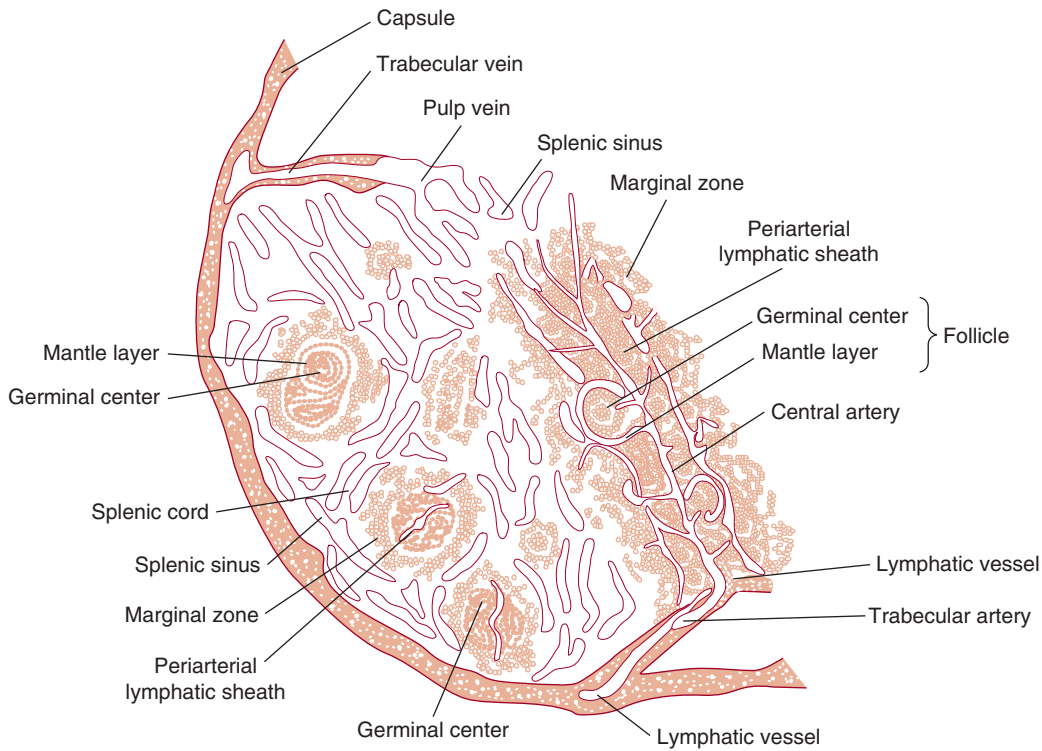

Figure 6-4. Structure of the spleen. A branch of the splenic artery enters the pulp and becomes a central artery. Surrounding the central artery is a periarterial lymphoid sheath (PALS). At the circumference of the PALS is the marginal zone, which generally separates the white pulp of the PALS from the red pulp. Follicles of B cells with occasional germinal centers (malpighian corpuscles) are located at the outer margins of the PALS for the depicted central artery and the PALS of central arteries that are in a different plane from that of the figure.

Figure 6-5. Normal human spleen. The splenic tissue is composed of red and white pulp. The red pulp (R), shown here as masses of red cells, is imparted a red color in living tissue as a result of the natural color of hemoglobin in red cells and in stained sections as a result of the intensified red (eosinophilic) stain taken up by hemoglobin. The red pulp contains venous sinuses separated by cords of red cells (cords of Billroth), which cannot be seen in a light micrograph. The white pulp is composed of spherical aggregates of lymphocytes (lymphatic nodule [LN]) with a lighter staining germinal center and an outer, relatively thin, darker stained marginal zone, which separates white pulp from red pulp. Thick-walled central arteries are usually evident penetrating the white pulp. The central artery is cut obliquely in the white pulp at the upper left. Two arteries are seen penetrating the nodule in the center-left of the field and a single artery penetrating the white pulp in the lower-center of the field. The central artery is often seen in the lymphatic nodule in an eccentric position. Other nodules do not show a vessel in this plane of section. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

Figure 6-6. Normal human spleen (higher magnification of white pulp). The white pulp is composed of spherical aggregates of lymphocytes (lymphatic nodules [LN]) with a lighter staining germinal center and an outer, relatively thin, darker stained marginal zone, which separates white pulp from red pulp. The lymphatic nodules largely consist of B lymphocytes. Thick-walled central arteries are usually evident penetrating the white pulp, often in an eccentric position as noted by the asterisks. The T-cell-rich periarteriolar lymphoid sheath surrounds the central artery, which is cut longitudinally in the lymphatic nodule at the left. A single central artery penetrating the lymphatic nodule in the upper-right part of the field is in a characteristically eccentric position. R, red pulp. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

CD4+ T cells that appear especially well equipped for rapid antibody immune responses to bloodborne antigens.³⁹⁻⁴¹ However, like the red pulp, the marginal zone may become congested and remove damaged and senescent red cells and parasites.

The Red Pulp

The splenic red pulp is composed of a reticular meshwork, called the splenic cords of Billroth, and splenic sinuses.⁴² This region predominantly contains erythrocytes but also has large numbers of macrophages and dendritic cells as well as fewer numbers of granulocytes, cytolytic CD8+ T cells, and natural killer (NK) cells.

As the central arteries branch and decrease in size, the PALS also branches and decreases in diameter to but a few cells surrounding the arteriole. The small arteriole finally emerges from its sheath and then terminates in either the marginal zone or the red pulp. Here these vessels are suspended and anchored by adventitial reticular cells in the periarterial beds. They often terminate abruptly as arteriolar capillaries or as vessels with a trumpet-like flare with widened slits called interendothelial slits. The blood flows through these slits into filtration beds composed of large-meshed loculi that open to one another.

The blood in the red pulp and marginal zone drains into venous sinuses that form anastomosing, blind-ending vessels. These venous sinuses actually are specialized postcapillary venules. The endothelial cells are shaped as tapered rods that are stiffened by basal, longitudinal, intermediate cytoskeletal filaments and contractile filaments of actin and myosin. These intracellular contractile filaments can shorten the vein, causing the endothelium to buckle and form interendothelial gaps, favoring transmural passage.

The endothelial cells are attached to a basement membrane. Although this appears to be fashioned of fibers, the basement membrane actually is an extracellular membranous wall with large, regular defects that expose considerable basal endothelial surface. This includes the interendothelial slits through which blood may flow from the filtration bed and into the vein. Ordinarily the interendothelial slits are

narrow or even closed unless forced apart by cells in transmural transit or by endothelial contraction.

Splenic arterioles terminate at varied distances from the walls of venous vessels. Blood flowing from arterioles that terminate at the venous vessel wall may flow directly into the splenic vein. However, blood flowing from arterioles that terminate at a distance from a vein must traffic through the spleen. In so doing, the blood either may pass quickly through a nonsinusoidal venous aperture or slowly through sinusoidal interendothelial slits and the fibroblast stroma.

The fibroblast stroma contains reticular cells and myofibroblast cells, which are also called barrier cells. The latter may fuse with each other to form a syncytial membrane that connects the arterial terminals with venous interendothelial slits or apertures. Like other myofibroblasts, these cells contain actin and myosin and may contract, thereby approximating splenic arterial and venous vessels with one another. Thus, the fibroblast stroma may affect the relative proportion of blood that flows through the stroma or the sinusal interendothelial slits. Such redistribution might occur during periods of acute physiologic stress, allow for increased expulsion of red cells from the spleen, and account for some of the increase in hematocrit observed during strenuous exercise.⁴³

SPLENIC FUNCTION

Red Cell Clearance

Mixed within the stroma of the red pulp and marginal zone are monocytes and macrophages. As the blood passes through the stroma, monocytes adhere to the stroma, where the microenvironment is conducive to their maturation into macrophages and large, dendritic, lysosome-rich phagocytes. These cells assist the reticular cells in mechanical filtration. More importantly, these cells have phagocytic activity that allows them to ingest imperfect erythrocytes, store platelets, and remove infectious agents, such as plasmodia, from the circulation.⁴⁴ In addition, the monocytes and macrophages have nonphagocytic functions, such as the

presentation of antigens to T cells or the elaboration of immunomodulatory cytokines.

Collectively, the anatomy of the spleen allows the marginal zone and red pulp to cull defective erythrocytes. As the blood passes slowly through the sinusoidal interendothelial slits and the fibroblast stroma, the erythrocytes must undergo alterations in shape to squeeze through the mechanical barrier generated by this filtration compartment. Normal red cells that are supple may pass through readily because the interendothelial slits can open to approximately $0.5\ \mu\text{m}$. However, erythrocytes containing large, rigid inclusions, such as plasmodium-containing erythrocytes, are delayed or sequestered.⁴⁵ Antibody-coated red cells, as present in autoimmune hemolytic anemia, are also recognized and removed by macrophages in the splenic red pulp. Polymorphisms of Fc γ RII (CD32) or Fc γ RIII (CD16) that affect immunoglobulin (Ig) G binding *in vitro* can alter the efficiency of clearance of antibody-coated red cells *in vivo*.⁴⁶

When these filtration beds sequester imperfect red cells, the blood pools inside the spleen, causing stasis and congestion. This stimulates sphincter-like contraction of the distal vein, resulting in proximal plasma transudation that produces a viscous luminal mass of high-hematocrit blood. During episodes of enhanced red cell sequestration, as occurs during malarial crises or hemolytic episodes in a small proportion of patients with sickle cell disease, the splenic volume and weight may increase 10- to 20-fold (Chap. 56).⁴⁷ Although the white pulp may enlarge, particularly in germinal centers, the marginal zones and red pulp become greatly widened with pooled erythrocytes and macrophages in this setting.

Regulation of Blood Volume

The spleen also can play a role in modulating blood volume. Release of high-hematocrit blood through splenic contraction occurs in response to activation of the baroreflex, which also may be activated during conditions of decreased blood pressure and cardiac output.^{48,49} On the other hand, physiologic agents such as atrial natriuretic peptide, nitric oxide, and adrenomedullin can induce fluid extravasation from the splenic circulation into lymphatic reservoirs.⁵⁰ Excessive splenic extravasation can contribute to the inability to maintain adequate intravascular volume during septic shock. There also is evidence that the splenic afferent and renal sympathetic nerves play a role in maintaining renal microvascular tone.⁵⁰ This splenorenal reflex can influence blood pressure and, during septic shock, help promote renal sodium and water reabsorption and release of the vasoconstrictor angiotensin II. On the other hand, in portal hypertension, the splenorenal reflex can promote renal sodium and water retention and possibly play a role in the hemodynamic complications of portal hypertension through neurohormonal modulation of the mesenteric vascular bed.

Splenic Immune Function

The spleen and its responses to antigens are similar to those of lymph nodes, the major difference being that the spleen is the major site of immune responses to bloodborne antigens, while lymph nodes are involved in responses to antigens in the lymph.⁴² Antigens and lymphocytes enter the spleen through the vascular sinuses, because the spleen lacks high endothelial venules. Upon entry, the lymphocytes home to the white pulp. T cells, which express the chemokine receptor CCR7, migrate to the PALS in response to CCL19 and CCL21, and B cells, which express CXCR5, migrate to the lymphoid follicles in response to CXCL13.^{37,51} Dendritic cells also express CCR7 and hence migrate to the same area as do naïve T cells. T and B cells migrate within these compartments for about 5 and 7 hours, respectively. In the absence of an immune response, these cells migrate through a reticulum arranged around the circumference of the central artery.

Upon immune activation in response to antigen, the lymphocytes may remain in the spleen to sustain a primary or secondary immune response. Activation of B cells is initiated in the marginal zones that are adjacent to CD4+ T cells in the PALS. Activated B cells then migrate into germinal centers or into the red pulp.⁵² Lymphoid nodules appear and expand by recruiting lymphocytes from the blood and the peripheral zone of the follicles, termed the mantle zone. These cells then proliferate and differentiate in the center of a lymphoid nodule, forming a germinal center.⁵³ In their path from the marginal zone to the follicles, B cells pass into the PALS, where they remain in contact with T lymphocytes for a few hours, allowing ample time for T- and B-cell interaction in response to antigens. If they are not recruited in an immune response to antigen, both T and B lymphocytes exit the spleen via deep efferent lymphatics, not the splenic veins.

These efferent lymphatics are not distinguished as separate structures within the PALS, being quite thin-walled and often packed with efferent lymphocytes. However, they are important in moving nonreactive lymphocytes out of the spleen and in producing high-hematocrit pulp blood. After leaving the spleen, the efferent lymphocytes become the afferent lymphatics of the perisplenic mesenteric lymph nodes or empty into the thoracic duct. This duct empties into the left subclavian vein, thus returning the lymphocytes to the venous circulation.

LYMPH NODES

The lymphoid nodes are secondary lymphoid tissues. They form part of a network that filters antigens from the interstitial tissue fluid and lymph during its passage from the periphery to the thoracic duct. Thus, the lymph nodes are the primary sites of immune response to tissue antigens.

LYMPH NODE ANATOMY

The lymph nodes are round or kidney-shaped clusters of mononuclear cells that normally are less than 1 cm in diameter (Fig. 6-7). A collagenous capsule surrounds a typical lymph node and has an indentation called the hilus where blood vessels enter and leave.

Lymph nodes typically are present at the branches of the lymphatic vessels and form part of the extensive network of lymphatic channels that extends throughout the body. Several afferent lymphatic channels that drain lymph from regional tissues into the lymph node perforate the capsule of each lymph node. The lymph draining from the node leaves through one efferent lymphatic vessel at the hilus. The lymph from the node, in turn, empties into efferent lymphatic vessels that eventually drain into larger lymphatic channels leading eventually to the thoracic duct. The thoracic duct, in turn, drains into the left subclavian vein, thus returning lymph into the systemic circulation.

Clusters of lymph nodes are located strategically in areas that drain various superficial and deep regions of the body, such as the neck, axillae, groin, mediastinum, and abdominal cavity. The lymph nodes that receive lymph that drains from the skin, termed somatic nodes, are superficial. The lymph nodes that receive their lymph from the mucosal surface of the respiratory, digestive, or genitourinary tract, termed visceral nodes, are usually deep within body cavities.

LYMPH NODE STRUCTURE

Beneath the collagenous capsule is the subcapsular sinus, into which the afferent lymphatic channels drain (Fig. 6-8). This sinus is lined with phagocytic cells. Fibrous trabeculae radiate from the medulla adjacent to the hilus of the node to the subcapsular sinus, thus breaking the node into several follicles, called cortical follicles. These trabeculae, together

Figure 6-7. Normal human lymph node. Low power. Capsule (*Cap*) is a thin connective tissue covering. Below the capsule is the subcapsular sinus. Lymphatics penetrate the capsule and enter the subcapsular sinus. The cortex is composed of adjacent lymphatic nodules, usually with fine connective tissue trabecula extending from the capsule separating the nodules. The nodule has a germinal center that stains lighter than the outer mantle zone because of the proliferating medium-sized and large lymphocytes with less dense staining properties. The medulla is composed of interconnecting medullary cords composed of lymphocytes and interspersed light staining channels, the medullary sinuses. Lymph flows from the subcapsular sinus down the trabecular sinuses and into the medullary sinuses and exits the node via efferent lymphatics at the hilum. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

with the capsule and a network of reticulin fibers, support the various cellular components of the node and serve as the scaffolding for lymphatic spaces, namely, the subcapsular and cortical sinuses. These lymphatic spaces are continuous with medullary sinuses and the solitary efferent lymphatic channel exiting the hilum.

Each cortical follicle contains dense collections of small, mature, recirculating lymphocytes. These consist of a B-cell area (cortex), a T-cell-rich area (paracortex), and a central medulla with cellular cords that contain T cells, B cells, plasma cells, and macrophages.¹ Some follicles contain lightly staining areas of 1- to 2-mm in diameter, called germinal centers. Germinal centers are the specialized sites for the

generation of memory B cells and antibody affinity maturation via the process of immunoglobulin variable-region somatic hypermutation.⁵⁴ Follicles without germinal centers are called primary follicles, and those with germinal centers are called secondary follicles. Primary lymphoid follicles contain nodules that consist predominantly of small, mature, recirculating B lymphocytes.

Within 1 week after antigenic stimulation, secondary follicles develop a germinal center that contains proliferating B cells and macrophages.^{55,56} The small, nonreactive B cells are apparently forced to the periphery of the follicle, where they form a dense follicular mantle. The B cells within the germinal center, on the other hand, are highly

Figure 6-8. Structure of the lymph node. The lymph enters via afferent lymphatic channels and exits via the efferent lymphatic channel. The *large arrows* indicate the direction of the lymphatic flow into and out of the lymph node. The legend shows the symbols used for the T-cell zone (*x*) and the B-cell zone (*shade*) of each follicle. The follicle in the lower left part of the node contains a primary follicle lacking a germinal center. The follicle immediately above this follicle contains a germinal center. Thus, the entire follicle delineated by the dashed lines is a secondary follicle. The cortex, paracortical area, and medulla are also shown.

activated, typically forming blasts that have abundant cytoplasm and round, cleaved, or convoluted shapes. Follicular dendritic cells also are found within the germinal centers. These cells can trap and retain antigens for months, possibly in the form of immune complexes.⁵⁷ The germinal centers of the secondary follicle may gradually regress after the antigenic stimulus is eliminated.

Surrounding the lymphoid follicles of the superficial cortex are sheets of lymphocytes that extend to the deep cortex, the paracortex, that blend into medullary cords of cells. The paracortical zones are formed mostly of T cells. The ratio of T cells to B cells in these zones is approximately 3:1. The medulla, however, contains scattered B cells, dendritic cells, macrophages, rare NK cells, and, during an immune response, plasma cells. The superficial cortex and medulla of the lymph nodes are the thymic-independent areas, while the deep cortex is particularly enriched with T cells, forming an area that sometimes is referred to as the thymic-dependent area. The major T-cell population found within the lymph node consists of CD4+ T cells. The scattering of CD4+ T cells in the follicles, and in more prominent numbers in the interfollicular zones, reveals the proximity of CD4+ T and B cells important for T-B cooperation during proliferation and maturation of antigen-stimulated B cells.⁵⁸

The T-cell-rich paracortex is also relatively enriched with specialized NK cells and other innate lymphoid cell (ILC) populations that likely have roles in shaping innate and adaptive immune responses in lymph nodes, as well as other secondary lymphoid tissues (SLT), through the production of immunomodulatory cytokines. The NK cell population present in the lymph node paracortex is predominantly composed of the CD56^{bright} subset that can rapidly produce cytokines, such as interferon- γ and tumor necrosis factor- α , in response to monocyte-derived cytokines (IL-12, IL-15, and IL-18).^{59,60} However, these NK cells show relatively weak cytotoxicity in comparison to CD56^{dim} NK cells that predominate in the blood (Chap. 77).⁶¹ There is accumulating evidence that CD56^{bright} NK cells represent the immediate precursors to CD56^{dim} NK cells and likely differentiate into the latter just prior to their egress from lymph nodes.⁶²⁻⁶⁴ Moreover, CD34+CD45RA+ hematopoietic progenitor cells capable of giving rise to CD56^{bright} NK cells are also enriched in the lymph node paracortex indicating that these tissues are also likely sites of NK cell development.⁶⁵⁻⁶⁷

Lymphocytes primarily enter lymphatic tissues from the blood by migrating across the tall, active endothelium of specialized postcapillary venules called *high endothelial venules*.⁶⁸ Cellular adhesion molecules and various chemokines, including CXCL13, CCL19, and CCL21, are responsible for the pattern of lymphocyte trafficking and determine the associations among stromal (e.g., reticular and endothelial) and parenchymal (e.g., T and B lymphocytes, dendritic cells, and macrophages) cells in the lymphoid tissues.^{54,69}

LYMPH NODE FUNCTION

The lymph node is the site where different types of lymphocytes, macrophages, and dendritic cells can interact with one another to generate an immune response to antigens carried within the lymph. As the lymph passes across the nodes from afferent to efferent lymphatic vessels, particulate antigens are removed by the phagocytic cells and transported into the lymphoid tissue of the lymph node.¹ Abnormal cells within the lymph, such as neoplastic cells, also can be trapped within the lymph node.

Within the lymph node, antigen is presented to T cells as processed peptides by MHC molecules of antigen-presenting cells (Chap. 76). Various T-cell subsets comprise a network of interactive cells. CD4+ and CD8+ cell-mediated contacts, as well as T-cell-derived soluble factors, induce and regulate the immune response. T-cell recognition

is mediated by the TCR for antigen. Which T cells are activated is determined by the specificity of the TCRs, the structure of MHC molecules, and the nature of antigen-presenting cells, including the dendritic reticular cells, macrophages, and B cells.

Along with TCR recognition of processed antigen presented in the MHC of the antigen-presenting cell, adequate T-cell activation requires secondary signals, or costimulation, delivered through accessory molecules, such as CD28.⁷⁰ Without these secondary signals, T cells may become anergic or specifically nonresponsive to antigen stimulation.⁷¹ This specific suppression is thought to play an important regulatory role in the maintenance of self-tolerance.^{72,73}

T-cell recognition of specific antigen may induce release of soluble factors, such as interleukins, that can activate the T cells themselves or have paracrine effects on other neighboring leukocytes.⁷⁴ Also, activated T cells express surface molecules, such as CD40-ligand (CD154), that also can activate B cells, dendritic cells, or macrophages.^{75,76}

The T-dependent immune response includes the formation of early germinal centers within days after antigen exposure. There is a mixture of B cells and activated CD4+ T cells in the lymphoid follicles. T-B cooperation involves the accessory B-cell antigen CD40 and the CD154 antigen expressed on activated T cells (Chap. 76). Activated B cells differentiate and take on the cytomorphologic characteristics of centroblasts and comprise the largest numbers of cells in the early germinal center.⁵⁶ Subsequently, centroblasts give rise to smaller B cells, the centrocytes. B cells undergo affinity maturation within the germinal center. During this process, the genes encoding the surface immunoglobulin of B cells undergo high rates of mutation, called somatic hypermutation.^{53,77} B cells that express immunoglobulin with little or no affinity for antigen undergo apoptosis.⁷⁸ The resulting cellular debris is tingible, or capable of being stained, and is found prominently within macrophages specifically designated tingible body macrophages. On the other hand, B cells expressing surface immunoglobulin with high affinity for antigen are selected to proliferate and differentiate to memory B cells or plasma cells.⁵⁴ As well as promoting activation of B cells, CD4+ T cells, and CD8+ T cells may give rise to circulating memory T cells.^{79,80}

Following the release of specific antibody, antigen-antibody complexes may form and become sequestered on the surface of follicular dendritic cells within the germinal centers. These antigen-antibody complexes produce a coating of small, bead-like, immune-complex-coated bodies called *iccosomes*. Iccosomes may be presented to CD4+ T cells by B cells and dendritic cells. Iccosomes also appear to assist in anamnestic recall following reentry of antigen in the host.⁸¹ T- and B-cell memory functions depend upon persistence of antigen.⁸²

PERIPHERAL LYMPHOID TISSUES

MUCOSA-ASSOCIATED LYMPHOID TISSUES

The mucosa-associated lymphoid tissues (MALTs) are diffusely organized aggregates of lymphocytes that protect the respiratory and gastrointestinal epithelium.⁸³ The lymphoid aggregates associated with the respiratory epithelium are sometimes referred to as the bronchial-associated lymphoid tissue. The lymphoid aggregates associated with the intestinal epithelium are sometimes referred to as the gut-associated lymphoid tissue (GALT). Lymphocytes in the GALT are located in three main regions: within the epithelial layer, scattered through the lamina propria, and clustered in organized collections in the lamina propria. The latter includes the tonsils, adenoids, appendix, and specialized structures called Peyer patches found in the ileum (Fig. 6-9). Most intraepithelial lymphocytes are CD8+ T cells, 10 percent of which express the γ/δ form of the TCR (Chap. 76). On the other hand, the intestinal lamina propria contains a mixed population of cells, including

Figure 6–9. A cross-section of human terminal ileum. The columnar epithelium shown to the left is organized into villi. A series of lymphatic nodules in the mucosa extending from the lamina propria to the submucosa is part of the gastrointestinal-associated lymphoid tissue (GALT). In the ileum, this highly organized lymphatic tissue is referred to as Peyer patches. They each contain a germinal center. The GALT is a subset of the mucosa-associated lymphatic tissue. Scattered lymphatic nodules may also be seen in the mucosa of other parts of the small bowel and colon but they are usually isolated single nodules. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

activated CD4+ T cells as well as a recently described and heterogeneous population of ILC. ILCs are now known to be key players in mucosal immunity; they release immunomodulatory cytokines, and a subset also produces IL-22 which supports epithelial homeostasis.⁸⁴ Similar to the lymphoid follicles of the spleen and lymph nodes, the mucosal follicles in the lamina propria contain mostly B cells, which sometimes are organized into germinal centers.

Solitary lymph nodules with follicular and germinal center structures occur in the mucosa and submucosa of the respiratory tract, the gastrointestinal tract (particularly within the ileum), the urinary tract, and the vagina. Microfolds overlying specialized epithelial cells in the gut transport antigenic material by pinocytosis, with potential subsequent activation of the immune response. During states of chronic inflammation, lymphoid nodules may form as a localized center of lymphocytes with marked follicular activity. The Waldeyer ring of pharyngeal lymphoid tissues and Peyer patches in the ileum contain prominent aggregated nodular lymphoid tissue. No capsule or efferent or afferent lymphatic vessels are present in these accessory lymphoid tissues.

The MALT are rich in plasma cells and eosinophils. The plasma cells are a source of secretory immunoglobulin that is transferred into the lumina of the bronchi and gastrointestinal tract. The majority of plasma cells in the mucosa of the bronchi and gut contain IgA.⁸⁵ IgA is released from the plasma cell and then combines with a secretory piece synthesized within the mucosal epithelium to become secretory IgA (Chap. 75). Secretory IgA then is secreted across the microvilli of mucosal epithelium into the lumen, where it may prevent colonization of mucosal membranes by pathogens. Lymphoid nodules along mucosa-lined tracts serve as precursors of IgA-producing cells. These nodules form a barrier against many microorganisms and antigens.⁸⁶

Peyer Patches

Peyer patches are the most important and highly organized of the GALT.⁸³ They are found in the lamina propria of the ileum (near the

ileocolonic junction) and consist of up to 50 or more lymphoid nodules covered by a single layer of columnar epithelium (see Fig. 6–9). They are well developed in youth and regress with age. Antigens from the intestinal epithelium are collected by specialized epithelial cells called M cells, allowing for generation of specific immune responses against intestinal pathogens.⁸⁷ Peyer patches are the sites at which B cells differentiate in response to these antigens into the plasma cells found within the intestine.⁸⁸

Tonsils

The tonsils are the major component of the Waldeyer ring of pharyngeal lymphoid tissues. They are covered by variable epithelial surfaces that have deep, branching depressions called crypts. Fused lymphatic nodules lie adjacent to the crypts, and germinal centers are prominent. A pseudocapsule of condensed connective tissue surrounds the tonsils, and septae within the structures form lobulations. Together with the other lymphoid tissues of the Waldeyer ring, the tonsils provide the initial barrier to pathogens entering the oral pharynx.

Part III **Epochal Hematology**

7. Hematology of the Fetus and Newborn 99

8. Hematology during Pregnancy 119

9. Hematology in Older Persons 129

CHAPTER 7

HEMATOLOGY OF THE FETUS AND NEWBORN

James Palis and George B. Segel

SUMMARY

During embryogenesis, hematopoiesis occurs in spatially and temporally distinct sites, including the extraembryonic yolk sac, the fetal liver, and the preterm marrow. The development of primitive erythroblasts in the yolk sac is critical for embryonic survival. Primitive erythroblasts differentiate within the vascular network rather than in the extravascular space and circulate as nucleated cells. Although it is widely assumed that primitive red cells remain nucleated throughout their life span, primitive erythroblasts ultimately enucleate upon terminal differentiation. After 7 weeks of gestation, hematopoietic progenitors are no longer detected in the yolk sac. Hematopoietic stem cells emerge from major arterial vessels at 5 weeks of gestation. The liver serves as the primary source of red cells from the 9th to the 24th week of gestation. Like primitive erythropoiesis in the yolk sac, definitive erythropoiesis in the fetal liver is necessary for continued survival of the embryo. In contrast to the yolk sac, where hematopoiesis is restricted to maturing primitive erythroid, macrophage, and megakaryocytic cells, hematopoiesis in the fetal liver consists of definitive erythroid, megakaryocyte, and multiple myeloid, as well as lymphoid lineages. Hematopoietic cells are first seen in the marrow of the 10- to 11-week embryo, and they remain confined to the diaphyseal regions of long bones until 15 weeks of gestation. Lymphopoiesis is present in the lymph plexuses and the thymus beginning at 9 weeks of gestation. Yolk sac stem cells were first thought to seed the liver and eventually the marrow. However, later experiments in avian and amphibian embryos indicate that the hematopoietic stem cells that seed the marrow arise within the body of the embryo proper rather than from the yolk sac. The aorta-gonad-mesonephros (AGM) region generates hematopoietic stem cells that seed the liver and the marrow to provide lifelong hematopoiesis. Hemoglobin (Hgb) Gower-1 ($\zeta_2\epsilon_2$) is the major hemoglobin in embryos younger than 5 weeks. Hgb F ($\alpha_2\gamma_2$) is the major hemoglobin of fetal life. The fetal hemoglobin concentration in blood decreases after birth by approximately 3 percent per week and is generally

Acronyms and Abbreviations: ADP, adenosine diphosphate; AGM, aorta-gonad-mesonephros; ATP, adenosine triphosphate; ATPase, adenosine triphosphatase; BFU-E, burst-forming unit–erythroid; BPG, bisphosphoglycerate; BPI, bacterial permeability-increasing protein; cAMP, cyclic adenosine monophosphate; CFU-E, colony-forming unit–erythroid; CFU-GEMM, colony-forming unit–granulocyte-erythroid-macrophage; CFU-GM, colony-forming unit–granulocyte-macrophage; CFU-Meg, colony-forming unit–megakaryocyte; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; MCV, mean cell volume; NBT, nitroblue tetrazolium; NK, natural killer; RDW, red cell distribution width; SIDS, sudden infant death syndrome; TNF, tumor necrosis factor; TPO, thrombopoietin.

less than 2 to 3 percent of the total hemoglobin by 6 months of age. The mean hemoglobin level in cord blood at term is 16.8 g/dL, with 95 percent of the values falling between 13.7 and 20.1 g/dL. The red cells of the newborn are macrocytic, with a mean cell volume in excess of 110 fL/cell. The red cell, hemoglobin, and hematocrit values decrease only slightly during the first week after birth, but decline more rapidly in the following 5 to 8 weeks, producing the physiologic anemia of the newborn. The absolute number of neutrophils in the blood of term and premature infants is usually greater than that found in older children. Segmented neutrophils are the predominant leukocytes in the first few days after birth. As their number decreases, the lymphocyte becomes the most numerous cell type and remains so during the first 4 years of life. Phagocytosis of bacteria by neutrophils from premature and term infants is normal. Bactericidal activity varies according to the conditions of testing and the clinical status of the neonates. The platelet counts in term and preterm infants are between 150 and 400 $\times 10^9/L$, comparable to adult values. The absolute number of lymphocytes in the newborn is equivalent to that in older children, with lower values in premature infants at birth. The absolute number of CD3+ and CD4+ (helper/inducer phenotype) T-cell subsets in blood of newborns is significantly higher than in adults. Humoral (B-cell) immunity also develops early in gestation, but it is not fully active until after birth. In the newborn, approximately 15 percent of lymphocytes have immunoglobulin on their surface, with all immunoglobulin isotypes represented. The term newborn has reduced mean plasma levels (<60 percent of adult levels) of factors II, IX, X, XI, and XII, prekallikrein, and high-molecular-weight kininogen. In contrast, the plasma concentration of factor VIII is similar and von Willebrand factor is increased compared to older children and adults.

FETAL HEMATOLYMPHOPOIESIS

PRODUCTION OF EMBRYONIC AND FETAL HEMATOPOIETIC CELLS

During embryogenesis, hematopoiesis occurs in spatially and temporally distinct sites, including the extraembryonic yolk sac, the fetal liver, the thymus, and the preterm marrow. The origin of hematopoietic cells is closely tied to gastrulation, the formation of mesoderm cells, and to the emergence of the endothelial lineage. Hematopoiesis is first established soon after implantation of the blastocyst, with the appearance of primitive erythroid cells in blood islands of the yolk sac beginning at day 18 of gestation.¹ The spatial and temporal association of embryonic red cells and endothelial cells in these blood islands suggests that the transient erythromyeloid potential of the yolk sac arises from heman-gioblast precursors that also contain endothelial potential.² This concept is supported by *in vitro* studies of human embryonic stem cells cultured as embryoid bodies.^{3,4} Hematopoietic stem cells, containing erythromyeloid and lymphoid potential, subsequently arise from intraembryonic vasculature, particularly the aorta (Fig. 7-1). These hematopoietic stem cells provide for fetal and long-term postnatal blood cell production. The ontogeny of the hematopoietic system remains a topic of active research using mammalian and several nonmammalian model systems.

Yolk Sac Hematopoiesis

“Primitive” red cells derived from the yolk sac constitute a distinct transient erythroid lineage that differs from “definitive” red cells that subsequently mature in the fetal liver and marrow. The development of primitive erythroblasts is critical for embryonic survival. In the mouse, targeted disruption of the transcription factors SCL (TAL1), LM02

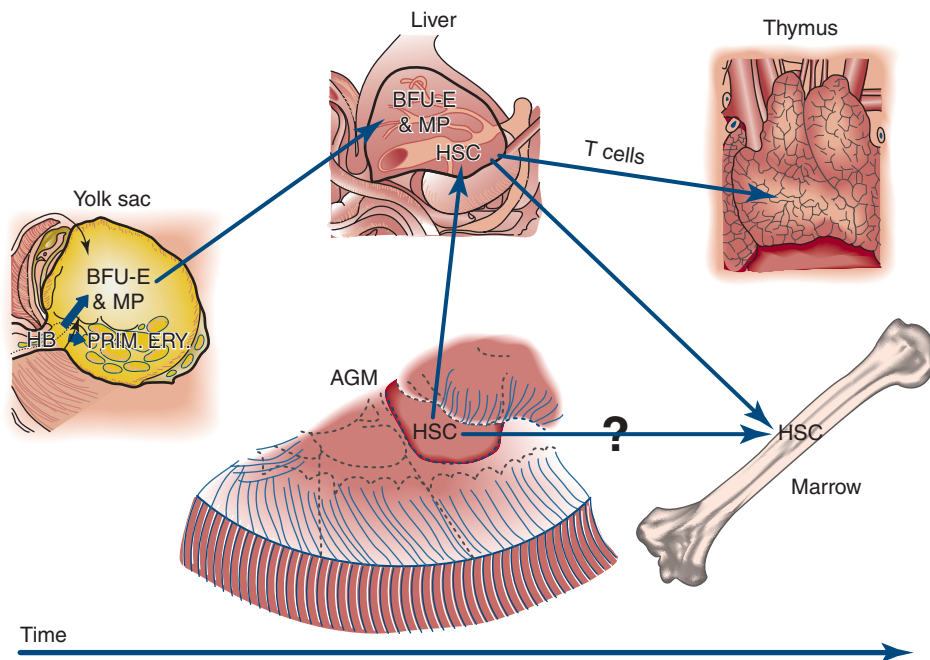

Figure 7-1. Hypothetical model of human hematopoietic ontogeny based on amphibian, avian, murine, and human developmental data. The yolk sac provides two transient populations of committed progenitors that are thought to arise from a mesoderm-derived hemangioblast (HB) precursor. The first wave of progenitors produces primitive erythroblasts (*PRIM. ERY.*) (see text). The second wave produces burst-forming unit-erythroid (*BFU-E*) and several myeloid progenitors (*MP*) that seed the liver. Long-term hematopoietic stem cells (*HSCs*) arise later in the aorta-gonad-mesonephros (*AGM*) region that subsequently populate the liver and ultimately the marrow to generate the full panoply of definitive hematopoiesis. The *HSCs* from liver also provide naïve lymphoid cells to the thymus, and T-lineage maturation occurs there.

(RBTN2), and GATA-1 abrogates primitive erythropoiesis in the yolk sac and leads to early embryonic death.⁵⁻⁷ In the human, primitive erythroblasts begin to enter the embryo proper at days 21 to 22 of gestation with the onset of cardiac contractions⁸ and circulate until approximately 12 weeks of gestation. Yolk sac erythroblasts have several characteristics that distinguish them from their later definitive counterparts. Primitive erythroblasts circulate as nucleated cells, accumulating embryonic hemoglobins and completing terminal differentiation within the vascular network.⁹ Because of their extremely large size, with an estimated MCV of >400 fL/cell, yolk sac erythroblasts have been termed *megaloblasts*. Although it is widely assumed that primitive red cells remain nucleated throughout their life span, human primitive erythroblasts, like their murine counterparts, ultimately enucleate upon terminal differentiation.¹⁰⁻¹²

In the mouse, primitive red cells are derived from a transient population of primitive erythroid progenitors that is confined to the yolk sac.¹³ Ultrastructural examination of the human yolk sac reveals the presence, not only of primitive erythroblasts, but also of macrophage cells and megakaryocytes.¹¹ These findings are consistent with hematopoietic progenitor studies in the mouse embryo and in human embryonic stem cells differentiated *in vitro*, which support the concept that “primitive” hematopoiesis in the yolk sac consists of primitive erythroid, macrophage, and megakaryocyte lineages.¹³⁻¹⁵

The initial wave of primitive erythroid progenitors is followed by a second wave of yolk sac-derived definitive erythroid progenitors, termed *burst forming units-erythroid* (BFU-E). BFU-E are present in the human yolk sac as early as 4 weeks’ gestation and are found in the fetal liver by 5 weeks’ gestation.¹⁶ These findings suggest that the fetal liver is initially seeded by hematopoietic progenitors derived from the yolk sac (see Fig. 7-1).¹⁷ Erythroid and nonerythroid progenitors are evident also in the nonliver regions of the embryo proper.¹⁸ After 7 weeks’ gestation, hematopoietic progenitors are no longer detected in the yolk sac.¹⁹

Hepatic Hematopoiesis

The liver serves as the primary source of red cells from the 9th to the 24th weeks of gestation. Between 7 and 15 weeks’ gestation, 60 percent of the liver cells are hematopoietic.²⁰ Erythroid cells differentiate in close

physical association with macrophages and extrude their nuclei prior to entering the blood. These fetal-liver-derived definitive “macrocytes” are smaller than yolk sac-derived primitive megaloblasts and contain one-third the amount of hemoglobin. Differentiation of murine erythroid cells in the fetal liver is critically dependent on erythropoietin signaling through its receptor and the Janus kinase 2 (JAK2) pathway.^{21,22} Fetal-liver-derived erythroid progenitors can differentiate *in vitro* with erythropoietin alone, in contrast to adult marrow-derived BFU-E, which requires erythropoietin plus interleukin (IL)-3 or stem cell factor.^{23,24} Erythropoietin transcripts are present during the first trimester in the liver, which remains a primary site of erythropoietin transcription throughout fetal life.²⁵ Erythropoietin transcripts also are present in the developing human kidney as early as 17 weeks’ gestation and increase after 30 weeks.²⁵ Like primitive erythropoiesis in the yolk sac, definitive erythropoiesis in the fetal liver is necessary for continued survival of the embryo. Targeted disruption of the *c-myc* transcription factor in the mouse blocks fetal liver erythropoiesis and leads to fetal death.²⁶ This mutation does not affect primitive erythropoiesis, indicating fundamental differences in the transcriptional regulation of these distinct forms of erythropoiesis.

In contrast to the yolk sac, where hematopoiesis is restricted primarily to erythromyeloid lineages, hematopoiesis in the fetal liver eventually will consist of definitive erythroid, megakaryocyte, multiple myeloid, as well as, lymphoid lineages. Megakaryocytes are present in the liver by 6 weeks’ gestation. Platelets are first evident in the circulation at 8 to 9 weeks’ gestation.²⁰ Granulopoiesis is present in the liver parenchyma as early as 7 weeks’ gestation and small numbers of circulating leukocytes are present at the 11th week of gestation. Despite the low number and immature appearance of hepatic neutrophils, the fetal liver contains abundant hematopoietic progenitor cells, including the multipotential colony-forming unit-granulocyte-erythroid-monocyte-macrophage (CFU-GEMM) and colony-forming unit-granulocyte-monocyte (CFU-GM).²⁷ CFU-GM growth depends upon several cytokines, including granulocyte colony-stimulating factor (G-CSF), granulocyte-monocyte colony-stimulating factor (GM-CSF), and interleukins. When compared to adult marrow-derived myeloid progenitors, these fetal liver-derived myeloid progenitors have a similar

dose–response *in vitro* to G-CSF.²⁸ G-CSF is expressed by hepatocytes at 14 weeks' gestation.²⁹

Lymphopoiesis

Lymphopoiesis is present in the lymph plexuses and the thymus beginning at 9 weeks' gestation.²⁰ B cells with surface immunoglobulin (Ig) M are present in the liver, and circulating lymphocytes also are seen at 9 weeks' gestation. T lymphocytes are found only rarely before 12 weeks' gestation.³⁰ Lymphocyte subpopulations are detected by 13 weeks' gestation in fetal liver.³¹ Absolute numbers of major lymphoid subsets in 20- to 26-week-old fetuses, as defined by the antigens CD2, CD3, CD4, CD8, CD16, CD19, and CD20, are similar to those in newborns (see “Neonatal Lymphopoiesis” below).^{32,33}

Marrow Hematopoiesis

Hematopoietic cells are first seen in the marrow of the 10- to 11-week embryo,¹ and they remain confined to the diaphyseal regions of long bones until 15 weeks' gestation.³⁴ Initially, there are approximately equal numbers of myeloid and erythroid cells in the fetal marrow. However, myeloid cells predominate by 12 weeks' gestation, and the myeloid-to-erythroid ratio approaches the adult level of 3:1 by 21 weeks' gestation.²⁰ Macrophage cells in the fetal marrow, but not in the fetal liver, express the lipopolysaccharide receptor CD14.²⁹ The marrow becomes the major site of hematopoiesis after the 24th week of gestation and remains so throughout the remainder of fetal life.

ONTOGENY OF HEMATOPOIETIC STEM CELLS

The reconstitution of the entire hematopoietic system by transplantation with cord blood indicates that hematopoietic stem cells are circulating in the blood at birth.³⁵ The immunologic reconstitution of an immunodeficient human fetus with fetal-liver-derived cells also indicates that hematopoietic stem cells exist in the late gestation fetal liver.³⁶ It was first postulated that hematopoietic stem cells originate independently in each hematopoietic site (yolk sac, liver, and marrow) of the embryo.³⁷ However, experiments in the mammalian embryo indicate that the liver rudiment, like the marrow, is seeded by exogenous hematopoietic cells.^{38,39} It was initially thought that the liver, and eventually the marrow, were seeded by yolk sac–derived hematopoietic stem cells.⁴⁰ However, experiments in avian and amphibian embryos indicate that the hematopoietic stem cells that ultimately provide for long-term adult hematopoiesis arise within the body of the embryo proper rather than from the yolk sac.^{41,42} Subsequent investigations in the mouse embryo indicate that stem cells capable of engrafting myeloablated adult recipients originate in the aorta-gonad-mesonephros (AGM) region of the embryo proper.⁴³ Cells capable of long-term engraftment of immunodeficient mice also first originate at 35 days of gestation in the aorta region of human embryos.⁴⁴ This correlates anatomically with the transient appearance of clusters of CD34+ blood cells closely associated with the ventral wall of the aorta in several mammalian species, including the 5 weeks' gestation human embryo.^{45,46} These findings, as well as direct visualization of developing zebrafish embryos,⁴⁷ support the concept that hematopoietic stem cells arise from “hemogenic” aortic endothelium through an endothelial-to-hematopoietic transition and then seed the liver, and eventually the marrow, to provide lifelong hematopoiesis (see Fig. 7–1). Studies in the murine embryo indicate that the placenta also serves as a site of hematopoietic stem cell origin and expansion.⁴⁸ It is not known if the placenta serves a similar function during human development. The underlying relationship of the transient erythromyeloid hematopoiesis derived from the yolk sac to long-term hematopoietic stem cell–derived intraembryonic hematopoiesis remains unclear. However, studies in the mouse indicate that resident macrophage populations in multiple organs of the adult, particularly microglia in

the brain, are ultimately derived from the yolk sac of the embryo and undergo limited maintenance after birth from hematopoietic stem cells.^{49,50}

SYNTHESIS OF FETAL HEMOGLOBINS

Human hemoglobin (Hgb) is a tetramer composed of two α -type and two β -type globin chains (Table 7–1). The α -globin gene cluster is located on chromosome 16 and contains the ζ gene 5' to the pair of α -globin genes. The β -globin gene cluster is located on chromosome 11 and contains five globin genes oriented 5' to 3' as ϵ - γ ^A- γ ^G- δ - β .⁵¹ During embryogenesis the genes on both chromosomes are activated sequentially from the 5' to the 3' end. This globin “switching” is related not only to the relative positions of the globin genes within their respective chromosomal clusters, but also to interacting upstream “locus control regions.”⁵²

Hgb Gower-1 ($\zeta_2\epsilon_2$) is the major hemoglobin in embryos younger than 5 weeks' gestation (see Table 7–1).⁵³ Hgb Gower-2 ($\alpha_2\epsilon_2$) has been found in embryos with a gestational age as young as 4 weeks and is absent in embryos older than 13 weeks.⁵⁴ Hgb Portland ($\zeta_2\gamma_2$) is found in young embryos, but persists in infants with homozygous α -thalassemia (Chap. 48). Synthesis of the ζ and ϵ chains decreases as those of the α and γ chains increase (Fig. 7–2). The ζ -to- α -globin switch precedes the ϵ -to- γ -globin switch as the liver replaces the yolk sac as the main site of erythropoiesis.^{9,55}

Hgb F ($\alpha_2\gamma_2$) is the major hemoglobin of fetal life (see Fig. 7–2).⁵⁶ Synthesis of Hgb A can be demonstrated in fetuses as young as 9 weeks' gestation.⁵⁷ In fetuses of 9 to 21 weeks' gestation, the amount of Hgb A ($\alpha_2\beta_2$) rises from 4 to 13 percent of the total hemoglobin.⁵⁷ These levels of Hgb A have enabled the antenatal diagnosis of β -thalassemia using globin-chain synthesis. After 34 to 36 weeks' gestation the percentage of Hgb A rises, whereas that of Hgb F decreases (see Fig. 7–2). The mean synthesis of Hgb F in term infants was 59.0 ± 10 percent (1 SD) of total hemoglobin synthesis as assessed by ¹⁴C-leucine uptake.⁵⁸ The amount of Hgb F in blood varies in term infants from 53 to 95 percent of total hemoglobin.⁵⁹

The fetal hemoglobin concentration in blood decreases after birth by approximately 3 percent per week and is generally less than 2 to 3 percent of the total hemoglobin by 6 months of age. This rate of decrease in Hgb F production is closely related to the gestational age of the infant and is not affected by the changes in environment and oxygen tension that occur at the time of birth.⁶⁰ Hgb A₂ ($\alpha_2\delta_2$) has not been detected in fetuses. Normal adult levels of Hgb A₂ are achieved by 4 months of age.⁶¹ Increased proportions of Hgb F at birth have been reported in infants who are small for gestational age, who have experienced chronic intrauterine hypoxia, who have trisomy 13, or who have died from sudden infant death syndrome (SIDS).^{62–66} Decreased levels of Hgb F at birth are found in trisomy 21.⁶⁷

TABLE 7–1. Embryonic Hemoglobins

Hemoglobin	Chain Composition	Primary Site	Appearance
Gower-1	$\zeta_2\epsilon_2$	Yolk sac	<5–6 weeks
Gower-2	$\alpha_2\epsilon_2$	Yolk sac	4–13 weeks
Portland	$\zeta_2\gamma_2$	Yolk sac	4–13 weeks
Fetal (F)	$\alpha_2\gamma_2$	Liver	Early, 53–95% at term
Adult (A)	$\alpha_2\beta_2$	Marrow	9 weeks, 5–45% at term

FETAL BLOOD

The cellular composition of fetal blood changes markedly during the second and third trimesters. The mean blood hemoglobin concentration in fetuses progressively increases from 9.0 ± 2.8 g/dL at age 10 weeks to 16.5 ± 4.0 g/dL at age 39 weeks.⁶⁸ There is a concomitant decrease in the MCV of fetal red cells from a mean of 134 fL/cell at 18 weeks' gestation to 118 fL/cell at 30 weeks' gestation.⁶⁹ The total white blood cell count averages 2×10^9 /L between 10 and 17 weeks of gestation,³¹ and increases during the middle trimester to between 4.0 and 4.5×10^9 /L, with an 80 to 85 percent preponderance of lymphocytes and 5 to 10 percent neutrophils.⁶⁹ The percentage of circulating nucleated red cells decreases from a mean of 12 percent at 18 weeks to 4 percent at 30 weeks.⁶⁹ The platelet count remains greater than 150,000/ μ L from 15 weeks' gestation to term.^{69,70}

Large numbers of committed hematopoietic progenitors circulate in the fetal blood. Blood samples obtained by fetoscopy at 12 to 19 weeks' gestation reveal a mean of 20,450 BFU-E/mL and 12,490 CFU-GM/mL.⁷¹ This is in striking contrast to adult blood, which contains many fewer erythroid progenitors and 30 to 250 CFU-GM/mL.^{70,72} Most (70–80%) circulating hematopoietic progenitors at 26 to 28 weeks' gestation are cycling.⁷² In contrast, adult-marrow-derived progenitors in the bloodstream are relatively quiescent with only 0 to 5 percent cycling.

NEONATAL HEMATOPOIESIS

NEONATAL ERYTHROPOIESIS AND RED CELLS

Hemoglobin, Hematocrit, and Indices

The mean hemoglobin level in cord blood at term is 16.8 g/dL, with 95 percent of the values falling between 13.7 and 20.1 g/dL.⁷³ This variation reflects perinatal events, particularly asphyxia,⁷⁴ and also the amount

of blood transferred from the placenta to the infant after delivery. Early cord clamping appears to heighten the occurrence of anemia at 2 months and to impair cardiopulmonary adaptation.⁷⁵ Delay of cord clamping may increase the blood volume and red cell mass of the infant by as much as 55 percent.^{76,77} This results in fewer transfusions and fewer days requiring oxygen and ventilation in preterm infants.⁷⁵ The mean total blood volume after birth is 86 mL/kg for the term infant and 89 mL/kg for the premature infant.⁷⁸ The blood volume per kilogram decreases over the ensuing weeks, reaching a mean value of approximately 65 mL/kg by 3 to 4 months of age.

Normally the hemoglobin and hematocrit values rise in the first several hours after birth because of the movement of plasma from the intravascular to the extravascular space.⁷⁹ A venous hemoglobin concentration of less than 14 g/dL in a term infant and/or a fall in hemoglobin or hematocrit level in the first postnatal day are abnormal. Table 7-2 shows the normal red cell values from capillary blood samples for term infants in the first 12 weeks after birth.⁸⁰ Capillary hematocrit values in newborns are higher than those in simultaneous venous samples, particularly during the first postnatal days, and the capillary-to-venous ratio is approximately 1.1:1.⁸¹ This difference reflects circulatory factors and is greater in preterm and sick infants.

The red cells of the newborn are macrocytic, with an MCV in excess of 110 fL/cell. The MCV begins to fall after the first week, reaching adult values by the ninth week (see Table 7-2).^{80,82} The blood film from a newborn infant shows macrocytic normochromic cells, polychromasia, and a few nucleated red blood cells. Even in healthy infants there may be mild anisopoikilocytosis.⁸³ Three to 5 percent of the red cells may be fragments, target cells, or otherwise distorted. By 3 to 5 days after birth, nucleated red blood cells are not found normally in the blood of term or premature infants, but they may be present in markedly elevated numbers in the presence of hemolysis or hypoxic stress. As

expected from these findings, the red cell distribution width (RDW) is markedly elevated in the newborn period.⁸⁴

There are significant numbers of circulating progenitor cells in cord blood.^{85–87} Cord blood BFU-E and colony-forming unit–erythroid (CFU-E) differentiate more rapidly than their adult counterparts.⁸⁸ Furthermore, the proportion of cord blood hematopoietic progenitors in the mitotic cycle is approximately 50 percent, intermediate between the proportions found in fetal and adult progenitor cells.^{72,86}

In several,^{89,90} but not all,⁹¹ studies, premature infants at birth had lower hemoglobin levels, higher reticulocyte counts, and higher nucleated red cell counts than did the term infants. The reticulocyte counts of premature infants are inversely proportional to their gestational age, with a mean of 8 percent reticulocytes evident at 32 weeks' gestation and 4 to 5 percent at term.⁹² Infants who are small for their gestational ages have higher red cell counts, hematocrit levels, and hemoglobin concentrations as compared with infants whose size is appropriate for their gestational age.^{90,93}

Erythropoietin and Physiologic Anemia of the Newborn Erythropoietin is the primary regulator of erythropoiesis (Chaps. 32 and 33). Although erythropoietin is present in cord blood, it falls to undetectable levels after birth in healthy infants.⁹⁴ Subsequently, the reticulocyte count falls to less than 1 percent by the sixth day after birth.^{80,95} The red cell, hemoglobin, and hematocrit values decrease only slightly during the first week, but decline more rapidly in the following 5 to 8 weeks (see Table 7-2),⁸⁰ producing the physiologic anemia of the newborn. The lowest hemoglobin values in the term infant occur at approximately

2 months of age.⁸² When the hemoglobin concentration falls below 11 g/dL, erythropoietic activity begins to increase. Erythropoietin can be measured after the 60th postnatal day,⁹⁶ corresponding to the recovery from physiologic anemia. If there is sufficient stimulus, such as hemolytic anemia or cyanotic heart disease, the newborn infant is able to produce erythropoietin prior to the 60th postnatal day.⁹⁴

The fall in hemoglobin level is more pronounced in the premature infant. In one study of premature infants, the mean hemoglobin level at 2 months was 9.4 g/dL, with a 95 percent range of 7.2 to 11.7 g/dL.⁹⁷ In healthy premature infants erythropoietin becomes detectable when the hemoglobin level falls to approximately 12 g/dL. In infants with a lower percentage of Hgb F (as from transfusion) and, consequently, better oxygen delivery, erythropoietin does not rise until the hemoglobin falls to approximately 9.5 g/dL.⁹⁸ The mean values for iron-sufficient premature infants reached those of term infants by 4 months for red cell count, 5 months for hemoglobin level, and 6 months for mean corpuscular volume and mean corpuscular hemoglobin.⁹⁷

Blood Viscosity The viscosity of blood increases logarithmically in relation to the hematocrit.^{99,100} Hyperviscosity was found in 5 percent of infants,¹⁰¹ and in 18 percent of infants who were small for gestational age.¹⁰² Newborn infants with hematocrit values of greater than 65 to 70 percent may become symptomatic because of increased viscosity.¹⁰³ In one study of infants with documented hyperviscosity and a mean hematocrit greater than 65 percent, 38 percent displayed symptoms of irritability, hypotonia, tremors, or poor suck reflex.¹⁰⁴ Partial plasma exchange transfusion reduced blood viscosity, improved cerebral blood

flow, and relieved the symptoms. However, cerebral blood flow was normal in the asymptomatic infants with hyperviscosity, and, consequently, there was no benefit from exchange transfusion.¹⁰⁴ Studies of neurodevelopmental status do not show any clear long-term benefits for the use of partial exchange transfusions in asymptomatic neonates.¹⁰⁵

Red Cell Antigens The blood group antigens on neonatal red cells differ from those of the older child and adult. The *i* antigen is expressed strongly, whereas the *I* antigen and the *A* and *B* antigens are expressed only weakly on neonatal red cells. The *i* antigen is a straight-chain carbohydrate that is replaced by the branched-chain derivative, *I* antigen, as a result of the developmental acquisition of a glycosyltransferase.¹⁰⁶ By 1 year of age the *i* antigen is undetectable, and the ABH antigens increase to adult levels by age 3 years (Chap. 136). The ABH, Kell, Duffy, and Vel antigens can be detected on the cells of the fetus in the first trimester and are present at birth.¹⁰⁷ The *Lu^a* and *Lu^b* antigens also are detectable on fetal red cells and are more weakly expressed at birth, increasing to adult levels by age 15 years.¹⁰⁷ The *Xg* antigen is variably expressed in the fetus and is weaker on newborn than on adult red cells. Moreover, particularly poor expression of *Xg* has been noted in newborns with trisomy 13, 18, and 21.¹⁰⁷ The Lewis group (*Le^a/Le^b*) antigens are adsorbed on the red cell membrane and become detectable within 1 to 2 weeks after birth as the receptor sites develop. Anti-*A* and anti-*B* isohemagglutinins develop during the first 6 postnatal months, reaching adult levels by 2 years of age.

Red Cell Life Span The life span of the red cells in the newborn infant is shorter than that of red cells in the adult (Chap. 33). The average of several studies of mean half-life of newborn red cells is 60 to 80 days.¹⁰⁸ The reasons for this shortened survival are unclear, but the known susceptibility to oxidant injury of newborn red cells may be a contributing factor.

Iron and Transferrin The serum iron level in cord blood of the normal infant is elevated compared to maternal levels. The mean value is approximately 150 ± 40 mcg/dL (1 SD).¹⁰⁹ Infants on an iron-supplemented diet have a median serum iron level of 125 mcg/dL at 1 month of age and of approximately 75 mcg/dL at 6 months of age. The total iron-binding capacity rises throughout the first year. The median transferrin saturation falls from almost 65 percent at 2 weeks to 25 percent at 1 year, and saturations as low as 10 percent may be observed in the absence of iron deficiency.¹¹⁰ The mean serum ferritin levels in iron-sufficient infants are high at birth, 160 mcg/L, rise further during the first month, and then fall to a mean of 30 mcg/L by 1 year of age.¹¹¹ The amount of stainable iron in the marrow at birth is small but increases in both term and premature infants during the first weeks after birth. Stainable marrow iron begins to decrease after 2 months and is gone by 4 to 6 months in term infants and earlier in premature infants.¹¹² Iron is preferentially allocated to erythropoiesis if the availability of iron is limited.¹¹³ This makes the availability of adequate iron particularly important to avoid iron lack in the brain, heart, and skeletal muscle.

Red Cell Functions

Oxygen Delivery The oxygen affinity of cord blood is greater than that of maternal blood, because the affinity of Hgb F for 2,3-bisphosphoglycerate (2,3-BPG) is less than that of Hgb A.¹¹⁴ Levels of 2,3-BPG are lower in newborn red cells than in adult cells and even more decreased in the red cells of premature infants,¹¹⁵ and this low 2,3-BPG level further heightens the oxygen affinity of newborn red cells. Consequently, the red cell oxygen equilibrium curve of the newborn is shifted to the left of that of the adult (Fig. 7-3). The mean partial pressure of oxygen (pO_2) at which hemoglobin is 50 percent saturated with oxygen at 1 day of age in term infants is 19.4 ± 1.8 torr, as compared with the normal adult value of 27.0 ± 1.1 torr.¹¹⁶ This results in a decrease in the oxygen released at the tissue level, as shown in Fig. 7-3. As the partial pressure of oxygen

Figure 7-3. The oxygen equilibrium curves are based on the assumption that the Hgb concentration is 15 g/dL and that there is full O₂ saturation of Hgb at a partial pressure of arterial oxygen (P_{aO_2}) of 100 torr. The O₂ released is the difference in O₂ content between a P_{aO_2} of 90 torr and the mixed venous P_{aO_2} of 40 torr. The O₂ available is the difference in O₂ content between a P_{aO_2} of 90 torr and a mixed venous P_{aO_2} of 20 torr. This is the maximum O₂ available without evoking compensatory mechanisms such as increased cardiac output.

(P_{O_2}) falls from 90 torr in arterial to 40 torr in the venous blood, 3.0 mL/dL of oxygen are released from newborn blood, whereas 4.5 mL/dL are released from adult Hgb A-containing blood. The shift to the left of the oxygen equilibrium curve is even more pronounced in the premature infant, requiring a larger fall in P_{O_2} to release an equivalent amount of oxygen. After birth the oxygen equilibrium curve shifts gradually to the right, reaching the position of the adult curve by 6 months of age. The position of the curve in the premature infant correlates with gestational age rather than with postnatal age,¹¹⁶ and its shift to the adult position is more gradual.

Metabolism Many differences have been found between the metabolism of the red cells of newborn infants and that of adults.^{117,118} Some of the differences may be explained by the younger mean cell age in the newborn, but others seem to be properties of the fetal cell. The glucose consumption in newborn red cells is lower than that in adult red cells.¹¹⁹ Elevated levels of glucose phosphate isomerase, glyceraldehyde-3-phosphate dehydrogenase, phosphoglycerate kinase, and enolase beyond those explainable by the young cell age have been found in neonatal cells.^{115,120} The level of phosphofructokinase is low in red cells of term and premature infants.^{115,120,121} The pentose phosphate shunt is active in red cells of term and premature infants,¹²² but glutathione instability leads to a heightened susceptibility to oxidant injury. The result of oxidant stress is depletion of adenosine triphosphate (ATP) and adenine nucleotides leading to iron release, denaturing of membrane proteins, and hemoglobin and membrane peroxidation.¹²³ The levels of ATP and adenosine diphosphate (ADP) are higher in the red cells of term and preterm infants,¹²¹ but may merely reflect the younger age of the erythrocyte population. Finally, lower-than-adult activities have been found for several other red cell enzymes, including cytochrome *B₅* reductase¹²⁴ and glutathione peroxidase.¹²⁵

Membrane The membrane of the newborn red cell also is different from that of the adult red cell. Ouabain-sensitive adenosine triphosphatase (ATPase) is decreased,¹²⁶ and active potassium influx is significantly less in neonatal red cells.¹²⁷ Newborn cells are more

*All white cell counts are expressed as cells $\times 10^9/L$.

Data from Altman PL, Dittmer DS: *Blood and Other Body Fluids*. Federation of American Societies for Experimental Biology, Washington, DC, 1961 and Dallman PR: *Pediatrics*, 16th edition. New York, NY: Appleton-Century-Crofts, 1977.

sensitive to osmotic hemolysis and to oxidant injury than are adult cells. Newborn red cell membranes have higher total lipid, phospholipid, and cholesterol per cell than adult red cells.^{128,129} The patterns of phospholipid and phospholipid fatty acid composition also differ from those in adult red cells. Red cells of newborns have the same pattern of membrane proteins on polyacrylamide gel electrophoresis¹³⁰ and the same rate of mobility in an electric field¹³¹ as do red cells from adults. After trypsin treatment of newborn and adult cells, however, there is a difference in electrophoretic mobility, indicating that the surface trypsin-resistant proteins are different.¹³¹ The relationship of the metabolic and membrane alterations in neonatal red cells to their shorter life span is not clear.

WHITE CELLS

Granulocytopoiesis and Monocytopoiesis

Colony-Stimulating Factors and Granulomonopoiesis The absolute number of neutrophils in the blood of term and premature infants usually is greater than that found in older children (Table 7-3).¹³² The neutrophil count tends to be lower in the premature than in the term infant, and the proportion of myelocytes and band neutrophils is higher.¹³³ Serum and urinary colony-stimulating activity are elevated during the period of neutrophilia.¹³⁴ When granulopoiesis was studied in cord blood, blood, and marrow of infants, the macrophage colony-forming unit was predominant despite the clinical neutrophilia, and this pattern was not altered by different sources of colony-stimulating factors.^{135,136} The endogenous cytokines produced by mononuclear cells from cord or systemic venous blood support the growth of neutrophil colonies in assays using marrow from adults.¹³⁵ However, there is diminished GM-CSF, G-CSF, and IL-3 production in stimulated newborn compared to adult mononuclear cells,¹³⁷⁻¹³⁹ which may limit the response to bacterial infection in the newborn. Furthermore, preterm infants have a reduced neutrophil storage pool and a restricted capacity to increase their progenitor proliferation, and their neutrophil count may fall precipitously with neonatal bacterial infection.¹⁴⁰ Dysregulation, as well as

diminished capacity of neonatal granulopoiesis, may impair the neonatal response to infection.¹⁴¹ Smaller numbers of CFU-GM colonies were observed in the blood of sick infants, who also have diminished endogenous production of colony-stimulating factors in culture.¹³⁶ The clinical use of cytokines to treat neonatal sepsis remains controversial,¹⁴² but circulating neutrophils are increased in preterm infants treated with recombinant G-CSF, and the infants' length of stay in the neonatal intensive care unit is shortened.¹⁴³

White Cell and Differential Counts Table 7-3 gives the values for the white cell and differential counts during the first 2 weeks after birth. The absolute number of segmented neutrophils rises in both term and premature infants in the first 24 hours.¹⁴⁴ In term infants, the mean value increases from $8 \times 10^9/L$ to a peak of $13 \times 10^9/L$ and then falls to $4 \times 10^9/L$ by 72 hours of age, remaining at this level through the following 7 days. In the premature infant, the mean values for neutrophils are $5 \times 10^9/L$ at birth, $8 \times 10^9/L$ at 12 hours, and $4 \times 10^9/L$ at 72 hours. The mean count then falls gradually to $2.5 \times 10^9/L$ by the 28th postnatal day. The level after the first 72 hours is very stable for an individual infant, whether term or premature. Immature forms, including an occasional promyelocyte and blast cell, may be seen in the blood of healthy infants in the first few days after birth and are more frequent in premature infants than in term infants.¹⁴⁴ Segmented granulocytes are the predominant cells in the first few days after birth. As their number decreases, the lymphocyte becomes the most numerous cell and remains so during the first 4 years of life. An absolute eosinophil count of greater than $0.7 \times 10^9/L$ was found in 76 percent of premature infants at 2 to 3 weeks of age. The onset of the eosinophilia coincided with the establishment of steady weight gain in the infants.¹⁴⁵ It is increased by the use of total parenteral nutrition, endotracheal intubation, and blood transfusions.

Phagocyte Functions

Bacterial infections are a major cause of morbidity and mortality in the newborn period.¹⁴⁶ The infections frequently are caused by organisms of low virulence in normal children and adults, including *Staphylococcus* and Lancefield group B β -hemolytic streptococci, but, also, by

Pseudomonas, and other Gram-negative bacilli. Cellular defense mechanisms and humoral immunity of the newborn differ from those found later in life, and these undoubtedly contribute to the unusual susceptibility to infection noted in the neonatal period.¹⁴⁶

Opsonins and Complement Engulfment and destruction of bacteria by neutrophils depend on opsonic activity of the plasma and on chemotaxis, phagocytosis, and the bacteriocidal capacity of the leukocyte. The serum factors necessary for optimal phagocytosis (opsonins) include the immunoglobulins and complement components. In term infants, opsonic activity is normal for *Staphylococcus aureus*,^{147,148} but it is low for yeast¹⁴⁹ and *Escherichia coli*.^{147,148} Diminished opsonic antibody is associated with group B streptococcal infection and represents one risk factor for neonatal infection.¹⁵⁰

In premature infants, opsonic activity is low for *S. aureus* and *Serratia marcescens*,¹⁴⁷ but is normal for *Pseudomonas aeruginosa*.¹⁵¹ When serum concentrations of fibronectin and IgG subclasses C3 and C4 were measured at birth, 1 month, 3 months, and 6 months, early gestational age was correlated with lower initial levels.¹⁵² The decreased opsonic activity for some organisms in premature infants is attributed to diminished IgG levels, because additional IgG will correct the opsonic defect both *in vivo* and *in vitro*.¹⁴⁷ The added IgG improves bacterial opsonization by serum of premature infants in part because complement consumption and deposition of C3 on the bacterial surface are augmented.^{153,154}

Complement components appear in fetal blood before 20 weeks' gestation and increase markedly during the third trimester. However, in many newborns both the classical and alternative complement pathways are decreased in activity and in levels of individual components.¹⁵⁵ The mean level of C3, the first common component of the two pathways of complement activation, is approximately 65 percent of that in normal adults.^{156–158} There is no transplacental transfer of this protein, and levels in infants are lower than those in their mothers.¹⁵⁶ Total serum hemolytic complement (CH₅₀) and alternative pathway activity (PH₅₀) in newborns are lower than in adults, as are mean levels of C1q, C2–C9, properdin, and factors B, I, and H.^{157–159} In general, the mean levels in full-term infants are greater than 50 percent of those in normal adult controls and may be somewhat less in premature infants. There is considerable overlap, however, between levels in infants and in controls. A functional deficiency in the alternative pathway has been detected in infants.¹⁶⁰

Fibronectin mediates more efficient interactions between phagocytes and infectious agents. Fibronectin, a 450-kDa glycoprotein found in plasma and in the intercellular matrix, promotes the attachment of staphylococci to neutrophils¹⁶¹ and enhances opsonic activity of antibodies against group B streptococci.¹⁶² Because both these bacteria are common pathogens for neonates, the deficiency in fibronectin observed in neonates¹⁶³ may further compromise opsonic capacity and hence bactericidal activity in the neonate.

The administration of intravenous IgG may be useful in the treatment or prophylaxis of infection in preterm infants based on the reduced placental transfer of maternal antibody and the restricted endogenous synthesis of IgG.¹⁶⁴ IgG administered to septic neonates appears to enhance serum opsonic capacity as well as to increase the quantity of circulating neutrophils.¹⁶⁵ In premature neonates, added IgG heightens granulocyte phagocytosis.^{165,166} Intravenous IgG has been reported to effectively treat infected premature neonates, but these reports involved small numbers of subjects.^{167,168} The clinical efficacy of IgG prophylaxis against neonatal pathogens is not firmly established.^{169,170} New IgG preparations with consistent, adequate levels of antibodies directed against neonatal pathogens can be achieved by selection of sera with high levels of functional antibodies,¹⁷¹ or potentially by the addition of monoclonal antibodies, and these may prove more effective.

Chemotaxis Chemotactic function of leukocytes is low in neonates, whereas random motility is normal.^{172–174} Neonatal serum does not generate as much chemotactic factor as does adult serum, even after the addition of purified C3. The defect in chemotaxis may be related to decreased granulocyte deformability and impaired capping of cell surface receptors.¹⁷⁵ The role of observed cyclic adenosine monophosphate (cAMP) and membrane potential alterations in the defective chemotaxis is not clear.¹⁷⁵ The ability of neutrophils to roll along the blood vessel endothelium also is impaired in neonates. Diminished upregulation and surface migration of β_2 integrins and fewer L-selectin receptors reduce the ability of neonatal neutrophils to interact with adhesion molecules on the endothelium.¹³⁹

The densities of the C3bi receptor (CD11b/CD18) and of the low-affinity receptor for immunoglobulin, FcRIII (CD16), are decreased on neutrophils of premature infants, whereas term infants' cells show a lesser impairment.^{176–178} The deficient upregulation of C3bi correlates with decreased adherence and chemotaxis by neonatal neutrophils.¹⁷⁹ Low FcRIII is associated with impaired chemotaxis of neonatal neutrophils,¹⁸⁰ although decreased FcRIII might also be responsible for subtle defects in adherence and subsequent phagocytosis of opsonized¹⁷¹ and unopsonized¹⁸¹ organisms by neutrophils.

Adherence Neutrophil cell adhesion molecules are central to the bonding of neutrophils to the vascular endothelium, and reduction of these molecules diminishes the capacity of neonatal neutrophils to properly adhere and migrate (Chap. 19).¹⁸² Although L-selectin, a key adhesion molecule, is expressed at high levels on hematopoietic progenitor cells, it decreases markedly during the first 3 days of life and remains low compared to adult levels during the first weeks, impairing the neutrophil's ability to "roll" as part of the adhesion process. Also, there are defects in expression of CD18/CD11b, which are members of the β_2 -integrin family of adhesion molecules.¹⁸³ These characteristics likely contribute to the newborn susceptibility to bacterial infections.

Phagocytic and Bactericidal Activity Phagocytosis of bacteria and latex granules by neutrophils from premature and term infants is normal.^{147,151,184} Bactericidal activity varies according to the conditions of testing and the clinical status of the neonates. The intracellular killing of *S. aureus* and *S. marcescens* in cells from most term and low-birth-weight infants is normal,^{147,185} as is that of *E. coli* in term infants.¹⁴⁸ Similar studies have shown defective bactericidal activity against *S. aureus* in some infants in the first 12 hours after birth,¹⁸³ *P. aeruginosa* in cells from premature infants,¹⁵¹ and *Candida albicans* in granulocytes from term and premature infants.¹⁸⁶ With bacteria-to-neutrophil ratios of 1:1, newborn cells kill *S. aureus* and *E. coli* as effectively as controls; however, at the higher ratio of 100:1, killing and oxidative responses as measured by chemiluminescence are markedly depressed, although phagocytosis is normal.¹⁸⁴ Depressed activity also has been found in cells from newborns who have had clinical stress, either from infection or other disorders, shown both as decreased chemiluminescence and impaired bactericidal activity against *S. aureus*, *E. coli*, and group B streptococci.^{187–189} The decreased granulocyte function shown in these studies also is found in liquid culture, where neutrophils from newborns do not survive as long as those from adults, perhaps because of decreased resistance to autooxidation.¹⁸⁸ Although superoxide dismutase levels are normal and superoxide production is normal or increased in neutrophils from newborns, glutathione peroxidase and catalase levels are decreased.^{189,190} The relationship of these *in vitro* cellular defects to bacterial infections in the newborn is still not clear.

Antimicrobial proteins and peptides are present in neutrophil cytoplasmic granules. Bacterial permeability-increasing protein (BPI), located in the primary granules, is markedly lower in newborns, particularly preterm newborns.^{191,192} BPI is an antimicrobial protein that binds and neutralizes endotoxin. Other granule components, such as

myeloperoxidase (bacterial killing) and defensins (antimicrobial proteins), are not diminished.

Monocytes from newborn infants have normal nitroblue tetrazolium (NBT) reduction,¹⁹³ normal antibody-dependent cellular cytotoxicity,¹⁹⁴ and normal *in vitro* killing of *S. aureus* and *E. coli*.¹⁹⁵ However, they are slower than monocytes from adults in phagocytosis of polystyrene spheres,¹⁹⁶ and they have reduced ATP production.¹⁹⁷ Furthermore, chemotaxis to serum-derived factors is decreased, as is monocyte appearance in skin windows.¹⁹⁸ These functional aspects may contribute to the observed susceptibility of newborns to a variety of infectious agents.

Cytokine Effects on Neonatal Phagocytic Function There is a complex interaction between cytokines produced by lymphocytes and macrophages, and the activation status of neutrophils during infection. There is decreased production of interferon- γ by neonatal leukocytes.^{199,200} Interferon- γ causes the upregulation of the C3bi receptor and induces the surface expression of the high-affinity immunoglobulin receptor FcRI (CD64)²⁰¹ on neutrophils. C3bi is required for adherence and efficient chemotaxis by neutrophils. Low levels of this receptor also impair complement-mediated phagocytosis and oxidative metabolism. FcRI also mediates oxidative responses, and appears on neutrophils of adults during infection. The diminished production of G-CSF and GM-CSF by neonatal mononuclear cells¹³⁷⁻¹³⁹ may not only limit progenitor colony growth, but may also impair neonatal neutrophil functions, including chemotaxis, superoxide production, and C3bi expression, which are enhanced by these factors.^{202,203} Tumor necrosis factor (TNF)- α and IL-4, cytokines that modulate neutrophil functions, also may be produced at lower levels in neonates.²⁰⁴

THROMBOPOIESIS AND PLATELETS

The platelet counts in term and preterm infants are between 150 and 400 $\times 10^9/L$ (150,000 to 400,000/ μL), comparable to adult values.^{205,206} Thrombocytopenia of fewer than 100 $\times 10^9/L$ (100,000/ μL) may occur in high-risk infants with respiratory distress or sepsis,²⁰⁷ small-for-date infants,²⁰⁸ and newborns with trisomy syndromes.²⁰⁹ Even normal newborns are unable to regulate thrombopoiesis and myelopoiesis in a wholly effective manner.²¹⁰ Although committed megakaryocyte progenitors (colony-forming unit-megakaryocyte [CFU-Meg]) are increased in the marrow and cord blood of newborns, they are less able to produce adequate numbers of platelets when severely stressed. Reduced levels of G-CSF, GM-CSF, and IL-3 may play a role in the impaired response.²¹¹ Thrombopoietin (TPO) is a major regulator of platelet production in adults. TPO transcripts have been detected as early as 6 weeks postconception and the primary source of TPO in the fetus and neonate is thought to be the liver.²¹² Serum TPO levels are higher in preterm and term neonates compared to adults. However, thrombocytopenic newborns do not increase serum TPO levels as robustly as thrombocytopenic adults, which may contribute to the high incidence of thrombocytopenia seen in sick infants.²¹²

Platelet Functions

Bleeding Time and Closure Time The expected inverse relationship between the platelet count and bleeding time has been described in term and preterm newborns.²¹³ However, the bleeding time often is longer than would be predicted by the platelet count because of sepsis or respiratory distress resulting in impaired platelet function, aggravating the effects of thrombocytopenia.

The bleeding time reflects platelet function and capillary integrity, as well as the platelet count, and traditionally has been used to assess these parameters. However, there are technical difficulties in applying a technique for measuring bleeding time to neonates or preterm infants because of the need for venous occlusion of the forearm, where the test

normally is performed, and for a minimal incision to avoid scarring of the skin. Bleeding times were measured using an automatic device to minimize trauma in normal neonates, with venous occlusion of 20 torr for infants who weigh less than 1000 g, 25 torr for those who weigh 1000 to 2000 g, and 30 torr for those who weigh more than 2000 g. In 82 observations, 97 percent of the measurements were below 3.5 minutes, which was suggested as the upper limit for normal in these infants.²¹⁴ A similar upper limit (200 seconds) for the bleeding time of normal infants has been obtained using an automated device and vertical incisions.²¹⁵ Generally, newborn infants have shorter bleeding times than do children and adults, which may reflect their higher hematocrit, increased concentration of von Willebrand factor, and higher proportion of high-molecular-weight multimers of von Willebrand factor.²¹⁶ Children have longer bleeding times than either adults or newborns,²¹⁷ and the upper limit measured with an automated pediatric device may be as high as 13 minutes before age 10 years, compared to an upper limit of 7 minutes in adults measured with the same device.²¹⁷

The bleeding times in newborns may be prolonged for a variety of reasons, including neonatal infection and respiratory distress syndrome, which do not necessarily result in thrombocytopenia.²¹⁸ Platelets from healthy newborns are relatively deficient in phospholipid metabolism, granule secretion, and aggregation,²¹⁹ but there is heightened platelet adhesion because of increased large von Willebrand multimers. The result of these differences is shortened bleeding and closure times in normal neonates (see below).

The use of indomethacin for treatment of patent ductus arteriosus in preterm infants has been questioned because this agent interferes with prostaglandin metabolism and the production of thromboxane A₂, an important initiator of platelet aggregation. Although bleeding times are prolonged from a normal 3.5 minutes to approximately 9 minutes in indomethacin-treated patients,²²⁰ indomethacin did not result in an increase in periventricular or intraventricular hemorrhage in preterm infants treated for patent ductus arteriosus.

The closure time to assess platelet function may replace the bleeding time, particularly for neonates and young children in whom bleeding times are difficult to perform and interpret. Newborn infants have closure times that are shorter than those of adults, likely related to their higher hematocrits, increased von Willebrand multimers and hence ristocetin cofactor, and higher leukocyte counts.²²¹⁻²²³ The normal adult value for collagen-epinephrine closure time is less than 164 seconds, and for collagen-ADP closure time is less than 116 seconds. However, each laboratory must determine its own normal range for these tests.

Platelet Aggregation and Metabolism A variety of differences have been described in the platelet function of neonates. These include decreases in ADP release, in platelet factor 3 activity, in platelet adhesiveness, and in platelet aggregation in response to ADP, epinephrine, collagen, or thrombin.^{224,225} These defects result from intrinsic differences in neonatal compared to adult platelets.²²⁶ Paradoxically, these insufficiencies have little effect on the bleeding time of neonates. The *in vitro* findings do not appear related to a significant defect in prostaglandin synthesis or to storage pool deficiency of adenine nucleotides.²²⁴ Furthermore, electron micrographs of neonatal platelets do not differ from those of platelets from normal adults.²²⁷ This leaves unexplained the *in vitro* observations in neonatal platelets, which may be related to platelet membrane immaturity. These *in vitro* abnormalities may aggravate the impairment in platelet function and the predisposition to bleeding that result from neonatal diseases, particularly respiratory distress syndrome and sepsis.

Maternal aspirin ingestion also results in abnormalities in platelet aggregation in the newborn in response to collagen.^{228,229} However, aspirin has been studied extensively in patients with preeclampsia, and there is no significant bleeding in the fetus or newborn.^{230,231}

Newborn infants commonly have petechiae, particularly on the head, neck, and shoulders, after vertex deliveries. They are presumably caused by trauma associated with passage through the birth canal and disappear within a few days. Petechiae usually are not present in infants delivered by cesarean section.

Platelet Antigens and Glycoproteins The glycoprotein complex GPIIb/IIIa represents approximately 15 percent of platelet surface protein and exhibits two allelic forms, PI^{A1} and PI^{A2}.²³² The PI^{A1} antigen can be identified on fetal platelets by 16 weeks' gestation.²³³ PI^{A1} antigen is observed in a higher percentage of fetuses between 18 and 26 weeks' gestation than in adults. Approximately 2 percent of the population in the United States of European descent is homozygous for PI^{A2} and thus are PI^{A1}-negative. The complete expression of the PI^{A1} antigen during early gestation likely permits sensitization in women who are PI^{A1}-negative even during their first pregnancy.²³³ The membrane glycoprotein GPIb, as well as the GPIIb/IIIa complex, is expressed by 18 weeks of gestation.²³³ The difference between PI^{A1} and PI^{A2} is a leucine 33–proline 33 amino acid polymorphism in glycoprotein IIIA.²³² Prenatal diagnosis of the glycoprotein genotype using DNA from amniocytes and the polymerase chain reaction can establish the potential for neonatal alloimmune thrombocytopenia,²³⁴ as well as the diagnosis of Glanzmann thrombasthenia. Rarely, other fetal platelet antigens, such as PI^{E2}, DUZO^a, Ko^a, and Bak^a have caused maternal sensitization and neonatal alloimmune thrombocytopenia.²³⁵ The gestational ages for expression of these antigens have not been defined but are sufficiently early to permit sensitization.

NEONATAL LYMPHOPOIESIS

T-Lymphocyte Functions—Cellular Immunity

The absolute number of lymphocytes in the newborn is equivalent to that in older children, ages 6 months to 2 years, with lower values in premature infants at birth. Thymus-derived cells (T cells) develop early in gestation.²³⁶ Tables 7–4 and 7–5 show the various lymphocyte subsets in infants and children.^{237,238} The absolute number of CD3+ and CD4+

(helper/inducer phenotype) T-cell subsets in blood of newborns is higher than in adults.²³⁹ This is a result of an increased total lymphocyte count in neonates (and older children) as compared with adults.²⁴⁰ The percentages of major lymphoid subsets (CD2, CD3, CD4, CD8, CD19) and natural killer (NK) cells are not markedly different in neonates, children, and adults when measured by flow cytometry methods.^{241,242} However, functional defects are present in the NK cell population.²⁴² Furthermore, the responses of T-helper type 1 (Th1 cell-mediated immunity) and T-helper type 2 (Th2-assisted humoral immunity) differ in newborns and adults in response to various antigens such as vaccines, infectious agents, and environmental antigens.²⁴³ The numbers of T and B lymphocytes are sustained or increased during the first 2 postnatal months.²⁴⁴ There is a trend toward increased CD4 and decreased CD8 lymphocytes in newborns and children, resulting in an increased CD4:CD8 ratio.^{245,246} In spite of this, T-cell suppressor activity may be increased in newborns.²⁴⁷ Most responses of the cellular immunity system, such as antigen recognition and binding, antibody-dependent cytotoxicity, and graft-versus-host reactivity are present in the newborn,²⁴⁷ although some are decreased in comparison with adults.²⁴⁸ The *in vitro* response to phytohemagglutinin of cord blood lymphocytes is increased,^{249,250} but the response of the newborn to 2,4-dinitrofluorobenzene, a potent inducer of delayed hypersensitivity, is not as consistent as that seen in older children.²⁵¹ Impaired T-cell production of interferon- γ and other lymphokines may be related to immature macrophage rather than to T-lymphocyte function, because intercellular cooperation is a requisite for these processes.²⁵² Furthermore, cord blood T lymphocytes form a functional IL-2 receptor complex and have normal IL-2 receptors, but they do not upregulate interferon- γ in response to IL-2.²⁵³

B-Lymphocyte Functions—Humoral Immunity

Humoral (B-cell) immunity also develops early in gestation,²³⁶ but it is not fully active until after birth. In the newborn, approximately 15 percent of lymphocytes have immunoglobulin on their surface, with all immunoglobulin isotypes represented.²⁵⁴ A percentage of these cells are CD5+ B cells (B-1 cells), which produce polyreactive autoantibodies whose function is yet unclear.²⁵⁵ The proportion of CD5+ B cells is markedly higher in the fetus compared to adults. The percentages of B cells expressing specific immunoglobulin isotypes are not related to the plasma levels of those isotypes. Variation in antibody response to specific antigens relates to the interaction of macrophages, T cells, and B cells. B lymphocytes are well represented in newborns, but T-lymphocyte-independent B-lymphocyte responses are limited during the first year.²⁵⁶ T-lymphocyte-dependent B-lymphocyte antibody production matures much earlier.²⁵⁶

Fetal lymphocytes synthesize little immunoglobulin, presumably because of the sheltered environment *in utero*. Animals kept germ-free after birth have few plasma cells and markedly decreased production of immunoglobulins.²⁵⁷ IgG levels of term infants are similar to maternal levels because of transplacental transfer.²⁵⁸ IgM, IgD, and IgE do not cross the placenta,^{258,259} and the levels of these immunoglobulins and of IgA are low or not detectable at birth. Breastfeeding provides some transfer of antibodies, particularly secretory IgA, lysozyme, and lactoferrin. Large numbers of lymphocytes and monocytes (10⁶ cells/mL) are found in colostrum and milk during the first 2 months postpartum.²⁶⁰ These may provide local gastrointestinal protection against infection,^{261,262} and there is some evidence for absorption of immunoglobulin and transfer of tuberculin sensitivity to the infant.

Although the newborn infant can produce specific IgG antibody,²⁶³ only small amounts of IgG are usually produced by the fetus. IgG levels in premature infants are reduced in relation to gestational age because of the low placental transport early in pregnancy.^{264–266} The ability of the fetus to produce IgM and IgA with appropriate stimuli is indicated by

Data from Shearer WT, Rosenblatt HM, Gelman RS, et al: Lymphocyte subsets in healthy children from birth through 18 years of age: The Pediatric AIDS Clinical Trials Group P1009 Study. *J Allergy Clin Immunol* 112:973, 2003.

the presence of these antibodies in many newborn infants who have had prenatal infections²⁶⁷ and by the presence of IgM isohemagglutinins in more than half of term newborn infants.²⁶⁸ In human newborns and in fetal animals, the IgM response is predominant, and the appearance of IgG after exposure to specific antigens is delayed. These differences from the adult may relate to functional immaturity of B and T lymphocytes,^{269–271} to increased activity of suppressor T cells,^{258,269} and perhaps to altered macrophage function.²⁷²

Newborns also may have relative splenic hypofunction, suggested by the large number of “pocked” red cells seen in the blood films of neonates, particularly premature infants. These “pocks” represent residual intraerythrocyte inclusions, which remain because of monocyte and macrophage hypofunction.^{273,274}

COAGULATION IN THE NEONATE

Plasma Coagulation Factors

When the term newborn is compared to older children and adults, several differences in the coagulation and fibrinolytic systems are apparent.^{275–281} A comprehensive evaluation of the developmental changes in the levels of clotting factors and coagulation tests in preterm and term infants has been published.^{282,283} The term newborn has reduced mean plasma levels (<60 percent of adult levels) of factors II, IX, X, XI, XII, prekallikrein, and high-molecular-weight kininogen (Table 7-6). This is not a result of impaired mRNA expression, at least in the case of factors II and X.²⁸⁴ In contrast, the plasma concentration of factor VIII is similar and von Willebrand factor is increased compared to that of older

children and adults. In spite of the lower levels of factors, the functional tests (prothrombin and partial thromboplastin times) are only slightly prolonged compared to adult normal values (Table 7-6). Although different coagulation factors show different postnatal patterns of maturation, near-adult values are achieved for most components by 6 months of age.²⁷⁸

Factors II (prothrombin), VII, IX, and X require vitamin K for the final γ -glutamyl carboxylation step in their synthesis.²⁸⁵ These factors decrease during the first 3 to 4 days after birth. This fall may be lessened by administration of vitamin K,²⁸⁶ effectively preventing classic, early occurring (first few days after birth) hemorrhagic disease of the newborn. Inactive prothrombin molecules have been found in the plasma of some newborns, but they disappear after administration of vitamin K.²⁸⁷ Early occurring hemorrhagic disease is most often associated with maternal administration of medications such as phenytoin (Dilantin)²⁸⁸ and warfarin,²⁸⁹ which reduce the vitamin K-dependent factors. In rare cases, no contributing factor is found.

A hemorrhagic diathesis also may occur later, 2 to 12 weeks after birth, as a result of lack of vitamin K, and is called *late hemorrhagic disease of the newborn* or *acquired prothrombin complex deficiency*.^{290,291} The etiology of the vitamin K lack is unclear but may result from poor dietary intake, particularly related to breastfeeding, alterations in liver function with cholestasis and decreased vitamin K absorption, or a toxic or infectious impairment of hepatic utilization.²⁹⁰ Unfortunately, intracranial hemorrhage frequently is the presenting event in this condition. This problem can be prevented by parenteral or oral vitamin K, but the preferred route of administration remains controversial.²⁹² The

APTT, activated partial thromboplastin time; HK, high-molecular-weight kininogen; INR, international normalized ratio; PK, prekallikrein; PT, prothrombin time; TCT, thrombin clotting time; VWF, von Willebrand factor.

*All factors except fibrinogen are expressed as units per milliliter (U/mL), where pooled plasma contains 1.0 U/mL. All values are expressed as the mean of 40 to 77 samples for each population. The range of values encompassing 95 percent of the population is shown in parentheses.

Data from Andrew M, Paes B, Milner B, et al: Development of the human coagulation system in the full-term infant. *Blood* 70:165, 1987 and Monagle P, Massicotte P: Developmental haemostasis: Secondary haemostasis. *Sem in Fetal and Neonatal Medicine* 16:294–300, 2011.

parenteral route may result rarely in neuromuscular complications,²⁹³ and an association of intramuscular vitamin K prophylaxis and cancer in infancy was suggested but not substantiated. Oral administration, however, appears less reliable and may require repeated doses.²⁹⁰ The current recommendation of the American Academy of Pediatrics suggests that vitamin K₁, 0.5 to 1.0 mg, be administered intramuscularly at birth.²⁹⁴ Even the lower (0.5 mg) parenteral dose may be excessive for preterm (<32 weeks' gestation) infants, although no toxic effects have been reported as a result of very high plasma values.²⁹⁵ Recent data suggest that 0.2 mg vitamin K may be appropriate prophylaxis for infants delivered at fewer than 32 weeks' gestation, but additional oral supplementation is needed when feeding is established.²⁹⁶ A mixed micellar vitamin K₁ preparation is particularly well absorbed and may permit prophylaxis with a single oral dose,²⁹⁷ but the efficacy and safety of oral prophylaxis require further study.

Table 7-6 shows the values for coagulation factors in healthy 30 to 36 weeks' gestation premature infants. More prominent decreases in factors IX, XI, and XII are noted, which tend to prolong the partial thromboplastin time. Table 7-6 also shows the values for coagulation factors in 28 to 31 weeks' gestation infants. All of the coagulation factors are lower at earlier gestational ages.

There are no significant differences in mean prothrombin time determinations between 30 and 36 weeks' gestation premature and full-term infants who have not received vitamin K.²⁹⁸ Premature infants given vitamin K have a longer mean prothrombin time than do term infants similarly treated. In some small infants there is no improvement in prothrombin time or levels of prothrombin, and factors VII and X after the intramuscular administration of vitamin K.^{286,299} These results suggest a greater degree of "immaturity" of the liver in the small infants.

Bleeding and Thrombosis

Significant bleeding occurs more often in low-birth-weight infants than in term newborn infants. Increased capillary fragility is frequently found in premature infants in the first 2 days after birth and is not associated with thrombocytopenia.²⁸⁶ Bleeding under the scalp or in other superficial areas may be caused by trauma at birth coupled with increased

capillary fragility. The more serious disorders of periventricular-intraventricular hemorrhage and pulmonary hemorrhage probably are not caused by coagulation disorders, although such disorders may increase the bleeding.³⁰⁰ Hypoxia seems to affect the clotting status of low-birth-weight infants.³⁰¹ Many infants with markedly abnormal prothrombin times have had hypoxia during delivery or shortly thereafter.²⁹⁶ Cardiovascular collapse seen with episodes of cardiac arrest or with profound shock may cause disseminated intravascular coagulation and generalized bleeding. In many sick premature infants, a combination of shock, sepsis, liver immaturity, hypoxia, and other factors may contribute to the pathogenesis of coagulation abnormalities.

Arterial and venous thromboses are relatively frequent in newborns as compared to other age groups, but greater than 90 percent of arterial and greater than 80 percent of venous clots are related to catheters. Spontaneous thromboses are much less common, and most involve the renal veins or, rarely, the pulmonary vasculature.³⁰² Relative hypercoagulability in the newborn could result from a difference in the vascular endothelium, activation of the coagulation cascade, diminished coagulation inhibitor activity, or a defect in fibrinolysis. Inhibitors of coagulation include antithrombin, heparin cofactor II, protein C, and protein S.^{283,303} The levels of proteins C and S, which are vitamin K dependent, as well as antithrombin and heparin cofactor II, are low in the newborn; they are in a range associated with thrombotic episodes in adults with inherited deficiencies.³⁰³ In addition, the presence of factor V Leiden may occur in as many as 6 percent of newborns.³⁰⁴ This produces resistance to the action of protein C and may heighten the susceptibility to thrombosis (Chap. 130). Hyperprothrombinemia caused by the 20210A allele prothrombin gene may affect 1 percent of the population,³⁰⁵ but the elevated prothrombin level predisposing to thrombosis occurs in older patients.³⁰⁶ The combined deficiency of these anticoagulant proteins may further intensify the thrombotic risk. However, the precise role of these inhibitors of coagulation in newborn hypercoagulability is uncertain because a proportionate decrease in vitamin K-dependent procoagulant factors (II, VII, IX, X) also is present, and an additional inhibitor, α_2 -macroglobulin, is increased (Chap. 130). Table 7-7 shows the values for plasma inhibitors of coagulation in premature and term infants.

TABLE 7-8. Hematologic Effects of Maternal Drugs on the Fetus and Newborn

Drug	Effect	Certainty*	Mechanism	Reference
Antiretroviral agents in combination	Decreased hemoglobin	Established	Unknown—only seen with combination of zidovudine, lamivudine + nelfinavir	318
Aspirin	Bleeding; kernicterus	Established; potential	Interference with platelet function	123, 224, 228
			Displacement of bilirubin from albumin	317
Diazoxide	Bleeding	Questionable	Thrombocytopenia	307
Nalidixic acid	Hyperbilirubinemia	Potential	Oxidant damage to hemoglobin	315
Nitrofurantoin	Hyperbilirubinemia	Potential	Oxidant damage to hemoglobin	314, 316
Phenytoin (Dilantin/phenobarbital)	Bleeding	Suspected	Depletion of vitamin K–dependent coagulation factors by hepatic enzyme induction and factor degradation	288
Rifampin/isoniazid	Bleeding	Suspected	Depletion of vitamin K–dependent coagulation factors	313
Sulfonamides	Kernicterus	Established	Displacement of bilirubin from albumin	317
Thiazides	Bleeding	Suspected	Thrombocytopenia	308, 309
Warfarin (Coumadin)	Bleeding	Established	Known depletion of vitamin K–dependent coagulation factors by blocking carboxylation	288, 289

*Certainty reflects the level of confidence in the data, assigned in increasing order from potential through questionable, suspected, and established.

Data from Haley TJ, Berndt WO: *Handbook of Toxicology*. Washington, DC: Hemisphere Publishing; 1987.

HEMATOLOGIC EFFECTS OF MATERNAL DRUGS ON THE FETUS AND NEWBORN

Hemostatic Effects

A number of maternally administered pharmacologic agents have been implicated in hematologic abnormalities of the fetus or newborn (Table 7-8). Maternal aspirin ingestion results in impaired platelet aggregation but does not foster neonatal bleeding. Other agents taken by the mother, including diazoxide and thiazides, might be associated with neonatal thrombocytopenia.³⁰⁷⁻³⁰⁹

The newborn's plasma coagulation factors may be depressed by maternal warfarin ingestion.²⁸⁹ This drug is best avoided during pregnancy because it is teratogenic (first trimester) and may cause growth retardation of the fetus as well as bleeding.²⁸⁹ In contrast, heparin does not cross the placenta, and maternal treatment with heparin appears to be safe for the fetus.³¹⁰

Phenytoin (Dilantin) and/or phenobarbital also may reduce the newborn's vitamin K–dependent factors, possibly by microsomal enzyme induction, which enhances their degradation.²⁸⁷ Furthermore, phenytoin may depress the platelet count as a result of prenatal exposure³¹¹ and cause teratogenic effects, for example, the fetal hydantoin syndrome.³¹² The decision to use this agent during pregnancy should reflect an assessment of the need for this specific drug, and also the risk of maternal seizures to the fetus and mother versus the potential side effects of treatment. Newborns of mothers taking rifampin and isoniazid also may have depressed vitamin K–dependent factors.³¹³

Hyperbilirubinemia and Kernicterus

Nitrofurantoin and nalidixic acid may cause oxidant injury to the red cell membrane and hemoglobin.^{314,315} If there is glucose-6-phosphate dehydrogenase deficiency, or if reduced glutathione is diminished, as in newborn red cells, these drugs have the potential to induce hemolysis and heighten neonatal hyperbilirubinemia (Chap. 47). Although this problem has not been documented by transplacental transfer of nitrofurantoin or nalidixic acid, hemolysis has occurred in glucose-6-phosphate

dehydrogenase-deficient infants who acquired the drugs from breast milk.^{315,316} Alternatively, sulfonamides may cause displacement of bilirubin bound to albumin and heighten the risk of kernicterus.³¹⁷ Salicylates, phenylbutazone, and naproxen may have a similar effect at very high plasma concentrations.³¹⁷ Ideally, all these medications should be avoided during pregnancy unless their indication outweighs the potential risk to the fetus and newborn.

CHAPTER 8

HEMATOLOGY DURING PREGNANCY

Martha P. Mims

SUMMARY

Normal pregnancy involves many changes in maternal physiology, including alterations in hematologic parameters. These changes include expansion in maternal plasma volume. The increase in plasma volume is relatively larger than the increase in red cell mass resulting in a decrease in hemoglobin concentration. An increase in the levels of some plasma proteins alters the balance of coagulation and fibrinolysis. Worldwide, the predominant cause of anemia in pregnancy is iron deficiency. Fetal requirements for iron are met despite maternal deficiency, but maternal iron deficiency has a number of adverse consequences including an increased frequency of preterm delivery and low-birth-weight infants. Bleeding disorders in pregnancy are a common reason for hematologic consultation and evoke concern for both the mother and child. Life-threatening bleeding caused by disseminated intravascular coagulation is seen with some complications unique to pregnancy, including placental abruption, retained dead fetus, and amniotic fluid embolism. von Willebrand disease is the commonest inherited bleeding disorder, but because of increases in factor VIII level and von Willebrand factor during pregnancy, excessive bleeding at delivery is rarely a problem in such patients. Factor levels fall rapidly postpartum, and serious hemorrhage can occur during this period. Carriers of hemophilia A and B should be monitored during pregnancy to determine if factor levels will be adequate for delivery at term. Caution should be exercised at delivery and during the first few days of life with offspring of hemophilia carriers until hemophilia testing is completed and the infant's status is known. Acquired hemophilia as a result of factor VIII autoantibodies is rare, but can occur during pregnancy or the puerperium. Thrombocytopenia is not uncommon in pregnancy, and its causes include several conditions that are unique to pregnancy, such as preeclampsia. Idiopathic thrombocytopenic purpura (ITP) is common, it is often exacerbated in pregnancy, and is managed conservatively if possible; close followup of newborns of mothers with ITP is essential. HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome and TTP (thrombotic thrombocytopenic purpura)/hemolytic uremic syndrome are also seen in pregnancy and the puerperium. HELLP syndrome is managed by immediate delivery, if possible, whereas TTP, usually, can be managed with plasma exchange. Inherited and acquired prothrombotic

Acronyms and Abbreviations: DDAVP, desmopressin acetate, a synthetic analogue of the pituitary hormone vasopressin; DIC, disseminated intravascular coagulation; ESR, erythrocyte sedimentation rate; ET, essential thrombocythemia; HELLP, hemolysis, elevated liver enzymes, low platelets syndrome; ITP, idiopathic thrombocytopenic purpura; PNH, paroxysmal nocturnal hemoglobinuria; PT, prothrombin time; PTT, partial thromboplastin time; PV, polycythemia vera; TTP, thrombotic thrombocytopenic purpura; VTE, venous thromboembolism; VWD, von Willebrand disease; VWF, von Willebrand factor.

conditions can be exacerbated by pregnancy and can result in adverse reproductive outcomes as well as maternal venous thromboembolism. The strongest evidence for an association between a thrombophilia and recurrent fetal loss exists for antiphospholipid antibody syndrome; however, evidence is mounting for a connection between inherited thrombophilias and the severity of some complications of pregnancy. These thrombophilias increase the risk of maternal venous thromboembolism in pregnancy and the puerperium. Treatment of hematologic malignancies in pregnancy can present a difficult dilemma both in terms of staging studies and management. In many cases of Hodgkin lymphoma, treatment can be delayed safely until after delivery. In contrast, in aggressive lymphomas and acute leukemias rapid initiation of chemotherapy is often necessary to save the life of the mother. In general, the teratogenic effects of chemotherapy are greatest in the first trimester; however, care must be taken in later trimesters to avoid cytopenias of both mother and fetus at delivery. Hemorrhagic and thrombotic complications associated with pregnancy in females with essential thrombocythemia and polycythemia vera present a unique challenge because of the lack of controlled trials in these situations.

BLOOD VOLUME, ERYTHROPOIETIN LEVEL, AND HEMOGLOBIN CONCENTRATION

Maternal blood volume increases by an average of 40 to 50 percent above the nonpregnant level.¹ Plasma volume begins to rise early in pregnancy, with most of the escalation taking place in the second trimester and prior to week 32 of gestation.² Red cell mass increases significantly beginning in the second trimester and continues to expand throughout pregnancy, but to a lesser extent than plasma volume.² Erythropoietin levels increase throughout pregnancy, reaching approximately 150 percent of their prepregnancy levels at term.^{3,4} The overall effect of these changes in most women is a slight drop in hemoglobin concentration, which is most pronounced at the end of the second trimester and slowly improves approaching term.

PLATELET AND WHITE CELL COUNTS

The effect of pregnancy on maternal platelet count is somewhat more controversial; some studies demonstrate a mild decline in platelet count over the course of gestation,⁵ whereas others do not.⁶ In general, white cell counts rise during pregnancy with the occasional appearance of myelocytes or metamyelocytes in the blood.⁷ During labor and the early puerperium, there is a rise in the leukocyte count. Leukocytosis appears to be linearly related to the duration of labor.⁸

PLASMA PROTEINS

The levels of some plasma proteins also increase during pregnancy. In particular, C-reactive protein concentration is higher in pregnant women and rises even further during labor.⁹ Erythrocyte sedimentation rate (ESR) rises during pregnancy, and is affected by both hemoglobin concentration and gestational age.¹⁰ The rise in ESR during pregnancy, in large part a result of an increase in levels of plasma globulins and fibrinogen, makes its use as a marker of inflammation difficult. The levels of many of the procoagulant factors increase during pregnancy whereas activity of the fibrinolytic system diminishes in preparation for the hemostatic challenge of delivery. Plasma levels of von Willebrand

factor (VWF), fibrinogen, and factors VII, VIII, and X all increase markedly, whereas factors II, V, IX, and XII are essentially unchanged and factor XIII declines.¹¹ Levels of protein C and antithrombin remain stable throughout pregnancy whereas total and free protein S fall with increasing gestational age.¹² Fibrinolysis is also impaired by increases in plasminogen activator inhibitors I and II, the latter a product of the placenta.¹³

● ANEMIA IN PREGNANCY

IRON DEFICIENCY

Worldwide, the contribution of anemia to maternal and fetal morbidity and mortality is well recognized; in some parts of Africa, more than 75 percent of pregnant women are anemic, and there is a significant correlation between maternal mortality and anemia.¹⁴ It has been suggested that iron deficiency may protect against placental malaria, but epidemiologic studies have not been conducted to verify this supposition.¹⁵ In pregnant women, anemia is defined as a hemoglobin concentration of less than 11 g/dL in the first and third trimesters, and less than 10.5 g/dL in the second trimester.¹⁵ In both the industrialized and the developing world, iron-deficiency anemia (Chap. 43) is the commonest cause of anemia.¹⁶ On average approximately 1 g of iron is required during a normal pregnancy; 300 mg of iron are required by the fetus and the placenta, whereas expansion of the maternal red cell mass requires 500 mg, and 200 mg are lost via excretion.¹⁷ These requirements exceed the iron storage of most young women and in general cannot be met by the diet. Even in cases of maternal iron deficiency, the fetal requirements for iron are always met; thus there is no correlation between the hemoglobin of the fetus and that of the mother.¹⁸

Iron-deficiency anemia during the first two trimesters of pregnancy is associated with a twofold increased risk for preterm delivery and a threefold increased risk for delivery of a low-birth-weight infant.¹⁹ However, a large randomized trial comparing routine iron prophylaxis in pregnancy versus iron supplementation given only as needed demonstrated no significant differences in adverse maternal or fetal outcomes.²⁰ As in nonpregnant individuals, iron-deficiency anemia can generally be diagnosed using laboratory values such as serum ferritin, and transferrin saturation levels (Chap. 43). *Pica*, the ingestion of non-nutritive substances, is said to be more common among iron-deficient pregnant women than among other populations with iron deficiency. Ice, clay or dirt, and starch are the most frequent substances ingested (Chap. 43); to some extent, however, the choice appears to be cultural and much more widespread than most practitioners realize.²¹

FOLATE AND VITAMIN B₁₂ DEFICIENCY

Apart from iron deficiency, folate deficiency is the next most frequent nutritional deficiency leading to anemia in pregnant women. In the United States, where foodstuffs are supplemented with folate and the level of awareness of the association between folate deficiency and neural tube defects in the embryo is high, folate deficiency is relatively unusual. Folate requirements in pregnancy are roughly twice those in the nonpregnant state (800 mcg/day vs. 400 mcg/day), and if diet is insufficient may exceed the body's stores of folate (5–10 mg) relatively quickly.²² Anemia related to folate deficiency most often presents in the third trimester and responds to folate supplementation with reticulocytosis within 24 to 72 hours.¹⁶ Reports of severe pancytopenia and even states resembling the HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome as a result of folate deficiency in pregnancy have appeared in the literature.^{23,24} Despite these case reports, a review of 21 trials measuring the effect of folate supplementation on biochemical and hematologic parameters and pregnancy outcome

(excluding neural tube defects) revealed improvement in low hemoglobin level in late pregnancy, but had no measurable effect on any substantive measures of pregnancy outcome (Chap. 41).²⁵

Vitamin B₁₂ (cobalamin) deficiency during pregnancy is rare, in part because deficiency of this vitamin leads to infertility. Serum cobalamin levels are known to fall during pregnancy.²⁶ A shift from the serum to tissue stores is proposed to account for the drop in serum B₁₂ levels. However, values less than 180 pmol/L usually are not observed in healthy women, and these low-normal levels are not accompanied by increased levels of methylmalonic acid, an indicator of cellular deficiency of cobalamin (Chap. 41).²⁷

RED CELL APLASIA

A rare cause of anemia in pregnancy is pure red cell aplasia (Chap. 36). In pure red cell aplasia, anemia tends to occur early in pregnancy and often resolves within weeks of delivery. The pathogenic mechanism leading to red cell aplasia does not appear to be transferred to the fetus, but does tend to recur in subsequent pregnancies.^{28,29} Conservative treatment, if feasible, is probably best until delivery; successful prenatal treatments with glucocorticoids and with intravenous immunoglobulin have been reported.^{30,31}

● BLEEDING DISORDERS AND CAUSES OF THROMBOCYTOPENIA

Bleeding disorders in pregnancy require consideration of maternal bleeding and hemorrhagic complications in the newborn. Data on the fetus are often lacking, and the practitioner must base decisions on past experience and the mother's previous reproductive history.

DISSEMINATED INTRAVASCULAR COAGULATION

Life-threatening bleeding is seen with some pregnancy-unique complications, resulting in disseminated intravascular coagulation (DIC). Because of the changes in coagulation factor levels, D-dimer, and platelet count during pregnancy, the normal range for tests routinely used to diagnose DIC in a nonpregnant state cannot be extrapolated directly to DIC in pregnancy. Serial measurement of the prothrombin time (PT), partial thromboplastin time (PTT), D-dimer, and fibrinogen are likely to be more helpful than measuring a single value.³² The DIC score developed by the International Society on Thrombosis and Hemostasis has been modified for pregnancy and this score may be more useful in identifying DIC.³³

Complications of pregnancy that lead to DIC include placental abruption, a retained dead fetus, and amniotic fluid embolism (Chap. 129). Although amniotic fluid embolism is a significant cause of maternal death in developed countries, the mortality decreased from 86 percent in 1979 to less than 30 percent in 1994 and 1995, perhaps from a better supportive therapy.³⁴ Amniotic fluid embolism is most likely to occur in older multiparous women whose pregnancies have gone beyond the 40th week and during tumultuous labor. Amniotic fluid enters the maternal circulation through tears in the chorioamniotic membranes, injury to the uterine veins, or uterine rupture. Its onset is heralded by maternal vascular collapse with dyspnea, hypotension, and cardiac arrhythmias followed by DIC that is manifested by oozing from intravenous lines, hematuria, hemoptysis, and excessive uterine bleeding. Atypical presentations have also been reported in which there is rapid deterioration of the fetus, followed by maternal respiratory and cardiovascular deterioration with development of DIC.³⁵

In amniotic fluid embolism, DIC appears to involve an abnormal host response to exposure to various foreign antigens with the subsequent release of endogenous mediators which drive the clinical manifestations.³⁶ Treatment is not significantly different than in other cases of DIC with bleeding (Chap. 129); however, there are some reports of successful management with uterine artery embolization.³⁷

Placental abruption has also led to development of DIC, and the spectrum of hemostatic failure is broad and appears to be related to the degree of placental separation.³⁸ Volume resuscitation, delivery of the fetus, and infusion of blood products to correct the maternal coagulation defect are indicated. Regional anesthesia is contraindicated because of the risk of bleeding in the epidural space and of the pooling of blood in the lower limb vascular bed, which could worsen hypovolemia.³⁸ Fetal trophoblast cells have distinct properties which may activate coagulation including expression of tissue factor, suppression of fibrinolysis, and exposure of anionic phospholipids.³⁹ Finally, intrauterine fetal death can also lead to DIC. Thromboplastic substances and specifically tissue factor released from dead fetal tissues into the maternal circulation are thought to trigger DIC; however, this is not usually detectable by laboratory tests until 3 or 4 weeks after fetal demise. Overt DIC is present in approximately 50 percent of women who retain a dead fetus for 5 weeks or longer.⁴⁰

VON WILLEBRAND DISEASE

Although von Willebrand disease (VWD) is transmitted in an autosomal dominant fashion, women appear to be disproportionately affected with bleeding symptoms, primarily menorrhagia and postpartum hemorrhage (Chap. 126). In normal women and in types 1 and 2 (but not type 3) VWD patients, levels of factor VIII and VWF rise during pregnancy, with the most pronounced increase in the third trimester.³⁹ As a result, prophylactic administration of VWF-containing factor concentrates at delivery is often unnecessary in type 1 and type 2 VWD patients; however, the risk of postpartum hemorrhage is significant (13–29 percent) as levels fall rapidly after birth.⁴¹ Thus in type 1 patients, factor VIII levels should be tested not only late in the third trimester, but also for 1 to 2 weeks postpartum. These patients should be monitored for increases in menstrual blood flow for at least 1 month. Risk of bleeding appears to be minimal when factor VIII levels are greater than 50 U/dL. There are several reports of severe thrombocytopenia developing late in pregnancy in patients with type 2B VWD,^{42,43} and at least one of these patients developed a pulmonary embolus while receiving cryoprecipitate for postpartum hemorrhage. Despite the possible risk of thrombosis, these patients may require treatment with plasma-derived VWF-containing concentrates at delivery or postpartum if there is abnormal bleeding, and with platelets if thrombocytopenic bleeding is not controlled with infusion of VWF concentrate. Type 3 VWD patients require infusion of a plasma-derived VWF-containing concentrate at delivery, typically 40 to 80 IU/kg, followed by doses of 20 to 40 IU/kg daily for a week then tapered over the next few weeks.⁴⁴ Use of desmopressin acetate (DDAVP) antepartum is controversial because of the theoretical risk of vasoconstriction and placental insufficiency and the risk of maternal hyponatremia. Guidelines for management of VWD at delivery and during the puerperium have been published and are also reviewed in Chap. 126.^{45,46}

COAGULATION FACTOR DEFICIENCIES

Carriers of hemophilia A and B generally have factor levels approximately 50 percent of normal; however, a wide range of values have been reported as a result of random inactivation of the X chromosome (Chaps. 10 and 123).^{47,48} Ideally, carriers are identified before pregnancy when prenatal counseling can be offered. Baseline factor levels

should be tested at the first visit during pregnancy and again in the third trimester, but it should be noted that factor IX levels generally do not rise during the course of the pregnancy.⁴⁷ The sex of the fetus should be determined to guide the obstetrician at delivery. With the recognition that maternal serum contains cell free fetal DNA, genomic strategies have been developed to determine fetal gender as early as 7 weeks of gestation. Similarly, strategies to determine whether a male fetus is affected by hemophilia based on testing of maternal blood have now been developed and will doubtless enter the clinical arena in the near future.⁴⁹ Cranial hemorrhage is the commonest site of bleeding in newborns with severe hemophilia, and has the highest potential for long-term serious sequelae. Risk factors for cranial hemorrhage include prolonged labor and use of instruments during delivery.⁴⁸ To protect a potentially affected or known hemophilic fetus, vacuum extraction should be avoided at delivery and forceps should be used only with caution. All intramuscular injections should be withheld from the newborn until hemophilia testing is completed. If an infant's hemophilia status is not known, testing should be done on cord blood to avoid potential bleeding or bruising after a blood draw.⁴⁸ The mother's factor level should be followed for a few days after delivery and menstrual bleeding should be monitored to ensure adequate hemostasis.

There is also an association between pregnancy and acquired hemophilia caused by factor VIII autoantibodies (Chap. 127). This condition usually appears 1 to 4 months postpartum, but emerges during pregnancy in up to 14 percent of patients.⁵⁰ In general, the Bethesda titer of the inhibitor is low and in most cases the inhibitor disappears spontaneously. Inhibitors can recur in subsequent pregnancies.⁵¹

Rarely, pregnant women with factor deficiencies other than factors VIII and IX may be identified. The most important of these to recognize is deficiency of factor XIII, which is associated with habitual hemorrhagic abortions and postpartum hemorrhage. In rare pregnancies reaching term, bleeding complications, including intracranial hemorrhage in the infant, have been observed.^{52,53} Treatment of this deficiency with fresh-frozen plasma, cryoprecipitate, or plasma-derived factor XIII concentrates (now available in the United States) prevents abortion in women, although there are no controlled studies.⁵⁴ Most authorities recommend more frequent prophylactic therapy during pregnancy (every 3 weeks vs. every 5–6 weeks) with booster doses during labor or before cesarean section to ensure a level of 5 percent or greater.⁵⁵ Although rare, congenital afibrinogenemia, hypofibrinogenemia, and dysfibrinogenemia (Chap. 125) can cause hemorrhagic and thrombotic pregnancy complications. Most experts recommend fibrinogen replacement (using cryoprecipitate or fibrinogen concentrate) to maintain a level of 60 to 100 mg/dL during pregnancy and for 6 weeks postpartum.⁵⁶

CAUSES OF THROMBOCYTOPENIA

Thrombocytopenia in pregnancy is relatively common, with up to 5 percent of all pregnant women exhibiting asymptomatic thrombocytopenia.⁵⁷ Many causes of thrombocytopenia in pregnancy are identical to those seen in the nonpregnant state, with some predisposing to bleeding whereas others predispose to clotting. However, there are several conditions leading to thrombocytopenia that are unique to pregnancy, including gestational thrombocytopenia, preeclampsia/HELLP syndrome/eclampsia, and acute fatty liver of pregnancy.

Gestational and Immune Thrombocytopenia

Gestational thrombocytopenia and idiopathic thrombocytopenic purpura (ITP) are best discussed together as they can be difficult to differentiate and, in fact, may be two extremes of a spectrum of disease. In general, gestational thrombocytopenia is asymptomatic and is said to occur later in pregnancy and be less severe than ITP. Most sources

suggest that gestational thrombocytopenia occurs in the second and third trimesters, with platelet counts rarely falling below 70,000/ μL .⁵⁸ Gestational thrombocytopenia can sometimes be diagnosed with certainty only after delivery; usually there is no past history of low platelets, except perhaps with previous pregnancies, the platelet count returns to normal after delivery, and there is no association with fetal thrombocytopenia. It is not clear whether or not gestational thrombocytopenia is a variant of immune-mediated platelet destruction (Chap. 117).⁵⁸

In contrast to gestational thrombocytopenia, ITP can occur at any point in pregnancy and the fall in platelet count can be severe. Diagnosis is essentially the same as it would be in any patient in that alternative causes of thrombocytopenia must be ruled out. As in other cases, treatment of ITP in pregnancy must take into account the severity of the thrombocytopenia and the presence or absence of symptoms. In general, platelet counts less than 10,000/ μL require treatment regardless of the trimester; platelet counts of 30,000 to 50,000/ μL without bleeding require no treatment, and platelet counts of 10,000 to 30,000/ μL in later trimesters or in the presence of bleeding require treatment. Although glucocorticoid and intravenous immunoglobulin are safe in pregnancy, they may have no effect on fetal counts and should only be used to treat the mother.⁵⁹ Splenectomy for ITP in pregnancy is best done in the second trimester if platelet counts are extremely low and unresponsive to treatment.⁵⁸ One small study evaluated the safety of anti-D antibodies during pregnancy; all 10 of the women studied achieved a platelet count greater than 30,000/ μL , but larger studies are needed before this intervention can be recommended.⁶⁰ Similarly, there are case reports of rituximab administration for treatment of refractory ITP in pregnancy; at least one report demonstrated transient inhibition of neonatal B-lymphocyte development.⁶¹ There are no adequate and well-controlled studies of either eltrombopag or romiplostim in pregnant women and both are considered pregnancy category C drugs. In animal studies, both drugs crossed the placental and fetal effects included thrombocytosis, postimplantation loss, increase in fetal mortality, but no major structural malformations were reported.⁶² Case reports describing the use of romiplostim in pregnancy have appeared and in one report the newborn had severe thrombocytopenia at birth complicated by intracranial hemorrhage.⁶³ Maternal platelet counts of greater than 50,000/ μL usually are safe for both vaginal and cesarean delivery. In most cases, spinal anesthesia should not be used if the platelet count is less than 75,000/ μL .⁶⁴ Less than 5 percent of babies born to mothers with ITP have platelet counts less than 20,000/ μL , although there does seem to be some correlation between very severely depressed maternal platelet count and severe thrombocytopenia in the newborn.⁶⁵ No clear recommendations can be given for measuring fetal platelet count prior to or at delivery as measurements are fraught with error; however, if the fetal platelet count is known to be less than 20,000/ μL , cesarean section is probably reasonable. Newborns of mothers with ITP should be monitored for 5 to 7 days after delivery to ensure that the platelet count does not drop (Chap. 117).

Eclampsia and HELLP Syndrome

The spectrum of hypertensive disorders of pregnancy ranging from preeclampsia to severe preeclampsia and HELLP syndrome to eclampsia (see Chap. 51) may also result in thrombocytopenia, although thrombosis is more of an issue than is bleeding. There is some debate in the literature as to whether thrombocytopenia can be diagnosed in preeclampsia without HELLP syndrome; however, data from one large study⁵⁷ indicated that approximately 15 percent of cases of preeclampsia are complicated by thrombocytopenia. In general, the symptoms of preeclampsia, including hematologic manifestations, resolve with delivery; however, in a small proportion of cases they persist, worsen, or even develop immediately postpartum. When symptoms persist postpartum,

the differentiation from thrombotic thrombocytopenic purpura (TTP)/hemolytic uremic syndrome becomes more difficult. Some data suggest that maternal recovery from the HELLP syndrome is accelerated by administration of intravenous dexamethasone⁶⁶; however, a meta-analysis demonstrated no clear advantage to the use of glucocorticoids to decrease maternal or perinatal morbidity or mortality.⁶⁷ A collaborative randomized controlled trial of glucocorticoids in HELLP syndrome (COHELLP) is underway to determine the effectiveness of dexamethasone to accelerate the postpartum recovery of patients with class I HELLP syndrome.⁶⁸ Observation or treatment of HELLP with glucocorticoids alone postpartum should probably not persist beyond the third postpartum day. If the patient is not clearly improving, plasma exchange should be initiated as one would do for thrombotic thrombocytopenic purpura (TTP).^{69,70} Although not associated with hypertension, acute fatty liver of pregnancy is another rare disorder that can present in the third trimester with severe liver dysfunction, but thrombocytopenia, if present, is generally mild and does not require treatment (Chaps. 51, 117, and 129).

● THROMBOPHILIA

FETAL LOSS AND COMPLICATIONS

Pregnancy is a prothrombotic state. Inherited prothrombotic conditions contribute to 50 percent of the cases of venous thromboembolism and pulmonary embolism, as well as to stroke in pregnancy and the puerperium. Hereditary thrombophilias (Chap. 130) may also predispose to fetal loss through placental vascular disorders. The best evidence for an association between a thrombophilia, albeit acquired, and recurrent fetal loss exists for antiphospholipid antibody syndrome in which the association between the antibodies and pregnancy loss has been recognized for more than 20 years.⁷¹ As many as 20 percent of women with recurrent fetal loss have antiphospholipid antibodies,⁷² and studies show that without treatment up to 90 percent will experience fetal loss.⁷³ One study suggests that poor pregnancy outcomes occur more frequently in primary antiphospholipid syndrome when patients have more than one positive laboratory test (lupus anticoagulant, immunoglobulin [Ig] G/IgM anticardiolipin, IgG/IgM antihuman β_2 -glycoprotein I antibodies).⁷⁴ In a randomized controlled trial including 90 women with a history of recurrent miscarriage associated with phospholipid antibodies (or antiphospholipid antibodies), lupus anticoagulant, and cardiolipin antibodies (or anticardiolipin antibodies), the rate of live births with low-dose aspirin (75 mg/day) and unfractionated heparin (5000 U subcutaneously twice per day) was 71 percent (32 of 45 pregnancies) and 42 percent (19 of 45 pregnancies) with low-dose aspirin alone (odds ratio: 3.37 [95% confidence interval: 1.40 to 8.10]).⁷⁵ A rarer acquired cause of fetal loss and thrombosis in pregnancy is paroxysmal nocturnal hemoglobinuria (PNH; Chap. 40). Though no clinical trials data exist, recommendations are to provide prophylactic or intermediate-dose low-molecular-weight heparin antepartum and for 6 weeks postpartum. Eculizumab should be considered both prior to and following delivery.⁷⁶

Although an association between inherited thrombophilias and pregnancy loss has been elusive and there are inconsistencies between studies, there is an association between factor V Leiden and recurrent fetal loss.^{77,78} Less-convincing data exist for prothrombin 20210A, but there is no clear association with homozygous methylene tetrahydrofolate reductase C677T polymorphism (hyperhomocysteinemia).⁷⁹ Clinical trials examining the use of low-molecular-weight heparins or aspirin to prevent adverse pregnancy outcomes in women with inherited thrombophilias have been criticized for lack of an untreated control group.⁸⁰⁻⁸² Pregnancy outcomes from a large ongoing trial conducted with a no-treatment control have yet to be published.⁸³ Studies

evaluating a role for inherited thrombophilias in preeclampsia and intrauterine growth retardation indicate that these factors may not be causative, but may contribute to disease severity.^{80,81}

THROMBOEMBOLIC EVENTS

Risk Factors

Estimates place the relative risk of arterial and venous thromboembolism (VTE) in pregnant women (Chaps. 133 and 134) at two to six times that of nonpregnant women.^{11,82} Factors specific to pregnancy that increase the risk of VTE include obstruction of venous return by the gravid uterus, acquired prothrombotic changes in hemostatic proteins, and venous atonia caused by hormonal factors.⁸⁴ Additional risk factors include cesarean section (especially emergency), obesity, and increasing age. Approximately 80 percent of deep vein thromboses in pregnancy occur in the iliofemoral veins on the left, probably as a consequence of compression of the left iliac vein by the right iliac and ovarian arteries.^{85,86} Rates of VTE immediately postpartum are difficult to assess as many occur after the patient is discharged; one large study estimates rates as much as 5 times higher in postpartum women than pregnant women.⁸⁷ Inherited thrombophilias (Chap. 130) are associated with more than half of VTE in pregnancy. Factor V Leiden and the prothrombin gene mutation are the commonest abnormalities associated with VTE in pregnancy, accounting for 44 and 17 percent, respectively. In general 1 in 500 factor V Leiden heterozygotes and 1 in 200 heterozygous carriers of the prothrombin 20210 gene mutation will have a VTE in pregnancy. Homozygosity for either of these mutations increases risk about fourfold. Based on recent studies, the risk for VTE during pregnancy is 1 in 113 for protein C deficiency, approximately 1 in 3 for type I antithrombin deficiency, and 1 in 42 for type II antithrombin deficiency. Risk for carriers of protein S deficiency is similar to that for protein C deficiency.⁸⁸⁻⁹⁰

Diagnostic Methods

Diagnosis of VTE in pregnancy is complicated both because the presenting complaints—leg edema, back pain, and chest pain—are common in pregnancy, and because radiologic studies used to make the diagnosis in nonpregnant individuals are relatively contraindicated in pregnant women. Compression ultrasonography is the initial test of choice in pregnant women. If this test is nondiagnostic, several other tests may be considered. If pulmonary embolus is suspected, lung ventilation perfusion scanning, which gives relatively low-dose radiation, may be used. Magnetic resonance imaging or magnetic resonance venography are also informative if available. Measurement of D-dimers is a useful adjunct in nonpregnant patients to rule out VTE (D-dimers are sensitive, but not specific, for VTE). However, D-dimer levels rise over the course of normal pregnancy^{91,92} and with several complications of pregnancy, including preterm labor, hypertension, and placental abruption,⁹³ and thus may not be useful in excluding VTE.

Prophylaxis

Prophylaxis for VTE is a controversial issue as only a few prospective studies have been done to assess the risk of use.^{94,95} There is general agreement, however, that because of its teratogenic potential, warfarin should not be used during pregnancy and that low-molecular-weight heparins are the anticoagulant of choice because they do not cross the placenta and have a lower risk of osteoporosis and heparin-induced thrombocytopenia than unfractionated heparin.⁹⁶ Most experts now agree that risk assessment should be based on both personal and family history of VTE as well as the presence of a known hypercoagulable state. Based on the most recent Chest Guidelines,⁹⁷ all women with prior history of VTE should be offered postpartum prophylaxis with

prophylactic or intermediate dose low molecular weight heparin for 6 weeks. For pregnant women with a low risk of recurrence (e.g., a single VTE with a transient risk factor unrelated to pregnancy or estrogen use) surveillance is recommended antepartum, whereas those with higher risk should receive prophylactic or intermediate dose low molecular weight heparin prior to delivery. Women with no prior VTE are divided into four categories. Those with higher risk of VTE in pregnancy including Factor V Leiden or Prothrombin 20210 homozygotes or compound heterozygotes with a family history of VTE should receive prophylactic or intermediate dose low molecular weight heparin antepartum and postpartum prophylaxis with prophylactic or intermediate dose low molecular weight heparin for 6 weeks. Factor V Leiden or Prothrombin 20210 homozygotes or compound heterozygotes without a family history of VTE should undergo surveillance antepartum and should receive postpartum prophylaxis with prophylactic or intermediate dose low molecular weight heparin for 6 weeks. Pregnant women with no personal history of VTE with any other thrombophilia and a family history of VTE should undergo surveillance antepartum and should be offered postpartum prophylaxis with prophylactic or intermediate-dose low-molecular-weight heparin for 6 weeks. Finally, women with lower risk thrombophilias and no personal or family history of VTE should be offered surveillance post antepartum and postpartum. Patients with two or more episodes of VTE should probably be treated throughout pregnancy and the puerperium.⁹⁸⁻¹⁰² As noted above, women who meet the criteria for antiphospholipid antibody syndrome should receive antepartum prophylactic or intermediate dose unfractionated or prophylactic low molecular weight heparin and low dose aspirin throughout pregnancy. Treatment of VTE in pregnancy should be with full-dose low-molecular-weight heparin. Ideally, women on treatment doses of heparin have elective induction of labor. Heparin is usually discontinued 24 hours prior to induction; however, women deemed to be at very high risk of recurrent VTE can then receive intravenous heparin up to 4 to 6 hours prior to delivery.^{100,101} Great care should be taken with epidural anesthesia, and it should be avoided if there is any question of a significant anticoagulant effect. Heparins and warfarin are safe postpartum, even when breastfeeding.¹⁰³

TREATMENT OF HEMATOLOGIC MALIGNANCIES IN PREGNANCY

Although not common, leukemias and lymphomas do occur in pregnancy and present problems with proper diagnosis, staging, and treatment (Chaps. 88-90). The literature suggests that the incidence of Hodgkin lymphoma is 1:1000 to 1:6000 pregnancies, whereas the incidence of non-Hodgkin lymphoma is manyfold lower.¹⁰⁴ Leukemia in pregnancy is uncommon.

HODGKIN LYMPHOMA

Neither the histology nor the outcome of patients who present during pregnancy is worse than that of other patients.¹⁰⁴ Diagnosis, usually by biopsy of a lymph node, is usually not problematic, but staging can be difficult. Posterior-anterior chest films with abdominal shielding and marrow biopsy (in the presence of B symptoms, leukopenia, or thrombocytopenia) should be done and present little risk to the fetus. Laboratory studies, including blood counts, liver functions tests, and ESR, should be done, but care should be taken in interpreting the alkaline phosphatase and ESR measurements, which both rise during the course of a normal pregnancy. Evaluation for the presence of abdominopelvic disease is difficult because computed tomography imaging is contraindicated in pregnant women. Abdominal ultrasonograms are safe, but provide limited information. If necessary, magnetic resonance imaging

scans can probably be done safely in pregnancy; however, this is rarely necessary and most experts recommend waiting until after the first trimester. The toxicities of treatment and the risks of delaying treatment until later in pregnancy or postpartum need to be considered carefully in each case. Fetal risks of chemotherapy are greatest in the first trimester during the period of organogenesis, with folate antagonists and antimetabolites carrying the largest risk.¹⁰⁵ Despite the changes in physiology that occur during pregnancy, there is no evidence that dosing should be changed. If chemotherapy is indicated, it should be delayed until the second trimester; however, single-agent vinblastine has been given in the first trimester with a low incidence of fetal abnormalities.¹⁰⁶ Treatment should be timed so that there is the maximum amount of time possible between the last dose of chemotherapy and delivery to avoid cytopenias in either the mother or the fetus. In some cases, radiotherapy may be a feasible alternative in the second and third trimesters of pregnancy. Of 16 patients who received radiotherapy for supradiaphragmatic Hodgkin lymphoma (clinical stages IA and IIA) during pregnancy, 11 received full mantle irradiation, and all patients had lead shielding of the uterus.¹⁰⁷ All 16 pregnancies were carried to completion with full-term deliveries of normal infants. However, a review of the records of 382 women treated with radiotherapy for Hodgkin lymphoma suggests that the risk of breast cancer after radiation therapy is nearly sevenfold greater with irradiation around the time of pregnancy.¹⁰⁸ Additional studies are needed to confirm these findings, but this potential risk should be borne in mind by the clinician when making therapeutic decisions.¹⁰⁹ Relapse of Hodgkin lymphoma usually occurs within the first 2 years following treatment, and patients are counseled to avoid pregnancy during this period. Vigilance for second cancers in these patients is also advised as is monitoring for hypothyroidism in those who receive radiation therapy, especially during subsequent pregnancies when hypothyroidism could have profound maternal and fetal effects.

NON-HODGKIN LYMPHOMA

As compared with Hodgkin lymphoma, other lymphomas (Chap. 95) are less frequent in pregnancy, tend to present with a higher stage disease, and have a poorer prognosis.¹¹⁰ Burkitt or Burkitt-like lymphoma can involve the breasts of young pregnant or lactating women and typically behaves aggressively.^{111,112} A recent review of more than 100 cases of Non-Hodgkin lymphoma in pregnancy, 75 percent of the patients had stage IV disease at diagnosis and nearly half had involvement of reproductive organs, primarily the breast. Very few cases of placental or fetal involvement were observed.¹¹³ In patients with high-grade lymphomas, chemotherapy often cannot be delayed and difficult decisions must be made. However, in one report of 16 pregnant patients who received aggressive chemotherapy for non-Hodgkin lymphoma during their pregnancies, all survived to delivery.¹¹⁴ Half of the 16 patients received chemotherapy in their first trimester and all 16 delivered healthy infants despite episodes of myelosuppression during the pregnancies. In a subsequent report, the health of 84 children born to mothers who received chemotherapy for hematologic malignancies during pregnancy revealed no abnormalities in physical or cognitive development and no increase in cancers at a median followup of 18.7 years.¹¹⁵ Rituximab in pregnancy, both as a single agent and in combination with chemotherapy, has not been associated with abnormalities of the newborn when given in the first, second, or third trimester¹¹⁶; however, there is one report of prolonged lymphopenia in a neonate whose mother received rituximab in pregnancy.^{61,116,117} A retrospective study of 231 pregnancies associated with maternal rituximab exposure identified 153 pregnancies with known outcomes. Among these pregnancies there were 90 live births, 22 of which were premature. There were four neonatal infections and two congenital malformations.¹¹⁸

ACUTE LEUKEMIA

Leukemia is distinctly uncommon in pregnancy; estimates derived from studies beginning in the 1950s place the incidence at approximately 1:75,000 pregnancies (Chaps. 88 and 91).^{119,120} Acute leukemias make up nearly 90 percent of the total, followed by chronic myeloid leukemia, which comprises an additional 10 percent; chronic lymphocytic leukemia is extremely rare.¹²¹ The acute leukemias require urgent treatment, and while pregnancy itself does not alter the course of the leukemia, the outcome is much worse if treatment is delayed.¹²² A summary of data on 96 pregnant women reported in the literature from 1983 to 1995 who were treated with cytotoxic chemotherapy for leukemias (most of which were acute) revealed that most patients received regimens that included multiple drugs and were not different from those given to nonpregnant patients.¹²³ Nearly one-third of patients were treated in the first trimester of pregnancy. Among the 96 pregnancies, there were 2 maternal deaths, 2 children were stillborn, 2 therapeutic abortions were performed, 1 child had chromosomal abnormalities, and 8 had congenital defects. Seven of the eight children born with congenital defects were born to mothers who had been treated in the first trimester. It was not possible to identify a drug (or drugs) that was most likely responsible for adverse outcomes. Treatment in the first trimester carries a high risk of fetal anomaly or miscarriage. For patients with acute myelogenous leukemia (AML) receiving a standard induction regimen of cytarabine and an anthracycline, it is probably best to avoid idarubicin, which is more lipophilic with elevated placental transfer. Doxorubicin has been extensively studied in pregnancy women with breast cancer and is probably the anthracycline of choice in pregnant patients with AML.¹²⁴ Although few cases of fetal cardiotoxicity related to anthracyclines have been reported, fetal cardiac function should be monitored in pregnancy. Very few data exist for consolidation therapy in pregnancy. Case reports of treatment of acute promyelocytic leukemia in pregnancy with all-*trans*-retinoic acid¹²⁵⁻¹²⁷ suggest that it may be safe after the first trimester. Arsenic trioxide is not recommended for use at any stage of pregnancy because of its high potential for embryotoxicity.¹²⁸ For patients who require chemotherapy postpartum, breastfeeding is not recommended so as to avoid exposure of the newborn to cytotoxic drugs in the breast milk.¹²⁹ Patients with chronic myeloid leukemia have been successfully treated in pregnancy with interferon- α , hydroxyurea, leukapheresis, and even busulfan.¹³⁰⁻¹³² A review of 125 women treated with imatinib mesylate during pregnancy revealed that most pregnancies had successful outcomes; however, 12 infants had abnormalities, 3 of which involved complex malformations.¹³³

Supportive treatment with antiemetics, including ondansetron, aprepitant and metoclopramide, is safe, and these agents do not cause congenital malformations.¹³⁴ Little data exist for the effects of growth factors including granulocyte colony-stimulating factors, but there are no reports of teratogenic effects.¹³⁵ Care should be taken with prescribing antibiotics and quinolones in specific should be avoided in pregnancy as should sulfonamides. When antifungal therapy is required, amphotericin may be the drug of choice as there have been no reports of teratogenicity with this agent. Fluconazole appears to be safe at doses less than 150 mg per day, but ketoconazole and voriconazole can cause fetal malformations and should be avoided altogether.¹³⁶

● ESSENTIAL THROMBOCYTHEMIA

The management of pregnant patients with essential thrombocythemia (ET) is a challenge because thrombosis is the main complication of ET (Chap. 85) and is accentuated by the prothrombotic state of pregnancy. In addition, of all the myeloproliferative neoplasms, ET has the highest proportion of affected females of child-bearing age. One study

reviewed 155 pregnancies in 86 women with ET, and only 59 percent of these pregnancies resulted in a live neonate.¹³⁷ First-trimester abortion was seen in 31 percent of pregnancies, the main cause being placental infarction. Maternal thrombotic or hemorrhagic complications were infrequent, but were more common than in normal pregnancy. Pregnancy did not appear to adversely affect the course and prognosis of ET.

A meta-analysis revealed a benefit for aspirin treatment, whereas the benefit of heparin prophylaxis has not been established, but may have a role in selected cases.¹³⁸ If cytoreductive therapy becomes necessary, interferon- α is the drug of choice. A similar incidence of pregnancy complications in patients with ET was reported in a series from the Mayo clinic.¹³⁹ Another large single institution study of 68 young ET patients demonstrated that for both polycythemia vera (PV) and ET, most thromboses in young patients occurred at the time of diagnosis and also suggested, but did not prove, the benefit of aspirin.¹⁴⁰ The most detailed analysis was published by the Italian Society of Hematology in its guidelines.¹³⁸ The Society's report analyzed pooled outcome data from 461 pregnancies in women with ET. The mean age of the pregnant patients was 29 years, and the mean platelet count at the beginning of pregnancy was $1000 \times 10^9/L$, which declined to $400 \times 10^9/L$ in the second trimester. This decrease in the platelet count during pregnancy documented for the first time the anecdotal observation that some women with ET spontaneously normalize their platelet count during their pregnancy. (The authors of this chapter have rarely observed this phenomenon; however, in one of their ET patients a spontaneous, but transient, ET remission occurred in the first pregnancy, but not in the following pregnancy.) The Italian study found that 44 percent of pregnancies were unsuccessful in women with ET, a figure that is threefold higher than in the general population. Among the 461 pregnancies there were 13 pre- or postpartum significant bleeding events. The median duration of gestation was 38 weeks because of abortions and preterm deliveries. Cesarean section was necessary in 15 percent of the patients. The platelet count at the beginning of pregnancy did not predict pregnancy outcome. Placental infarctions were reported in 18 pregnancies and these were associated with intrauterine fetal growth retardation (11 pregnancies). Placental abruption was reported in 3.6 percent of ET pregnancies compared to 1 percent in the non-ET population. Preeclampsia was seen at a rate equal to that seen in non-ET pregnancies. Postpartum thrombotic episodes were reported in 5.2 percent of the pregnancies and included venous thrombosis, pulmonary embolism, sagittal sinus thrombosis, transient ischemic attacks, and Budd-Chiari syndrome (rates for all problems were significantly higher than in non-ET pregnancies). The impact of therapy was difficult to evaluate because management of ET pregnancies was heterogeneous; no specific therapy for ET was given in 48 percent of the pregnancies. Aspirin therapy at doses ranging from 75 to 500 mg per day was used in 106 pregnancies, low-molecular-weight heparin (pre-/postpartum) was used in 26 pregnancies, interferon- α was used in 19 pregnancies, and a handful of patients had various chemotherapies and radioactive phosphorus. When the outcome of the ET pregnancies was reviewed, 74 percent of patients treated with aspirin during pregnancy had successful pregnancies, whereas 55 percent of the patients not receiving aspirin had successful pregnancies. Based on the detailed analyses of all variables, this panel of experts felt that there was no direct evidence of the efficacy of aspirin in pregnant ET women, but that "it seems possible that aspirin increases the rate of successful pregnancies." The panel also recommended that ET patients with a thrombotic episode (peripheral or placental) during pregnancy should receive low-molecular-weight heparin at therapeutic doses and oral anticoagulant therapy (PT international normalized ratio 2 to 3) for at least 6 weeks postpartum. Longer periods of anticoagulation were recommended for patients with familial thrombophilia. Pregnant women deemed candidates for platelet-lowering therapy (a history

of major thrombosis, or of major bleeding, platelet count greater than $1000 \times 10^9/L$, familial thrombophilia or cardiovascular risk factors) were recommended to receive interferon. The Italian panel also recommended avoidance of anagrelide in pregnancy because of uncertainty about its teratogenic potential; however, several normal infants have been born to women who inadvertently took this drug during pregnancy (FDA documents submitted by the manufacturer). Although the risk of congenital anomalies among infants of women treated with hydroxyurea during pregnancy was thought to be substantial, of 15 infants born to women treated with hydroxyurea at conception and/or during pregnancy, no malformations were observed, and only one stillbirth was reported in a woman who also had eclampsia. At least one publication has identified the presence of the *JAK2* V617F mutation as a risk factor for pregnancy complications; however, to date there is no consensus on whether to manage these patients differently.¹⁴¹ A review of 158 young women with ET experiencing 237 pregnancies demonstrated that pregnancy complications are associated with higher risk of subsequent thrombosis.¹⁴²

● POLYCYTHEMIA VERA

Although there is significant overlap in the clinical features of PV and ET, there are some noteworthy differences (Chap. 84). In PV, the number of reported pregnancies is low because most PV patients are past childbearing age, and comorbid conditions are more frequent. One authoritative review suggests maintaining the hematocrit below 45 percent¹⁴¹ in pregnancy, and another recommends using interferon- α when myelosuppression is indicated.¹⁴³ Another noted authority in PV recommends that the hematocrit be kept lower than 35 percent in pregnancy.¹⁴⁴ However, because of a dearth of data and controlled studies, optimal management of PV pregnancies is poorly defined and agreed upon protocols are not available. None of the available information allows definite therapeutic recommendations; however, some authorities recommend that, at a minimum, all pregnant patients with PV be treated with low-dose aspirin.¹⁴⁴

● HEMOGLOBINOPATHIES

SICKLE SYNDROMES

Although pregnancy in patients with sickle cell trait is typically uneventful, these patients probably have an increased risk for urinary tract infection.¹⁴⁵ Earlier studies suggested an increased risk for preeclampsia in patients with sickle cell trait, but a large study demonstrated that sickle cell trait is not an independent risk factor for preeclampsia (Chap. 49).¹⁴⁶

Patients with sickle cell anemia should receive at least 1 mg of folate per day; however, they should not receive iron supplementation until a ferritin level is checked and iron deficiency is documented.¹⁴⁷ Because of the risk of fetal malformation, hydroxyurea should be discontinued at least 3 months before pregnancy. However, successful outcomes have been reported in sickle cell disease patients who were exposed to the drug while pregnant.¹⁴⁸ Women with sickle cell anemia and their fetuses have an increased risk of complications during pregnancy. A large study of more than 17,000 deliveries to women with sickle cell anemia compared with controls demonstrated that infectious complications, including pneumonia, systemic inflammatory response syndrome, and sepsis, were more common in the women with sickle cell anemia. Furthermore, thrombotic complications such as cerebral vein and deep vein thrombosis and pregnancy complications including preeclampsia, eclampsia, abruption and antepartum bleeding were significantly more common in patients with sickle cell anemia. As in previous reports, rates of intrauterine growth retardation and preterm

labor, as well as rates of maternal mortality, were higher in mothers with sickle cell anemia.¹⁴⁹ The issue of prophylactic versus need-based transfusion in sickle cell patients is controversial. A Cochrane Review identified only two small randomized studies conducted in the United States in the 1980s addressing this issue. These studies demonstrated no difference in perinatal outcome between the offspring of mothers with sickle cell disease who were assigned to treatment with prophylactic transfusions and those who were not.^{1,150}

Although the incidence of cesarean section in sickle cell patients is reported to be as high as 36 percent,¹⁵¹ delivery can generally be accomplished vaginally. Most experts recommend avoiding induction of labor as this can lead to sickle crisis.¹⁵² Epidural anesthesia is reported to be safe and to decrease the risk of peripartum painful crises.¹⁵³

THALASSEMIA SYNDROMES

β -Thalassemia Syndromes

Preconception evaluation of patients with β -thalassemia syndromes is recommended and should include assessment of transfusion needs, chelation therapy, body iron status and organ function, and the presence of antibodies to red cell antigens.¹⁵⁴ Patients with β -thalassemia minor generally tolerate pregnancy well; however, doses of at least 4 mg of folate per day are recommended in the preconception period and the first trimester as there is some data to suggest an increased risk of neural tube defects in their offspring.¹⁵⁵ Transfusion and iron chelation therapy has improved both life expectancy and fertility in patients with β -thalassemia intermedia and major, and successful pregnancies have been reported in both disorders.¹⁵⁶ A high rate of maternal mortality is reported in women with thalassemia and cardiac iron overload emphasizing the need for aggressive management of iron status prior to undertaking a pregnancy.¹⁵⁷ During pregnancy, regular transfusions are recommended to keep the hemoglobin level at 10 mg/dL and transfusion requirements often increase as compared to prepregnancy values.¹⁵⁸ Iron-chelation therapy with deferoxamine in pregnancy is controversial and most authorities recommend a hiatus during pregnancy; however, no fetal abnormalities have been reported in pregnancies in which it was continued (Chap. 48).¹⁵⁹

α -Thalassemia Syndromes

Patients with the silent carrier state or α -thalassemia trait have no increase in pregnancy complications; however, identification of patients with heterozygous α -thalassemia trait is important in assessing the risk of having a fetus that has hemoglobin H or hemoglobin Bart. Although women with hemoglobin H are generally able to have successful pregnancies, the chronic anemia often worsens, requiring blood transfusion. Patients with hemoglobin H are sensitive to oxidizing compounds and medications, which should be borne in mind, particularly during pregnancy (Chap. 48).

CHAPTER 9

HEMATOLOGY IN OLDER PERSONS

William B. Ershler, Andrew S. Artz, and Bindu Kanapuru

SUMMARY

This chapter presents a current appraisal of our understanding of aging followed by a more detailed description of age-associated changes in hematopoiesis and their clinical consequences. Those who are older than the age of 75 years comprise a rapidly growing segment of the population. Marrow, like other organs, undergoes characteristic changes with advancing age, and many of these changes are evident by standard examination. For example, within the marrow space, hematopoietic cells occupy approximately one-half the volume at mid-life, with adipose tissue making up the difference. Yet, in the absence of disease, blood counts are generally maintained within a range established as normal for younger individuals. This is possible because hematopoietic stem cells increase in number with age and are of sufficient functional capacity to respond to homeostatic signals. Older people are more likely to have chronic diseases that may produce additional stress on marrow reserve. Anemia, for example, is present in just over 10 percent of community-dwelling individuals older than age 65 years; for those residing in nursing homes, the prevalence is closer to 50 percent. One distinction between anemias in older people compared with younger people is that for approximately one-third of older anemic patients, a specific cause for the anemia cannot be determined. This “unexplained anemia” is likely the result of multiple factors, including inappropriately low erythropoietin response, inflammatory cytokines, androgen deficiency, and, in some persons, incipient myelodysplasia. Platelet and neutrophil changes with age have been incompletely characterized but are likely to be subtle and of little clinical consequence. There is a well-characterized, age-associated involution of the thymus gland that precedes the histologic changes within the marrow, and marrow-derived T- and B-cell precursors are affected. Older people have fewer naïve, reactive T cells and an increase in relatively inert memory T cells. Thus, the capacity to react to new antigenic challenges is reduced and there is an increased susceptibility to certain infections and vaccines. Also evident are deficient regulatory functions, which may explain the observed increase in autoantibody, paraproteins, and inflammatory cytokines in those of advanced age. In the absence of disease, however, these alterations are of little consequence. In the presence of chronic debilitating disease, they are likely to become more pronounced and as such, contribute to an exaggerated decline in overall function. Similar conclusions can be drawn regarding

dysregulated inflammatory pathways and coagulation. In balance, advancing age is associated with a procoagulant profile that may be of clinical importance in the presence of underlying atherosclerotic vascular disease.

● A PRIMER ON AGING

The world's population is aging at an unprecedented rate and the implications for health care delivery are profound.¹⁻⁴ Over the next several decades, the percentage of the population older than age 65 years will nearly double.⁵ In anticipation, an increased research effort is being made to better understand the basic biology of aging and the mechanisms whereby individuals become susceptible to disease.^{6,7}

A central dogma of gerontology is that aging is not a disease. Yet, intrinsic biologic aging is the major risk factor for virtually all major diseases of developed societies, including cancer, diabetes, atherosclerotic cardiovascular and cerebrovascular disease, diabetes, neurodegenerative diseases (e.g., Alzheimer and Parkinson), osteoporosis and infection. Examination of the mechanisms by which biologic aging contributes to the pathogenesis of these diseases has now become recognized in the mainstream of scientific inquiry over a broad range of disciplines.⁷ However, from a biogerontologist's perspective, there remain certain features of aging that transcend the more discipline-focused investigations.

One of these common features of aging is heterogeneity. For example, for any measurable variable, the range of values among normal older individuals is much wider than the range of normal among younger individuals.^{8,9} This variation is particularly relevant for hematologists consulted to examine older, but otherwise healthy, individuals with laboratory values outside the “normal range.”

Although functional declines that accompany normal aging have been well characterized,^{10,11} in general these are not of sufficient magnitude to account for symptoms or be mistaken for disease. For example, that kidney function declines with age is well recognized,^{12,13} and, in fact, has proven to be a useful biologic marker of aging. Yet, clinical consequences of this change in renal function, in the absence of a disease or the exposure to an exogenous nephrotoxic agent, do not occur commonly. Similarly, the marrow changes with age. Marrow stem cells increase in number and proliferative capacity, yet the *in vitro* proliferative potential of progenitor cells is less.¹⁴⁻¹⁶ Although clinically significant cytopenias do not occur in the absence of disease, mild to moderate anemia that has not been fully characterized occurs with increasing frequency, especially in the frail elderly.¹⁷⁻²⁰ Furthermore, in frail individuals even a mild reduction in hemoglobin level is associated with untoward clinical outcomes.^{19,21,22}

Certain immune functions decrease with age,²³⁻²⁵ but these may be of only marginal clinical significance. For example, whether the laboratory-observed declines in immune function contribute to a heightened susceptibility to infection is a subject of debate, but data support an association of age-associated qualitative change in lymphocyte function and susceptibility to reactivation of tuberculosis^{26,27} or herpes zoster^{28,29} and diminished response to influenza vaccine.³⁰⁻³³ There is compelling evidence that a profound decline in immunity is causally related to certain malignancies,³⁴ but there remains debate over whether the more modest decline associated with normal aging is sufficient to account for the observed increased rate of cancer in the elderly.^{35,36} In fact, there is some evidence that cancer incidence is even lower in frail elderly,³⁷ a population known to be functionally immunodeficient.³⁸ Similarly, development of autoantibodies appear with increasing frequency

Acronyms and Abbreviations: EPESE, Established Populations for the Epidemiological Study of the Elderly; HSCs, hematopoietic stem cells; IADL, independent activities of daily living; IL, interleukin; NHANES III, National Health and Nutrition Examination Survey III; PAI-1, plasminogen activating inhibitor-I; TNF, tumor necrosis factor; UA, unexplained anemia; WHO, World Health Organization.

with advancing age, but these are considered markers of an acquired humoral immune dysregulation, and with regard to autoantibody, not of clinical importance.³⁹ In contrast, essential monoclonal gammopathy, a clonal B lymphocyte expansion that increases in frequency with age and that stabilizes at a clone size that does not impair normal immunoglobulin synthesis or inhibit hematopoiesis, does have a probability of undergoing clonal evolution to a B-cell malignancy, such as myeloma, lymphoma, or monoclonal light-chain amyloidosis at a rate of 1 percent per year (Chap. 106).⁴⁰

THEORIES OF AGING

Providing a rational, unifying explanation for the aging process has been the subject of a great number of theoretical expositions. Yet, no single proposal suffices to account for the complexities observed (Table 9–1).

Genetic Effects

That genetic controls are involved seems obvious when one considers that lifespan is highly species-specific. For example, mice generally live approximately 30 months and humans approximately 90 years. However, the aging phenomenon is not necessarily a direct consequence of primary DNA sequence. For example, mice and bats have 0.25 percent difference in their primary DNA sequence, but bats live for 25 years, 10 times longer than mice. Thus, regulation of gene expression seems likely to be the major source of species longevity differences.

Progeria Syndromes Gerontologists have long been intrigued by the concept of accelerated aging and by examining those rare individuals who are so affected. From work with invertebrate models a number of genes have been identified that associate with longevity. Yet, the identification and functional analysis of analogous genes in humans remains elusive. With regard to genetic examples of accelerated aging, two syndromes have been well characterized: Hutchison-Guilford syndrome (early-onset progeria) and Werner syndrome (adult-onset progeria).^{41,42} Although neither these nor other progeria syndromes manifest a complete phenotype of advanced age, the identification of the genes responsible for these particular syndromes is beginning to pay dividends by providing clues to the molecular mechanisms involved in the aging process. For example, Werner syndrome is now defined by mutations in a single gene on chromosome 8 that encodes a protein containing a helicase-like domain.^{43,44} The activity of the Werner protein helps to maintain telomere structure and homology-dependent recombination.⁴⁵ Similarly, a mutation in the lamin A (*LMNA*) gene localized to chromosome 1 has been causally related to the Hutchison-Guilford syndrome.⁴⁶ The product of the mutated *LMNA* gene (termed *progerin*) accumulates, producing a variety of nuclear distortions of which telomere dysfunction and associated replicative senescence are notable.⁴⁷

Examination of aging in yeast has also been informative with regard to the genetic controls of aging. These single-cell organisms follow the

replicative limits of mammalian cells and it has been observed that “life span” is related to silencing large chromosomal regions. Mutations in these silencing genes lead to increased longevity.⁴⁸

Thus, if there are certain genes that regulate normal aging, or at least are associated with the development of an aged phenotype, it stands to reason that acquired mutations of those genes might influence the rate of aging. Over the years several theories have been proposed that relate to this supposition. In general, they hypothesize a random or stochastic accumulation of damage, either to DNA or protein that leads eventually to dysfunctional cells, cell death and subsequent organ dysfunction, and ultimately death. Prominent among these is the *somatic mutation theory*,⁴⁹ which predicts that genetic damage from background radiation, for example, accumulates and produces mutations that ultimately result in functional decline. A variety of refinements have been suggested to this theory, invoking the importance of mutational interactions,⁵⁰ transposable elements,⁵¹ and changes in DNA methylation status.⁵²

A related hypothesis is Burnet’s *intrinsic mutagenesis theory*,⁵³ which proposes that spontaneous or endogenous mutations occur at different rates in different species and that this accounts for the variability observed in life span. Closely related to this notion is the *DNA repair theory*.⁵⁴ Initially, there was great excitement about this idea as it was found that long-lived animals had demonstrably more active DNA repair mechanisms than shorter-lived species.⁵⁴ However, longitudinal studies within a species have not revealed a consistent decline in repair mechanisms with age. This, of course, does not rule out the possibility that repair of certain specific and critical DNA lesions is altered with advancing age. We now understand that there are multiple DNA repair mechanisms, including base excision repair, transcription-coupled repair, and even mitochondrial DNA repair mechanisms. Disorders involving one or a subset of repair mechanisms could lead to accumulation of DNA damage and dysfunction.

In yet another intrinsic/stochastic model, Orgel⁵⁵ proposed the *error catastrophe theory* in which he suggested that random errors in protein synthesis occur and when the proteins involved are those responsible for DNA or RNA synthesis, there is resultant DNA damage and the consequences thereof to daughter cells. Although this model has appeal, there has been no reported evidence for impaired or inaccurate protein synthesis machinery with advancing age. However, a candidate protein that may eventually be shown to be so affected is telomerase. This critical enzyme is necessary for maintaining telomere length and cell replicative potential. *In vitro* cellular senescence is associated with diminished telomerase activity,⁵⁶ but whether this relates to aging of the organism as a whole remains controversial.⁵⁷

Posttranslational Effects

Evidence that exogenous factors are involved in the acquisition of age-associated damage to DNA and protein is derived from a number of observations, many of which are circumstantial or correlative, but nonetheless provocative. It now appears that the accumulation of abnormal protein within senescent cells, as predicted by the *error catastrophe theory*, actually reflects posttranslational events, such as oxidation or glycation, and resultant crosslinking. There is theoretic appeal to the concept that key proteins, such as collagen or other extracellular matrix proteins, and DNA become dysfunctional with age as a consequence of the impairment produced by these crosslinks.^{58–60}

Glycation One mechanism producing crosslinks is called *glycation*, the nonenzymatic reaction of glucose with the amino groups of proteins. Presumably, glycation would occur more readily in the presence of higher serum levels of glucose, and, thus, this theory fits well with the observed, age-associated dysregulation of glucose metabolism and prevalent hyperglycemia in geriatric populations. Of course, these

TABLE 9–1. Theories of Aging

Intrinsic-stochastic	Somatic mutation ^{50,51}
	Intrinsic mutagenesis ⁵⁵
	Impaired DNA repair ⁵⁶
	Error catastrophe ⁵⁸
Extrinsic-stochastic	Ionizing radiation ^{50,51,53,58}
	Free radical ^{63,64}
Genetically determined	Neuroendocrine ²⁹⁸
	Immune ⁷⁷

findings also point out the theory's deficiency as a unifying mechanism, as there is no question that individuals with well-maintained glucose levels throughout their life span will still be subject to the acquired changes typical of aging.

Free Radical Hypothesis

Another mechanism held responsible for crosslinking is the damage produced by free radicals, which forms the basis of the *free radical hypothesis* initially promoted by Harman.^{61,62} This theory offers that aging is the result of DNA and protein damage (e.g., mutagenesis or crosslinking) by atoms or molecules that contain unpaired electrons (free radicals). These highly reactive species are produced as byproducts of a variety of metabolic processes and are normally inhibited by intrinsic cellular antioxidant defense mechanisms. Nitrate-based free radicals are also generated by *in vivo* processes and another set of nitrogen free-radical scavenging mechanisms are in place. If free radical generation increases with age, or the defense mechanisms that scavenge free radicals (e.g., glutathione) or repair free radical damage decline, the accumulated free radical damage may account for altered DNA and protein function. Evidence to support this widely held notion is incomplete. It is known that free radical generation in mammals correlates inversely with longevity⁶³ and, similarly, the level of free radical inhibiting enzymes, such as superoxide dismutase were higher in those species with longer life spans.⁶³ However, efforts at enhancing antioxidant mechanisms with dietary vitamin E have resulted in only a modest enhancement of median survival in mice and no effect on maximum life span.^{64–66}

Much attention has been focused on mitochondrial function in the context of free radical damage because the bulk of oxidative metabolism and the production of reactive oxygen species occur in these organelles. Although mitochondrial DNA codes for antioxidant enzymes in addition to enzymes involved in energy production, it is currently believed that energy production declines with age as a result of mitochondrial DNA damage by those reactive products. Indeed, mitochondrial damage increases with age in experimental models,^{67–69} and the shortened survival of knockout mice deficient in mitochondrial antioxidant enzymes has supported the potential importance of this mechanism.⁷⁰

The most compelling data to date in support of the free radical hypothesis come from experiments in which transgenic *Drosophila* producing enhanced levels of superoxide dismutase and catalase had a maximum survival 33 percent greater than controls.²⁶ Furthermore, it is known that flies produce high levels of free radicals associated with their impressive metabolic requirements, and that survival is enhanced dramatically when the ability to fly is experimentally hindered.⁶⁵ However, the generalizability of these findings has been questioned. It has been noted that transgenic mice overexpressing free radical scavenging enzymes have produced very modest effects on life span.⁷¹ Thus, the conclusion that augmentation of free radical scavenging mechanisms increases longevity in mammalian species is not established.

Neuroendocrine Theory

From a different perspective, very good evidence implicates a nonrandom, perhaps genetically regulated endogenous mechanism involved in aging. For example, the *neuroendocrine* theory suggests that the decrements in neuronal and associated hormonal function are central to aging. It has been suggested that age-associated decline of hypothalamic–pituitary–adrenal axis function results in a physiologic cascade leading, ultimately, to the “frail” phenotype. This hypothesis is appealing because it is well established that this neuroendocrine axis regulates much of development and also the involution of ovarian and testicular function. Furthermore, age-associated declines in growth hormone and related factors,⁷² dehydroepiandrosterone,⁷³ and secondary sex steroids⁷⁴

are implicated in age-associated impairments, including a reduction in lean body mass and bone density. Furthermore, pharmacologic reconstitution using these or related hormones has met with some success at reversing age-associated functional decline.^{75,76}

Immunologic Theory

Similarly, it has been argued that involution of the thymus gland and subsequent decline in immune function discussed below is a key regulator of aging.⁷⁷ The argument is based upon the observation that the decline in immune function occurs in all mammalian species, but occurs later in those with longer survival.⁷⁸ Furthermore, dietary restriction is associated with maintained thymic mass and measurable immune function as well as prolonged survival, suggesting an association of a decline in immunity with primary aging processes.

The possibility is highlighted by the observation that differences in maximum survival of different mouse strains has been associated with specific alleles in the major histocompatibility complex, which, in turn, code for immunologic determinants.⁷⁹ This hypothesis, although not without its appeal, is not widely accepted as a major explanation for aging. Perhaps this relates to the fact that biologic aging is a universal phenomenon and certain features are held in common, even in organisms with primitive or no immune function. (The same could also be said for the neuroendocrine theory.) It is obvious that the immune system is of great importance in minimizing the chance of early death, particularly from infectious diseases. However, immunologic reconstitution of middle aged or old animals has not been shown to prolong survival.⁸⁰

LIFE SPAN: MEDIAN AND MAXIMUM SURVIVAL

From the perspective of those who study aging, an important distinction is made between median (life expectancy) and maximum life span. Over the past century, a dramatic increase in median survival has been mostly attributable to modern sanitation and refrigeration, as well as public health measures, including vaccination and antibiotics.⁸¹ Early deaths have been diminished and more individuals are reaching old age. In the United States today, expected survival from birth is approximately 80 years.⁸² Median survival is what concerns public health officials and healthcare providers. In contrast, maximum survival is the focus of those gerontologists interested in the biology of aging and longevity.

The oldest human being alive today is approximately 120 years old. It is intriguing that the oldest age limit has remained stable, unchanged by the public health initiatives mentioned above. In the laboratory, limits on age have been established for a variety of species. *Drosophila*, free of predators, disease or fly swatters, can live 30 days, whereas C57BL/6 mice in a laboratory environment and allowed to eat a healthy diet *ad libitum*, may survive 40 months. Unlike health-related interventions in humans, certain experimental interventions in lower species are associated with a prolongation of maximum survival. In *Drosophila*, for example, transgenic offspring producing extra copies of the free radical scavenging enzymes superoxide dismutase and catalase survive approximately 33 percent longer than controls.⁸³ In nutritional intervention studies involving lower species, controlled restriction of dietary intake (dietary restriction) has become a common experimental paradigm exploited in the investigation of primary processes of aging and maximum survival.^{84,85}

Dietary Restriction

Dietary restriction typically involves a reduction of 30 to 40 percent in caloric intake with careful attention to the provision of adequate amounts of essential nutrients. It is associated with both a delay in the

acquisition of age-related diseases (including cancer) and a reduction in the rate of achieving certain established biomarkers of aging (i.e., a retardation in primary aging). The critical questions remain: What is the mechanism of the effect of dietary restriction, and will it be applicable to higher species? With regard to the latter, there are now comprehensive and interactive studies within the United States in which dietary restriction is being examined in nonhuman primates^{86,87} and human studies are also underway.^{88,89} Although it appears that the calorie restricted monkeys in these studies are assuming a more youthful phenotype in a variety of physiologic measures,^{86,90,91} it remains too early to predict whether maximum survival will be affected.

CELLULAR SENEESCENCE AND ORGANISMAL AGING

After a finite number of divisions, normal somatic cells invariably enter a state of irreversibly arrested growth, a process termed *replicative senescence*.⁹² In fact, it has been proposed that escape from the regulators of senescence is what oncologists term *malignant transformation*. However, the role of replicative senescence as an explanation of organismal aging remains the subject of vigorous debate (for review, see references 93 and 94). The controversy relates, in part, to the fact that certain organisms (e.g., *Drosophila*, *Cunninghamella elegans*) undergo an aging process, yet all of their adult cells are postreplicative.

What is clear is that the loss of proliferative capacity of human cells in culture is intrinsic to the cells and not dependent on environmental factors or even culture conditions.⁹² Unless transformation occurs, cells age with each successive division. The number of divisions turns out to be more important than the actual amount of time passed. Thus, cells held in a quiescent state for months, when allowed back into a proliferative environment, will continue approximately the same number of divisions as those that were allowed to proliferate without a quiescent period.⁹⁵ The question remains whether this *in vitro* phenomenon is relevant to animal aging.⁹⁵ Although when various species are compared, replicative potential is directly and significantly related to life span,⁹⁶ within an organism there is great variability in proliferative capacity from tissue to tissue and organ to organ. As such, age-associated changes in the marrow or gut might relate to replicative senescence, whereas in muscle or brain other processes most certainly are involved. But, added to this heterogeneity within an individual, is that fact that certain commonly employed models of aging (e.g., *Drosophila*, *C. elegans*) undergo an aging process despite a long held belief that all of their adult cells were post replicative.^{94,97,98} However, this notion has been countered by the demonstration of multipotent intestinal stem cells within the midgut near the intestinal basement membrane of *Drosophila*.⁹⁹ Unlike intestinal stem cells in vertebrates that interact with stromal cells within a niche, analogous cells within *Drosophila* reside on the surface of the basement membrane and interact directly with daughter cells. Nevertheless, the presence of such cells has rekindled an interest in *Drosophila* as a model for stem cell biology, cancer, and whole-animal aging.^{100,101}

CELLULAR SENEESCENCE AND CANCER

A feature of cellular senescence is diminished proliferative capacity. In fact, it is now understood that genes considered tumor suppressors (e.g., p53, RB [retinoblastoma gene]) prevent cancer by inducing programmed cell death (apoptosis), particularly in cells at risk for neoplastic transformation. Alternatively, they can prevent potential cancer cells from proliferating by inducing permanent withdrawal from the cell cycle (cellular senescence). Although little is known about how cells choose between apoptotic and senescence responses, both are crucial for suppressing cancer^{102,103} and both are highly relevant to functional decline and longevity.¹⁰⁴

There are a multitude of oncogenic stimuli that may result in either cancerous transformation or cellular senescence.^{105,106} Epigenetic changes within chromatin, histones, or nucleic acids may be caused by pharmacologic agents or altered expression of proteins.^{107–109} Such changes can alter the expression of protooncogenes or tumor-suppressor genes and are a frequent occurrence among malignant tumors. Thus the senescence response aborts the uncontrolled proliferative response an assortment of potentially oncogenic stimuli.

Although diverse stimuli can induce a senescence response, they appear to converge on one or both of the two pathways that establish and maintain the senescence growth arrest. These pathways are governed by the gatekeeper tumor-suppressor proteins p53 and pRB.^{104,110,111} Furthermore, the senescence response to dysfunctional telomeres requires the integrity of the p53 pathway.^{112,113} Overexpression of the *RAS* gene may also trigger a p53-dependent damage response by producing high levels of reactive oxygen species.^{113–115} However, oncogenic *RAS* can also induce p16, an activator of the pRB pathways, which provides a second barrier to the proliferation of potentially oncogenic cells. There is an emerging consensus that senescence occurs through one pathway or the other, with the p53 pathway mediating senescence primarily as a result of telomere dysfunction and DNA damage and p16/pRB pathway—mediating senescence primarily as a result of oncogenes, chromatin disruption, and various stresses.

A more speculative, but potentially important consequence of cellular senescence may be its impact on stem cells.¹¹⁶ Embryonic stem cells, whether human or rodent, express a high level of telomerase and thus are considered resistant to replicative senescence.^{117,118} However, mammalian adult stem cells or progenitor cells do not proliferate indefinitely.^{119–122} The ability of stem cells to undergo senescence and apoptosis is likely to be an important mechanism for preventing cancer.^{123,124}

AGING AND HEMATOPOIESIS

Aging is a universal phenomenon that affects all normal cells, tissues, organ systems, and organisms. Accordingly, the marrow undergoes changes with age. Age-related hematologic changes are reflected by a decline in marrow cellularity, an increased risk of clonal myeloid neoplasms¹²⁵ and anemia,^{17,126–130} and a decline in adaptive immunity.^{131–134}

MARROW: ANATOMIC CHANGES

The percentage of marrow space occupied by the hematopoietic tissue declines from 90 percent at birth to a level of approximately 50 percent at age 30 years and 30 percent at age 70 years.^{135,136} A similar change occurs in the thymus, where involution begins at an earlier age and is reflected anatomically by a reduction in lymphoid mass with an increase in fat¹³⁷ and functionally by a steady decrease in the production of naïve T cells.^{80,138} Fat infiltration into the marrow and thymus results in a diminished volume of hematopoietic tissue.

Although age-related change in the marrow is well described, the exact mechanisms that regulate these changes remains speculative.¹³⁹ For example, it remains unclear whether the age-associated expansion of marrow fat is a cause or an effect of aging and whether the changes seen in marrow and histologically similar changes within the thymus are intrinsically related. Because of the intricate association of hematologic and immune functions and these common histologic patterns of change with age, both changes in blood and innate immunity are discussed below in the sections on Blood Cell Changes with Age and Aging and Immunity.

MARROW: STEM CELLS

The ontogeny of hematopoietic stem cells is the focus of much attention.^{140,141} In fetal development the manufacture of blood cells occurs

in several organs, but after birth this function is subsumed by the marrow.^{142–148} The process of embryonic and fetal hematopoiesis is described in Chap. 7. Hematopoietic cells appear in the medullary cavities of bone around 14 weeks of gestation,¹⁴⁹ and by birth the marrow is the primary site of hematopoiesis.

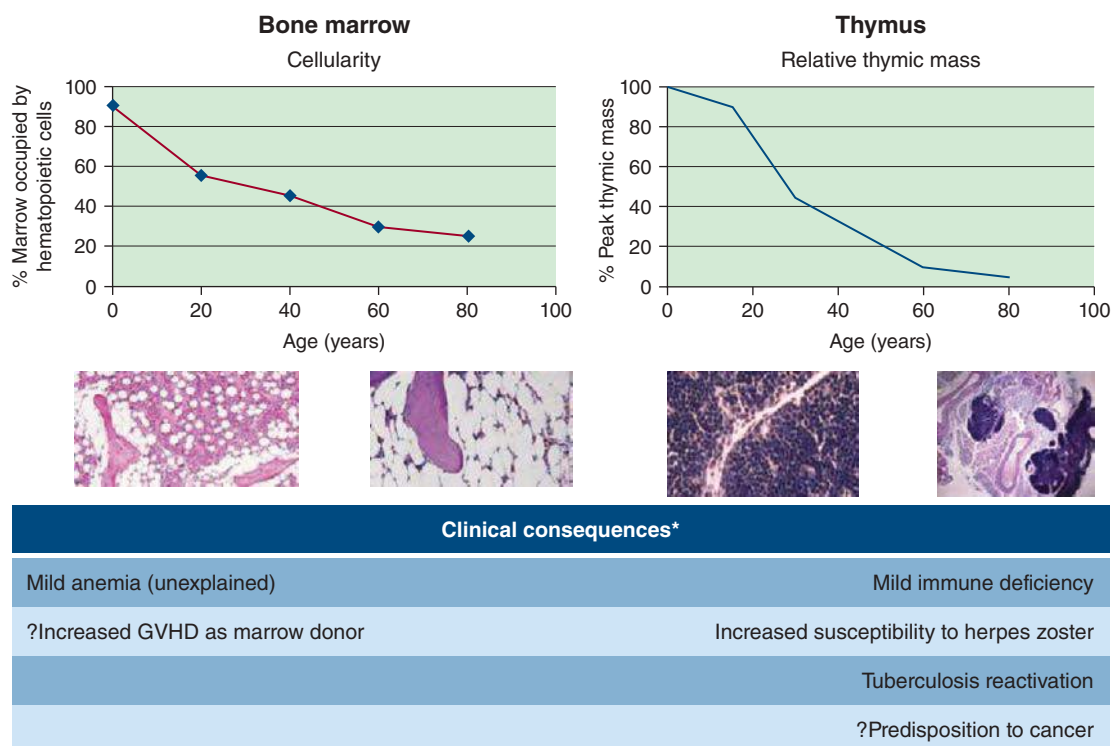

Unlike the commonly held notion that stem cell compartments diminish either in number or function with age ultimately resulting in an inability to meet homeostatic demands, age-related hematopoietic stem cell (HSC) changes appear to be an exception, at least for murine species in which this question has been most directly addressed.^{150,151} Early work demonstrated that marrow serially transplanted could reconstitute hematopoietic function for an estimated 15 to 20 life spans.¹⁵² Furthermore, the capacity for old marrow to reconstitute proved superior to that of young.¹⁵³ Subsequently, a number of investigators using a variety of techniques have concluded that HSC frequency in old mice and humans is approximately 2 to 10 times greater than in the young.^{16,150,151,154–156} Some evidence suggests that the intrinsic function of HSCs changes somewhat with age, most notably in a shift in lineage potential from lymphoid to myeloid development. This may contribute to an observed relative increase in neutrophils and decrease in lymphocytes in the blood of older people.¹⁵⁷

There is an intrinsic change in HSCs with age, most notably resulting in a shift in lineage potential from lymphoid to myeloid development. This may contribute to a relative increase in neutrophils and decrease in lymphocytes in the blood of older persons.¹⁵⁷ As HSCs age, they accumulate genotypic (mutational) and phenotypic alterations. Indeed, human stem-progenitor cells from healthy volunteers were found to accumulate 13 exonic (private) mutations per year of age.^{157a} Current opinion is that such changes are responsible for the development of immune

senescence and that such changes are responsible for the development of immune senescence, as well as the increased occurrence of age-associated diseases such as myelodysplasia and leukemia. Thus, the process of “immunosenescence,” as it affects the innate and adaptive immune system, may result from HSC aging. For example, an age-related decrease in the provision of B-cell precursors may be the result of HSC aging.¹⁴⁸

MARROW DURING ADULT LIFE

The most apparent change seen in the marrow with aging is decreased cellularity (Fig. 9–1).¹³⁵ Under normal circumstances, the marrow is the only site of hematopoiesis. Foci of extramedullary hematopoiesis may occur in the liver, spleen, or lymph nodes in pathologic states, but they are not of functional consequence. Until puberty the entire skeleton remains hematopoietically active, but by age 18 years only the vertebrae, ribs, sternum, skull, pelvis, proximal epiphyseal regions of humerus and femur remain active sites of blood production, with other medullary sites infiltrated with fatty tissue. By age 40 years, the marrow in sternum, ribs, pelvis and vertebrae is composed of equal amounts of hematopoietic tissue and fat and cellularity declines gradually thereafter. By age 65 years, marrow cellularity is estimated to be approximately 30 percent,^{135,136} with a corresponding increase in marrow fat. Age-associated imbalanced bone remodeling and osteoporosis results in decreased trabecular bone which itself may contribute to diminished hematopoiesis.¹⁵⁸ The presence of fat correlates with the occurrence and severity of osteoporosis, both of which are evident with aging.¹⁵⁹ Several age-related qualitative changes have been identified in hematopoietic cells, including skewed X-chromosome inactivation, telomere shortening,^{160–162} accumulation of mitochondrial DNA mutations,^{163,164} and

*Consequences of aging in the bone marrow and thymus in the absence of disease.

Figure 9–1. Aging of marrow and thymus. Marrow cellularity declines from birth in a manner comparably to thymic mass. This is reflected histologically by the increased presence of fat. The clinical consequences of these age-associated changes, in the absence of disease, are a mild anemia and immune deficiency. The latter is reflected by an increased predisposition to certain infections (e.g., herpes zoster or reactivation of latent tuberculosis) and possibly to the increased predisposition to cancer. GVHD, graft-versus-host disease.

micronuclei formation,¹⁶⁵ any of which could result in cellular dysfunction. Furthermore, growth hormone production declines with age, and this, too, is linked with deposition of fat within the marrow.¹⁶⁶ Administration of growth hormone to old rats reduces marrow fat and increases hematopoietic tissue.¹⁶⁷

BLOOD CELL CHANGES WITH AGE

Red Cells

Anemia is a significant health problem in the elderly because of a high prevalence and significant associated morbidity, including reduced quality of life, clinical depression, falls, functional impairment, slower walking speed, reduced grip strength, loss of mobility, worsening comorbidities, and mortality.^{168,169}

In older men and women, anemia defined using the World Health Organization (WHO) criteria of hemoglobin levels less than 13 g/dL for men and 12 g/dL for women¹⁷⁰ is associated with an increase in mortality.¹⁷¹⁻¹⁷⁶ It has been pointed out that the WHO criteria do not take into account inherent ethnic variations, particularly with respect to Americans of African descent who have lower levels of hemoglobin without significant adverse outcomes.^{177,178} In a study that analyzed 1018 Americans of African descent and 1583 Americans of European descent adults aged 71 to 82 years, anemia defined by the WHO criteria was associated with increased mortality in those of European descent but not those of African descent.^{177,178} The reasons for these ethnic differences are undefined. However, the difference is one of degree. In general, the impact of anemia on functional status and mortality in Americans of African descent becomes apparent at hemoglobin levels approximately 1 g/dL lower than in whites. The issue of establishing criteria for the diagnosis of anemia is relevant in the context of age, as well. Older women, for example, have better physical performance and function at hemoglobin values between 13 and 15 g/dL than at between 12.0 and 12.9 g/dL,¹⁷⁹ suggesting perhaps that the cut off level of 12 g/dL is too low. Nevertheless, the WHO definition remains the standard used in most current epidemiologic surveys and many clinical laboratories.

Prevalence of Anemia

In the third National Health and Nutrition Examination Survey (NHANES III) database, a nationally representative sample of community-dwelling persons and determined age- and sex-specific prevalence rates of anemia in the total U.S. population,¹²⁷ of those individuals older than age 65 years approximately 11 percent were anemic by WHO criteria (see Table 9-1). The prevalence of anemia was lowest (1.5%) among males between 17 and 49 years of age and highest (26.1%) in males older than 85 years. Among those 65 years and older, the prevalence rate was notably higher in Americans of African descent as compared to Americans of European descent and Americans of Hispanic descent. Prevalence rates of anemia in the elderly vary in community-dwelling and institutionalized populations. Also, anemia is more common among frail elderly. In the nursing home, for example, anemia prevalence approaches 50 percent or higher.^{126,180-182}

Unexplained Anemia

Hematologists are usually successful in uncovering the cause of anemia in young adults. However, in older populations a specific explanation cannot be defined by routine evaluation in approximately one-third of anemic patients (Table 9-2).^{20,183,184} Typically, this anemia is mild (hemoglobin concentration in the 10-12 g/dL range), normocytic, and hypoproliferative (low reticulocyte index). It has been postulated that the cause relates to a number of factors including declining testosterone level,¹⁸⁵ occult inflammation,¹⁸⁶ impaired renal function with inappropriately low serum erythropoietin,¹⁸⁷ or incipient myelodysplasia.¹⁸⁸ Likely, unexplained anemia represents an amalgam of these and perhaps

TABLE 9-2. Anemia Prevalence in the Elderly Using the WHO* Criteria

Study	Age (Years)	Population	Prevalence
Guralnik, 2004 ¹²⁷	≥65	Community-dwelling elderly American	10.6%
Ferrucci, 2007 ²⁹⁹	≥70	Community-dwelling elderly Italian	11%
Denny ³⁰⁰	≥71	Community dwelling	24%
Joosten ¹²⁸	≥65	Hospitalized	24% (defined as hemoglobin <11.5 g/dL)
Artz ¹²⁶	Most ≥65	Nursing home	48%
Robinson ¹⁸²	≥65	Nursing home	59.6%

*World Health Organization anemia criteria; hemoglobin <13 g/dL for adult men and <12 g/dL for adult women.

other factors, such as shortened red cell survival, refractoriness of the erythroid precursors to erythropoietin stimulation, and/or the presence of as yet undiagnosed illness.

Serum Erythropoietin and Aging

Data on erythropoietin levels in nonanemic older persons are inconsistent. Some suggest that nonanemic older persons have higher erythropoietin levels compared to younger adults,¹⁸⁹⁻¹⁹¹ but other studies fail to confirm these findings.¹⁰⁻¹² One longitudinal analysis clearly demonstrates that serum erythropoietin levels rose gradually in healthy individuals who maintained normal hemoglobin levels but the rise was not observed in those who were to develop diabetes or hypertension during the evaluation period.¹⁹² An explanation for the rise in serum erythropoietin with age is not established, but in theory, it could be the result of age-associated shortened red cell survival or reduced sensitivity of erythroid progenitor cells to the erythropoietin signal. Studies in older subjects are ongoing to define the basis for the increasing need for erythropoietin to maintain normal levels of red cells.

Leukocytes

Although no significant change is seen in the blood leukocyte count with normal aging,^{193,194} among those who acquire features of frailty, an increased neutrophil count may be observed.^{157,195} Furthermore, several qualitative neutrophil defects have been described. For example, a decreased respiratory burst response to soluble signals,¹⁹³ defective phagocytosis,¹⁹⁴ and impaired neutrophil migration to sites of stress¹⁹⁶ have been described in accordance with advanced age. Although the exact cause for these functional changes has not been clarified, it may be associated with an age-related alteration in actin cytoskeleton and receptor expression in leukocytes.¹⁹⁷ A mild decrease in the blood lymphocyte count is first noticeable in the fourth decade with a gradually progressive decrease thereafter throughout the remainder of the lifespan.¹⁹⁸ Qualitative alterations in T-lymphocyte function in the elderly have also been demonstrated.¹⁹⁹

Platelets

At present, knowledge about the influence of age on platelet counts has been limited to cross-sectional data derived from selected populations. From those data, no or very limited changes in platelet number are

noted with age.^{200–203} To date, a longitudinal data set describing alterations in platelet number with advancing age has not been produced nor are there conclusive studies describing age-associated changes in platelet function.

AGING AND COAGULATION

Coagulation Factors and Aging

A number of proteins critical to clot formation and fibrinolysis change in characteristic ways with advancing age.^{204–206} Plasma concentrations of factor VII coagulant activity and antigen,^{204–208} and factor VIIIc,^{191,206,209} as well as von Willebrand factor,^{191,209} fibrinogen,^{191,206,208,210} fibrinopeptide A,^{191,206,207} and tissue plasminogen activator antigen^{191,211–213} increase with age. In healthy centenarians, levels of activated factor VII, activation peptides of prothrombin, factors IX and X, and thrombin–antithrombin complex concentration were increased, which are signs of higher-than-expected coagulation enzyme activity.²⁰⁶ Age-associated increases in levels of protein C occur in both sexes. Aging is also associated with increasing levels of free protein S.²⁰⁴ In contrast, antithrombin tends to decrease with age in males and increases with age in females following menopause.²¹⁴ Higher D-dimer and plasmin–antiplasmin complexes indicate an accompanying increase in fibrinolytic activity.^{206,215} In contrast, plasma tissue-plasminogen activator inhibitor levels increase with increasing age, as do levels of thrombin-activatable fibrinolysis inhibitor in women²¹⁶ and its proenzyme form, procarboxypeptidase U, in both sexes.²¹⁷ These latter findings are suggestive of a possible age-dependent compromise in fibrinolytic activity.²¹⁸ Thus, procoagulant and, in some studies, fibrinolytic activities appear to be increased in older subjects by both *in vitro*^{206,219,220} and *in vivo* studies,^{190,221} but the changes in fibrinolytic activity are inconsistent. Older patients may show an exaggerated anticoagulant response to warfarin.²²²

Aging as a Prothrombotic State

Activation of the coagulation system and increase in procoagulant markers are associated with the pathogenesis of atherosclerosis.^{223,224} However, procoagulant markers, most notably D-dimer,²²⁵ fibrinogen, and factor VIII,²²⁶ also increase with advancing age, and may, in fact, correlate better with aging than with cardiovascular disease.^{223,224} In a study examining 1729 participants age 70 years and older in the Established Populations for the Epidemiological Study of the Elderly (EPESE) cohort, increasing age was associated with high D-dimer levels. For example, 23 percent of the participants age 90 to 99 years had high D-dimer levels (>600 mcg/L) compared to 13 percent in the 80- to 89-year-old age group and 7 percent in the 70- to 79-year-old age group.²¹⁵ Investigators measured fibrinogen concentrations in healthy subjects ages 19 to 96 years and found levels to be significantly higher in participants older than age 60 years when compared to younger subjects.²²⁷ Healthy individuals across the life span had fibrinogen levels increased by 25 mg/dL per decade of life, and levels as high as 320 mg/dL were found in more than 80 percent of people older than 65 years of age.²²⁸ Other markers of activated coagulation, such as plasminogen activating inhibitor-I (PAI-1) and factor VIII also increased with age.^{209,229,230} Thus, it is now apparent that aging is associated with markers of activated coagulation. In this context, it is notable that the incidence of venous thrombosis and pulmonary emboli increases dramatically in geriatric populations.^{231,232} Bleeding complications from anticoagulation therapy are also increased in older patients. No interventional study has identified an at-risk population of normal-age subjects without prior thrombosis in whom prophylactic anticoagulation is of value.

Coagulation and Functional Decline

In the EPESE study, increases in D-dimer and interleukin (IL)-6 were related to increases in both morbidity and mortality.²¹⁵ In fact, the

correlation for adverse outcomes was stronger with D-dimer than IL-6.²³³ In this, and other studies,^{234–236} D-dimer and other markers of activated coagulation were associated with limitation in a wide variety of functional domains, including independent activities of daily living (IADL), lower-extremity function, and performance on cognitive testing. The age-associated changes in coagulation markers occur earlier than other aging biomarkers, and hence it has been argued that they could be early predictors of those elderly at increased risk for functional decline.²³⁷

This age-associated prominence of coagulation factors has also been reproduced in animals. For example, when stress associated with physical restraint was compared in aged versus young C57BL/6J mice, significantly increased expression of PAI-1 mRNA was noted in almost all the tissues in older mice.²³⁸ Similar results were seen for expression of tissue factor mRNA in aged mice.²³⁸ In both these experimental models an increase in microthrombi was noted with clots distributed through multiple organ systems in the older mice.

In humans, both the presence of depression and/or psychological stress are associated with increased coagulation^{239–241} and decreased fibrinolytic activity.²⁴² In elderly subjects without cardiovascular disease, physical exhaustion, a characteristic frequently used to distinguish frail from nonfrail individuals, was associated with significant increases in both inflammatory and coagulation factors as assessed by fibrinogen, C-reactive protein, and white cell levels.²³⁹ Frail and prefrail subjects from the Cardiovascular Health Study had significantly higher levels of fibrinogen, factor VIII, and D-dimer levels as compared to the nonfrail group. The association with frailty persisted even after adjusting for the presence of cardiovascular disease and diabetes.²⁴³ Frailty is also associated with increased risk of venous thromboembolism when compared to nonfrail individuals of the same age, especially in association with increased factor VIII levels.²⁴⁴

AGING AND IMMUNITY

Whether related to primary processes of aging or not, the thymus gland undergoes a very characteristic pattern of involution beginning well in advance of other phenotypic changes attributed to aging (see Figs. 9–1 and 9–2; Chap. 6).²⁴⁵ Among the consequences are a decreased generation of naïve T cells.²⁴⁶ Despite this, the total lymphocyte count does not decline greatly because peripheral T cells are capable of expanding to fill the T-cell niche in the absence of generation of new T cells. However, when they do so, the repertoire for antigen recognition becomes less comprehensive. Thymic involution may result from the aging T-cell progenitor population,²⁴⁷ from the defects in rearrangement of T-cell receptor β genes,^{248,249} from loss of self-peptide expressing thymic epithelium,²⁵⁰ and/or from the loss of thymic trophic cytokines.²⁵¹ Thymic epithelial cells produce a variety of colony-stimulating factors and hematopoietic cytokines, such as IL-1, IL-3, IL-6, IL-7, transforming growth factor- β , oncostatin M, and leukemia inhibitory factor,^{252–254} which influence the complex process of T-cell production. It is proposed that thymic atrophy and decreased thymopoiesis is an active process and mediated by the upregulation of thymosuppressive cytokines (leukemia inhibitory factor, IL-6, and oncostatin M), which results in the altered peripheral lymphatic tissue T-lymphocyte function with aging.²⁵⁵

There is a notable shift in the overall blood T-cell population toward lymphocytes with memory T-cell markers,²⁵⁶ and many of these are thought to have attained replicative senescence.²⁵⁷ With the decreasing numbers of naïve T cells in the peripheral lymphatic tissue and increasing memory T cells reaching senescence, elderly persons have difficulties responding to old and new antigens and demonstrate impaired reactions to vaccinations. The decreased efficacy of vaccines

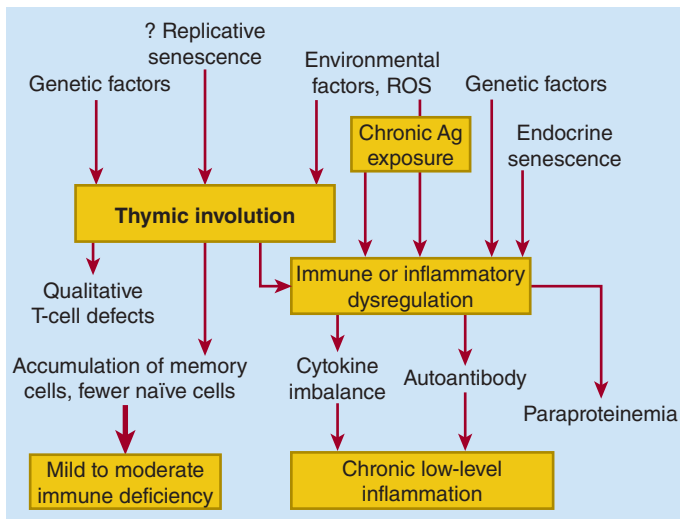

Figure 9–2. Immunity and aging. A variety of factors have been associated with thymic involution, the consequence of which is a mild to moderate immune deficiency. Dysregulated inflammatory pathways are also observed with advancing age and these may be of greater clinical importance. Ag, antigen; ROS, reactive oxygen species.

may also be a result of alterations in antigen presentation with age. Within the T-helper cell fraction there is a shift to the T-helper (Th) type 2 subset and away from Th1,²⁵⁸ thereby influencing cytokine production and overall immune response.

In addition to the anatomic changes within marrow and thymus (see Figs. 9–1 and 9–2), similar age-associated morphologic changes within the paracortical and medullary zones of secondary lymphoid tissues (spleen, and lymph nodes) occur, including a decline in the paracortical and medullary zones and increased deposition of fat within the germinal centers.^{259,260} It remains unclear to what extent these changes contribute to the overall change in immune function with age.

A wide range of lymphocyte functional changes have been described in the context of aging; however, cataloguing these would be beyond the scope of this chapter. Such changes are detailed in several excellent reviews.^{24,261–264} Briefly stated, there is a shift in the T-cell population toward memory T cells,²⁵⁶ which attain replicative senescence in response to repeated antigen exposures.²⁵⁷ With the relative and absolute decrease in numbers of naïve T cells in the peripheral lymphatic tissue and the accumulation of functionally diminished memory senescent T cells, primary and secondary immune responses are reduced in elderly persons.

Coincident with the age-related changes in lymphocyte function is the increase in levels of circulating proinflammatory cytokines, measurable in some, even in the absence of definable inflammatory disease. IL-6 is the prototype in this regard. In young adults, expression of IL-6 is tightly regulated and serum levels are usually unmeasurable or very low in the absence of inflammatory conditions. Animal studies reveal an increased production of IL-6^{265,266} from mononuclear cells and lymphoid cells after stimulation with lipopolysaccharide or other mitogens. Similarly, in humans serum IL-6 levels increase significantly with age.^{267–271} Other inflammatory proteins, including tumor necrosis factor- α (TNF- α) and C-reactive protein are also seen at higher levels in the elderly.^{272–274} Visceral adipose tissue from older mice express greater levels of both IL-6 and TNF- α mRNA than tissue from younger mice,²⁷⁵ and thus, some of the age-associated rise in IL-6 may be the consequence of those metabolic shifts mentioned above.

CLINICAL CONSEQUENCES

Marrow Aging

Although a number of measureable changes occur in the marrow, not the least of which is a reduction in cellularity, apparent compensatory stem cell changes allow the sustenance of normal or near-normal blood counts throughout the life span. It is notable from transplant experience that even when marrow is donated from a 65-year-old person to a human leukocyte antigen (HLA)-matched younger recipient, the donor marrow supports hematopoiesis for the life of the recipient, although allogeneic marrow from older donors has a greater chance of being associated with graft-versus-host disease.²⁷⁶

Unexplained Anemia

To the extent that marrow contains continuously repopulating cell lines, it is quite remarkable that changes attributable to aging alone (i.e., in the absence of disease) are quite subtle. Nonetheless “unexplained anemia” (UA) accounts for up to one-third of cases of anemia in older patients and its frequency increases with advancing age.²⁰

UA is usually mild, with hemoglobin levels approximately 1 g/dL lower than the WHO standard. The red cells are typically of normal size and examination of the blood film reveals no evidence for intravascular destruction or morphologic features suggestive of myelodysplasia. Although inflammatory cytokine levels may be elevated, the intensity of inflammation is insufficient to produce increased levels of hepcidin; thus, UA has a distinct pathogenesis from the anemia of chronic disease (Chap. 37). Because UA is typically mild, it is likely to be overlooked. In fact, in one population-based cohort that included elderly patients with even more significant anemia, the medical records of affected individuals did not mention anemia as a problem in 75 percent of the cases.¹⁷¹ However, there is now evidence that this casual acceptance of lower hemoglobin levels in older populations may not be advisable.¹⁶⁸ Not only can a decline in important functional measures be related to mild anemia,^{172,277–280} but longitudinal studies demonstrate increased mortality among individuals with even mild anemia.^{174,179,281} Furthermore, a retrospective cohort study of the U.S. Veterans Administration National Surgical Quality Improvement database, indicated that of 310,311 subjects age 65 years and older who underwent noncardiac surgery, the 30-day mortality and cardiac event rates increased by 1.6 percent for each 1 percent decrease in hematocrit below the level of 39 percent.²⁷⁵ Thus, although in younger individuals mild anemia may be well tolerated, in many older individuals it is associated with important negative consequences. That stated, it remains to be established whether the correction of anemia for those with UA will result in improved quality of life, physical function, or survival.

For elderly patients with UA, the presence of macrocytosis; thrombocytopenia; neutropenia; splenomegaly; or unexplained constitutional findings of fever, chills, or weight loss; or symptoms of early satiety; or bone pain should prompt consideration of a marrow examination to rule out myelodysplasia or other diseases affecting marrow function, most of which occur with increasing frequency with advancing age.

Immune Senescence

The complex alterations in immune function with age have been described comprehensively in several reviews.^{261–264} The changes may explain an age-associated predisposition to certain infections (herpes zoster, tuberculosis reactivation) and perhaps a failure to mount a sufficient vaccine response (e.g., influenza hemagglutinin^{282–286}). The more profound immune deficiency commonly observed in older people most often reflects the debilitating effects of concurrent diseases, most of which occur more commonly with age, and side effects of the medicines used to manage those diseases.

Inflammation/Coagulation Dysregulation and Frailty

Presumably on the basis of chronic inflammatory stimuli, there is an age-associated activation of coagulation²³² and fibrinolytic²⁸⁷ pathways that favor thrombus formation. Fibrinogen levels are typically high with more than 80 percent of those age 65 years and older having levels above 320 mg/dL.²²⁷ Similarly an analysis of D-dimer levels in the EPESE, including 1727 community elderly, revealed an age-associated increase that correlated with declining overall physical function.²¹⁵ Furthermore, when combining D-dimer and IL-6 levels, those individuals who had elevations of both were at greatest risk for mortality over a 4-year interval.²³³ In the Cardiovascular Health Study, which included relatively healthy elderly, higher fibrinogen and factor VIII levels were associated with a greater risk for cardiovascular disease and mortality, even after adjustment for other cardiovascular risk factors.^{232,288} Summarizing what has now become a robust literature, higher IL-6, TNF- α , D-dimer, and C-reactive protein are each associated with negative physiologic consequences, including reduced lower-extremity muscle mass and strength,^{289,290} cognitive decline,²⁹¹ insulin resistance,²⁹² subclinical and clinical cardiovascular disease,^{293,294} renal insufficiency,²⁹⁵ loss of bone mineral density,²⁹⁶ depression,²⁹⁷ anemia,¹⁸⁶ dementia,²³⁵ and mortality.²⁸⁹ As a result, a general consensus has emerged that activated inflammatory mediators are, at least in part, contributing to the physiology of aging, and to the extent that these pathways are dysregulated, important functional outcomes are impaired.

CHAPTER 10

GENETIC PRINCIPLES AND MOLECULAR BIOLOGY

Lynn B. Jorde*

SUMMARY

The understanding of hematology is dependent upon an appreciation of genetic principles and the tools that can be used to study genetic variation. All the genetic information that makes up an organism is encoded in the DNA. This information is transcribed into mRNA, and then the triplet code of those mRNAs is translated into protein. Changes that affect the DNA or RNA sequence or its expression, either in the germline or acquired after birth, can cause hematologic disorders. These may be mutations that change the DNA sequence, including single base changes, deletions, insertions, and duplications, or they may be epigenetic changes that affect gene expression without any change in the DNA sequence.

The detection of mutations that cause a variety of diseases is now possible and has become a routine method for the diagnosis of some disorders. Large-scale DNA sequencing can be used to identify disease-causing genes and to carry out genetic testing. The development of methods to disrupt or prevent expression of specific genes has made it possible to produce mouse models of human hematologic diseases, and such models have the potential to serve as means to better understand pathophysiology and to study treatment strategies.

Inheritance patterns depend upon the biologic effect and chromosomal location of the mutation. Common autosomal recessive hematologic diseases include sickle cell disease, the thalassemias, and Gaucher disease. Hereditary spherocytosis, thrombophilia caused by factor V Leiden, most forms of von Willebrand disease, and acute intermittent porphyria are characterized by autosomal dominant inheritance. Mutations that cause glucose-6-phosphate dehydrogenase deficiency, hemophilias A and B, and the most common form of chronic granulomatous disease, are all carried on the X chromosome and, therefore, manifest X-linked inheritance, with transmission of the disease state from a heterozygous mother to her son. Understanding the genetics of a disorder is necessary for accurate genetic counseling.

Acronyms and Abbreviations: BACs, bacterial artificial chromosomes; bp, base pairs; cDNA, complementary DNA; CNV, copy number variant; CpG, cytosine phosphate guanine; ENU, *N*-ethyl-*N*-nitrosourea; G6PD, glucose-6-phosphate dehydrogenase; HNPCC, hereditary nonpolyposis colorectal cancer; lncRNA, long noncoding RNA; miRNA, microribonucleic acid; mRNA, messenger ribonucleic acid; mtDNA, mitochondrial DNA; NADH, nicotinamide adenine dinucleotide (reduced form); PACs, P1-derived artificial chromosomes; PCR, polymerase chain reaction; RISC, RNA-induced silencing complex; RNAi, RNA interference; rRNA, ribosomal ribonucleic acid; RT-PCR, reverse transcriptase polymerase chain reaction; SCID, severe combined immunodeficiency; siRNA, small interfering ribonucleic acid; SNP, single nucleotide polymorphism; STR, short tandem repeat; tRNA, transfer ribonucleic acid; YAC, yeast artificial chromosome.

*In the previous edition, this chapter was written by Ernest Beutler and portions of that chapter have been retained.

GENETICS AND HEMATOLOGIC DISORDERS

Many of the hematologic diseases described in this text have a genetic basis. Often the disease is caused by a mutation in a single gene. Some of these disorders, such as sickle cell disease (Chap. 49), thalassemia (Chap. 48), glucose-6-phosphate dehydrogenase (G6PD) deficiency (Chap. 47), and factor V Leiden (Chap. 130), are common, whereas others, such as congenital dyserythropoietic anemia type I (Chap. 39), chronic granulomatous disease (Chap. 66), and afibrinogenemia (Chap. 125), are rare. All are caused by mutations in a gene that result in the formation of a defective protein or an insufficient amount of a normal protein. The principal focus of this chapter is such genetic disorders. However, a number of acquired hematologic diseases, including lymphomas, leukemias, and other clonal hematologic diseases, are the consequence of acquired damage to the genetic apparatus. Understanding these diseases requires an appreciation of how the genetic apparatus functions.

All of the information required for the development of a complete adult organism is encoded in the DNA of a single cell—the zygote. This information, designated the *genome*, includes the data needed for the synthesis of all enzymes; all the plasma proteins, including the clotting factors, complement components, and the transport proteins; all the membrane proteins, including receptors; and all of the cytoskeletal proteins. The units of information into which the genome is organized are the *genes*, which are composed of sequences of DNA. By serving as the blueprints of proteins in the body, genes ultimately influence all aspects of body structure and function. There are approximately 21,000 protein-coding genes and an additional 10,000 genes that do not encode proteins but affect the regulation of genes.¹ An error in one of these genes often leads to a recognizable genetic disease. To date, more than 20,000 genetic traits and diseases have been identified and cataloged.

DNA, RNA, AND PROTEINS: HEREDITY AT THE MOLECULAR LEVEL

DNA

DNA has three basic components: the pentose sugar molecule, deoxyribose; a phosphate molecule; and four types of nitrogenous bases. Two of the bases, *cytosine* and *thymine*, are single carbon-nitrogen rings called *pyrimidines*. The other two bases, *adenine* and *guanine*, are double carbon-nitrogen rings called *purines*. The four bases are commonly represented by their first letters: A, C, T, and G.

Watson and Crick demonstrated how these molecules are physically assembled together as DNA, proposing the *double-helix model*, in which DNA appears like a twisted ladder with chemical bonds as its rungs (Fig. 10-1).^{2,3} The two sides of the ladder are made up of the sugar and phosphate molecules, held together by strong phosphodiester bonds. Projecting from each side of the ladder, at regular intervals, are the nitrogenous bases. The base projecting from one side is bound to the base projecting from the other by a weak hydrogen bond. Therefore, the nitrogenous bases form the rungs of the ladder; adenine pairs with thymine, and guanine pairs with cytosine. Each DNA subunit—consisting of one deoxyribose molecule, one phosphate group, and one base—is called a *nucleotide*.

DNA directs the synthesis of all the body's proteins. Proteins are composed of one or more *polypeptides* (intermediate protein compounds), which are, in turn, composed of sequences of *amino acids*. The body contains 20 different types of amino acids, which are specified by the four nitrogenous bases. To specify (code for) 20 different amino acids with only four bases, different combinations of bases, occurring in groups of three, are used. These triplets of bases are known as *codons*. Each codon specifies a single amino acid in a corresponding protein.

Figure 10–1. Watson-Crick model of the DNA molecule. The DNA structure illustrated here is based on that published by James Watson and Francis Crick in 1953. Note that each side of the DNA molecule consists of alternating sugar and phosphate groups. Each sugar group is united to the sugar group opposite it by a pair of nitrogenous bases (adenine-thymine or cytosine-guanine). The sequence of these pairs constitutes a genetic code that determines the structure and function of a cell. (Reproduced with permission from Patton KT, Thibodeau GA: *Anatomy & physiology, 8th edition*. St. Louis, MO: Mosby/Elsevier, 2013.)

Because there are 64 ($4 \times 4 \times 4$) possible codons but only 20 amino acids, there are many cases in which several codons correspond to the same amino acid.

The genetic code is universal: All living organisms use precisely the same DNA codes to specify proteins except for mitochondria, the cytoplasmic organelles in which cellular respiration takes place—they have their own extranuclear DNA. Several codons of mitochondrial DNA encode different amino acids than do the same nuclear DNA codons.

DNA replication consists of breaking the weak hydrogen bonds between the bases, leaving a single strand with each base unpaired. The consistent pairing of adenine with thymine and of guanine with cytosine, known as *complementary base pairing*, is the key to accurate replication. The unpaired base attracts a free nucleotide only if the nucleotide has the proper complementary base. When replication is complete, a new double-stranded molecule identical to the original is formed. The single strand is said to be a *template*, or molecule on which a complementary molecule is built, and is the basis for synthesizing the new double strand.

Several different proteins are involved in DNA replication. The most important of these proteins is an enzyme known as *DNA polymerase*. This enzyme travels along the single DNA strand, adding the correct nucleotides to the free end of the new strand and checking to make sure that its base is actually complementary to the template base. This mechanism of DNA proofreading substantially enhances the accuracy of DNA replication.

MUTATIONS

A *mutation* is any inherited alteration of genetic material. Mutations may cause disease or be subtle, silent substitutions that do not change amino acids. A base pair change that alters a single amino acid is termed a *missense* mutation, and a base pair change that produces a premature stop codon is termed a *nonsense* mutation. Because they typically result in a complete loss of gene product, nonsense mutations usually produce a more-severe disease phenotype than do missense mutations. For example, nonsense mutations in the factor VIII gene are much more likely to produce severe hemophilia A than are missense mutations. This is an example of a *genotype-phenotype* correlation, which can be useful in predicting the severity of disease. A *frameshift* mutation involves the insertion or deletion of one or more base pairs of the DNA molecule. These mutations change the entire “reading frame” of the DNA sequence because the deletion or insertion is not a multiple of three base pairs (bp; the number of base pairs in a codon). Frameshift mutations can thus greatly alter the amino acid sequence and typically lead to a premature stop codon downstream of the mutation. (“In-frame” insertions or deletions, in which a multiple of three bases is inserted or lost, tend to have less-severe disease consequences than do frameshift mutations.) *Splice-site* mutations describe alterations of the DNA sequence at intron–exon boundaries (see section on Genes to Proteins above). These result in a mature mRNA transcript that contains introns or lacks exons. Table 10–1 gives examples of hematologic diseases caused by different types of mutations.

Mutations are rare events. The rate of *spontaneous mutations* (those occurring in the absence of exposure to known mutagens) in humans is approximately 10^{-4} to 10^{-6} per gene per generation. This rate varies from one gene to another, with larger mutation rates for larger genes. At the nucleotide level, the human mutation rate is approximately 10^{-8} per nucleotide per generation.^{4,5} Certain DNA sequences have particularly high mutation rates and are known as *mutational hot spots*. In particular, sequences consisting of a cytosine base followed by a guanine base (CpG) are highly susceptible to mutation and are known to account for a disproportionately large percentage of disease-causing mutations.

FROM GENES TO PROTEINS

DNA is formed and replicated in the cell nucleus, but protein synthesis takes place in the cytoplasm. The DNA code is transported from nucleus to cytoplasm, and subsequent protein is formed through two basic processes: transcription and translation. These processes are mediated by RNA, which is chemically similar to DNA except that the sugar molecule is ribose rather than deoxyribose, and uracil rather than thymine is one of the four bases. The other bases of RNA, as in DNA, are adenine, cytosine, and guanine. Uracil is structurally similar to thymine, so it also can pair with adenine. Whereas DNA usually occurs as a double strand, RNA usually occurs as a single strand.

In *transcription*, RNA is synthesized from a DNA template, forming *messenger RNA (mRNA)*. *RNA polymerase* binds to a *promoter* site, a sequence of DNA that specifies the beginning of a gene. RNA polymerase then separates a portion of the DNA, exposing unattached DNA bases. One DNA strand then provides the template for the sequence of mRNA nucleotides.

The sequence of bases in the mRNA is thus complementary to the template strand, and except for the presence of uracil instead of thymine, the mRNA sequence is identical to the other DNA strand. Transcription continues until a *termination sequence* is reached. Then the RNA polymerase detaches from the DNA, and the transcribed mRNA is freed to move out of the nucleus and into the cytoplasm.

When the mRNA is first transcribed from the DNA template, it reflects exactly the base sequence of the DNA. In eukaryotes, many RNA sequences are removed by nuclear enzymes, and the remaining sequences are spliced together to form the functional mRNA that migrates to the cytoplasm. The excised sequences are called *introns*, and the sequences that are left to code for proteins are called *exons*.

In *translation*, RNA directs the synthesis of a polypeptide, interacting with *transfer RNA (tRNA)*, a cloverleaf-shaped strand of approximately 80 nucleotides. The tRNA molecule has a site where an amino acid attaches. The three-nucleotide sequence at the opposite side of the cloverleaf is called the *anticodon*. It undergoes complementary base pairing with an appropriate codon in the mRNA, which specifies the sequence of amino acids through tRNA.

The site of actual protein synthesis is in the *ribosome*, which consists of roughly equal parts of protein and *ribosomal RNA (rRNA)*. During translation, the ribosome first binds to an initiation site on the mRNA sequence and then binds to its surface, so that base pairing can occur between tRNA and mRNA. The ribosome then moves along the mRNA sequence, processing each codon and translating an amino acid by way of the interaction of mRNA and tRNA.

The ribosome provides an enzyme that catalyzes the formation of covalent peptide bonds between the adjacent amino acids, resulting in a growing polypeptide. When the ribosome arrives at a termination signal on the mRNA sequence, translation and polypeptide formation cease; the mRNA, ribosome, and polypeptide separate from one another; and the polypeptide is released into the cytoplasm to perform its required function.

All cells receive the same complement of genes. Nonetheless, some proteins are tissue-specific. Several circumstances can account for this. Some enzymes that appear to perform the same function are encoded by different genes in different tissues. For example, the pyruvate kinase of leukocytes and that of erythrocytes are under separate genetic control (Chap. 47). In other cases, alternative splicing of the primary mRNA can produce different polypeptides, a phenomenon that is particularly prominent with some of the red cell membrane proteins. Differences in posttranslational processing, including proteolysis and glycosylation of the same polypeptide by different enzymes in different tissues, can lead to different final products. However, in most instances a mutation

that affects an enzyme in one type of blood cell will also affect the same enzyme in other blood cells, in liver, in brain, and in other tissues.

MENDELIAN GENETICS

Traits caused by single genes are called mendelian traits (after Gregor Mendel). Each gene occupies a position along a chromosome known as a *locus*. The genes at a particular locus can take different forms (i.e., they can be composed of different nucleotide sequences) called *alleles*. A locus that has two or more alleles that each occurs with an appreciable frequency (classically defined as 1%) in a population is said to be *polymorphic* (or a *polymorphism*). Polymorphisms that involve a single nucleotide are termed *single nucleotide polymorphisms (SNPs)*, while those that involve the presence or absence of larger pieces of DNA are termed *copy number variants (CNVs)*.^{6,7} Sometimes genetic variants, such as the alleles responsible for sickle cell disease, thalassemia, or G6PD deficiency, reach polymorphic levels because the deleterious effects that they may have are counterbalanced by beneficial effects on survival, such as increased resistance to malaria.⁸ They are known as *balanced polymorphisms*. *Short tandem repeats (STRs)* are a special form of polymorphism consisting of differing numbers of repeating units of one to six nucleotides, for example, ATATATATAT. Such sequences are unstable in evolution of a species and tend to be very polymorphic. Instead of only two possible genotypes, as in the case of most SNPs, there may be 5, 10, or more different numbers of repeats at a given locus in different individuals. As a result, STRs are very useful in genetic mapping and in forensic analysis.⁹ In addition, an expanded number of repeat copies of some STRs located within or near genes is an important cause of inherited disease.¹⁰

Because humans are diploid organisms, each chromosome is represented twice, with one member of the chromosome pair contributed by the father and one by the mother. At a given locus, an individual has one allele whose origin is paternal and one whose origin is maternal. When the two alleles are identical, the individual is *homozygous* at that locus. When the alleles are not identical, the individual is *heterozygous* at that locus. The composition of genes at a given locus is known as the *genotype*. The outward appearance of an individual, which is the result of both genotype and environment, is the *phenotype*.

DOMINANCE AND RECESSIVENESS

In his experiments with garden peas, Gregor Mendel established that many traits can be either *dominant* or *recessive*. In dominant traits, such as von Willebrand disease or porphyria cutanea tarda type II, one copy of a disease-causing allele is sufficient for disease causation, so heterozygotes are typically affected. In recessive traits, such as β -thalassemia, two copies of the disease-causing allele must be present, so the affected individual is a homozygote. A *carrier* is an individual who has a disease gene but is phenotypically normal. Many alleles for a recessive disease occur in heterozygotes that carry one copy of the gene but do not express the disease. When recessive alleles are lethal in the homozygous state, they are eliminated from the population when they occur in homozygotes. By “hiding” in carriers, however, recessive genes for diseases are passed on to the next generation (the word “recessive” comes from the Latin for “hidden”).

GENE DUPLICATION

Crossing over during meiosis usually occurs with great precision. Homologous genes pair with each other, and although genes that were together on the chromosome before meiosis may now be on opposite chromosomes of the pair, each chromosome still contains a

complete set of genes (see Fig. 10–1). Occasionally, however, an error occurs and pairing during meiosis is imperfect. Under these circumstances—unequal crossing over (see Fig. 10–5)—one of the daughter chromosomes contains a duplicated gene, while the other one exists with a gene deleted. Once a duplication has occurred, further duplications occur more readily, because pairing of the first of the duplicate genes on one chromosome with the second gene of the duplicate on the other produces one chromosome with a triplicated gene and one with a single gene (Chap. 48). Duplication has probably played a very important role in the course of evolution¹¹ because the presence of two genes with the same function allows experiments of nature: Mutations can accumulate on one of the genes while the original function is still provided by the duplicate. Examples of the results of gene duplication abound in hematology, particularly with respect to the hemoglobin loci. The γ -chain loci are duplicated, and there are also two nearly identical copies of the α -chain locus (Chap. 48). Furthermore, the close similarity of their amino acid sequence and the fact that they are tightly linked indicate that the β , γ , and δ loci represent the result of duplication of a single ancestral gene. The process of unequal crossing over takes place not only between genes, but also within genes. When this occurs, one would anticipate that a portion of the amino acid sequence of a protein is represented twice on one chromosome and is missing on the other. The Lepore hemoglobins, leading to a thalassemic clinical state, are an example of this type of unequal crossing over (Fig. 48–8). These abnormal hemoglobins have the amino acid sequence of the δ chain at the amino end, and the sequence of the β chain at the carboxyl end. The complement to this kind of abnormality, the “anti-Lepore” hemoglobin, also has also been found (Chap. 49). Similarly, a mutation of the glucocerebrosidase gene causing Gaucher disease has been found to be the result of a crossover between the active gene and the pseudogene.¹² The two types of haptoglobin represent an ancestral gene and one in which a major part of that gene has been duplicated.¹³

TRANSMISSION OF GENETIC DISEASES

The known single-gene diseases can be classified into four major modes of inheritance: autosomal dominant, autosomal recessive, X-linked dominant, and X-linked recessive.¹⁴ The first two types involve genes known to occur on the 22 pairs of autosomes. The last two types occur on the X chromosome; very few disease-causing genes are found on the Y chromosome.

The *pedigree* chart summarizes family relationships and shows which members of a family are affected by a genetic disease (Fig. 10–2).¹⁵ Generally, the pedigree begins with one individual in the family, the *proband*. This individual is usually the first person in the family diagnosed or seen in a clinic.

Figure 10–2. Pedigree for an autosomal dominant disease. (Reproduced with permission from Jorde LB, Carey JC, Barnshad MJ: *Medical Genetics*, 4th edition. Philadelphia, PA: Mosby/Elsevier, 2010.)

AUTOSOMAL DOMINANT INHERITANCE

Diseases caused by autosomal dominant genes are rare, with the most common occurring in fewer than 1 in 500 individuals. Therefore, it is uncommon for two individuals who are both affected by the same autosomal dominant disease to produce offspring together. Affected offspring are usually produced by the union of a normal parent with an affected heterozygous parent. The affected parent can pass either a disease gene or a normal gene to the next generation. On average, half the children will be heterozygous and will express the disease, and half will be normal.

The pedigree in Fig. 10–2 shows the transmission of an autosomal dominant trait or disease. Several important characteristics of this pedigree support the conclusion that the trait is inherited in autosomal dominant fashion:

1. The two sexes exhibit the trait in approximately equal proportions, and males and females are equally likely to transmit the trait to their offspring.
2. No generations are skipped. If an individual has the trait, one parent must also have it. If neither parent has the trait, none of the children have it (with the exception of new mutations, as discussed later in this section).
3. Affected heterozygous individuals transmit the trait to approximately half their children, and because gamete transmission is subject to chance fluctuations, all or none of the children of an affected parent may have the trait. When large numbers of matings of this type are studied, however, the proportion of affected children closely approaches one-half.

The probability that an at-risk individual (e.g., someone with a positive family history) will develop a genetic disease is termed the *recurrence risk*. When one parent is affected by an autosomal dominant disease (and is a heterozygote) and the other is unaffected, the recurrence risk for each child is one-half.

An important principle is that each birth is an independent event, much like a coin toss. Thus, even though parents may have already had a child with the disease, their recurrence risk remains one-half. Even if they have had several children, all affected (or all unaffected) by the disease, the law of independence dictates that the probability that their next child will have the disease is still one-half. Parents' misunderstanding of this principle is a common problem encountered in genetic counseling.

If a child is born with an autosomal dominant disease and there is no history of the disease in the family, the child is probably the product of a new (or *de novo*) mutation.¹⁶ The gene transmitted by one of the parents has thus undergone a mutation from a normal to a disease-causing allele. The genes at this locus in most of the parent's other germ cells are still normal. In this situation the recurrence risk for the parent's subsequent offspring is not greater than that of the general population. The offspring of the affected child, however, will have a recurrence risk of one-half. Because these diseases often reduce the potential for reproduction, many autosomal dominant diseases result from new mutations.

Occasionally, two or more offspring have symptoms of an autosomal dominant disease when there is no family history of the disease. Because mutation is a rare event, it is unlikely that this disease would be a result of multiple mutations in the same family. The mechanism most likely responsible is termed *germline mosaicism*.¹⁷ During the embryonic development of one of the parents, a mutation occurred that affected all or part of the germline, but few or none of the somatic cells of the embryo. Thus, the parent carries the mutation in the parent's germline but does not actually express the disease. As a result, the unaffected parent can transmit the mutation to multiple offspring. This phenomenon, although relatively rare, can have significant effects on recurrence risks.¹⁸

AUTOSOMAL RECESSIVE INHERITANCE

Like autosomal dominant diseases, diseases caused by autosomal recessive genes are rare in populations, although there can be numerous carriers. Sickle cell disease is seen in approximately 1 in 600 Americans of African descent, but it occurs in the heterozygote state in approximately 1 in 12 members of this population.¹⁹ Under most circumstances, carriers are phenotypically normal. Like autosomal dominant diseases, many autosomal recessive diseases are characterized by incomplete penetrance and variable expressivity.

Figure 10–3 shows a pedigree for an autosomal recessive condition such as sickle cell disease. The important criteria for discerning autosomal recessive inheritance include the following:

1. Males and females are affected in equal proportions.
2. Consanguinity (marriage between related individuals) is sometimes present, especially for rare recessive diseases.
3. The disease may be seen in siblings of affected individuals, but usually not in their parents.
4. On average, one-fourth of the offspring of carrier parents will be affected.

In most cases of recessive disease, both of the parents of affected individuals are heterozygous carriers. On average, one-fourth of their offspring will be normal homozygotes, one-half will be phenotypically normal carrier heterozygotes, and one-fourth will be homozygotes with the disease. Thus, the recurrence risk for the offspring of carrier parents is 25 percent. However, in any given family, there are chance fluctuations.

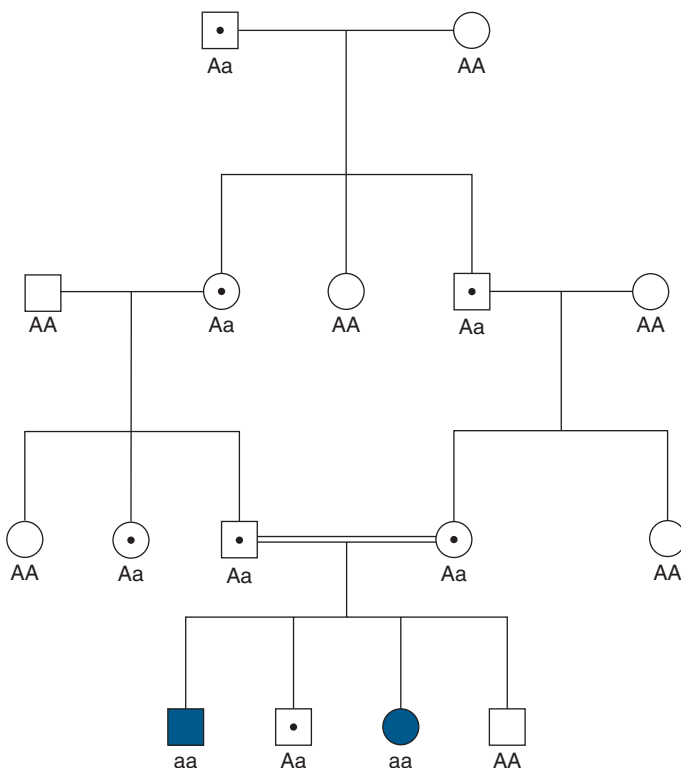

Figure 10–3. Pedigree for sickle cell disease. The double bar denotes a consanguineous mating. Because sickle cell disease is relatively common in some populations, most cases do not involve consanguinity. (Reproduced with permission from Jorde LB, Carey JC, Barnshad MJ: *Medical Genetics*, 4th edition. Philadelphia, PA: Mosby/Elsevier, 2010.)

If two parents both have a recessive disease, they each must be homozygous for the disease. Therefore, all their children also must be affected. This distinguishes recessive from dominant inheritance because two parents both affected by a dominant gene are nearly always both heterozygotes and thus one-fourth of their children will be unaffected.

Because carrier parents usually are unaware that they both carry the same recessive allele, they often produce an affected child before knowing of their condition. Carrier detection tests can identify heterozygotes by measuring the reduced amount of a critical enzyme. This enzyme is totally lacking in a homozygous recessive individual, but a carrier, although phenotypically normal, will typically have half the normal enzyme level. Increasingly, carriers are now detected by direct examination of their DNA to reveal a mutation. Carrier detection tests are available for many hematologic recessive diseases, including sickle cell disease, α - and β -thalassemia, Gaucher disease, and hemochromatosis.^{20–22}

PENETRANCE AND EXPRESSIVITY

The *penetrance* of a trait is the percentage of individuals with a specific genotype who also exhibit the expected phenotype. Incomplete penetrance means that individuals who have the gene disease-causing genotype may not exhibit the disease phenotype at all, even though the genotype and the associated disease may be transmitted to the next generation. Penetrance can increase with age, and it can differ between the sexes. For example, the penetrance of hemochromatosis, an autosomal recessive condition, increases with age as iron accumulates in organs such as the heart and liver. The penetrance of the hemochromatosis genotype is higher in males than females because females deplete their iron supplies by menstruation, childbirth, and lactation.²³

Expressivity is the extent of variation in phenotype associated with a particular genotype. If the expressivity of a disease is variable, penetrance may be complete but the severity of the disease can vary greatly. Many hematologic conditions, including sickle cell disease and β -thalassemia, have variable expressivity. This can be a result of the effects of other genes (*modifier loci*), an example of which is variants in the *BCL11A* gene that increase fetal hemoglobin levels and attenuate the effects of sickle cell disease.²⁴ Similarly, the factor V Leiden variant is more likely to produce thrombophilia if a second mutation of a gene encoding another coagulation factor, such as protein C, is coinherited.²⁵ In addition, different mutations at a locus can cause variation in severity. For example, a mutation that alters only one amino acid of the factor VIII gene usually produces a mild form of hemophilia A, whereas a “stop” codon (premature termination of translation) usually produces a more-severe form of this clotting disorder.^{26,27} Nongenetic (“environmental”) factors can also influence expression, as in hemochromatosis, where alcohol abuse can increase the severity of expression.²⁸

X-LINKED INHERITANCE

Some genetic conditions are caused by mutations in genes located on the sex chromosomes, and that mode of inheritance is termed *sex linked*. Only a few diseases are known to be inherited as X-linked dominant or Y chromosome traits, so only the more common X-linked recessive diseases are discussed here.

Because females receive two X chromosomes, one from the father and one from the mother, they can be homozygous for a disease allele at a given locus, homozygous for the normal allele at the locus, or heterozygous. Males, having only one X chromosome, are *hemizygous* for genes on this chromosome. If a male inherits a recessive disease gene on the X chromosome, he will be affected by the disease because the

Y chromosome does not carry a normal allele to counteract the effects of the disease gene. Because a single copy of an X-linked recessive gene will cause disease in a male, whereas two copies are required for disease expression in females, more males are affected by X-linked recessive diseases than are females.

X INACTIVATION

In the late 1950s, Mary Lyon proposed that one X chromosome in the somatic cells of females is permanently inactivated, a process termed *X inactivation* (Fig. 10–4).^{29–33} This proposal, the Lyon hypothesis, explains why most gene products coded by the X chromosome are present in equal amounts in males and females, even though males have only one X chromosome and females have two X chromosomes. This phenomenon is called *dosage compensation*. The inactivated X chromosomes are observable in many interphase cells as highly condensed intranuclear chromatin bodies, termed *Barr bodies* (after Barr and Bertram, who discovered them in the late 1940s). Normal females have one Barr body in each somatic cell, whereas normal males have no Barr bodies.

X-inactivation occurs very early in embryonic development—approximately 7 to 14 days after fertilization. In each somatic cell, one of the two X chromosomes is inactivated. In some cells, the inactivated X chromosome is the one contributed by the father; in other cells it is the one contributed by the mother. Once the X chromosome has been inactivated in a cell, all the descendants of that cell have the same chromosome inactivated. Thus inactivation is said to be random but *fixed*.

Some individuals do not have the normal number of X chromosomes in their somatic cells. For example, males with Klinefelter syndrome typically have two X chromosomes and one Y chromosome. These males do have one Barr body in each cell. Females whose cell nuclei have three X chromosomes have two Barr bodies in each cell, and females whose cell nuclei have four X chromosomes have three Barr bodies in each cell. Females with Turner syndrome have only one X chromosome and no Barr bodies. Thus, the number of Barr bodies is always one less than the number of X chromosomes in the cell. All but one X chromosome are always inactivated.

Figure 10–4. The X inactivation process. At fertilization, the female zygote inherits one maternal chromosome (X^m) and one paternal X chromosome (X^p). At some time early in embryogenesis, one X in each cell is inactivated at random and condenses to form the Barr body. The active X remains active not only for the lifetime of that cell but for the lifetime of all of its progeny. A tumor with a clonal origin will consist entirely of cells in all of which either X^m or X^p is active. A tumor with a multicentric origin may contain both X^m and X^p cells.

Persons with abnormal numbers of X chromosomes, such as those with Turner syndrome or Klinefelter syndrome, are not physically normal. This situation presents a puzzle because they presumably have only one active X chromosome, just as individuals with normal numbers of chromosomes do. This is probably because the distal tips of the short and long arms of the X chromosome, as well as several other regions on the chromosome arm, are not inactivated. Thus, X inactivation is also known to be *incomplete*.

Although the mechanisms underlying X inactivation are only partially understood, the gene responsible for initiating X inactivation, *XIST*, has been identified.³⁴ This gene encodes a *long noncoding RNA* (*lncRNA*) that coats one of the X chromosomes, which is then inactivated (it is estimated that the human genome contains approximately 9000 *lncRNA* genes¹). Methylation of X chromosome DNA, a process in which DNA is inactivated when cytosine bases are enzymatically converted to 5-methylcytosine, occurs on the inactivated X chromosome. Inactive X chromosomes can be at least partially reactivated *in vitro* by administering 5-azacytidine, a demethylating agent.

Characteristics of Pedigrees

X-linked pedigrees show distinctive modes of inheritance. The most striking characteristic is that females seldom are affected. To express an X-linked recessive trait, a female must be homozygous: either both her parents are affected, or her father is affected and her mother is a carrier. Such matings are rare.

The following are important principles of X-linked recessive inheritance:

1. The trait is seen much more often in males than in females.
2. Because a father can give a son only a Y chromosome, the trait is never transmitted from father to son.
3. The gene can be transmitted through a series of carrier females, causing the appearance of one or more “skipped generations.”
4. The gene is passed from an affected father to all his daughters, who, as phenotypically normal carriers, transmit it to approximately half their sons, who are affected. Good examples of X-linked hematologic disorders include hemophilia A (clotting factor VIII deficiency), hemophilia B (clotting factor IX deficiency), and G6PD deficiency.

Recurrence Risks

The most common mating type involving X-linked recessive genes is the combination of a carrier female and a normal male. On average, the carrier mother will transmit the disease-causing allele to half her sons (who are affected) and half her daughters (who are carriers). The other common mating type is an affected father and a normal mother. In this situation, all the sons must be normal because the father can transmit only his Y chromosome to them. Because all the daughters must receive the father’s X chromosome, they will all be heterozygous carriers. Because the sons *must* receive the Y chromosome and the daughters *must* receive the X chromosome with the disease gene, these are precise outcomes and not probabilities. None of the children will be affected.

Once the mode of genetic transmission is clear, the diagnostic alternatives can be narrowed considerably. For example, methemoglobinemia transmitted as an autosomal dominant disorder is a result of hemoglobin M, whereas methemoglobinemia transmitted as an autosomal recessive disorder is a result of cytochrome b5 reductase (the reduced form of nicotinamide adenine dinucleotide [NADH] diaphorase) deficiency (Chap. 49). Hemolytic anemia with autosomal dominant transmission is likely to be a result of hereditary spherocytosis, but sex-linked transmission of the hemolytic state suggests a deficiency of G6PD or, more rarely, phosphoglycerate kinase. A bleeding disorder that is transmitted in an X-linked fashion may be caused by a deficiency

of factor VIII or factor IX, but autosomal recessive inheritance should suggest to the physician a deficiency of other clotting factors, such as factor X, XI, or V. Careful analysis of the family history not only will make possible more appropriate genetic counseling to the patient and family, but also will shorten the road to a correct diagnosis.

EPIGENETICS AND GENOMIC IMPRINTING

Although this chapter focuses on DNA sequence variation and its consequence for disease, there is increasing evidence that the same DNA sequence can produce dramatically different phenotypes because of chemical modifications that alter the *expression* of genes (these modifications are collectively termed *epigenetic*; Chap. 12). Epigenetic alteration of gene activity can have important disease consequences. For example, a major cause of one form of inherited colon cancer (termed *hereditary nonpolyposis colorectal cancer [HNPCC]*) is the methylation of a gene whose protein product repairs damaged DNA.³⁵ When this gene becomes inactive, damaged DNA accumulates eventually resulting in colon tumors.³⁶

LINKAGE ANALYSIS AND GENE IDENTIFICATION

Locating genes on specific regions of chromosomes has been one of the most important goals of human genetics. The location and identification of a gene can tell much about the function of the gene, its

interaction with other genes, and the likelihood that certain individuals will develop a genetic disease.

Mendel's second law, the principle of independent assortment, states that an individual's genes will be transmitted to the next generation independently of one another. This law is only partly true, however, because genes located close together on the same chromosome do tend to be transmitted together to the offspring. Thus Mendel's principle of independent assortment holds true for most pairs of genes but not those that occupy the same region of a chromosome. Such loci demonstrate *linkage* and are said to be linked.

During the first meiotic stage, the arms of homologous chromosome pairs intertwine and sometimes exchange portions of their DNA (Fig. 10-5) in a process known as *crossover*. During crossover, new combinations of alleles can be formed. For example, two loci on a chromosome have alleles *A* and *a* and alleles *B* and *b*. Alleles *A* and *B* are located together on one member of a chromosome pair, and alleles *a* and *b* are located on the other member. The genotype of this individual is denoted as *AB/ab*.

As Fig. 10-5A shows, the allele pairs *AB* and *ab* would be transmitted together when no crossover occurs. However, when crossover occurs (Fig. 10-5B), all four possible pairs of alleles can be transmitted to the offspring: *AB*, *aB*, *Ab*, and *ab*. The process of forming such new arrangements of alleles is called *recombination*. Crossover does not necessarily lead to recombination, however, because double crossover between two loci can result in no actual recombination of the alleles at the loci (Fig. 10-5).

The analysis of recombination in families is used to determine the locations of disease-causing genes.³⁷ Millions of SNPs have been identified in the human genome, and their chromosome locations

Figure 10-5. Genetic results of crossing over. **A.** No crossing over. **B.** Crossing over with recombination. **C.** Double crossing over, resulting in no recombination. (Reproduced with permission from McCance KL, Huether SE, Brashers VL, et al: Pathophysiology: The biologic basis for disease in adults and children, 6th edition. St. Louis, MO: Mosby/Elsevier, 2010.)

are known.³⁸ If a SNP demonstrates close linkage with a disease phenotype in a family or a series of families, then the disease-causing locus must be located near the SNP. This establishes the approximate location of the disease-causing locus. Linkage can be used in some cases to help diagnose genetic disease in family members by determining whether a parent who has a disease-causing allele has transmitted a linked SNP allele to their offspring.

The Human Genome Project was initiated in 1990 and completed in 2003. Its main goals were to discover polymorphisms useful for linkage throughout the genome (the “gene map”) and to determine the entire human DNA sequence.^{39–41} These goals have been accomplished, and DNA sequencing has become far cheaper and more efficient in recent years (Chap. 11). Consequently, many thousands of individuals have now been sequenced, and the genes responsible for approximately 4000 mendelian conditions have been identified.^{14,42,43} This has greatly increased our understanding of the mechanisms that underlie many diseases and has permitted more accurate genetic testing and diagnosis.

● THE METHODS OF MOLECULAR BIOLOGY

CLONING DNA

The sequencing of DNA and the preparation of probes requires that a fragment of DNA is amplified manyfold to provide a relatively pure sample for study. The classical method by which this is achieved, *cloning*, is a central technique of molecular biology.³ It is generally accomplished by inserting the DNA into a vector, a bacteriophage or plasmid, that normally replicates within a bacterial cell. When such a phage or plasmid contains a foreign DNA fragment, the fragment also undergoes replication and can then be purified in greatly amplified form. If the DNA is not available in pure form to begin with, it must be purified from a collection of DNA fragments that is designated a *library*. An adequate genomic library consists of millions of fragments of the genetic material of a cell that have been ligated into a suitable vector. Another valuable type of library is made by transcribing mRNA from a tissue into complementary DNA (cDNA) using the enzyme reverse transcriptase. Such a cDNA library is particularly useful for the isolation of genes because in it are represented only the intron-free portions of genes that are being actively transcribed in a tissue. In contrast, a genomic library represents all of the genetic material, coding and noncoding, transcribed and non-transcribed. Many different vectors have been designed and they possess the capacity to replicate fragments of DNA of widely differing sizes, varying from yeast artificial chromosomes (YACs), which may incorporate a million or more base pairs of DNA, to bacterial artificial chromosomes (BACs) and P1-derived artificial chromosomes (PACs), which can contain 100,000 bp, to cosmids (20,000 to 30,000 bp). Much smaller inserts, ranging in size from approximately 3000 to 12,000 bp can be cloned into bacteriophages.

THE POLYMERASE CHAIN REACTION

Amplification of the desired part of the genome may be achieved, when some of the sequence is already known, by using the polymerase chain reaction (PCR), a technique that is much simpler and more rapid than cloning.⁴⁴ For example, one may wish to determine the sequence of a portion of a gene for diagnostic purposes, but cloning the gene(s) of interest is too time-consuming and labor intensive to be practical. Two primers matching opposite strands of DNA on either side of the region of interest are used to amplify the intervening specific segment of DNA by more than a million-fold. Successive cycles of DNA synthesis from the primers and chain separation by heating between the cycles are the basis of this powerful technique.

PCR can be carried out just a few nanograms of DNA, as opposed to the micrograms required for cloning. The amount of DNA in a several-year-old blood stain, a single hair, or even the back of a licked postage stamp is often sufficient for analysis. PCR is so sensitive that under optimal conditions the DNA from a single cell may be amplified. Moreover, the stability of DNA is such that very old preserved material may be used. Thus, it is possible to amplify the DNA from blood films, mummies, and other ancient biologic material.⁴⁵ In addition, because it does not require cloning, the procedure is much faster than older techniques. Genetic testing for sickle cell disease, for example, can be done in a single day with PCR.

Amplifying by PCR cDNA produced by reverse-transcribing mRNA in tissue extracts (reverse transcriptase polymerase chain reaction [RT-PCR]) provides a very sensitive means for measuring the expression of genes in tissues.⁴⁶ In the early cycles of PCR, the rate of amplification is a function of the amount of template; thus it allows for quantification of mRNA or DNA. For this purpose, a housekeeping mRNA is also measured and the ratio of this reference mRNA to tested mRNA is used. Thus, the slope of the curve can be used to measure the amount of mRNA or DNA in a specimen. This process, which has been designated *real-time PCR*, has been automated by using fluorescent probes that are destroyed during the amplification process or a dye that binds only to double-stranded DNA.

DNA SEQUENCING

The chain termination technique has traditionally been used to determine the sequence of DNA.⁴⁷ It depends upon synthesizing a labeled strand of DNA, with the DNA to be sequenced serving as the template. The mixture of nucleotides used contains a nucleotide analogue that results in chain termination when incorporated. Gel electrophoresis of the labeled products produces “ladders” of polynucleotides. The size of each fragment depends on the point at which there exists a nucleotide corresponding to the chain terminating analogue in the mixture. Sequencing can be done rapidly and accurately by automated methods in which the elongation of the strand is terminated by a fluorescent nucleotide and electrophoresis is carried out in capillary tubes rather than slab gels.⁴⁸ Although DNA sequencing formerly required cloning of the fragment to be studied, amplification by PCR serves as a simpler alternative.

The development of new *high-throughput DNA sequencing* technology has decreased the cost of DNA sequencing by many orders of magnitude (this technology is also sometimes termed “next-generation” or “massively parallel” sequencing; see Chap. 11 for further details).^{49–51} In one common approach, genomic DNA is chopped at random into small segments, typically 100 to several hundred bp in size. Short synthetic DNA sequences, termed *adapters*, are joined to the ends of the genomic DNA fragments. These double-stranded DNA fragments are separated into single strands and then attached to a solid surface, such as a glass slide. Each individual DNA fragment is amplified by PCR into a cluster of thousands of identical copies, using the adapters as primer sequences (the multiple copies provide a signal strong enough to be visualized by a specialized camera). A sequencing reaction then occurs, in which these fragment clusters serve as templates for synthesizing complementary sequences. Similar to the Sanger sequencing process described previously in the section on DNA sequencing, new complementary bases (to which a base-specific fluorescent label is attached) are added one at a time. The fluorescent signal from each cluster is recorded by a camera, revealing the base-pair sequence of each fragment. The key advantage of this approach is that millions of different DNA fragments are sequenced simultaneously, in contrast to older methods in which only a few dozen fragments are sequenced at a time.

INTERFERENCE WITH GENE EXPRESSION

Antisense RNA and DNA

It is possible to interdict the expression of a gene at several different levels. The translation of mRNA can be inhibited and the mRNA degraded by *antisense* RNA or DNA, molecules that have a sequence complementary to the mRNA that is to be inactivated. When such oligonucleotides are present, they inhibit gene expression through a variety of mechanisms. For example, they form a double strand with the RNA, just as two complementary strands of DNA will hybridize to form the normal double-stranded form of DNA. Because the double-stranded form cannot be translated and is probably degraded rapidly, the production of its protein product is inhibited specifically. In experimental systems, antisense DNA or stable DNA analogues, such as the methylphosphonates, can be transfected directly into cells or the RNA can be made off of a plasmid with the appropriate DNA template and a promoter. Originally this approach was used, for example, to suppress lymphoma growth with DNA oligonucleotides antisense to introns of the oncogene *c-myc*, to suppress marrow cells from patients with chronic myelogenous leukemia by antisense DNA directed at the BCR-ABL junction, or to suppress BCL-2-positive lymphoma cells in culture by BCL-2 antisense.⁶⁴ Because antisense RNA can be produced *in vivo* by transcribing the complementary strand of a gene, it may represent a natural regulatory mechanism.

Interfering RNA

RNA plays a much broader role in the physiologic regulation of genes than merely the formation of antisense mRNAs. siRNAs (small interfering ribonucleic acids) and the closely related miRNAs (microribonucleic acids) represent a mechanism for silencing of genes, through a process known as RNA interference (RNAi^{52,53}). In the case of siRNA, double-stranded RNA is cleaved by the “dicer” enzyme into approximately 22 bp segments that trigger the destruction through the RNA-induced silencing complex (RISC) of the homologous targeted mRNA. Although siRNAs tend to operate through RISC and slice the targeted mRNA, the miRNAs that represent endogenous duplexes can decrease the amount of target mRNA(s) or can also posttranscriptionally regulate gene expression by complexing with the same RISC and interfering with the targeted mRNA translation. miRNAs may play an important role in hematopoietic differentiation⁵⁴ and seem to be widely used as a gene regulatory and antiviral measure. The use of siRNA has become very useful to molecular biologists as a powerful method for the down-regulation of genes in experimental systems.

Ribozymes

Cleaving RNA at defined sequences, much as restriction endonucleases cleave DNA, is one of the known enzymatic functions of RNA, and this function provides a means by which the expression of a gene can be interdicted in experimental systems. This *ribozyme* approach has been used, for example, in preventing replication of the HIV-1 virus⁵⁵ and by cleaving BCR-ABL fusion transcript with a view to developing a treatment for chronic myelogenous leukemia.⁵⁶

Transgenic and Knockout Animal Models

The insertion of DNA fragments into the nucleus of a fertilized ovum provides a means for altering the genetic constitution of animals. Animals that have been engineered in this manner are referred to as *transgenic*. The use of promoters that are inducible or tissue specific permits studies of the effect of a gene product that might be lethal if expressed in all tissues or at all times during embryogenesis. Transgenic mice that carry the human sickle β -globin gene have been produced and when superimposed on a murine thalassemic genotype produce high enough

levels of human hemoglobin S to have some potential as an animal model of sickle disease (Chaps. 48 and 49).⁵⁷ Another valuable technique for the study of gene function is targeted disruption (“knocking out”) of genes. In this technique, a DNA construct that contains regions homologous to the gene being targeted and selectable markers is transfected into an embryonic mouse stem cell. Once a cell in which recombination has occurred within a gene is found, it can be implanted into a blastocyst, with the hope that some of the progeny of the implanted cell will become germ cells. If this does occur, the knockout can be propagated and homozygous animals bred. The value of the technique is often limited by the fact that the knockout may be lethal (e.g., G6PD75 deficiency and Gaucher disease) or may not have any abnormal phenotype. But in some diseases, such as hemochromatosis,⁵⁸ knockout models of various forms of the disease are valuable resources. In situations in which a knockout proves to be lethal, or where it would be useful to limit the deficiency to a single-organ system, the Cre/LoxP site-specific recombination system has proven to be very useful.⁵⁹ The LoxP sequence, a 13-bp inverted repeat, is inserted so that it flanks the gene that is to be removed. Site specific recombination is catalyzed by the P-1 bacteriophage Cre recombinase, excising the intervening DNA targeted by the LoxP sequence and ligating the remaining 5' and 3' DNA. Tissue-specific excision can be achieved by inserting the Cre-recombinase downstream from a tissue-specific promoter. Random mutagenesis with agents such as *N*-ethyl-*N*-nitrosourea (ENU) can identify functions of genes whose role in a metabolic pathway was unsuspected. For example, a mutation in a membrane serine protease of unknown function revealed that it was a negative regulator of hepcidin, and subsequent investigations revealed that mutations of this gene caused hereditary iron deficiency in humans.⁶⁰

● GENE THERAPY

In somatic cell *gene therapy*, the DNA of a specific set of a patient's somatic cells is altered. It is also possible to carry out germline therapy, which affects all cells, including reproductive cells, but for technical and ethical reasons this is not being pursued in humans. Most commonly, somatic cell therapy is used for conditions in which a mutation has caused the absence of a gene product in a cell (e.g., adenosine deaminase in T cells, which leads to an autosomal recessive form of severe combined immunodeficiency [SCID]).⁶¹ A vector is used to carry a normal copy of the mutated gene into the patient's cells. These vectors are usually viruses, such as retroviruses or adenoviruses, which have been genetically modified so that they contain the normal human gene and cannot make copies of themselves (otherwise they could cause a viral infection). Once inside the patient's cells, the normal human gene begins to encode the missing gene product. For diseases caused by a gain of function, techniques such as antisense DNA or RNA and RNAi (discussed in the section on Interference with Gene Expression.) are being used.

Gene therapy has faced a number of technical hurdles, including immune responses against the vector, limited efficiency of antisense and RNAi approaches, and difficulties in producing sufficient quantities of a desired gene product. In one case, an immune response against an adenoviral vector proved fatal, and several cases of leukemia have resulted from the insertion of a modified retrovirus near an oncogene.⁶² Nevertheless, gene therapy has now been successful in treating a number of inherited conditions, including X-linked and ADA SCID, β -thalassemia, hemophilia B, and X-linked adrenoleukodystrophy.^{63–66} In addition to the treatment of hereditary diseases, gene therapy is being used to alter tumor cells in the treatment of various types of cancer. It is hoped that further research will lead to safe, efficient and cost-effective treatment of many human diseases through gene therapy.

CHAPTER 11

GENOMICS

Lukas D. Wartman and Elaine R. Mardis

SUMMARY

The introduction of next-generation sequencing platforms, coincident with genome-scale preparatory and analytical approaches and the completion of the Human Genome Reference, has ushered in the era of genomics. This chapter introduces the fundamentals of next-generation sequencing methods, provides an overview of the basics of data analysis, and explores the myriad applications developed to exploit the scale and throughput of next-generation sequencing toward questions of biomedical importance. Specifics of cancer genomics, complex disease genomics, and how they pertain to hematologic basic science and clinical practice are discussed, along with the modern-day realities of the consenting process.

HISTORY OF GENOMICS: SANGER SEQUENCING

The scientific discipline known as genomics has dramatically changed since the publication of the Human Reference Genome in 2003, primarily as a result of the introduction and broad-based implementation of new sequencing technologies.¹ Prior to the mid-2000s, Sanger sequencing was the predominant DNA sequencing approach, and was used to complete the sequencing of the first human reference genome. Frederick Sanger and his colleagues developed Sanger or “chain termination” sequencing in the late 1970s.² In their original method, four reactions were used to accomplish chain termination by incorporating separate di-deoxynucleoside triphosphates (ddNTPs), each included with a mix of three unmodified deoxynucleoside triphosphates (dNTPs) and a

Acronyms and Abbreviations AML, acute myeloid leukemia; ATAC-seq, uses the hyperactive Tn5 transposase to simultaneously fragment and add sequencing adaptors to accessible DNA; bp, base pair; ChIP-seq, chromatin immunoprecipitation sequencing; ddNTP, di-deoxynucleotide triphosphate; DNase-seq, uses DNase I to fragment DNA based on DNase I hypersensitive sites as a marker of chromatin accessibility; dNTP, deoxynucleotide triphosphate; FAIRE-seq, formalin crosslinking of DNA to proteins prior to random fragmentation; FFPE, formalin-fixed, paraffin embedded; *FLT3*-ITD, internal tandem duplications of *FLT3* gene; Gb, gigabase, i.e., billion base pairs; GINA, The Genetic Information Nondiscrimination Act; GWAS, genome-wide association study; lncRNA, long noncoding RNA; indel, term for the *insertion* or the *deletion* of bases; MDS, myelodysplastic syndromes; miRNA, microRNA; MNase-seq, micrococcal nuclease (MNase) determines nucleosomal footprints and boundaries by pairing with NGS as a marker of chromatin accessibility; MRD, minimal residual disease; NGS, next-generation sequencing; PCR, polymerase chain reaction; RNA-seq, RNA sequencing; siRNA, short-interfering RNA; SNP, single nucleotide polymorphism; snoRNA, small nucleolar RNA; snRNA, small nuclear RNA; Tb, terabase, i.e., trillion base pairs; WGBS, whole-genome bisulfite sequencing; ZMW, zero-mode waveguide.

fourth, radiolabeled dNTP. Each reaction consisted of the DNA template to be sequenced in a mixture containing a DNA primer, a DNA polymerase, a mixture of four dNTPs, and one of the four ddNTPs. Here, the chemistry of ddNTPs, which lack the 3' hydroxyl group present in a native dNTP, resulted in chain termination when incorporated into a growing DNA chain, as DNA polymerase cannot add another nucleoside without the 3' hydroxyl group present. With multiple rounds of primer elongation, the ddNTPs incorporate randomly in the newly synthesized strands according to the complementary nucleotides of the DNA template. By denaturing the newly synthesized strands from the DNA templates and resolving each of the four DNA fragment mixtures on separate lanes by gel electrophoresis, one could read out the sequence of the DNA template from the resulting autoradiograph. Significant improvements to the original Sanger sequencing protocol included the use of fluorescently labeled ddNTPs to allow for sequencing to occur in one reaction rather than four,³ improved thermally stable DNA polymerases that permitted temperature cycling (“cycled sequencing”), and the use of capillary electrophoresis rather than standard gel electrophoresis for automated separation matrix filling between samples.⁴⁻⁷ Modern Sanger capillary sequencers typically generate DNA sequencing reads in the range of 400 to 900 base pairs (bp). The main limitation of Sanger sequencing is that the sequencing reaction is decoupled from the electrophoretic separation and detection steps. To piece together the sequence for a large segment of DNA or entire genome, genomic DNA must be randomly fragmented and subcloned into a bacterial vector, with each cloned DNA isolated and sequenced. The resulting sequencing reads are assembled computationally to recreate larger fragments that recapitulate the starting DNA nucleotide sequence. This process is expensive, time-consuming, and laborious. However, with the availability of robotic DNA isolation and sequencing reactions, coupled with high-throughput capillary sequencers, the human genome, among the genomes of many other organisms, was decoded. Currently, Sanger sequencing is still in use to complete smaller scale sequencing projects and to validate findings from next-generation sequencing studies.

MODERN GENOMICS: NEXT-GENERATION SEQUENCING

OVERVIEW OF NEXT-GENERATION SEQUENCING

The method for next-generation sequencing (NGS), or massively parallel digital sequencing, is distinct from Sanger sequencing in that the sequencing reactions alternate with cycles of signal detection to provide the data readout at a significantly accelerated scale.^{8,9} The use of NGS in the years after the completion of the Human Genome Project has greatly increased the use of genomics and has significantly impacted the pace of biomedical research.¹⁰ Although there are several different NGS platforms offered commercially, they are methodologically quite similar. Unlike Sanger sequencing, NGS does not require subcloning of DNA, propagation in a bacterial host, and isolation of individual templates prior to sequencing. Instead, DNA is randomly fragmented into a pool of small pieces (generally 100 to 500 bp) and then ligated with specific synthetic DNA linkers (or adaptors) at the fragment ends to generate a NGS “library.” The library fragments are subsequently amplified by a process that isolates individual library fragments to a specific location prior to amplification. In general, this *in situ* amplification occurs on a covalently modified surface (a bead or flat silicon surface) with complementary linkers covalently attached to it, using a specific dilution of library fragments as input. In this step, the individual library fragment amplification permits sufficient signal output for detection

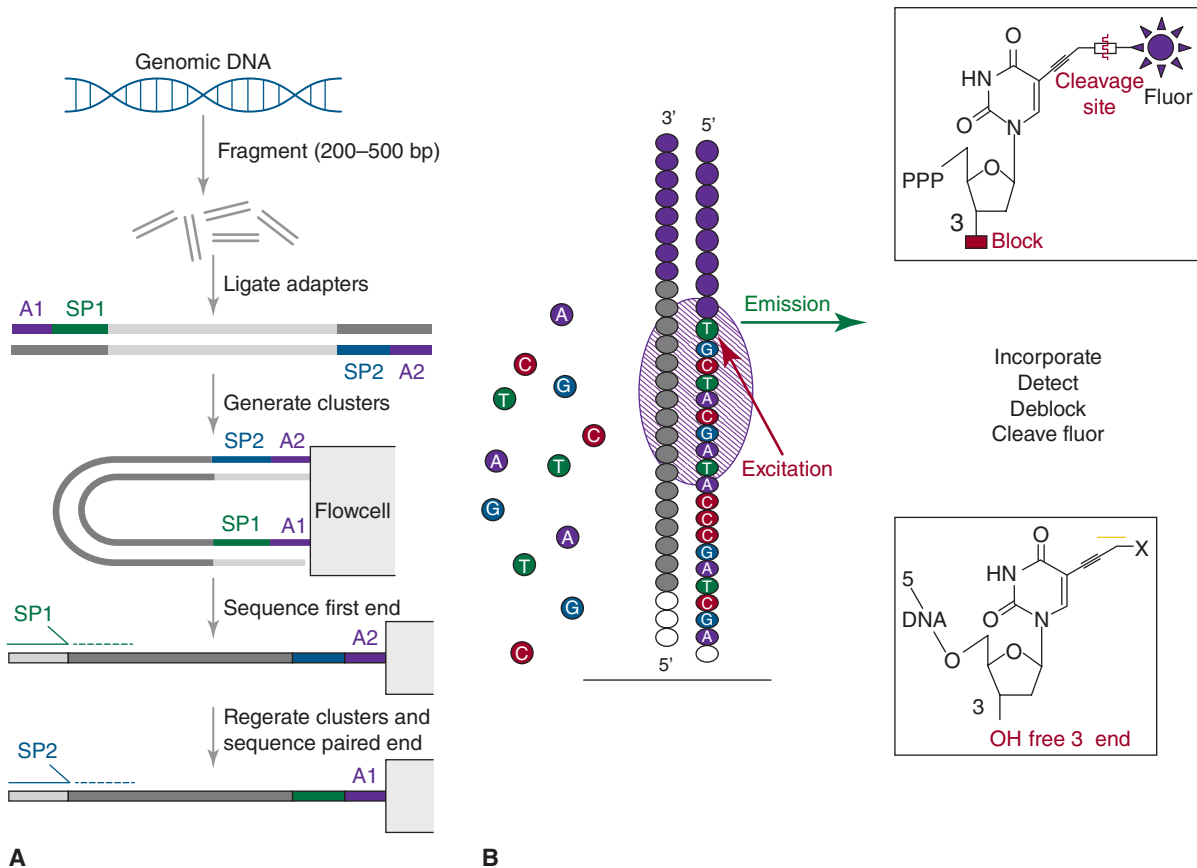

Figure 11-1. Illumina library construction and sequencing process. Panel **A** represents the library construction process whereby high-molecular-weight genomic DNA is fragmented, ligated with adaptors, and amplified on a solid support prior to annealing of adaptor-complementary primers. Panel **B** represents the stepwise sequencing process whereby reagents are introduced to extend the primed fragments, the incorporated fluorescent nucleotides are detected, the 3' end is deblocked, and the fluorescent groups on the incorporated nucleotides removed prior to the next stepwise sequencing-by-synthesis series. (Reproduced with permission from Mardis, ER: *Next-generation sequencing platforms*. *Annu Rev Anal Chem (Palo Alto Calif)* 6:287–303, 2013.)

during the sequencing steps that follow. Because each sequencing read derived from an amplified library fragment originates from that single unique fragment, NGS data are digital in nature. This fact underlies an important concept for digital sequencing methods: the number of specific sequencing reads generated is directly proportional to the amount of input nucleic acid, accurately reflecting amplified regions of a genome, for example. However, as the generation of libraries and the amplification of fragments involve polymerase chain reaction (PCR) amplification, inaccuracies can result via amplification biases or from PCR enzyme substitution errors in which the wrong base is incorporated during amplification.

SEQUENCING BY SYNTHESIS: THE ILLUMINA PLATFORM

Currently, there are two commercially available NGS platforms in common use. One uses an approach called *sequencing by synthesis* that occurs in the microfluidic channels of a silicon-derived “flow cell” device (Fig. 11-1).¹¹ Here, enzymatic amplification of library fragments on the flow cell surface results in hundreds of millions of DNA clusters, and the sequencing of each cluster occurs in parallel with all of the other clusters by a stepwise series of events. Solexa marketed the first commercially available sequencer using this technology in 2006, and was acquired by Illumina in 2007. Illumina offers a variety of different

sequencing machines with varying run times (from hours to days), sequencing capacities (from 25 million reads to nearly 3 billion reads per flow cell), and overall output (from approximately 0.5 gigabase (Gb) to greater than 1.5 terabase (Tb) of sequenced bases per run).

SEQUENCING BY SYNTHESIS: OVERVIEW OF METHODOLOGY

As in Sanger sequencing, the sequencing-by-synthesis steps begin with annealing sequencing primers complementary to the adaptors to the amplified library fragments on the flow cell surface. Then, a solution containing DNA polymerases and fluorescently-labeled, chemically modified dNTPs are added to the flow cell to begin an incorporation step. The DNA polymerases incorporate the complementary dNTP onto the 3' ends of the primed fragments in each cluster. Each incorporation reaction is terminated after a dNTP is added, because of a blocking group at the 3' position. After a cycle of dNTP incorporation on the flow cell, a laser-based detection system scans the flow cell surfaces to excite the incorporated fluorescent groups and to collect the unique light emission of each of the four fluorescently labeled dNTPs. Chemical deblocking steps follow to (1) remove the fluorophore by cleavage (the fluorescently-labeled dNTPs are known as “reversible dye terminators”) and (2) unblock the 3' hydroxyl group to permit the next cycle of incorporation, detection and blocking.

Unlike Sanger sequencing, Illumina's sequencing-by-synthesis method generates relatively short read lengths, typically 100 to 300 bp. The limitations on read length are primarily a signal-to-noise issue, where increasing numbers of steps in the sequencing-by-synthesis approach produces increasing noise at each step that competes with true signal detection. Hence, the data quality of Illumina reads tends to decrease with increasing step numbers. Illumina error rates are low, in the 0.1 to 0.3 percent range, and the predominant error type is base substitution.¹² Ultimately, a complex, repetitive genome such as the human genome cannot be assembled from 300-bp read lengths, so algorithms were developed to align reads to the reference genome as a first step toward data interpretation.¹³ One approach by which Illumina has improved read mapping is by enabling paired-end sequencing that permits the sequence read off first one end and then the other of each amplified fragment cluster on the flow cell. Paired end reads of this type physically are linked and defined by the fragment size, permitting their accurate placement onto the reference genome by alignment, and effectively permitting more reads to contribute to coverage from a given sequencer run (when compared to single-end reads).¹⁴ Furthermore, as described later, the expected read placement onto the reference genome, when not met, is a source of information used to interpret structural variation.

SEQUENCING BY PH CHANGE SENSING: THE ION TORRENT PLATFORM

The second type of NGS platform in common use is the sequencing by pH sensing method that is marketed by Life Technologies (now a part of Thermo Fisher) as their Ion Torrent platform (Fig. 11-2). Life Technologies acquired Ion Torrent in 2010.¹⁵ The sequencing by pH-sensing method involves similar steps of library construction as described for sequencing by synthesis. However, the library DNA fragments are diluted and combined with (1) individual micron-scale beads that have covalently attached complementary adaptors on their surface and (2) PCR reagents, including DNA polymerase, into an emulsion PCR reaction. In emulsion PCR, one generates individual aqueous micelles that permit bead-based amplification of library fragments prior to sequencing. The emulsion PCR process generates beads carrying copies of identical DNA fragments suitable for sequencing. The DNA-coated beads are purified from the emulsion, enriched for those beads with amplified DNA on their surfaces, and then deposited into individual wells of a specifically constructed semiconductor plate, known as an Ion Chip. Sequencing primers (complementary to the adaptors) are annealed to the bead-amplified fragments, and then the sequencing process is initiated by the addition of DNA polymerase and flow of a single

Figure 11-2. Ion Torrent library construction and sequencing process. Panel **A** represents the specifics of the Ion Torrent library amplification process, which requires an emulsion PCR amplification on the surface of a bead with covalently attached adaptor-complementary primers, followed by emulsion breaking and bead addition to the Ion Chip for sequencing. The sequencing process, illustrated in panel **B**, flows sequential high-purity dNTP solutions across the chip surface for incorporation. Upon incorporation, there is a release of hydrogen ions that are detected by the pH-sensing capability of the chip, detected in panel **C**. (Used with permission from Thermo Fisher Scientific.)

dNTP-containing buffer solution across the Ion Chip surface. The flow of the four nucleotides occurs in a stepwise fashion, with a detection step and an intervening wash. When a specific dNTP is incorporated into the elongating strands of DNA fragments on a specific bead, hydrogen ions are released, and a highly sensitive pH sensor built into the Ion Chip can read out the subsequent change in pH for the well containing that bead. If no dNTP is incorporated at that cycle, no change in pH is registered for that well. This approach follows for all wells containing beads on the Ion Chip, resulting in massively parallel sequencing. As with the Illumina technology, read lengths are short, in the 100 to 400 bp range. Unlike the Illumina platform that uses paired-end reads, Ion Torrent sequencing reads are single-end reads. The source of most sequencing errors generated by the Ion Torrent platform are insertion/deletion errors in stretches of identical bases on the template strand as a result of the difficulty of discerning the pH change ratio associated with incorporation of the same nucleotide above four consecutive identical nucleotides.¹⁶ Advantages of the Ion Torrent are that run times are very short (in the 2- to 7-hour range), and the cost per run is relatively inexpensive. The output, read length, run time, and cost vary by the Ion Chip type used (up to 2 Gb).

NEXT-GENERATION SEQUENCING TECHNOLOGY IN DEVELOPMENT: SINGLE-MOLECULE SEQUENCING

There is one commercially available platform for single-molecule sequencing, the Pacific Biosciences RSII instrument.¹⁷ Single-molecule sequencing differs primarily from the previous platforms discussed in that no PCR amplification is required prior to data generation. This has obvious advantages in eliminating some sources of bias that result from the use of PCR, but has a disadvantage in that higher input amounts of DNA are typically required. The other major difference in the Pacific

Biosciences approach is in the read length obtained, which ranges according to the template type but can exceed 50,000 bases with the input of very long molecules to the library construction.

The Pacific Biosciences approach couples primed DNA library fragments with DNA polymerase molecules that are specifically engineered for the sequencing system (Fig. 11-3). These complexes are introduced to the surface of a SMRTCell, a nanofabricated sequencing device, which consists of 150,000 zero-mode waveguides (ZMWs). In effect, the loading of complexes aims to place one DNA polymerase/DNA template complex into each ZMW in preparation for sequencing. The ZMW is a nanofabricated pore that focuses the laser excitation and detection optics at the bottom of the ZMW where the DNA polymerase complex is bound, isolating the detection area to the active site of the polymerase. The sequencing process initiates with the introduction of fluorescent nucleotides and buffers, and is continuously monitored by the excitation/detection optics during the run time. As fluorescently tagged nucleotides sample into the active site, they can be detected with sufficient dwell time upon their incorporation into the synthesized strand. Because each fluorescent group is specific to the nucleotide identity, the sequence is read out based on the detected emission wavelength. The fluorescent group is attached to the phosphate portion of the nucleotide, so incorporation removes it by cleavage during the phosphodiester bond formation, and it diffuses out of the ZMW focus.

Single-molecule sequencing has, by definition, an inherently higher error rate as a consequence of the signal-to-noise ratio associated with detecting a single event in real time. The predominant error type in Pacific Biosciences sequencing reads is an insertion/deletion error that may be a result of inaccuracies in detecting (1) a nucleotide that had a longer than average dwell time but was not incorporated, (2) a single nucleotide that incorporated but was mistaken for two (or more) nucleotides, or (3) by errors in detecting multiple nucleotide incorporations into a homopolymer stretch. In spite of an approximate 15 percent error rate, the errors

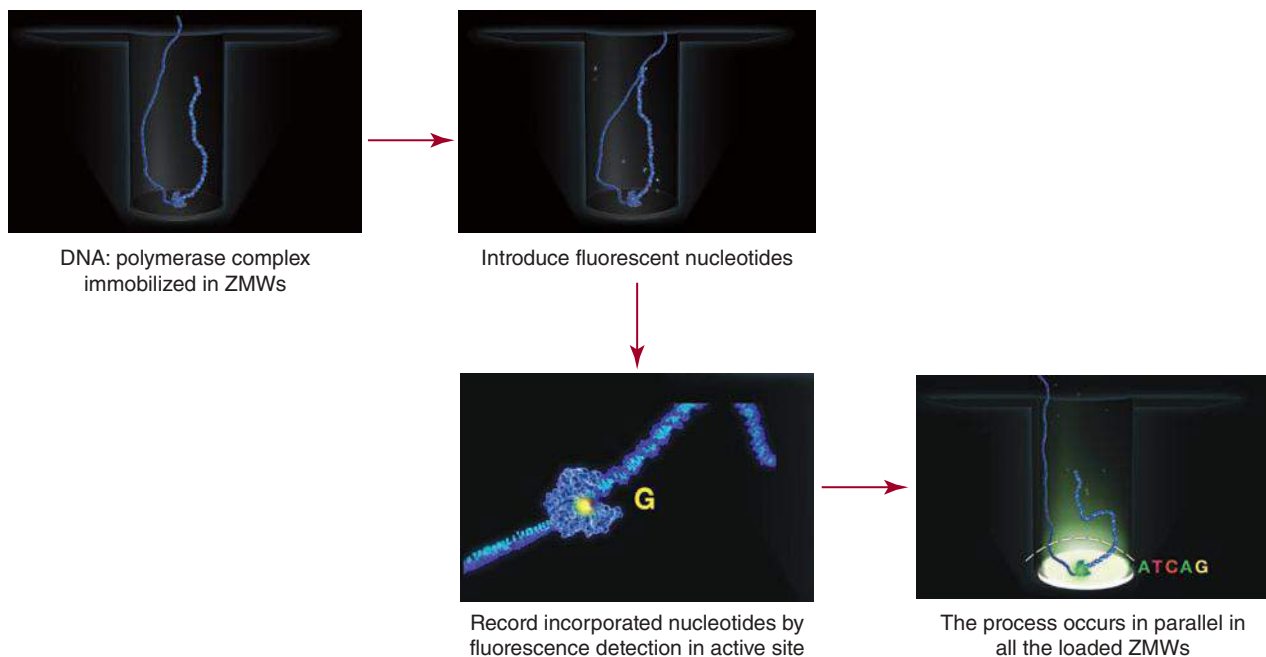

Figure 11-3. Pacific Biosciences real-time sequencing and detection process. The primed library fragments are complexed to DNA polymerases and applied to the surface of a SMRTCell, where they locate into zero-mode waveguides (ZMWs). After providing fluorescently labeled nucleotides and buffer, the sequencing process is monitored by real time detection, whereby incorporated nucleotides are detected in the active site of each ZMW-isolated polymerase complex by the laser/detection optics of the instrument. Here, the fluorescence events are recorded for each active ZMW throughout a preset duration, resulting in the final sequencing read data for each single DNA molecule. (Used with permission from Pacific Biosciences.)

are essentially random, which means that oversampling (or “coverage”) of the sequence of interest can correct most errors, resulting in a cumulative error rate of around 0.1 percent following read assembly.¹⁸ The very long read lengths possible on this platform enable read assembly, rather than read alignment needed in short read platform data analysis. Assembly has obvious advantages in its ability to represent novel content in a genome and to provide long-range haplotyping information.

Emerging DNA sequencing technologies are being developed around the central concept of translocating DNA molecules through nanopores, which can be either biologic or nanofabricated pores.¹⁹ In nanopore sequencing, detection of the nucleotide sequences occurs during nanopore translocation events that are sensed by changes in electrical current that correlate to sequence, or by laser-based detection of incorporated fluorescent nucleotides. Nanopore sequencing, while still somewhat theoretical, may offer rapid sequencing with very long read lengths.

TARGETED NEXT-GENERATION SEQUENCING: FROM GENE PANELS TO EXOMES AND BEYOND

Initially, NGS platforms were used for whole-genome sequencing of organisms with relatively small genomes, such as bacteria or model organisms (*Caenorhabditis elegans*, *Drosophila melanogaster*, etc.), or for combining large numbers of PCR products into a single sequencing run. As the throughput per run improved, larger genomes, including human genomes, were studied, including the first cancer genome.^{20,21} However, the cost and complexity of analysis for whole human genome studies, along with the difficulty of interpretation of variants identified

outside of the known genes, inspired the development of methods to focus sequencing onto these loci. In particular, hybrid capture techniques were developed that provided either a subset of known genes (all kinases, for example), or all the known genes (the “exome”) by a series of selective steps that led directly to NGS data generation (Fig. 11-4).²² At its essence, hybrid capture relies on synthetic DNA probes that are complementary to sequences of the known exons of genes in the genome of interest.^{23,24} In typical current protocols, the probes have covalently attached biotin moieties that enable downstream selection by streptavidin-coated magnetic particles. By combining a whole-genome library with the hybrid capture probes under conditions that favor hybridization (stoichiometry of probes to targets, temperature, and buffer conditions), probe:library fragment hybrids are formed. Following their selection by streptavidin magnetic bead binding and application of a magnetic force to isolate the beads, the noncaptured library fragments are removed, washes performed and the hybridized fragments eluted by denaturation from the probes. The resulting fragments are PCR amplified, quantitated, and sequenced by NGS. At present, the throughput of genome-scale NGS platforms permits the combination or “multiplexing” of the resulting fragments from several hybrid capture reactions into a sequencing run. Multiplexing is enabled by the inclusion of DNA barcodes that are synthesized onto the library adapters, and demultiplexing of the sequencing reads occurs downstream of the instrument run using the appropriate bioinformatics program. Although exome sequencing costs about one-tenth of whole-genome sequencing, it is important to note that typical yields from hybrid capture range from 85 to 90 percent of the targeted regions being covered at sufficient depth to confidently predict variants. Furthermore, the range of variant types

Figure 11-4. Overview of hybrid capture preparation for sequencing. This illustration presents a generalized overview of the process for hybrid capture selection prior to DNA or RNA sequencing. In general, probes are designed for the targeted regions of interest, which can constitute a small number of genes or hotspot loci, up to the full exome (all annotated genes in a genome). Following hybrid capture, the probe:library duplexes are isolated from solution by streptavidin magnetic beads. Release of the library fragments by denaturation is followed by amplification, quantitation, and sequencing. (Used with permission from Illumina, Inc.)

detected by hybrid capture is often limited. Single nucleotide variants and short insertion/deletion variants can be detected, but copy number and structural variants are difficult to detect reliably, especially if they are not anticipated by the addition of specially designed probes to capture them and by the specialized analyses required to detect them.

OVERVIEW OF NEXT-GENERATION DNA SEQUENCING ANALYSIS

It can be easily argued that the relative ease of performing biomedical experimentation imparted by NGS-based methods has conversely required more complicated analytical approaches to accurately interpret the resulting data.²⁵ As mentioned earlier, this is partly a result of the complexities of the human genome and the requirement for short reads to be aligned to the reference sequence as a first step for data analysis. It also is a result of computational infrastructure and software pipeline requirements to align and analyze data because of the sheer magnitude of data generated in a single experiment, which is exacerbated by multiple samples, multiple time points, and the need to integrate data of different types for the correlative analyses that are desired.

Most cancer-focused analyses have as a central goal the identification of DNA variants that are unique to the tumor cells (“somatic”) as compared to the inherited (“constitutional” or “germline”) genome. In practice, the desired comparison (whether the sequencing platform is a targeted gene panel, exome, or whole genome) is achieved by first aligning sequencing reads from the tumor library and from the matched normal library against the human genome reference sequence as separate entities. Algorithms that have specialized logic to identify different types of variation (single nucleotide, or “point” mutations, small insertions or deletions, copy number, or structural alterations) then are used to separately examine each set of read alignments and to identify the specific variation type relative to the human genome reference sequence. Lastly, the resulting variants that are identified are compared between the tumor and normal datasets, to identify those variants that appear unique to the tumor. As a means of interpreting the impact of all identified somatic variants on the sequence of amino acids in a given gene, for example, one must secondarily apply the annotation of the human genome onto identified single nucleotide and indel (term for the *insertion* or the *deletion* of bases) variants that occur within the coding regions and splice sites of known genes. Somatic single nucleotide variants (Chap. 10) can preserve the resulting amino acid (“synonymous”); can encode a different amino acid (“nonsynonymous”); can abolish a splice site and therefore alter the gene reading frame according to the intronic sequences up to the next encoded stop codon (“splice site”); and can omit (“readthrough”) or introduce a stop codon (“nonsense”). Indel mutations typically cause a shift in the open reading frame (“frameshift”) and result in a different amino acid sequence and length of the resulting protein, depending upon the number of added or deleted nucleotides. If the number added or deleted is a multiple of three nucleotides, the open reading frame is preserved but the protein sequence is altered accordingly.

Copy number gains or losses are defined by statistically significant variation in regional read density, and often are defined by the genes that lie in the altered region.^{26,27} Structural variants are broadly defined as chromosomal segments that are inserted, inverted relative to the germline sequence, or translocated relative to the germline sequence. Here, algorithms identify the different types of structural variants based on multiple read alignments that are spaced farther apart than expected defined by the insert size of the sequencing library used (“insertions”); or are spaced more closely than expected (“deletions”); or have the incorrect orientation of read direction for the read pairs aligned to the same chromosome (“inversions”); or have the forward and reverse reads

of multiple read pairs on different chromosomes (“translocations”). Insertions and inversions may result in a fusion protein by virtue of juxtaposition of exons from two genes on either the same (inversion) or different (insertion) chromosomes. Translocations also can result in gene fusions but involve juxtaposed exons from genes present on different chromosomes in the germline. There are multiple examples of gene fusions that result in proteins with a demonstrated role in oncogenesis.²⁸

Genetic susceptibility to hematologic malignancies can occur either by inheritance or by *de novo* mutations in genes, such as BRCA1/2, TP53, and others. Here, variants in the germline can be identified from aligned sequence read data to the human reference sequence, followed by annotation of the known cancer susceptibility genes. The pathogenicity of a given variant can be evaluated relative to databases of previously catalogued variants in these genes, if available. Identification of these variants typically will require consenting the patient and family members to a genetic counseling session to communicate the information about the germline susceptibility and its possible consequences for siblings and children (discussed below in “Next-Generation Sequencing as a Clinical Assay: Implications for the Practicing Hematologist”).

There are a variety of data analyses that integrate NGS data from different starting materials such as DNA and RNA from the same tumor, or across large groups of tumors (either from the same or different disease site). One example of data integration is evaluating RNA sequencing data to support a specific variant identified initially from tumor to normal DNA comparisons such as for a predicted fusion gene. In this example, the confirmed detection of the gene fusion in RNA provides confidence that the structural variant algorithm has identified a true positive. Such a result can also confirm cytogenetic results from conventional diagnostic assays. Similarly, the identification of a DNA level mutation that appears to introduce a protein truncating variant (frameshift or splice site mutation) can be evaluated by examining the RNA sequencing data for evidence of its transcription. Because these transcripts are often subject to nonsense-mediated decay (a surveillance pathway that reduces errors in gene expression by eliminating mRNA transcripts that contain premature stop codons), having RNA data to verify the transcript is present, and if so encodes the nonsense mutation, or is absent, can provide important information.

Hematologic malignancies have very specific considerations in experimental design and data analysis that should be noted. In particular, while high tumor cell content is typically derived from marrow biopsies, and therefore a majority of cells contributing DNA to NGS libraries are tumor cells, the matched normal sample can be problematic in the following regard. In patients with high circulating tumor cell content in the blood, the use of a skin, buccal swab, or mouthwash sample to provide the normal sample may have contaminating tumor cell content that will complicate the identification of somatic variants. Although consent to obtain a second normal sample once the patient achieves remission may be used to address this dilemma, not all patients achieve remission, and some patients will refuse the second biopsy because of discomfort. Flow sorting the blood or marrow to isolate a nonmalignant cell population (often normal T cells) can provide a matched normal if no alternative source is available.

The rapid and uncontrolled growth and cell division inherent to cancer cells often means that not all cancer cells in a patient will have the same somatic alterations. This has been demonstrated for leukemias and myelodysplastic syndromes and is referred to as genomic heterogeneity.^{29–36} In essence, every cancer cell carries the same set of founder mutations (sometimes referred to as “truncal”), but subclones can exist in the tumor cell population, each of which carries additional mutations unique to that subclone. As yet, the importance of heterogeneity has not been definitively demonstrated in the context of outcome, likelihood to relapse, resistance to therapy, or other possible clinical attributes. Tumor

subclones can be defined by their somatic mutational landscape from high depth NGS, where the digital nature of the NGS data is exploited by algorithmic clustering of mutations that share the same variant allele fraction (VAF). In particular, the VAF of any mutation is defined as the fraction of sequencing reads that contain the somatic variant (as compared to the germline or inherited nucleotide at that locus). Changes in the heterogeneity of cancer cell populations can be studied by comparing data from temporal sampling of a patient, such as at diagnosis and disease relapse.

NEXT-GENERATION SEQUENCING–BASED COMPREHENSIVE GENOMICS: FROM STUDIES OF THE TRANSCRIPTOME TO DNA METHYLATION TO CHROMATIN ACCESSIBILITY AND MODIFICATIONS

The study of modern genomics by NGS methods is not limited to the sequencing of genomic DNA but also can include (1) the characterization of RNA transcripts, (2) the physical structure of genomes including chromatin organization and protein-DNA interactions, and (3) the identification of specific chemical modifications to nucleotides and histones.³⁷

Analysis of the Transcriptome: RNA Sequencing

RNA sequencing (RNA-seq) involves the conversion of RNA into complementary DNA (cDNA) by reverse transcription followed by NGS library construction.³⁸ RNA-seq uses the digital nature of NGS technology to quantify levels of RNA transcripts. Previously, microarrays (designed with a fixed content of gene-specific probes) were used to assay gene expression by hybridization to reverse-transcribed RNA isolates. By contrast, RNA-seq offers the advantages of comprehensive and less-biased data analysis, with a broader dynamic range for detection of high and low abundance transcripts. With the single base resolution provided by RNA-seq, one can determine the expression of specific mutant alleles present in the germline or in cancer samples, which may be highly relevant for implementing a small molecule or immunotherapy-based targeted therapeutic. RNA-seq data can be analyzed to detect the expression of alternatively spliced isoforms of transcribed genes or to detect the transcriptional product(s) of gene fusions in cancer cells. RNA-seq can be produced as either single- or paired-end reads, where the latter are better suited to detect alternative splicing and gene fusions. Additionally, RNA-seq data can identify strand specificity of the DNA template, wherein RNA derived from the antisense strand may play an important role in regulating gene expression. Finally, the insert size of the RNA-seq libraries can be targeted to enrich for different subsets of the transcriptome. Small fragment size libraries (approximately 15 to 70 bp) enrich for microRNA (miRNA), short-interfering RNA (siRNA) and PIWI-interacting RNA (piRNA), intermediate size libraries (approximately 70 to 200 bp) enrich for small nuclear (snRNA) and small nucleolar RNA (snoRNA), and larger fragment libraries (excluding fragments less than 200 bp) enrich for messenger RNA (mRNA) and long noncoding RNA (lncRNA).

There are many protocols for RNA-seq, including different commercially available kits that exploit the aforementioned experimental focus areas. For example, protocols to study the “transcriptome,” which is defined as all the expressed RNA from a given cell or cell population, are often optimized to preferentially target one (or more) types of RNA that are pertinent to a particular area of clinical or research interest. Thus, a researcher interested only in detecting gene expression of annotated mRNA transcripts would choose either an RNA-seq protocol that included ribosomal RNA (rRNA) depletion (rRNA may

represent up to 60 percent of transcripts in a cell) or one that used an initial poly-A enrichment step (as rRNAs are not polyadenylated). By comparison, noncoding RNAs play a role in many cellular processes but are not polyadenylated, so even though poly-A enrichment would not be applied, a protocol that preserves strand specificity should be.

RNA is a less-stable molecule than DNA and hence assessing the quality of the isolated RNA prior to creating a sequencing library is of paramount importance. The source for the RNA may be fresh tissue, fresh-frozen tissue, or formalin-fixed, paraffin-embedded (FFPE) tissue, and each of these sources may influence the quality of the resulting RNA. RNA derived from FFPE tissue is often at least partially degraded because of formalin crosslinks with the RNA backbone that result in breakage. Similarly, the amount of RNA available from clinical specimens is often quite limited, making necessary the use of RNA amplification prior to library construction, or the use of hybrid capture probes to enrich the on-gene yield of sequencing data from low input sources.³⁹

As the analysis of RNA-seq data is distinct in many ways compared to DNA sequencing data analysis, multiple software tools are available to characterize differential gene expression, differential splicing, gene fusion detection, and allele-specific expression.^{40,41} In regard to cancer-specific analyses of RNA, a paired “normal” comparator from adjacent nonmalignant cells is often not available (or even understood), which complicates the analysis and interpretation of RNA-seq data. However, efforts are now cataloguing expression in normal human tissues and providing these results in public databases for comparison purposes.

Next-Generation Sequencing–Based Studies of Chromatin Modifications

Chromatin immunoprecipitation followed by NGS-based whole-genome sequencing is known as ChIP-seq.⁴² When studying chromatin modifications (Chap. 12), the targets are often transcription factors or specific histone modifications (such as methylation or acetylation) that may be important for regulation of gene expression. In brief, ChIP-seq begins with standard chromatin immunoprecipitation: protein and DNA are crosslinked in growing cell culture, the fixed and crosslinked DNA–protein complexes are fragmented, immunoprecipitated with an antibody specific for the protein of interest, and the DNA isolated from the precipitated material. After DNA isolation, a standard NGS library is prepared by adapter ligation and sizing, and the DNA is sequenced by standard NGS methods. Given the digital nature of NGS, the number of reads aligning to a particular area of the genome is directly proportional to the amount of input DNA from that region. Thus, one can determine “peaks” with a statistically significant increased number of aligned reads and infer that the genomic regions underlying the peaks are the specific areas where the protein of interest was bound to the DNA.^{43,44} Antibody specificity and avidity remain key determinants for the validity of ChIP-seq data, as does identifying the appropriate coverage cutoff value that determines a “peak.”

Next-Generation Sequencing–Based Studies of Chromatin Accessibility

The interaction of DNA and proteins to form chromatin plays an increasingly recognized role in the study of genomics and epigenomics (Chap. 12). Several methods using NGS-based approaches can interrogate the physical structure of DNA. These methods, which fragment DNA based on the accessibility of chromatin, allow for the determination of nucleosome positioning and inferred protein–DNA binding sites. Although these studies are not a direct method for determining specific protein–DNA binding sites, one can use sequence from the inferred protein–DNA binding sites as an indirect method for assaying

global transcription factor binding genome-wide without the limitations of ChIP-seq described above. NGS-based protocols used to determine chromatin accessibility differ in the approach to the DNA fragmentation step. Three commonly used protocols are DNase-seq, MNase-seq, and ATAC-seq. DNase-seq uses DNase I to fragment DNA based on DNase I hypersensitive sites as a marker of chromatin accessibility.⁴⁵ MNase-seq uses micrococcal nuclease (MNase) to cleave the DNA at accessible sites.⁴⁶ ATAC-seq uses the hyperactive Tn5 transposase to simultaneously fragment (with minimal sequence bias) and add sequencing adaptors to accessible DNA.⁴⁷ Another approach to studying chromatin accessibility is known as FAIRE-seq, which involves formalin crosslinking of DNA to proteins prior to random fragmentation via sonication.⁴⁸ A variation of this protocol, called chromosome conformational capture (or “3C”), in which chromatin domains are crosslinked, sequenced, and analyzed to determine higher-order structural associations, can provide details into the spatial organization of a genome.⁴⁹

Next-Generation Sequencing-Based Studies of Chemical Modifications to DNA: DNA Methylation and Hydroxy-methylation

Unless otherwise specified, DNA methylation is generally synonymous with cytosine methylation. Cytosine can undergo methylation or hydroxymethylation at its C5 position to form 5-methylcytosine (5-mC) or 5-hydroxymethylcytosine (5-hmC). Both cytosine methylation and 5-hydroxymethylation typically occur when a 5' cytosine is positioned directly adjacent to a downstream guanine (known as a CpG dinucleotide). There are approximately 26 million CpGs in the human genome. The first genome-wide platforms to detect DNA methylation changes at base pair resolution were microarrays designed to hybridize targeted CpGs across the genome (current methylation microarrays target approximately 500,000 CpGs). However, the design of CpG representation on a microarray was often biased toward gene promoters or other areas of predetermined interest.

Many protocols exist for differential fragmentation of a genome based on DNA methylation prior to array capture. For example, methylated cytosines are protected from cleavage by particular restriction enzymes: HpaII will cleave C-C-G-G but not C-5mC-G-G, whereas MspI will cleave both sites. By creating separate fragmentation libraries using each individual enzyme and then hybridizing each library to a separate array, differentially methylated sites can be determined.⁵⁰ Alternatively, one can perform DNA methylation studies using the sodium bisulfite conversion of cytosine to uracil (which is read as a thymidine). Both 5-mC and 5-hmC do not undergo bisulfite conversion and are read out as cytosine in a downstream assay. Microarrays that were designed for bisulfite-treated DNA have distinct paired probe sets that are designed to capture specific differentially methylated CpGs. NGS has enabled the direct sequencing of bisulfite converted DNA for unbiased evaluation of methylation and hydroxymethylation genome-wide.⁵¹ In whole-genome bisulfite sequencing (WGBS), a standard sequencing library is prepared with methylated C-containing adaptors, followed by the bisulfite conversion of the library. WGBS is complicated by numerous factors, including (1) the large amount of input DNA necessary for sequencing (bisulfite conversion results in DNA degradation), (2) incomplete conversion of cytosine to uracil, and (3) the analytic challenge of determining accurately which sequencing reads have been converted because of the presence of cytosine methylation or hydroxymethylation. To determine if cytosines are methylated versus hydroxymethylated, researchers have designed alternative protocols with an added chemical or enzyme-mediated conversion step or antibody-mediated differential capture of 5-mC and 5-hmC prior to sequencing.^{52,53} Capture-based methods can also be used to target only

5-mC prior to library preparation and sequencing, which may allow for genome-wide methylation studies at base pair resolution using smaller amounts of input DNA than WGBS.⁵⁴ A new transposase-based tagmentation method, similar to the approach used for ATAC-seq, also allows for WGBS with very small amounts of input DNA.⁵⁵

APPROACHES TO DNA SEQUENCING FOR RESEARCH PURPOSES

The study of genomics for research purposes has also shifted as a result of NGS technology. Prior to the broad availability of NGS platforms, most genomics research studies were genome-wide association studies (GWASs) that used a microarray platform to assay for significant changes in allele frequency from the panel of single nucleotide polymorphisms (SNPs) included on the array (modern arrays often have probes to detect the genotype of more than 1 million SNPs).⁵⁶ GWASs require large numbers of samples (cases and controls), and are powered to identify SNPs that are in linkage disequilibrium with an associated condition.⁵⁷ It is unlikely that the true pathologic variant will be discovered via a GWAS. Instead, the results of a GWAS could provide the basis for a targeted sequencing study to determine the pathologic alteration(s). In the era of decreasing cost and broad availability of NGS, most genomics studies have shifted to a more inclusive discovery platform, such as whole-genome sequencing or exome sequencing. Using a platform with single-base resolution rather than a defined content microarray increases the power to identify a pathologic variant, and the number of samples may decrease. However, for complex genetic diseases, in which multiple genes may play a causative role, the number of samples required remains large and can be cost prohibitive. In these situations, investigators often use a combination of GWAS methods (with cheaper microarrays) to perform the initial discovery work followed by region-specific NGS discovery sequencing.

Several ethical issues complicate the NGS-based study of human genomes. First, sequencing data may be potentially “identifiable,” meaning that one could potentially determine another person’s identity based on sequencing results obtained by a genomic study, when compared to data from a second genotyping assay (such as for diagnostic or criminal purposes). The Genetic Information Nondiscrimination Act (GINA) of 2008 made it illegal in the United States for employers and health insurance providers to discriminate based on the results of genetic findings. However, persons enrolling into genomics research trials must be informed of this theoretical risk of identifiability and be properly consented. Another consequence of genomics studies is that researchers must consider the return of genetic results to patients. The return of results is divided into two general categories: incidental findings and findings pertinent to the condition being studied. There is no standard approach for return of results as the approach varies on a case-by-case basis, depending on the sequencing study and the result to be communicated; however, new guidelines are emerging.⁵⁸ There is general consensus in the genomics research community that these issues, and how they will be handled for the particular study, must be clearly presented in the study protocol and the informed consent documentation.

The sequencing of cancer genomes, whether by whole-genome sequencing, exome sequencing, or multigene panels, is also associated with several specific considerations. Proper informed consent is again paramount. Proper sample banking is critical to avoid degradation of nucleic acids prior to their isolation, as high-quality DNA or RNA increases the likelihood of successful sequencing independent of the NGS platform used. For DNA sequencing studies of a cancer sample, a matched “normal” sample is often also sequenced to discern the somatic versus germline status of any identified alterations.

NEXT-GENERATION SEQUENCING AS A CLINICAL ASSAY: IMPLICATIONS FOR THE PRACTICING HEMATOLOGIST

Using NGS as a clinical assay platform offers many opportunities for new clinical tests and potential therapeutic interventions. Clinical sequencing requires the same high standards regarding sample banking, nucleic acid isolation and proper informed consent. Moreover, clinical sequencing must be done in an appropriately certified clinical laboratory environment. As the depth of coverage increases for NGS-based platforms, the statistical power to detect variation will increase up until the point that it is outweighed by the intrinsic error associated with the sequencing platform. For clinical NGS-based diagnostic tests, these error metrics must be predetermined for each protocol, whether it be whole-genome sequencing, a specific exome reagent, or a specific gene panel test.

NGS-based diagnostics have specific potential applications for both hematologic malignancies and nonmalignant hematologic conditions. For leukemias, lymphomas, myelodysplastic syndromes (MDS), myeloproliferative neoplasms and other hematologic malignancies (or premalignant conditions), the use of clinical sequencing can be employed to determine the spectrum of mutations that are driving the particular malignancy. For any given tumor, comprehensive sequencing may identify an “actionable” mutation that could lead to the use of a targeted therapy.

In the past, a clinician may have ordered a single gene test to determine if a particular molecular abnormality were present in a tumor sample, such as testing for *FLT3* internal tandem duplications (*FLT3*-ITD) in patients with acute myeloid leukemia (AML). The presence of such an alteration has prognostic implications and may have therapeutic significance pending the results of ongoing clinical studies with *FLT3* inhibitors. A single-gene or single “hot spot” assay that is designed to detect a specific alteration has several limitations that are now leading to wider use of NGS-based approaches to clinical diagnostics. To continue using *FLT3*-ITD alterations in AML as an example, the use of a more comprehensive sequencing platform could be used to discern the subclonal architecture of the cancer tissue. If the *FLT3*-ITD mutation was present only in a subclone but not in the founding clone, one would predict that a *FLT3* inhibitor would only be active in eradicating the subclone. Therefore, clinicians would need to incorporate another therapy to eradicate the founding clone, so as to achieve remission or prevent disease relapse. Ideally, the choice of this therapy would be determined based on the other mutations identified in the founding clone.

As clinicians better understand the mutational drivers of any particular tumor, they may be able to use targeted therapies directed at particular pathways rather than individual gene mutations. For example, researchers may be able to develop a drug that is effective if a patient with AML or MDS harbors a mutation in any of the genes involved in the spliceosome complex or associated proteins. A similar scenario could be envisioned targeting mutations in genes in the cohesin complex (protein complex that regulates the separation of sister chromatids in cell division) or genes that alter the hydroxymethylation of cytosine in DNA. Clinical trials built around these concepts will be necessary to establish their validity. Additionally, comprehensive sequencing can identify somatic mutations that result in the formation of neo-antigens expressed on the tumor cells. Clinicians could then use tumor-specific immunotherapy to target the malignancy.^{59,60}

Researchers are using NGS-based technology to detect minimal residual disease (MRD) in hematologic malignancies.^{61–63} An advantage of NGS-based methods of MRD detection is that the data not only provide information regarding the presence or absence of MRD but

also may reveal the clonal architecture of persistent disease from the mutations detected. Finally, clinicians could use knowledge gained by sequencing an individual's genome to determine the choice of therapy, whether for a malignant or non-malignant hematologic disease. In one such example, a therapy choice could be optimized based on pharmacogenomic studies in which the response or toxicity of a given drug is associated with underlying inherited genetic variation in the patient.⁶⁴ In a second example, a genomic assay might identify a somatic alteration corresponding to a targeted therapy that might help a patient with residual MRD to achieve remission. These examples are illustrative of the translational potential of NGS from research tool into clinical care.

CHAPTER 12

EPIGENETICS

Bradley R. Cairns

SUMMARY

Epigenetics involves a heritable change in phenotype without a change in genotype—with the inheritance of particular chromatin and transcription states often underlying the mechanism. Chromatin regulates gene expression by controlling the density and positioning of nucleosomes, and by the use of histone- and DNA-modifying enzymes. Chromatin and transcription factors drive proper differentiation decisions through their coregulation of key factors in development and proliferation. Of particular interest to hematologists are instances when misregulation/mutation of chromatin factors drives hematologic malignancies and myeloproliferative disorders. Here, fusion proteins that involve the mistargeting of chromatin regulators have been known for decades. More recently, high-throughput sequencing and other genomics approaches have revealed mutations in many types of chromatin regulators in hematologic malignancies, including mutations in chromatin remodelers, DNA methylation regulators, histone modification enzymes, and metabolic enzymes affecting epigenetic cofactors. Overall, these studies reveal a consistent theme: epigenetic and genetic mutations confer both variation and plasticity to the transcriptome, and when combined with selection, arrive at transcriptomes that promote proliferation, survival, and adaptability. This chapter addresses these mechanistic principles of chromatin, and their misregulation in hematologic malignancies, as well as emerging therapeutic approaches.

Acronyms and Abbreviations: AF, ALL1-fused gene; ALL, acute lymphocytic leukemia; AML, acute myeloid leukemia; BAF, BRG/BAF-associated factors; BCL, B-cell lymphoma family of regulator proteins that regulate cell death; BET, bromo and extraterminal; CHD, chromodomain remodeler; CMML, chronic myelomonocytic leukemia; DNAm, DNA methylation; DNMT, DNA methyltransferase; DOT1, a histone H3 methyltransferase; EGR1, early growth response protein 1; EZH2, enhancer of zeste homologue 2; H3, histone H3; HAT, histone acetyltransferase; HDAC, histone deacetylase; HIF, hypoxia-inducible transcription factor; 5hmC, 5-hydroxymethylcytosine; HMT, histone methyltransferase; HSC, hematopoietic stem cell; IDH, isocitrate dehydrogenase; Ifng promoter, interferon- γ promoter; ISWI, imitation SWI remodeler; MBD, methyl-domain binding; 5mC, 5-methylcytosine; MLL, mixed lineage leukemia; MTA, metastasis-associated; NuRD, nucleosome remodeling and deacetylation factor; NURF, nucleosome remodeling factor; 2OG, 2-oxoglutarate; PRC2, polycomb repressive complex 2; R-2HG, (R)-2-hydroxyglutarate; RAR, retinoic acid receptor; RNAP II, RNA polymerase II; SDH, succinate dehydrogenase; SRF, serum response factor; SWI/SNF, switch and sucrose nonfermenting remodeler; TDG, thymine DNA glycosylase; UHRF1, ubiquitin-like with PHD and ring finger domains; UTX, X-chromosome encoded ubiquitously transcribed tetratricopeptide repeat.

DEFINITION AND OVERVIEW

Epigenetics is defined as a heritable change in phenotype without a change in genotype. Although epigenetic mechanisms vary, this chapter focuses on the most common mechanism: chromatin. Changes in chromatin/epigenetics accompany many steps in transcription, replication, and recombination. However, the aspects of highest interest and relevance involve examples where epigenetic factors and enzymes *drive* differentiation decisions, and where misregulation/mutation of these factors *drives* pathologies, such as hematologic malignancies. This decision making must be precise, as differentiation along the lymphoid and myeloid lineages involves the regulated generation of multiple cell types in temporal order and proper proportion. Decisions are arrived through collaboration among signaling systems, transcription factors, and chromatin regulators—which together regulate the key genes governing self-renewal, differentiation, and survival. This chapter focuses on chromatin factors with central roles in these processes: ATP-dependent remodelers, DNA methylation (DNAm)/demethylation enzymes, and histone modification enzymes. As a complete treatment is beyond the scope of this chapter, the focus here will be conceptual, with particular examples provided to create a framework for understanding the many instances where chromatin factors influence decision-making.

Beyond their roles in normal blood cell development, misregulation of chromatin factors is now known to be common in hematologic malignancies. Indeed, high-throughput whole-genome and/or exome sequencing of leukemias and lymphomas has revealed mutations in many types of chromatin regulators, including mutations in chromatin remodelers, DNA methyltransferases (DNMT), and histone modification enzymes, as well as revealing fusion proteins that involve chromatin regulators.¹ In certain instances, modeling in the mouse supports these epigenetic mutations as the main drivers of the cancer phenotype. In other instances, epigenetic mutations cooperate with (and likely enable) additional genetic mutations, which cooperate to impact proliferation, survival, and plasticity, which can enable both cancer progression and therapy resistance. However, as many chromatin regulators are enzymes, they may be more targetable than mutations in DNA binding transcription factors, providing new therapeutic approaches.² This chapter expands on these concepts, addressing the mechanistic basis of chromatin misregulation in hematologic malignancies, as well as emerging therapeutic approaches.

CHROMATIN REMODELING AND DNA ACCESS

CHROMATIN REGULATES TRANSCRIPTION FACTOR BINDING

Chromatin has a major impact on gene expression, mediated through interplay with transcription factors. Sequence-specific DNA-binding transcription factors are the most important factors in defining whether and when a gene is transcribed, and also define the locations and character of chromatin regions, as they target chromatin remodeling and modifying proteins. However, the initial chromatin landscape can control whether transcription factors have access to the DNA at a particular gene/region. Access to DNA is deterred by nucleosomes, the main repeating unit of chromatin structure, which can block the binding sites of transcription factors to chromatin.³ Likewise, DNAm can also block the binding of transcription factors, many of which will not bind DNA if the cytosine in their binding site is methylated (DNAm is discussed more extensively in the section “DNA Methylation and Demethylation”).

Thus, the nucleosome and DNAm landscape together define the initial “open versus closed” chromatin state of a region with which the current repertoire of transcription factors within that cell type must contend. However, this landscape is dynamic, as signaling systems can modify transcription factors and chromatin components, altering their activity and the landscape both through their binding, and through their recruitment of nucleosome remodelers and chromatin modifiers.³⁻⁵

CHROMATIN REMODELERS CONTROL GENOME ACCESS

ATP-dependent chromatin remodeling complexes (termed hereafter *remodelers*) conduct central roles in regulating nucleosome occupancy and positioning (Fig. 12-1).³⁻⁵ For example, *remodelers* specialized for chromatin assembly (such as imitation SWI *remodeler* [ISWI]-family and chromodomain *remodeler* [CHD]-family *remodelers*) utilize ATP hydrolysis to facilitate tight-packed nucleosomes that lead to the occlusion of sites for site-specific DNA binding proteins, such as transcription factors. Access to chromatin at enhancers, promoters and other loci can be enabled by *remodelers* such as the switch and sucrose nonfermenting *remodeler* (SWI/SNF) complex, also termed the BRG/BAF-associated factors (BAF) complex, which can slide or eject the histone octamer, using the energy of ATP hydrolysis (Fig. 12-1). Notably, SWI/SNF can interact with (and facilitate the binding of) DNA-binding activators or repressors and can, therefore, help facilitate either activation or repression.³⁻⁵ Here, the ability of activators or repressors to interact with SWI/SNF complexes can be influenced by signaling cascades, which impart covalent modifications that enable or disable protein interactions. Taken together, ISWI and CHD *remodelers* often act to silencing genes via site blockage at enhancers and promoters, whereas SWI/SNF *remodelers* promote site exposure at those locations (Fig. 12-1), which is important for gene activation.

CHROMATIN REMODELING COMPLEXES IN BLOOD CELL DIFFERENTIATION

Clear roles for *remodelers* in blood cell differentiation are emerging. For example, SWI/SNF components affect the pool size of fetal hematopoietic stem cells (HSCs), and also impact HSC (and progenitor) proliferation and survival.⁶ SWI/SNF complex is also used for myeloid differentiation to granulocytes and for multiple steps in thymocyte development. More specifically, in mice SWI/SNF binds the interferon- γ (*Ifng*) promoter, and is required for its full transcription. Furthermore, mutations in the adenosine triphosphatase (ATPase) function of SWI/SNF are known to reduce β -globin expression and to prevent erythroid differentiation.⁷ Notably, B-cell lymphoma (BCL) factors BCL7A and BCL11B, which are considered members of SWI/SNF complex in many cell types, are common in hematologic malignancies; for example, mutations in BCL7A are found in approximately 20 percent of non-Hodgkin lymphoma and multiple myeloma cases, and mutations in BCL11B are found in 6 to 12 percent of T-cell acute lymphocytic leukemias (ALLs).⁸

Roles for ISWI- and CHD-family *remodelers* include roles for the well-characterized CHD-family *remodeler* nucleosome remodeling and deacetylation factor (NuRD), which interacts with histone deacetylase (HDAC) enzymes to silence genes. The metastasis-associated (MTA) subunits of NuRD help target NuRD subtypes to particular genes through their interaction with transcription factors and chromatin modifications.⁹ For example, in B-lymphocytes, MTA3 interacts with BCL6, a major regulator of B-cell differentiation, targeting NuRD repression and preventing terminal differentiation into plasma cells.¹⁰ Remarkably, expressing BCL6 in plasma cells while MTA3 is functional results in a reversion of the cell fate and reprogramming into

Figure 12-1. Roles for ATP-dependent chromatin remodelers in chromatin assembly or chromatin access. Imitation SWI *remodelers* (ISWI)- and chromodomain *remodelers* (CHD)-family *remodelers* are involved in chromatin assembly genome-wide, and also interact with site-specific repressors to organize nucleosome spacing at genes, which can occlude sites for DNA-binding proteins. Switch and sucrose nonfermenting *remodelers* (SWI/SNF)-family *remodelers* conduct both nucleosome repositioning/sliding as well as ejection to expose DNA to DNA-binding proteins.

B lymphocytes.¹⁰ Furthermore, the recruitment of the ISWI-family complex nucleosome remodeling factor (NURF) to the early growth response protein 1 (EGR1) locus (important for thymocyte maturation) involves interaction with the transcription factor serum response factor (SRF) by the NURF subunit BPTF, enabling its stable binding to promoters.¹¹ Notably, Ikaros (which drives lymphoid differentiation) acts to inhibit both the ATP-dependent remodeling and HDAC activities of NuRD at target genes to enable activation rather than silencing.¹² Taken together, these and other examples illustrate the use of *remodeler* function and recruitment to activate or repress key genes in blood differentiation.

● PRINCIPLES OF HISTONE MODIFICATION

HISTONE MODIFICATION CONCEPTS: WRITE, READ, ERASE

The process of transcriptional regulation is accompanied by the ordered placement of particular histone modifications at enhancers, promoters, and coding regions. There are dozens of different modifications that occur on histones, with the most common modifications

being acetylation, methylation, ubiquitylation, and phosphorylation. An inventory and functional analysis of all of these modifications, the enzymes that place and remove these modifications, is beyond the scope of this chapter; however, more important are the concepts, which can then be applied widely to various contexts.

First, the vast majority of histone modifications occur either on the extended aminoterminal “tails” of histones, whereas a minority also occur on the histone octamer “core.”¹³ The core of the histone octamer wraps the DNA, whereas histone tails serve as platforms for the regulated binding of proteins, and covalent modifications can either enhance or deter binding of chromatin *remodelers*, chromatin modifiers, and transcription factors, and help to orchestrate protein associations during transcription (Fig. 12–2). For example, methylation on histone H3 (H3) H3K4me can deter interaction with DNMTs and therefore cause passive DNA demethylation; in contrast, H3K4me3 can facilitate interaction with RNA polymerase II (RNAP II) machinery.¹⁴ Second, histone modifiers are typically targeted by site-specific DNA binding proteins (see Fig. 12–2), which are themselves responsive to developmental and environmental/metabolic signaling. Third, some histone modifiers are targeted or regulated by other histone modifications, which underlies (in part) why certain sets of histone modifications are coincident in regions.¹³

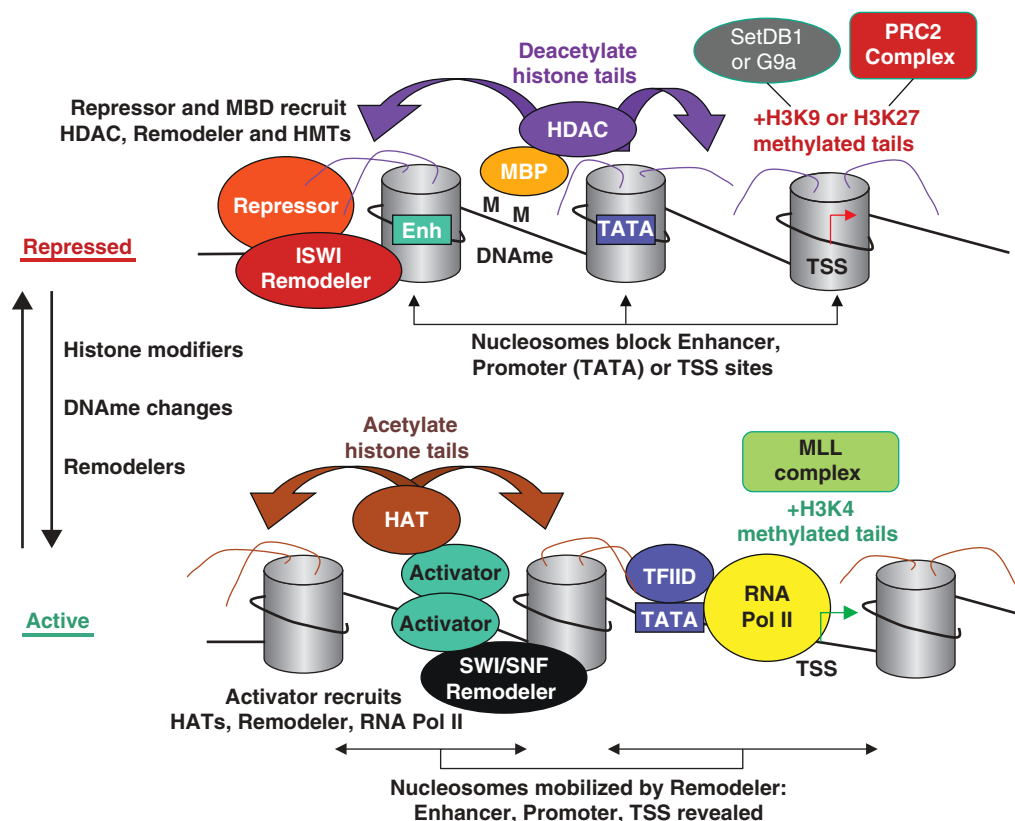

Figure 12–2. Chromatin changes that accompany the transition from a repressed to an active state. Repression (*top*) is enforced by site-specific DNA-binding repressors which recruit factors such as histone deacetylases (HDACs), histone methyltransferases (HMTs; for H3K9me or H3K27me), and DNA methyltransferases (not shown), which are used to methylate the DNA (M). Methyl-binding domain proteins (MBDs) bind to DNA methylation (DNAm) and also recruit a similar set of chromatin modifiers. These repressors also recruit imitation SWI remodeler (ISWI)-family *remodelers*, which help position nucleosomes on important *cis*-controlling elements like enhancers (Enh), the TATA box, or the transcription start site (TSS). The transition from the repressed state to the active state involves the modification and repositioning of nucleosomes, as well as DNA demethylation by passive or active modes. Nucleosomes are modified by histone acetyltransferases (HATs), and activating HMTs (mixed-lineage leukemia [MLL] complex, specific for H3K4me). Such modifications are believed to be recognized by the bromodomains present on *remodelers*, which then mobilize modified nucleosomes, allowing the transcription machinery to bind. Components of the transcription machinery, such as TFIID, can also detect histone modifications.

A major concept in histone modification biology is dynamic reversibility, termed *write, read, erase*.^{1,15,16} “Writing” involves the enzymatic *addition* of a covalent modification to an amino acid, within a particular protein sequence context. “Reading” involves the ability of a second protein/domain to bind that modification, within a particular protein sequence context, defining the *impact* of the modification. “Erasing” involves the *removal* of the covalent modification, within a particular sequence context, regenerating the prior/initial state. These concepts are actually quite general, and can be applied widely in protein signal transduction biology, with this terminology simply having become popularized in the chromatin field. Nevertheless, these terms are quite useful for framing histone modification cycles that accompany transcription cycles. One illustrative example is the addition of histone acetylation by histone acetyltransferase (HAT) enzymes, the binding of acetylated histone tails by the bromodomain (present in SWI/SNF *remodelers* and certain chromatin modifiers),^{17,18} and the removal of acetylation by HDAC enzymes.¹⁹ Finally, although this chapter discusses histone modifications and modifiers, histone modifiers often also modify additional chromatin proteins, including proteins that contain “histone mimic” regions. Although beyond the scope of this chapter, those chromatin modifications often go through similar “write, read, erase” cycles to enable additional layers of protein recruitment and release within a chromatin process.

● TRANSCRIPTION FACTOR-CHROMATIN MODIFIER PROGRAMS FOR DIFFERENTIATION

Within the context above, a common theme in cell differentiation is waves of transcription factor–chromatin modifier interactions that define the current chromatin and transcription state, and also help prepare the enhancers and promoters of genes needed for future states/cell types (see Fig. 12–2). Signaling systems inform cellular differentiation decisions, and define the next differentiation state by affecting transcription factor activity and their interaction with chromatin factors, creating a forward loop. Quite often, the transcription factor–chromatin modifier interactions of the new state (and cell type) also feedback to inhibit the prior program, as well as alternative differentiation programs, so as to ensure the proper developmental trajectory. An example that illustrates part of this program in action involves the transition between HSCs and erythroid progenitors, which involves a switch in the abundance and activity of transcription factors (e.g., GATA2 to GATA1) and histone methyltransferase (HMT) paralogs (e.g., enhancer of zeste homologue 2 [EZH2] to EZH1).^{20,21} This switch serves to repress a set of stem-related genes while activating a set of pro-differentiation genes. By extension, many studies show that loss-of-function mutations in chromatin factors can prevent developmental transitions, and if this block occurs at a highly proliferative progenitor stage, it can predispose to cancer.

● EPIGENETICS AND MEMORY: TRAINED IMMUNITY

Trained immunity refers to a type of memory in the innate immune system where genes that have been activated in the past (via infection or vaccination, termed *stimulation*) are “primed” for a more rapid and/or robust future response. Here, prior to initial stimulation, monocytes and macrophages bear “latent” enhancers neighboring proinflammatory genes, which lack histone modifications. Following stimulation, these latent enhancers acquire histone modifications (e.g., H3K4me and H3K27ac) that are correlated with gene activation and maintain those

modifications for days following withdrawal of the initial stimulus.²² Importantly, the retention of these modifications is correlated with a more robust or rapid activation in response to a second stimulus. Thus, chromatin states can confer a memory of prior transcriptional states that shapes future response. Here, one can infer within Fig. 12–2 that following activation, this system does not return to the initial repressed state, but rather to an intermediate “poised” state where histone modifications are retained at the enhancer.

● DNA METHYLATION AND DEMETHYLATION PRINCIPLES

DNA METHYLATION

DNAme is a major component of epigenetic regulation in mammals, with central roles in gene and transposon silencing, imprinting, and X-chromosome inactivation.²³ Furthermore, DNAme can predispose to cancer by at least two routes: first, through the improper placement of focal DNAme, leading to the silencing of tumor-suppressor genes; second, through hypomethylation of the genome, causing genome instability.² Here, basic principles of DNAme and demethylation are first discussed, with a later section “Epigenetic and Hematologic Malignancies” focusing on their misregulation in hematologic malignancies.

DNAme primarily involves cytosine methylation in a CpG context, and in mammalian genomes the vast majority (>85 percent) of such cytosines are methylated. DNAme is conducted by DNMTs, involving the *de novo* enzymes DNMT3a and DNMT3b (which can methylate unmethylated regions) or by the maintenance enzyme DNMT1, which partners with ubiquitin-like with PHD and ring finger domains factor (UHRF1) to fully methylate hemimethylated CGs during replication.²⁴ DNAme confers silencing through two modes. First, DNAme inhibits or prevents the binding of many transcription factors with CG sites in their consensus binding sequence, including cMyb,²⁵ cMyc, E2F-family,²⁶ nuclear factor- κ B,²⁷ CREB-family,²⁸ ETS-family, and AP2 factors.²⁹ Second, certain methyl-domain binding (MBD) proteins (e.g., MBD1, MBD2, MECP2) bind to methylated CpG sites and can recruit both HDAC, repressive HMTs, and CHD-family *remodelers* (e.g., NuRD) to establish and maintain repression.³⁰

Although most genomic CGs are methylated, mammalian genomes are punctuated by small regions (250 bp to 2 kb) where DNAme is notably absent, and these regions are strongly correlated with a high relative density of CG bases, termed *CpG islands*.³¹ (CpG islands are regions that have avoided the strong CG depletion that has occurred over the rest of the genome, as methylated cytosine can spontaneously deaminate to create uracil). Thus, methylated CGs are absent in regions where CGs are dense, a counterintuitive observation that underscores that CG-rich regions must attract active mechanisms to either prevent DNMT activity or remove DNAme (see section “TET Proteins and Active DNA Demethylation”). CpG islands reside in the promoters of most genes that are constitutively transcribed, such as housekeeping/metabolic genes, and these islands remain unmethylated under virtually all conditions and cell types. However, CpG islands vary in size and composition; those of intermediate CG density are often found at developmental genes; notably, these intermediate CpG islands are typically unmethylated in stem cells, but undergo developmentally regulated DNAme to confer silencing in cell types where their expression might confer alternative fates.³² Notably, CpG islands often contain binding sites for transcription factors; for those transcription factors that display methylation-sensitive binding (listed above), a lack of DNAme in these regions can permit their binding, whereas CpG island methylation can prevent binding. Taken together, proper regulation of DNAme is critical, as the improper placement of focal DNAme can lead to gene silencing.

TET PROTEINS AND ACTIVE DNA DEMETHYLATION

DNAme is chemically highly stable, and therefore very useful in stable propagation of epigenetic states, even through germline inheritance. Although stable, DNA demethylation can occur, and does so mainly through two routes: (1) “passive” demethylation (dilution of DNAme by the failure to conduct maintenance DNAme after DNA replication), and (2) “active” demethylation, mainly involving proteins of the TET family. TET proteins are dioxygenase enzymes that oxidize the methyl group of 5-methylcytosine (5mC) to 5-hydroxymethylcytosine^{33,34} (5hmC) and additional oxidized intermediates (not addressed further). Here, 5hmC and other intermediates cause DNA demethylation by one of two modes: first, following replication the maintenance DNMT1 and its partner, UHRF1, do not recognize these oxidized products as 5mC, leading to passive demethylation.²⁴ Second, glycosylases with roles in DNA repair (e.g., thymine DNA glycosylase [TDG]) can remove 5-hydroxymethylcytosine (5hmC) and similar oxidized intermediates, which are then replaced with an unmodified cytosine by base-excision repair systems.³⁵ An important aspect of TET-family dioxygenases is their use of iron and 2-oxoglutarate (2OG) as cofactors during the oxidation reaction; a feature that renders TET enzymes sensitive to concentrations of these metabolites and related compounds, which can act as inhibitors during metabolic dysregulation (see section “Misregulation of Dna Methylation/Demethylation In Hematologic Malignancies”).

EPIGENETICS AND HEMATOLOGIC MALIGNANCIES

CONCEPTS IN CANCER EPIGENETICS

Misregulation of epigenetic factors is common in cancer, and a higher level of understanding is achieved by recognizing recurring themes. Epigenetic factors are often misregulated by one of three modes: fusion, loss-of-function (via mutation or expression changes), or gain-of-function (via mutation or expression changes). Notably, each mode impacts the genome and transcriptome in a particular manner, as described below:

Theme 1: Fusion Proteins

Fusion proteins are commonly observed in hematologic malignancies, and are often the product of reciprocal chromosomal translocations. Common configurations involve fusions of DNA-binding proteins to chromatin modifiers, or proteins that interact with chromatin modifiers. This creates a dominant gain-of-function protein that targets chromatin-modifying activity to genes important for proliferation, development, or survival. A well-studied and conceptually informative example involves fusion of the aminoterminal portion of the HMT mixed-lineage leukemia (MLL) protein to other proteins that interact with chromatin modifiers.^{36,37} Oncogenic MLL fusions are typically driven by the endogenous MLL promoter and retain the DNA-binding domain and additional regions present in the MLL aminoterminal, but omit the catalytic HMT domain normally present at the MLL C-terminus. MLL is normally part of a large complex that methylates histones (H3K4me3) at the promoters of active genes. Oncogenic MLL-fusion proteins can dimerize with normal full-length MLL, and retain the ability to bind DNA binding and also the ability to interact with chromatin and DNA-binding factors.

As previewed above, the fusion partner of MLL is often a protein that interacts with and recruits chromatin modifiers, providing a route to aberrant/constitutive recruitment of chromatin modifiers to particular loci. The most common MLL fusions involve fusion of the MLL

N-terminus to the ALL1-fused (AF) genes (AF9) and AF4 proteins (partial internal tandem duplications are also leukemogenic, which likely also affect interactions with chromatin modifiers). Interestingly, the AF9 and AF4 partners are themselves members of more than one chromatin and transcription complex,^{38,39} and therefore capable of recruiting a range of chromatin modifiers, including a H3 methyltransferase, DOT1 (which methylates histone H3K79),^{40–42} or TIP60, CBP, and EP300 (which acetylate histones H3 and H4). AF4 is also a member of a complex important for transcriptional elongation,^{38,39} which interacts with acetylated histone tails via a bromo and extraterminal (BET)-family bromodomain present in the BRD4 subunit. MLL fusions also involve direct fusion to a chromatin modifier, including fusion to the HAT enzymes CBP or EP300. (Fusion of MLL to TET proteins are covered separately in the context of DNAme in the section “Misregulation of Dna Methylation/Demethylation In Hematologic Malignancies”).

Regarding mechanism, current thinking supports the targeting of MLL fusions to constitutively activate key genes involved in blood development, causing a block in differentiation. This block (and continued proliferation) provides the opportunity for other genetic and epigenetic events that enhance proliferation and survival. Confirmed targets for MLL fusions include *HoxA9* and the *Meis1* gene in mouse, where the fusion contributes to their transcriptional activation.⁴¹ However, it is likely that a larger repertoire of target genes is involved, as ectopic expression of *HoxA9* and *Meis1* in mice is effective at inducing leukemias only under certain contexts. Finally, it is important to note that MLL fusions represent one particular class and mechanism; in contrast, fusions involving the retinoic acid receptor (RAR) (e.g., RAR-PLZF) are known to block differentiation through the constitutive recruitment of repressive chromatin modifiers (e.g., HDACs), conferring repression of genes important for activation.^{43,44} Thus, as illustrated in Fig. 12–3, proper differentiation involves waves of transcription that involve activating a new program and silencing the former program.

The involvement of multiple enzymes in MLL fusions has inspired therapeutic approaches based on enzyme inhibition.² For example,

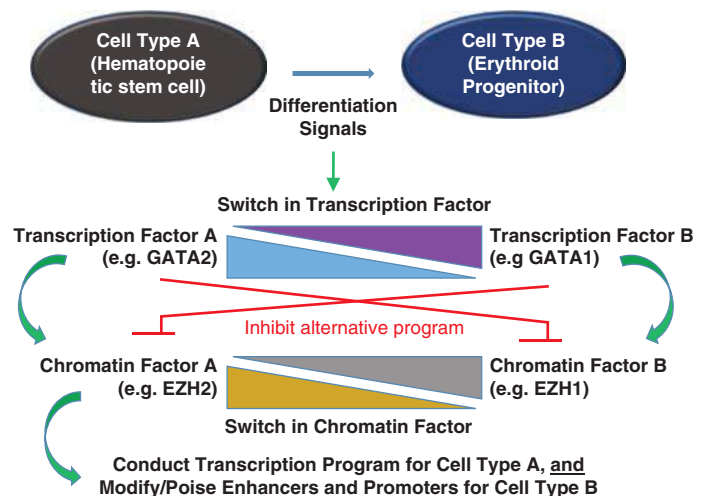

Figure 12–3. Conceptual model for a developmental switch involving transcription factors, chromatin modifiers, and a feedback loop. Here signals for differentiation alter transcription factor and chromatin modifier abundance and activity. This collaboration defines the current chromatin and transcription state and helps prepare the enhancers and promoters of genes needed for future states/cell types, with an example given related to HSC-to-erythroid transition.²¹ Furthermore, the transcription factor-chromatin modifier interactions of the new state (cell type) can feed back to inhibit the prior program, ensuring the proper developmental trajectory.

DOT1 (a histone H3 methyltransferase) inhibitors have proven useful in mouse models of MLL-fusion-induced leukemia (and in cell lines),⁴⁵ and have entered phase I clinical trials (NCT01684150). Notably, the involvement of BRD4 in this system, along with its known importance in transcriptional activation in MYC-driven cancers, provides additional therapeutic possibilities. Here, inhibitors of BET-family bromodomains (JQ1 and others) have proven very effective in cell lines from patients, laying the foundation for clinical trials.^{46–49}

Theme 2: Loss-of-Function Mutations in Chromatin Modifiers

Loss-of-function mutations in chromatin modifiers are now very common in many cancers. The key concept in this theme is that the loss of epigenetic control confers both gene-specific and genome-wide epigenetic variation, eliciting transcriptome variation and plasticity. As a result, individual cells with transcriptomes that promote growth, survival, and/or metastasis can be selected from a diverse population. For example, this epigenetic variation can allow cells to sample a transcriptome that promotes invasion and later convert to a transcriptome that favors colonization. One mode involves the aberrant epigenetic silencing of tumor-suppressor proteins, either by the acquisition of “silencing” histone modifications, DNAm, or both. Epigenetic variation and selection are themselves powerful tools; however, they can also combine with genetic mutations to provide a further fitness benefit and reinforce oncogenic properties.

Examples of mutations in epigenetic factors in hematologic malignancies are numerous; even a partial list of factors and their impact is beyond the scope of this chapter.¹ However, mutations in certain factors are found in many hematologic malignancies and help to illustrate the concepts above; consequently, they are treated further here. One example that builds on an earlier section “Epigenetics and Hematologic Malignancies” involves mutations in *MLL* genes. *MLL* is actually a family of five similar genes; however, whereas *MLL1* is most commonly involved in leukemogenic fusion proteins (discussed earlier), mutations in *MLL2* are very common in lymphomas, with mutation rates as high as 89 percent for follicular lymphoma.⁵⁰ Other chromatin factors are also mutated at high frequency in BCLs, including the HAT complex members *EP300* and *CREBBP*.⁵⁰

Mutations that affect the addition or removal of the repressive histone modification H3K27me₃, are increasingly common in hematologic malignancies. For example, mutations in the polycomb repressive complex 2 (PRC2) complex, which adds H3K27me₃, are associated with myeloproliferative diseases, myelodysplastic syndromes, and T-cell ALL.^{51–53} In addition, mutations in the main enzyme that removes H3K27me₃, known as X-chromosome encoded ubiquitously transcribed tetratricopeptide repeat (UTX), are common in multiple myeloma.⁵⁴ Furthermore, mutations in these enzymes are known to synergize with mutations in other epigenetic enzymes, such as TET proteins, in myeloid disorders.⁵¹ Notably, many genes that become improperly methylated in cancer cells were marked by H3K27me earlier in their development and were DNA demethylated. Thus, proper regulation of H3K27me₃—a modification present at many silent but “poised” developmental genes—appears critical for tumor prevention.

Theme 3: Gain-of-Function Mutations in Chromatin Modifiers

Gain-of-function of epigenetic enzymes typically occurs either through upregulation of expression (through copy number variation or promoter fusions) or via mutations that upregulate the activity of the enzyme. The main concept in this theme is that high levels and/or the inability to turn off an epigenetic enzyme can lead to sustained activation or silencing of target loci, depending on the main function of

the modification. Among many examples is EZH2, the main enzyme for H3K27me addition, which is either greatly overexpressed or hyperactivated (via mutation) in various hematologic malignancies.⁵⁵ For example, *EZH2* is highly expressed in mantle cell lymphomas, whereas activating mutations (conferred by amino acid substitutions in the catalytic domain) are common in diffuse large B-cell and follicular lymphomas.⁵⁶ This hyperactivity has led to therapeutic strategies involving selective competitive inhibitors that mimic the cofactor S-adenosyl-methionine, the methyl donor for the EZH2 enzyme, which have proven effective in mouse xenografts.⁵⁶

MISREGULATION OF DNA METHYLATION/DEMETHYLATION IN HEMATOLOGIC MALIGNANCIES

Over the past several years, several studies have made striking links between hematologic malignancies and the misregulation of DNAm. High-throughput sequencing of leukemias and lymphomas have revealed three different types of mutations: (1) loss-of-function mutations in the *de novo* DNMT3a enzyme; (2) loss-of-function mutations in particular TET proteins; and (3) gain-of-function mutations in the metabolic enzymes isocitrate dehydrogenase (IDH)1 and IDH2, which create small molecule inhibitors of TET proteins (expanded below in this section). To begin, hypomorphic mutations in *DNMT3a* are common in acute myeloid leukemias (AMLs),⁵⁷ although precisely how a reduction in DNMT3a activity promotes leukemia is not yet understood. Of the three TET-family genes, particular TET genes are mutated at high frequency in hematologic malignancies. Strikingly, mutations in *TET2* are found in almost half of chronic myelomonocytic leukemias (CMML),^{58,59} and are also common in certain T-cell lymphomas. The key emerging concept is that defects in DNA demethylation by *TET2* mutations may lead to increases in DNAm at certain CpG island regions (including those bearing H3K27me),⁶⁰ which may confer gene silencing of developmental and/or tumor-suppressor type genes; however, clear cause-and-effect links have not yet been made. Consistent with this mechanism, *TET2* mutations are often found with mutations in *EZH2*, which catalyzes H3K27me addition.^{51,59}

Of particular interest are recent links between metabolic dysregulation, hematologic malignancies, and gliomas. Remarkably, gain-of-function mutations in the TCA cycle enzymes IDH1 and IDH2 are oncogenic.^{61–66} Normally, IDH1/2 convert isocitrate to 2OG (also known as α -ketoglutarate), a cofactor for both TET enzymes and *JmjC*-class lysine demethylases. Notably, oncogenic IDH1/2 mutations create proteins that additionally convert 2OG to (R)-2-hydroxyglutarate (R-2HG).^{66,67} This both depletes the normal cofactor for TETs and *JmjC* demethylases and further creates a potent “oncometabolite” inhibitor of TET enzymes and prolyl hydroxylases (which regulate hypoxia-inducible transcription factor [HIF] proteins). Additionally, mutations in other Krebs cycle enzymes (e.g., succinate dehydrogenase [SDH]) accumulate succinate, which can likewise inhibit TET, *JmjC*, and prolyl hydroxylases⁶⁸; notably, SDH mutations and HIF mutations are both common in neuroendocrine tumors.⁶⁸ These observations have inspired multiple therapeutic approaches, including: (1) reversing the impact of these oncometabolites on the epigenome (e.g., via DNMT, HDAC or HMT inhibitors); (2) implementing selective inhibitors of these gain-of-function IDH mutant proteins to prevent (R)-2HG production; (3) using selective inhibitors of prolyl-hydroxylases; and (4) the use of ascorbic acid (vitamin C), which can enhance TET protein activity by affecting the reduction-oxidation (redox) state of iron, an essential cofactor for TET enzymes.

CHAPTER 13

CYTOGENETICS AND GENETIC ABNORMALITIES

Lucy A. Godley, Madina Sukhanova, Gordana Raca, and Michelle M. Le Beau

SUMMARY

Cytogenetic and genetic analysis provides pathologists and clinicians with a powerful tool for the diagnosis and classification of hematologic malignant diseases. The detection of an acquired, somatic mutation establishes the diagnosis of a neoplastic disorder and rules out hyperplasia, dysplasia, or morphologic changes from toxic injury or vitamin deficiency. Specific cytogenetic and genetic abnormalities have been identified that are very closely, and sometimes uniquely, associated with morphologically distinct subsets of leukemia or lymphoma, enabling clinicians to predict their clinical course and likelihood of responding to particular treatments. The detection of one of these recurring abnormalities is helpful in establishing the diagnosis and adds information of prognostic importance. In many cases, the prognostic information derived from cytogenetic and genetic analysis is independent of that provided by other clinical features. Patients with favorable genetic prognostic features benefit from standard therapies with a well-known spectra of toxicities, whereas those with less-favorable clinical and cytogenetic or genetic characteristics may be better treated with more intensive or investigational therapies. Pretreatment cytogenetic analysis also can be useful in choosing between post-remission therapies that differ widely in cost, acute and chronic morbidity, and effectiveness. The appearance of new abnormalities in the karyotype of a patient under observation often signals clonal evolution and more aggressive behavior. The disappearance of a chromosomal abnormality present at diagnosis is an important indicator of complete remission following treatment, and its reappearance may herald disease recurrence.

Acronyms and Abbreviations ALCL, anaplastic large cell lymphoma; ALL, acute lymphocytic or lymphoblastic leukemia; AML, acute myeloid leukemia; AMML, acute myelomonocytic leukemia; APL, acute promyelocytic leukemia; CDS, commonly deleted segment; CLL, chronic lymphocytic leukemia; CMA, chromosome microarray analysis; CML, chronic myeloid leukemia; del, deletion; DLBCL, diffuse large B-cell lymphoma; EBV, Epstein-Barr virus; FAB, French-American-British; FISH, fluorescence *in situ* hybridization; FLT3, FMS-like tyrosine kinase; HSC, hematopoietic stem cell; IGH, immunoglobulin heavy chain; inv, inversion; ITD, internal tandem duplication; JAK, Janus kinase; LOH, loss of heterozygosity; MALT, mucosa-associated lymphoid tissue; MAPK, mitogen-activated protein kinase; MDS, myelodysplastic syndrome; Ph, Philadelphia chromosome; PI3K, phosphatidylinositol 3'-kinase; qRT-PCR, quantitative reverse transcriptase polymerase chain reaction; RA, refractory anemia; RAEB, refractory anemia with excess blasts; RAR α , retinoic acid receptor- α ; RARS, refractory anemia with ring sideroblasts; RARS-t, refractory anemia with ringed sideroblasts and thrombocytosis; RCMD, refractory cytopenia with multilineage dysplasia; SNP, single nucleotide polymorphism; STAT, signal transducer and activator of transcription; t, translocation; t-, therapy-related; TKI, tyrosine kinase inhibitor; WHO, World Health Organization.

● GENETIC CONSEQUENCES OF GENOMIC REARRANGEMENTS

Over the past two decades, the genes that are located at the breakpoints of a number of the recurring chromosomal translocations have been identified. Alterations in the expression of the genes or in the properties of the encoded proteins resulting from the rearrangement play an integral role in the process of malignant transformation.^{1,2} The altered genes fall into several functional classes, including tyrosine or serine protein kinases, cell surface receptors, growth factors and, the largest class, transcription factors. These latter proteins are involved in the induction or repression of gene transcription, often functioning in a tissue-specific fashion to regulate cell growth and differentiation.

There are two general mechanisms by which chromosomal translocations result in altered gene function. The first is deregulation of gene expression (Chap. 10). This mechanism is characteristic of the translocations in lymphoid neoplasms that involve the immunoglobulin genes in B-lineage tumors and the T-cell receptor genes in T-lineage tumors. These rearrangements result in the inappropriate or constitutive expression of an oncogene. The second mechanism is the encoding and expression of a novel fusion protein, resulting from the juxtaposition of coding sequences from two genes that are normally located on different chromosomes. Such chimeric proteins are “tumor specific” in that the fusion gene typically does not exist in nonmalignant cells. Thus, the detection of such a fusion gene or protein product can be important in diagnosis and in the detection of residual disease or early relapse. Moreover, they may also be appropriate targets for tumor-specific therapies. An example is the chimeric BCR-ABL1 protein resulting from the t(9;22) in chronic myeloid leukemia (CML) (see “Methods of Cell Preparation” below). All of the translocations cloned to date in the myeloid leukemias result in a fusion protein.

Chromosomal translocations result in the activation of genes in a dominant fashion. A number of human tumors result from homozygous, recessive mutations. These mutations lead to the absence of a functional protein product, suggesting that these genes function as “suppressor” genes, whose normal role(s) is to limit cellular proliferation. The hallmark of tumor suppressor genes is the loss of genetic material in malignant cells, resulting from chromosomal loss or deletion, as well as by other genetic mechanisms (Chap. 10).¹ A subset of tumor suppressor genes act by haploinsufficiency, whereby loss of one allele results in a reduction in the level of the protein product by half, thereby perturbing normal cellular processes. This mechanism is common in the recurring deletions in myeloid neoplasms (Chap. 83).

Extensive experimental evidence indicates that more than one mutation is required for the pathogenesis of hematologic malignancies. That is, expression of translocation-specific fusion genes or deregulated expression of oncogenes is required, but insufficient to induce leukemia. Thus, an important aspect of leukemia biology is the elucidation of the spectrum of chromosomal and molecular mutations that cooperate in the pathways leading to leukemogenesis. Where known, we describe the cooperating mutations associated with specific cytogenetic subsets of leukemia or lymphoma.

● METHODS OF CELL PREPARATION

Cytogenetic analysis of malignant diseases should be based upon the study of the tumor cells themselves. In leukemia, the specimen is usually obtained by marrow aspiration and is typically cultured for 24 to 72 hours. When a marrow aspirate cannot be obtained, a marrow biopsy (bone core specimen) or a blood sample for patients who have circulating immature myeloid or lymphoid cells, can often be processed

successfully. An involved lymph node or tumor mass specimen may be examined for the analysis of lymphoma cells.

For specimen collection, 1 to 5 mL of marrow are aspirated aseptically into a syringe coated with preservative-free sodium heparin and transferred to a sterile 15-mL centrifuge tube containing 5 mL of culture medium (RPMI 1640, 100 units sodium heparin). The use of Vacutainer tubes containing heparin as an anticoagulant should be avoided, as the heparin contains preservatives that suppress cell growth. If a marrow aspirate cannot be obtained, a marrow biopsy may be taken and placed into the collection tube. Approximately 75 percent of marrow biopsies can be minced to generate suspension of cells that will yield adequate numbers of metaphase cells for complete analysis. For blood specimens, 10 mL are drawn aseptically by venipuncture into a syringe coated with preservative-free heparin. To avoid loss of cell viability, it is critical that the specimen be transported at room temperature to the cytogenetics laboratory without delay. Overnight shipment of specimens frequently results in loss of cell viability, and most laboratories experience a high proportion (25–50 percent) of inadequate analyses using such specimens. For optimally handled specimens, approximately 95 percent of all cases should be adequate for cytogenetic analysis. Those cases that are inadequate generally represent samples from patients with hypocellular marrows.

● CHROMOSOME NOMENCLATURE

Chromosomal abnormalities are described according to the International System for Human Cytogenetic Nomenclature (Table 13–1).³ To describe the chromosomal complement, the total chromosome number is listed first, followed by the sex chromosomes, and numerical and structural abnormalities in ascending order. The observation of at least two cells with the same structural rearrangement, for example, translocations, deletions or inversions, or gain of the same chromosome, or three cells each showing loss of the same chromosome, is considered evidence for the presence of an abnormal clone. However, one cell with a normal karyotype is considered evidence for the presence of a normal cell line. Patients whose cells show no alteration or nonclonal (single cell) abnormalities are considered to be normal. An exception to this is a single cell characterized by a recurring structural abnormality. In such instances, it is likely that this represents the karyotype of the mutated subclone in that particular patient.

● METHODS THAT COMPLEMENT KARYOTYPE ANALYSIS

FLUORESCENCE *IN SITU* HYBRIDIZATION

Cytogenetic analysis of human tumors is often technically difficult because of the presence of multiple abnormalities and requires highly skilled personnel. These factors have led investigators to seek alternative methods for identifying chromosomal abnormalities, such as fluorescence *in situ* hybridization (FISH).⁴ The FISH technique is based on the same principle as Southern blot analysis, namely, the ability of single-stranded DNA to anneal to complementary DNA.⁴ FISH can be performed on marrow or blood films, or fixed and sectioned tissue, as it does not require dividing cells. The target DNA is the nuclear DNA of interphase cells, or the DNA of metaphase chromosomes that are affixed to a glass microscope slide. Commercial probes are now available for the most common abnormalities, and are directly labeled with fluorochrome, which simplifies the technique by eliminating the probe preparation and detection steps. With the development of dual- and triple-pass filters, most laboratories now have the capacity to hybridize and detect two to three probes simultaneously. Table 13–1 summarizes

the most frequently used commercially available FISH probes. Several types of probes can be used to detect chromosomal abnormalities by FISH. Hybridization of centromere-specific probes has been used to detect monosomy, trisomy, and other aneuploidies in both leukemias and solid tumors, as well as the sex chromosome complement in the transplant setting (Fig. 13–1).

Translocations and deletions can also be identified in interphase or metaphase cells by using genomic probes that are derived from the breakpoints of recurring translocations or within the deleted segment (see Fig. 13–1). In some cases, FISH analysis provides more sensitivity, in that cytogenetic abnormalities have been identified by FISH in samples that appeared to be normal by conventional cytogenetic analyses. Advantages of FISH include (1) the rapid nature of the method and the ability to analyze large numbers of cells; (2) its high sensitivity and specificity; and (3) the ability to obtain cytogenetic data from samples with a low mitotic index or from terminally differentiated cells. A further increase in sensitivity in cases with a low percentage of malignant cells can be achieved by performing FISH analysis on samples that have been enriched previously for specific subpopulations of cells. For example, the use of FISH in combination with plasma cell enrichment techniques is routinely applied in the clinical setting to maximize the detection rate of specific chromosome rearrangements in myeloma.^{5,6} The major disadvantage of FISH testing is the inability to interrogate more than a few abnormalities. FISH is most powerful when the analysis is targeted toward those abnormalities that are known to be associated with a particular tumor or disease. In a clinical setting, cytogenetic analysis could be performed at the time of diagnosis to identify the chromosomal abnormalities in an individual patient's malignant cells. Thereafter, FISH with the appropriate probes could be used to detect residual disease or early relapse, and to assess the efficacy of therapeutic regimens. For example, the use of FISH to detect the t(9;22) in CML patients following therapy with an oral tyrosine kinase inhibitor, or sex chromosome determination after a sex-mismatched transplant, is widespread. Material from patients newly presenting are often analyzed most efficiently by conventional cytogenetic analysis, combined with quantitative reverse transcriptase polymerase chain reaction (qRT-PCR) analysis if a specific chromosome rearrangement is suspected, for example, a *BCR-ABL1* fusion. Molecular qRT-PCR monitoring of the blood and marrow of CML patients is now part of the recommended testing for patient followup.⁷

MICROARRAY ANALYSIS

Several microarray-based technologies play an important role in the diagnosis and experimental analysis of hematologic malignancies, including high-density copy number/single nucleotide polymorphism (SNP) array testing (also known as chromosomal microarray analysis [CMA]), microarray-based gene expression profiling, and high-throughput SNP genotyping. CMA allows genome-wide detection of copy number abnormalities (deletions and duplications) at a much higher resolution than karyotyping; it also enables detection of loss of heterozygosity (LOH) that occurs without concurrent changes in the gene copy number, that is, uniparental disomy (UPD) (Chap. 10), and can be attributed to somatic mitotic recombination (also referred to as copy-neutral LOH) (Fig. 13–2). CMA is clinically available as an adjunct test to karyotyping and FISH, and it facilitates detection of genomic abnormalities in a substantial proportion of patients with myelodysplastic syndromes (MDSs) and leukemia with a normal karyotype; it can also be used as a cost-effective alternative to large panels of FISH probes, and as a very useful tool to characterize chromosomal abnormalities of uncertain significance. Microarray-based gene expression profiling has been applied to study a variety of hematopoietic

TABLE 13-1. Glossary of Cytogenetic Terminology

Aneuploidy—An abnormal chromosome number because of either gain or loss of chromosomes.

Banded chromosomes—Chromosomes with alternating dark and light segments as a result of special stains or pretreatment with enzymes before staining. Each chromosome pair has a unique pattern of bands.

Breakpoint—A specific site on a chromosome containing a DNA break that is involved in a structural rearrangement, such as a translocation or deletion.

Centromere—The chromosome constriction that is the site of the spindle fiber attachment. The position of the centromere determines whether chromosomes are *metacentric* (X-shaped, e.g., chromosomes 1–3, 6–12, X, 16, 19, 20) or *acrocentric* (inverted V-shaped, e.g., chromosomes 13–15, 21, 22, Y). During mitosis, the two exact copies of the DNA in each chromosome are separated by shortening of the spindle fibers attached to opposite sides of the dividing cell.

Clone—In the cytogenetic sense, this is defined as two cells with the same additional or structurally rearranged chromosome, or three cells with loss of the same chromosome.

Deletion—A segment of a chromosome is missing as the result of two breaks and loss of the intervening piece (interstitial deletion). Molecular studies of many recurring deletions have shown that, in each case, the deletions were interstitial, rather than terminal (single break with loss of the terminal segment).

Diploid—Normal chromosome number and composition of chromosomes.

Fluorescence *in situ* hybridization (FISH)—A molecular-cytogenetic technique based on the visualization of fluorescently-labeled DNA probes hybridized to complementary DNA sequences from metaphase or interphase cells, used to detect numerical and structural abnormalities. A short nomenclature description is used to describe the results of *in situ* hybridization. For interphase FISH, the abbreviation “nuc ish” is followed immediately by the locus designation in parentheses (or multiple loci separated by a comma), a multiplication symbol, and the number of signals observed. The number of cells scored is placed in brackets. For example, normal results for the *BCR-ABL1* probe are described as “nuc ish (ABL1, BCR)×2[400].” A case with the t(9;22) resulting in the *BCR-ABL1* fusion analyzed using a dual-color, dual-fusion probe would be described as “nuc ish (ABL1×3), (BCR×3), (ABL1 con BCR×2)[400].”

Haploid—Only one-half the normal complement, i.e., 23 chromosomes.

Hyperdiploid—Additional chromosomes; therefore, the modal number is 47 or greater.

Hypodiploid—Loss of chromosomes with a modal number of 45 or less.

Inversion—Two breaks occur in the same chromosome with rotation of the intervening segment. If both breaks were on the same

side of the centromere, it is called a paracentric inversion. If they were on opposite sides, it is called a pericentric inversion.

Isochromosome—A chromosome that consists of identical copies of one chromosome arm with loss of the other arm. Thus, an isochromosome for the long arm of No. 17 [i(17)(q10)] contains two copies of the long arm (separated by the centromere) with loss of the short arm of the chromosome.

Karyotype—Arrangement of chromosomes from a particular cell according to an internationally established system such that the largest chromosomes are first and the smallest ones are last. A normal female karyotype is described as 46, XX and a normal male karyotype is 46, XY. An *idiogram* is an idealized representation (diagram) of the chromosomes.

Pseudodiploid—A diploid number of chromosomes accompanied by structural abnormalities.

Recurring Abnormality—A numerical or structural abnormality noted in multiple patients who have a similar neoplasm. Such abnormalities are characteristic or diagnostic of distinct subtypes of leukemia and lymphoma that have unique morphologic and/or immunophenotypic features. Recurring abnormalities represent genetic mutations that are involved in the pathogenesis of the corresponding diseases; many recurring abnormalities have prognostic significance.

Translocation—A break in at least two chromosomes with exchange of material. In a reciprocal translocation, there is no obvious loss of chromosomal material. Translocations are indicated by t; the chromosomes involved are noted in the first set of brackets and the breakpoints in the second set of brackets. The Ph translocation is t(9;22)(q34.1;q11.2).

Nomenclature symbols:

p—Short arm

q—Long arm

+—If before the chromosome, indicates a gain of a whole chromosome (e.g., +8)

——If before the chromosome, indicates a loss of a whole chromosome (e.g., –7) and if after the chromosome indicates loss of part of the chromosome (e.g., 5q–, loss of part of the long arm of chromosome 5)

?—Indicates uncertainty about the identity of the chromosome or band listed just after the ?

t—translocation

del—deletion

inv—inversion

i—isochromosome

mar—marker chromosome

r—ring chromosome

Data from Rowley JD: Chromosome abnormalities in human cancer. In De Vita VT, Hellman S, Rosenberg S (eds): *Practice and Principles of Oncology* 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1991.

malignancies, often revealing complex but unique expression signatures for each disease subtype. For example, gene expression profiling has shown that diffuse large B-cell lymphoma (DLBCL) comprises at least three different subtypes—germinal center B-cell (GCB)-like, activated B-cell (ABC)-like, and primary mediastinal B-cell lymphoma (PMBL)—each with a distinct oncogenic mechanism, prognosis, and response to therapies (Chap. 98).⁸ Expression profiling studies led to the recognition

of a novel genetic subtype of high-risk B-cell acute lymphocytic or lymphoblastic leukemia (ALL), which has a similar expression signature as Ph-chromosome-positive ALL (Chap. 91).^{9,10} High-throughput array-based SNP genotyping, enabling the analysis of large numbers of cases and controls, has facilitated genome-wide association studies for the identification of disease susceptibility loci.¹¹ Future diagnostic evaluation, identification of high-risk cases and management decisions will be

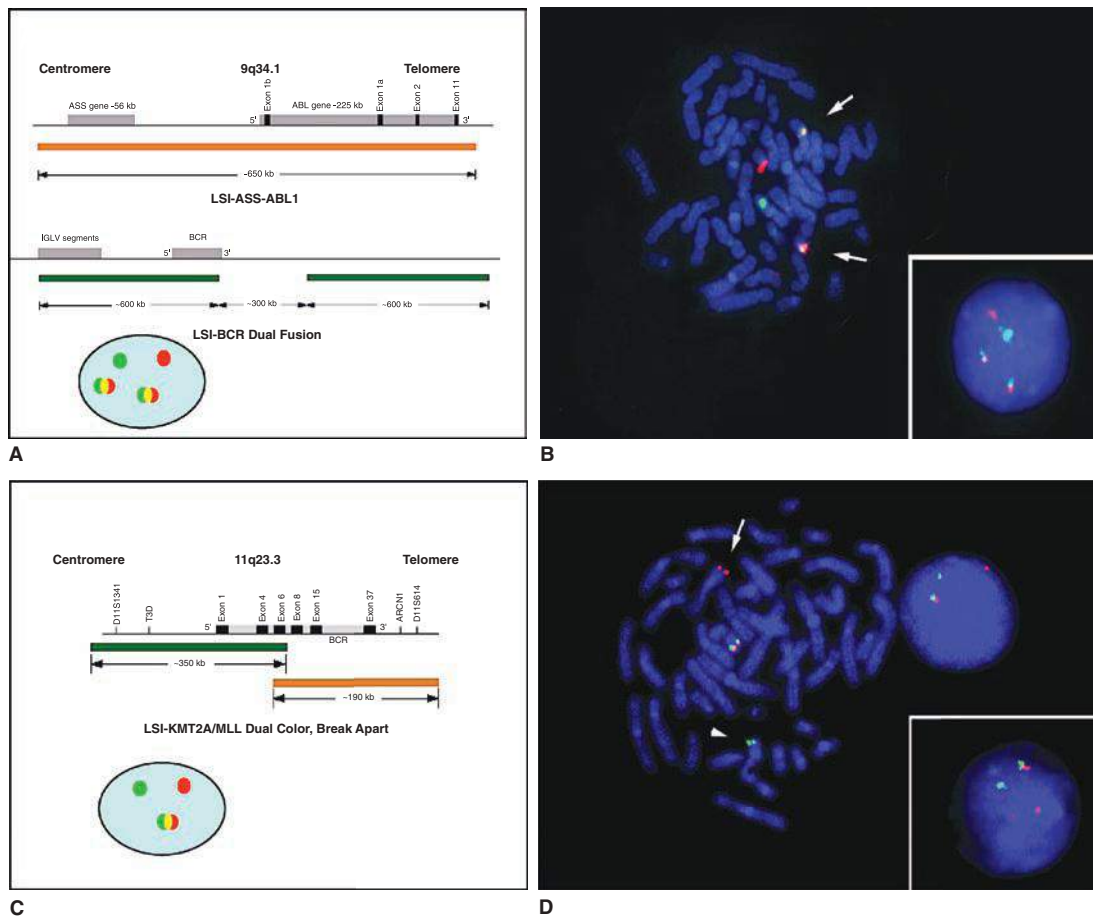

Figure 13-1. Fluorescence *in situ* hybridization (FISH) analysis. Panels **B** and **D** illustrate images of metaphase and interphase cells following FISH; the cells are counterstained with 4,6-diamidino-2-phenylindole-dihydrochloride (DAPI). **A.** Schematic of the *BCR* and *ABL1* loci, location of the *BCR* and *ABL1* dual fusion probe (Vysis, Inc), and configuration of signals in interphase cells. **B.** Hybridization of the *BCR-ABL1* dual fusion probe to metaphase and interphase cells with the t(9;22). In cells with the t(9;22), only one green and one red signal is observed on the normal 9 and 22 homologs, and two yellow fusion signals (arrows) are observed on the der(9) and the der(22) (Ph) chromosomes as a result of the juxtaposition of the *ABL1* and *BCR* sequences. **C.** Schematic of the *KMT2A/MLL* gene, location of the *KMT2A* break-apart probe (Vysis, Inc.), and configuration of signals in interphase cells. **D.** Hybridization of the *KMT2A* break-apart probe to metaphase and interphase cells with a t(11q23.3). In cells with a *KMT2A* translocation, a yellow fusion signal is observed for the germline configuration on the normal chromosome 11 homolog, a green signal is observed in the der(11) chromosome, and a red signal is observed on the partner chromosome.

increasingly based on genomic and even proteomic profiling of patients' germline and tumor samples, which will likely utilize a combination of array-based and next-generation sequencing-based technologies.

SPECIFIC CLONAL DISORDERS

CHRONIC MYELOID LEUKEMIA

The first consistent chromosomal abnormality in any malignant disease was identified in CML (Chap. 89). The Philadelphia (Ph) chromosome results from a translocation involving chromosomes 9 and 22, t(9;22) (q34.1;q11.2), (Fig. 13-3), and arises in a pluripotential stem cell that gives rise to both lymphoid and myeloid lineage cells. The standard t(9;22) is identified in approximately 92 percent of CML patients, whereas 6 to 8 percent have variant translocations that involve a third chromosome in addition to chromosomes 9 and 22 (see Chap. 89, Fig. 89-8). The genetic consequences of the t(9;22) or the complex translocations are to move a segment of the Abelson (*ABL1*) oncogene on chromosome 9 next to a segment of the *BCR* gene on 22. Analyses of leukemia cells from rare patients with typical CML lacking the t(9;22)

has revealed a rearrangement involving *ABL1* and *BCR* that is detectable only at the molecular level (1 to 2 percent of cases).¹²

The t(9;22) and resultant *BCR-ABL1* fusion is the *sine qua non* of CML.¹² The *BCR-ABL1* fusion protein is located on the cytoplasmic surface of the cell membrane and acquires a novel function in transmitting growth-regulatory signals to the nucleus via the RAS/MAPK, phosphatidylinositol 3'-kinase (PI3K)/AKT, and Janus kinase (JAK)/signal transducer and activator of transcription (STAT) signal transduction pathways. The tyrosine kinase activity of the *BCR-ABL1* fusion protein can be specifically inhibited by several commercially available oral tyrosine kinase inhibitors (TKIs): imatinib mesylate (Gleevec/STI571, Novartis Pharmaceuticals, East Hanover, NJ), dasatinib (Sprycel, BMS-354825, Bristol-Myers Squibb, Princeton, NJ), and nilotinib (Tasigna, AMN107, Novartis Pharmaceuticals, East Hanover, NJ) (Chap. 89). Additional oral agents are also being tested in clinical trials.^{13,14} The *BCR-ABL1* translocation can be detected by cytogenetic and FISH analysis, qRT-PCR, and Southern blot analysis to diagnose the disease and detect residual disease. Studies of patients treated with TKIs show a strong correlation between *BCR-ABL1* levels as measured in the blood by qRT-PCR and the percentage of Ph⁺ cells in the marrow.

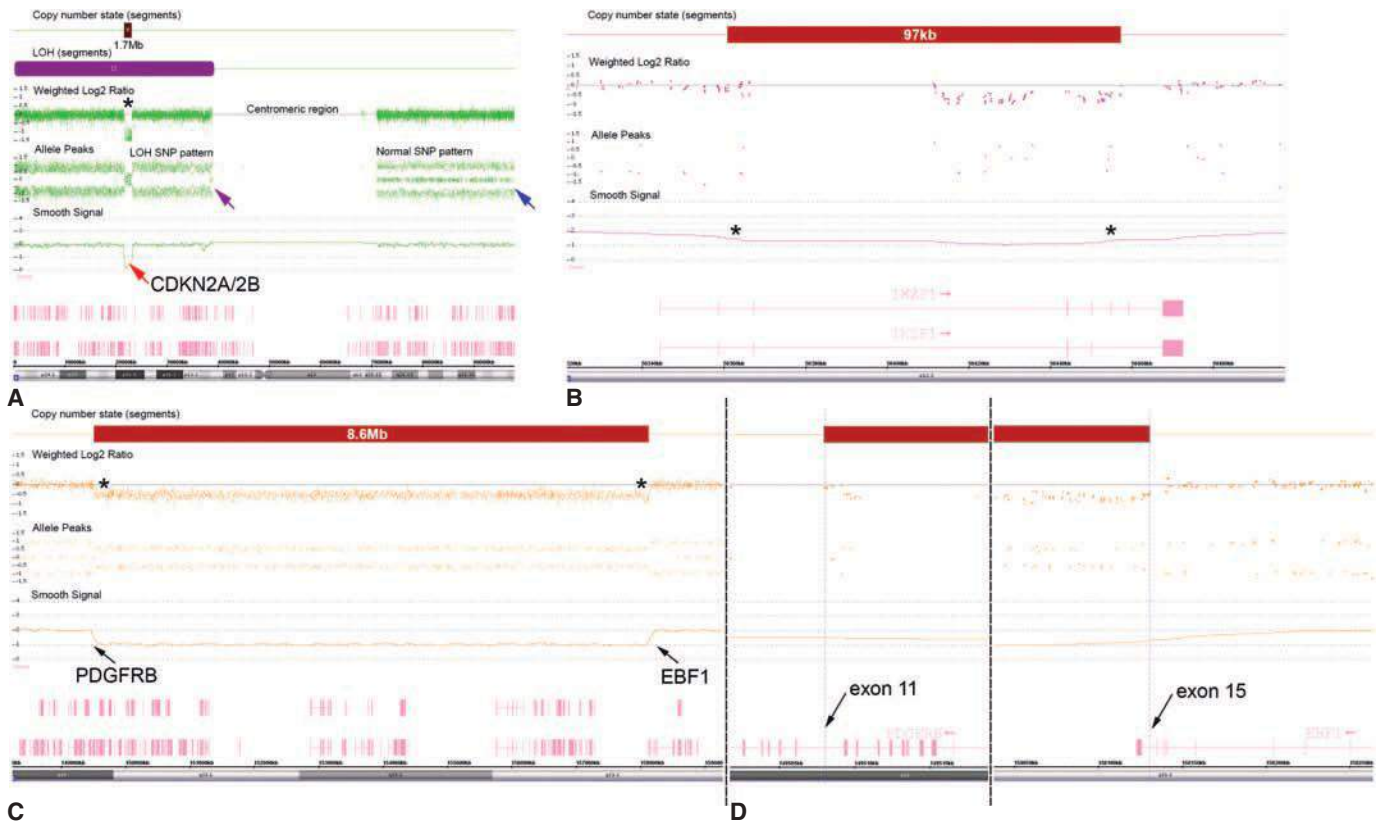

Figure 13-2. Representative results for three B-cell ALL samples illustrating detection of submicroscopic deletions and LOH by CMA. **A.** A 1.7-Mb deletion affecting the *CDKN2A* and *CDKN2B* tumor suppressor genes at 9p (shown by the dark bar on the top and the red arrow). The deletion is accompanied by an extended region of a copy-number neutral LOH affecting the entire short arm of chromosome 9 (indicated by the purple bar) and resulting in biallelic loss of *CDKN2A* and *CDKN2B*. The normal SNP pattern is indicated with a blue arrow, whereas the abnormal pattern associated with LOH is identified by the purple arrow. **B.** *IKZF1* deletion detected by SNP array is associated with an adverse treatment outcome of pediatric B-cell ALL patients. **C.** Array plot showing 5q32-q33.3 deletion that fuses the *PDGFRB* and *EBF1* genes in a case of Ph+ like ALL (**D**).

The rearranged chromosomes are identified with arrows. **A.** *t(9;22)(q34.1;q11.2)*, CML. **B.** *t(8;21)(q22;q22.3)*, AML-M2. **C.** *inv(16)(p13.1q22)*, AMMoL-M4Eo. **D.** *t(15;17)(q24.1;q21.1)*, APL. **E.** *t(9;11)(p21.3;q23.3)*, AMoL-M5. **F.** *del(5)(q13q33)*, t-AML.

Several types of genetic changes are associated with imatinib resistance, including point mutations leading to amino acid substitutions in the BCR-ABL1 kinase domain that interfere with imatinib binding, as well as the acquisition of additional copies of the Ph chromosome or BCR-ABL1 gene amplification, both of which can be detected by FISH.¹⁴ Besides duplications of the BCR-ABL1 fusion, additional TKI resistance-associated genomic lesions, including acquired regions of LOH on chromosomes 1, 8, 9, 17, 19, and 22, have been detected by SNP array analysis.¹⁵ Although some patients who achieve a complete cytogenetic response on imatinib develop clonal karyotypic abnormalities, most commonly +8, -7, or del(20q), the majority of them do not go on to develop the clinical features of MDS.¹⁶ The significance of these early findings will be elucidated by the analysis of a large number of patients who have had complete cytogenetic responses to TKIs and are being followed prospectively.

As they enter the more aggressive stages of accelerated and blast phase disease, historically 80 percent of CML patients showed karyotypic evolution with the appearance of new chromosomal abnormalities in very distinct patterns in addition to the Ph chromosome. A change in the karyotype was considered to be a grave prognostic sign.¹⁷ The most common changes, a gain of chromosomes 8 or 19, or a second Ph chromosome (by gain of the first), or an i(17q), frequently occurred in combination to produce modal chromosome numbers of 47 to 50. Other genetic changes identified in CML in blast crisis include mutations in the TP53, RBL, MYC, CDKN2A (p16), KRAS/NRAS, or RUNX1/AML1 genes. With the advent of TKI therapy, the natural history of CML has been altered, and the karyotype in blast phase appears to differ from that seen previously. However, the pattern of abnormalities is not yet well described.

Rarely, marrow biopsies from patients will appear similar to those patients with CML, but will lack a Ph chromosome or the BCR-ABL1 fusion. Most often these patients have a MDS or myeloproliferative neoplasm (MPN), most commonly chronic myelomonocytic leukemia, refractory anemia with excess blasts (RAEB), or the poorly understood disorder of “atypical CML.” Some of the latter have JAK2^{V617F} mutations and a phenotype consistent with chronic neutrophilic leukemia (Chaps. 84 and 89). Cytogenetic analysis of marrow biopsies from these patients commonly have a normal karyotype, +8, +13, del(20q), or i(17q). These patients have a substantially shorter survival than do those whose cells have the t(9;22). Because each of the oral TKIs blocks kinase activities in addition to BCR-ABL1, they have proven to be effective in other disorders, including chronic MPNs with platelet-derived growth factor receptor (PDGFR)- β rearrangements, a myeloproliferative variant of hypereosinophilic syndrome that expresses the FIP1L1-PDGFR fusion protein, and in patients with mast cell malignancies that express an activating point mutation in KIT (Chap. 89).¹⁸

OTHER MYELOPROLIFERATIVE NEOPLASMS

A cytogenetically abnormal clone is present in 15 percent of untreated polycythemia vera patients compared with 40 percent of treated patients (Table 13-2).¹⁹ When the disease transforms to acute myeloid leukemia (AML), almost 100 percent have a cytogenetically abnormal clone. The presence of a chromosome abnormality at diagnosis does not necessarily predict a short survival or the development of leukemia. However, a change in the karyotype may be an ominous sign. Marrow cells frequently contain additional chromosomes (+8 or +9). Trisomy 8 and 9 may occur together which is otherwise rare.¹⁹ Structural rearrangements most often involve a del(13q) or del(20q), noted in 30 percent of patients. Loss of chromosome 7 (20 percent) and del(5q) (40 percent) are often observed in the leukemic phase, and may be related to the prior treatment received by these patients (Chap. 84).

Cytogenetic analysis of cells from patients with primary myelofibrosis has revealed clonal abnormalities in 60 percent of patients (Chap. 86).¹⁹ These abnormalities are similar to those noted in other myeloid disorders. The most common anomalies are +8, -7, or a del(7q), del(11q), del(13q), and del(20q).¹⁹ A change in the karyotype may signal evolution to AML. Fewer than 10 percent of patients with essential thrombocythemia have an abnormal clone (Chap. 85). Recurring abnormalities include +8 and del(13q). Although del(5q) and inv(3)/t(3;3) are associated with thrombocytosis, they are characteristic of MDS or AML, rather than essential thrombocythemia.

Mutant JAK2^{V617F} is a constitutively active tyrosine kinase that activates the STAT, PI3Ks, and mitogen-activated protein kinases (MAPKs) signalling pathways downstream of the erythropoietin receptor, thrombopoietin receptor, or the granulocyte colony-stimulating factor (G-CSF) receptor to promote proliferation and transformation of hematopoietic progenitor cells (Chap. 84). JAK2 mutations occur in polycythemia vera (95 percent), essential thrombocythemia (approximately 50 percent), and myelofibrosis (approximately 50 percent) (Chaps. 84 to 86).²⁰ In refractory anemia with ring sideroblasts (RARS) with thrombocytosis (RARS-t), a MDS/MPN, unclassified by the World Health Organization (WHO) classification, 60 percent of patients have the JAK2^{V617F} mutation, and present with higher white blood cell and platelet counts (Chap. 87).²¹ Less commonly, activation of the JAK-STAT pathway in MPNs may result from JAK2 exon 12 mutations (1 to 2 percent of polycythemia vera cases) or mutation of the thrombopoietin receptor, MPL (approximately 2 percent of essential thrombocythemia and approximately 5 percent of myelofibrosis). The majority of essential thrombocythemia and myelofibrosis patients with nonmutated JAK2 carry somatic mutations in the calreticulin gene (CALR) (Chaps. 85 and 86).^{22,23}

MYELOYDYSPLASTIC SYNDROMES

The MDSs are a heterogeneous group of neoplasms, including refractory cytopenia with unilineage dysplasia, RARS, refractory cytopenia with multilineage dysplasia (RCMD), RAEB-1,2, MDS with isolated del(5q), MDS unclassifiable, and childhood MDS, including refractory cytopenia of childhood (Chap. 87).²⁴ Clonal chromosome abnormalities can be detected in marrow cells of approximately 50 percent of patients with primary MDS at diagnosis (refractory anemia [RA], 25 percent; RARS, 10 percent; RCMD, 50 percent; RAEB -1,2, 50 to 70 percent; MDS with isolated del (5q), 100 percent) (see Table 13-2).^{25,26} The proportion varies with the risk that a subtype will transform to AML, which is highest for RCMD and RAEB. The common chromosome changes, +8, del(5q), -7/del(7q), and del(20q), are similar to those seen in AML *de novo*. The recurring translocations that are closely associated with the distinct morphologic subsets of AML *de novo* are almost never seen in MDS. With the exception of MDS with isolated del(5q), the chromosome changes show no close association with the specific subtypes of MDS. MDS with isolated del(5q) occurs in a subset of older patients, frequently women, with RA, generally low blast counts, and normal or elevated platelet counts.²⁷ These patients have an interstitial deletion of 5q, typically as the sole abnormality, and can have a relatively benign course that extends over several years (Chap. 87).²⁷ Diagnostic and prognostic information for the patients with a normal karyotype can be provided by CMA, which can detect abnormalities in 10 to 15 percent of these cases. Some abnormalities detectable by CMA, including submicroscopic microdeletions in 4q24 affecting the TET2 gene, as well as LOH 7q, LOH 11q, and LOH 17p, were shown to be associated with a poor outcome in MDS.^{28,29}

Cytogenetic abnormalities in MDS are predictive of survival and progression to AML.²⁶ Patients with a “very good outcome” have -Y or del(11q) as the sole abnormality; those with a “good outcome” have

AML, acute myeloid leukemia; CML, chronic myeloid leukemia; CMML, chronic myelomonocytic leukemia; MDS, myelodysplastic syndrome; PMF, primary myelofibrosis; PV, polycythemia vera.

*Genes are listed in order of citation in the karyotype; e.g., for CML, *ABL1* is at 9q34.1 and *BCR* at 22q11.2.

[†]Rare patients with CML have an insertion of *ABL1* adjacent to *BCR* in a normal-appearing chromosome 22.

[‡]Cytogenetic abnormalities considered in the WHO 2008 Classification as presumptive evidence of MDS in patients with persistent cytopenias(s), but with no dysplasia or increased blasts.

normal karyotypes, del(5q) alone, or with one additional abnormality, del(12p) alone, or del(20q) alone; those with an “intermediate outcome” have del(7q), +8, +19, i(17q), or any other single or double abnormality; those with a “poor outcome” have –7, inv(3q)/t(3;3), double abnormalities, including –7/del(7q), and complex karyotypes with 3 abnormalities; and those with a “very poor outcome” have complex karyotypes with more than three abnormalities, typically with abnormalities of chromosome 5.²⁶ With larger data sets, the inclusion of additional rare recurring cytogenetic abnormalities has facilitated a refinement of the cytogenetic risk groups, and provided the clinician with more information to predict the expected outcome for their patient.^{30,31}

ACUTE MYELOID LEUKEMIA DE NOVO

Clonal chromosomal abnormalities are detected in 80 to 90 percent of patients with AML. The most frequent abnormalities are +8 and –7, which are seen in most subtypes of AML.¹ Specific rearrangements are closely associated with particular subtypes of AML as recognized by the WHO and French-American-British (FAB) classification schemes (see Table 13–2; Chap. 88).³²

Translocation 8;21

The 8;21 translocation [t(8;21)(q22;q22.3)], described in 1973, was the first translocation identified in AML (see Fig. 13–3). The t(8;21) is common and is observed in 5 to 10 percent of all patients with AML with an

abnormal karyotype and in 10 percent of patients with AML with maturation. This translocation is the most frequent abnormality in children with AML and occurs in 15 to 20 percent of karyotypically abnormal cases. Loss of a sex chromosome (–Y in males, –X in females), or a del(9q) with loss of 9q22, accompanies the t(8;21) in 75 percent of cases. The presence of the t(8;21) identifies a morphologically and clinically distinct subset of AML, and most cases with the t(8;21) are classified as AML with maturation. AML with the t(8;21) has a favorable prognosis in adults (overall 5-year survival of 70 percent), but the outcome in children is poor.³³ At the molecular level, the t(8;21) involves the *RUNX1/AML1* gene, which encodes a transcription factor, also known as core-binding factor, that is essential for hematopoiesis. The *RUNX1* gene on chromosome 21 is fused to the *RUNX1T1/ETO* gene on chromosome 8 and results in a *RUNX1-RUNX1T1* chimeric protein. Transformation by *RUNX1-RUNX1T1* likely results from transcriptional repression of normal *RUNX1* target genes via aberrant recruitment of nuclear transcriptional corepressor complexes.³³

Inversion 16 and Translocation 16;16

Another clinical–cytogenetic association involves acute myelomonocytic leukemia (AMML) with abnormal eosinophils, including large and irregular basophilic granules, and positive reactions with periodic acid–Schiff and chloroacetate esterase. Most patients have an inversion of chromosome 16, inv(16)(p13.1q22) (see Fig. 13–3), but some have a t(16;16)(p13.1;q22), and the WHO classification system now recognizes

these as a distinct form of AML (Chap. 88). These aberrations are relatively common, occurring in 5 percent of AML and 25 percent of AMML patients.¹ These patients have a good response to intensive chemotherapy with a complete remission rate of approximately 90 percent and an overall 5-year survival of 60 percent.³³ The breakpoint at 16q22 occurs within the *CBFβ* gene, which encodes one subunit of the RUNX1/CBFβ transcription factor. Thus, like the t(8;21), the inv(16) disrupts the RUNX1/AML1 pathway regulating hematopoiesis. Secondary cooperating mutations of *KIT*, *KRAS*, and *NRAS* are common in core-binding factor-associated leukemias, although only *KIT* mutations confer a poor prognosis.³³

Translocation 15;17

The t(15;17)(q24.1;q21.1) (see Fig. 13–3) is specific for acute promyelocytic leukemia (APL) and has not been found in any other disease.³⁴ Rare variant translocations, which occur in less than 2 percent of cases, include the t(11;17)(q23.2;q21.1) and t(5;17)(q35.1;q21.1), which result in the ZBTB16 (PLZF)-RARA and NPM1-RARA fusion proteins, respectively. Establishing the diagnosis of APL with the typical t(15;17) is important, because this disease is sensitive to therapy with all-*trans* retinoic acid, whereas other cases of AML and some of the APL-like disorders associated with the variant translocations do not respond to this treatment (Chap. 88). The t(15;17) results in a fusion retinoic acid receptor- α protein (PML-RARA). The oncogenic potential of the APL fusion proteins appears to result from the aberrant repression of RARA-mediated gene transcription through histone deacetylase (HDAC)-dependent chromatin remodeling. Genetic mutations that cooperate with PML-RARA include *FLT3* internal tandem duplications (ITDs), observed in 35 percent of patients.

Translocations Involving 11q

Recurring translocations involving 11q23.3 are seen in approximately 35 percent of acute monocytic leukemia patients and are of great interest in acute leukemia for at least three reasons.^{1,35} First, there are more than 50 different recurring rearrangements that involve 11q23.3 and, thus, along with 14q32.3, 11q23.3 is one of the bands most frequently involved in rearrangements in human tumor cells.^{35,36} The most common breakpoints in the translocation partners include 1p32, 4q21.3, and 19p13.3 in ALL (Chap. 91), and 1q21, 2q21, 6q27, 9p21.3, 10p12, 17q25, 19p13.3, and 19p13.1 in AML (Chap. 88). Second, these translocations occur in both lymphoid and myeloid leukemias. One common translocation in infants, t(4;11)(q21.3;q23.3), has a lymphoblastic phenotype, whereas other translocations, such as the t(9;11)(p21.3;q23.3) (see Fig. 13–3) and t(11;19)(q23.3;p13.1), are common in acute monocytic leukemias. Finally, translocations involving 11q23.3 have a very unusual age distribution, comprising about three-quarters of the chromosome abnormalities in leukemia cells of children younger than 1 year of age.³⁵ With the exception of the t(9;11) which may have an intermediate outcome, translocations of 11q23.3 are associated with a poor outcome.³² Translocations of 11q23.3 involve *KMT2A/MLL*, a very large gene (>100 kb) with multiple transcripts of 12 to 15 kb. *KMT2A* protein is a histone methyltransferase that assembles in protein complexes that regulate gene transcription via chromatin remodeling.³⁶ All of the *KMT2A* translocations identified to date result in fusion proteins.

Trisomy 11

Trisomy 11 is a rare abnormality, noted as a sole aberration in 1 to 2 percent of MDS or AML, and confers an unfavorable outcome.³⁷ It is notable that an ITD of the *KMT2A* gene is detected in 90 percent of AMLs with +11 as the sole abnormality and in 10 percent of AML cases with a normal karyotype. The rearrangement is the result of a duplication of

KMT2A exons 2 to 6 or 2 to 8 mediated by recombination between *Alu* repetitive elements and may produce a partially duplicated protein.

Inversion 3 and t(3;3)

Each of the other recurring rearrangements in AML occurs in fewer than 3 percent of patients. A unique feature of abnormalities involving the long arm of chromosome 3 [inv(3)(q21.3q26.2) or t(3;3)(q21.3;q26.2)] is the presence of platelet counts greater than $100 \times 10^9/L$, sometimes greater than $1000 \times 10^9/L$, and an increase in marrow megakaryocytes, especially micromegakaryocytes.¹ Most of the recurring translocations described above occur in younger patients with a median age in the 30s, whereas other abnormalities, such as del(5q), or -7/del(7q), occur in patients with a median age greater than 50 years. Moreover, many of the latter patients have occupational exposure to mutagenic agents, such as solvents, petroleum, and pesticides.

Mutations

The prognosis of patients with AML is also determined by mutations, most commonly of the *FLT3*, *NPM1*, *CEBPA*, or *KIT* genes (Table 13–3).³⁸ Mutations of the *FLT3* gene, including both point mutations within the tyrosine kinase domain and ITDs, are among the most common genetic changes seen in AML, occurring in 15 to 35 percent of cases. *FLT3*-ITD mutations may occur in any subtype of AML, but are most common in APL and AML with a normal karyotype, and are associated with a poor prognosis, particularly in those cases with loss of the remaining wild type *FLT3* allele.³⁹ Mutations of the *FLT3* tyrosine kinase domain (codons 835 or 836 of the second tyrosine kinase domain) are noted in 5 to 8 percent of AML.³⁹ Mutations of *NPM1* also occur frequently in AML (35 percent of adult cases, and 80 to 90 percent of acute monocytic leukemia), but are less frequent in patients with recurring cytogenetic abnormalities. In the absence of *FLT3* mutations, *NPM1* mutations are associated with a favorable prognosis.⁴⁰ *NPM1* mutations, most commonly involve exon 12, resulting in alterations at the C-terminus, that is, replacement of tryptophan(s) at position 288 and 290, and aberrant localization of the protein to the cytoplasm. *CEBPA* mutations (6 to 15 percent of all AMLs), are often biallelic, and are usually associated with intermediate risk cytogenetics, but are generally associated with a favorable prognosis.³⁸ Mutations of *KIT* are noted in 2 percent of AMLs, and have prognostic significance among AMLs with t(8;21) and inv(16)/t(16;16) (20 to 25 percent), in which they are associated

TABLE 13–3. Gene Mutations in MDS and AML

Mutated Gene	Disease		
	MDS	AML	t-MDS/t-AML
<i>FLT3</i> (ITD)	2.4%	15–35%	0%
<i>FLT3</i> (TKD)	1%	5–8%	<1%
<i>NRAS</i>	10–15%	10%	10%

<i>PTPN11</i>	~1%	~1%	3%
<i>NPM1</i>	Rare	35%	4–5%
<i>CEBPA</i>	1–8%	6–18%	Rare
<i>JAK2</i> ^{V617F}	2–5%	2–5%	2–5%
<i>DNMT3A</i>	8%	10%	16%

with a poor prognosis.³³ With respect to epigenetic changes, transcriptional silencing via DNA methylation of the *CDKN2B* (*p15^{INK4B}*) gene is observed in a high percentage of patients with AML or therapy-related myeloid neoplasm, and is associated with $-7/\text{del}(7q)$, and a poor prognosis.⁴¹

Whole-genome and exome sequencing studies implicated a number of additional genes in pathogenesis of AML, including *DNMT3A*, *TET2*, *ASXL1*, *IDH1*, *IDH2*, *PHF6*, *WT1*, *TP53*, *RUNX1*, and *EZH2*. Still, AML genomes have a relatively few mutations compared to other adult cancers (average of 13 mutations), and only approximately 20 genes appear to be mutated in AML with a significant frequency.⁴² Several of the newly identified genetic abnormalities have prognostic importance in AML, including *DNMT3A*, *TET2*, *ASXL1*, and *PHF6* mutations, and *KMT2A-PTD*, which are all associated with a poor outcome.⁴³ As more data accumulate regarding the clinical relevance of the specific mutation in homogeneously treated clinical cohorts it will become important to develop and implement assays that allow for cost-effective, rapid molecular profiling in the clinical setting.

In addition, the emerging molecular analysis of tumor tissue presents an opportunity to identify individuals with germline predisposition to cancer.^{44–46} Depending on the type of bioinformatic analysis that is performed on tumor tissue, it is possible to identify germline mutations when analyzing an individual's primary tumor, as every cell in that person's body will contain the germline mutation. For example, the current standard for molecular analysis in the case of a patient presenting with a new AML is to perform mutational analysis of *CEBPA*. *CEBPA* is mutated sporadically in AML, but the familial form is associated with biallelic *CEBPA* mutations, most commonly with the germline mutation found within the 5' end of the gene, accompanied by the acquisition of a second 3' mutation in the leukemia. Germline 3' *CEBPA* mutations have also been identified.^{47,48} In approximately 10 percent of AML patients found to have biallelic *CEBPA* mutations within their leukemia cells, one of these mutated alleles is actually a germline mutation and, therefore, any AML patient found to have biallelic *CEBPA* mutations should undergo genetic counseling and molecular testing of germline tissue.^{44,49–51} This type of scenario may become more common as next-generation sequencing of tumor tissue is performed more frequently. The American College of Medical Genetics and Genomics (ACMG) has published a series of commentaries and recommendations regarding disclosure of genetic information when clinical genetic sequencing is

performed.^{52,53} The ACMG recommends disclosure of genetic information regarding 24 genes that confer germline cancer predisposition.⁵³ Figure 13–4 shows the frequency of common cytogenetic abnormalities in AML occurring *de novo*.

THERAPY-RELATED MYELOID NEOPLASMS

Therapy-related myeloid neoplasms (t-MNs), comprised of therapy-related MDS (t-MDS) and therapy-related AML (t-AML), are a late complication of cytotoxic therapy used in the treatment of both malignant and nonmalignant diseases.⁵⁴ In patients who received alkylating agents, the characteristic recurring chromosome abnormalities observed are loss of part or all of chromosomes 5 [$\text{del}(5q)$] and/or part or all of chromosome 7 [$-7/\text{del}(7q)$] (see Fig. 13–4). Clinically, these patients have a long latency period (5 years), present with MDS, which often progresses rapidly to AML with multilineage dysplasia and a poor prognosis. In our experience, 92 percent of t-MN patients had an abnormal karyotype and 70 percent had an abnormality of one or both chromosomes 5 and 7,⁵⁵ and these observations have been confirmed in other series.⁵⁶ In contrast, only approximately 20 percent of patients with AML *de novo* have a similar abnormality of chromosomes 5 or 7 or both.¹

By cytogenetic and molecular analysis, investigators have defined a 970-kb commonly deleted segment (CDS) containing 19 genes on the long arm of chromosome 5 (5q31.2) predicted to contain a myeloid tumor suppressor gene.⁵⁷ A second, nonoverlapping CDS in 5q32 is implicated in MDS with an isolated $\text{del}(5q)$.⁵⁸ Parallel studies revealed a 2.5-Mb CDS within 7q22 containing 16 genes. Molecular analysis of the genes within these regions did not reveal inactivating mutations in the remaining alleles, nor was there evidence of transcriptional silencing.⁵⁷ These observations are compatible with a haploinsufficiency model (gene dosage effect resulting from the loss of one allele), and several candidate haploinsufficient genes (*EGR1*, *APC*, *CSNK1A1*, *RPS14*) have been identified on 5q. The *EGR1* transcription factor is downstream of cytokine signaling pathways. In a mouse model, loss of a single allele of *Egr1* cooperates with mutations induced by an alkylating agent in the development of myeloid diseases.⁵⁹ *RPS14* encodes an essential component of the 40S subunit of ribosomes, and haploinsufficiency of this gene appears to be responsible for the defect in erythropoiesis in MDS with an isolated $\text{del}(5q)$.⁶⁰ Other studies show that haploinsufficiency of two micro-RNAs, miR-145 and miR-146a, encoded by sequences near the

Figure 13–4. Frequency of recurring abnormalities in myeloid leukemias.

RPS14 gene, cooperate with loss of *RPS14* and mediate the megakaryocytic dysplasia seen in this disease.⁶¹ These studies raise the possibility that haploinsufficiency for one or more of these genes in hematopoietic stem cells (HSCs) may contribute to the pathogenesis of MDS or AML with a *del(5q)*, and a study demonstrated that haploinsufficiency for two *del(5q)* genes, *EGR1* and *APC*, together with loss of *TP53* leads to AML in a mouse model.⁶²

A second subtype of t-AML has been identified that is distinctly different from the more common leukemia that follows alkylating agents or irradiation. This type of t-AML is seen in patients receiving drugs known to inhibit topoisomerase II, for example, etoposide, teniposide, and doxorubicin. Clinically, these patients have a shorter latency period (1 to 2 years), present with overt leukemia, often with monocytic features, without a preceding myelodysplastic phase, and have a more favorable response to intensive induction therapy. Balanced translocations involving the *KMT2A* gene at 11q23.3, or the *RUNX1/AML1* gene at 21q22.3 are common in this subgroup.⁵⁴

ACUTE LYMPHOBLASTIC LEUKEMIA

ALL is the most frequent leukemia in children (Chap. 91). In both childhood and adult ALL, the identification of prognostic subgroups based on recurring cytogenetic abnormalities (Table 13-4) and molecular markers has resulted in the application of risk-adapted therapies.⁶³ The most useful prognostic indicators are karyotype (including ploidy), age, white blood cell count, and response to initial therapy (day 14 marrow response and end-induction minimal residual disease). Based on these parameters, the Children's Oncology Group has defined four risk groups: lower risk (5-year event-free survival [EFS], at least 85 percent), with either the *ETV6/RUNX1* fusion, or simultaneous trisomies of chromosomes 4, 10, and 17; standard and high risk (those remaining in the respective National Cancer Institute risk groups); and very high risk (5-year EFS, 45 percent or below), with extreme hypodiploidy (fewer than 44 chromosomes), or the *BCR-ABL1* fusion, and induction failure.⁶⁴ Genome-wide profiling studies using CMA revealed a high frequency of submicroscopic copy-number abnormalities in pediatric ALL, including deletions of *PAX5* (32 percent), *IKZF1* (*IKAROS*, 29 percent), *CDKN2A/B* (50 percent), *BTG1*, and *EBF1* (8 percent). Many of these abnormalities disrupt genes and pathways controlling B-cell development and differentiation, and the most clinically significant among them appears to be genetic alterations of *IKZF1*, which are invariably associated with a very poor outcome in B-cell progenitor ALL.⁹

Translocation 9;22

The incidence of the t(9;22) in ALL is 30 percent in adults (the incidence may approach 50 percent in adults older than 60 years of age) and 5 percent in children. Thus, the Ph chromosome is the most frequent rearrangement in adult ALL. Approximately 70 percent of the patients show additional abnormalities, a frequency that is substantially higher than that observed in CML with +*der(22)t(9;22),+21*, abnormalities of 9p, +8, -7, and +X (noted in descending frequency). Monosomy 7 is associated with a poorer outcome.⁶⁵ A chromosomally normal cell line is frequently noted in the marrow of Ph chromosome-positive ALL patients (70 percent), but is rare in untreated CML. Most cases have a B-lineage phenotype (CD10+, CD19+, and TdT+), but there is frequent expression of myeloid-associated antigens (CD13 and CD33). The disease in both adults and children is characterized by high white blood cell counts, a high percentage of circulating blasts, and a poor prognosis. As in CML, the t(9;22) in ALL results in a *BCR-ABL1* fusion gene. However, in more than half of the patients, the break in *BCR* is more proximal, resulting in a smaller fusion protein with even greater tyrosine

kinase activity (*BCR-ABL1*^{P190}). Genetic alterations of the *IKZF1* gene are detectable in up to 80 percent of patients with Ph chromosome-positive ALL, and are associated with an unfavorable outcome even with the use of TKIs.⁶⁶

Translocations Involving 11q

Translocations involving the *KMT2A* gene at 11q23.3 are observed in 5 percent of ALL patients.⁶⁷ Of these, the most common is the t(4;11)(q21.3;q23.3) (Fig. 13-5). The t(11;19)(q23.3;p13.3) is second in frequency. However, this rearrangement is not limited to ALL in that approximately 50 percent of these cases have AML, usually monoblastic. Of note is the high frequency of translocations involving 11q23.3 in infant ALL (60 to 80 percent). Patients with the t(4;11) have a pro B-cell phenotype (CD10-, CD19+), with coexpression of monocytic (CD15+), or, less commonly, T-cell markers. Clinically, both children and adults have aggressive features with hyperleukocytosis, extramedullary disease, and a poor response to conventional chemotherapy.⁶⁷ Adults with the t(4;11) have a remission rate of 75 percent, but a median EFS of only 7 months. Rearrangements affecting *KMT2A* represent a major class of mutations in acute leukemia and identify patients with a poor outcome.

Translocation 12;21

The t(12;21)(p13.2;q22.3) has been identified in a high proportion (approximately 25 percent) of childhood precursor B-cell leukemia, but is uncommon in adults (approximately 5 percent of ALL cases) (Fig. 13-6).⁶⁸ The translocation is not easily detected by cytogenetic analysis because of the similarity in size and banding pattern of 12p and 21q. However, the rearrangement can be detected reliably using reverse transcriptase polymerase chain reaction (RT-PCR) or FISH analysis. The t(12;21) defines a distinct subgroup of patients characterized by an age between 1 and 10 years, B-cell lineage immunophenotype (CD10+, CD19+, HLA-DR+), and a favorable outcome, particularly when other favorable risk factors are present. In one study, patients with the t(12;21) had a 5-year EFS of 91 percent as compared to 65 percent for patients without this rearrangement. However, the t(12;21) may be associated with late disease recurrences. The t(12;21) results in a fusion protein containing the N-terminus of *ETV6/TEL*, a transcriptional repressor of the ETS family, and most of the *RUNX1/AML1* transcription factor.

Hyperdiploidy

The leukemia cells of some patients with ALL are characterized by a gain of many chromosomes (see Fig. 13-6). Two distinct subgroups are recognized: a group with 1 to 4 extra chromosomes (47 to 50), and the more common group with more than 50 chromosomes. Chromosome numbers usually range from 51 to 60, and a few patients may have up to 65 chromosomes. Hyperdiploidy (>50 and usually <66 chromosomes) is common in children (approximately 30 percent), but is rarely observed in adults (<5 percent). Certain additional chromosomes are common (X chromosome, and chromosomes 4, 6, 10, 14, 17, 18, and 21). Chromosome 21 is gained most frequently (100 percent of cases). Patients who have hyperdiploidy with more than 50 chromosomes have all of the previously recognized clinical factors that indicate a good prognosis, including age between 1 and 9 years, low white blood cell count (median 6700/ μ L), and favorable immunophenotype (early pre-B cell or pre-B cell).⁶⁹ The favorable prognosis associated with high hyperdiploidy is associated with gains of chromosomes 4, 10, and 17, whereas a gain of chromosomes 5 and i(17q) is associated with a poor outcome.⁶⁹

ALCL, anaplastic large cell lymphoma; DLBCL, diffuse large B-cell lymphoma; LPL, lymphoplasmacytoid lymphoma; MALT, mucosa-associated lymphoid tissue; MCL, mantle cell lymphoma; NFκB, nuclear factor κB; NK, natural killer; PCFCL, primary cutaneous follicular center lymphoma; PCMZL, primary cutaneous marginal zone lymphoma; SIg, surface immunoglobulin; SLL, small lymphocytic lymphoma; SNCL, small noncleaved cell lymphoma; TF, transcription factor.

*The percentage refers to the frequency within the disease overall. The number in the parentheses refers to the frequency within the morphologic or immunologic subtype of the disease.

[†]Genes are listed in order of citation in the karyotype; e.g., for precursor B ALL, *ETV6* is at 12p13.2 and *RUNX1* is at 21q22.3.

[‡]By cytogenetic analysis, the frequency in children is approximately 5%, and in adults it is approximately 25%; using molecular probes, this frequency is 30% in adults overall, and 50% in adults older than 60 years of age.

Figure 13-5. Partial karyotypes of trypsin-Giemsa-banded metaphase cells depicting recurring chromosomal rearrangements observed in lymphoid malignant diseases. The rearranged chromosomes are identified with arrows. **A.** $t(4;11)(q21.3;q23.3)$ in ALL. **B.** $t(1;19)(q23;p13.3)$ in pre-B cell ALL. **C.** $t(8;14)(q24.2;q32)$ in B-cell ALL and Burkitt lymphoma. **D.** $inv(14)(q11.2q32.1)$ in T-cell leukemia/lymphoma. **E.** $t(8;14)(q24.2;q11.2)$ in T-cell leukemia/lymphoma. **F.** $t(14;18)(q32.3;q21.3)$ in B-cell lymphoma.

Translocation 1;19 and translocation 8;14

The $t(1;19)(q23;p13.3)$ has been identified in approximately 6 percent of children with a B-lineage leukemia (see Fig. 13-5). The leukemia cells have cytoplasmic immunoglobulin and are CD10+, CD19+, CD34-, and CD9+. A reciprocal translocation involving the long arms of chromosomes 8 and 14 [$t(8;14)(q24.2;q32.3)$] is observed in mature B-cell ALL (see Fig. 13-5).⁷⁰ These patients have a high incidence of central nervous system involvement and/or abdominal nodal involvement at diagnosis. Although the outcome for both children and adults with a $t(8;14)$ has been poor, the use of high intensity chemotherapy has markedly improved the outcome (EFS of 80 percent in children).⁷⁰

Philadelphia Chromosome-like Acute Lymphocytic/Lymphoblastic Leukemia

Ph-like ALL is a novel subgroup of high-risk ALL, characterized by increased expression of HSC genes, and a similar gene expression profile to Ph-positive ALL. Like Ph-positive ALL, Ph-like cases are also characterized by a high frequency of *IKZF1* deletions and mutations, which confer a poor prognosis.^{9,10} Ph-like ALL comprises up to 15 percent of pediatric ALL and up to 30 percent of adult ALL and is associated with

a higher risk of relapse compared to other Ph-negative cases. Genetic alterations responsible for the activated kinase and cytokine receptor signaling signature in Ph-like ALL are starting to be elucidated, and include point mutations and gene fusions affecting *CRLF2*, *JAK2*, *ABL1*, *PDGFRB*, *EPOR*, *EBF1*, *FLT3*, *IL7R*, *SH2B3*, and other genes.⁷¹

T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA

T lymphoblastic leukemia/lymphoma has a distinct pattern of recurring karyotypic abnormalities.⁷² Rearrangements involving 14q11.2 (see Fig. 13-5) and two regions of chromosome 7, (7q34) and (7p14), are particularly frequent in T-cell malignancies (see Table 13-4). The most common are the $t(10;11)(q24.3;q11.2)$ (7 percent of childhood and 30 percent of adult cases, *TLX1* gene); the cryptic $t(5;14)(q35.1;q32.1)$ (*TLX3*, 20 percent of childhood and 10 to 15 percent of adult cases), $t(11;14)(p13;q11.2)$ (approximately 3 percent, *LMO2* gene), and $t(7;9)(q34;q34.3)$ (approximately 2 percent, *NOTCH1* gene). Approximately 30 percent of patients have activating mutations of the *NOTCH1* gene. Patients with T-cell ALL are most often young males and often have a mediastinal tumor mass, high white blood cell count, and leukemia

Figure 13-6. Frequency of recurring abnormalities in acute lymphocytic/lymphoblastic leukemias (ALL) and non-Hodgkin lymphomas (NHL).

cells in the cerebrospinal fluid. These same clinical characteristics are associated with lymphoblastic lymphoma, another T-cell malignancy.

CHRONIC LYMPHOCYTIC LEUKEMIA

The chromosomal abnormalities associated with chronic lymphocytic leukemia (CLL) have been delineated through the use of FISH (Chap. 92).⁷³ When conventional cytogenetic techniques are used, only 50 percent of CLL patients have detectable chromosomal abnormalities. The most common abnormality is trisomy 12 (20 to 60 percent), followed by structural abnormalities of 13q and 14q (see Table 13–4). However, when FISH analysis is used to study specific abnormalities, chromosomal abnormalities can be detected in greater than 80 percent of patients. The most frequent chromosomal changes seen by FISH are: loss or deletion of 13q (55 percent); deletion of 11q, the location of the *ATM* gene (18 percent); trisomy of 12q (16 percent); deletion of 17p, the location of the *TP53* gene; and deletion of 6q (6 percent). The LOH affecting 17p frequently coincides with the *TP53* mutations (7 percent) and can be detected by CMA.⁷⁴ Patient survival correlates with cytogenetic subtype, with a shorter median survival observed in patients with 17p (32 months) or 11q (79 months) deletions, than in those with no detectable abnormality (111 months), trisomy of 12q (114 months), or $-13/\text{del}(13q)$ (133 months). Two micro-RNA genes (miR-16–1 and miR-15a) are possible target genes in the 13q14.3 region. FISH probes capable of detecting the deletions of 11q, 13q, and 17p, trisomy 12, and immunoglobulin heavy chain (*IGH*) translocations are commercially available, and facilitate the application of risk-adapted treatment strategies.

The prognosis of patients with CLL is also determined by two other molecular abnormalities: the status of the *IGH* variable region and the expression level of CD38 (Chap. 92). Patients whose CLL cells express *IGH* genes containing somatic mutations have a 24-year median survival compared to only 6 to 8 years in those patients who do not have somatic *IGH* gene mutations.⁷⁵ This simple grouping of patients based on the mutation status of the *IGH* gene may reflect the fact that CLL cells that have few or no *IGH* mutations also often contain chromosomal aberrations that confer a poor prognosis, for example deletions of 11q or 17p, or trisomy 12, whereas CLL cells with *IGH* mutations often contain deletions of 13q, which confer a more favorable clinical course. Unfortunately, testing for somatic mutations in the *IGH* gene is not currently commercially available. *ZAP-70*, an enzyme normally expressed in T lymphocytes and critical for T-cell activation, is upregulated in CLL cells that contain unmutated *IGH* genes, conferring a poor prognosis (Chap. 92).⁷⁶ Patients whose CLL cells have mutated *IGH* and lack expression of *ZAP-70* and CD38, a membrane protein with signaling activity have the longest treatment-free period after initial diagnosis.⁷⁷

T-cell CLL and large granular lymphocytic leukemia are uncommon disorders in which the malignant lymphocytes have a T-cell immunophenotype. Rearrangements involving band 14q11.2 with or without an accompanying break in 14q32.1 have been reported in T-CLL as well as in T-cell lymphomas (see Table 13–4).⁷² The most common is $\text{inv}(14)(q11.2q32.1)$.

LYMPHOMA

Cytogenetic analyses of patients with lymphoma have demonstrated that more than 90 percent of cases are characterized by clonal chromosomal abnormalities and, more importantly, many of the recurring abnormalities correlate with histology and immunophenotype (see Table 13–4; Chaps. 95 and 96).⁷⁸ For example, the $t(14;18)$ is observed in a high proportion of follicular small cleaved cell lymphomas (70 to 90 percent), most patients with a $t(3;22)(q27;q11.2)$ or $t(3;14)(q27;q32.3)$ have DLBCL, and patients

with a $t(8;14)(q24.2;q32.3)$ have either small noncleaved cell or DLBCL (Chap. 98). Band 14q32.3, the location of *IGH* is frequently involved in translocations in B-cell neoplasms (approximately 70 percent). In contrast, a large proportion of T-cell neoplasms are characterized by rearrangements that involve 14q11.2, 7q34, or 7p14, the locations of the T-cell receptor genes (Chap. 104). Gene expression profiling has proven useful in distinguishing unique genetic subtypes of lymphoma.⁷⁹

The $t(8;14)$ is characteristic of both endemic and nonendemic Burkitt tumors, as well as Epstein-Barr virus (EBV)–negative and EBV-positive tumors (see Fig. 13–5; Chap. 102). Moreover, the $t(8;14)$ has also been observed in other lymphomas, particularly small noncleaved cell (non-Burkitt) and large cell immunoblastic lymphomas, HIV-associated Burkitt lymphoma (100 percent) and HIV-related DLBCL (30 percent).⁸⁰ Two other variant translocations also occur in Burkitt lymphoma, $t(2;8)(p12;q24.2)$ and $t(8;22)(q24.2;q11.2)$. All three translocations involve chromosome band 8q24.2. These same translocations have been seen in some patients with B-cell ALL. The $t(8;14)$ involves a break within the *IGH* locus on chromosome 14, and a break either 5' or within the *MYC* gene on chromosome 8, and relocates the *MYC* coding exons to chromosome 14. *MYC* is a transcription factor that plays a critical role in a number of cellular processes including DNA replication, proliferation, and apoptosis; its oncogenic properties are a result of its constitutive expression.

Between 70 and 90 percent of follicular lymphomas (Chap. 99) and 20 percent of DLBCL have the $t(14;18)$ (see Fig. 13–6), in which the *BCL2* gene at 18q21.3 is juxtaposed to the *IGH* J segment, leading to the deregulated expression of *BCL2*.⁸¹ Common secondary abnormalities include -7 , $+18$, and $\text{del}(6q)$. Other malignancies that overexpress *BCL2*, but do not harbor the $t(14;18)$, include hairy cell leukemia and CLL. The *BCL2* gene encodes a 26-kDa mitochondrial membrane protein that functions to increase cell survival through antiapoptosis and preventing programmed cell death.

The $t(11;14)(q13.3;q32.3)$ is observed in virtually all cases of mantle cell lymphoma (Chap. 100), 3 percent of myeloma (Chap. 107), and up to 20 percent of prolymphocytic leukemias (Chap. 92).^{82,83} Many cases also have deletions or point mutations of the *ATM* gene (11q22.3). Mantle cell lymphomas are currently regarded as a poor prognostic group with a median survival from diagnosis of 3 years. This translocation results in the activation of the cyclin D1 (*CCND1*) gene by the *IGH* gene (J region).⁸² The *CCND1* gene is located 100 to 130 kb away from the breakpoint on 11q13.3. The D-type cyclins act as growth factor sensors, causing cells to go through the restriction start point of the cell cycle at G₁ and committing them to divide via phosphorylation and inactivation of RB1.

The *BCL6* gene was cloned from the recurring breakpoint at 3q27 in cells characterized by a $t(3;22)(q27;q11.2)$, $t(3;14)(q27;q32.3)$ or, rarely, $t(2;3)(p12;q27)$.⁷⁸ *BCL6* rearrangements occur in 40 percent of DLBCLs and, in some series, up to 10 percent of follicular lymphomas. The translocations lead to the truncation of the *BCL6* gene within the first exon or the first intron, substitution of its promoter sequences with an *IG* promoter, and deregulated expression. The *BCL6* gene product is a 96-kDa POZ/Zn finger, nuclear protein that acts as a potent transcriptional repressor. It is predominantly expressed in the B-cell lineage, particularly in mature B cells, and may suppress genes involved in lymphocyte activation, differentiation, cell cycle arrest, and apoptosis. Somatic mutations have been identified in the 5' regulatory regions of *BCL6* in approximately 20 percent of DLBCLs without translocations leading to deregulation of *BCL6*, suggesting that overexpression of *BCL6* is more broadly involved than initially recognized.⁸⁴

Extranodal marginal zone B-cell lymphomas of mucosa-associated lymphoid tissue (MALT lymphoma) are comprised of several genetic subgroups, one characterized by trisomy 3 plus other abnormalities

(60 percent), and another by the t(11;18)(q21.2;q21.3) (25 to 50 percent) and its variants (Chap. 101).⁸⁵ Of note is that the t(11;18) is not observed in primary large B-cell gastric lymphoma. The t(11;18) results in the fusion of the apoptosis-inhibitor gene *BIRC3* (*API2*), to a novel gene at 18q21.3, *MALT1*, whose product activates the nuclear factor κ B (NF κ B) pathway.

A number of recurring chromosomal abnormalities have been recognized in T-cell leukemias and lymphomas (see Table 13–4; Chap. 104). Similar to B-cell neoplasms, in which rearrangements frequently involve the chromosomal bands containing the immunoglobulin gene loci, T-cell neoplasms often have rearrangements involving band 14q11.2, the site of the T-cell receptor α -chain (*TRA*) and δ -chain (*TRD*) genes or, less often, one of two regions of chromosome 7 (7q34 and 7p14) to which the T-cell receptor β -chain (*TRB*) and γ -chain (*TRG*) genes have been localized, respectively.⁷⁸ These translocations result from aberrant V-D-J recombination events. With few exceptions, the involved gene on the partner chromosome encodes a transcription factor, whose expression is deregulated or activated as a result of the rearrangement (see Table 13–4). As a consequence of a chromosomal rearrangement that brings an oncogene under the controlling influence of promoters and enhancers that are active in T-cell receptor synthesis, T-cells may gain a proliferative advantage, resulting in malignant clonal expansion.

A distinctive subtype of lymphoma, namely, anaplastic large cell lymphoma (ALCL) is characterized by a young age at presentation, and skin and/or lymph node infiltration by large, often bizarre lymphoma cells, which preferentially involve the paracortical areas and lymph node sinuses (Chap. 98). The majority of such tumors express one or more T-cell antigens, a minority express B-cell antigens, and some express both T- and B-cell antigens (the null phenotype). A reciprocal translocation, t(2;5)(p23.2;q35.1), t(1;2)(q25;p23), or variant rearrangement involving the *ALK* tyrosine kinase gene at 2p23.2 appears to be restricted to ALCL of either T-cell or null phenotype, and is present in a high percentage of these cases.⁸⁶ The tumor cells are positive for CD30 on the cell membrane and in the Golgi region, and *ALK* expression is detectable in 60 to 85 percent of cases, where it confers a more favorable outcome (5-year survival, 80 percent in ALK+ vs. 40 percent in ALK– tumors). The t(2;5) has also been found in CD30+ primary cutaneous lymphomas.

MYELOMA

As in CLL, the application of molecular cytogenetic tools, such as FISH, has led to the discovery of numerous chromosomal abnormalities in myeloma, its precursor essential monoclonal gammopathy (Chaps. 105 and 106), and plasma cell leukemia (Chap. 107).^{83,87} Monoclonal gammopathy is characterized by chromosomal aneuploidy, *IGH* translocations (45 percent of patients), and deletions of 13q (15 to 50 percent). Plasma cell myeloma is a malignancy of postfollicular B cells and is characterized by the acquisition of complex chromosomal rearrangements. As in monoclonal gammopathy, the earliest changes involve deletions of 13q14, and translocations of the *IGH* gene, which deregulate the expression of oncogenes located near the translocation breakpoints. Loss of chromosome 13 or a del(13q) is the most frequently observed chromosomal loss in myeloma and confers a poor prognosis.⁸³ With the use of FISH, deletions of 13q are detected in 40 to 50 percent of patients with myeloma and may be associated with specific 14q translocations.

Among the most frequent chromosomal rearrangements noted in plasma cell malignancies are translocations involving the *IGH* locus on 14q32. *IGH* translocations are detectable by interphase FISH analysis in approximately 10 percent of patients with monoclonal gammopathy, 40 to 50 percent of patients with myeloma, and more than 60 percent of patients with plasma cell leukemia.⁸³ The t(11;14)(q13.3;q32.2) is found in 15 percent of cases, and results in cyclin D1 overexpression and may deregulate expression of *MYEOV* (myeloma overexpressed

gene). The t(4;14)(p16.3;q32.3) is noted in approximately 15 percent of patients and deregulates the expression of the fibroblast growth factor receptor 3 gene (*FGFR3*) translocated to the der(14), and the *WHSC1/MMSET* domain remaining on the der(4) chromosomes. The t(14;16)(q32.3;q23), noted in 5 percent of cases, results in the overexpression of the *MAF* transcription factor gene. Cyclin D3 overexpression occurs in the context of the t(6;14)(p21.1;q32.3), observed in 4 percent of patients. The translocation partners for the remaining 10 to 15 percent of myeloma cases are currently unknown. The t(4;14) and t(14;16) are both associated with a poor clinical outcome, whereas the t(11;14) confers a favorable prognosis. Translocations involving unknown partners confer an intermediate prognosis.

Chromosome 1 abnormalities are prevalent in multiple myeloma, frequently resulting in both gain of 1q and loss of 1p, and are associated with a shorter survival.⁸⁸ Furthermore, gene expression profiling studies that identified a high-risk disease signature noted a significant enrichment of genes located on chromosome 1.⁸⁸ For this reason, it is now recommended that a comprehensive FISH testing panel for multiple myeloma include detection of chromosome 1 abnormalities, particularly using probes for 1q.

Additional events occur with disease progression, including mutations of *NRAS* and *KRAS*, *MYC* deregulation, and epigenetic alterations. Activating mutations of *NRAS* or *KRAS* have been identified in monoclonal gammopathy (approximately 5 percent), and at a higher frequency in myeloma (30 to 40 percent); but the frequency may be higher in patients who relapse (80 percent).⁸⁹ Several genes are silenced through aberrant promoter hypermethylation in both monoclonal gammopathy and myeloma, including *DAPK1* (67 percent), *SOCS1*, *CDKN2B* (*p15*), and *CDKN2A* (*p16*).⁸³

CHAPTER 14

METABOLISM OF HEMATOLOGIC NEOPLASTIC CELLS

Zandra E. Walton, Annie L. Hsieh, and Chi V. Dang

SUMMARY

The quantum physicist Erwin Schrodinger surmised in his monograph “What is Life?” that the organized matter known as *life* needs to feed on “negative entropy” to avoid decay.¹ He concluded that this feeding on negative entropy is achieved through metabolism, a term derived from Greek that describes an exchange of materials. Because of this centrality to life, metabolism’s core pathways—glycolysis and respiration—evolved early in Earth’s history and are highly conserved. At every stage of life, metabolism provides the needed nutrients, energy, and building blocks. Embryogenesis, for instance, requires metabolism of maternally derived nutrients to support cellular repair, growth, division, and differentiation. In particular, cell replication requires that the instructions emanating from the DNA sequence, modulated by the epigenome, couple with the import of nutrients and metabolic pathways to produce the components and energy necessary to build two copies of a cell and maintain high replication fidelity of the genome. During growth and development, and especially during adulthood, metabolism also plays the important role of providing bioenergetics for cellular and organismal homeostasis. Metabolism can also feature prominently in disease, and this chapter discusses how the metabolic pathways central to life and normal biology can be subverted in cancer to fuel abnormal growth.

Food, through metabolism, provides the nutrients necessary for homeostasis, repair, and reproduction of many organisms. To align supply and demand, mammalian metabolism is linked to sleep cycles through the central circadian clock that senses light and dark phases of the day via the eye and central nervous system. The central regulation of feeding and sleeping cycles coordinates nutrient availability from food with the circadian oscillation of metabolism of individual cells, which all have a molecular clock comprised of a network of transcription factors that regulates cell metabolism.²

Food is digested, absorbed through the gastrointestinal tract, and in part processed or stored in the liver, which is a key metabolic organ.³ Processed lipids in the form of lipoproteins are synthesized in the liver and disseminated throughout to supply the needs of various organs. Amino acids, with glutamine circulating at the highest level (0.5 mM), supply cells with building blocks for proteins. Some amino acids (nonessential) are synthesized by humans, but essential amino acids must be available from the diet. Complex carbohydrates are broken down and circulate as glucose, a vital nutrient for virtually all mammalian cells. In this regard, an endocrine system (insulin and glucagon) has evolved to control the circulating levels of this precious bioenergetic molecule. When in excess, amino acids and sugars contribute to lipogenesis, and the extra energy is stored as fat depots in adipose tissues. Excess glucose is stored as glycogen, which is deployed to release glucose in starved conditions. It is believed that, during our evolution, periods of gorging and feeding were separated by significant durations of starvation; hence, we have evolved mechanisms to survive starvation.

In contrast to the fed state, when insulin level increases in response to rising glucose to trigger cellular glucose uptake and storage, the starved state triggers glucagon secretion from the pancreas, which mobilizes cellular glycogen stores as nutrient. Prolonged starvation depletes liver and muscle glycogen stores—the only major glycogen stores—and prompts the mobilization of fat stores. The released fatty acids provide glycerol as a substrate for making glucose through gluconeogenic pathways and fatty acids for mitochondrial oxidation. Further prolonged starvation triggers the liver to convert fatty acids to ketone bodies, which can cross the blood–brain barrier to feed

Acronyms and Abbreviations: ABC, activated B-cell type; ALL, acute lymphoid leukemia; AML, acute myeloid leukemia; AMPK, adenosine monophosphate kinase; ASC2, ASC amino-acid transporter 2; ATRA, all-*trans* retinoic acid; BPTES, a glutaminase inhibitor; CDK, cyclin-dependent kinase; CL, cardiolipin; COO, cell of origin; DFMO, α -difluoromethylornithine; DLBCL, diffuse large B-cell lymphoma; eIF5A, eukaryotic translation initiation factor; ERK, extracellular regulated kinase; ETC, mitochondrial electron transport chain; Ets, E26, E twenty-six; F1,6BP, fructose 1,6 biphosphate; F2,6BP, fructose 2,6 biphosphate; FAO, fatty acid oxidation; FDG-PET, fluorodeoxyglucose positron emission tomography; FH, fumarate hydratase; FOS, a protooncogene; G3P, glycerol 3-phosphate; G6PD, glucose-6-phosphate dehydrogenase; GAP, glyceraldehyde 3-phosphate; GCB, germinal center B-cell type; GDP, guanosine-5'-diphosphate; GLS, glutaminase; GLUT, glucose transporter; GM-CSF, granulocyte-macrophage colony-stimulating factor; GOT, glutamate oxaloacetate transaminase; GPI, glucose phosphate isomerase; GPT, glutamate pyruvate transaminase; GTP, guanosine-5'-triphosphate; 2-HG, 2-hydroxyglutarate; HIF, hypoxia-inducible factor; HSC, hematopoietic stem cell; IDH, isocitrate dehydrogenase; IMPDH, inosine monophosphate dehydrogenase; LDHA, lactate dehydrogenase A; LKB1, Liver kinase B1; LSC, leukemic stem cell; Max, Myc-associated factor X; MDM2, mouse double minute 2 homolog; Miz-1, Myc-interacting zinc finger protein 1; MLL2, mixed-lineage leukemia protein 2; Mlx, Max-like protein X; MondoA, member of the MYC network of transcription factors

that upregulates glycolysis (known as MLXIP, MLX interacting protein); mTOR, mammalian target of rapamycin; mTORC1, mTOR complex 1; MYC, a protooncogene that is a major regulator of cell growth and metabolism; NADH, nicotinamide adenine dinucleotide; NADPH, nicotinamide adenine dinucleotide phosphate; NAMPT, nicotinamide phosphoribosyltransferase; NRF2, nuclear respiratory factor-2; NTP, nucleotide triphosphate; ODC, ornithine decarboxylase; OGDH, oxoglutarate dehydrogenase; OXPHOS, oxidative phosphorylation; ρ 53, activates oxidative phosphorylation and inhibits glycolysis; PC, phosphatidyl choline; PDH, pyruvate dehydrogenase; PDK, pyruvate dehydrogenase kinase; PE, phosphatidyl ethanolamine; PEP, phosphoenol pyruvate; PFK, phosphofructokinase; PG, glycerophosphoglycerol; PGC1 α , an activator of mitochondrial biogenesis; PI, phosphatidyl inositol; PI3K, phosphoinositol 3'-kinase; PML, promyelocytic leukemia; PRPS, 5-phosphoribosyl-pyrophosphate synthetase; PS, phosphatidyl serine; PTEN, phosphatase and tensin homologue deleted on chromosome 10, an antioncogene; RAS, name given to a family of related proteins belonging to small GTPase involved in signal transduction; ROS, reactive oxygen species; rRNA, ribosomal RNA; SAM, S-adenosylmethionine; SCO_2 , cytochrome c oxidase; SDH, succinate dehydrogenase; SLC1A5, ASC amino-acid transporter 2; SOD, superoxide dismutase; TCA, tricarboxylic acid; TET, family of dioxygenases that catalyze conversion of 5-methylcytosine to 5-hydroxymethylcytosine; TFEB, transcription factor EB; THF, tetrahydrofolate; VHL, von Hippel-Lindau protein.

the brain. How whole organisms initiate autophagy (self-eating) during markedly prolonged starvation has not been thoroughly studied. But autophagy is clearly necessary for mammalian development, particularly upon birth when deletion of specific autophagic regulators results in death.⁴ Although autophagy plays an important role in mitochondrial and organellar homeostasis and cancer metabolism, it is discussed in Chap. 15; this chapter focuses primarily on intermediary metabolism.

Although most of our cells are differentiated and do not proliferate, stem cell compartments are ubiquitous among tissues, allowing for replacement of used or damaged cells. The hematopoietic stem cell and hematopoiesis constitute probably the best-studied stem cell system.⁵ Cytokines, growth factors, and the extracellular matrix provide the cues for stem cells to maintain their quiescent state or to awaken and differentiate to replenish lost cells. In response to growth factors in the presence of nutrient-replete states, stem cells self-renew, proliferate, and then differentiate. In nutrient-deprived states, normal metabolic checkpoints forbid growth factor stimulated cells from proliferating.⁶ All of the mechanisms used by normal cells during fed and starved states are potentially exploitable by neoplastic cells for their survival. Genetic mutations drive neoplastic cells to grow and proliferate regardless of the availability of nutrients; in contrast, normal cells sense nutrients and do not proliferate under starved conditions. In this chapter, basic cell metabolism is covered along with discussions about growth signaling and its intersection with metabolism. Alterations in metabolism found in hematologic neoplastic cells are discussed in the context of therapeutic opportunities that are rapidly emerging from the latest basic research and translational efforts.

● CELL GROWTH AND METABOLISM

HOMEOSTASIS

The canonical cell has significant bioenergetic needs for maintenance and homeostasis.⁶ Protein synthesis and maintenance of cellular membrane potentials consume most of the ATP produced under homeostatic conditions.⁷ In many differentiated or quiescent cells, it is believed that fatty acid oxidation provides the bulk of the energy, followed by the use of glucose. In this regard, mitochondrial respiration is essential for adult tissues and cells. It is notable, however, that specialized cell functions in the various organs could require different metabolic pathways. Glucocorticoid hormone-producing cells, for example, express specialized metabolic pathways. Although cardiac muscle cells depend heavily on fatty acid oxidation, skeletal muscle cells use glucose. The brain depends largely on glucose, but it can feed on ketone bodies under starved states. For differentiated cells, which are the bulk of cells in mammals, homeostasis drives the demand for nutrients, to “the availability of which are determined by feeding and interorgan (liver, muscle, and endocrine tissues) metabolic interplays. For example, lactate produced by exercising muscle circulates back to the liver and is processed via the Cori cycle to produce glucose.³ Glucose plasma level is tightly controlled by the pancreas, which produces insulin and glucagon, and by the liver (as well as kidney) that can produce glucose through gluconeogenesis.

CELL GROWTH: SIGNALING, NUTRIENTS, AND METABOLISM

Normal cell growth and proliferation are triggered by extracellular cues. Yeast cells, for example, only require the presence of nutrients to initiate cell growth or an increase in cell size.⁶ During this growth phase, nutrients are imported and channeled into biomass, which is largely

comprised of ribosomes. It is estimated that ribosomes constitute more than 50 percent of cellular dry mass, and hence ribosome biogenesis is highly regulated and vitally important for cell growth and proliferation. Once a critical cell size (mass) is reached with a balanced nucleotide pool, DNA synthesis begins. Yeast cells sense nutrients, particularly glucose and glutamine, through pathways involving RAS and target of rapamycin complex 1 (TORC1), which silence transcriptional repressors of ribosome biogenesis.⁸ With nutrient deprivation, activation of these transcriptional repressors provides a metabolic checkpoint that restrains cells from growing in the absence of adequate bioenergetic support. Hence, the normal feedback loops couple nutrient availability with cell growth: no nutrients, no growth. The normal feedback loops can be artificially disrupted by deletion of transcriptional repressors of ribosomal biogenesis, rendering yeast mutants constitutively activated for growth. These mutants resemble mammalian cancer cells, which have mutations that drive autonomous cell growth with disregard for nutrient availability. The severance of nutrient sensing from growth signaling causes addiction of these yeast mutants to nutrients, such that deprivation of glucose or glutamine results in nonviable mutants. Similarly, cancer cells are addicted to nutrients.⁶

Cell growth in multicellular organisms requires additional cues in addition to the availability of nutrients. Mammalian cells live in a community of cells and are constantly bathed in nutrients derived from the circulation, but they do not proliferate unless there are appropriate cues from growth factors and the extracellular matrix. Mammalian cells can be envisioned as bioreactors that require at least two signals to grow: (1) growth factor and (2) nutrients.⁶ Cell growth is arrested in the absence of either growth factor or nutrients. Similar to yeast cells, metabolic checkpoints are critical to the growth of normal mammalian cells.

Growing cells largely depend on glucose, glutamine and other amino acids.⁹ Indeed, the core metabolic pathways including glycolysis, glutaminolysis, and the tricarboxylic acid (TCA) cycle link amino acid and glucose metabolism to lipogenesis and nucleotide synthesis (Fig. 14–1). Glycolysis starts with the transport of glucose into cells through several transporters, known as GLUTs, with SLC2A1 (GLUT1) being one that is coupled with cell growth stimulation. Once inside the cell, glucose is phosphorylated in an ATP-consuming step by hexokinases (HK) with HKII being stimulated by many growth signals and directly regulated by the MYC oncogene or the hypoxia inducible factor 1 alpha (HIF-1 α). Glucose-6-phosphate (G6P) is used by the pentose phosphate pathway to produce ribose for nucleotide synthesis (Fig. 14–1) or converted to fructose phosphate via an isomerization reaction catalyzed by glucose phosphate isomerase (GPI).⁹ Fructose-6-phosphate is further phosphorylated with consumption of a second ATP through a rate-limiting step catalyzed by phosphofructokinase (PFK) to fructose-1,6-bisphosphate (F1,6BP). F1,6BP is converted by aldolase and an isomerase to the three-carbon phosphorylated molecule, glyceraldehyde 3-phosphate (GAP), which is oxidized and phosphorylated using inorganic phosphate by the dehydrogenase, GAPDH, to 1,3-bisphosphoglycerate. The energy gained by nicotinamide adenine dinucleotide (NAD⁺)-mediated oxidation and phosphorylation is released from 1,3-bisphosphoglycerate by phosphoglycerate kinase, which transfers the high-energy phosphate bond to adenosine diphosphate (ADP) to form ATP. The resulting 3-phosphoglycerate (3-PG) provides a substrate for serine and glycine synthesis, for the production of glycerol, or for the production of phosphoenol pyruvate (PEP) in glycolysis. Pyruvate kinase mediates the transfer of the high-energy phosphate bond from PEP to ADP producing ATP and pyruvate, which is the terminal substrate of glycolysis. Collectively, glycolysis uses ATP to charge up several intermediates for their transformations and uses NAD⁺ to oxidize intermediates and generate energy through new high-energy phosphate bonds with inorganic phosphate. Each glucose molecule results in the production of a net two ATP molecules from ADP through glycolysis.

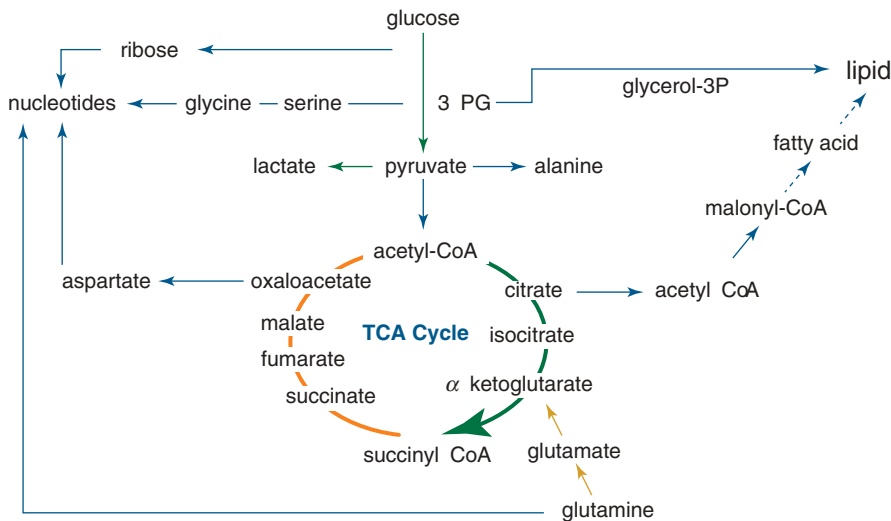

Figure 14-1. Central metabolic pathways involving glycolysis, glutaminolysis, and the tricarboxylic acid (TCA) cycle. Glucose is shown metabolized to pyruvate, which can be converted to lactate, alanine, or acetyl-coenzyme A (*acetyl-CoA*). Upstream of pyruvate, glucose carbons are shunted toward the pentose phosphate pathway for ribose synthesis, glycine, and glycerol synthesis. Acetyl-CoA (2-carbon unit) combines with oxaloacetate (4-carbon) to form citrate (6-carbon), which is subsequently metabolized in the TCA cycle to generate isocitrate, α -ketoglutarate, and other intermediates as depicted. Glutamine is shown to enter the TCA cycle via α -ketoglutarate, after being converted to glutamate. Glucose gives rise to glycerol and citrate, which contributes 2-carbon units for fatty acid synthesis, and contributes to lipid synthesis. Glutamine and glucose are depicted to contribute to nucleotide synthesis.

Pyruvate, derived from glucose through glycolysis, from malate through malic enzyme or from alanine through transamination, could enter the mitochondria through specific transporters and be converted to acetyl-coenzyme A (CoA) by pyruvate dehydrogenase (PDH) (see Fig. 14-1).¹⁰ PDH activity can be attenuated by phosphorylation, mediated by PDH kinase (PDK), which is activated by hypoxia to divert glucose carbons away from the TCA cycle toward lactate production. Under aerobic conditions, acetyl-CoA combines with oxaloacetate coming from a complete turn of the TCA cycle to produce citrate, which can be extruded into the cytoplasm to participate in lipid synthesis or which can be converted to isocitrate in the TCA cycle. Isocitrate is further oxidized to α -ketoglutarate by isocitrate dehydrogenase (IDH) with the production of either nicotinamide adenine dinucleotide (NADH) or nicotinamide adenine dinucleotide phosphate (NADPH) and release of a carbon dioxide molecule. There are three IDH isozymes with IDH1 being located in the cytosol, while IDH2 and IDH3 are in the mitochondrion. NADH in the mitochondrion contributes to the high-energy electrons that drive production of ATP through the electron transport chain. NADPH produced by cytosolic IDH1 or mitochondrial IDH2 could participate in reductive biosynthesis of fatty acids or nucleobases.

In addition to being a key TCA cycle intermediate at the crossroads of several metabolic pathways, α -ketoglutarate (or oxoglutarate) serves as a cofactor for many important oxygenases, such as those involved in the hydroxylation and degradation of the hypoxia inducible factors (HIFs), modification of ribosomes, or those involved in demethylation of DNA and histones.^{11,12} Notably, glutamine can enter the TCA cycle at this junction. α -Ketoglutarate is further oxidized by oxoglutarate dehydrogenase (OGDH) to produce succinyl-CoA and carbon dioxide. Succinyl-CoA, which is also used for heme synthesis, is then converted to succinate with the production of a guanosine-5'-triphosphate (GTP) from guanosine-5'-diphosphate (GDP). Succinate is then converted to fumarate by succinate dehydrogenase (SDH), which is mutated in certain familial cancer syndromes. Fumarate hydratase (FH), which is also mutated in cancer syndromes, converts fumarate to malate that is, in turn, converted to oxaloacetate. Oxaloacetate can serve as a substrate for glutamate oxaloacetate transaminase (GOT) for the production of aspartate for nucleotide synthesis, or it can further cycle forward into the TCA cycle by combining with acetyl-CoA to form citrate, thus completing the TCA (citric acid or Krebs) cycle (see Fig. 14-1).

Glutamine also serves as a key metabolic substrate for growing cells (see Fig. 14-1). Glutamine is imported by membrane transporters, such as SLC1A5 or ASCT2.^{13,14} Once in the cytosol, glutamine can

contribute to protein synthesis or glucosamine or nucleobase biosynthesis by donating its nitrogen. Glutamine is further imported into the mitochondrion and converted to glutamate by glutaminase (GLS) with the release of ammonia. Glutamate is converted to α -ketoglutarate by either glutamate dehydrogenase (primarily in nongrowth states) or aminotransferases (GOT or glutamate pyruvate transaminase [GPT]). In this manner, glutamine serves as a major growth substrate for growing cells. Hence, the TCA cycle is a metabolic roundabout that uses carbons from glucose, glutamine, and fatty acids to generate carbon skeletons for biosynthesis, NADH for the production of ATP, or α -ketoglutarate for catalyzing key oxygenase reactions.

Oxidation of glucose, glutamine, and fatty acids produces energy for growing cells. On the other hand, synthesis of fatty acids and other building blocks require the reductive power of NADPH for bond formation. NADPH is produced from several well-characterized pathways, including the pentose phosphate pathway, malic enzyme, IDH, and the folate pathway.¹⁵ Glucose-6-phosphate dehydrogenase (G6PD) is well-known for its role in oxidation of G6P to 6-phosphogluconolactone and the concurrent reduction of NADP⁺ to NADPH, which contribute to an antioxidant state through maintaining reduced glutathione. Specifically, loss of G6PD function is associated with severe hemolytic anemia in patients who inherit hypomorphic alleles of G6PD (see Chap. 47). Malic enzyme mediates the oxidation of malate to pyruvate using nicotinamide adenine dinucleotide phosphate (NADP⁺), which is reduced to NADPH. IDH1 oxidizes isocitrate to α -ketoglutarate with the production of NADPH from NADP⁺. Lastly, it was recently documented that the folate pathway plays a major role in NADPH production through the oxidation of methylene-tetrahydrofolate (THF) to formyl-THF.¹⁵ The largest consumer of NADPH, on the other hand, involves fatty acid synthesis with reduction of glutathione following closely behind. Thus production of NADPH is critical for both biosynthesis and for redox homeostasis.

● SIGNAL TRANSDUCTION: ONCOGENES, TUMOR SUPPRESSORS AND METABOLISM

Growth factors and nutrients drive the growth and proliferation of cells (Fig. 14-2 and Chap. 17). Growth factor engagement of a (usually dimeric) growth factor receptor triggers allosteric alterations that lead to autophosphorylation, in the case of the receptor tyrosine

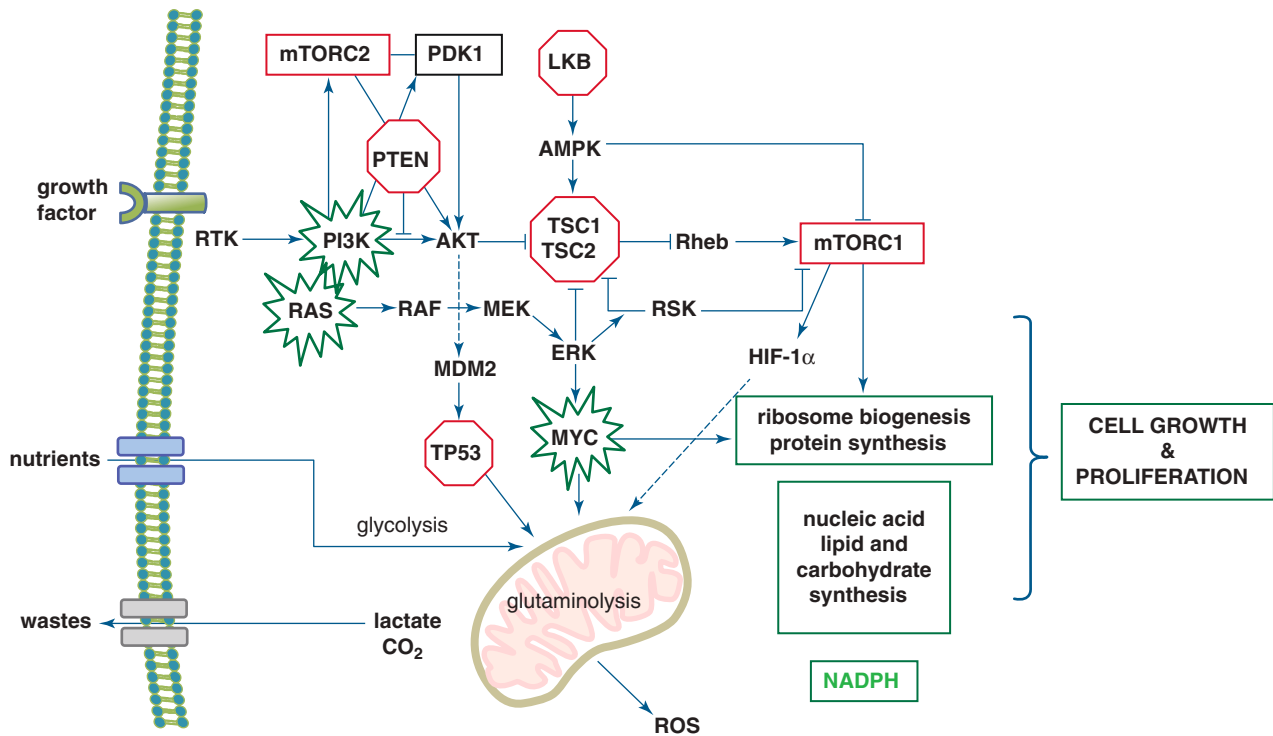

Figure 14-2. Canonical signal transduction pathways emanating from a receptor tyrosine kinase and their connections to metabolism. The phosphoinositid 3'-kinase (PI3K)-PTEN-Akt and Ras-Raf-ERK (extracellular regulated kinase) pathways are shown with connections to MYC and hypoxia-inducible factor 1 (HIF-1 α), which trigger metabolic transcriptional programs. All of these pathways coordinate a response to growth factors and drive nutrients into the cell to generate ATP and building blocks for lipid, nucleotide, and protein synthesis. The net result is cell growth and generation of waste products, such as reactive oxygen species (ROS), lactate and carbon dioxide. Tumor suppressors (red octagons) and protooncogenes (green bursts) are highlighted.

kinase family, or phosphorylation by Janus kinase in the cases of the hematopoietic cytokine receptor family. The phosphorylated receptor then recruits adaptor molecules that initiate a cascade of phosphorylation events, which culminate in the activation of concurrent pathways through phosphoinositid 3'-kinase (PI3K)/PTEN/AKT and RAS-RAF-ERK (extracellular regulated kinase) (Fig. 14-2). These cascades relay signals to mTOR complex, which is a vital hub for metabolic sensing and short-term post-transcriptional control of cell growth.¹⁶ mTOR, potentially coupled with additional outputs of the RAS-RAF-ERK pathway, also activates a genomic response to the growth signal. In essence, the mTOR pathway provides an immediate response to growth stimulus and nutrients followed thereafter by a transcriptional response that provides an increase in specific mRNAs needed for the production of new building blocks for the growing cell. The initial growth response occurs in cells that have a basal number of ribosomes, which serve to translate delayed early response genes. The cascade down the ERK pathway also activates the expression of early response genes such as FOS and MYC. The activation of MYC is probably mediated through the ERK-activation of Ets transcription factors, whose regulatory motifs are found in the MYC gene.¹⁷ Furthermore, ERK phosphorylates and stabilizes the MYC protein, enhancing ERK's ability to drive a transcriptional response to growth.^{18,19}

The immediate sensing of nutrients is mediated through the adenosine monophosphate kinase (AMPK) and mTOR pathways, which, in turn, modulate cellular responses through phosphorylation of regulatory proteins (see Fig. 14-2).^{9,16,20} In the presence of nutrients, the import of branched-chain amino acids is sensed through lysosomes to activate mTOR complex 1 (mTORC1). Import of glutamine, which is converted to glutamate, is thought to play an important role in

activating mTOR through the antiporter, SLC7A1, which exports glutamate in exchange for leucine. Leucine is one of the most potent activators of mTORC1, which, in turn, phosphorylates key regulatory proteins to increase protein translation, mitochondrial biogenesis and respiration, glycolysis, and lipogenesis. Many of these effects are also mediated through mTORC1's regulation of transcription factors such as PGC1 α (mitochondrial biogenesis), HIF-1 α (glycolysis), and SREBP (lipogenesis). mTORC1 also phosphorylates and inactivates the transcription factor TFEB, which is a master positive regulator of lysosome biogenesis.¹⁶ Presumably, inhibition of TFEB would also diminish the machinery involved in autophagy. Although mTORC1 also stimulates ribosome biogenesis, the mechanism by which this occurs is not yet known. Activation of the mTORC2 complex is less well defined, but mTORC2 is responsible for the subsequent activation of AKT that plays a critical role in activating glycolysis. Thus, growth factor signaling stimulates nutrient uptake that in turn activates mTOR to stimulate cell growth.

In nutrient-deprived states, the AMPK pathway regulates cellular responses that optimize energy production and diminish energy utilization pathways (see Fig. 14-2).^{20,21} AMPK is allosterically altered by binding to adenosine monophosphate (AMP), which makes AMPK permissive for phosphorylation and activation by the tumor suppressor LKB1. The phosphorylated AMPK in turn phosphorylates and regulates many pathways involved in energy regulation. One of the earliest discoveries was that AMPK phosphorylates and inactivates acetyl-CoA carboxylase, which is involved in fatty acid synthesis. Thus, by diminishing lipogenesis, AMPK is able to inhibit an energy consuming process as well as inhibit cell growth by curbing lipogenesis. AMPK also attenuates protein synthesis through phosphorylation of RNA polymerase I,

which is required for ribosome biogenesis. On the other hand, AMPK increases energy yield by stimulating glycolysis through phosphorylation and activation of PFK-2. AMPK stimulates mitochondrial biogenesis through phosphorylation of PGC1 α and increases autophagy to recycle energy by phosphorylating ULK-1.²¹ Thus, increased AMPK activity conserves energy and maximizes energy production.

Together with posttranscriptional responses to growth signaling and nutrients, the nuclear transcriptional response is necessary to sustain the growth program through production of components of the ribosome and mRNAs that give rise to all other components of the cell. mTOR through its direct activation of specific transcription factors contributes to lipogenesis and mitochondrial biogenesis. Growth signaling also activates the MYC protooncogene, that regulates gene expression broadly to support cell growth and proliferation (see Figs. 14–2 and 14–3).¹⁹ Loss of function of *Drosophila* dMYC results in decreased cell and body size, a phenotype that underscores MYC's role in cell growth.²² This phenotype mimics the loss of ribosome protein gene function in a group of mutant flies termed *Minutes*. Hence, *Drosophila* genetics links MYC to cell growth control. Furthermore, MYC is the only transcription factor capable of stimulating the activity of RNA polymerases I, II, and III, all of which are involved in ribosome biogenesis.

MYC dimerizes with its partner Max to bind a specific DNA sequence, termed E-box (CACGTG), and activate transcription.²³ It can also inhibit transcription partly through direct binding to Miz-1 and diminishing the expression of Miz-1 target genes, including the cyclin-dependent kinase (CDK) inhibitor p21 and genes involved in autophagy. Upon MYC activation, it is binding to proximal promoters accounts for most of its transcriptional function in normal cells. When MYC is experimentally expressed at levels comparable to those found in cancers,¹⁹ excess MYC triggers p53-dependent checkpoints (see Fig. 14–3) that cause cell growth arrest or apoptosis. In multistep tumorigenesis, therefore, p53 is often lost, unleashing MYC's full oncogenic potential. A high, unchecked level of MYC allows it to alter the transcriptome by amplifying selected target genes.²⁴ MYC was first shown to

directly regulate genes involved in glycolysis, thereby linking an oncogenic transcription factor to metabolism.^{6,19} Since these initial observations, high-throughput methods have mapped MYC to a broad swath of metabolic enzyme genes involved in glycolysis, glutaminolysis, and lipogenesis. MYC also directly regulates genes involved in mitochondrial biogenesis and the production of ribosomes. Specifically, genes highly induced by MYC include those involved in nucleolar function and ribosome biogenesis, such as Ncl, NPM1, fibrillarin, and NOP52. Collectively, these studies uncover MYC's role as a central regulator of cell growth through coupling of energy metabolism with cellular biosynthetic processes.

Ribosome biogenesis is a critically important process for cell growth or cell mass accumulation.^{25,26} Ribosomes are produced through RNAs that are transcribed by RNA polymerases I (rRNA [ribosomal RNA]), II (mRNA), and III (tRNAs [transfer RNAs] and small RNAs). rRNA is synthesized in the nucleolus from high copy numbers of rDNA, whose chromatin structure and transcription depends on nutrient availability. Under nutrient limitation, rDNA chromatin becomes less accessible, thereby restricting ribosome biogenesis.²⁶ Ribosomal proteins produced from mRNAs reenter the nucleolus, where components of ribosomes are assembled into mature ribosomal particles, which are exported to the cytosol. The production of rRNAs and proteins also provides an opportunity for bioenergetic sensing of adequate nutrients to support nucleic acid and protein synthesis required for growth. In this regard, specific ribosomal protein subunits (RPL5, RPL11, and others) can bind and inhibit MDM2 (mouse double minute 2 homolog), which binds to and mediates the degradation of p53.²⁵ Thus, it is surmised that ribosomal proteins in excess of rRNAs would activate p53, triggering checkpoints that block progression through the cell cycle, presumably in response to nutrient limitation sensed as an imbalance in rRNA and ribosomal protein synthesis.

In addition to sensing ribosome biogenesis, p53 also responds to genotoxic stresses by directly regulating metabolism (see Fig. 14–2). P53, in general, activates oxidative phosphorylation and inhibits glycolysis.²⁷ P53 can activate HK, which phosphorylates glucose in the first step of glycolysis, and stimulate TIGAR that shunts glucose to the pentose phosphate pathway through decreasing the levels of fructose-2,6-bisphosphate (F2,6BP), which allosterically activates PFK. P53 also increases the efficiency of mitochondrial function through induction of cytochrome c oxidase (SCO₂).²⁸ Overall, it appears that the normal function of p53 is to rewire metabolism to mitigate oxidative stress through increased production of NADPH and the antioxidant glutathione. Gain of p53 function through specific mutations, on the other hand, appears to alter metabolism through specific target genes that are involved in cholesterol biosynthesis or phospholipase function.^{29,30}

Other tumor suppressors are also involved in metabolism (see Fig. 14–2). PTEN negatively modulates PI3K, and hence its loss stimulates the PI3K pathway that is a potent regulator of cell metabolism through stimulation of glycolysis and activation of mTOR, AKT, MYC, and HIF.³¹ The tumor suppressor LKB1, which is lost in some lung cancers, normally activates the AMPK pathway and diminishes lipogenesis.²¹ Loss of the von Hippel-Lindau (VHL) tumor suppressor activates HIF, which transcriptionally regulates glucose metabolism.³² In addition to any direct roles they play in regulating the cell-cycle machinery, tumor suppressors—similar to protooncogenes—also regulate metabolism. By coopting cellular responses to growth factor stimulation in the presence of nutrients, activation of oncogenes and disablement of tumor suppressors achieve coordinated posttranscriptional and transcriptional mobilizations that drive nutrients into ATP production and the building blocks for growing cells.

Growth factor stimulation also results in the production of metabolic wastes and toxins, including carbon dioxide, lactate, and reactive

Figure 14–3. Diagram depicting fates of growth factor-stimulated normal cells and MYC transforming cell. Upon engaging a growth factor (pink square), the stimulated cell reacts as a bioreactor, which grows and duplicates itself. MYC overexpression triggers checkpoints via p53, which induces cell death. With loss of p53 MYC's full transforming potential is unleashed through its transcriptional activities.

oxygen species (ROS) (Fig. 14–2). In this regard, various mechanisms have evolved to eliminate these wastes that accumulate as cells discard entropy into the environment after consuming “negative entropy” (macromolecules) to survive and grow. Carbon dioxide and protons are neutralized by carbonic anhydrase. Lactate is exported by monocarboxylate transporters.³³ Reactive oxygen species (ROS) are generated by the mitochondria and other cellular reaction pathways, such as via NADPH oxidases or disulfide bond formation.³⁴ ROS participates in signaling at ambient levels; however, very high levels of ROS result in oxidative cellular stress.^{34,35} In particular, electrons leaking from the mitochondrial electron transport chain (ETC) contribute to a large fraction of cellular ROS.³⁵ Electrons are donated to the chain by NADH or succinate at mitochondrial complexes I, II, and III, which all generate ROS. Complexes I and II release ROS into the mitochondrial matrix, whereas complex III releases ROS into space on both sides of the inner mitochondrial membrane. Complex I accepts electrons from NADH, which is generated from TCA cycle oxidation, and passes them on to ubiquinone or coenzyme Q that also accepts electrons from succinate via complex II (SDH). Coenzyme Q then passes electrons to complex III, which, in turn, passes them onto cytochrome c. Finally, electrons are passed from cytochrome c to complex IV or cytochrome c oxidase that generates water from electrons, protons, and oxygen, which serves as the final electron acceptor. Upon accepting electrons at complexes I, III, and IV, a proton is pumped into the intermembrane space, creating a proton gradient across the inner mitochondrial membrane. The proton gradient is dissipated through complex V or ATP synthase with the generation of ATP from ADP. During the process of making ATP, leakage of electrons from complexes I, II, and III generates superoxide from oxygen.

Superoxide is highly reactive and could damage membranes and proteins if unattenuated. Hence, superoxide dismutases (SODs) have evolved to convert superoxide to hydrogen peroxide, which is, in turn, neutralized by catalases and converted to water and oxygen. In addition to enzymatic ROS neutralizers, the family of peroxiredoxins also plays an important role in titrating mitochondrial and cytosolic ROS by neutralizing hydrogen peroxide. Because oxidative stress imposed by ROS is a part of normal metabolism, a system of cellular response to this stress has evolved. Immediate response to ROS is mediated by SOD, catalase, peroxiredoxins, and glutathione. A sustained response to ROS is mediated chiefly through NRF2, which is a transcription factor that is negatively regulated by KEAP1, a protein that is directly inhibited by oxidative modification of sensitive cysteine residues.³⁶ NRF2 activates many genes involved in redox homeostasis, including SODs and catalase. Intriguingly, KEAP1 has been identified as a tumor suppressor in human cancers, illustrating that increased NRF2 activity or antioxidant response is protumorigenic in the setting of heightened metabolic rates and oxidative stress.

METABOLISM AND THE EPIGENOME

Cells have evolved a genome that mediates posttranscriptional and transcriptional mechanisms to import nutrients and harness energy and building blocks for the growing cell. In turn, metabolic intermediates generated from various nutrients can modulate gene expression, seemingly as an adaptive response to the metabolic milieu.^{37–39} The epigenome is richly regulated by metabolic intermediates such as acetyl-CoA, S-adenosylmethionine (SAM), α -ketoglutarate, NAD⁺, and N-acetylglucosamine.⁴⁰ Acetyl-CoA mediates histone acetylation and modulates gene expression by rendering the genome accessible to specific transcriptional factors. SAM permits methylation of histones and DNA to prevent access of the transcriptional machinery to certain DNA sequences. α -Ketoglutarate serves as a cofactor for histone and DNA demethylation reactions, thereby countering the modifications

provided by SAM. NAD⁺ serves as a cofactor for sirtuins that play a key role in histone deacetylation. N-acetylglucosamine, which is produced from glucose and glutamine, serves to modify histones. Other metabolic intermediates such as propionate, butyrate, formate, and crotonate also play a role in modifying histones, which have emerged as the metabolic sensor for gene expression.⁴⁰

The evolution of cancers is not only driven by hard-wired somatic DNA mutations and predisposing germline alleles but also by erasable covalent modifications of DNA and histones. A deregulated epigenetic regulatory system, which randomly silences or makes more accessible portions of the genome, could enhance the adaptability of cancer cells and thus provide a selection advantage that does not require DNA mutations. In this regard, deep sequencing of human cancers, particularly leukemias, has revealed that chromatin-modifying proteins, such as MLL2 (mixed-lineage leukemia protein 2), are frequently mutated at the somatic level.^{41,42} Thus, somatic mutations in chromatin modifiers are surmised to increase the degrees of freedom for cancer cell adaptation to the dynamic tumor microenvironment and permit tumor progression.

HEMATOLOGIC NEOPLASMS AND METABOLISM

Normal hematopoietic stem cells (HSCs) and committed multipotent progenitor cells appear to have different metabolic programs, which may be adopted in the neoplastic state. The HSC resides in a hypoxic environment, and hence low mitochondrial mass and high glycolytic rates appear favored for survival. One of the mechanisms by which the hypoxic HSC niche induces stem cell quiescence is through HIF-1 α and inhibits, which transactivates genes involved in glycolysis and inhibits DNA replication.³² Two studies of HSCs documented that HIF-1 α is essential for the quiescent state, such that deletion of HIF-1 α resulted in HSC proliferation and depletion of the HSC compartment.^{43,44} Conversely, loss of VHL stabilized HIF-1 α resulted in an expansion of the HSCs incapable of replenishing hematopoietic cells, resulting in cytopenia. Intriguingly, three studies showed that the LKB1 tumor suppressor also plays a role in HSC quiescence; loss of LKB1 resulted in cell proliferation and loss of the HSC compartment.^{45–47} Interestingly, loss of LKB1 in HSCs does not seem to be mediated solely through AMPK, as loss of AMPK in HSCs did not phenocopy the HSC nonquiescent phenotype seen with LKB1 loss. Instead, one study identified the mitochondrial biogenesis coregulators, PGC1 α and PGC1 β , as being central to the LKB1 loss phenotype.⁴⁵ Loss of LKB1 in HSCs was associated with decreased expression of PGC1 α and PGC1 β and decreased mitochondrial DNA content and membrane potential. These studies collectively suggest that both HIF-1 α and LKB1 are necessary for induction of quiescence by the hypoxic microenvironment. Loss of either HIF-1 α or LKB1 resulted in increased HSC proliferation and, presumably, commitment toward progenitors, thereby depleting the HSC pool. Although the hypoxic HSC microenvironment suggests that glycolysis predominates, it should be noted that hypoxic cells can still respire and consume oxygen. In fact, cytochrome c oxidase only ceases to function at oxygen tension well below 0.5 percent (as compared to the ambient 21 percent oxygen or approximately 6 percent oxygen found in perfused normal tissues). As such, the observation that loss of LKB1 is associated with a mitochondriopathy in HSCs suggests that mitochondrial function is essential for HSC maintenance, and may resolve the paradox that HSCs seem to rely also on glutamine oxidation (Fig. 14–4).

The HSC uses symmetric commitment to replenish and maintain the stem cell pool and asymmetric division for the generation of committed progenitors (see Fig. 14–4). HIF-1 α and LKB1 appear to play a

Figure 14-4. Metabolic features of hematopoietic stem cells undergoing symmetric and asymmetric division. Some of these features appear to be preserved in leukemic stem cells.

role in maintaining symmetric commitment. Fatty acid and glutamine oxidation, which requires mitochondrial function, may be required for asymmetric commitment toward progenitors. Surprisingly, despite anticipated HIF-mediated upregulation of glycolysis, the inducible glucose transporter GLUT1 is not highly expressed in HSCs and is only expressed upon differentiation.⁴⁸ Instead, the glutamine transporter ASCT2 (SLC1A5) is more highly expressed in HSCs, suggesting that glutamine oxidation via the TCA cycle unexpectedly plays a role in hypoxic stem cell metabolism. Consistent with the notion that hypoxic cells continue to respire, recent studies with human B cells or fibroblasts illustrate this capacity to oxidize glutamine in hypoxia when glucose is largely shunted away from the TCA cycle as lactate.^{49,50} Interestingly, glutamine metabolism also appears to influence cell fate. For example, persistent glutamine metabolism in HSCs seems required for erythroid differentiation as glutamine deprivation blunts erythroid nucleotide synthesis and favors differentiation toward the myelomonocytic lineage even in the presence of erythropoietin.⁴⁸ Fatty acid oxidation, on the other hand, appears to be necessary for asymmetric division. Activation of peroxisome proliferator-activated receptor (PPAR)- δ , which augments mitochondrial function and fatty acid oxidation through the promyelocytic leukemia (PML)-PPAR δ -fatty acid oxidation (FAO) pathway, increases asymmetric stem cell division, whereas inhibition of FAO enhances symmetric stem cell commitment.⁵¹ These findings suggest that mitochondrial oxidation of fatty acids and glutamine may play a role in asymmetric division and lineage commitment, while hypoxia-promoted glycolysis and, surprisingly, glutamine oxidation may be associated with the quiescent HSC pool. How these metabolic cues may affect cellular states through the epigenome is not yet known, however.

LEUKEMIAS

The history of the treatment of acute lymphocytic leukemia (ALL) underscores the importance of metabolism in our understanding of cancer. In fact, the first antimetabolite drug effective against any cancer, 4-aminopteroylglutamic acid (aminopterin), disrupts folate metabolism, which is intimately tied to NADPH production and nucleotide biosynthesis.⁵² The dependency of ALL on asparagine also provided a therapeutic opportunity through the use of L-asparaginase, which depletes plasma asparagine from patients.⁵³ The use of these antimetabolites

led to the current state of therapy in which more than 90 percent of children with ALL achieve complete a substantial improvement from the uniformly lethal disease it presented as 60 years ago. Despite this remarkable clinical progress, our understanding of metabolism in acute leukemias is still rudimentary. However, advances in metabolomics and next-generation DNA sequencing have revealed new insights that provide additional texture to this understanding.

Leukemias have diverse oncogenic drivers, with many chromosomal translocations found in ALLs and some acute myelogenous leukemias (AMLs).^{54,55} Whatever the oncogenic driver may be, the leukemic cells share common central metabolic pathways that support growth and replication, particularly glycolysis, glutaminolysis, and FAO (see Fig. 14-1). However, the fluxes through each of these pathways are likely different and dependent on the genomic alterations that are hard-wired by mutations. Much of our current understanding comes from *in vitro* studies of leukemic cell lines that have revealed their high glycolytic rates and use of glutamine. Many early studies, including those of Otto Warburg, revealed that leukemic cells have very high rates of conversion of glucose to lactate.⁵⁶ Recent studies extend these observations; specifically, high glycolytic rates in primary and relapsed AML correlate with resistance to all *trans*-retinoic acid (ATRA). For these cases better overall survival and attainment of complete remission are achieved with induction chemotherapy.⁵⁷ Another study documents that primary childhood ALLs have gene expression profiles that suggest increased glycolysis and decreased oxidative phosphorylation and FAO.⁵⁸ Gene expression profiling also catalogued another link between glucose metabolism and leukemia with the discovery that MondoA expression is significantly elevated in ALL.⁵⁹ MondoA belongs to a family of transcription factors, including carbohydrate response element binding protein, which senses nutrient states and regulates metabolism.²³ MondoA was discovered as an extended family member of the MYC:Max network of transcription factors. MondoA dimerizes with Mlx (Max-like protein X) to bind target DNA sequences and regulate glucose metabolism. Thus ALL seems to depend on MondoA, with lowered MondoA expression in ALL reducing glycolytic metabolism and enhancing ALL cell differentiation.

Studies of AML cell lines *in vitro* also revealed their dependency on glutamine, which contributes in part to oxidation-reduction (redox) homeostasis through the generation of glutathione.^{60,61} Primary AML

cells, in contrast with normal CD34+ cells, depend on glutamine and undergo apoptosis with glutamine withdrawal.^{62,63} Apoptosis appears to follow diminished mTORC1 activation. Furthermore, reduction of glutamine transport via ASCT2 (SLC1A5) diminishes AML cell line survival, underscoring the importance of glutamine metabolism in AML.⁶³ Clinical and laboratory experience with L-asparaginase also emphasizes the centrality of glutamine metabolism in ALL. L-Asparaginase is a highly effective agent against ALL, not only via the enzymatic activity embodied in its name, but also via “off-target” glutaminase activity.⁶³ Because glutamine also plays a critical role in the survival of ALL cells, they are likewise sensitive to L-asparaginase. The glutaminase activity of L-asparaginase additionally serves to reinforce the asparaginase activity of the drug, as glutamine released from the leukemic microenvironment can be used to regenerate asparagine in conjunction with aspartate via asparagine synthetase.⁵³ In one study, metabolites in the marrow of pediatric ALL were compared with those found in blood before and after standard therapy. Metabolites that were relatively depleted in the marrow prior to therapy include glutamine, glucose, and certain fatty acids.⁶⁴ These observations suggest that lymphoblasts or the microenvironment have heightened glycolysis, glutaminolysis, and perhaps fatty acid consumption. Upon therapy, there was severe depletion of asparagine and glutamine, with a more rapid recovery of peripheral glutamine levels after (therapy as also corroborated by another study).⁶⁵ Intriguingly, obese children with ALL do not respond well to L-asparaginase therapy, even with a significant reduction in asparagine and glutamine levels.⁶⁶ This phenomenon appears to be partly from the induction of glutamine synthetase in the marrow, which releases glutamine from adipocytes.⁶⁶ The notion that the tumor microenvironment, particularly mesenchymal cells, might contribute to the production of asparagine appears to be supported by the finding that marrow aspartate levels were higher than in the blood after L-asparaginase treatment while asparagine levels remained low. Thus, metabolism in the tumor microenvironment may affect therapeutic outcome.

Leukemic stem cells (LSCs) appear to adopt the ability of normal HSCs to use oxidative phosphorylation (see Fig. 14–4). Accumulating evidence suggests that FAO and ROS may also play important roles in LSC and HSC survival, self-renewal, and differentiation.^{51,67} In one study, AML LSCs with high clonogenicity were isolated from stem cells with low ROS levels.⁶⁸ Gene expression analysis comparing these cells with leukemic cells with high ROS levels or with normal CD34+ HSCs revealed elevated expression of Bcl-2, which plays a role in mitochondrial metabolism, in addition to its canonical role in apoptosis.⁶⁹ The LSCs with high Bcl-2 expression appear to be metabolically quiescent as compared with normal CD34+ HSCs, demonstrating low oxygen consumption and lactate production. In contrast, ROS-high leukemic cells are more metabolically active and have lower colony-forming units. The ROS-low cells are dependent on oxidative phosphorylation and incapable of mounting a glycolytic response, as evidenced by inhibition of Bcl-2 resulting in diminished oxidative metabolism and decreased survival of the LSCs. By contrast, ROS-high leukemic and normal HSCs can mount a glycolytic response in response to Bcl-2 inhibition. In a separate study, inhibition of Bcl-2 with a small molecule in combination with the fatty oxidation inhibitor etomoxir resulted in a decrease in the AML LSC compartment,⁶⁸ suggesting that FAO may play a role in the survival of LSCs. If the AML LSCs are similar, at least in part, to normal HSCs, which use FAO for generation of progenitors, then the proliferation of AML cells from LSCs may require fatty acids. Collectively, these results suggest that LSCs may rely on oxidative phosphorylation and may use fatty acids as a source of fuel for survival and generation of more differentiated AML cells from the LSC pool. Use of FAO is expected to increase ROS, which seems to be required for myeloid differentiation from the HSC compartment. In this regard, induction of

ROS, such as through the use of iron chelators, has been suggested as a therapeutic strategy that forces LSCs to differentiate.⁶⁷

Frequent mutations in AML, such as FLT3-ITD,^{70,71} result in constitutive receptor tyrosine kinase activation, which culminates in activation of PI3K, as well as many downstream events that are associated with increased glycolysis and glutaminolysis (see Fig. 14–2). It is surmised that these pathways would increase the dependency of AML cells on metabolism and mitochondrial function. In this regard, AML cells are sensitive to inhibition of mitochondrial complex I with metformin.⁷² Intriguingly, a large study of 400 AML patients revealed a serum metabolic signature pointing to heightened glycolysis and TCA cycle activity in AML that is associated with resistance to cytosine arabinoside.⁷³ These observations led to a metabolic prognostic score based on the levels of six circulating metabolites. Although this study documents the alteration of metabolism in AML patients, the general applicability of the metabolic prognostic score remains to be determined.

The metabolic pathways (glycolysis, glutaminolysis, and FAO) associated with different leukemic states are surmised to support cellular function, but it could be speculated that these specific pathways are compatible with maintenance of the epigenome of that cellular state. Specifically, the concentrations (and fluxes) of specific metabolic intermediates (e.g., SAM, acetyl-CoA, and α -ketoglutarate) associated with specific metabolic states could modulate the epigenome. The epigenetic influence of metabolism is perhaps best illustrated by the discovery of germline mutations in key metabolic enzymes found in familial cancer syndromes and of somatic mutations of IDH1 and IDH2 in a variety of cancers, including AML and angioimmunoblastic lymphoma.⁴²

Somatic mutations of IDH were first discovered in gliomas through deep sequencing.⁷⁴ Whole-genome sequencing subsequently revealed the same in a karyotypically normal case of AML.⁷⁵ These findings bolstered the notion that hardwired mutations of metabolism could be tumorigenic. A breakthrough in our understanding of IDH mutations in hematologic neoplasm came from a landmark biochemical study of mutant IDH, which revealed a neomorphic activity of the mutant enzymes.⁷⁶ Instead of just being inactive, unable to convert isocitrate to α -ketoglutarate (Fig. 14–5), the mutant enzymes reduces α -ketoglutarate to form the oncometabolite 2-hydroxyglutarate (2-HG), which can be detected at high levels in AML.⁷⁷ The role of 2-HG in cell growth was illustrated by studies of the leukemic granulocyte-macrophage colony-stimulating factor (GM-CSF)-dependent TF1 cell line, which when deprived of GM-CSF displays diminished growth partially rescuable by exposure to 2-HG.^{78,79} Biochemical studies of 2-HG indicate that it could compete with α -ketoglutarate in many oxygenase reactions that depend on α -ketoglutarate as a cofactor, specifically enzymes that are involved in DNA or histone demethylation.

The ability of 2-HG to interfere with epigenetic modifications suggests that IDH mutations promote tumorigenesis through the epigenome.³⁹ In this regard, genomics of AML reveal the mutual exclusivity of mutations of either IDH1 or IDH2 with mutations in TET2.⁴² TET2 produces a DNA demethylating enzyme and hence it appears that high levels of 2-HG production via IDH mutations phenocopies the loss of TET2 in AML. Furthermore, whole-genome methylation analysis uncovers distinct methylomes associated with IDH mutations, underscoring the role of IDH mutations in altering the epigenome in a way that makes myeloid progenitor cells permissive for leukemogenesis.⁸⁰ The emergence of specific drugs that inhibit IDH1 or IDH2 reveal that inhibition of mutant IDHs results in differentiation of AML cells. These observations indicate that the epigenome maintained by high levels of 2-HG prevents activation of a myeloid differentiation program, similar to the PML-RAR mutation found in acute PML, which can be induced to differentiate with retinoids. Intriguingly, IDH mutations are also found in other cancers, including angioimmunoblastic lymphomas, but not in other types of lymphomas.⁸¹

Figure 14–5. Neomorphic enzymatic activity of mutant isocitrate dehydrogenases (IDHs). IDH1 is shown localized in the cytosol, while IDH2 and IDH3 are found participating in the TCA cycle in mitochondria. Isocitrate generated from citrate is oxidized by IDH2 or IDH3 to produce α -ketoglutarate, which is further oxidized in the TCA cycle. IDH1 is depicted to convert isocitrate to α -ketoglutarate in the cytosol. Mutant IDH1 is shown to reduce α -ketoglutarate to 2-hydroxyglutarate (2-HG) with the production of NADP⁺ from NADPH. Glutamine is the main source of α -ketoglutarate that serves as substrate for mutant IDHs.

LYMPHOMAS

The lymphomas are a broad group of lymphoid malignancies spanning from the more indolent to the most aggressive forms, each with a spectrum of genomic alterations.^{82–85} The majority of lymphomas evolve from B-cells at different stages of differentiation in the course of the germinal center reaction (Chap. 78). B-cells activated by T-cell-dependent antigens undergo rapid bursts of growth, forming germinal centers where somatic hypermutation occurs for generation of antibody diversity and plasmacytic differentiation. These phases of B-cell development demand high levels of bioenergetic support and are the stages from which lymphomagenesis is launched. Mantle cell lymphoma arises from the mantle zone. Burkitt lymphoma, emanating from MYC activation, emerges from the pregerminal center compartment. The germinal center type B-cell lymphoma arises from the germinal center compartment, and the activated B-cell (ABC) type of lymphoma develops from the plasmacytic stage. The lymphomas retain the high energetic demands of the precursor cells, and hence the aggressive lymphomas are staged and followed by fluorodeoxyglucose positron emission tomography (FDG-PET), which documents the high levels of glucose uptake and retention in these lymphomas.^{86,87} It should be noted that the basis for high FDG-PET is the uptake and retention of 2-deoxyglucose through phosphorylation by HKs. A highly positive FDG-PET does not indicate whether glucose ends up being converted to lactate or being oxidized through the TCA cycle.

Burkitt lymphoma and diffuse large B-cell lymphoma (DLBCL) have high glycolytic flux driving glucose to lactate production. In clinically advanced cases, these lymphomas can present with severe lactic

acidosis without any evidence of septicemia.^{88,89} The high glycolytic flux is driven by MYC or PI3K activation of glycolysis in these lymphomas and by HIF-1 α , which is stabilized in hypoxic regions of the lymphomas (see Fig. 14–2). High glycolytic flux renders models of lymphomas sensitive to glycolytic inhibitors as well as inhibitors of monocarboxylate transporters that export lactate.⁹⁰ Inhibition of these transporters and subsequent buildup of lactate result in the inability of lactate dehydrogenase to recycle NADH to NAD⁺, culminating in inhibition of glycolysis because GAPDH requires NAD⁺ for its function upstream in the glycolytic pathway. The inhibition of glycolysis causes lymphoma cells to rely further on oxidative phosphorylation, rendering them sensitive to the antidiabetic drug and mitochondrial complex I inhibitor, metformin.

Genetic alterations in lymphomas including B-cell receptor mutations and MYC activation link the genome to alterations in cell metabolism. B-cell receptor activating mutations increase PI3K signaling and render DLBCLs highly glycolytic.⁹¹ High glycolytic rates allow for the synthesis of ribose, glycine, and aspartate, which are building blocks for nucleotide biosynthesis (see Fig. 14–1). Glutamine is also essential for the production of nucleotides and fatty acids. In this regard, glutaminolysis is increased by oncogenic MYC in a model of human Burkitt lymphoma.^{49,92–94} Hypoxic lymphoma cells increase glucose flux to lactate but continue to respire in a glutamine dependent fashion, such that inhibition of GLS with the small molecule BPTES diminishes lymphoma progression in preclinical xenograft models.⁴⁹

The rapid proliferation of aggressive lymphomas demands ample nucleotide pools for RNA and DNA synthesis. Many of the key nucleotide metabolic genes are direct targets of the MYC transcription factor, which plays a prominent role in many types of lymphomas.^{95,96}

Activation of normal lymphocytes results in a significant increase in 5-phosphoribosyl-pyrophosphate synthetase (PRPS). PRPS2 is not only a target of MYC essential for lymphomagenesis in transgenic mice, but its expression couples the regulation of protein synthesis with nucleotide synthesis.⁹⁷ *Prps2* transcription is directly activated by MYC, and the 5'-untranslated region (UTR) of *Prps2* requires the oncogenic translational factor eIF4E for its translation, thereby linking protein synthesis with the regulation of nucleotide metabolism. *IMPDH1* and *IMPDH2*, which encode the inosine monophosphate dehydrogenases that catalyze the oxidation of inosine monophosphate to xanthosine monophosphate in nucleotide biosynthesis, are also MYC target genes. Increased expression of inosine monophosphate dehydrogenases (IMPDHs) is a feature of lymphomas, and IMPDH is also thought to play an additional role as a transcription factor.⁹⁸ Mycophenolic acid is an immunosuppressant that targets IMPDH in lymphocytes, but its role in the therapy of lymphomas is not well-studied. However, it is not only the size of the nucleotide pool that is lymphomagenic, but also the imbalanced nature of that pool. DNA replication fidelity relies on balanced pools of nucleotides, with deoxyguanosine triphosphate (dGTP) tending to be limiting amongst the deoxynucleoside triphosphates (dNTPs).^{99,100} As such, the relative deficiency of deoxycytidine kinase in lymphomas could result in diminished deoxycytidine triphosphate (dCTP) pools that can induce replication stress and genomic instability.¹⁰¹ Alterations in nucleotide pools along with increased ROS production by mitochondria could then provide a mutator phenotype for the progression of lymphomas, which have relatively high mutational rates among cancers.

Polyamines play an important role in cell growth by providing polycations involved in DNA replication and dynamics. The synthesis of the polyamines, spermine and spermidine, starts with the synthesis of their precursor, putrescine, from ornithine catalyzed by ornithine decarboxylase (ODC), whose gene is one of the first recognized MYC targets.¹⁰² ODC is essential for transgenic murine lymphomagenesis and its activity could be inhibited by α -difluoromethylornithine (DFMO), which has not had a significant clinical impact despite being studied over the last several decades.¹⁰³ Spermidine is also involved as a cofactor in a unique posttranslational alteration of lysine to hypusine. Although this unusual amino acid is found in all eukaryotes, the only known protein containing hypusine is eukaryotic translation initiation factor eIF5A, which is required for lymphocyte activation.¹⁰⁴ Hypusinated eIF5A attenuates the translation of MYC, thereby providing a negative feedback loop, whose disruption accelerates MYC-mediated lymphomagenesis. The tumor-suppressive function of spermidine-dependent hypusinated eIF5A could underlie the reason why DFMO has not made a significant clinical impact.

Intriguingly, gene expression profiling also identified a group of DLBCL that displays high levels of expression of genes involved in oxidative phosphorylation, termed the OXPHOS group of DLBCL.¹⁰⁵ The OXPHOS group depends more on FAO for survival and growth as compared to the B-cell receptor group, which could also be defined by gene expression profiling. FAO requires functional peroxisomes or mitochondria.¹⁰⁶ Fatty acids longer than 12 carbons are conjugated with carnitine and then transported into peroxisomes or mitochondria via carnitine-palmitoyl transferase. Upon entry into the mitochondrial matrix, fatty acids are degraded into acetyl-CoA for further oxidation in the TCA cycle. In this regard, it is notable that MYC induces mitochondrial biogenesis in proliferating cells through activation of genes involved in the genesis and function of mitochondria.^{19,107}

In addition to FAO as a signature of a subset of DLBCL, alterations in lipid contents have also been documented. Using MYC-inducible models of lymphoma, glycerophosphoglycerol (PG) and cardiolipin (CL) were found to be elevated in a MYC-dependent manner.¹⁰⁸ Both PG and specifically CL are important for mitochondrial membrane

integrity. These phospholipids are also elevated in human lymphomas with high MYC expression. On the other hand, phosphatidyl serine (PS), phosphatidyl inositol (PI), and the most abundant mammalian membrane phospholipid, phosphatidyl ethanolamine (PE), were decreased in these lymphomas. Intriguingly, ³¹P-MRS imaging has been used to determine the abundance of PE and phosphatidyl choline (PC) relative to nucleotide triphosphate (NTP) in DLBCL and has uncovered that poor clinical response to cyclophosphamide, hydroxydaunorubicin, methotrexate, and prednisone (CHOP)-based therapy correlates with a higher pretreatment ratio of phosphomonoesters to NTP levels.¹⁰⁹

The study of the OXPHOS subgroup of lymphomas also underscores observations that high aerobic glycolysis in lymphomas is not exclusive of OXPHOS, which relies on functional mitochondria that generate the majority of ATP.¹⁰⁵ The cell-of-origin (COO) classification of DLBCL into germinal center B-cell type (GCB) or ABC groups of lymphoma does not discretely segregate different metabolic features, although the ABC group tends to have higher expression of MYC. A significant fraction of DLBCL, however, has translocations or alterations in expression that increase Bcl-2 and MYC levels, resulting in a highly resistant group of "double-hit" DLBCL.¹¹⁰ The ability of MYC to induce metabolic rewiring and biomass accumulation (discussed above) and the effect of Bcl-2 on mitochondrial metabolism and apoptosis make this group of lymphomas particularly resistant to standard therapy.

MYELOMAS

Multiple myeloma is characteristically a MYC-driven cancer, particularly since MYC is overexpressed through spurious chromosomal rearrangements and MYC amplification.^{111,112} In this regard, it is anticipated that heightened glycolysis and glutaminolysis play vital roles in myeloma development and progression. Although few studies have delineated the metabolic changes in myeloma, clinical FDG-PET scans are used to monitor disease response to therapy,¹¹³ suggesting that myeloma has increased glucose uptake and retention relative to neighboring normal marrow. Moreover, expression of the glucose transporters GLUT4, GLUT8, and GLUT11 are elevated in myeloma.¹¹⁴ The dependency of myeloma on glycolysis appears to sensitize myeloma cell lines to PDK1 inhibition, which diverts pyruvate away from lactate and into acetyl-CoA.¹¹⁵ These observations suggest that inhibition of glucose metabolism could potentiate response of myeloma to therapies.

It is notable that several studies showed significant inhibition of myeloma growth and survival with inhibition of NAD⁺ synthesis through nicotinamide phosphoribosyltransferase (NAMPT).¹¹⁶ The production of NAD⁺ is required for multiple metabolic processes, including glycolysis that depends on NAD⁺ for oxidation of glycolytic intermediates. In this regard, a preclinical model of B-cell neoplasia with plasmacytoid features displays sensitivity to a combination of NAMPT and lactate dehydrogenase A (LDHA) inhibition. The expression of NAMPT, which is a direct target of MYC, is elevated in myeloma.¹¹⁶ The NAMPT inhibitor, FK866, diminishes myeloma tumorigenesis, triggers autophagic cell death, and synergizes with proteasome inhibitors, which have significant clinical activity in multiple myeloma.¹¹⁷ Collectively, these studies suggest an important role of glucose metabolism in myeloma. However, relatively little is known currently about glutamine or fatty acid metabolism in this disease.

More than ninety years have passed since Otto Warburg first documented metabolic alterations in cancers, including the high rate conversion of glucose to lactate termed the Warburg effect or aerobic glycolysis. Much of our understanding of cancer metabolism has resulted from studies of solid tumors, which share many basic metabolic features with hematologic neoplasms. In particular, the central metabolic pathways of glycolysis and glutaminolysis seem to be similarly exploited by solid

and hematologic neoplasm alike for cell growth, proliferation, and survival. Glucose and glutamine flux into cells provides for the production of ATP and building blocks for the growing cell. Furthermore, glutamine and glucose are also substrates for glutathione synthesis, which is vital for redox homeostasis of growing cells that produce ROS as metabolic byproducts. Resting cells, on the other hand, tend to rely on FAO, which provides the most efficient energy production. In this regard, evidence has emerged indicating that neoplastic stem cells also rely on FAO and, hence, could be targeted therapeutically via this route. Glucose, glutamine, and mitochondrial metabolism pathways offer similar inhibition strategies for proliferating hematologic neoplastic cells. One of the most remarkable therapeutic developments, however, is the discovery of IDH mutations in AML and lymphoma and the development of specific drugs targeting the mutant forms of IDH1 and IDH2. Furthermore, alterations of the AML methylome and the ability of mutant IDH inhibitors to induce differentiation of AML cells underscore the link between metabolites and the epigenome. It is through advances in our understanding of cancer metabolism that we have been able to develop therapies like these for mutant IDH, capitalize on the avidity of glucose uptake by hematologic neoplasms for diagnostic and followup FDG-PET scanning, and develop many more metabolic strategies that are hoped to provide new gains against these deadly malignancies.

CHAPTER 15

APOPTOSIS MECHANISMS: RELEVANCE TO THE HEMATOPOIETIC SYSTEM

John C. Reed

SUMMARY

Apoptosis was originally coined to describe the morphologic features of a form of cell death characterized by cell shrinkage, membrane blebbing, and nuclear condensation. This type of cell death occurs in a wide variety of physiologic contexts, and thus is sometimes referred to as programmed cell death. Apoptosis occurs in all animal species as a means to balance cell proliferation with cell loss. The physiologic benefits of apoptosis include eliminating cells that are unneeded, defective, or infected, and maintenance of tissue homeostasis by continuously renewing adult tissues so as to maintain appropriate organ mass. In the hematopoietic system, production of leukocytes is delicately balanced against cell death, until a need arises for rapidly generating immune and inflammatory cells for combating pathogens. The life span of hematopoietic cells is regulated by numerous cytokines and lymphokines, as well as by signals derived from microanatomical niches through cell adhesion molecules and other regulators. Defects in the regulation of hematopoietic cell life span contribute to myriad diseases, including disorders characterized by inappropriate cell accumulation, such as leukemia, lymphoma, and autoimmunity, and diseases where pathologic loss of cells occurs, such as immunodeficiency and various blood dyscrasias.

Acronyms and Abbreviations: ALL, acute lymphocytic leukemia; ALPS, autoimmune lymphoproliferative syndrome; Asp, aspartic acid; B-CLL, B-cell chronic lymphocytic leukemia; BH, Bcl-2 homology domain; CARDs, caspase recruitment domains; caspases, cysteine aspartyl proteases; CLLs, chronic lymphocytic leukemias; CHOP, C/EBP homologous protein; CML, chronic myelogenous leukemias; CTL, cytolytic T lymphocyte; Cyt-c, cytochrome c; DD, death domain; DEDs, death effector domains; DISC, death-inducing signaling complex; DLBCL, diffuse large B-cell lymphoma; DR, death receptor; EBV, Epstein-Barr virus; ER, endoplasmic reticulum; FasL, Fas ligand; FKHD, forkhead transcription factors; IAP, inhibitor of apoptosis; IBD, inflammatory bowel disease; IgH, immunoglobulin heavy chain; IKKs, I- κ B kinases; IL, interleukin; KSV, Kaposi sarcoma virus; MALT, mucosa-associated lymphoid tissue; miRNAs, microRNAs; MLKL, mixed-lineage kinase domain-like; MMs, multiple myelomas; MOMP, mitochondrial outer membrane permeabilization; MPT, mitochondrial permeability transition; NHLs, non-Hodgkin lymphomas; NK, natural killer; PARP, poly-ADP ribosyl polymerase; PCD, programmed cell death; PI3K, phosphatidylinositol 3'-kinase; pro/pre-B-cells, B-lymphocyte progenitors; ROS, reactive oxygen species; TNF, tumor necrosis factor; TNFR1, TNF receptor-1; UBCs, ubiquitin conjugating enzymes.

It is now well established that defects in the normal mechanisms that control programmed cell death (PCD) occur commonly in human diseases. Cell numbers in the body are governed not only by cell division, which determines the rate of cell production, but also by cell death, which dictates the rate of cell loss. In the course of a typical day, an average adult human produces, and in parallel eradicates, approximately 50 to 70 billion cells, representing approximately 1 million cells per second. Normally, these two processes of cell division and cell death are tightly coupled so that no net increase in cell numbers occurs, or so that such increases represent only temporary responses to environmental stimuli. However, alternations in the expression or function of the genes that control PCD can upset this delicate balance, contributing to or causing disease.

In most cases, PCD occurs by apoptosis. Apoptosis is defined by its morphologic features. As viewed with the assistance of the light- (or, preferably, electron-) microscope, the characteristics of the apoptotic cell include chromatin condensation and nuclear fragmentation (pyknosis), plasma membrane blebbing, and cell shrinkage. Eventually, the cell breaks into small membrane-surrounded fragments (apoptotic bodies), which are cleared by phagocytosis, without inciting an inflammatory response. The release of apoptotic bodies is what inspired the term “apoptosis” from the Greek, meaning “to fall away from” and conjuring notions of the falling of leaves in the autumn from deciduous trees.¹

In recent years, the molecular machinery responsible for apoptosis has been elucidated, revealing a family of intracellular proteases, caspases (cysteine aspartyl proteases), which are responsible directly or indirectly for most of the morphologic and biochemical changes that characterize the phenomenon of apoptosis.^{2,3} Diverse regulators of the caspases have also been discovered, including activators and inhibitors of these cell death proteases. Inputs from signal transduction pathways into the core of the cell death machinery have also been identified, demonstrating ways of linking environmental stimuli to cell death responses or cell survival maintenance. Knowledge of the molecular mechanisms of apoptosis is providing insights into the pathogenesis of many diseases, revealing strategies for possible novel treatments.

● CASPASES—PROTEASES THAT CAUSE APOPTOSIS

Intracellular proteases called *caspases* are responsible for most of the morphologic changes that we recognize as “apoptosis,” as well as many of the biochemical changes often associated with this route of cell demise. Specifically, activation of a family of intracellular cysteine proteases that cleave their substrates at aspartic acid residues, known as “caspases” for cysteine *aspartyl*-specific proteases.⁴ These proteases are present as inactive zymogens in essentially all animal cells, but can be triggered to assume active states, generally involving their proteolytic processing at conserved aspartic acid (Asp) residues. During activation, the zymogen proproteins are cleaved to generate the large (~20 kDa) and small (~10 kDa) subunits of the active enzymes, typically liberating an N-terminal prodomain from the processed polypeptide chain. The active enzymes consist of heterotetramers composed of two large and two small subunits, generally with two active sites per molecule.^{2,3}

The observation that caspases cleave their substrates at Asp residues and are also activated by proteolytic processing at Asp residues makes evident that these proteases collaborate in proteolytic cascades, where caspases activate themselves and each other. Humans contain 11 caspases. They can be subgrouped according to either their amino-acid sequence similarities or their protease specificities.

From a functional perspective, it is useful to view the caspases as either upstream “initiator” caspases or downstream “effector” caspases.⁵ The zymogen forms of upstream initiator caspases possess large N-terminal prodomains, which function as protein interaction modules, allowing them to interact with various proteins that trigger caspase activation. In contrast, the proforms of downstream effector caspases contain only short N-terminal prodomains, serving no apparent function. Downstream caspases are largely dependent on upstream caspases for their proteolytic processing and activation. The substrates of effector caspases are myriad, as revealed in recent years by unbiased proteomics approaches. Substrates

include cytoskeletal and nuclear matrix proteins, chromatin-modifying (e.g., poly-ADP ribosyl polymerase [PARP]) and DNA repair proteins, inhibitory subunits of endonucleases (CIDE-family proteins), protein kinases (often separating the autorepressing regulatory domains from catalytic domains) and other signal transduction proteins.

CASPASE ACTIVATION PATHWAYS

Several pathways for activating caspases have been delineated (Fig. 15-1). The simplest is exploited by cytolytic T lymphocytes (CTLs)

Figure 15-1. Pathways for caspase activation. The major pathways for caspase activation in mammalian cells are presented. The extrinsic (left, upper) is induced by members of the tumor necrosis factor (TNF) family of cytokine receptors such as TNF receptor-1 (TNFR1), Fas, and the tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) receptors. These proteins recruit adapter proteins to their cytosolic death domains (DDs), including the Fas-associated death domain (FADD), which then bind the death effector domain (DED)-containing procaspases, particularly procaspase-8, inducing their activation. Cytolytic T lymphocytes (CTLs) and natural killer (NK) cells introduce the protease granzyme B into target cells (right, upper). This protease cleaves and activates multiple members of the caspase family. The intrinsic pathway (left, lower) is initiated by release of cytochrome c from mitochondria, induced by various stimuli, including elevations in the levels of pore-forming proapoptotic Bcl-2 family proteins, such as Bax and Bak. In the cytosol, cytochrome c binds and activates Apaf-1, allowing it to associate with and activate procaspase-9. Active caspase-9 (intrinsic) and caspase-8 (extrinsic) have been shown to directly cleave and activate the effector protease, caspase-3. Because other caspases also become involved in these pathways (not shown), the schematic represents an oversimplification of the events that occur *in vivo*. Additionally, disturbances in the function of the endoplasmic reticulum (ER) are also linked to the intrinsic and extrinsic apoptosis pathways, through both Ca²⁺ transfer to mitochondria and via transcriptional mechanisms that include induction of CHOP expression, which, in turn, stimulates expression of death receptor 5 (DR5) and Bim (proapoptotic Bcl-2 family member) (right, lower). Rectangles indicate proapoptotic proteins whereas ellipses indicate antiapoptotic proteins.

and natural killer (NK) cells, which introduce apoptosis-inducing proteases, particularly granzyme B (a serine protease), into effective intracellular compartments of target cells via perforin-dependent mechanisms.⁶ Unlike the caspases, granzyme B is a serine protease. However, similar to the caspases, granzyme B specifically cleaves its substrates at Asp residues. Granzyme B is capable of cleaving and activating multiple caspases and some caspase substrates.⁷ Endogenous and viral inhibitors of granzyme B have been identified, accounting for resistance to this apoptotic inducer.^{8–10}

Another caspase-activation pathway is represented by tumor necrosis factor (TNF) family receptors. Eight of the approximately 30 known members of the TNF family in humans contain a so-called death domain (DD) in their cytosolic tails.¹¹ Several of these DD-containing TNF family receptors use caspase activation as a signaling mechanism, including TNF receptor-1 (TNFR1)/CD120a; Fas/APO1/CD95; death receptor (DR)-3 (DR3)/Apo2/Weasle; DR4/ tumor necrosis factor-related apoptosis-inducing ligand receptor 1 (TRAILR1); DR5/TRAILR2; and DR6. Ligand of these receptors at the cell surface results in receptor clustering and recruitment of several intracellular proteins, including certain procaspases, to the cytosolic domains of these receptors, forming a “death-inducing signaling complex” that triggers caspase activation and leads to apoptosis.^{12,13}

The specific caspases summoned to the DISC are caspase-8 and, in some cases, caspase-10. These caspases contain so-called death effector domains (DEDs) in their N-terminal prodomains that bind to a corresponding DED in the Fas-associated death domain (FADD), a bipartite adapter protein containing a DD and a DED. FADD functions as a molecular bridge between the DD and DED domain families, and is, in fact, the only protein in the human genome with this dual domain structure. Consequently, cells from mice in which the *fadd* gene has been knocked out are resistant to apoptosis induction by TNF family cytokines and their receptors. Cells derived from *caspase-8* knockout mice also fail to undergo apoptosis in response to ligands or antibodies that activate TNF family DRs, demonstrating an essential role for this caspase in this pathway.¹⁴ However, mice lack the highly homologous protease, caspase-10, which is found in humans, having arisen from an apparent gene duplication on chromosome 2.¹⁵ Thus, caspases 8 and 10 may play redundant roles in human cells.

Mitochondria also play important roles in apoptosis, releasing cytochrome c (Cyt-c) into the cytosol, which then causes assembly of a multi-protein caspase-activating complex, referred to as the “apoptosome.”^{16,17} The central component of the apoptosome is Apaf1, a caspase-activating protein that oligomerizes upon binding Cyt-c and which specifically binds procaspase-9. Apaf1 and procaspase-9 interact with each other via their caspase recruitment domains (CARDs). Such CARD–CARD interactions play important roles in many steps in apoptosis pathways. In addition to Cyt-c, mitochondria also release several other proteins of relevance to apoptosis, including endonuclease G, AIF (an activator of nuclear endonucleases), and SMAC (Diablo) and Omi (HtrA), antagonists of a family of caspase-inhibitory proteins known as the IAPs (inhibitors of apoptosis) (see section “Inhibitors of Apoptosis” below).

The central importance of the Cyt-c–dependent pathway for apoptosis is underscored by the observation that cells derived from mice in which either the *apaf1* or *procaspase-9* genes have been ablated are incapable of undergoing apoptosis in response to agents that trigger Cyt-c release from mitochondria.¹⁸ Nevertheless, such cells can die by nonapoptotic routes,¹⁹ demonstrating that mitochondria control both caspase-dependent and caspase-independent cell death pathways. Moreover, distinguishing mitochondria-driven apoptotic from nonapoptotic cell death can be challenging in many contexts because of the similar morphologic features caused probably by some of the proteins released from these organelle such as endonuclease G and AIF, which

promote chromatin condensation and DNA fragmentation. The mitochondrial mechanisms for apoptotic and nonapoptotic cell death are activated by myriad stimuli, including growth factor deprivation, oxidants, Ca²⁺ overload, DNA-damaging agents, microtubule-modifying drugs, and much more.^{17,20} In this sense, mitochondria are sometimes viewed as central integrators of cell stress signals that dictate ultimately cell life and death decisions.

Mitochondria can also participate in cell death pathways induced via TNF family DRs, through crosstalk mechanisms involving proteins such as Bid, BAR, and Bap31.^{21–24} However, mitochondrial (“intrinsic”) and DR (“extrinsic”) pathways for caspase activation are fully capable of independent operation in most types of cells.²⁵

Cell death mechanisms are also linked to endoplasmic reticulum (ER). In most cases, however, these ER-initiated signals ultimately seem to impinge on mitochondria as the downstream effectors of the cell death pathway. In this regard, the ER is a central regulator of intracellular Ca²⁺, and ER membranes form close contacts with mitochondria to create structures where Ca²⁺ effluxes from ER into mitochondria, thereby impacting mitochondrial function in profound ways that can either promote cell life or cause death. Too much Ca²⁺ entry into mitochondria, for instance, triggers a phenomenon called mitochondrial permeability transition (MPT) in which the organelles swell and eventually rupture.

However, in addition to the role of ER Ca²⁺ and mitochondria-driven cell death, another pathway for apoptosis has been linked to accumulation of unfolded proteins in the ER. Specifically, ER stress induces expression of the proapoptotic transcription factor CHOP, which, in turn, stimulates expression of DR5 (TRAILR2), causing caspase-8-dependent apoptosis.²⁶ Additionally, CHOP has been reported to directly stimulate transcription of the gene encoding Bim, a proapoptotic member of the Bcl-2 family (see section “Suppressors of Apoptosis” below) that stimulates Cyt-c release from mitochondria. Thus, ER stress has multiple potential routes of stimulating cell death pathways, with the predominant pathway probably varying among cell types and pathophysiologic contexts.

Although diverse mechanisms exist for activating initiator Caspases, as outlined above, in most instances, the biochemical mechanisms appear to be remarkably similar. Much of caspase activation and can be explained by the “induced proximity model,”²⁷ in which forcing dimerization of procaspases results in conformational states that promote protease activation, typically resulting in cleavage events that lock the proteases into their fully active state. This mechanism is clearly operative in the caspase-activation pathways induced by TNF family receptors (extrinsic pathway) and Cyt-c/mitochondria (“intrinsic pathway”).

● SUPPRESSORS OF APOPTOSIS

Given the critical importance of making the correct choices about cell life–death decisions in complex multicellular organisms, it is not surprising that the pathways governing caspase activation are under exquisite control by networks of proteins that directly or indirectly communicate with these proteases. A delicate balance between proapoptotic and antiapoptotic regulators of apoptosis pathways is at play on a continual basis, ensuring the survival of long-lived cells and the proper turnover of short-lived cells in a variety of tissues, including the marrow, thymus, and peripheral lymphoid tissues. The antiapoptotic proteins responsible for creating roadblocks to cell death have been mapped to specific caspase-activation pathways.

BCL-2 FAMILY

The Bcl-2 family represents a large group of proteins (number >26 in humans) that control mitochondria-dependent steps in cell-death pathways, including dictating whether Cyt-c is or is not released from these

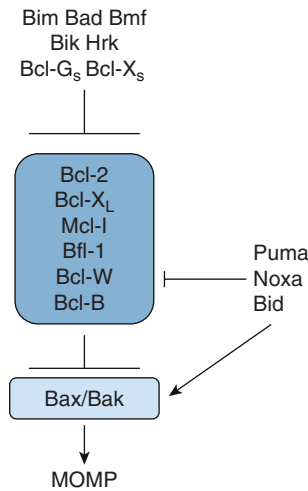

Figure 15-2. Network of interactions among Bcl-2 family proteins. The functional and physical interactions among proapoptotic and antiapoptotic Bcl-2 family proteins are depicted. Illustrative members of the Bcl-2 family are shown.

organelles (Fig. 15-2). Both proapoptotic and antiapoptotic Bcl-2 family proteins have been delineated.²⁸ These proteins are best known for their roles in controlling the intrinsic (mitochondrial) cell-death pathway,²⁰ although effects on the ER-pathway for cell death have also been documented.²⁹ Even though the human genome encodes at least 26 Bcl-2 family proteins, only six of these are antiapoptotic (in humans, Bcl-2, Bcl-X_L [BCL2L1], Bcl-W [BCL2L2], Mcl-1 [BCL2L3], Bfl-1 [BCL2L5], and Bcl-B [BCL2L10]). Several types of animal viruses also harbor Bcl-2 family genes within their genomes, including herpes viruses implicated in cancer such as the Epstein-Barr virus (EBV) and Kaposi sarcoma virus (KSV). The relative ratios of anti- and proapoptotic Bcl-2 family proteins dictate the ultimate sensitivity or resistance of cells to various apoptotic stimuli, including growth factor deprivation, hypoxia, radiation, anticancer drugs, oxidants, and Ca²⁺ overload.

Various Bcl-2 family members play important roles in controlling the life spans of hematopoietic cells, as evidenced by phenotypes generated in genetically engineered mice (gene knockouts and transgenics) and also (in some cases) by human clinical experiences with experimental therapeutics targeting some of these proteins. For example, antiapoptotic protein Bcl-2 is required for survival of mature T cells and B cells, with deficiency of Bcl-2 causing lymphopenia. Conversely, the proapoptotic protein Bim is necessary for limiting expansion of T and B lymphocytes, with deficiency of Bim causing lymphocytosis. Bim also plays important role in eradicating autoreactive T cells in the thymus (“negative selection”), having important implications for mechanisms of autoimmune diseases.³⁰ Bcl-X_L is required for platelet homeostasis, such that either genetic or pharmacologically induced Bcl-X_L deficiency causes thrombocytopenia. Antiapoptotic protein Mcl-1 is particularly important for survival of the myeloid lineage in mice, as well as contributing to lymphocyte survival. Conversely, antiapoptotic protein Bcl-W is not required for hematopoiesis in mice, despite being widely expressed in myeloid lineage cells. It should be noted that direct comparisons of gene manipulations in mice with the human circumstance are not always possible because of genomic differences in the Bcl-2 family genes of mice versus humans (e.g., human Bfl-1 versus murine A1; human Bcl-B versus murine Boo/Diva).

Many members of the Bcl-2 family have a hydrophobic stretch of amino acids near their carboxyl-terminus that anchors them in the outer mitochondrial membrane.¹⁷ In contrast, other Bcl-2 family members

such as Bid, Bim, and Bad, lack these membrane-anchoring domains, but dynamically target mitochondria in response to specific stimuli. Still others have the membrane-anchoring domain but keep it latched against the body of the protein until stimulated to expose it (e.g., Bax).³¹

Based on their predicted (or experimentally determined) three-dimensional structures, Bcl-2 family proteins can be broadly divided into two groups. One subset of these proteins is probably similar in structure to the pore-forming domains of bacterial toxins, such as the colicins and diphtheria toxin.³²⁻³⁵ These α -helical pore-like proteins include both antiapoptotic proteins (Bcl-2, Bcl-X_L, Mcl-1, Bfl-1, Bcl-W, Bcl-B) and proapoptotic proteins (Bax, Bak, Bok, and Bid). Most of the proteins in this subcategory can be recognized by conserved stretches of amino acid sequence homology, including the presence of Bcl-2 homology (BH) domains, BH1, BH2, BH3, and sometimes BH4. However, this is not uniformly the case, as the Bid protein contains only a BH3 domain but has been determined to share the same overall protein-fold with Bcl-X_L, Bcl-2, and Bax.^{33,34} Where tested to date, these proteins have all been shown to form ion-conducting channels in synthetic membranes *in vitro*, including Bcl-2, Bcl-X_L, Bax, and Bid,³⁶⁻⁴⁰ but the significance of this pore activity remains unclear.

The other subset of Bcl-2 family proteins appears to have in common only the presence of the BH3 domain, including Bad, Bik, Bim, Hrk, Bcl-G_s, p193, APR (Noxa), and PUMA. These “BH3-only” proteins are uniformly proapoptotic. Their cell-death-inducing activity depends, in most cases, on their ability to dimerize with antiapoptotic Bcl-2 family members, functioning as *trans*-dominant inhibitors of proteins such as Bcl-2 and Bcl-X_L.^{41,42} However, some of these proteins (e.g., Bid, PUMA, Bim) can also interact with proapoptotic proteins (e.g., Bax, Bak), functioning as agonists of the killers, in addition to dimerizing with antiapoptotics (e.g., Bcl-2; Bcl-X_L) to function as antagonists of these cell-survival proteins (see Fig. 15-2).^{28,43} Binding of Bid to Bax or Bak promotes insertion of these proteins into membranes where they oligomerize, apparently forming large pores through which molecules such as Cyt-c, SMAC, and Omi can escape from mitochondria or causing an increase in the permeability of the outer membrane of mitochondria through more complex mechanisms.^{44,45} Bax and Bak thus induce mitochondrial outer membrane permeabilization (MOMP), which is a critical event that not only causes release of death-inducing mitochondrial proteins but also secondarily causes necrosis by uncoupling of oxidative phosphorylation (when Cyt-c becomes limiting) and diversion of electrons from the respiratory chain into production of toxic free radicals.^{46,47}

The BH3 domain mediates dimerization among Bcl-2 family proteins. This domain consists of an amphipathic α -helix of approximately 16 amino acids that inserts into a hydrophobic crevice on the surface of antiapoptotic proteins such as Bcl-2 and Bcl-X_L.⁴⁸ The BH3-only proteins link a wide variety of environmental stimuli to the mitochondrial pathway for apoptosis, with some examples outlined below.

In addition to mitochondria, mechanistic links for Bcl-2 family proteins to ER stress and autophagy have also been delineated. For example, Bax and Bak can bind the ER stress signaling protein, IRE-1, thereby stimulating its intrinsic autokinase activity and its endoribonuclease activity.⁴⁹ Proapoptotic (Bak/Bax) and antiapoptotic (Bcl-2/Bcl-X_L) family members also have opposing effects on basal ER Ca²⁺ levels, probably via effects on Ca²⁺ channel proteins in ER membranes (e.g., IP3Rs, BI-1, and TmBim3). Autophagy protein Beclin contains a BH3-like domain that mediates interactions with antiapoptotic Bcl-2 family proteins, which sequester Beclin and thereby reduce autophagic flux.⁵⁰ Autophagy, which is a lysosome-dependent catabolic pathway, can either promote cell survival by providing access to nutrients during times of nutrient insufficiency and hypoxia, or it can cause cell death when stimulated to an extreme.⁵¹

FLIP

The c-FLIP proteins are another type of apoptosis suppressor that operates via directly binding to certain caspases and their upstream activator, FADD. The *c-FLIP* gene of humans resides in a tandem gene cluster on chromosome 2, which contains the genes encoding procaspases 8 and 10, suggestive of gene duplication events. Two isoforms of c-FLIP are produced from a single gene, including the long form, which is highly similar in overall sequence to procaspases 8 and 10, containing tandem copies of DEDs, followed by a pseudocaspase domain that lacks enzymatic activity. The shorter isoform consists only of the DED domains, thus resembling analogous proteins encoded in the genomes of some mammalian viruses.⁵² FLIP-S is exclusively ant apoptotic whereas FLIP-L can be either pro- or antiapoptotic, depending on its levels of expression relative to procaspases 8 and 10.⁵³ In general, FLIP proteins form complexes with procaspases 8 and 10, preventing their dimerization and activation, as well as competing for binding to adapter protein FADD, which is required for caspase recruitment to DR complexes.^{54,55} Thus, in most circumstances, FLIP proteins create blockades in the extrinsic pathway for apoptosis.

Additionally, a role in suppressing nonapoptotic cell death (necroptosis) has been described for FLIP in partnership with caspase-8.⁵⁶ In this regard, TNFR1 signaling has been shown to stimulate caspase-independent cell death in some circumstances (commonly called “necroptosis”) via a mechanism that is suppressed by FLIP and caspase-8 but that is dependent on the protein kinase Rip3 (see section “Inhibitors of Apoptosis” below). It is thought that dimers consisting of the longer isoform of c-FLIP plus caspase-8 direct the proteolytic activity of caspase-8 to substrates that promote cell survival rather than cell death.⁵⁷ Among the relevant substrates is the kinase Rip1, an upstream activator of Rip3. Thus, FLIP proteins play complex roles in cell death regulation mediated by various members of the TNF Receptor family.

INHIBITORS OF APOPTOSIS

The IAP proteins ($n = 8$ in humans) suppress apoptosis via a diversity of mechanisms, including directly binding to and inhibiting certain caspases.^{58,59} IAPs are characterized by the presence of protein interaction domains called BIRs (baculovirus internal repeats), numbering between 1 and 3 per protein. Most IAPs also carry RING domains that endow them with E3 ligase activity through interactions with ubiquitin conjugating enzymes (UBCs). Some of the apoptogenic proteins released from mitochondria, notably SMAC and HtrA2, bind certain BIRs and thereby compete for protein interactions on the surface of IAPs. Some examples of IAP mechanisms are provided here.

XIAP (so-called because its encoding gene resides on the X-chromosome) contains 3 BIR domains. BIR2 of XIAP binds downstream effector proteases, caspases-3 and -7, to suppress apoptosis at a distal point. BIR3 of XIAP binds upstream initiator protease, caspase-9, to suppress an apical step in the mitochondrial pathway for apoptosis.

The c-IAP1 (BIRC2) and c-IAP2 (BIRC3) proteins are also capable of binding to caspases 3, 7, and 9, although they are less potent by far as direct enzymatic inhibitors and may rely on their E3 ligase activity for controlling caspase degradation. However, these IAP family members also participate in other cell death-relevant mechanisms by impacting signal transduction by TNF family receptors. Binding of TNF to one of its principal cellular receptors expressed widely on cells, TNFR1, is capable of triggering at least three different signaling pathways, each involving overlapping but distinct protein complexes that are assembled at the receptor (Fig. 15-3). One of these TNFR1-initiated pathways causes caspase activation and apoptosis by DISC assembly (described in the section “Caspase Activation Pathways,” and Fig. 15-1 above). Another pathway causes activation of the kinase Rip3, usually via the upstream

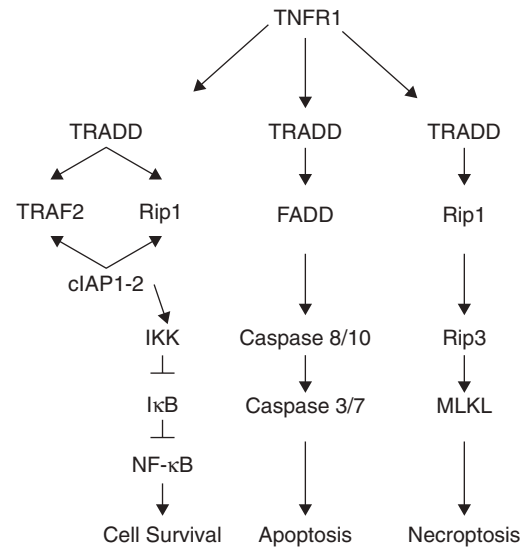

Figure 15-3. Opposing pathways for cell death and cell survival are induced by tumor necrosis factor receptor (TNFR). TNFR1 is the best studied of the death domain (DD)-containing TNF family receptors, which include in humans Fas (CD95), tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) receptor-1 (TRAILR1, DR4), TRAILR2 (DR5), DR3, and DR6. DD-containing adapter protein TRADD (tumor necrosis factor receptor death domain) binds the DD in the cytosolic domain of TNFR1, which then connects to at least one of three different pathways that are outlined here. A cell survival pathway results in nuclear factor (NF)-κB activation, whereby TRADD recruits the DD-containing protein Rip1 and also binds the E3 ligase/adapter protein TRAF2 (tumor necrosis factor receptor-associated factor 2). Rip1 and TRAF2 bind c-IAP1 (inhibitor of apoptosis 1) and c-IAP2. The resulting complex promotes noncanonical ubiquitination of the kinase Rip1, triggering a signal transduction kinase pathway that results in activation of I-κB kinases (IKKs) that cause I-κB ubiquitination and proteasomal degradation, thereby releasing sequestered NF-κB to allow its translocation into the nucleus where it stimulates expression of multiple antiapoptotic genes. In the TNFR1-mediated apoptosis pathway, the DD of TRADD associates with the DD of FADD, which, in turn, binds caspases 8 and 10 via their death effector domains (DEDs), triggering protease activation and thereby stimulating apoptosis. The TNFR1-mediated pathway for necrosis (necroptosis) involves a cascade of events that include recruitment of Rip1, which, in turn, activates Rip3, which activates mixed-lineage kinase domain-like (MLKL) kinase and which causes mitochondrial and probably lysosomal changes that stimulate reactive oxygen species (ROS) generation and lead to necrosis.

kinase Rip1, which associates with TNFR1 complexes.⁶⁰ The Rip3-dependent cell death pathway is caspase-independent, leading to nonapoptotic cell death (“necroptosis”) through a process involving reactive oxygen species (ROS) generated by mitochondria. Another serine/threonine kinase, mixed-lineage kinase domain-like (MLKL) protein, appears to be a critical downstream mediator of Rip3-induced necroptosis. This Rip3-dependent pathway for necroptosis is suppressed by c-IAP1 and c-IAP2, probably via their roles as E3 ligases and possibly involving ubiquitin/proteasome-mediated reductions in Rip3 protein levels.⁶¹ Finally, TNFR1 stimulates a cell survival pathway in which c-IAP1 and c-IAP2 participate. In this TNFR1-mediated survival pathway, the kinase Rip1 comes together with the E3 ligases c-IAP1, c-IAP2, and tumor necrosis factor receptor-associated factor 2 (TRAF2) to stimulate noncanonical (lysine 63, rather than lysine 48) ubiquitination of Rip1, initiating a signal transduction pathway that causes activation of transcription factor nuclear factor (NF)-κB. NF-κB influences the expression of many target genes involved in host defenses and immune regulation, among

which are several genes that suppress apoptosis. As a result, this NF- κ B pathway nullifies the caspase pathway, negating apoptosis,⁶² in addition to accounting for the untoward inflammatory actions of this cytokine. Several antiapoptotic genes are among the direct transcriptional targets of NF- κ B (REL)-family proteins, including the genes encoding c-FLIP, c-IAP2, Bcl-X_L, and Bfl-1.

In this regard, the c-IAP1 and c-IAP2 proteins were first identified because of their association with TNF receptor complexes. These IAPs bind the kinase Rip1 via their BIR3 domains, mediating noncanonical ubiquitination of Rip1 via interactions of atypical UBCs with their RING domains and possibly also indirectly via interactions of the E3 ligase TRAF2, which binds their BIR1 domains. The noncanonical ubiquitination of Rip1 is required for TNFR1-mediated NF- κ B activation and suppression of cytokine-induced apoptosis. The c-IAP1 and c-IAP2 proteins also control the “alternative” pathway for NF- κ B activation via yet another mechanism, which involves classical lysine 48 mediated polyubiquitination of the kinase Nik.

Additional members of the IAP family not described here (Survivin, Apollon/Bruce, ML-IAP, etc.) also have interesting mechanisms of interacting with components of cell-death pathways and they also can have other roles beyond cell-death regulation. For example, XIAP, c-IAP1, and c-IAP2 have other documented cellular activities, which include, for example, their interactions with kinases (e.g., Rip2) or kinase-binding adapter proteins (TAB/Tak) involved in processes such as innate immunity and morphogenesis. In these circumstances, the

most relevant activity of IAPs appears to be their noncanonical E3 ligase activity, as well as a protein scaffold role where they serve as platforms for assembling multiprotein complexes. Additional roles for IAP family members include cell division, where, for example, the Survivin protein plays a fundamental role in chromosome segregation and cytokinesis.

Several of the IAPs are opposed by proteins released from mitochondria, SMAC and Htra2. SMAC and Htra2 bind BIR domains on IAPs, thus displacing caspases and other associated proteins. In many cases, SMAC binding to IAPs induces their polyubiquitination and proteasomal degradation. Thus, factors that cause MOMP take the breaks off the caspases by eliminating various IAP family proteins.

SIGNAL TRANSDUCTION AND APOPTOSIS REGULATION

Various receptor-mediated signal transduction pathways converge on the core components of the cell death machinery outlined above, including receptors for growth factors, lymphokines and cytokines. Some examples illustrating the intimate links between receptor-mediated signal transduction and apoptosis pathways are provided here (Fig. 15–4).

LYMPHOKINES

Many lymphokine receptors signal via Jak/STAT pathways. STAT family transcription factors are known to stimulate transcription of the

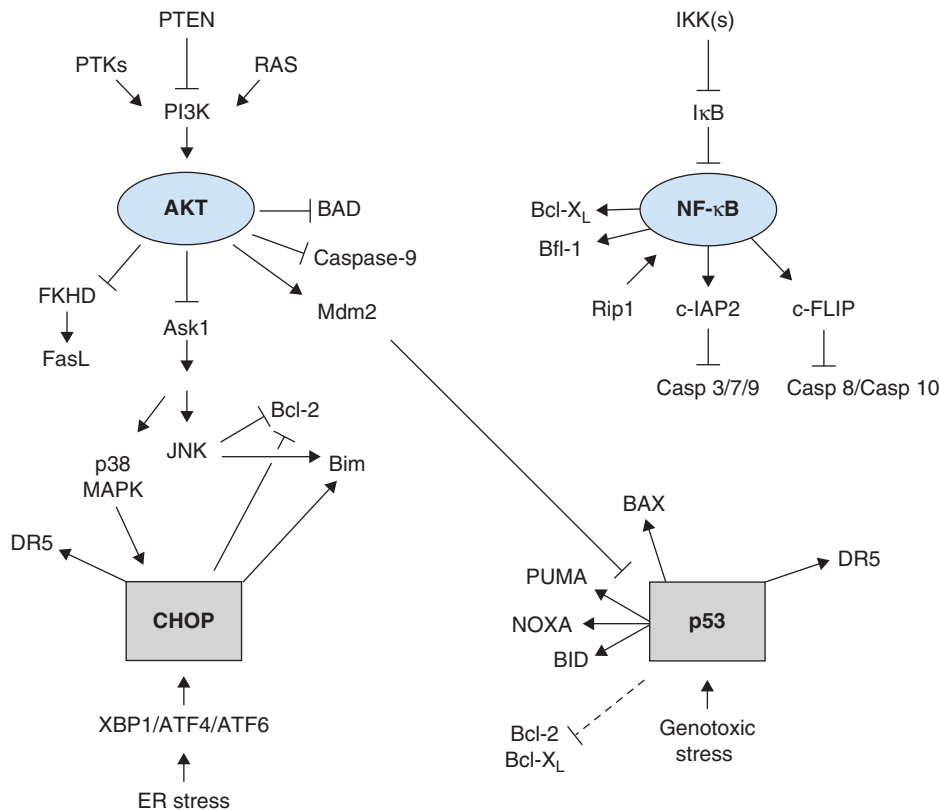

Figure 15–4. Signal transduction and apoptosis regulation. Some of the transcription factors and kinases that play prominent roles in apoptosis regulation are depicted, including kinases Akt (PKB) and the transcription factors p53, NF- κ B, and CHOP. Illustrative examples of the connections to apoptosis-regulating proteins and genes are shown, without attempting to be comprehensive. The protein kinase Akt (PKB) is activated in response to second-messengers produced by PI3K, a lipid kinase that is activated by many growth factor receptors and oncoproteins. PTEN is a lipid phosphatase that prevents accumulation of these second messengers, the expression of which is lost in many tumors through gene deletions, gene mutations, and other mechanisms.⁸⁹ Akt can phosphorylate and either activate (arrows) or inactivate (⊥) multiple proteins directly or indirectly relevant to apoptosis.⁹⁰ Expression of the transcription factor CHOP is stimulated by transcription factors that are elaborated during ER stress, including XBP1, ATF4, and ATF6. See text for additional details.

BCL-X gene as at least one of their mechanisms of suppressing apoptosis. Examples with relevance to hematopoietic system include erythropoietin-mediated stimulation of survival of erythrocyte precursors and interleukin (IL)-3 and IL-7-mediated stimulation of survival of B-lymphocyte progenitors (pro/pre-B-cells). Additionally, Jak family nonreceptor protein tyrosine kinases are capable of stimulating phosphatidylinositol 3'-kinase (PI3K) activity,⁶³ which, in turn, causes activation of Akt family kinases. The murine gene encoding Akt was first discovered by virtue of its similarity to the *v-akt* oncogene found in some murine leukemia viruses and through its activation in thymomas caused by retrovirus insertions near the *c-akt* gene.⁶⁴ Humans contain three *AKT* genes. Akt can phosphorylate multiple proteins within the core apoptosis machinery. For example, the proapoptotic Bcl-2 family member Bad is a target of Akt, where phosphorylation of Bad causes its sequestration by 14-3-3 family proteins, thus inhibiting Bad from heterodimerizing with Bcl-X_L.⁶⁵ Akt also can phosphorylate human caspase-9, blocking apoptosis downstream of mitochondria.⁶⁶ Another substrate of Akt that is relevant to apoptosis is forkhead transcription factors (FKHD). Some FKHD family members appear to control apoptosis, perhaps by affecting transcription of the gene encoding FasL.⁶⁷ Phosphorylation of FKHD by Akt prevents its entry into the nucleus.

CYTOKINES

Several cytokines stimulate the activation of NF- κ B (REL) family transcription factors. NF- κ B directly binds the promoters and induces expression of several antiapoptotic genes, including the *BCL-2* family members *BCL-X* and *BFL-1*, the IAP-family member *C-IAP2*, and *C-FLIP*.⁶² Thus, elevations in NF- κ B activity can increase cellular resistance to apoptosis, affecting (1) the Intrinsic (mitochondrial) pathway through elevations in antiapoptotic Bcl-2 family proteins, (2) the extrinsic (TNF family DR) pathway through upregulation of c-Flip, and (3) downstream common pathways involving effector caspases as a result of overexpression of c-IAP2.

The first example of NF- κ B involvement in malignancy was provided by studies of the avian Rev-T retrovirus, a transforming retrovirus that causes rapidly fatal lymphomas in young chickens and which carries the *v-Rel* oncogene. The cellular homologue of this viral oncogene is *C-REL*, which encodes the p65 subunit of NF- κ B. Amplification of the *C-REL* gene has been reported in non-Hodgkin lymphomas (NHLs), occurring particularly in diffuse large B-cell lymphoma and commonly associated with extranodal presentation.⁶⁸ Other genetic alterations associated with dysregulation of NF- κ B include chromosomal translocations involving the I- κ B family member *BCL-3* in B-CLL.⁶⁹ I- κ B family proteins bind and sequester NF- κ B complexes, preventing the transcription factor from entering the nucleus.⁷⁰ Typically, I- κ B is regulated by ubiquitin-mediated turnover by the 26S proteasome. Mutations in I- κ B thus may enhance NF- κ B activity, either by producing unstable proteins or reducing the affinity of I- κ B for NF- κ B. The anticancer activity of drugs that inhibit the proteasome, approved for multiple myeloma, may be attributable in part to suppression of I- κ B degradation, thereby inhibiting NF- κ B induction.⁷¹

GENOTOXIC STRESS

Gamma-radiation and many DNA-damaging anticancer drugs potently stimulate apoptosis of hematopoietic cells. The principal mediator of apoptosis induced by genotoxic stress is p53. The p53 protein is a tetrameric transcription factor, whose levels are controlled by the E3 ligase Mdm2. This transcription factor directly induces expression of BH3-only proteins Noxa (APR), Bid, and PUMA,⁷²⁻⁷⁴ thus linking p53 to the death machinery. Additionally, p53 directly binds and transcriptionally

activates the human *BAX* gene promoter. Loss of p53 activity occurs in many human malignancies by a variety of mechanism, including gene deletion, gene mutations that result in mutant p53 proteins lacking transcriptional activity, and *MDM2* gene amplification. Small molecule drugs that block Mdm2 protein interaction with p53 have shown promising preclinical activity against hematopoietic malignancies.

Interestingly, in addition to its role as a nuclear transcription factor, evidence has emerged suggesting that p53 may promote apoptosis also via nontranscriptional mechanisms under some circumstances. Specifically, a cytoplasmic pool of p53 reportedly associates with mitochondria, directly inducing activation of the Bax and inhibiting Bcl-2 and Bcl-X_L.⁷⁵ Importantly, even mutant p53 is capable of activating this cell-death pathway, raising hopes of finding pharmacologic interventions that would entice mutant p53 to attack mitochondria and trigger apoptosis of cancer cells in which this important tumor-suppressor gene product has suffered somatic mutations that inactivate its nuclear (transcriptional) functions.

HEMATOLOGIC DISEASES AND APOPTOSIS

Either insufficient or excessive apoptosis plays important roles in a wide diversity of hematologic diseases. Convincing evidence has gathered to support a major role for insufficient apoptosis in the context of most (if not all) hematologic malignancies, where defects in apoptosis prolong cell life span and thereby promote cell accumulation, as well as complementing the proapoptotic effects of certain oncogenes (e.g., *C-MYC*; *CYCLIN-D1*), permitting growth factor independent cell survival, and promoting resistance to chemotherapy, radiation, and immune-mediated cell killing. Defects in apoptosis also seem to underlie some aspects of autoimmunity, where a failure to eradicate autoreactive lymphocytes occurs. Conversely, excessive apoptosis has been implicated in the depletion of CD4+ T-lymphocytes seen in chronic HIV infection, bacteria-mediated killing of macrophages, myelodysplastic disorders where marrow failure occurs resulting in anemia and failed myelopoiesis, and many other conditions. Some examples of the human diseases that have been linked to genomic alterations of apoptosis genes are highlighted here, without an attempt to be comprehensive.

ALTERNATIONS IN APOPTOSIS GENES IN HEMATOLOGIC MALIGNANCIES

Defects in apoptosis (cell death) are recognized as one of the hallmarks of essentially all cancers. Not surprisingly, therefore, myriad examples of alternations in genes regulating the core apoptosis machinery have been delineated in human cancers. Hematologic malignancies have, in fact, revealed many of the first and most striking examples of the critical importance of cell death as a constraint to inappropriate cell expansion and accumulation. Here, some illustrative examples are provided without an attempt to be comprehensive, particularly focusing on the families of apoptosis-regulating genes outlined above with emphasis on genomic alterations. Additionally, myriad epigenetic mechanisms modulate the expression of apoptosis genes in hematologic malignancies, which are not covered here.

BCL-2 FAMILY

The Bcl-2 family derives its name from discovery of the founding member as a result of its involvement in B-cell lymphomas and leukemias. The human *BCL-2* gene is involved in t(14;18) chromosomal translocations found commonly in NHLs. In this regard, the *BCL-2*

gene normally resides on chromosome 18, but it becomes merged with the immunoglobulin heavy-chain (IgH) locus on chromosome 14, probably as a result of aberrant actions of the V-D-J gene recombination machinery responsible for antibody generation in B-cells. In this context, the *BCL-2* gene becomes deregulated in its expression via the powerful *cis*-acting enhancer elements of the IgH locus. Chromosomal translocations activating *BCL-2* occur in most indolent NHLs (especially follicular B-cell lymphomas) as well as a substantial proportion of aggressive NHLs (perhaps commonly arising from progression of a previously undiagnosed low-grade B-lymphoma). Gene amplification provides another mechanism for *BCL-2* gene dysregulation, and is reported in nearly 20 percent of aggressive B-NHLs, particularly diffuse large B-cell lymphomas (DLBCLs). Thus, by studying the cytogenetics of B-cell malignancies, the world's first example of an antiapoptotic gene (*BCL-2*) was discovered.

Additionally, loss of genes encoding microRNAs (miRNAs) that posttranscriptionally suppress *BCL-2* by inducing Bcl-2 mRNA degradation accounts for the widespread dysregulation of *BCL-2* gene in B-cell chronic lymphocytic leukemia (B-CLL). In this context, approximately 90 percent of B-CLLs have homozygous loss of function mutations or deletions involving *miRNA15* and *miRNA16* on chromosome 13q14, thus derepressing *BCL-2* gene expression. This somatic loss of *miRNA15* and *miRNA16* genes in CLL was the first example of miRNA genes operating as tumor suppressors.

Genetic lesions responsible for dysregulation of other members of the Bcl-2 family have also been identified in various types of hematologic and nonhematologic malignancies. Among these somatic genetic mechanisms is the amplification of the *BCL-X* (*BCL2L2*) or *MCL-1* (*BCL2L3*) gene loci, which occurs probably in one in 10 human solid tumors. Conversely, homozygous gene mutations that inactivate the proapoptotic *BAX* gene have also been identified in occasional hematopoietic malignancies and some solid tumors. In this regard, deletions or inactivating mutations in the tumor-suppressor p53 also reduce the expression of several proapoptotic Bcl-2 family genes, including the *BAX*, *PUMA*, *NOXA*, and *BID* genes, which are direct transcriptional targets of p53 (see above).⁷⁶ The incidence of p53 gene deletions and mutations varies among hematologic malignancies, ranging from rare (<5 percent) in T-cell leukemias and low-grade B-cell lymphomas to frequent (>30 percent) in disorders such as high-grade B-cell lymphomas, Burkitt lymphomas, and relapsed/aggressive acute lymphocytic leukemia (ALL), chronic lymphocytic leukemias (CLLs) that have progressed to Richter syndrome, and chronic myelogenous leukemias (CML) in blast crisis.⁷⁷

INHIBITORS OF APOPTOSIS

Genomic lesions involving the IAP family genes are also associated with hematologic malignancies. For example, in marginal zone mucosa-associated lymphoid tissue (MALT) B-cell lymphoma, the most common of the extranodal NHLs, t(11;18)(q21;q21) chromosomal translocations occur frequently.⁷⁸ These translocations fuse the three BIR domains of c-IAP2 with portions of the gene encoding MALT1, a caspase-like protein. The predominant mechanism by which the resulting c-IAP2/MALT1 fusion protein suppresses apoptosis appears to be hyperactivation of NF- κ B. In this regard, the BIR1 domain of c-IAP1 binds NF- κ B-inducing E3 ligase TRAF2, and this interaction has been shown to be critical for NF- κ B induction by c-IAP2/MALT1 fusion proteins. Additionally, the C-terminal region of MALT1 also binds a related NF- κ B-inducing E3 ligase, TRAF6, making additional contributions to NF- κ B stimulation. Interestingly, *TRAF2* gene amplification has also been described in a significant number of human malignancies.

CASPASES

Inactivating mutations have been described in a variety of cancers. In approximately 15 percent of NHLs, mutations that alter the activity of caspase-10 have been reported. The resulting mutant caspase-10 proteins may operate as dominant-negative inhibitors of DR-mediated apoptosis.⁷⁹ Although exhaustive analysis has not been performed to date, overall mutations inactivating caspase-encoding genes appear to be relatively rare in hematopoietic malignancies, though epigenetic silencing may be more common.

TUMOR NECROSIS FACTOR FAMILY DEATH RECEPTORS

Somatic mutations in the *FAS* (*CD95*) gene have been found in multiple myelomas (MMs) and NHLs.⁸⁰ Missense mutations within the DD of Fas (CD95) were associated with retention of the wild-type allele, suggesting a dominant-negative mechanism, whereas missense mutations outside the DD were associated with allelic loss.⁸⁰ The observation that tumor-suppressor p53 can induce transcription of the DRs Fas (CD95) and DR5 (TRAILR2) in some types of tumor cells,^{81,82} suggests an additional cancer-relevant mechanism by which reductions in the expression of TNF family DRs could occur in human malignancies, namely, secondarily to genomic lesions that inactivate p53 or that cause overexpression of endogenous p53 antagonists.⁸³

OTHER GENOMICALLY BASED DISEASES INVOLVING APOPTOSIS GENES

Hereditary deficiency of XIAP is a very strong risk factor for early onset inflammatory bowel disease (IBD). This function of XIAP is probably not related to its role in apoptosis, but rather stems from the function of XIAP as a component of NACHT and Leucine rich repeat domain-containing receptor (NLR) family protein complexes involved in innate immunity. Causative mutations have been identified in the *FAS* (*CD95*) gene of humans in patients with autoimmune lymphoproliferative syndrome (ALPS), also known as Canale-Smith syndrome.⁸⁴ Thus, the Fas/Fas ligand (FasL) system plays a critical role in lymphocyte homeostasis *in vivo*. At least some of the mutant Fas proteins found in humans with ALPS have been shown to operate as *trans*-dominant inhibitors of wild-type Fas, probably explaining the dominant inheritance pattern of this disorder. Likewise, germline mutations in Fas and FasL have been discovered as the underlying basis for the lymphoproliferative autoimmune phenotype of *lpr/lpr* and *gdl/gdl* strain mice, respectively.^{85,86} In contrast to humans, however, the mutations in the *fas* gene of *lpr*-strain mice produce disease with a recessive inheritance pattern.⁸⁵ FasL, like most TNF family members, is a trimer, and the receptor also forms trimers and probably higher-order oligomers, thus explaining why some Fas mutants display dominant-negative effects on wild-type Fas while others do not. Indeed, mutant versions of Fas from some patients with hereditary ALPS have been demonstrated to antagonize wild-type Fas,⁸⁷ probably forming mixed oligomers of wild-type and mutant molecules. Additionally, mutations in caspase-10 gene that produce altered proteins that interfere with Fas-induced apoptosis have been identified in patients with ALPS.⁸⁸

These examples of autoimmune disorders associated with hereditary alternations in apoptosis-regulatory genes highlight the intricate linkages between cell death regulation and host-pathogen interactions. Many components of the apoptosis machinery play important roles in aspects of innate and adaptive immunity, possibly reflecting the notion that altruistic cell suicide may be the best defense against pathogens for multicellular organisms. Moreover, a subfamily of the caspases (e.g.,

caspases 1, 4, and 5 in humans) has as its primary role the proteolytic processing and activation of inflammatory cytokines (pro-IL-1 β , pro-IL-18, etc.), with apoptosis representing a secondary function that is observed mostly in the context of excessive stimulation.

CONCLUSIONS

Programmed cell-death mechanisms play critical roles in hematopoietic and immune cell homeostasis. Elaboration of the complex cell-death pathways and the networks of proteins that modulate these pathways have provided insights into the underlying mechanisms of cell life-death decisions, although many mechanistic details remain still to be revealed. In several cases, the available information has already sparked efforts to translate the base of information into therapeutic strategies. Among the experimental therapeutics targeting components of the cell death machinery that have entered clinical testing are small molecule inhibitors of Bcl-2 family and IAP family proteins, as well as large molecule modulators of TNF family DRs. Compounds that modulate upstream inputs into cell death pathways are also advancing through clinical evaluations, such as small molecule inhibitors of Mdm2 (which cause p53 protein accumulation) and small molecule inhibitors of Akt family kinases. Many other targets within the cell-death pathways are the subject of preclinical drug discovery efforts today. The stage is thus set for continued progress in manipulating cell-death pathways for therapeutic benefit of multiple diseases, including disorders of the hematopoietic system.

CHAPTER 16

CELL-CYCLE REGULATION AND HEMATOLOGIC DISORDERS

Yun Dai, Prithviraj Bose, and Steven Grant

SUMMARY

Complex feedback pathways regulate the passage of cells through the G_1 , S , G_2 , and M phases of the growth cycle. Two key checkpoints control the commitment of cells to replicate DNA synthesis and to mitosis. Many oncogenes and defective tumor-suppressor genes promote malignant change by stimulating cell-cycle entry, or disrupting the checkpoint response to DNA damage. Advances in the understanding of genetic and epigenetic mechanisms of gene regulation provide the basis for novel therapeutic approaches. This chapter presents the pathways and the genetic and epigenetic alterations that regulate cell replication, and highlights the various oncogenes and tumor-suppressor genes that are involved in hematologic malignancies.

Mitosis is the final step of a defined program—the cell cycle—that can be separated into four phases: the G_1 , S , G_2 , and M phases (Fig. 16–1). A number of surveillance systems (checkpoints) control the cell cycle and interrupt its progression when DNA damage occurs or when cells have failed to complete a necessary event.¹ These checkpoints have been

Acronyms and Abbreviations: ALL, acute lymphoid leukemia; AML, acute myelogenous leukemia; APC, anaphase-promoting complex; APL, acute promyelocytic leukemia; ATM, ataxia-telangiectasia mutated; ATR, ATM and Rad3 related; cdc, cell division cycle; cdk, cyclin-dependent kinase; CDKI, cyclin-dependent kinase inhibitor; Chk, checkpoint kinase; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CTD, carboxy-terminal domain; DDR, DNA damage response; DSIF, DRB-sensitivity-inducing factor; ER, endoplasmic reticulum; FLAM, flavopiridol, cytarabine, mitoxantrone; GADD, growth arrest and DNA damage; HAT, histone acetyltransferase; HDAC, histone deacetylase; HDACI, histone deacetylase inhibitor; HR, homologous recombination; Id1, inhibitor of DNA-binding 1; INK4, inhibitor of kinase 4; JAK, Janus-associated kinase; MAPK, mitogen-activated protein kinase; MCL, mantle cell lymphoma; MDM2, murine double minute protein 2; MLL, mixed-lineage leukemia; MTA, 5'-deoxy-5'-(methylthio)adenosine; MTAP, methylthioadenosine phosphorylase; NELF, negative elongation factor; N-TEF, negative transcription elongation factor; ODC, ornithine decarboxylase; PDGF, platelet derived growth factor; PI3K, phosphatidylinositol 3'-kinase; PLZF, promyelocytic leukemia Kruppel-like zinc finger; PML, promyelocytic leukemia; P-TEFb, positive transcription elongation factor; RAR α , retinoic acid receptor α ; RB, retinoblastoma gene; rPTK, receptor protein-tyrosine kinase; STAT, signal transducer and activator of transcription; TGF- β , transforming growth factor- β ; TKI, tyrosine kinase inhibitor; UPR, unfolded protein response.

given an empirical definition: When the occurrence of event B is dependent on the completion of prior event A, the dependence is a result of a checkpoint if a loss-of-function mutation can be found that relieves the dependence.¹ Three major cell-cycle checkpoints have been discovered: the DNA damage checkpoint, the replication checkpoint, and the spindle-pole body duplication checkpoint.^{2–4} The functional consequence of failure to “satisfy” the requirements of a cell-cycle checkpoint is usually death by apoptosis. However, small numbers of genetically altered cells may survive. Cells with defective checkpoints have an advantage when selection favors multiple genetic changes. Cancer cells often are missing one or more checkpoints, which facilitates a greater rate of genomic evolution.⁵

A disturbance of cell-cycle regulation is an important pathway in the development of many hematologic malignancies as a result of mutations in tumor-suppressor genes or oncogenes. Until the end of the 20th century, it was believed that the only mechanism by which the “gatekeepers” of the cell cycle could be inactivated was deletion or mutation (gain-of-function or loss-of-function mutations). Progress in the understanding of the regulation of gene expression put emphasis on another mechanism of gene inactivation, called *epigenetic regulation* (Chap. 10). This term summarizes several molecular modifications, including histone deacetylation, CpG-island hypermethylation, ubiquitination, and phosphorylation, etc.

● CYCLINS AND CYCLIN-DEPENDENT KINASES

Table 16–1 lists Cdks, associated partners, and their functions.

Early experiments on the control of mitosis in human cells provided evidence for the existence of factors called *M-phase* and *S-phase promoting factors*.⁶ The key element of S-phase promoting factor was thought to be cell division cycle (cdc) 2. Experiments performed in *Xenopus* eggs showed that cdc2 is an M-phase-specific histone H1 kinase,⁷ but is just one subunit of a regulatory complex. A second component is cyclin B, which is synthesized in interphase and degraded in mid-mitosis. More than 10 members of the mammalian cyclin family have been identified. Most of these cyclins interact with a group of cdc2-related kinases called *cyclin-dependent kinases* (cdks),^{8,9} while others are involved in alternate splicing processes.¹⁰ Phosphorylation of tyrosine 15 is the key event in regulating human cdc2 activity. Threonine 14 also is phosphorylated in G_2 phase. Dephosphorylation at both phosphorylation sites is required for mitotic initiation. Cdc2 interacts with cyclin B in mitosis, whereas the cdc2/cyclin A complex is formed before mitosis and is required for progression through late G_2 phase.¹¹ Thus, cyclins A and B are also called the *mitotic cyclins*, because they are upregulated in late G_2 or G_2/M phase and undergo proteolysis in M phase. The exit from mitosis is characterized by the abrupt ubiquitination and subsequent degradation of cyclin B. Cells with a defective cyclin B degradation mechanism or without mitotic cyclin B easily become aneuploid. There is evidence that cyclin A acts at the G_2/M transition and binds cdk2 in S phase. Cyclin A is mandatory for the downregulation of anaphase-promoting complex (APC).¹² Overexpression of cyclin A in G_1 phase leads to an accelerated entry into S phase.¹³ Because cdc2 is able to interact with mitotic and G_1 cyclins, it is likely that one protein kinase potentially can fulfill several different functions in the cell cycle at various checkpoints. Notably, there is increasing evidence that cdc2 is directly involved in regulating the DNA damage response (DDR), including DNA damage checkpoint activation and DNA repair (particularly homologous recombination [HR]).¹⁴ There are several cdc2-related protein kinases in humans that interact with the corresponding cyclins. Originally, three cdc2-related proteins were isolated, which

TABLE 16–1. CDKs, Associated Cyclins, and their Functions

Cdk	Associated Partner Cyclin	Function
Cdk1	Cyclin A, B	G ₂ /M
Cdk2	Cyclin A, D, E; C	G ₁ /S; S; G ₂ /M
Cdk3	Cyclin C	G _{0 exit}
Cdk4	Cyclin D	G ₁ ; G ₁ /S
Cdk5	p35, p39	Neuronal processes (neuron survival/death, migration, cortical layering, synaptic plasticity, etc.)
Cdk6	Cyclin D	G ₁ ; G ₁ /S
Cdk7	Cyclin H, Mat1	Cdk1, 2, 4/6 activation; transcriptional regulation
Cdk8	Cyclin C, MED12, MED13	Transcriptional regulation
Cdk9	Cyclin T1, T2	Transcriptional regulation
Cdk10	Ets-2	G ₂ /M
Cdk11	RanBPM, RNPS1, casein kinase, cyclin L	RNA splicing; transcriptional regulation; apoptosis
Cdk12	Cyclin K, L (?)	Transcriptional regulation; alternative splicing
Cdk13	Cyclin K, L (?)	Transcriptional regulation; alternative splicing

cyclins L1 and L2, and the type T cyclins (T₁, T_{2a}, and T_{2b}) fall outside these two major groups.

Cyclin A binds and activates cdk2 mainly in S phase. However, microinjection of anti-cyclin A antibodies into cells causes cell cycle arrest just before S phase.¹¹ This observation, together with the finding that overexpression of cyclin A leads to accelerated S-phase entry, suggests that cyclin A is involved in transformation.¹³ Cyclin A is able to compensate for loss of cyclin E function. Cyclin E is important for the duplication of centrosomes. In cyclin E-defective cells, cyclin A can take over the function of cyclin E in S phase, whereas cyclin A is important for centrosome amplification in G₂-arrested cells, irrespective of whether cyclin E is present.³⁶ The importance of cyclin A in cell division is underlined by other reports.³⁷ In addition to its role at the G₁/S boundary, cyclin A acts in late G₂ phase, where it complexes with cdk1. Cyclin E, the other cyclin that interacts with cdk2, may control the progression from G₁ to S phase, and the time point when cdk2 “switches” from cyclin E to cyclin A binding is right after prereplication complex assembly terminates while DNA replication initiates. Cells overexpressing cyclin E progress much faster through G₁ into S phase, but the time required for DNA synthesis remains normal.³⁸ On the other hand, a bifurcation in cdk2 activity determines whether cells immediately commit to the next cell cycle or enter a transient state of quiescence as they exit mitosis.³⁹ Cyclin E levels are also regulated by environmental factors, including transforming growth factor- β (TGF- β) and irradiation. These effects are, in part, mediated by small proteins, the cyclin-dependent kinase inhibitors. Cyclin E accumulates at the G₁/S boundary of the cell cycle, where it stimulates functions associated with entry into and progression through S phase.⁴⁰ In normal cells, cyclin E levels are highly regulated so that peak cyclin E-cdk2 kinase activity occurs only for a short interval near the G₁/S boundary.⁴⁰ Cyclin E-cdk2 complexes

become active during S phase and are then rapidly ubiquitinated after phosphorylation.⁴¹ The poor prognostic implications of overexpression of cyclin E has been observed in a variety of human malignancies,⁴² leading to a high cyclin E level throughout the cell cycle. The direct linkage between cyclin E overexpression and tumorigenesis is not completely understood. It has been suggested that the cyclin E-cdk2 complex phosphorylates and inactivates the RB protein⁴³ or leads to genomic instability via generation of aneuploid cells.⁴⁴ Cyclin E overexpression delays progression through early phases of mitosis and causes mitosis to be executed aberrantly, thus dysregulating mitotic progression.⁴⁵

The B-type cyclins associate with cdk1 to form the classical mitotic cyclin-cdk complexes.⁴⁶ Cyclin B is synthesized in S phase and accumulates, and in the midst of M phase is ubiquitinated and degraded, allowing the cell to exit from mitosis. The G₂/M checkpoint is very often defective in malignant cells, leading to uncontrolled M-phase entry and aneuploidy. The cellular localization of the cdk1-cyclin B complexes is strictly cell-cycle-dependent. Although the complexes accumulate in the cytoplasm during G₂ and S phase, they move to the nucleus in mitosis and bind to the mitotic spindle.^{47,48} The cyclin B family has different family members with distinct functions. At mitotic entry, cyclin B₁-cdk1 promotes chromosome condensation, nuclear membrane dissolution, mitotic aster assembly, and Golgi breakdown, whereas cyclin B₂-cdk1 can only induce Golgi disassembly.⁴⁹ At prophase, cyclin B₁ accumulates in the nucleus⁵⁰ and then localizes to condensed chromatin, spindle microtubules, centrosomes, and chromatin during prometaphase.⁵¹ Distinct sequence elements are responsible for the localization of cyclin B₁ to the chromatin, centrosomes, and kinetochores during mitosis.⁵²

The three cyclin D molecules—D₁, D₂, and D₃—function mainly in G₁ phase, where they bind cdk4 and cdk6. These complexes phosphorylate RB, restraining its inhibitory effects on E2F and related transcription factors. Cyclin D₁ is the major D cyclin in most cell types. All three cyclin D molecules act in late G₁ phase, just before entry into S phase. Cyclin D₁ also exhibits a variety of non-cell-cycle regulatory functions. For example, cyclin D₁ regulates microRNA biogenesis by induction of Dicer, a central regulator of microRNA maturation.⁵³ Many tumors have high cyclin D₁ levels without amplification or mutation of the cyclin D₁ structural gene. Instead, cyclin D levels may be regulated by a feedback loop dependent on RB. Alterations of the RB gene in cancer may secondarily cause upregulation of cyclin D transcription. As a result of its central role in cell-cycle control, the cyclin D-cdk4 complex is an important target for anticancer drugs. Mice lacking cyclin D₁ are completely resistant to ErbB-2-driven breast cancer.⁵⁴ ErbB-2-induced mammary tumor development is also prohibited by the inactivation of the cyclin D₁ partner cdk4, underlining the role of this complex in human malignancies.⁵⁵ As aberrations of the p16-cdk4-cyclin D-RB pathway are common in the majority of cancers, the development of selective cdk4 inhibitors (e.g., palbociclib) launched promising efforts to target tumors displaying either cyclin D₁ overexpression (e.g., breast cancer, mantle cell lymphoma, multiple myeloma) or cdk4 amplification (e.g., liposarcoma).⁵⁶ Moreover, cyclin D₁-cdk4 is also involved in regulation of glucose metabolism in postmitotic cells, suggesting a novel cell-cycle-independent function of this complex.⁵⁷ However, cdk6, a functional homologue of cdk4, may also play an important role in tumorigenesis under certain circumstances. For example, acute myelogenous leukemia (AML) cells carrying mixed-lineage leukemia (MLL) rearrangements (e.g., MLL-AF9, MLL-AF4, and MLL-AF6) specifically rely on cdk6, rather than cdk4, to proliferate,⁵⁸ suggesting that cdk6 might represent a target in MLL-driven leukemia.⁵⁹ Interestingly, SUMOylation stabilizes the cdk6 protein, which may contribute to progression of some tumors (e.g., glioblastoma).⁶⁰ Notably, cyclin D-dependent cdk4/6 also phosphorylates a variety of substrates (e.g., RB1 and its relatives RBL1 and RBL2, SMAD2, SMAD3, FOXM1, MEP50,

etc.), forming a central node in a complex signaling network that governs the overall transcriptional and biologic response of cells to activation or inhibition of the kinases.⁶¹

Cdk7 plays dual functions in regulation of cell cycle and gene transcription. In the former case, cdk7, together with its partner cyclin H, acts as a cdk-activating kinase, which fully activates various cell-cycle-regulatory cdks (e.g., cdk1, cdk2, cdk4, and cdk6) by phosphorylating their T loop in a context-specific manner.⁶² For example, whereas cdk7 is required to determine cyclin specificity and activation order of cdc1 and cdk2 during S and G₂ phases, it is also required to maintain the activity of cdk4 as cells exiting quiescence and G₁ progression through the restriction point.⁶³ Cdk7, as a component of the general transcription factor TFIIF (cdk7/cyclin H/Mat1 complex), phosphorylates the carboxy-terminal domain (CTD, serines 5 and 7) of RNA polymerase II, which is responsible for transcription initiation and promoter clearance, a critical step in switching initiation to elongation during transcription.⁶⁴ As transcription factors that co-opt the general transcriptional machinery to sustain the oncogenic state, pharmacologic inhibition of cdk7 may represent a novel approach to treat tumor types (e.g., T-cell acute lymphoblastic leukemia [T-ALL]) that are particularly dependent on transcription.⁶⁵

Cdk9, as a catalytic subunit, partners with the regulatory subunit cyclin T, an 87-kDa cyclin C-related protein with three isoforms, to form a complex known as positive transcription elongation factor b (P-TEFb).⁶⁶ The so-called cdk9-related pathway consists of two cdk9 isoforms (cdk9-42 and cdk9-55), cyclin T₁, cyclin T_{2a}, cyclin T_{2b}, and cyclin K.²⁷ Cdk9 and its binding partner cyclin T₁ comprise the P-TEFb.⁶⁷ P-TEFb hyperphosphorylates the CTD (primarily serine 2) of RNA polymerase II, essential for transcription elongation. P-TEFb also phosphorylates the negative transcription elongation factors (N-TEFs), including DRB-sensitivity inducing factor (DSIF) and the negative elongation factor (NELF), to release the transcription block (a pause immediately after transcription initiation) of both N-TEFs on hypophosphorylated forms of RNA polymerase II. In addition, cdk9 also plays a role in ribosomal RNA processing through activation of RNA polymerase II.⁶⁸ In normal cells, the activity of P-TEFb is stringently maintained in a functional equilibrium to accommodate transcriptional demands for different biologic activities.⁶⁹ As a rule in oncogenic transformation, upregulated antiapoptotic or prosurvival proteins in transformed cells must be sustained by constitutive RNA polymerase II activity that governs transcription elongation, in which cdk9 is the primary processivity factor.⁷⁰ In other words, transformed cells are addicted to transcription because of the requirement for continuous production of antiapoptotic proteins, particularly those with short half-lives. Of note, abnormal activities in the cdk9-related pathway occur in many human malignancies.⁷¹ For example, high levels of cdk9/cyclin T₁ expression are found in several types of hematologic malignancies, including B- and T-cell precursor-derived lymphomas, anaplastic large cell lymphoma, and follicular lymphomas, whereas strong nuclear staining for both proteins are observed in Hodgkin and Reed-Sternberg cells of classical Hodgkin lymphoma. In this context, selective cdk9 inhibitors preferentially target malignant cells in preclinical hematologic tumor models, including leukemia and multiple myeloma.^{72,73} Mcl-1, the Bcl-2 family antiapoptotic protein with an estimated half-life of less than 3 hours,⁷⁴ represents one of the most common downstream targets for cdk9 inhibition.⁷⁵ Moreover, cdk9 inhibition disrupts the process of cytoprotective autophagy, for example, through downregulation of the adaptor protein SQSTM1/p62, resulting in an inefficient form of autophagy from cargo-loading failure, which, in turn, triggers apoptosis via upregulation of the BH3-only protein NBK/Bik.⁷⁶ Moreover, cdk inhibitors also induce upregulation of other BH3-only proteins such as Bim and Noxa.⁷⁷ Although it remains to be determined whether these events stem from inhibition of

specific cdk(s), it is now clear that in addition to cell cycle-regulatory cdks, transcription-regulatory cdks, such as cdk9, represent another class of therapeutic targets. In addition, P-TEFb forms a complex with the HIV tat protein that binds the transactivation response element. The modification of RNA polymerase II by cdk9/cyclin T facilitates the efficient multiplication of the viral genome.⁷⁸ Other binding partners of cdk9 include tumor necrosis factor receptor-associated factor 2,⁷⁹ as well as inhibitory MAQ1 (or HEXIM1) and 7SK small nuclear RNA.⁸⁰ Furthermore, cdk9 is expressed throughout the cell cycle⁸¹ and is also involved in viral (HIV, herpes) replication.²⁷

Other members of the transcription-regulatory cdk subfamily include cdk8 and cdk12. Cdk8 is a subunit of the large Mediator complex (~1.2 MDa) composed of 25 to 30 proteins, which acts as a molecular bridge between DNA-binding transcription factors and RNA polymerase II. Cdk8 binds to cyclin C, MED12, and MED13 in the cyclin C-cdk8 module of the Mediator.⁸² The cdk8/cyclin C pair facilitates phosphorylation of both serine 2 and serine 5 at the CTD of RNA polymerase II.⁸³ Cdk8 can perform both positive and negative functions in transcriptional regulation during different transcription stages (e.g., preinitiation and elongation), which provide a mechanism to respond to different promoter contexts (e.g., transcription factors or cdk8 module binding).⁸² Unlike cdk7 and cdk9, which govern global gene expression, cdk8 promotes only gene-specific transcription. Recently, cdk8 expression has been detected in 70 percent colorectal cancers and correlated with β -catenin activation, suggesting that cdk8 may act as an oncogene in certain types of cancer (e.g., colorectal and pancreatic cancer).^{84,85} Cdk12 and cdk13 have been identified as CTD kinases, both of which are unusually large proteins that contain a central kinase domain and share the same partner, cyclin K.⁸⁶ Cdk12/cyclin K₁ phosphorylates the CTD (preferably serine 2) of RNA polymerase II.⁸⁷ Interestingly, cdk12/cyclin K only regulates expression of a small subset of genes, predominantly long genes with high exon numbers and DDR genes, including critical regulators of genomic stability, for example, *BRCA1*, *ATR* (ataxia-telangiectasia mutated [ATM] and Rad3 related), *FANCI*, and *FANCD2*.⁸⁸

The cdk10 gene encodes two different cdk-like putative kinases; it is postulated that they exert their function at the G₂/M transition.²⁹ These two isoforms predominate in human tissues, except in brain and muscle, and the relative isoform levels do not vary during the cell cycle.²⁹ Cdk10 interacts with the N-terminus of the Ets2 transcription factor, which contains the highly conserved pointed transactivation domain. The pointed domain is implicated in protein-protein interactions and Ets2 requires an intact pointed domain to bind Cdk10, which inhibits Ets2 transactivation in mammalian cells.³¹ This could be an important factor for the development of follicular lymphoma, because cdk10 is overexpressed in this cancer.⁸⁹ In addition, cdk10 silencing increases Ets2-driven transcription of c-RAF, resulting in mitogen-activated protein kinase (MAPK) pathway activation and loss of tumor cell reliance upon estrogen signaling.⁹⁰ Cdk10 promoters are frequently hypermethylated in malignant tumors, resulting in low expression levels of cdk10 and impaired cell-cycle regulation.⁹⁰

Cdk11 is associated with cyclin L.⁹¹ It is part of the large family of p34(cdc2)-related kinases whose functions appear to be linked with cell-cycle progression, tumorigenesis, and apoptotic signaling. Cdk11 interacts with the p47 subunit of eukaryotic initiation factor 3 during apoptosis and is therefore directly involved in cell death mechanisms.⁹² Casein kinase 2 phosphorylates the cdk11 aminoterminal domain, suggesting that cdk11 participates in signaling pathways that include casein kinase 2 and that its function may help to coordinate the regulation of RNA transcription and processing events.⁹¹ So far two isoforms of cdk11 have been identified, a larger p110 and a smaller p46 isoform. During Fas- or tumor necrosis factor- α -induced apoptosis,

the caspase-processed p46 isoform is generated from the larger p110 isoform and it promotes apoptosis when it is ectopically expressed in human cells. Cdk11 also stabilizes the microtubule assembly of cells⁹³; cdk11 is therefore mandatory for the maintenance of sister chromatid cohesion⁹⁴ and its disruption can contribute to the development of cancer.⁹⁵

SUBSTRATES AND INHIBITORS OF CYCLIN-DEPENDENT KINASES

Many cyclin–cdk substrates have been identified by immunoprecipitation or two-hybrid assays, but only a few of them are thought to exert a direct function in cell-cycle control. The regulation of the cell cycle has been studied extensively during the last decade and a consensus paradigm of cell-cycle regulation has been suggested.^{50,96} According to this paradigm, the important switch of the cell cycle is the RB family of proteins (Fig. 16–2). In its hypophosphorylated state, RB binds to and inhibits a class of transcription factors, of which the best characterized is the E2F transcription factor. Hyperphosphorylation causes RB to detach from its binding site, permitting transcriptional activation of genes necessary for DNA synthesis and cell division. This phosphorylation of RB is regulated in a cell-cycle–dependent manner.⁹⁷ A widely accepted model suggests that RB is phosphorylated by different regulators such as cyclin E/cdk2 at the so-called “R” point, a time point during G₁ when cell cycle progression becomes independent of exogenous stimuli.⁹⁸ Interference with RB function impairs G₁ checkpoint regulation and fosters unrestrained cell growth, a nearly universal characteristic of

malignancy. RB controls the activity of several other cell-cycle regulatory elements such as Skp2.⁹⁹ The Skp2 regulation follows an autocrine loop where Skp2 triggers degradation of the cdk inhibitor p27^{kip1}, followed by cyclin E/cdk2 activation, consecutive cdk2-induced RB-phosphorylation, and further E2F-dependent Skp2 expression.¹⁰⁰ Causes of reduced RB activity include changes in the structural gene, the sequestration and inactivation of the protein by viral oncogene products, and hyperphosphorylation of RB as a result of increased cdk4 and cyclin D activity or deletion of the gene for the p16^{INK4A} inhibitor of cdk4. Deletions, mutations, and translocations of RB are common in various malignancies, while homozygous deletions of the p16^{INK4A} gene are even more frequent. Many different transforming viruses (papillomavirus, simian virus 40) produce proteins that interact with RB. Both cyclin D₁–cdk4 and cyclin D₁(D₂, D₃)–cdk6 complexes are able to phosphorylate RB.^{101,102} The time point of RB phosphorylation correlates strongly with the appearance of the cyclin D₁–cdk4 complex.¹⁰³ The link between RB and cyclin D is supported by the observation that loss of RB function leads to a decrease in the cellular cyclin D level.¹⁰⁴ However, cyclin D is not the only cyclin that is involved in the RB regulatory pathway.^{99,102} Ectopic expression of both cyclin A and cyclin E restores RB hyperphosphorylation and causes cell-cycle arrest in cancer cell lines. Perhaps the cdk2–cyclin A complex contributes to additional phosphorylation of RB, whereas the cdk2–cyclin E complex prolongs the phosphorylation time.¹⁰⁵

The key regulatory element for the G₁-to-S transition is the RB–E2F complex. After RB is phosphorylated by cdk4 and/or cdk6 complexes during G₁ phase and cdk2 at G₁/S interphase, E2F proteins are released and promote the transcription of genes essential for the transition to S phase.^{99,106} As mentioned above, the p16^{INK4A}/cyclin D₁/cdk4/RB/E2F cascade is probably one of the most important cascades in cell-cycle control, and is frequently affected in human cancer. For example, this pathway is defective in nearly 100 percent of AML cell lines and most of the primary AML samples, although the exact mechanism of inactivation is not always clear. Two RB-related pocket proteins, p107 and p130, also form complexes with the transcription factor E2F,¹⁰⁷ bind to the region of the adenovirus E1A protein required for transformation, and are able to induce G₁ arrest when they are overexpressed in human malignant cell lines.^{108,109} Unlike RB, the p107 and p130 proteins contain a so-called spacer region that interacts with cdk2/cyclin A and cdk2/cyclin E,¹¹⁰ although it seems to be unlikely that these two complexes regulate the activity of p107 and p130.¹⁰⁵ Instead, p107 may bind and inactivate the cyclin A and cyclin E complexes. Thus, p107 may regulate the cell cycle by several different mechanisms. Because both p107 and p130 are regulated through phosphorylation, efficient cell-cycle entry is accompanied by phosphorylation of all the RB-related proteins.¹¹¹

In addition to its cell-cycle regulatory properties, RB also influences hematopoietic differentiation.¹¹² RB interacts with the transcription factor PU.1, which blocks erythroid differentiation in the proerythroblast stage when ectopically overexpressed in marrow cells,^{113,114} and represses GATA-1 activity.¹¹⁵ An important event in this differentiation process is the interaction between hematopoietic stem cells and the microenvironment of the marrow. In addition, hypophosphorylated RB promotes monocytic over neutrophilic differentiation in bipotent progenitor cells, an event that is switched to neutrophilic differentiation if RB expression is inhibited. This finding points to an important property of RB independent of cell-cycle control.¹¹⁶

Besides regulation by phosphorylation, specific protein inhibitors of cdk enzymatic activity have been identified.¹¹⁷ The cyclin-dependent kinase inhibitors (CKIs) cause cells to arrest in G₁ phase, followed by differentiation and/or senescence. The first CKI identified was p21^{cip1}.¹¹⁸ It binds to several cyclin/cdk complexes, including cyclin A/cdk2, cyclin D/cdk4, and cyclin E/cdk2 (see Fig. 16–2).^{97,119} Several different cell-cycle

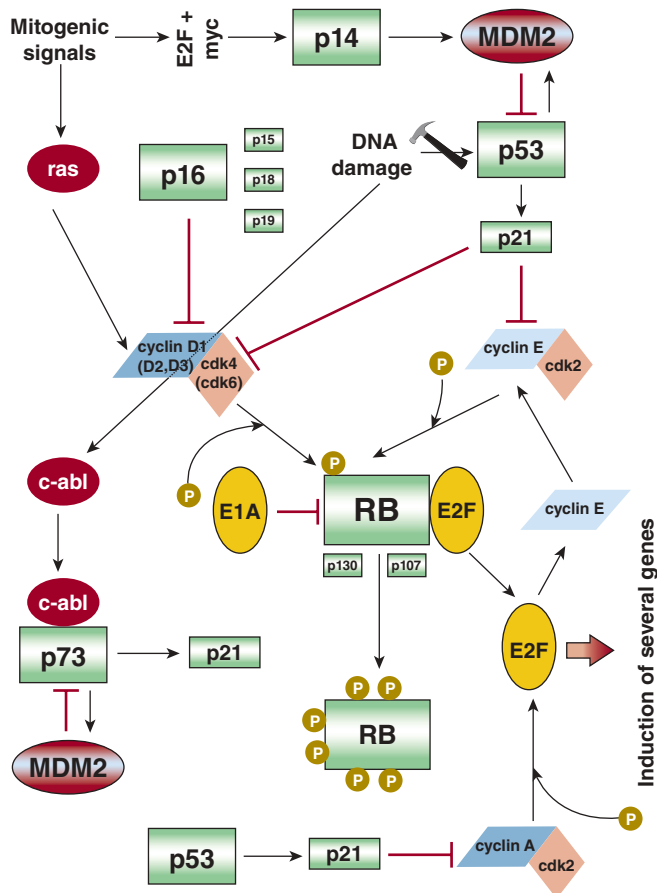

Figure 16–2. Interactions between cyclin-dependent kinase inhibitors (p16, p14, p21), p53, and the retinoblastoma protein (RB).

regulatory pathways are affected by p21^{cip1}. In addition, a basal p21^{cip1}-cdk2 axis determines quiescent and cycling cell states and thus controls population heterogeneity in both normal cells and tumors, which can make anticancer treatment selectivity challenging.¹²⁰ The molecule has a p53 binding site in its promoter, and an increase in p53 levels results in transcriptional activation of p21^{cip1}, slowing cell-cycle progression. In addition to this p53-dependent pathway, p21^{cip1} is also regulated in a p53-independent manner. For example, histone deacetylase inhibitors (HDACIs) are able to induce p21^{cip1} expression in p53^{null} leukemia cells through an alternative nuclear factor (NF)- κ B-dependent mechanism, which may limit the antileukemia activity of these agents.^{121,122} Several binding partners of p21^{cip1}, including Pim-1, have been identified. Pim-1 associates with and phosphorylates p21^{cip1} *in vivo*, which influences the subcellular localization of p21^{cip1}.¹²³ p21^{cip1} is phosphorylated by Pim-1 at two distinct sites, Thr145 and Ser146; phosphorylation on Thr¹⁴⁵ results in a nuclear localization of p21^{cip1} and a disruption of the cell cycle, while phosphorylation on Ser¹⁴⁶ leads to a cytoplasmic localization of p21^{cip1},¹²⁴ suggesting that overexpression of Pim-1 in certain tumors plays a key role in tumorigenesis.¹²⁵ Like RB, expression and function of p21^{cip1} is also affected by several different mechanisms, including mutation and histone deacetylation (see “The Role of Histone Deacetylases in Cell-Cycle Regulation” below). Other members of the p21^{cip1} family of CDKIs include p27^{kip1} and p57^{kip2}.^{101,126} As a cdk inhibitor, p27^{kip1} has tumor-suppressor activity. Besides cdk, p27^{kip1} regulates additional cellular processes, including cell motility, some of which seem to mediate the oncogenic activities of p27^{kip1}. For example, the constellation of high p27^{kip1} and low Myc expression is characteristic of chronic lymphocytic leukemia (CLL) cells.¹²⁷ These activities of p27^{kip1} are regulated through multiple phosphorylation sites. The multiple functions of p27^{kip1} are dependent on a number of different conditions, and dictate whether the protein displays anti- or protumorigenic properties.¹²⁸ High-level expression of p27^{kip1} leads to a cell-cycle block in G₁ phase after treatment of cells with TGF- β . One major difference between p21^{cip1} and p27^{kip1} is that the former binds predominantly to cdk2 whereas the latter binds cdk4.

The cellular levels of a number of cell-cycle regulators, including p21^{cip1} and p27^{kip1}, are regulated by ubiquitination and subsequent proteolysis. Polyubiquitinated proteins are degraded by the 26S proteasome complex. There are two major ubiquitination systems in the cell; they are designated SCF and APC.^{108,110} SCF is named for three of its core components, Skp, Cullin, and an F-box-containing protein. Important examples of SCF substrates are Cln1, Sic1, Wee1, Cdc6/Cdc18, E2F, cyclin D₁, cyclin E, p21^{cip1}, p27^{kip1}, and p57^{kip2}.¹²⁹

A second group of CDKIs belongs to the inhibitor of the kinase 4 (INK4) family and includes *p15^{INK4B}*, *p16^{INK4A}*, *p18^{INK4C}*, and *p19^{INK4D}*.^{104,107,130,131} They all bind and inhibit the cyclin D₁-cdk4 and/or cyclin D₁-cdk6 complex, which regulate cell-cycle progression via RB.^{104,130} TGF- β is also a potent inducer of *p15^{INK4B}*,¹⁰⁴ one of the mechanisms by which the cytokine regulates the proliferation of hematopoietic cells (Chap. 16). *p16^{INK4A}* is probably the most important CDKI, because the gene is inactivated by several mechanisms (deletion, mutation, hypermethylation) in many different human cancers.¹³² Surprisingly, *p16^{INK4A}* and *p14^{ARF}* are overexpressed in some cases of human hematologic malignancies.¹³³ This overexpression is probably a result of defects downstream of *p16^{INK4A}*, particularly caused by mutations in the RB gene.¹³⁴ In hematologic malignancies, the highest frequencies of *p14^{ARF}*, *p15^{INK4B}*, or *p16^{INK4A}* inactivations are found in T-ALL,¹³⁵ secondary high-grade lymphomas, and mantle cell lymphoma (MCL).^{136,137} The potency of *p14^{ARF}* and *p16^{INK4A}* in terms of tumorigenicity becomes obvious because the reexpression of both genes by either retroviral transfection or demethylation of the promoter regions results in a complete reversion of the malignant phenotype.^{138,139} *p14^{ARF}* has multiple

tumor-suppressor functions, some of which are mediated by signaling to p53. On the other hand, it has been shown that *p14^{ARF}* is able to drive tumor progression in a p53-independent fashion, especially in myc-driven lymphomas.¹⁴⁰

● PHARMACOLOGIC INHIBITION OF CYCLIN-DEPENDENT KINASES

Perturbations of the cell cycle, for example, overexpression of cyclins or underexpression of endogenous CDKIs, are nearly universal in human malignancies, and cdk, as critical regulators of cell-cycle progression and RNA transcription, represent attractive targets for anticancer drug development, as their inhibition can lead to both cell-cycle arrest and apoptosis.^{141,142} Additionally, pharmacologic inhibition of transcriptional cdk, for example, cdk9, affects proteins with short half-lives, for example, the antiapoptotic proteins Mcl-1 and XIAP (X-linked inhibitor of apoptosis), cell-cycle regulators, p53, and NF- κ B-responsive gene products.¹⁴² Hematologic malignancies may be particularly susceptible to cdk inhibition and apoptosis induction. A number of pharmacologic CDKIs have been developed and subjected to various phases of preclinical and clinical testing in hematologic malignancies (for a review, see Ref. 143). The selective cdk4/6 inhibitor palbociclib has been approved by the FDA as a potential treatment for hormone-responsive metastatic breast cancer. In MCL, a disease characterized by cyclin D₁ overexpression, this agent has demonstrated encouraging clinical activity.¹⁴⁴ Whether selective or broad-spectrum inhibition is the superior therapeutic strategy continues to be debated,¹⁴³ and may be tumor type-specific. The “pan-CDKI” flavopiridol (alvociclib), the first CDKI to enter the clinic, has shown promising activity in patients with genetically high-risk chronic lymphocytic leukemia (CLL), particularly when administered by a pharmacologically derived “hybrid” schedule,^{145,146} but recent developmental efforts for this agent have focused on AML, where it was recently granted “orphan drug” status.¹⁴⁷ Flavopiridol induces apoptosis in primary leukemic blasts and recruits surviving leukemic cells into a proliferative state, thereby priming such cells for killing by S-phase-active cytotoxic agents such as cytarabine.^{148,149} These observations led to the design of “timed sequential therapy” regimens, for example, FLAM (flavopiridol, cytarabine, mitoxantrone), which exhibited promising clinical activity in AML patients with nonfavorable cytogenetics.¹⁵⁰ Interestingly, both “bolus” and “hybrid” schedules of administration of flavopiridol produce comparably encouraging results in this setting.¹⁵¹ Other rational combinations involving pan-CDKIs such as flavopiridol or roscovitine involve those with proteasome inhibitors (PIs),^{152,153} HDACIs¹⁵⁴ or BH3-mimetics.⁷⁵ The first strategy has been explored in phase I trials in patients with recurrent or refractory indolent B-cell neoplasms,^{155,156} and a phase I trial of bortezomib and dexamethasone plus the pan-CDKI dinaciclib in patients with relapsed myeloma is ongoing as of this writing (NCT01711528). Synergism in preclinical studies in leukemia between pan-CDKIs and HDACIs is based predominantly on reciprocal effects on the cytoprotective NF- κ B pathway and the endogenous cdk inhibitor p21^{WAF1/CIP1}, besides Mcl-1/XIAP downregulation.¹⁵⁴ Some of these phenomena have been recapitulated in patients with AML.¹⁵⁷

● CELL-CYCLE CHECKPOINTS

The cell cycle progresses in an orderly fashion and is monitored by safety mechanisms known as cell-cycle checkpoints, which, upon activation, function to halt cell division.¹⁵⁸ When DNA damage occurs, distinct, albeit overlapping and cooperating, checkpoint pathways are activated,

which block S-phase entry (the G_1/S -phase checkpoint), delay S-phase progression (the intra-S- or S-phase checkpoint), or prevent mitotic entry (the G_2/M -phase checkpoint). These events direct phase-specific DNA repair mechanisms through repair-specific gene transcription. If repair fails, checkpoints trigger apoptosis.¹⁵⁹ Checkpoints are thus important quality control measures that ensure the proper sequence of cell-cycle events and allow cells to respond to DNA damage.¹⁶⁰

The G_1/S checkpoint is the first defense against genomic stress in cycling cells. In response to DNA damage, the G_1/S checkpoint prevents cells from entering the S-phase by inhibiting the initiation of DNA replication. At this checkpoint, the checkpoint kinase Chk2 is activated by the proximal transducer ATM to phosphorylate (and thereby inhibit) the cdc25A phosphatase, thus preventing activation of cyclin E(A)/cdk2 and temporarily halting the cell cycle. G_1 arrest is sustained by ATM/Chk2-mediated phosphorylation of murine double minute protein 2 (MDM2) and p53, resulting in p53 stabilization and accumulation. p53 transcriptionally activates the endogenous cdk inhibitor p21, which, in turn, inhibits cyclin E(A)/cdk2 and preserves the association of Rb with E2F.¹⁶⁰

The intra-S or S-phase checkpoint is activated in response to structural DNA damage as well as stalled replication forks. Upon activation of this checkpoint, ATR/Chk1 and ATM/Chk2 phosphorylate cdc25A, resulting in enhanced proteolysis of the phosphatase and inhibition of its function through 14-3-3 σ binding. Cyclin E(A)/cdk2 is thereby inhibited, and progression through the S-phase halted.¹⁵⁸

The G_2/M checkpoint prevents mitotic entry of cells that have either incurred DNA damage during G_2 , or that have escaped the G_1/S and intra-S checkpoints despite earlier genomic insults. The key downstream target of the G_2/M checkpoint is the promotive cyclin B/cdk1 (cdc2) complex. During interphase, this complex is inactivated through phosphorylation by Myt1 and Wee1.¹⁵⁸ Chk1 may phosphorylate Wee1, mediating binding of Wee1 to 14-3-3 proteins, which, in turn, may stimulate the kinase activity of Wee1 against cdk1 (cdc2). Thus, both Chk1 and 14-3-3 proteins may act together as positive regulators of Wee1.¹⁶¹ Activation of cyclin B/cdk1 (cdc2) requires dephosphorylation by the cdc25 phosphatases (A, B, and C). Notably, phosphorylation/inactivation of cdk1 (cdc2) involves two inhibitory sites, for example, Tyr15 and Thr14, and dephosphorylation of both sites is necessary for full cdk1 (cdc2) activation. Initiation of the G_2/M checkpoint is mediated by ATR/Chk1, which phosphorylates (and thereby inhibits) cdc25A, B, and C, whereas maintenance of this checkpoint requires p53 and its downstream effectors p21, 14-3-3 σ , and growth arrest and DNA damage (GADD) 45.¹⁵⁸

Checkpoint dysfunction is common in human cancers and is considered a pathologic hallmark of neoplastic transformation.¹⁶² Conversely, agents used for cancer treatment, such as cytotoxic chemotherapy and ionizing radiation, activate cell-cycle checkpoints.¹⁵⁸ Cancer cells are particularly dependent upon the S- and G_2/M -phase checkpoints for repair of DNA damage because of preexisting defects in G_1/S checkpoint mechanisms, such as p53 and RB mutations. Because the S-phase checkpoint facilitates slowing, rather than arrest, of the cell cycle, a cancer cell harboring DNA damage may progress through the S-phase checkpoint, only to halt at the G_2/M checkpoint. The latter is, therefore, a key guardian of the cancer cell genome, and its abrogation can lead to enhanced tumor cell death while sparing normal cells, which maintain an intact G_1/S -phase checkpoint. G_2/M checkpoint abrogation prevents cancer cells from repairing DNA damage, forcing them into a premature and lethal mitosis (“mitotic catastrophe”).¹⁶⁰

Based upon these concepts, synergism between DNA-damaging agents (cytotoxic chemotherapy) and G_2/M checkpoint abrogators have been examined both preclinically and in clinical studies. In human AML cell lines, the Chk1 inhibitor MK-8776 (SCH900776) markedly

increased cytarabine-induced apoptosis, with negligible impact on normal myeloid progenitors,¹⁶³ leading to a phase I trial of the combination in patients with relapsed and refractory acute leukemias.¹⁶⁴ Chk1 inhibitors increase HDACi lethality in human leukemia cells.¹⁶⁵ This may reflect the ability of HDACi to induce DNA damage in AML cells,¹⁶⁶ inhibit both homologous recombination and nonhomologous end-joining mechanisms of DNA repair,¹⁶⁷ and downregulate/inactivate Chk1.¹⁶⁸ However, clinical development of MK-8776 has been halted. Based upon the ability of Hsp90 inhibitors to downregulate Chk1, a phase I study of the combination of cytarabine and the Hsp90 inhibitor tanespimycin was conducted in adults with recurrent or refractory acute leukemia; however, the combination exhibited limited clinical activity.¹⁶⁹

Wee1 is a validated therapeutic target in AML.¹⁷⁰ The combination of cytarabine and the Wee1 inhibitor AZD1775 synergistically induces apoptosis in myeloid cell lines.¹⁷¹ Similarly, genome-wide short hairpin RNA screens strongly implicate cell-cycle checkpoint proteins, particularly Wee1, as critical mediators of AML cell survival after cytarabine exposure.¹⁷² In AML cell lines, synergistic inhibition of proliferation by the combination of AZD1775 and Ara-C occurred regardless of p53 functionality.¹⁷³ Another combinatorial strategy in AML involves coadministration of AZD1775 with HDACi.¹⁷⁴ Besides inducing DNA damage and inhibiting DNA repair, HDACi downregulate several proteins critical to checkpoint function, such as ATR, Chk1, and Wee1,^{168,175–177} and Wee1 inhibition promotes premature mitotic entry of cells bearing unrepaired DNA damage.¹⁷⁸ Efforts to extend these pre-clinical findings to the clinic are underway.

● ONCOGENES

Table 16–2 lists the common genomic aberrations seen in hematologic malignancies. Tables 16–3 and 16–4 list common somatic mutations encountered in the major myeloid and lymphoid malignancies, respectively.

The complicated cell-cycle network has its parallel in the several different oncogenes and tumor-suppressor genes that influence carcinogenesis and tumor progression. The products of oncogenes, the oncoproteins, lead to or facilitate the transformation of a normal into a malignant cell. Oncogenes can be carried into the cell by viruses or they can arise from mutations in normal cellular genes. In addition, they can also arise from leukemia- or lymphoma-associated translocations where two usually separated genes are fused together and form a novel fusion protein. The familiar concept of this kind of protooncogene activation can be blurred by the fusion proteins because they possess unique capabilities not shared by either of the individual fusion partners. Oncoproteins can interact directly with cell-cycle regulatory proteins or control their activity through phosphorylation and dephosphorylation. Not all mutations in oncogenes lead to an altered function of the resulting product. The nomenclature in the oncogene and tumor-suppressor gene field is not always clear. As a general guideline, if a mutation causes a functional loss of the gene product (loss of function), and the recessive loss of function leads directly to uncontrolled cell division, the underlying gene can be named a *tumor-suppressor gene*. On the other hand, if the mutation leads to an altered gene product (gain of function) that interacts abnormally with other proteins to influence the cell cycle, this gene is an *oncogene*, acting in a dominant fashion. Translocations are typical of oncogenes, whereas homozygous deletions and hypermethylation of CpG-nucleotide repeats in the promoter regions (“epigenetic silencing”) are characteristic features of tumor-suppressor genes.

Numerous oncogenes/oncogene candidates are described in the literature, and most of them are involved in the pathogenesis and development of many different tumors types, especially the

TABLE 16–2. Common genomic aberrations seen in the major hematologic malignancies.

Chromosomal abnormality	Genes/loci affected or fusion gene where applicable	Functional consequence, if known	Approximate incidence (in newly diagnosed patients)	Prognostic/therapeutic implications, if any
ACUTE MYELOID LEUKEMIA				
t(8;21)(q22;q22) – diagnostic of AML regardless of blast count	<i>RUNX1-RUNX1T1 (AML1-ETO)</i>	Fusion protein alters transcriptional regulation of normal RUNX1 target genes and activates new target genes to prevent apoptosis and/or differentiation	7% in adults; most frequent abnormality in children with AML	Favorable prognosis in adults (not children) unless c-kit mutated; respond particularly well to high dose cytarabine-based regimens; generally not allografted in CR1
inv(16)(p13.1;q22) or t(16;16)(p13.1;q22) – diagnostic of AML regardless of blast count	<i>CBFB-MYH11</i>	Fusion protein disrupts function of RUNX1/CBFB transcription factor → repression of transcription; association with M4 FAB subtype and abnormal bone marrow eosinophils	5% in adults	Favorable prognosis unless c-kit mutated; respond particularly well to high dose cytarabine-based regimens; generally not allografted in CR1
t(15;17)(q24.1;q21.1) – diagnostic of AML (APL) regardless of blast count	<i>PML-RARA</i>	Fusion protein causes transcriptional repression, preventing differentiation of promyelocytes	13% (APL, most common form of AML related to therapy with bismolane for psoriasis)	Differentiation block overcome by pharmacologic doses of ATRA; high cure rates; low/intermediate risk patients can be cured without chemotherapy
11q23 rearrangements	<i>KMT2A (MLL)</i> and various partner genes, e.g., <i>AF9</i> (most common partner) or partial tandem duplication	Complex effects (CDKs important in leukemogenesis); can also result in lymphoid phenotype (e.g., <i>KMT2A-AF4</i> fusion with t(4;11)(q21;q23)	6% in young adults and up to 12% in children; often seen in AML following therapy with DNA topoisomerase II inhibitors	Poor prognosis unless t(9;11)(p22;q23) leading to <i>KMT2A-AF9</i> fusion (intermediate prognosis); MLL translocations predict improved outcome with high dose daunorubicin
inv(3)(q21;q26.2) or t(3;3)(q21;q26.2) or ins(5;3)(q14;q21q26.2)	<i>MECOM (EV1)</i>	<i>MECOM (EV1)</i> activation can promote or repress transcription depending on binding partners through interaction with transcriptional and epigenetic regulators	1% (3q abnormalities as a whole in 4.4%)	Adverse prognosis; association with thrombocytosis and increased, often abnormal, bone marrow megakaryocytes
t(6;9)(p23;q34)	<i>DEK-NUP214 (DEK-CAN)</i>	Fusion protein is a nucleoporin that acts as a transcription factor and also alters nuclear transport	1%	Poor prognosis; high incidence of <i>FLT3-ITD</i> ; association with basophilia, dysplasia and pancytopenia
Trisomy 8			13%	Intermediate prognosis
Loss of chromosome 7 or del7q	<i>CUX1, EZH2</i>	<i>CUX1</i> encodes a transcription factor and <i>EZH2</i> a histone methyltransferase; both act as tumor suppressors	-7 seen in 9%	Poor prognosis; strong associations with older age, secondary AML, complex karyotype and prior therapy with alkylating agents or radiation
Loss of chromosome 5 or del5q	<i>RPS14, miR-145/146a, EGR1, NPM1, APC, CTNNA1</i>	Unclear; cooperative loss of multiple genes on 5q likely required for pathogenesis	-5 seen in 6%	Poor prognosis; strong associations with older age, secondary AML, complex karyotype and with prior therapy with alkylating agents or radiation
del17p	<i>TP53</i>	Loss of tumor suppressor “guardian of genome”, failure of cell cycle checkpoint mechanisms, disruption of DDR	<i>TP53</i> mutations seen in only 9% of older patients with <i>de novo</i> AML, but much more common in secondary and <i>t</i> -AML	Very poor prognosis, high risk of treatment failure not overcome even by allogeneic HSCT; strong association with complex karyotype

(continued)

TABLE 16–2. Common genomic aberrations seen in the major hematologic malignancies. (Continued)

Chromosomal abnormality	Genes/loci affected or fusion gene where applicable	Functional consequence, if known	Approximate incidence (in newly diagnosed patients)	Prognostic/therapeutic implications, if any
Complex karyotype (≥ 3 acquired, unrelated abnormalities in the absence of t(8;21), inv(16)/t(16;16) or t(15;17))	Multiple		10-12%, increases with age; much more common in secondary or t-AML	Very poor prognosis; 5q, 17p and 7q abnormalities most common; <i>TP53</i> alterations the most important prognostic factor
Monosomal karyotype (≥ 2 monosomies, or a single monosomy in the presence of structural abnormalities)	Multiple		13%, increases with age	Extremely poor prognosis not overcome even by allogeneic HSCT
CHRONIC MYELOID LEUKEMIA				
t(9;22)(q34;q11)	<i>BCR-ABL1</i> (vast majority of cases characterized by the p210 "major" fusion protein)	Fusion protein (constitutively active tyrosine kinase) drives all aspects of pathogenesis in chronic phase; other pathways also important in advanced phases	All cases (atypical CML, Bcr-Abl negative, is a separate entity)	High degree of "oncogene addiction" in chronic phase allows successful targeting of the Bcr-Abl kinase by small molecule inhibitors; outcomes dismal in blastic phase with loss of addiction to Bcr-Abl signaling
MYELODYSPLASTIC SYNDROMES				
del5q33.1 or del5q31	<i>RPS14</i> , <i>miR-145/146a</i> , <i>EGR1</i> , <i>APC</i> , <i>CTNNA1</i>	In 5q- syndrome, haploinsufficiency of <i>RPS14</i> leads to impaired maturation of 40S ribosomal units, causing premature <i>TP53</i> -dependent apoptosis of erythroid precursors	15% overall	Most common chromosomal abnormality in MDS; del5q31 more common with higher risk or t-MDS; del5q33.1 seen in the indolent 5q- syndrome responsive to lenalidomide; del5q considered "good" in IPSS-R
del7q or loss of chromosome 7	<i>EZH2?</i>	Unclear loss of which genes on 7q pathogenic, since vast majority of patients with <i>EZH2</i> mutations do not have del7q or -7	10% in <i>de novo</i> MDS; up to 50% in t-MDS	del7q considered "intermediate" in IPSS-R; -7 considered "poor"
Trisomy 8	<i>c-MYC</i> , others?	Higher expression of anti-apoptotic genes, <i>c-MYC</i> overexpression?	<10%	Considered "intermediate" in IPSS-R
del20q	Unknown	Unknown	<5%	Considered "good" in IPSS-R
Loss of Y chromosome	Multiple	Not felt to be pathogenic in MDS	Common normal finding in men	Considered "very good" in IPSS-R
Complex karyotype (≥ 3 abnormalities)	Multiple		18%	Considered "very poor" in IPSS-R if >3 abnormalities; "poor" if only 3
t(5;12)(q33;p13)	<i>ETV6-PDGFRB</i> (<i>TEL-PDGFRB</i>)	Fuses <i>ETV6</i> transcription factor gene with <i>PDGFR</i> beta gene	Rare	Seen in the context of MDS/MPN; responds to imatinib
B-CELL ACUTE LYMPHOBLASTIC LEUKEMIA				
t(9;22)(q34;q11)	<i>BCR-ABL1</i> (most cases characterized by the p190 "minor" fusion protein)	Fusion protein leads to constitutively active tyrosine kinase; often associated with <i>IKZF1</i> splicing abnormalities	25-30% in adults, 2-5% in children	Traditionally "high risk", with allogeneic HSCT in CR1 commonly recommended; cure rates improved in "TKI era"

(continued)

TABLE 16–2. Common genomic aberrations seen in the major hematologic malignancies.(Continued)

Chromosomal abnormality	Genes/loci affected or fusion gene where applicable	Functional consequence, if known	Approximate incidence (in newly diagnosed patients)	Prognostic/therapeutic implications, if any
t(8;14)(q24.2;q32) or t(2;8)(p12;q24.2) or t(8;22)(q24.2;q11.2)	<i>c-MYC</i> , immunoglobulin heavy and light chain genes	Constitutive expression of oncogenic <i>c-MYC</i>	1% (Burkitt's lymphoma/leukemia – FAB L3 morphology; mature B-cell phenotype)	Poor prognosis; high incidence of CNS involvement and TLS; treated with short, intensive regimens
t(12;21)(p12;q22)	<i>ETV6-RUNX1 (TEL-AML1)</i>	Fusion protein inhibits transactivation of gene expression by normal <i>RUNX1</i>	15-25% in children, 3-4% in adults	Favorable prognosis
Intrachromosomal amplification of chromosome 21 (secondary chromosomal abnormalities common)	<i>RUNX1 (AML1)</i>		3-5% of older children	Poor prognosis with standard risk regimens, overcome by intensive therapy (high risk regimens)
11q23 abnormalities	<i>KMT2A (MLL)</i> , most commonly <i>KMT2A-AF4(AFF1)</i> caused by t(4;11)(q21;q23); 2 nd most common is t(11;19)(q23;p13.3)	<i>KMT2A</i> encodes a histone methyltransferase that regulates transcription of genes such as <i>IKZF1</i> and <i>HOX</i> genes	5-7% overall; 60-80% in infants	Poor prognosis; frequent co-expression of myeloid antigens; about half the patients with t(11;19)(q23;p13.3) have AML, mostly FAB M5a subtype
t(1;19)(q23;p13.3) or der(19)t(1;19)(q23;p13.3) and its variant t(17;19)(q21;p13.3)	<i>PBX1-TCF3 (PBX1-E2A)</i> or <i>HLF-E2A</i>	Activation of gene transcription by fusion protein via unclear mechanisms	30% of childhood precursor B-cell ALL (5% of all pediatric ALL)	Studies with conflicting results; probably favorable prognosis
del9p	<i>PAX5, JAK2</i> (in Down syndrome associated ALL)		5-10%	Poor prognosis
Hyperdiploidy	Multiple		40%	Favorable prognosis in patients with >50 chromosomes
Hypodiploidy	Multiple		5-6%	Poor prognosis
T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA				
Translocations involving 7p14 (TCR γ) or 7q34(TCR β) or 14q11.2 (TCR α/δ)	<i>TCR</i> genes; multiple partners – usually cell cycle inhibitors or transcription factors		35%	
Cryptic interstitial deletion at 1p32	<i>SIL-TAL1</i>	Fusion gene functions as transcription factor	9-30% of childhood T-ALL; frequency decreases in adults	
11q23 abnormalities	<i>KMT2A (MLL)</i> with various partners		8%	
t(10;11)(p13;q14)	<i>CALM-AF10</i>		10%	
t(9;9)(q34;q34)	<i>NUP214-ABL1</i>	Fusion of nuclear pore complex component with intracellular tyrosine kinase as a result of episomal amplification of in-frame fusion	Up to 6%	Responsive to imatinib?

(continued)

TABLE 16–2. Common genomic aberrations seen in the major hematologic malignancies.(Continued)

Chromosomal abnormality	Genes/loci affected or fusion gene where applicable	Functional consequence, if known	Approximate incidence (in newly diagnosed patients)	Prognostic/therapeutic implications, if any
del9p21	p16 (INK4/ARF)	Loss of endogenous CDK inhibitor function	65% in children; 15% in adults	
del6q			20-30%	
CHRONIC LYMPHOCYTIC LEUKEMIA				
del13q	<i>MIR15A</i> , <i>MIR16-1</i> , <i>RB1</i> , associated with <i>MYD88</i> mutations	Loss of tumor suppressor function of Rb; loss of miR15a and miR16-1 derepresses Bcl-2 but also increases TP53 mRNA; MYD88 is a critical adaptor molecule of the IL-1 TLR pathway that activates NF-κB and augments BTK signaling	55%	Favorable prognosis when sole cytogenetic abnormality; MYD88 mutations associated with mutated <i>IGHV</i> ; BTK (BCR pathway) inhibition highly effective in CLL
del11q	<i>ATM</i> ; associated with <i>SF3B1</i> mutations	<i>ATM</i> is a proximal transducer of the DDR network; <i>SF3B1</i> functions in mRNA splicing	18%	Poor prognosis but overcome by FCR; the most common type of karyotypic evolution over time; associated with bulky lymphadenopathy
Trisomy 12q	Associated with <i>NOTCH1</i> and <i>FBXW7</i> mutations		16%	Unclear - conflicting study results; <i>NOTCH1</i> mutations confer unfavorable prognosis and are associated with unmutated <i>IGHV</i>
del17p	<i>TP53</i>	Loss of tumor suppressor "guardian of genome", failure of cell cycle checkpoint mechanisms, disruption of DDR	7%	Poor prognosis not overcome by cytotoxic chemotherapy; alemtuzumab and BCR pathway inhibitors effective, as well as allogeneic HSCT
del6q			7%	
T-CELL PROLYMPHOCYTIC LEUKEMIA				
t(14;14)(q11;q32) or inv(14)(q11;q32) or t(X;14)(q28;q11)	<i>TCR-TCL1</i> <i>MTCP1-TCR</i>	Overexpression of the <i>TCL-1</i> oncogene or its homolog <i>MTCP1</i>	90%	
Chromosome 8 abnormalities	idic(8p11), t(8;8), trisomy 8q	Up-regulation of oncogenic c-MYC	70-80%	
MULTIPLE MYELOMA				
del13q14 or monosomy 13 or hypodiploidy	Multiple		48%	Intermediate risk with modern therapies only if detected on karyotyping, or by FISH in presence of other abnormalities (otherwise standard risk)
del17p13	<i>TP53</i>	Loss of tumor suppressor "guardian of genome", failure of cell cycle checkpoint mechanisms, disruption of DDR	11%	High risk
Gain of 1q21	<i>CKS1B</i>	<i>CKS1B</i> favors cell cycle progression by promoting degradation of the endogenous CDK inhibitor p27 with release of CDKs and mitotic entry	30-43%	Controversial; conflicting study results
del1p	<i>FAM46C</i> , <i>CDKN2C</i>	Loss of endogenous CDK inhibitor function leads to excessive proliferation	30%	High risk

(continued)

TABLE 16–2. Common genomic aberrations seen in the major hematologic malignancies.(Continued)

Chromosomal abnormality	Genes/loci affected or fusion gene where applicable	Functional consequence, if known	Approximate incidence (in newly diagnosed patients)	Prognostic/therapeutic implications, if any
t(11;14)(q13;q32)	<i>CCND1-IgH</i>	Overexpression of cyclin D1	21% (10-31%)	Standard risk; very high prevalence in non-secretory cases; associated with lower levels of monoclonal proteins, CD20 expression, lambda light chains and lymphoplasmacytic morphology
t(6;14)(p25;q32)	<i>CCND3-IgH</i>	Overexpression of cyclin D3		Standard risk
t(8;14)(q24;q32)	<i>c-MYC-IgH</i>	c-MYC overexpression		Standard risk
t(4;14)(p16.3;q32.3)	<i>MMSET-IgH</i>	MMSET is a histone methyltransferase and its deregulation/overexpression is key to pathogenesis; FGFR3 also often overexpressed	14%	Intermediate to high risk; adverse prognosis overcome by bortezomib/HSCT
t(14;16)(q32.3;q23)	<i>IgH-c-MAF</i>	MAF encodes a transcription factor that can activate or repress transcription depending on binding site/partner		High risk
t(14;20)(q32;q11)	<i>IgH-MAFB</i>	MAF encodes a transcription factor that can activate or repress transcription depending on binding site/partner		High risk
Hyperdiploidy (trisomies of odd numbered chromosomes other than 1, 13, 21)	Multiple		39%	Standard risk; in the presence of concurrent trisomies, "high risk" cytogenetics become standard risk
NON-HODGKIN'S LYMPHOMA (selected abnormalities)				
Chromosomal abnormality	Fusion gene created, where applicable	Pathogenetic mechanism	Disease association	Therapeutic relevance
t(2;5)(p23;q35) and variants	<i>ALK-NPM</i> and others	Constitutively active tyrosine kinase triggers malignant transformation and activates anti-apoptotic pathways	ALK+ anaplastic large cell lymphoma	ALK targeting with small molecule inhibitors, e.g., crizotinib
t(11;14)(q13;q32)	<i>CCND1-IgH</i>	Overexpression of cyclin D1 drives cellular proliferation	Mantle cell lymphoma (almost all cases)	Efficacy of CDK4/6 inhibitors, e.g., palbociclib
t(14;18)(q32;q21)	<i>IgH-BCL2</i>	Constitutive expression of anti-apoptotic Bcl-2 promotes cellular survival	Follicular lymphoma (80%), diffuse large B-cell lymphoma (30%)	Selective targeting of Bcl-2 with BH3-mimetics, e.g., venetoclax
t(11;18)(q21;q21)	<i>API2 (IAP2)-MALT1</i>	Overexpression of BCL10 results in NF-κB activation through BCL10/MALT1 signaling complex; FOXP1 is a transcription factor of unknown function	MALT lymphoma (extranodal marginal zone lymphoma)	Nuclear expression of BCL10 or NF-κB in gastric MALT lymphoma associated with resistance to antibiotic therapy
t(14;18)(q32;q21)	<i>IgH-MALT1</i>			
t(1;14)(p22;q32)	<i>BCL10-IgH</i>			
t(3;14)(p13;q32)	<i>FOXP1-IgH</i>			

(continued)

TABLE 16–2. Common genomic aberrations seen in the major hematologic malignancies.(Continued)

Chromosomal abnormality	Genes/loci affected or fusion gene where applicable	Functional consequence, if known	Approximate incidence (in newly diagnosed patients)	Prognostic/therapeutic implications, if any
9p24 amplification	Contains genes that encode PD-L1, PD-L2, JAK2	PDL-1 commonly over-expressed; MHC class II transactivator rearrangements (38% of PMBL) lead to PD-1 overexpression also	Primary mediastinal B-cell lymphoma	PD-1 immune checkpoint pathway a potential target
3q27 abnormalities (mutations, rearrangements)	Locus for <i>BCL6</i> transcriptional repressor	Bcl-6 overexpression results in down-regulation of many target proteins, including p53 tumor suppressor	Diffuse large B-cell lymphoma (almost all cases)	New inhibitors that disrupt Bcl-6 function being developed

hematologic malignancies. Among the chromosomal translocations, some of the most well-studied are found in AML and other myeloid neoplasms. These include t(8;21)(q22;q22), leading to the AML1-ETO or RUNX1-RUNX1T1 rearrangement, del4(q12;q12), t(5;12)(q31-q32;p13), leading to the TEL-platelet derived growth factor receptor (PDGFR) β rearrangement, t(15;17)(q22;12), leading to the promyelocytic leukemia (PML)-retinoic acid receptor (RAR) α rearrangement, inv16(p13;q22) or t(16;16)(p13;q22), leading to the CBF β -MYH11 rearrangement, t(9;22)(q34;q11), leading to the BCR-ABL rearrangement, t(3;3)(q21;q26), t(8;16)(p11;p13), t(6;9)(p23;q34), t(7;11)(p15;p15), t(9;11)(p22;q23), t(6;11)(q27;q23), t(11;19)(q23;p13.1), and t(11;19)(q23;p13.3), all of which translocate the *MLL* gene located at 11q23, t(16;21)(p11;q22), and t(1;22)(p13;q13).^{179,180} Leukemias carrying *MLL* rearrangements are driven by dysregulated epigenetic mechanisms in which fusion proteins containing N-terminal sequences of *MLL* can cause human leukemia without the requirement for a “second hit.”¹⁸¹ *MLL*-rearranged leukemias provide a paradigm for how epigenetic dysregulation can lead to cancer through inappropriate chromatin structure with subsequent activation of target genes with oncogenic activity. An improved molecular understanding of how *MLL* fusions upregulate binding targets has led to the identification of a number of potential mechanism-based therapeutic vulnerabilities for this poor-prognosis malignancy. Potential novel therapeutic approaches include inhibition of P-TEFb (cdk9/cyclin T), the histone modifying enzymes DOT1L (methyltransferase) or TIP60 (acetyltransferase), and disruption of the interaction of *MLL* fusions with other epigenetic systems such as CpG island methylation and polycomb genes, for example, PRC2.¹⁸¹ In contrast, in secondary myeloid leukemias, recurrent numerical and unbalanced cytogenetic abnormalities predominate such as del(5q), del(7q), 7/del(7q), and del(20q), and are often associated with a poor prognosis.^{180,182} Table 16–2 lists some of the fusion partners. Apart from the chromosomal translocations in AML as described above, there also aberrant fusion proteins in acute lymphoid leukemia (ALL), such as t(9;22), which is also found in chronic myelogenous leukemia (CML), t(4;11) in prolymphoblastic leukemia, and t(12;21) in childhood ALL. Some lymphomas are characterized by chromosomal translocations that juxtapose an oncogene to the immunoglobulin heavy-chain gene, which then drives overexpression of the oncogene, for example, t(8;14) in Burkitt lymphoma, t(11;14) in MCL, or t(14;18) in follicular lymphoma; for a review see Ref. 125.¹⁸³ The same is true of myeloma, where abnormalities such as t(4;14), t(6;14), t(11;14), t(14;16), and t(14;20) are frequently seen. An excellent overview of chromosomal rearrangements in cancer and the affected genes is available.¹⁸⁰

The precise mechanism by which the fusion proteins lead to tumorigenesis is not always well understood. Nevertheless, in patients with AML, abnormal expression of the transcription factor RUNX1 (AML1) is able to promote cell-cycle progression by shortening G₁ phase and by repressing p21^{cp1} promoter activity. RUNX1 is absolutely required for the establishment of adult-type hematopoiesis¹⁸⁴; it regulates genes specific to the lymphoid, myeloid, and megakaryocyte lineages,¹⁸⁵ and mice lacking RUNX1 do not develop definitive hematopoiesis, indicating a role in adult hematopoietic stem cell formation.¹⁸⁶ In contrast, the fusion product AML1/ETO, derived from the t(8;21), slows cell-cycle progression, suggesting that one gene in different “fusion situations” can cause different effects on the cell cycle.¹⁸⁷ Activation of the RUNX1-repression domain or fusing the gene to ETO results in downregulation of cdk4 and Myc, directly linking this fusion protein to cell-cycle checkpoints.¹⁸⁷ Additional evidence for the direct involvement of RUNX1 in cell-cycle control comes from the observation that the transcription factor binds to the p19^{INK4D} promoter and downregulates p19^{INK4D} expression in megakaryocytes.¹⁸⁸ Inhibiting the oligomerization domain of ETO interferes with RUNX1/ETO oncogenic activity and these cells lose their progenitor cell characteristics, arrest cell-cycle progression, and undergo cell death.¹⁸⁹ Another interesting chromosomal translocation fusion product that affects cell-cycle control is found in patients with acute PML (APL) or its variant form (vAPL). The PML-RAR α , which results from t(15;17)(q22;12), upregulates cyclin A₁ expression, whereas PML itself seems to be a negative regulator of cell growth because its overexpression leads to growth suppression and G₁ arrest in a variety of different cell types.¹⁹⁰ PML is crucial for the growth-inhibiting activity of retinoic acid and its absence abrogates the retinoic acid-dependent transactivation of p21^{cp1}.¹⁹¹ Another mechanism by which PML elicits irreversible growth arrest is believed to involve activation of the tumor-suppressor pathway p16^{INK4A}/RB.¹⁹² Recent data point toward a linkage between PML and the nucleoporins, especially Nup98 and Nup214. In some AML specimens, these nucleoporins are expressed as oncogenic fusion proteins and become directed—complexed with PML—to common cytoplasmic compartments during the M-to-G₁ transition of the cell cycle. In APL cells, the loss of function of normal PML causes an increase in cytoplasmic-bound versus nuclear-membrane-bound nucleoporins.¹⁹³ Consequently, PML by itself is a tumor-suppressor gene that positively regulates cell-cycle progression. Further evidence for a tumor-suppressor gene function of PML comes from transgenic mice models where PML^{-/-} mouse embryonic fibroblasts are enriched in S phase and the G₀/G₁ phase is minimized.¹⁹⁴ In APL, this regulatory role is disrupted by the fusion to RAR α . One mechanism by which

TABLE 16–3. Common somatic mutations encountered in the major myeloid malignancies.

Gene	Functional class of encoded protein	Nature of mutation and functional consequence	Approximate incidence	Prognostic and/or therapeutic implications, if any
ACUTE MYELOID LEUKEMIA (AML)				
<i>FLT3</i> (most commonly mutated gene in AML)	Tyrosine kinase (signaling molecule)	Internal tandem duplications or tyrosine kinase domain mutations ("class I" mutations that confer survival and proliferation advantages)	Up to 35% (25% ITD, 10% TKD); higher in CN AML (31% ITD; 11% TKD)	<i>FLT3-ITD</i> AML characterized by higher WBC counts and blast %, early relapses and poor survival; multiple inhibitors in development; allogeneic HSCT in CR1 usually recommended; prognostic impact of TKD mutations unclear; conflicting studies
<i>NPM1</i> (most commonly mutated gene in CN AML)	Nucleophosmin	"Class II" mutations that impair differentiation of hematopoietic cells	27% (53% of CN AML)	Mutated <i>NPM1</i> with WT <i>FLT3</i> confers favorable prognosis in CN AML if <i>IDH1/2</i> also mutated; patients generally not allografted in CR1; may predict improved outcome with high dose daunorubicin
<i>MLL-PTD</i>	Histone methyltransferase	Partial tandem duplication; for translocations see Table 2	5-7% of CN AML	Poor prognosis; mutually exclusive of <i>NPM1</i> ; <i>DOT1L</i> inhibitors in early clinical trials; <i>CDK9</i> and <i>HDAC</i> inhibitors appear promising
<i>DNMT3A</i>	DNA methyl transferase	Loss of function mutations causing reduced methylation in mutant genomes	22%	Strongly associated with intermediate risk cytogenetics; independent predictor of poor outcome that may be overcome by high dose daunorubicin; mutually exclusive with <i>MLL</i> translocations
<i>IDH1/2</i>	Krebs cycle enzymes	<i>IDH</i> mutants produce 2-hydroxyglutarate from alpha-ketoglutarate, which inhibits TET enzymes, causing DNA hypermethylation	15-30%	Increased frequency in older patients; new small molecule <i>IDH</i> inhibitors promising; <i>IDH2</i> R140Q mutations associated with improved survival
<i>TET2</i>	Catalyzes alpha-ketoglutarate-dependent conversion of 5-methylcytosine to 5-hydroxymethylcytosine, leading to DNA demethylation	Loss of function mutations→ increased promoter methylation→ increased self-renewal and impaired differentiation	10%	<i>TET2</i> mutations mutually exclusive with <i>IDH1/2</i> mutations and confer poor prognosis in patients with intermediate risk AML
<i>ASXL1</i>	Member of polycomb family of chromatin binding proteins; epigenetic modifier; functions as ligand-dependent coactivator of retinoid acid receptor	Loss of function mutations	3-5% in younger patients, 16% in older patients	Poor prognosis; may be mutually exclusive of <i>NPM1</i> mutations
<i>CEBPA</i>	Myeloid transcription factor	"Class II" mutations that impair differentiation of hematopoietic cells	13% of CN AML	Biallelic <i>CEBPA</i> mutations associated with favorable prognosis in patients with intermediate risk AML
<i>RUNX1 (AML1)</i>	Myeloid transcription factor – master regulator of hematopoiesis	Gain of function mutations in proximal Runt homology domain, or loss of function mutations in distal transactivation domain	5%	Mutually exclusive of <i>FLT3</i> and <i>NPM1</i> mutations

(continued)

TABLE 16–3. Common somatic mutations encountered in the major myeloid malignancies. (Continued)

Gene	Functional class of encoded protein	Nature of mutation and functional consequence	Approximate incidence	Prognostic and/or therapeutic implications, if any
<i>TP53</i>	Master regulator of cell cycle, DNA damage response and apoptosis (tumor suppressor)	17p deletions and inactivating point mutations; MDM2 overexpression; other mechanisms of loss of function	<i>TP53</i> mutations seen in only 9% of older patients with <i>de novo</i> AML, but much more common in secondary and <i>t</i> -AML	Extremely poor prognosis; MDM2 (negative regulator of TP53) antagonists in clinical trials; mutually exclusive of <i>FLT3</i> and <i>NPM1</i> mutations
<i>PHF6</i>	X-linked tumor suppressor	Loss of function mutations	3%	Mutations confer poor prognosis
<i>NRAS</i>	Survival signaling molecule	“Class I” mutations that confer survival and proliferation advantages	13% of CN AML; <i>RAS</i> mutated in 19% of elderly patients with AML	<i>RAS</i> mutations predict for benefit of post remission HiDAC
<i>WT1</i>	Transcription factor that may act both as a tumor suppressor gene and an oncogene	Loss of function mutations	10%; most frequent in CN AML	Unclear effect on prognosis; likely negative impact
<i>KIT</i>	Tyrosine kinase (signaling molecule)	Activating mutations	30-40% of CBF AML	Mutated <i>c-KIT</i> confers adverse prognosis in CBF AML; ?role of TKIs
MYELODYSPLASTIC SYNDROMES (MDS)				
<i>SF3B1</i>	RNA splicing protein – core component of U2 snRNP, which recognizes the 3' splice site at intron-exon junctions	Spliceosome mutations→decreased or increased transcription of normal pre-mRNA, exon skipping, intron retention and cryptic splice sites; <i>SF3B1</i> mutations lead to abnormal splicing of ABCB7	24%	Extremely strong correlation with ringed sideroblasts; indolent course with prolonged survival (RARS); acquisition of <i>JAK2</i> V617F causes RARS-T
<i>TET2</i>	Catalyzes alpha-ketoglutarate-dependent conversion of 5-methylcytosine to 5-hydroxymethylcytosine, leading to DNA demethylation	Loss of function mutations→increased promoter methylation→increased self-renewal and impaired differentiation	20-22%	Predict response to HMAs, but overall confer poor prognosis, even after HSCT
<i>SRSF2</i>	RNA splicing protein	Spliceosome mutations→decreased or increased transcription of normal pre-mRNA, exon skipping, intron retention and cryptic splice sites	14%	Co-occurrence of <i>TET2</i> and <i>SRSF2</i> mutations highly specific for CMML; mutually exclusive with <i>SF3B1</i> mutation; progression from <i>SRSF2</i> -mutated RCMD-RS to RAEB may involve appearance of <i>STAG2</i> mutations
<i>ASXL1</i>	Member of polycomb family of chromatin binding proteins; epigenetic modifier; functions as ligand-dependent coactivator of retinoic acid receptor	Loss of function mutations in C-terminal generate a dominant-negative protein that inhibits its wild type counterpart and other members of polycomb protein complex	10%; >40% of patients with CMML	Poor prognosis
<i>DNMT3A</i>	DNA methyl transferase	Loss of function mutations causing reduced methylation in mutant genomes	10-15%	Poor prognosis, even after HSCT

(continued)

TABLE 16-3. Common somatic mutations encountered in the major myeloid malignancies. (Continued)

Gene	Functional class of encoded protein	Nature of mutation and functional consequence	Approximate incidence	Prognostic and/or therapeutic implications, if any
<i>RUNX1 (AML1)</i>	Myeloid transcription factor – master regulator of hematopoiesis	Gain of function mutations in proximal Runt homology domain, or loss of function mutations in distal transactivation domain	7-15%; higher in t-MDS	Poor prognosis; <i>RUNX1</i> mutations often accompanied by activation of Ras pathway
<i>U2AF1</i>	RNA splicing protein	Spliceosome mutations→decreased or increased transcription of normal pre-mRNA, exon skipping, intron retention and cryptic splice sites	5-10%	
<i>TP53</i>	Master regulator of cell cycle, DNA damage response and apoptosis (tumor suppressor)	17p deletions and inactivating point mutations	5-15%; higher in t-MDS	Poor prognosis, even after HSCT
<i>EZH2</i>	Tumor suppressor - histone methyltransferase (catalytic subunit of polycomb repressive complex, PRC2)	Loss of function mutations→loss of PRC2 activity→increase in hematopoietic stem cell number and activity	6%	Poor prognosis, including in lower risk patients
<i>IDH1/2</i>	Krebs cycle enzymes	IDH mutants produce 2-hydroxyglutarate from alpha-ketoglutarate, which inhibits TET enzymes, causing DNA hypermethylation	3.5%	<i>IDH2</i> more frequently mutated than <i>IDH1</i> and often co-mutated with <i>SRSF2</i> ; <i>IDH</i> mutations cause differentiation block; inhibitors in development
<i>ETV6 (TEL)</i>	Transcription factor		0.2-2.7%	Poor prognosis; <i>ETV6-PDGFRB</i> rearrangement in MDS/MPN responds to imatinib
<i>NRAS</i>	Survival signaling molecule	Ras-Raf-MEK-ERK pathway activation	10-15%	Poor prognosis
<i>CBL</i>	Tyrosine kinase-associated ubiquitin ligase that negatively regulates Ras pathway and JAK-STAT signaling by targeting receptor TKs for degradation	Mutants encode a dominant negative protein that inhibits the ubiquitin ligase activity of the wild type protein and of its homolog, CBLB	<5%; 15% of patients with CMML	Unclear impact on prognosis
<i>JAK2</i>	Tyrosine kinase (JAK-STAT signaling critical to hematopoiesis)	Activating mutations (V617F)	5%; 50% in RARS-T	None; evolution from RARS to RARS-T involves acquiring <i>JAK2</i> V617F in <i>SF3B1</i> mutants
PHILADELPHIA CHROMOSOME NEGATIVE MYELOPROLIFERATIVE NEOPLASMS (Ph neg MPNs)				
<i>CSF3R</i>	WBC growth factor receptor	Activating mutations lead to oncogenic signaling through SRC family (TNK2 or JAK) kinases	59% of patients with atypical CML or chronic neutrophilic leukemia	Could help diagnose CML-like disorders without the Philadelphia chromosome or Bcr-Abl
<i>JAK2</i>	Tyrosine kinase (JAK-STAT signaling critical to hematopoiesis)	Activating mutations in exons 14 (V617F) and 12	Present in almost all cases of PV and about half of cases of ET and MF	JAK-STAT pathway overactive with or without mutations in <i>JAK2</i> ; small molecule TKI ruxolitinib approved for MF and PV

(continued)

TABLE 16-3. Common somatic mutations encountered in the major myeloid malignancies. (Continued)

Gene	Functional class of encoded protein	Nature of mutation and functional consequence	Approximate incidence	Prognostic and/or therapeutic implications, if any
<i>MPL</i>	Thrombopoietin receptor	Activating mutations, e.g., W515L	5-10% of cases of ET or MF	<i>MPL</i> W515L activates JAK-STAT signaling; associated with older age, female sex, lower Hgb level and higher platelet count
<i>CBL</i>	TK-associated ubiquitin ligase that negatively regulates signal transduction by targeting receptor TKs for degradation (tumor suppressor)	Mutants encode a dominant negative protein that inhibits the ubiquitin ligase activity of the wild type protein and of its homolog, CBLB (inactivating mutations)	6% of cases of MF	Enhanced JAK-STAT signaling
<i>LNK</i>	Membrane-bound adaptor protein that inhibits wild type and mutant JAK2 signaling	Inactivating mutations	Rare cases of JAK2 V617F-negative ET or MF; more common in blast phase of MF (13%)	Enhanced JAK-STAT signaling
<i>CALR</i>	Endoplasmic reticulum chaperone (calreticulin)	Frameshift mutations in exon 9 create mutant protein with novel C-terminal→altered subcellular localization and impaired Ca ²⁺ binding	Absent in PV; present in most (~73%) patients with ET or MF without JAK2 or <i>MPL</i> mutations (helps distinguish clonal MPNs from reactive causes of thrombocytosis)	Predicts for more indolent clinical course than JAK2 V617F; patients have lower Hgb levels and higher platelet counts; mutant <i>CALR</i> activates JAK-STAT signaling in myeloid cells
<i>TET2</i>	Catalyzes alpha-ketoglutarate-dependent conversion of 5-methylcytosine to 5-hydroxymethylcytosine, leading to DNA demethylation	Loss of function mutations→increased promoter methylation→increased self-renewal and impaired differentiation	16% in PV, 5% in ET, 17% in MF; 14% in post-PV or post-ET MF; incidence increases with age	No effect on survival, leukemic transformation or thrombosis; may correlate with anemia in MF
<i>ASXL1</i>	Member of polycomb family of chromatin binding proteins; epigenetic modifier; functions as ligand-dependent coactivator of retinoic acid receptor	Loss of function mutations in C-terminal generate a dominant-negative protein that inhibits its wild type counterpart and other members of polycombprotein complex	8% of patients with MPNs	
<i>IDH1/2</i>	Krebs cycle enzymes	IDH mutants produce 2-hydroxyglutarate from alpha-ketoglutarate, which inhibits TET enzymes, causing DNA hypermethylation	<5% of cases of MF (much higher (~22%) in blast phase); 1-2% of cases of ET and PV	
<i>EZH2</i>	Tumor suppressor-histone methyltransferase (catalytic subunit of polycomb repressive complex, PRC2)	Loss of function mutations→loss of PRC2 activity→increase in hematopoietic stem cell number and activity	13% in MF; 12% in MDS/MPN overlap syndromes	Independently associated with shorter survival in patients with MF
<i>DNMT3A</i>	DNA methyl transferase	Loss of function mutations causing reduced methylation in mutant genomes	7-10%	
<i>IKZF1</i>	Transcription factor	Generally deletions (del7p) rather than mutations; late events	Rare in chronic phase MPNs, but 19% in blast phase	Important step in leukemic transformation

(continued)

TABLE 16–3. Common somatic mutations encountered in the major myeloid malignancies. (Continued)

Gene	Functional class of encoded protein	Nature of mutation and functional consequence	Approximate incidence	Prognostic and/or therapeutic implications, if any
CHRONIC MYELOID LEUKEMIA (CML)				
<i>BCR-ABL</i>	Constitutively active tyrosine kinase (fusion protein)	Point mutations that confer resistance to one or more small molecule TKIs	40-90% of cases of resistance to imatinib (15% T315I)	“Gatekeeper” T315I mutant inhibited only by ponatinib
<i>c-MYC</i>	Oncoprotein	Overexpression often due to acquired trisomy 8	34% of cases with clonal evolution (trisomy 8)	Genomic instability characteristic of progression to advanced phases
<i>TP53</i>	Master regulator of cell cycle, DNA damage response and apoptosis (tumor suppressor)	Loss of function often associated with isochromosome 17	Mutated in 25-30% of patients in myeloid blast phase	Inactivation of tumor suppressor genes characteristic of progression to blast phase
<i>p16 (INK4A/ARF)</i>	Endogenous CDK inhibitor (tumor suppressor)	Deletions affect exon 2 of locus	Deleted in 50% of cases of lymphoid blast phase	Inactivation of tumor suppressor genes characteristic of progression to blast phase

this fusion protein (and also the PML Kruppel-like zinc finger [PLZF]-RAR α fusion derived from the rare t[11;17]) affects cell-cycle control is its strong interaction with SMRT or N-CoR, two corepressor elements that are important for the recruitment of HDACs, as described below in “The Role of Histone Deacetylases in Cell-Cycle Regulation.” In accordance with this is the finding that retrovirally transduced PML-RAR α induces a maturation arrest in the corresponding cells, implying that these cells are unable to express certain transcription factors as a consequence of the conformational changes caused by the recruitment of HDACs.¹⁹⁵ A variant of this chromosomal translocation results in a fusion protein between RAR α and the PLZF protein, which is observed in a subset of patients with APL.^{195,196}

The translocation t(9;22), which fuses the *BCR* gene to the *c-ABL* gene, is a characteristic feature of CML (Chap. 88). The chromosome 9 breakpoints, where the *c-abl* gene is located, involve a large region of about 200 kb, but fusion genes invariably include the *abl* exon 2. The corresponding breakpoints on chromosome 22 are located in a much smaller region, including the *BCR* gene.¹⁹⁷ The *bcr-abl* fusion protein localizes to the cytoskeleton and displays enhanced tyrosine kinase activity.¹⁹⁸ It is also found in some cases of ALL and in occasional cases of AML.^{199,200} *Bcr-abl* not only regulates cell proliferation, apoptosis, differentiation, and adhesion, but also induces resistance to cytostatic drugs by modulation of DNA repair mechanisms, cell-cycle checkpoints, and the Bcl-2 family of apoptosis regulators. Upon DNA damage, *bcr-abl* enhances repair of DNA lesions and prolongs activation of cell-cycle checkpoints (e.g., G₂/M), providing more time for repair of otherwise lethal lesions, so that these cells have a significant survival advantage.¹⁹⁹ The *bcr-abl* fusion product is so far the only oncogenic product that is sufficient to induce malignant growth *in vivo* without the presence of other abnormal molecular changes. Several reports have shown that *bcr-abl*-positive cells display pronounced G₂/M delay in response to various chemotherapeutics and irradiation. The exact mechanism of G₂/M delay in *bcr-abl*-positive cells has not been characterized in detail, but it seems that the *cdc2*-cyclin B₁ regulation is affected. In addition, *bcr-abl*, through both kinase-dependent and kinase-independent mechanisms, converts p27^{kip1} from a nuclear tumor suppressor to a cytoplasmic oncogene, which may contribute to *bcr-abl* tyrosine kinase inhibitor (TKI)-resistance.²⁰¹ The *bcr-abl* signal transduction process involves adapter molecules such as GRB2 and GAB2, as well as signaling pathways (e.g., phosphatidylinositol 3'-kinase [PI3K],

Janus-associated kinase [JAK]-signal transducer and activator of transcription [STAT]).¹⁹⁸ In addition, although there is no direct evidence that the abnormal *bcr-abl* product affects the M checkpoint itself, some data suggest that *bcr-abl*-positive CML cells contain elevated MAD2 and BUB1 levels, proteins that inhibit the APC and therefore cause mitotic spindle arrest.²⁰² Amplification of the fusion sequence is frequently used to detect minimal residual disease in patients under therapy with interferon- α , TKIs,²⁰³ and after stem cell transplantation.²⁰⁴ The *etv6* gene is the only known non-*bcr* fusion partner of *abl*, sometimes observed as *etv6-abl* in ALL or myeloproliferative syndromes (t[9;12][q34;p13]).²⁰⁵ The affected cells show only a minor response to imatinib.

Mutant-activated receptor protein-tyrosine kinases (rPTKs) comprise a family of very-well-characterized oncogenes. The constitutive activation of rPTK usually is achieved by mutations that lead to the dimerization and activation of their cytoplasmic catalytic domains.²⁰⁶ Other possible causes of rPTK dimerization are chromosomal translocations that create chimeric proteins. In the t(2;5) translocation, found in several anaplastic large cell lymphomas, N-terminal nucleophosmin sequences on the long arm of chromosome 5 are fused to the cytoplasmic domain of the ALK protein on chromosome 2.^{207,208} The characteristic translocation of chronic myelomonocytic leukemia, t(5;12), fuses sequences from the transcription factor *TEL* to the cytoplasmic domain of the PDGFR β (*TEL-PDGFR β*), resulting in the formation of a *TEL-PDGFR β* fusion protein and constitutive activation of the receptor tyrosine kinase (RTK),²⁰⁹ while targeting Id1 (inhibitor of DNA-binding 1) inhibits growth of leukemia cells expressing oncogenic FLT3-ITD and BCR-ABL tyrosine kinases.²¹⁰ Patients with the t(5;12) translocation respond to imatinib, as the drug also inhibits the PDGFR. The chromosomal area surrounding the *TEL* gene is a fragile site, because the *TEL* gene is involved in several other translocations in human acute leukemias (e.g., t[12;9]). One of the TGF- β receptors also is involved in oncogenesis, and mutations are frequently found in colon cancer. TGF- β receptor signaling acts through the SMAD family of transcription factors.

Two important oncogene families encode the Ras and Rho family proteins. Ras itself is a G protein, and activating mutations in H-Ras, K-Ras, and N-Ras have been found in nearly all kinds of human cancers. Several different Ras mutations are able to transform normal cells in tissue culture.^{211,212} Mutations in many different Ras-related pathways have been identified in cancer (e.g., Raf1, p110 PI3K, Rin1, Mek1),

TABLE 16-4. Common somatic mutations encountered in the major lymphoid malignancies.

Gene	Functional class of encoded protein	Nature of mutation and functional consequence	Approximate incidence	Prognostic and/or therapeutic implications, if any
CHRONIC LYMPHOCYTIC LEUKEMIA (most mutations frequencies higher with time and with treatment)				
<i>TP53</i>	Master regulator of cell cycle, DNA damage response and apoptosis (tumor suppressor); strong correlation with del17p	Deletions and inactivating point mutations	7-12%	Poor prognosis; BCR pathway inhibitors, alemtuzumab and allogeneic HSCT only effective currently approved treatments
<i>NOTCH1</i>	Transmembrane receptors, signaling through which regulates cell death, proliferation and differentiation	Gain of function frameshift mutations lead to a truncated, constitutively active protein that lacks degradation signals	10-12%	Strong correlation with trisomy 12; may predict for lack of benefit of adding rituximab to fludarabine plus cyclophosphamide (CLL8 trial); associated with unmutated <i>IGHV</i> and poor outcome
<i>FBXW7</i>	Ubiquitin ligase known to be a tumor suppressor	Loss of function mutations→impaired degradation of Notch1, c-Myc, c-Jun, cyclin E1, Mcl-1	2.5% (newly diagnosed patients)	Associated with trisomy 12 and with <i>NOTCH1</i> mutations; nearly exclusive of <i>SF3B1</i> mutations
<i>SF3B1</i>	RNA splicing protein – core component of U2 snRNP, which recognizes the 3' splice site at intron-exon junctions	Spliceosome mutations→decreased or increased transcription of normal pre-mRNA, exon skipping, intron retention and cryptic splice sites; associated with aberrant DDR	9-18%	Found primarily in patients with del11q and normal karyotype; confer adverse prognosis; almost mutually exclusive with <i>NOTCH1</i> and <i>FBXW7</i> mutations
<i>BIRC3</i>	Negative regulator of non-canonical NF-κB pathway	Inactivating mutations, deletions and insertions that disrupt gene function→non-canonical NF-κB activation	4% (newly diagnosed patients)	Associated with fludarabine refractoriness (24%); mutually exclusive of <i>TP53</i> abnormalities
<i>MYD88</i>	Critical adaptor molecule of the interleukin-1/toll-like receptor signaling (TLR) pathway	Mutations activate toll-like receptor pathway via IRAK1/4 to engage NF-κB and MAPK pathways	1.5% (newly diagnosed patients)	Younger patients; associated with del13q, mutated <i>IGHV</i> and low CD38/ZAP-70 expression; favorable outcome
<i>XPO1</i>	Exportin; controls localization of cyclin B and members of MAPK pathway		3.4% (newly diagnosed patients)	May be associated with CD38/ZAP-70 positivity, <i>NOTCH1</i> mutations and unmutated <i>IGHV</i>
<i>SAMHD1</i>	Enzyme that degrades the intracellular pool of dNTPs, limiting DNA synthesis; involved in DDR	Inactivating mutations lead to loss of tumor suppressor function→increased cellular survival and proliferation	3% (up to 11% in relapsed/refractory setting)	May serve as biomarker of chemoresistance, fludarabine in particular
<i>ATM</i>	Proximal transducer of DNA damage signals within DDR network	Mutations disrupt DDR and impair apoptosis	18%	<i>ATM</i> gene inactivation associated with del11q
<i>IGHV</i>	Immunoglobulin heavy chain variable region	"Mutated" indicates sequence >2% different from germline sequence; indicative of antigen exposure of B-cells	62%	Mutated <i>IGHV</i> generally confers favorable prognosis
<i>NFKBIE</i>	Inhibitor of NF-κB activity with specific role in B-cell biology		11% (advanced phase patients)	
<i>EGR2</i>	Transcription factor that participates in control of cellular differentiation	Missense mutations affect transcription of target genes	8% (advanced phase patients)	Associated with shorter time to treatment and poor survival

(continued)

TABLE 16-4. Common somatic mutations encountered in the major lymphoid malignancies. (Continued)

Gene	Functional class of encoded protein	Nature of mutation and functional consequence	Approximate incidence	Prognostic and/or therapeutic implications, if any
Wnt pathway genes	Critical for proliferation and cell fate determination of many cell types, including B-cells	Activating mutations in different genes→greater dependence on Wnt pathway signaling (already hyperactive in CLL)	14% overall	Not associated with any known CLL prognostic factor; multiple Wnt pathway inhibitors being developed
Ras/Raf/MAPK pathway genes	Major cellular pathway that controls proliferation, differentiation, transcription regulation and development	Activating mutations; some in subclones	<5%	May be amenable to therapeutic targeting by small molecule inhibitors
HAIRY CELL LEUKEMIA (HCL)				
<i>BRAF</i>	Serine-threonine kinase; part of the Ras/Raf/MAPK signaling pathway which regulates cell survival, proliferation and differentiation	Activating V600E mutation	Nearly all cases	Efficacy of small molecule kinase inhibitors, e.g., vemurafenib, dabrafenib; may help distinguish from other B-cell lymphomas and leukemias
B-CELL ACUTE LYMPHOBLASTIC LEUKEMIA (B-ALL)				
<i>RB1</i>	Tumor suppressor involved in cell cycle control	Various abnormalities lead to dysregulated cell cycle progression	51%	
<i>p16 (CDKN2A)</i> <i>p15 (CDKN2B)</i>	Endogenous CDK inhibitors	Various abnormalities (deletion, methylation) lead to unrestrained cell cycle progression	40% 70%	Poor prognosis
<i>TP53</i>	Master regulator of cell cycle, DNA damage response and apoptosis (tumor suppressor)	Deletions and inactivating point mutations	16% (92% in patients with low hypodiploidy, 63% with MYC translocations, 23% with complex karyotype)	Poor prognosis; more common in B-ALL than T-ALL; frequency increases with age; “double hit” of <i>TP53</i> do worst
<i>IKZF1</i>	Transcription factor	Splicing abnormalities	>80% of patients with Ph+ ALL	Poor prognosis independent of Ph status
“PHILADELPHIA CHROMOSOME LIKE” B-ALL (10-13% of children; 21-27% of adolescents /young adults)				
<i>ABL1, ABL2, CSF1R, PDGFRB</i>	Various rearrangements involving different fusion partners, e.g., <i>EBF1-PDGFRB, NUP214-ABL1</i>	Signaling pathway activation (CRKL phosphorylation seen with fusions involving <i>ABL1/2</i>)	12.6%	Sensitive to Bcr-Abl TKIs, e.g., imatinib, dasatinib
<i>EPOR</i>	Various rearrangements involving different fusion partners, e.g., <i>IGH-EPOR</i>	Activation of JAK-STAT signaling	3.9%	Sensitive to JAK1/2 inhibitor ruxolitinib
<i>JAK2</i>	Various rearrangements involving different fusion partners, e.g., <i>PAX5-JAK2, ATF7IP-JAK2, BCR-JAK2, STRB3-JAK2</i>	Activation of JAK-STAT signaling	7.4%	Sensitive to JAK1/2 inhibitor ruxolitinib
<i>CRLF2</i>	Various rearrangements involving different fusion partners, e.g., <i>P2RY8-CRLF2, IGH-CRLF2</i>	Activation of JAK-STAT signaling	49.7%	55% have concomitant JAK1/2 mutation; sensitive to ruxolitinib even without concomitant JAK mutations
<i>IL7R, FLT3, SH2B3 (LNK), JAK1, JAK3, TYK2, IL2RB</i>	Various alterations	Activation of JAK-STAT signaling	12.6%	Role for therapeutic JAK inhibition?
Ras/Raf/MAPK pathway genes	Major cellular pathway that controls proliferation, differentiation, transcription regulation and development	Activating mutations	4.3%	MEK inhibitors?

(continued)

TABLE 16-4. Common somatic mutations encountered in the major lymphoid malignancies. (Continued)

Gene	Functional class of encoded protein	Nature of mutation and functional consequence	Approximate incidence	Prognostic and/or therapeutic implications, if any
<i>NTRK3, DGKH</i>		Fusion proteins, e.g., ETV6-NTRK3	0.9%	ETV6-NTRK3 sensitive to ALK inhibitor crizotinib
<i>IKZF1</i>	Transcription factor	Deletions or point mutations	68% (vs. 16% in Bcr-Abl negative non-“Ph-like” ALL)	Inferior survival; more common in patients with kinase fusions than those with point mutations
T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA (T-ALL)				
<i>NOTCH1</i>	NOTCH1 signaling necessary for commitment to T-cell lineage and for thymic proliferation of T-cell progenitors	NOTCH1 may interact with PRC2, which influences stem cell renewal through epigenetic silencing of genes	>50%	<i>NOTCH1</i> and <i>FBXW7</i> mutant T-ALL may enjoy superior survival; miR223 appears to promote NOTCH1-driven T-ALL; gamma secretase inhibitors under study
<i>JAK1/JAK3/SH2B3 (LNK)</i>	Tyrosine kinases (JAK-STAT signaling critical to hematopoiesis)	Enhanced cellular survival and proliferation	More frequent in early T-cell precursor (ETP) ALL; also <i>FLT3</i> , transcription factors (<i>GATA3, ETV6, RUNX1, IKZF1</i>) and histone modifiers (e.g., <i>EZH2</i>) often mutated in ETP ALL	ETP ALL carries a poor prognosis and has a mutational spectrum similar to myeloid tumors; V658F mutation in JAK1 homologous to V617F in JAK2
Ras/Raf/MAPK pathway genes	Major cellular pathway that controls proliferation, differentiation, transcription regulation and development			
<i>PHF6</i>	X-linked tumor suppressor	Deletions or inactivating mutations→aberrant expression of TLX1 (HOX11) transcription factor oncogene	16% in children, 38% in adults	May explain greater incidence of T-ALL in males
MULTIPLE MYELOMA (MM)				
<i>KRAS, NRAS, BRAF</i>	Major cellular pathway that controls proliferation, differentiation, transcription regulation and development	Activating mutations lead to activation of the MAPK pathway	23%, 20% and 6% for KRAS, NRAS and BRAF, respectively	Can coexist, but usually only one clonal; combined MEK/BRAF inhibition worth exploring in clonal, BRAF-mutant multiple myeloma
<i>FGFR3</i>	Fibroblast growth factor receptor	Overexpression rather than mutation	23%	
<i>MAF</i>	Transcription factor	Overexpressed rather than mutation	13%	c-MAF overexpression associated with poor survival
<i>DIS3</i> and <i>FAM46C</i>	Ribonuclease (DIS3) involved in RNA processing; both genes encode RNA-binding proteins; FAM46C functions in regulation of translation	Point mutations with loss of heterozygosity lead to loss of tumor suppressor function of DIS3	11% each	<i>DIS3</i> aberrations more common in non-hyperdiploid cases; associated with del13q14 and IGH translocations and may predict for worse survival; these mutations rarely seen in other cancers
<i>LRK2</i>	Serine threonine kinase that phosphorylates translation initiation factor 4EBP	Mutations lead to disruption of translational control	8%	Protein homeostasis critical in MM because of high rate of immunoglobulin production; explains success of proteasome inhibitors
<i>TP53</i>	Master regulator of cell cycle, DNA damage response and apoptosis (tumor suppressor)	Deletions and inactivating point mutations	8%	Poor prognosis; strong correlation with del17p
<i>TRAF3, BIRC2, BIRC3, CYLD, BTRC, CARD11, IKBIP, IKBKB, MAP3K1, LTB, MAP3K14, RIPK4, TLR4, TRAF3, TRAF6, TRAF7, TRAF8, TRAF9, TRAF10, TRAF11, TRAF12, TRAF13, TRAF14, TRAF15, TRAF16, TRAF17, TRAF18, TRAF19, TRAF20, TRAF21, TRAF22, TRAF23, TRAF24, TRAF25, TRAF26, TRAF27, TRAF28, TRAF29, TRAF30, TRAF31, TRAF32, TRAF33, TRAF34, TRAF35, TRAF36, TRAF37, TRAF38, TRAF39, TRAF40, TRAF41, TRAF42, TRAF43, TRAF44, TRAF45, TRAF46, TRAF47, TRAF48, TRAF49, TRAF50, TRAF51, TRAF52, TRAF53, TRAF54, TRAF55, TRAF56, TRAF57, TRAF58, TRAF59, TRAF60, TRAF61, TRAF62, TRAF63, TRAF64, TRAF65, TRAF66, TRAF67, TRAF68, TRAF69, TRAF70, TRAF71, TRAF72, TRAF73, TRAF74, TRAF75, TRAF76, TRAF77, TRAF78, TRAF79, TRAF80, TRAF81, TRAF82, TRAF83, TRAF84, TRAF85, TRAF86, TRAF87, TRAF88, TRAF89, TRAF90, TRAF91, TRAF92, TRAF93, TRAF94, TRAF95, TRAF96, TRAF97, TRAF98, TRAF99, TRAF100</i>	Genes associated with regulation of the NF-κB signaling pathway	Activation of NF-κB signaling, e.g., through deletions and mutations in <i>CYLD</i> or inactivating mutations in <i>LTB</i>	<i>TRAF3</i> mutated in 5%; <i>CYLD</i> in 2%; others less frequent	Underlies fundamental role of NF-κB signaling and therapeutic efficacy of proteasome inhibitors

(continued)

TABLE 16–4. Common somatic mutations encountered in the major lymphoid malignancies.(Continued)

Gene	Functional class of encoded protein	Nature of mutation and functional consequence	Approximate incidence	Prognostic and/or therapeutic implications, if any
<i>MLL, MLL2, MLL3, UTX, WHSC1, WHSC1L1</i>	Histone modifying enzymes	Mutations lead to epigenetic derepression of transcription factor HOXA9		Aberrant HOXA9 expression could represent a new therapeutic target
<i>PRDM1</i>	Transcriptional repressor involved in plasmacytic differentiation	Missense and truncating frame shift or splice site mutations→loss of tumor suppressor function	5%	
<i>RB1</i>	Tumor suppressor involved in cell cycle control	Mutations lead to dysregulated cell cycle progression	3%	
<i>ACTG1</i>	Cytoplasmic actin found in nonmuscle cells		2%	
<i>EGR1</i>	Transcription factor	Somatic hypermutation	3%	Not clear if “driver” or “passenger” mutations
<i>IRF4 (MUM1)</i>	Transcription factor whose expression propels B-cells towards plasmacytic differentiation	Missense mutations, e.g., K123R, lead to gain of function		
<i>SP140</i>	Transcription factor (tumor suppressor)	Missense, frame shift and splice site alterations		
<i>CDKN2C, CDKN1B, CCND1</i>	Cell cycle regulatory genes	Overexpression of cyclins and/or deficiency of endogenous CDK inhibitors→enhanced proliferation	Cyclin D1 overexpressed in 36%	Efficacy of pharmacologic CDK inhibition, e.g., with dinaciclib, palbociclib
<i>PTPRD</i>	Tyrosine phosphatase that dephosphorylates STAT3, which promotes IL-6 signaling	Homozygous deletions of tumor suppressor gene		
<i>MAX</i>	Transcription factor that functions as heterodimerization partner for MYC	Loss of heterozygosity of tumor suppressor gene		
WALDENSTROM’S MACROGLOBULINEMIA (WM)/LYMPHOPLASMACYTIC LYMPHOMA (LPL)				
<i>MYD88</i>	Critical adaptor molecule of the interleukin-1/toll-like receptor (TLR) signaling pathway	Mutations, e.g., L265P, activate toll-like receptor pathway via IRAK1/4 to engage NF-κB and MAPK pathways	91% of all patients with LPL	Can help diagnose WM/LPL in cases of uncertainty; explains high efficacy of BTK (ibrutinib) and proteasome (bortezomib) inhibitors in WM
DIFFUSE LARGE B-CELL LYMPHOMA – GERMINAL CENTER B-CELL (GCB) AND ACTIVATED B-CELL (ABC)				
<i>EZH2</i>	Histone methyltransferase (catalytic subunit of polycomb repressive complex, PRC2)	Gain of function mutations, e.g., at Y641, promote lymphomagenesis through transcriptional silencing of key antiproliferative tumor suppressor genes, e.g., CDKN1A	22% of GCB DLBCL, not seen in ABC DLBCL	EZH2 inhibitors in early phase clinical trials
<i>PTEN</i>	Negative regulator of PI3K/Akt/mTOR pathway (tumor suppressor)	PTEN deletion leads to constitutive activation of and addiction to PI3K/Akt/mTOR signaling	11% of GCB DLBCL	Inhibitors of PI3K (e.g., idelalisib), Akt and mTOR (e.g., everolimus, temsirolimus) being explored
<i>BCL-2</i>	Founding member of Bcl-2 family of mitochondrial apoptosis regulators; anti-apoptotic	Promotes cellular survival and a major determinant of resistance to chemotherapy	The most mutated gene in GCB DLBCL; t(14;18) found in 34% of cases of GCB DLBCL	Selective Bcl-2 antagonist (BH3-mimetic) venetoclax in clinical trials

(continued)

TABLE 16-4. Common somatic mutations encountered in the major lymphoid malignancies. (Continued)

Gene	Functional class of encoded protein	Nature of mutation and functional consequence	Approximate incidence	Prognostic and/or therapeutic implications, if any
<i>BCL-6</i>	Transcription factor; represses many target genes involved in proliferation, survival, cell growth and metabolism	Routinely overexpressed in DLBCL; activation may underlie resistance to treatment	Mutated (70%) or rearranged (40%) in essentially all cases of DLBCL	Small molecule inhibitors that disrupt Bcl-6 function in development
<i>CARD11</i>	Part of signaling complex of adaptor proteins that lead to BCR-dependent NF- κ B activation upon antigenic stimulation	BCR signaling and NF- κ B activation critical in ABC DLBCL	Up to 10% of cases of ABC DLBCL	<i>CARD11</i> mutations predict for lack of efficacy of inhibition of upstream BCR pathway targets, e.g., BTK (ibrutinib) or PKC-beta
<i>CD79B</i>	B-cell co-receptor	BCR signaling and NF- κ B activation critical in ABC DLBCL	21% of cases of ABC DLBCL	<i>CD79B</i> mutations correlate with sensitivity to selective PKC-beta inhibitor sotrastaurin
<i>MYD88</i>	Critical adaptor molecule of the interleukin-1/toll-like receptor (TLR) signaling pathway	Mutations, e.g., L265P, activate toll-like receptor pathway via IRAK1/4 to engage NF- κ B and MAPK pathways \rightarrow IL-6 /IL-10 production \rightarrow autocrine JAK activation	30% of cases of ABC DLBCL	
<i>TNFAIP3 (A20)</i>	Negative regulator of NF- κ B pathway (tumor suppressor)	Inactivating mutations and deletions	Biallelic inactivation occurs in 30% of cases of ABC DLBCL	Can coexist with mutations in both <i>MYD88</i> and <i>CD79B</i>
<i>IRF4 (MUM1)</i>	Transcription factor whose expression propels B-cells towards plasmacytic differentiation	A direct target of the NF- κ B pathway that can be induced by both the BCR and TLR pathways	Constitutive NF- κ B activation is a pathogenic hallmark of ABC DLBCL	Lenalidomide selectively kills ABC DLBCL cells by cereblon-dependent IRF4 down-regulation
<i>c-MYC</i> (cases harboring additional oncogenic rearrangements involving <i>BCL2</i> , <i>BCL6</i> or <i>CCND1</i> designated "double hit")	Oncoprotein	Suppresses transcription of tumor suppressor <i>tristetraprolin</i>	10% of patients with newly diagnosed DLBCL carry an underlying <i>MYC</i> rearrangement (translocation, amplification)	May be possible to target <i>MYC</i> using BET bromodomain BRD4 inhibitors
<i>BTK/Syk/Lyn/PKC-β/MALT1/JAK-STAT</i>	Kinases involved in BCR signaling (JAK-STAT signaling driven by activating <i>MYD88</i> mutations)	Therapeutic targets without activating mutations	"Chronic active" BCR signaling and NF- κ B activation fundamental in ABC DLBCL	Multiple small molecule inhibitors being studied, e.g., ibrutinib (BTK), enzastaurin (PKC- β), ruxolitinib (JAK1/2)
FOLLICULAR LYMPHOMA (FL)				
<i>MLL2, CREBBP, EZH2, MEF2B</i>	Histone modifying enzymes	<i>CREBBP</i> , <i>MLL2</i> , <i>EZH2</i> alterations early events in lymphomagenesis and progression	Very high frequency overall; <i>EZH2</i> mutated in 7-27% (gain of function mutations, e.g., at Y641)	Potential role for <i>EZH2</i> inhibitors as in GCB DLBCL?
<i>HIST1H1B-E, OCT2 (POU2F2), IRF8, ARID1A</i>	Linker histones – proteins that facilitate folding of higher order chromatin structures and regulate access of histone modifying enzymes and chromatin remodeling complexes to target genes		27% (<i>HIST1H1B-E</i>), 8% (<i>OCT2/POU2F2</i>), 6% (<i>IRF8</i>), 11% (<i>ARID1A</i>)	Mutations in <i>HIST1H1B-E</i> and in <i>EZH2</i> or <i>ARID1A</i> largely mutually exclusive

(continued)

TABLE 16-4. Common somatic mutations encountered in the major lymphoid malignancies. (Continued)

Gene	Functional class of encoded protein	Nature of mutation and functional consequence	Approximate incidence	Prognostic and/or therapeutic implications, if any
<i>STAT6, SOCS1</i>	JAK-STAT signaling pathway genes	Mutations contribute to constitutive <i>STAT6</i> activation and promotion of tumor cell survival	<i>STAT6</i> 12%, <i>SOCS1</i> 8%	Eventual role for JAK inhibitors?
<i>CARD11, CD79B, TNFAIP3</i>	NF-κB pathway genes - mutually exclusive mutations	Constitutive activation of NF-κB	<i>CARD11</i> and <i>TNFAIP3</i> each 11% (overall one third)	Implications for therapy as for ABC DLBCL
<i>EBF1</i>	Transcription factor important in B-cell development	Loss of function mutations lead to reduction in <i>EBF1</i> target gene expression	17% overall (genes important in B-cell development)	
<i>BCL2</i>	Founding member of Bcl-2 family of mitochondrial apoptosis regulators; anti-apoptotic	Promotes cellular survival and a major determinant of resistance to chemotherapy; overexpression characteristic of FL	Mutation frequency 12% at diagnosis; 53% at transformation (<i>different from t(14;18) present in 80-90%</i>)	Correlate with risk for transformation and death; Bcl-2 antagonist (BH3-mimetic) venetoclax in clinical trials in FL
<i>NOTCH1/2</i>	Transmembrane receptors, signaling through which regulates cell death, proliferation and differentiation	Gain of function mutations lead to truncated protein that lacks degradation signals	6.3%	Female predominance, greater splenic involvement, lower frequency of <i>t(14;18)</i> ; gamma secretase inhibitors under study
<i>CDKN2A</i>	p16(INK4a) and p14 (ARF) tumor suppressors	Inactivation of tumor suppressor gene through deletion or methylation	Deletion (8%), methylation (19%)	May predict for inferior survival, particularly in rituximab-treated patients
MANTLE CELL LYMPHOMA (MCL)				
<i>IGHV</i>	Immunoglobulin heavy chain variable region	Mutations support antigen-driven selection in the clonogenic expansion of MCL tumor cells	15-40%	Correlate with <i>SOX11</i> negativity, indolent clinical course, non-nodal presentation
<i>SOX11</i>	Transcription factor overexpressed (<i>not mutated</i>) in the vast majority of cases of MCL	Promotes angiogenesis via PDGF, regulates <i>PAX5</i> expression and blocks terminal B-cell differentiation	>90% of cases of MCL, both cyclin D1 positive and negative (can help diagnose in latter situation)	Expression correlates with unmutated <i>IGHV</i> , aggressive clinical course and karyotypic complexity
<i>ATM</i>	Proximal transducer of DNA damage signals within DDR network	Mutations disrupt DDR and impair apoptosis	55% in <i>SOX11+</i> MCL; 0% in <i>SOX11-</i> cases; 42% overall	Correlate with <i>del11q</i>
<i>CCND1</i>	Cyclin D1	Activating mutations/overexpression drive cell cycle progression	Mutations more frequent in <i>SOX11-</i> cases (86% vs. 18%), and cases with mutated <i>IGHV</i> (58% vs. 19%); 14% overall	Likely acquired in germinal center microenvironment; <i>CDK4/6</i> inhibitor palbociclib effective in MCL
<i>TP53</i>	Master regulator of cell cycle, DNA damage response and apoptosis (tumor suppressor)	Deletions and inactivating point mutations	19-28%	Equally distributed regardless of <i>SOX11</i> or <i>IGHV</i> status; correlate with <i>del17p</i>
<i>WHSC1 (MMSET), MLL2, MEF2B</i>	Histone methyltransferases	<i>WHSC1</i> mutations increase H3K36 methylation→ genome wide hypomethylation of H3K27→ significant overexpression of proliferation and cell cycle regulation genes	Found virtually only in <i>SOX11+/IGHV</i> unmutated MCL (<i>WHSC1</i> 15%, <i>MLL2</i> 18%, <i>MEF2B</i> 5%); of all cases of MCL, <i>WHSC1</i> mutated in 10%; <i>MLL2</i> in 20% and <i>MEF2B</i> in 3.2%	<i>WHSC1</i> -mutant gene expression signature very similar to that seen in multiple myeloma with <i>t(4;14)</i> ; <i>MLL2</i> and <i>MEF2B</i> mutations similar to those in DLBCL or FL

(continued)

TABLE 16–4. Common somatic mutations encountered in the major lymphoid malignancies.(Continued)

Gene	Functional class of encoded protein	Nature of mutation and functional consequence	Approximate incidence	Prognostic and/or therapeutic implications, if any
<i>TRAF2, BIRC3</i>	BIRC3 is a negative regulator of non-canonical NF-κB pathway; TRAF2 transduces signals from TNF receptors to NF-κB	Inactivating or splice site mutations (<i>BIRC3</i>) and activating mutations (<i>TRAF2</i>) lead to enhanced NF-κB activation	6% (<i>TRAF2</i>); 10% (<i>BIRC3</i>)	<i>BIRC3</i> mutations correlate with del11q; both suggest NIK (rather than BCR) signaling and <i>alternative</i> NF-κB pathway activation (resistance to BCR pathway inhibitors, e.g., ibrutinib)
<i>TLR2</i>	Toll-like receptor 2 (TLR pathway mediates innate immunity independent of antigenic stimulation)	Mutations lead to significantly increased production of IL-6, IL-1RA and IL-8	Seen only in SOX-11-/ <i>IGHV</i> mutated MCL	
<i>NOTCH1/2</i>	Transmembrane receptors, signaling through which regulates cell death, proliferation and differentiation	Gain of function mutations lead to truncated protein that lacks degradation signals	9.5%	A subset of tumors with adverse biological and clinical features; i.e., blastoid morphology and worse survival
LARGE GRANULAR LYMPHOCYTIC LEUKEMIA (LGL leukemia)				
<i>STAT3</i>	Signal transducer and activator of transcription, e.g., transducing signals from cytokine receptor-associated Janus kinases to the nucleus	Activating mutations	40%	May correlate with greater prevalence of neutropenia and rheumatoid arthritis

and numerous downstream signaling effects of those mutations have also been defined. The Ras and the Rho families of oncoproteins are linked by a small G protein called *Rac*, which is required for transformation by Ras.^{213,214} The normal formation of actin filaments is required for G₁/S-phase entry. Recent data have shown the Rho-guanosine triphosphatases play a key role in the Wnt-signaling pathway, where they are involved in cellular polarization processes.²¹⁵ Thus, alterations in the Rho pathway may lead to premature entry into M phase by interference with cytoskeletal organization. The Ras/Raf/MEK/ERK cascade couples signals from the surface to the intracellular space and triggers cell proliferation signals that influence the cell cycle. Abnormal activation of this cascade occurs in several leukemias because of activating mutations in the Ras protooncogene.²¹⁶ Ectopic overexpression of Raf proteins is associated with cell proliferation, whereas overexpression of activated Raf is associated with cell-cycle arrest in G₁ phase.^{217,218} Different *Raf* genes have different functions in cells, although A-Raf and B-Raf share three conserved domains termed CR1, CR2, and CR3.²¹⁹ A-Raf is able to upregulate the expression of cyclin D₁, cdk2, cyclin E, and cdk4, whereas B-Raf and Raf-1 induce p21^{cip1}, leading to a G₁ arrest.^{216,219} The mode of action of these Raf molecules is not fully understood but one explanation why they act differently may be because they activate different downstream pathways, namely the MAPK (MEK [MAP/ERK (extracellular signal-regulated kinase)]). The three different MAPK cascades are the ERK-, c-Jun N-terminal kinase (JNK)/stress-activated protein kinase (SAPK)-, and p38 pathways. The MAP kinase pathways consist of three types of kinases in a series, MAPKKK, MAPKK, and MAPK (ERK), each sequentially activating the next kinase. The MAPK cascades all transmit responses from several different surface receptors to the nucleus.²²⁰ One explanation for the oncogenic effects of the MAPK pathway is that ERK activates c-Myc via phosphorylation on serine 62.²²¹ In addition, repression of c-Myc is required for terminal differentiation of many cell types, including hematopoietic cells. Thus, deregulated expression of c-Myc in both M1 AML cells and in normal myeloid cells derived from murine marrow blocks terminal differentiation and its associated growth arrest, and also induces apoptosis, which

is dependent on the extrinsic Fas/CD95 pathway. New data suggest a linkage between c-Myc downregulation, the p16^{INK4A}/cyclinD1/RB, and SMAC/Diablo apoptotic pathways.²²² Several different transcription factors have been implicated in the downregulation of c-Myc expression during differentiation, including CCAAT/enhancer binding protein (C/EBP) α, CTCE, BLIMP-1, and RFX1. Alterations in the expression and/or function of these transcription factors, or of the c-Myc and Max interacting proteins, such as MM-1 and Mxi1, can influence the neoplastic process.^{223,224}

Experiments on oncoproteins have focused on apoptosis, the lethal response of a cell to either DNA damage or to signaling through cell surface “death” receptors. Key regulators of apoptosis induced by DNA damage are the multiple members of the Bcl-2 family of proteins, which include Bcl-2, Bcl-x_L, Mcl-1, Bax, Bak, Bim, and Bad, among others. Bcl-2 is involved in the t(14;18) chromosomal translocation, which is found classically in follicular lymphoma.²²⁵ The disruption of these loci increases expression of Bcl-2, and results in the uncontrolled accumulation of malignant B cells, because of an impaired balance between growth and apoptosis.^{226,227} It also has been shown that Bcl-x_L, Bax, and Bad are involved in the regulation of AML cells. For example, the ratio between Bax and Bcl-2 is a prognostic factor in this myeloid neoplasm.²²⁸ Additionally, Mcl-1 may be even more critical to the development and maintenance of AML than Bcl-2 or Bcl-x_L.²²⁹ The nuclear HDAC complex, which regulates the structural conformation of DNA and therefore the activation of several genes, is targeted by ETO, the fusion partner of the *RUNX1* gene in some patients with AML. The t(8;21) translocation that occurs in such patients allows the formation of a stable complex between the HDAC complex and ETO, contributing to leukemogenesis.^{230,231} PLZF, PLZF-RARα, and BCL-6 are other oncogenes that target the HDAC complex.^{232,233}

TUMOR-SUPPRESSOR GENES

Almost every cancer harbors one or more abnormalities of tumor-suppressor genes. These include mutations, translocations, deletions, and

epigenetic modifications. In addition, at least two epigenetic mechanisms—the hypermethylation of CpG islands in the promoter region and the aberrant acetylation of histones (especially histone H4)—can silence tumor-suppressor genes in a variety of human cancer cell lines and primary tumors.

The products of three important tumor-suppressor genes (*RB*, *P53*, and *p16^{INK4A}*) are interconnected biochemically. The *RB* gene maps to chromosome 13q14 and has several downstream effectors, among which the transcription factor E2F is the best characterized.²³⁴ The *RB* gene family consists of three closely related proteins, RB, p107, and p130. All three proteins are able to interact with several E2F family members.

Transcriptional activation and repression are mediated via complexes consisting of RB family members, E2F family members, and so-called DP proteins.²³⁵ Besides its role in cell-cycle control, RB can modulate RNA polymerase activity, thus linking cell-cycle progression to transcriptional regulation. Many cellular proteins have been identified that bind to RB. These proteins can be divided into different groups, including transcription factors, growth factors, protein kinases, protein phosphatases, and nuclear matrix proteins. Mutations of RB are frequent in cancer e.g., leukemias; soft-tissue sarcomas; and breast, esophagus, prostate, and renal carcinomas.²³⁶ Several viral or oncoproteins can bind to and inactivate RB.^{112,237}

The p53 gene has been called a “guardian” of the genome because it transmits signals arising from various forms of DNA damage, leading to cell-cycle arrest or apoptosis. p53 protein is also the target of leukemogenic mutations. Damaging factors, such as hypoxic stress, chemicals, or irradiation either alter the p53 protein itself or can stabilize its cellular inhibitor, MDM2 (in humans the homologue is termed HDM2).²³⁸ The MDM2 protein inhibits p53 transcription and stimulates p53 degradation.^{239,240} For the former, MDM2 is able to bind to the transactivation domain of p53 through a p53-interacting domain on the MDM2 amino terminus, which inhibits p53 from binding to its transcriptional coactivators, thereby preventing activation of p53 transcriptional targets. For the latter, MDM2 binds to p53 through a RING-domain and ubiquitinates p53 through the E3 ubiquitin ligase activity of MDM2, causing p53 nuclear export and ultimate degradation.²⁴¹ Moreover, MDM2 is able to affect chromosomal stability independently of p53.²⁴² The MDM2 binding region contains several phosphorylation sites.²⁴³ These residues (e.g., serine 395) are phosphorylated by DNA damage-activated kinases (e.g., ATM and Chk2), which is required for p53 activation.²⁴⁴ The *p14^{ARF}* tumor-suppressor gene, which is encoded within the *p16^{INK4A}* locus by alternate splicing, controls MDM2 activity.²⁴⁵ In *de novo* AML, although p53 mutations are not common,²⁴⁶ overexpression of MDM2 is frequently encountered,²⁴⁷ and there is current interest in exploring MDM2 antagonists, for example, RO5503781, in combination with cytarabine in patients with relapsed or refractory AML. Additionally, the MDM2 antagonist nutlin-3A causes p53-dependent apoptosis in AML cells by disrupting the p53-MDM2 interaction²⁴⁸ and synergizes with BH3-mimetics,²⁴⁹ MEK/ERK inhibitors,^{250,251} aurora kinase inhibitors,²⁴⁹ cdk1 inhibitors,²⁵² XIAP antagonists,²⁵³ FLT3 inhibitors,^{254,255} and inhibitors of nuclear export, such as CRM1.²⁵⁶ The *p14^{ARF}* gene shares exons 2 and 3 with *p16^{INK4A}* but has a distinct exon 1. The discovery that two important tumor-suppressor genes are encoded by the same chromosomal locus and share several exons was unexpected and is unique in human biology. The *p16^{INK4A}* gene function depends on p53, because overexpression of *p16^{INK4A}* causes cell-cycle arrest in p53 wild-type cells but not in p53-deficient cells.²⁵⁷ The transcription of *p16^{INK4A}* is regulated by E2F, which is under the control of RB.²⁵⁸ This indicates the existence of yet another feedback loop, which links the RB pathway to p53.²⁵⁹ The Ras protein is another identified *p16^{INK4A}* factor involved in MDM2-p53-p21-RB regulation.^{260,261} Different signaling routes that connect DNA damage with p53 include a cascade of Ser/Thr

kinases, for example, ATM, ATR, Chk1 and Chk2, which phosphorylate p53.²⁶² Abnormalities of p53 are found in slightly more than 50 percent of all human tumors and, surprisingly, even in some normal cells. It is unclear if these “normal” cells represent a pool of premalignant cells in an otherwise healthy individual or, more likely, p53 changes are just one step in multistage tumorigenesis. Two different p53 homologues, p63 and p73, have been described, which show DNA binding, transactivation, and oligomerization domains similar to p53.²⁶³ This similarity in the DNA binding domain allows p63 and p73 to regulate p53 target genes, induce cell-cycle arrest and apoptosis, and therefore act as tumor suppressors.²⁶⁴ The p73 gene has been localized to chromosome 1p36, a common region of cytogenetic changes in cancer. p73 protein can also bind p53, inhibiting its transcriptional regulatory activity.²⁶⁵ Although p53 mutations are found frequently in almost all cancers, p63 and p73 mutations are much more rare.^{264,266} However, the p73 gene is inactivated by hypermethylation of CpG islands in its promoter region in both leukemias and lymphomas.²⁶⁷

Homozygous deletions of the *p16^{INK4A}/p14^{ARF}* gene locus on human chromosome 9p21 have been detected in gliomas,^{107,268} primary cancers of lung,^{107,269} bladder,²⁷⁰ head and neck,²⁷¹ as well as in acute T-cell leukemias^{272,273} and mesotheliomas.²⁷⁴ Because inherited mutations of *p16^{INK4A}* exon 2 may interfere with its expression and/or function, without causing an amino acid change in *p14^{ARF}*, it is clear that *p16^{INK4A}* inactivation alone is an important step in the evolution of malignant disease. However, in established tumor cell lines, nearly all chromosome 9p21 deletions disable the entire *p16^{INK4A}/p14^{ARF}* locus. Both proteins act as suppressors of the G₁-S transition, even though they function in two different pathways: *p16^{INK4A}* acts as an inhibitor of cyclin D₁/cdk4/6 complexes whereas *p14^{ARF}* stabilizes p53 by inhibition of MDM2. Several models provide insight into the different modes of action of *p16^{INK4A}* and *p14^{ARF}* on cell-cycle regulation. Interestingly, if the entire *p19^{ARF}/p16^{INK4A}* locus is disrupted in mice (the mouse homologue of *p14^{ARF}* is *p19^{ARF}*), the mice develop lymphomas, lymphoid leukemias, and sarcomas, suggesting that these tumor-suppressor genes do not act in a lineage-specific manner on cell-cycle regulation but in a more general way. Retroviral expression of *p16^{INK4A}* restores the normal phenotype in some cell types underlining the strong tumor-suppressor potency of *p16^{INK4A}*. The *p15^{INK4B}* gene, also located on chromosome 9p21, approximately 20 kb centromeric of *p16^{INK4A}*, is deleted somewhat less frequently. Analyses of primary tumors, however, show that not all 9p21 deletions encompass these three tumor suppressor genes. One mechanism for disruption of the *p15^{INK4B}/p14^{ARF}/p16^{INK4A}* region in T-cell leukemias may be the action of an illegitimate variable diversity joining (V[D]J) recombinase.²⁷⁵ Several other binding partners of *p16^{INK4A}* have been identified.²⁷⁶ The RB gene interacts with one of these factors, BRG1, to remodel chromatin structures. BRG1 also acts upstream of RB with *p16^{INK4A}* and functions as a tumor suppressor.²⁷⁶

The *p15^{INK4B}/p16^{INK4A}/p14^{ARF}* locus on chromosome 9p21 is a hotspot in the development of human cancer and approximately 50 percent of all human malignancies show abnormalities in at least one of these tumor-suppressor genes. Another gene lies about 100 kb telomeric of *p16^{INK4A}*, and this gene, methylthioadenosine phosphorylase (MTAP), encodes an important enzyme in purine metabolism. Some early gliomas show MTAP deletions without deletions of other genes on 9p21, suggesting that MTAP by itself has tumor-suppressor properties. The reexpression of MTAP in breast cancer cells severely inhibits their ability to form colonies in soft agar or collagen, supporting this hypothesis.²⁷⁷ In addition, MTAP-expressing cells are suppressed for tumor formation when implanted into severe combined immune deficiency (SCID) mice. Recent findings suggest that the enzyme ornithine decarboxylase (ODC) is overexpressed in MTAP-deleted tumors, providing evidence for a new pathway in tumorigenesis. Overexpression of

ODC has been observed in many tumors and is linked to the Ras pathway.²⁷⁸ Reexpression of MTAP in ODC overexpressing cells decreases ODC levels and inhibits tumor cell growth.²⁷⁹ In addition, high levels of 5'-deoxy-5'-(methylthio) adenosine (MTA) induce matrix metalloproteinase and growth factor gene expression in melanoma cells, leading to enhanced invasion and vasculogenic mimicry. In addition, MTA induced the secretion of β -fibroblast growth factor and the upregulation of activator protein-1, demonstrating a tumor-supporting role of MTA, which is increased in MTAP-deficient cells.²⁸⁰

The mechanisms by which the above-mentioned genes are inactivated are rather different. Especially in permanent cell lines, *p15^{INK4B}/p14^{ARF}/p16^{INK4A}* and MTAP are homozygously deleted. One allele of MTAP is also deleted in AML lines, but not in primary AML samples. Mutations in *p15^{INK4B}/p14^{ARF}/p16^{INK4A}* genes are rare, and if present, occur in exon 2. Hypermethylation of CpG islands in the promoter areas of *p15^{INK4B}/p14^{ARF}/p16^{INK4A}* are frequently found in hematologic malignancies.^{281–283} The availability of demethylating agents such as 5-azacytidine and 5-aza-2'-deoxycytidine (decitabine) makes this phenomenon an interesting target for chemotherapy.^{284,285} Decitabine has been used to treat patients suffering from different hematologic malignancies and was reported to have activity in advanced myelodysplastic syndrome (MDS), accompanied by demethylation of the *p16^{INK4A}* promoter.²⁸⁵ Azacytidine and decitabine are approved for the treatment of MDS^{286–288} and also widely used for the treatment of AML, particularly older patients considered unfit for cytotoxic chemotherapy, particularly when blast counts are low.^{289–291} However, *p16^{INK4A}* and *p15^{INK4B}* are not the only targets of these demethylating

agents in hematologic malignancies.²⁹² Transcriptional regulation by methylation is mediated by a multiprotein complex consisting of a MeCP2, a methylcytosine-binding protein with a transcriptional repressor domain that binds the corepressor mSin3A, which is itself one element of a multiprotein complex that includes HDAC1 and HDAC2.^{293,294} Therefore, reexpression of silenced genes can be achieved by demethylating DNA or by destabilizing HDACs, and it could be demonstrated that both mechanisms are tightly linked. HDACs and demethylating agents act synergistically to induce genes silenced in cancer by hypermethylation.¹³⁹ Another new mechanism of gene regulation and inactivation *in vivo* is degradation by microRNAs. This has also been shown for several members of the *p16^{INK4A}/cdk4/cyclin D₁/RB* pathway.²⁹⁵

THE ROLE OF HISTONE DEACETYLASES IN CELL-CYCLE REGULATION

HDACs catalyze the deacetylation of lysine residues in the histone N-terminal tails and are found in large multiprotein complexes with transcriptional corepressors. Human HDACs are grouped into three classes based on their similarity to known yeast factors: class I HDACs are similar to the yeast transcriptional repressor *yRPD3*; class II HDACs are similar to the yeast transcriptional repressor *yHDA1*; and class III HDACs are similar to the yeast transcriptional repressor *ySIR2* (Table 16–5; Fig. 16–3).^{296,297} Eleven different HDACs have been identified so far. The physiologic counterparts of

TABLE 16–5. Different Types and Classes of Histone Deacetylases

Enzyme	Mechanism of Deacetylase Activity	Tissue Expression	Interacting Protein
Class I			
HDAC1	Zn ²⁺ dependent	Ubiquitous	HDAC2, Sin3, CoREST, NuRD, RB/E2F1, p53, MYOD, NF- κ B, YY1, DNMT1, DNMT3A, MBD2, SP1, SP3, BRCA1, MeCP2, ATM, AML1-ETO, PML, PLZF, BCL6, AR, ER
HDAC2	Zn ²⁺ dependent	Ubiquitous	HDAC1, Sin3, CoREST, NuRD, RB, NF- κ B, BRCA1, DNMT1, AML1-ETO, PML, PLZF, BCL6
HDAC3	Zn ²⁺ dependent	Ubiquitous	HDAC4, HDAC5, HDAC7, RB, NF- κ B, STAT1, STAT3, GATA1, GATA2, NCoR/SMRT, AML1-ETO, PML, PLZF, PML-RAR α , PLZF-RAR α , BCL6,
HDAC8	Zn ²⁺ dependent	Ubiquitous	SMC3, EST1B, Hsp70
Class IIa			
HDAC4	Zn ²⁺ dependent	Tissue specific	MEF2, HDAC3-NCoR, GATA1
HDAC5	Zn ²⁺ dependent	Tissue specific	MEF2, HDAC3-NCoR, GATA1, GATA2
HDAC7	Zn ²⁺ dependent	Tissue specific	MEF2, HDAC3-NCoR, ER α
HDAC9	Zn ²⁺ dependent	Tissue specific	MEF2
Class IIb			
HDAC6	Zn ²⁺ dependent	Tissue specific	α -tubulin, Hsp90, HDAC11
HDAC10	Zn ²⁺ dependent	Tissue specific	RB
Class III			
Sirt1–7	NAD ⁺ dependent	?	p53
Class IV			
HDAC11	Zn ²⁺ dependent	Tissue specific	Interleukin 10, HDAC6

HDAC, histone deacetylase; NAD, nicotinamide adenine dinucleotide; NF- κ B, nuclear factor kappa B; RB, retinoblastoma.

Figure 16-3. Classes of human histone deacetylases.

the HDACs are histone acetyl transferases (HATs). In the nucleosome, positively charged hypoacetylated histones bind tightly to the phosphate backbone of the DNA and maintain the chromatin in an inactive, silent state. Both HAT and HDAC are recruited to target genes in complexes with sequence-specific transcription factors and their cofactors. Examples of these cofactors include NCoR or SMRT (Fig. 16-4). Several different transcription factors are assembled with these complexes, including Bcl-6, MAD1, PML, and ETO.²⁹⁶ HDACs are involved in different cellular mechanisms, including proliferation and differentiation. Irregular activation of HDACs leads to the loss of cell-cycle control.²⁹⁸ Gene silencing by HDAC complexes is an important

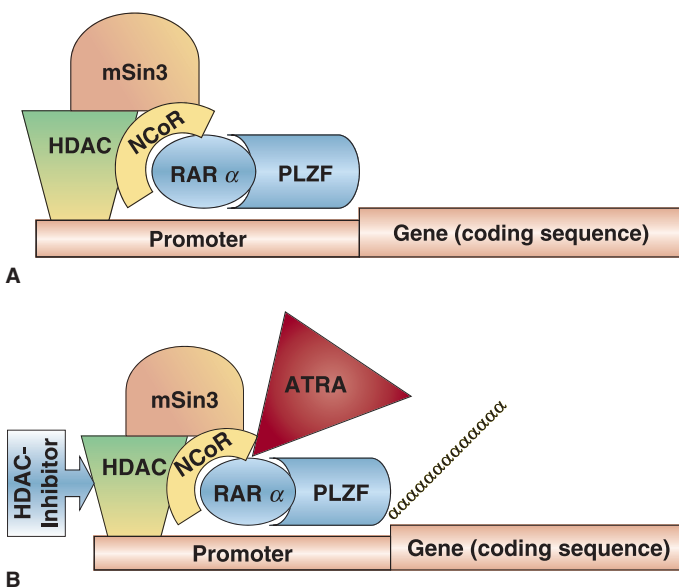

Figure 16-4. **A.** Transcriptional silencing by the recruitment of histone deacetylases (HDACs) in acute myelogenous leukemia (AML) with t(11;17). See text for further description. **B.** Transcriptional reactivation and induction of differentiation by histone deacetylase inhibitors and all-*trans*-retinoic acid (ATRA) in AML with t(11;17). See text for further description.

mechanism in the development of AML, most notably APL. The PML-RAR α fusion protein is an oncoprotein that represses retinoic acid-dependent transcription by recruitment of HDAC to RAR-regulated genes (Fig. 16-4B), halting myeloid maturation because of cell-cycle arrest. In the PML-RAR α fusion protein, the RAR α is not responsive to physiologic concentrations of retinoic acid and supra-physiologic doses of all-*trans*-retinoic acid are necessary to overcome the tight HDAC-recruitment and the consequent cell-cycle block.²⁹⁶ The rare translocation t(11;17) fuses the RAR α gene to the PLZF gene, which directly interacts with the NCoR-mSin3a-HDAC complex to suppress gene transcription. This block can only be overcome by the addition of a HDACI. Another well-known example of transcriptional silencing by the recruitment of an HDAC repressor is the AML1-ETO fusion protein which results from the t(8;21) translocation. As already described, the addition of an HDACI can relieve ETO-mediated transcriptional repression.²⁹⁹ Although 11 HDACs have been described, only limited information is available about their redundant biologic and physiologic functions. As shown in Figure 16-4B, inhibitors of HDAC activity lead to the reexpression of silenced genes and to the induction of differentiation. Most of these inhibitors, such as depsipeptide (romidepsin), belinostat or vorinostat,³⁰⁰ do not exhibit isoenzyme selectivity and may therefore be of limited therapeutic value, at least as single agents. These drugs are currently approved for patients with previously treated peripheral and cutaneous T-cell lymphomas, although they continue to be studied for other indications, for example, vorinostat for AML in combination with chemotherapy (NCT01802333). The pan-HDACI panobinostat, in combination with bortezomib and dexamethasone, has been approved in the treatment of patients with relapsed or refractory myeloma,³⁰¹ while the class I-selective HDACI entinostat is currently being studied in phase III clinical trials in advanced hormone-responsive breast cancer in conjunction with aromatase inhibitors (NCT02115282). Finally, pracinostat (pan-HDACI) and mocetinostat (isotype-selective) have been granted “orphan drug” status for AML,¹⁴⁷ and for MDS and diffuse large B-cell lymphoma with specific mutations in HATs (e.g., CREBBP and EP300), respectively. However, the HDACI valproic acid, an established antiepileptic agent, is the first drug within this group that selectively inhibits one HDAC, namely HDAC2.³⁰² Valproic acid induces proteasomal degradation of HDAC2. Basal and valproic acid-induced HDAC2 turnover strongly depend on the E2 ubiquitin conjugase Ubc8 and the E3 ubiquitin ligase RLIM. Thus, polyubiquitination and proteasomal degradation provide an isoenzyme-selective mechanism for downregulation of HDAC2.³⁰² This also underlines the importance of another cell-cycle element, the proteasome.

● THE PROTEASOME: THE RECYCLING MACHINERY

The proteasome is a 2.4 MDa, multicentric protease complex with an important role in cellular protein regulation. Its structure consists of a cylindrical core, the so-called 20S particle, composed of four stacked rings with a total of seven proteins in each ring. The second part of the proteasome, two copies of a 19S particle, is bound to the 20S core. Only proteins that have been ubiquitinated can be degraded in the proteasome. The ubiquitination of different substrate proteins involves the sequential action of three enzymes: E1 (an ATP-dependent ubiquitin-activating enzyme), E2 (a ubiquitin-conjugating enzyme), and E3 (ubiquitin-protein ligase). The ubiquitin-proteasome pathway plays a critical role in the degradation of intracellular proteins involved

in cell-cycle control, transcription activation, apoptosis, and tumor growth through an ATP-dependent mechanism.³⁰³ Proteins such as HDAC2 are tagged with several ubiquitin molecules and then degraded in the machinery.³⁰² Several tumors depend on rapid cell cycling, which requires expression and degradation of numerous regulatory proteins. Some of the proteins that undergo proteasome-mediated degradation include cyclins (cyclins A, B, D, E), endogenous cdk inhibitors (p27^{kip1}, p21^{cip1}), p53, RB, cdc25 phosphatase, and others.³⁰⁴ The rapid turnover of these proteins triggers the rapid growth rate of certain human malignancies, thus the proteasome is an excellent new target for the development of new drugs, as attested to by the success of the proteasome inhibitors bortezomib^{305,306} and carfilzomib³⁰⁷ in patients with MCL and myeloma. These agents inhibit the proteolytic activity of the proteasome and so cells accumulate in the G₂-M phase of the cell cycle with a decrease of cells in G₁.^{304,308} For example, p27^{kip1}, p21^{cip1} are upregulated in myeloma cells after the treatment with bortezomib, leading to cell-cycle arrest and apoptosis.³⁰⁹

The proteasome is also required for activation of the nuclear transcription factor NF- κ B, which in response to environmental stress or cytotoxic agents, plays a role in maintaining cell viability through the transcription of inhibitors of apoptosis, and the DDR including DNA-damage checkpoints³¹⁰ and DNA repair.³¹¹ Based on these observations, targeting the proteasome has become a successful approach to cancer treatment³¹² and with a better understanding of the human cell-cycle machinery, it will be possible in the future to identify new targets for antineoplastic therapies.

CHAPTER 17

SIGNAL TRANSDUCTION PATHWAYS

Kenneth Kaushansky

SUMMARY

Most external influences upon cells of any organ are mediated by biochemical and molecular mechanisms that are triggered by interactions with membrane, cytoplasmic, or nuclear receptors. Our understanding of the receptors and the intermediate molecules that couple them with cellular pathways that influence the proliferation, activation, differentiation, or survival of hematopoietic cells has expanded significantly. Proteins on the surface of blood cells that transmit vital information from the extracellular environment include single-pass, homodimeric, heterodimeric, and heterotrimeric transmembrane proteins that do, or do not, contain intrinsic kinase activity, but either way signal by inducing the tyrosine phosphorylation of a multitude of cytoplasmic proteins, seven transmembrane domain proteins that signal through G proteins, heterodimeric integrins that recruit large focal adhesions, and large families of heterodimeric proteins that induce serine and threonine phosphorylation. This chapter describes the receptors that influence blood cell production and function, the secondary mediators and the biochemical modifications they undergo to alert the cell to an external influence, the molecular mechanisms that allow for the coordination of multiple signals impacting a cell simultaneously, and the processes upon which they impact.

Acronyms and Abbreviations: AP2, adaptor protein-2; BCR, B-cell antigen receptor; BMP, bone morphogenic protein; CNTF, ciliary neurotrophic factor; CT-1, cardiotrophin-1; DD, death domain; DR, death receptor; EPO, erythropoietin; EPOR, erythropoietin receptor; ERK, extracellular response kinase; FADD, Fas-associated death domain; FAK, focal adhesion kinase; G-CSF, granulocyte colony-stimulating factor; Gab, Grb binding; GH, growth hormone; GM-CSF, granulocyte-macrophage colony-stimulating factor; GPCR, G-protein-coupled receptor; HCR, hematopoietic cytokine receptor; IAP, inhibitors of apoptosis; IKK, I- κ B kinase; IL, interleukin; IRS, insulin receptor substrate; ITAM, immunoreceptor tyrosine-based activation motif; ITIM, immunoreceptor tyrosine-based inhibitory motif; JAK, Janus family kinase; JNK, c-Jun N-terminal kinase; LIF, leukemia inhibitory factor; M-CSF, macrophage colony-stimulating factor; MAPK, mitogen-activated protein kinase; NR, nuclear receptor; OSM, oncostatin M; PI3K phosphoinositol 3'-kinase; PIAS, protein inhibitor of activated STATs; PIP, phosphoinositol phosphate; PKC, protein kinase C; PTP, protein tyrosine phosphatase; RACK, receptor for activated C kinase; RTK, receptor tyrosine kinase; SARA, SMAD anchor for receptor activation; SCID, severe combined immunodeficiency; SH2, Src homology 2; SOCS, suppressors of cytokine signaling; STATs, signal transducers and activators of transcription; SUMO, small ubiquitin-like modifier; TGF, transforming growth factor; TM, transmembrane; TNF, tumor necrosis factor; TPO, thrombopoietin; TRADD, TNF receptor death domain; TRAF, TNF receptor-associated factor; TRAIL, tumor necrosis factor-related apoptosis-inducing ligand.

● AN OVERVIEW OF CELL SIGNALING

Blood cells and their marrow-based progenitors are exquisitely responsive to their environment. A wide variety of cues are detected by mature blood cells that impact significantly on their function. For example, leukocytes respond to noxious stimuli by chemokine-induced migration toward inflammatory stimuli, cross endothelial cell barriers and the extracellular matrix by engaging integrins, and then respond to chemotactic gradients to enter inflammatory foci to contact and engulf microorganisms on encountering bacterial products. Likewise, platelets adhere to reactive endothelial surfaces or denuded subendothelial cell matrix by engagement of extracellular adhesive proteins. Adherent platelets can also recruit additional platelets and aggregate with them through interactions with platelet integrins, secrete growth factors that will recruit cells that mediate repair of vascular injury and then contract to strengthen the platelet plug by engagement of numerous granule substances. Even the anucleate erythrocyte responds to mechanical deformation and hypoxemia with adenosine triphosphate (ATP) release. Adrenergic receptors also play important roles in the normal erythrocyte response to parasitic infection or in the pathologic red cell's interactions with endothelial cell surfaces (e.g., patients with hemoglobinopathies). Each of these events induces an intracellular signal that leads to further cellular reactivity toward the initiating stimulus, or that prepares the cell for subsequent functional events. Like the functional activation of mature blood cells, the generation of blood cells is under tight regulation, mediated by soluble hematopoietic growth factors, cytokines, and components of the marrow microenvironment. Here again, the erythropoietin (EPO) response to anemia is sensed by erythroid progenitor cell surface receptors; their coordinated reaction involves a myriad of signals that impact on the survival, growth, and differentiation of both undifferentiated and lineage-committed cells. Although anemia induces red cell production and inflammation leads to the production and functional activation of leukocytes, many of the intracellular signals that mediate these two responses overlap substantially. This chapter illuminates a number of principles that mediate the growth and functional responses of blood cells and their progenitors in health and disease. A better understanding of how blood cells respond to their environment can lead to improved strategies to intervene in pathologic processes in which too many or too few blood cells are produced, or in which the functional activation of blood cells is insufficient or overly exuberant and leads to disease. Moreover, a thorough knowledge of how the signaling pathways that mediate growth and cell survival are disrupted in the hematologic malignancies has begun to allow the rational intervention in such diseases.

● TYPES OF RECEPTORS AND THEIR MECHANISMS OF ACTIVATION

THE HEMATOPOIETIC CYTOKINE RECEPTOR FAMILY

The Erythropoietin Receptor

The erythropoietin receptor (EPOR) was cloned in 1989,¹ settling several controversies and setting many important paradigms in receptor biology. Like other hematopoietic cytokines of this class (granulocyte colony-stimulating factor [G-CSF], thrombopoietin [TPO], and growth hormone [GH]), EPO binds to a homodimeric receptor^{2,3} with picomolar affinity.⁴ Numerous studies in these and multiple other cell-signaling systems demonstrate the importance of phosphorylation of vital cytoplasmic mediators in signal transduction,⁵⁻⁷ yet one initial conundrum was that the cloned EPOR bears no kinase domain.¹ Rather, subsequent

Figure 17-1. An illustration of cell surface receptors. Each member of the cell surface receptors is depicted as an extracellular region of one or multiple domains, with conserved disulfide bonds indicated by *thin cross lines*, and the conserved WS box indicated by a *thick cross line*. The founding member of each receptor class is indicated. EPOR, erythropoietin receptor; GPCR, G-protein-coupled receptor; gp130, glycoprotein 130; IL, interleukin; TGF, transforming growth factor; TNF, tumor necrosis factor. Each receptor subunit illustrated is a single-pass transmembrane protein with the exception of the heptahelical GPCR.

studies revealed that the EPOR employs a cytoplasmic kinase of the Janus family (JAK) to initiate signaling.⁸ JAK kinases bind to the cytoplasmic domain of hematopoietic receptors through motifs termed *Box1* and *Box2* domains. This information, along with the availability of the tertiary structure of EPOR and of EPO bound to EPOR,^{9,10} has provided a key insight into the initiation of signal transduction. EPOR exists as a preformed cell surface dimer (Fig. 17-1), in a conformation that separates the two cytoplasmic domains of the subunits (and hence the two tethered JAK molecules). EPO binds sequentially to the two subunits of the preformed EPOR dimer at two distinct faces of the molecule, first to one subunit with the high-affinity face of the ligand (also termed *site I*), and then to the second subunit of EPOR with a lower-affinity face (termed *site II*), but an interaction that reduces the off-rate of the ligand. Upon engagement of the two EPOR subunits, a conformational change ensues, shifting the distance between the two cytoplasmic domains of the receptor subunits, that is thought to bring the two inactive JAK molecules into sufficiently close juxtaposition to allow cross-phosphorylation and kinase activation. Once the two tethered JAK molecules are active, multiple additional tyrosine residues become phosphorylated, residues of the receptor itself and those on a number of tethered signaling molecules, events that trigger the totality of cellular EPO responses. Although direct proof for this model of signal initiation is not available for other cytokine receptors of this class, it is widely assumed that a variety of growth factors, interleukins, and hormones activate cellular events in the same manner.

The understanding that a single molecule of EPO can bind simultaneously to two EPOR molecules, and the realization that multiple other cytokines employ a similar stoichiometry of activation has allowed for therapeutic engineering of cytokines into peptide and chemical receptor antagonists. Following EPO binding to a first molecule of EPOR through site I, the receptor conformational change becomes dependent on binding of EPO site II to a second EPOR subunit. By altering the residues at site II, it is possible to block binding at site II, and hence block receptor activation. If site I is altered to increase its affinity for binding to a first receptor subunit so that the affinity of the mutant protein rivals that of the intact molecule, a potent rationally designed antagonist is generated. This strategy has been successfully employed to create pegvisomant, a GH antagonist useful for the treatment of acromegaly.

The engagement of two receptor subunits by a cognate ligand is one mechanism of inducing the receptor conformational change necessary

for JAK activation, but several other mechanisms exist that have been exploited by man and nature. Small molecules and dimeric antibodies can induce signaling through the EPOR and at least for the former, can serve as EPO mimetics for therapeutic use.¹¹ Moreover, the 55-kDa glycoprotein (gp55) of the Friend erythroleukemia virus hijacks the EPOR for virus-induced proliferation¹² by directly binding to EPOR and (presumably) by inducing the same receptor conformational changes as induced by the authentic hormone. Thus, there are many ways to activate EPOR, and many subtleties dependent on the actual tertiary structural changes induced.¹³

The Interleukin-6 Receptor Family The interleukin (IL)-6 family of cytokine receptors displays several properties distinct from those of EPOR and its related receptors.¹⁴ Unlike the receptors discussed thus far, the IL-6R family members are composed of a heterodimer. The α subunit of each receptor binds cognate ligand with modest affinity, but plays no role in signaling. Instead, a second receptor subunit, glycoprotein (gp)130 (named for its apparent molecular weight [Mr]), or oncostatin-M (OSM) receptor, molecules that alone have no affinity for ligand, but together with the α subunit enhance the binding affinity of the heterodimeric receptor, and are responsible for initiating signal transduction in the presence of ligand.¹⁵ In addition, soluble forms of some of the receptors, such as IL-6R, if loaded with IL-6, can bind to cells bearing only gp130 and activate the latter.¹⁶ Like EPOR and other members of that subfamily, gp130 and OSM-R engage JAKs to initiate signal transduction.¹⁷ Moreover, it is almost certain that the mature IL-6R complex is composed of at least two molecules of IL-6R and two of gp130,¹⁸ the latter required to bring the requisite two JAK molecules to the signaling complex. In addition to serving as signaling subunit for IL-6R, gp130 serves as the signaling receptor subunit for IL-11, OSM, leukemia inhibitory factor (LIF), ciliary neurotrophic factor (CNTF), cardiotrophin-1 and -2 (CT-1, CT-2), cardiotrophin-like cytokine (CLC), and IL-27, and OSM-R serves as a signaling subunit for OSM and IL-31. Similar to its role in the IL-6R, gp130 binds to each of these ligands only in the additional presence of a cytokine-specific receptor subunit (e.g., IL-11R, LIF-R) to form a complete signaling receptor. As a consequence of this shared coreceptor physiology, when two or more of the cytokine-specific receptors are present on a cell, the two corresponding ligands can compete for a limiting amount of gp130, and hence for cytokine-specific signaling. This physiology also allows therapeutically engineered cytokine-receptor complexes to stimulate signaling in all

cells that express gp130.¹⁹ Furthermore, the same principles that allow the rationale design of an EPO or GH antagonist can be used to engineer IL-6 antagonists for treatment of pathologic states dependent on interactions with receptors that require gp130 for receptor signaling.²⁰

The Interleukin-2 Receptor Family The IL-2 family of receptors is also quite complex, in most cases sharing one, two, or three subunits with receptors for other cytokines of the same class (see Fig. 17-1). IL-2R β is shared with the IL-15R, and IL-2R γ (also termed γ_c [for common]) is shared with the IL-4, IL-7, IL-9, IL-15, and IL-21 receptors.²¹ Another feature of the IL-2R not yet discussed for the EPOR or IL-6R families is that of a devoted JAK. While JAK2 is employed by all the EPOR subfamily members along with some of the IL-6R subfamily members, and JAK1 and TYK2 are also shared amongst these latter receptors, the fourth and final JAK family member, JAK3, is engaged almost exclusively by γ_c (one study identified JAK3 activation by IL-8, implying use by the CXCR1 and/or CXCR2 receptors).²² In addition to providing a more fundamental understanding of the principles of signal transduction, careful investigation of the IL-2 family of receptors also has afforded detailed insights into a number of clinically important immunodeficiency states.²³ The complexity of this family of receptors was illustrated by the progressive investigation into the origins of severe combined immunodeficiency (SCID).²⁴ As is discussed in Chap. 80, SCID is a severe loss of natural killer (NK) and T lymphocytes, and has been traced to deficiencies of either γ_c or JAK3, a phenotype recapitulated quite well (but not perfectly) by genetic elimination of the same molecules in mice. However, genetic elimination of IL-2 leads to a phenotype quite different than SCID of humans or engineered mice. Instead, of the multiple cytokines for which γ_c and JAK3 support signaling, only elimination of IL-7 or the IL-7R recapitulates the phenotype,^{25,26} a finding now consistent with the finding that IL-7 affects common lymphoid progenitors (Chap. 18), while other cytokines in the family affect more differentiated lymphoid cells.

THE TUMOR NECROSIS FACTOR RECEPTOR SUPERFAMILY

At present the tumor necrosis factor (TNF) superfamily of receptors and ligands comprises at least 30 receptors and 20 ligands,^{27,28} and illustrates several novel points in signal transduction pathways: trimeric binding (see Fig. 17-1), receptor promiscuity, and decoy receptors. Although many TNF ligand family members (TNF- α , TNF- β , CD40L [CD154], receptor activator of nuclear factor- κ B ligand [RANKL; osteoprotegerin ligand (OPGL)], OX40L, etc.) can bind to several receptors, the ligands are, for the most part, subfamily specific. For example, TNF- α only binds to the six TNF- α receptors and TNF-related apoptosis-inducing ligand (TRAIL) binds to the five TRAIL receptors,²⁹ although it can also bind to the receptor termed *osteoprotegerin* (OPG). Ligands in this family bind as trimers to homotrimeric receptors, leading to recruitment of secondary signaling molecules to the cytoplasmic domain of the receptors. In general, there are two classes of cytoplasmic domains in these receptors, based on whether they contain the death domain (DD), a region capable of binding signaling mediators that initiate apoptosis (Chap. 15). As such, receptors that do not contain a DD or other signaling domain can function as “decoy receptors,” diverting ligand from initiating programmed cell death in the target cell. For example, among the TNF- α receptors, TNFR1 (death receptor [DR]2) contains a DD, and among the five TRAIL receptors, DR4 and DR5 contain DDs, whereas TNFR2 and DcR1 and DcR2 and OPG act as decoy receptors for TNF and TRAIL, respectively. The biologic consequences of ligand binding to individual TNFR family members depend on the relative affinity of their cytoplasmic domains for multiple adaptor proteins; TNF receptor death domain (TRADD) and Fas-associated death domain (FADD)

engagement trigger apoptosis pathways, whereas recruitment of one of the seven TNF receptor-associated factor (TRAF) family members leads to activation of transcription factors such as nuclear factor- κ B (NF- κ B) and kinases such as c-Jun N-terminal kinase (JNK) that lead to cell survival, proliferation, and activation of inflammation.

THE RECEPTOR TYROSINE KINASES

The receptor tyrosine kinases (RTKs) comprise another class of receptors that contains members vital for hematopoiesis and mature blood cell function (see Fig. 17-1). The first hematopoietic member of this family to be identified was the eukaryotic version of the *v-fms* oncogene, designated *c-fms*. Further study revealed that the protooncogene is the sole receptor for macrophage colony-stimulating factor (M-CSF),³¹ and although somewhat distinct in possessing a split kinase domain, was immediately grouped with other RTKs, such as the receptors for insulin, vascular endothelial cell growth factor and epidermal growth factor, among several others. Subsequently, two additional hematopoietic receptor family members have been identified, *c-Kit* and *Flt-3*. These receptors were each cloned based on their homology to the viral oncogene *v-kit* or *c-fms*, respectively.^{32,33} Like all other members of the family, upon engagement of their cognate ligand the kinase domains of homodimeric RTKs become activated, leading to the phosphorylation of receptor cytoplasmic domain tyrosine residues and other tethered substrates. In an apparent example of convergent evolution, like members of the hematopoietic cytokine receptor (HCR) family, RTKs were also found to employ JAKs in their signaling pathways³⁴; as a result, many of the same secondary signaling pathways are activated by both classes of receptors. But perhaps serving as an even more striking example of convergent evolution, the tertiary structure of the index ligand for a hematopoietic RTK, M-CSF, bears substantial homology to essentially all the ligands of the HCR family, such as granulocyte-macrophage colony-stimulating factor (GM-CSF).³⁵

TRANSFORMING GROWTH FACTOR β FAMILY

The transforming growth factor (TGF) receptor family consists of seven type I and five type II receptors that heterodimerize to form receptors for multiple TGF- β family members, including the TGF- β /activin/nodal and bone morphogenic protein (BMP) subfamilies. The precise stoichiometry of binding involves a ligand dimer, stabilized by disulfide and/or hydrophobic bonds, and two type I and two type II subunits (see Fig. 17-1); the tertiary structure of the complex has been carefully investigated.³⁶ Both type I and type II receptors contain an N-terminal ligand binding, transmembrane, and cytoplasmic ser/thr kinase domains; the type I receptors additionally contain a Gly/Ser (GS)-rich domain.³⁶ For TGF- β subfamily members, the type II subunit bears a high-affinity ligand binding site, which on TGF- β or activin engagement recruits type I receptors, bringing the two cytoplasmic domains into close juxtaposition, enabling the type II kinase to phosphorylate Ser residues on the type I receptor GS domain, thereby activating the type I kinase. Cell-surface-bound coreceptors also exist and aid in generating the signaling complex for TGF- β , but not activin or BMP ligands. For BMP family members, the type I receptor bears the high-affinity ligand binding site, such that BMP initially binds to type I receptor, with the type II subunit subsequently recruited to form the signaling complex. Once the two receptor kinases are activated, they recruit and phosphorylate the SMAD (Sma- and Mad-related protein) adaptor proteins, allowing their nuclear translocation and transcriptional activation. However, SMAD-independent TGF- β signaling pathways also exist.³⁷

G-PROTEIN-COUPLED RECEPTOR FAMILY

Several molecules that play essential roles in blood cell development or function signal by engaging G-protein-coupled receptors (GPCRs), the largest family of cell surface receptors in organisms as diverse as yeast and humans, estimated to comprise approximately 1000 distinct gene products, or approximately 3 percent of the human genome. Also termed *serpentine* or *heptahelical receptors* (for their seven transmembrane domains that form four extracellular and three intracellular loops; see Fig. 17-1), GPCRs are so named because they use three small guanine nucleotide (or G)-binding proteins ($G\alpha$, $G\beta$, and $G\gamma$) for signal transduction. In the unstimulated state, all three G proteins bind to the intracellular loops of the receptor. Individual ligands engage GPCR in one of many different ways. For example, small lipophilic molecules (e.g., epinephrine) bind to transmembrane (TM) domains of the receptor, disrupting the interactions between TM3 and TM6, leading to conformational changes that alter G-protein binding.³⁸ Other GPCRs use additional extracellular domains (e.g., the “Venus flytrap” domain)³⁹ to bind and dimerize receptors. Still others, which are engaged by proteases, are activated by protease cleavage of the receptor amino terminus, leading to the “unmasking” of a hexapeptide at the new amino terminus, which then interacts with one of the receptor extracellular or TM domains.⁴⁰ By each of these and other mechanisms a conformational change occurs in the GPCR, allowing monomeric $G\alpha$ and dimeric $G\beta\gamma$ complexes to dissociate from the intracellular loops and each to engage secondary signaling pathways.⁴¹ Examples of critical molecules that employ GPCRs and display hematologic activity are thrombin, adrenergic hormones, and chemokines. The outcomes of such engagement include cellular growth and survival, functional activation, and migration.

INTEGRINS AND OTHER ADHESION MOLECULES

Although adhesion molecules were named for the vital structural role they play in tissue cohesion, physically bridging cells in the marrow with each other and with extracellular matrix macromolecules, and at sites at which mature blood cells interact with the endothelium, engagement of blood and progenitor cell integrins and other adhesion molecules also generates vital cellular signals that affect their survival, proliferation, and functional activation.⁴²⁻⁴⁴ In fibroblasts, cell adhesion is most clearly manifest at contact sites termed focal adhesions, and the signaling complexes that form on cytoplasmic domains of the integrins that support them are termed focal adhesion complexes.⁴⁵ Within such complexes are components of the actin cytoskeleton, kinases both specific for focal adhesions and several others found in other cytoplasmic sites,⁴⁶⁻⁴⁸ and a number of scaffolding molecules upon which adhesion strengthening and signaling take place. Moreover, growth factor receptors functionally interact with integrins, adding to signaling complexity. Thus, adhesion molecules must also be considered as signaling receptors.

NUCLEAR RECEPTORS

Nuclear receptors (NRs) are nascent transcription factors that play a wide variety of roles in cellular physiology by binding small lipophilic hormones. Some NRs, such as glucocorticoid hormone receptors, remain sequestered in the cytoplasm in the absence of their cognate ligand, and upon ligand engagement translocate to the nucleus and bind and activate palindromic, direct repeat, or inverted palindromic sequences that comprise nucleotide hormone response elements.⁴⁹ Other NRs, such as receptors for vitamin A metabolites (retinoids), remain bound to nuclear DNA and repress transcription, until engaged by ligand upon which nuclear coactivators are recruited leading to enhancement of

gene transcription.⁵⁰⁻⁵² Although sex, glucocorticoid, and thyroid hormones may play subtle roles in blood cell biology, retinoid receptors, which most commonly bind as heterodimers with the RXR receptor to retinoid response elements of the form PuGTTCA(N)2,5PuGTTCA, play vital developmental roles in a myriad of cell systems, and play similar roles in hematopoiesis. Amongst the hematopoietic targets of retinoid receptors are c-myc, C/EBP ϵ , and p21.⁵³ However, because this class of receptors represents a nearly direct pathway from stimulus to response, without intervening signaling, they are not discussed further in this chapter.

THE DIVERSITY OF DOWNSTREAM SIGNALS

PROTEIN PHOSPHORYLATION

Protein phosphorylation is the critical first and vital response to engagement of signaling molecules of nearly all classes of cell surface receptors, including those that affect blood cell production and function. Numerous studies reveal that protein tyrosine phosphorylation is detectable within a minute of the addition of a wide variety of hematopoietic cytokines to blood cells and their progenitors. Evidence from nearly all studies employing chemical inhibitors of kinase function or various knockout and knockin strategies shows that JAK activation is critical for hematopoietic cell survival, growth, and differentiation, and mature cell response to a wide range of stimuli (Fig. 17-2).^{54,55} Several studies have elucidated an important mechanism of regulation of JAK kinases, one that is altered in the myeloproliferative diseases polycythemia vera, essential thrombocytosis, and idiopathic myelofibrosis (Chaps. 84 to 86).

Based on homologies to a number of other proteins JAK kinases display 7 domains. These include (1) the domains that tether the kinase to the cytoplasmic domain of the cytokine receptor (JH3-JH7), (2) the kinase domain (JH1), and (3) a pseudokinase domain (JH2), so termed because of its homology to other tyrosine kinases but lack of kinase activity. Nevertheless, despite its lack of kinase activity, the pseudokinase domain inhibits the kinase activity of the kinase domain, as shown by single- and double-domain expression studies.⁵⁶ Based on the known structures of other kinases, the kinase and pseudokinase domains of JAK2 have been modeled.⁵⁷ Both structural and functional studies revealed that unexpectedly, the “pseudokinase” domain is, in fact, a kinase that phosphorylates two negative regulatory tyrosine residues, and suggests that the Val₆₁₇Phe mutation present in virtually all patients with polycythemia vera and approximately half with essential thrombocytosis and idiopathic myelofibrosis (Chaps. 84 to 86)⁵⁸⁻⁶¹ acts to stiffen the pseudokinase domain, altering its function.⁵⁷

Among the phosphorylation targets of JAKs and other immediately responsive kinases in both normal and neoplastic hematopoiesis are the signaling receptor itself, adaptor molecules (Shc, Grb2, IRS, Gab, Tensin2) that once modified recruit additional signaling substrates, regulatory subunits of secondary kinases (p85 phosphoinositol 3'-kinase [PI3K]), latent transcription factors (signal transducers and activators of transcription [STATs]), and several phosphatases (SHP2, SHIP). By catalyzing the phosphorylation of Tyr residues present in certain receptor motifs, RTKs and JAK2 modify many signaling proteins to acquire the capacity to bind Src homology (SH)-2 domain-containing proteins. Perhaps equally important are ser/thr phosphorylation sites induced by activated TGF- β receptors. However, most of the downstream signaling components of all of the receptors that use JAK2 and other kinases to transduce growth and differentiation cues have been derived from candidate gene approaches; the availability of antibodies to specific signaling mediators has dictated the molecules that have been studied. An unbiased approach to identifying the entire “signaling space” used by all

Figure 17–2. An illustration of signal transduction pathways. Signal transduction ensues when a hematopoietic growth factor (HGF) binds to its cognate receptor, resulting in a change in receptor conformation bringing two tethered JAK molecules into close proximity (attachment site to receptor is indicated by two *green boxes*, representing the box1 and box2 motifs). Molecules that become phosphorylated upon activation are indicated by **P**. A multiprotein complex that forms on a scaffolding molecule, such as Gab2, is indicated by the *triangle*. Stimulatory pathways (*vis-à-vis* cell proliferation) are indicated by *solid lines with arrowheads*. Inhibitory pathways are indicated by *broken lines with ball heads*. The nucleus and the mitochondria (MITO) are indicated.

of the receptors noted above is required if we are to fully understand the influence of the extracellular milieu on hematopoiesis. An example of such an approach has been reported.⁶³

MEMBRANE LIPID MODIFICATION

Upon recruitment to a doubly phosphorylated receptor cytoplasmic domain or adaptor protein, the p85 regulatory subunit of PI3K undergoes conformational changes enabling the binding of its p110 kinase subunit, resulting in activation of the kinase (see Fig. 17–2).⁶⁴ The major target of PI3K is membrane inositols, perhaps most importantly PI_{4,5} phosphate (PIP₂), converting the latter into PI_{3,4,5}P (PIP₃). Once present in adequate amounts, PIP₃ recruits proteins with pleckstrin homology domains to the inner cytoplasmic membrane, which become phosphorylated by their juxtaposition to another PH domain containing kinase, PDK.⁶⁵ Among the best known of the recruited proteins are protein kinase B (also termed Akt), a kinase that phosphorylates a broad range of substrates in a wide variety of cells, all with the ultimate effect of enhancing cell survival and/or cell cycling.⁶⁶ For example, Akt phosphorylates Bad, a proapoptotic protein that once so modified is targeted for degradation.⁶⁷ Akt indirectly activates NF- κ B,⁶⁷ a transcription factor that influences several cell-cycle and survival proteins,⁶⁸ including the antiapoptotic Bcl and IAP (inhibitors of apoptosis) proteins and the cell-cycle activators c-Myc and cyclin D. In addition, forkhead family members, which when present enhance transcription of cell-cycle inhibitors such as p27 and the proapoptotic protein Fas ligand, are phosphorylated and inactivated by Akt.⁶⁹ Akt is activated by the bcr-abl oncogene in blood cells of patients with chronic myelogenous leukemia (CML), as it is in patients with polycythemia vera, and blockade of PI3K reduces cell proliferation substantially.⁷⁰

NUCLEAR TRANSLOCATION

In addition to the posttranslational modification of signaling molecules illustrated in the preceding examples, relocation of signaling molecules is also a vital process that conveys information within the cell. This cellular strategy is well illustrated by the activation of NF- κ B,⁶⁸ a family of transcription factors activated by growth factor, nuclear, TGF/BMP family, and integrin receptors that affect genes vital for cell survival and growth. In the unstimulated cell, NF- κ B subunits reside in the cytoplasm, sequestered from their nuclear targets by virtue of its binding to I- κ B. Upon cellular activation of Akt, I- κ B kinase (IKK) is activated by phosphorylation, which then phosphorylates I- κ B, thereby releasing

NF- κ B and targeting I- κ B for proteasomal destruction, allowing NF- κ B to translocate to the nucleus and bind and activate target genes.

A second example of cytoplasmic sequestration blocking nuclear function involves the SMAD proteins that mediate TGF- β receptor signaling.³⁶ Once recruited to the phosphorylated type I TGF- β receptor, SMAD2 is phosphorylated, reducing its affinity for the SMAD anchor for receptor activation (SARA), a molecule that helps tether SMAD2 to the receptor. Once free of SARA, a SMAD2/SMAD4 complex forms, which is competent to translocate to the nucleus, either by the generation of a nuclear localization signal or because of the elimination of the SARA blockade of the SMAD2 nuclear pore complex interaction site. In addition to ingress, the formation of a SMAD2/SMAD4 complex also blocks a nuclear export signal present on the latter.⁷¹

ENGAGEMENT OF ADAPTOR PROTEINS

Another general theme to emerge from numerous studies on signal transduction is that multimolecular complexes of signaling intermediaries often assemble on scaffolding or adaptor proteins, which develop the capacity to assemble signaling complexes upon phosphorylation.⁷² Insulin receptor substrates (IRSs) were the first such adaptors identified, and are phosphorylated by the activated insulin receptor.⁷³ IRS proteins are also modified by several other receptor-activated kinases, including JAKs.⁵⁴ Grb-binding (Gab) proteins are a family of at least three adaptors, so named because of their ability to bind to the adaptor Grb2, a signaling intermediate necessary for Ras activation.⁷⁴ Both IRS and Gab proteins present multiple sites for phosphorylation, and once so modified present numerous SH2-binding and other protein-protein interacting motifs (see Fig. 17–2), which allow assembly of signaling complexes. Additional molecules serve this function in other signaling receptors, such as Tensin2 binding to the thrombopoietin receptor, c-Mpl,⁶³ which recruits p85 PI3K to the receptor, and paxillin binding on the cytoplasmic tails of α -integrin.⁴⁸ Paxillin presents four different types of protein-protein interaction domains (SH3, SH2, LD [Leu-Asp], and LIM [lin-11/Isl-1/Mec-3]) enabling it to bind downstream kinases (focal adhesion kinase [FAK], the related Pyk2 kinase, Src kinase, and paxillin-associated kinase [PAK]), other adaptor molecules (Crk, PIX, PKL), and phosphatases (PTP-PEST). As many cellular kinases can phosphorylate adaptor proteins (e.g., in addition to integrin engagement, GH binding leads to paxillin phosphorylation), such complexes can function as a nexus to coordinate multiple cellular stimuli into a concerted response.

Another example of the capacity of adaptor proteins to translate extracellular signals into intracellular physiologic change is found in the response to TNF ligands. The capacity of receptors that bear DDs to induce apoptosis is dependent on the binding of the adaptor protein FADD to the cytoplasmic domain of TNFR, which then recruits and activates the initiating caspases 8 and 10, leading to activation of the executioner caspases 3, 6, and 7 (Chap. 15).^{28,29,75} This extracellular signal-mediated apoptotic pathway stands in contrast to a second, cell-intrinsic apoptosis pathway, in which DNA damage, cell-cycle checkpoint defects, or loss of survival factors leads to enhanced expression of proapoptotic bcl family members (bax, bad, bclXs, bid). Once proapoptotic proteins overcome the level of antiapoptotic family members (bc12, BclXL), mitochondrial TM potential declines, leading to leakage of cytochrome c and SMAC, the former engaging the apoptotic protease-activating factor (APAF) adaptor, thereby activating caspase 9 and, subsequently, the executioner family of caspases, the latter inhibiting members of the IAP family that otherwise attenuate caspase action. It should also be noted that although these two apoptosis pathways can be discussed as distinct entities, merging at the level of caspase 3, they interact. For example, activation of caspase 8 by TNF family members can also cleave bid to cause mitochondrial leakage of cytochrome c, thereby engaging the cell intrinsic pathway, serving to amplify the extracellular signal pathway to programmed cell death.

Binding of TNF family members to their receptors does not always result in apoptosis. Although there are likely many mechanisms for this finding, one is mediated by the binding of adaptors. Different TNF family receptors employ one of six TRAFs to engage and activate IKK, which leads to the release of NF- κ B, a transcription factor that induces expression of several prosurvival and proliferation-associated genes.⁶⁸

● SIGNALING SPECIFICITY WITHIN EACH RECEPTOR FAMILY

Once a large number of receptor/cytokine systems were identified and tools to study some of their downstream signaling events developed, it became clear that most cytokine receptors stimulate a very similar cadre of signaling events as other members of the same family. For example, EPO, TPO, GH, GM-CSF, IL-6, and leptin all stimulate the phosphorylation of JAK2, yet lead to quite different cellular effects. One theory of hematopoiesis posits that growth factors merely serve to prevent apoptosis; the stochastic induction of one or another set of transcription factors is responsible for the distinct lineage differentiation events of hematopoiesis.⁷⁶ If this is true, then overlapping signaling events supported by a diverse range of cytokines might not be surprising as they would subserve the same end point, inhibition of programmed cell death. However, it is also clear that some cytokines and extracellular stimuli induce changes in critical transcription factors, and that the fate of multipotent progenitor cells can be influenced by the cytokines to which they are exposed; if so, each cytokine would need to induce distinct signals. Careful studies of signaling events have supported this hypothesis. For example, JAK3 is engaged only by cytokine receptors that use γ_c ,⁷⁷ and although EPO activates the same JAK as TPO (JAK2), the former leads to activation of STAT5,⁷⁸ whereas the latter leads to STAT1, STAT3, and STAT5 activation,⁷⁹ which targets a different set of genes. Moreover, engagement of integrin $\alpha\beta_1$ stimulates EPO-induced erythroid development, whereas stimulation of integrin $\alpha\beta_1$ mediates signals that inhibit erythropoiesis and enhances TPO-induced megakaryocyte growth.^{80,81} Additional examples of relative signaling specificity that separates sets of cytokines are the predominance of STAT5 activation by IL-2, compared with STAT1 and STAT3 by the closely related IL-21,⁸² and the almost exclusive engagement of STAT4

by IL-12 and STAT6 by IL-4 and IL-13.⁸³ This same STAT-mediated “lineage choice” is seen in pathologic hematopoiesis. Individuals more likely to express high levels of STAT1 who acquire the pathologic Jak2^{V617F} mutation are more likely to develop essential thrombocythemia than polycythemia vera.⁸⁴ Consequently, because our understanding of the entirety of downstream signals is far from complete, the cytoplasmic domains of cytokine receptors bear almost no homology other than that required to engage JAKs, and there already exists a modest degree of signaling specificity, it is likely that although several cytokines engage overlapping sets of signaling intermediaries, each will result in a unique set of signaling events. It is almost certain that the use of unbiased screens of the entirety of signaling molecules will be required to decipher all the interactions induced by ligand engagement of the multiple receptor families described in this chapter. Such efforts have been described for the epidermal growth factor receptor family,⁸⁵ and should be highly informative in studies of hematopoietic signaling.

● SIGNALING INSULATION

Many of the kinases and other intermediaries that play important roles in signal transduction are not absolutely substrate specific; nevertheless, they do participate in specific pathways free from interference from other pathways. Perhaps the best example of this is found in the mitogen-activated protein kinase (MAPK) pathway.⁸⁶ At least three major MAPK pathways operate in most cells, the p42/p44 ERK (extracellular response kinase), p38, and JNK, each of which is triggered by distinct stimuli (mitogens such as cytokines for ERK, inflammatory mediators and hypoxia for p38, and stress and noxious stimuli for JNK), but all of which eventuate in the activation of a cascade of kinases, a MAPK kinase kinase (also termed MEKK), which phosphorylates and activates a MAPK kinase (also termed a MEK), and finally the MAPK. The MAPKKK (MAP kinase kinase kinase) for ERK1/2 is Raf-1 and the MAPKK for ERK1/2 is MEK1; the MAPKKK for p38 is MEKK1 and the MAPKK is MKK3; and for JNK they are MEKK1 and MKK4 or MKK7, respectively. Because each of these kinases display only limited substrate specificity *in vitro*, it would be difficult to explain how MEKK1 activation does not lead to ERK activation without some mechanism to insulate the signals. Several scaffolding proteins have now been identified that assemble specific MAPKKK, MAPKK, and MAPKs.⁸⁷ By forming complexes of the cascade on pathway-specific scaffolding molecules, signaling integrity is preserved. Moreover, once the MAPK is activated, additional scaffolding molecules can link the specific MAPK to its target transcription factors.⁸⁸ Additional examples of “insulating” signaling scaffolds include those for NF- κ B and the TNF receptor,⁸⁹ the B-cell antigen receptor (termed BLNK),⁹⁰ and protein kinase C (PKC) and integrins (termed RACKs).⁹¹

● EXTINGUISHING SIGNALS

In addition to initiating signaling by extracellular ligands, the cell must also be able to extinguish the stimulus to prepare for additional events and to guard against continuous cell growth. Several mechanisms have been identified that extinguish the signals initiated by extracellular stimuli.

RECEPTOR DOWN-MODULATION

Shortly after binding to ligand, HCRs and RTKs are rapidly internalized,⁹² serving to down-modulate further signaling.⁹³ Receptor internalization is dependent on membrane clathrin,⁹³ which represents a major mechanism of endocytosis of cell-surface proteins, and on at least one element of ligand-induced signaling.⁹⁴ The sites on hematopoietic

receptors responsible for internalization are mapped,⁹⁵ potentially allowing intervention in this process. For example, activation of c-Mpl by TPO leads to engagement of the adaptor protein-2 (AP2) complex, which results in clathrin binding and receptor internalization. The kinetics of this process is delayed, taking approximately 30 minutes for near complete internalization, allowing the TPO signal to persist only a short time.⁹⁶

PHOSPHATASES

As discussed earlier in “The Diversity of Downstream Signals,” phosphorylation of numerous proteins and membrane lipids plays a vital role in signal transduction within the cell. Thus, elimination of these modifications through the action of phosphatases would be expected to terminate such signals. Moreover, because some of the same signals are activated in malignant transformation, protein tyrosine phosphatases (PTPs) might also be expected to play an important role in malignancy, and possibly in autoimmunity.

Hematopoietic cell phosphatase (also termed SHP1) bears two SH2 domains that interact with cytokine and inhibitory immune coreceptors at ITIM (immunoreceptor tyrosine-based inhibitory motif) sites that have been modified by Tyr phosphorylation. Once so engaged, SHP1 becomes activated and dephosphorylates associated phosphotyrosine activation sites on receptors, adaptor molecules, and their associated kinases.⁹⁷ One of the earliest clues that SHP1 plays an important role in hematopoietic signaling came from the discovery that the moth-eaten mouse phenotype is a result of a genetic loss of function of SHP1.⁹⁸ These mice demonstrate a massive expansion and tissue accumulation of monocytes and myeloid cells, resulting in chronic inflammation, massive immune defects, and premature death. Careful analysis of the mice revealed they manifest defective controls over the cellular activation and proliferation response to exogenous stimuli, such as that induced by engagement of the B-cell antigen receptor (BCR) complex. At steady state SHP1 is thought to engage the BCR (through presently unclear mechanisms) and maintains the antigen-binding subunits (immunoglobulin [Ig] α and Ig β) in a dephosphorylated, quiescent state. The phosphatase is displaced from the complex upon antigen engagement, but is later re-recruited to the complex once ITIM containing inhibitory coreceptors such as CD22, PIR-B, CD72, and Fc γ RIIb are phosphorylated and recruited to the activated complex.⁹⁹ Once recruited to the BCR complex, SHP1 removes the activating Tyr phosphate sites on the ITAM (immunoreceptor tyrosine-based activation motif) sites of Ig α / β , the coreceptor CD19, the adaptor BLNK and Lyn kinase, and the BCR returns to its quiescent state. Similar roles for SHP1 have been identified in T cells,¹⁰⁰ NK cells,¹⁰¹ monocytes and macrophages,¹⁰² and erythroid cells.¹⁰³ The latter is of particular interest, as mutation of the site on EPOR to which SHP1 binds causes familial erythrocytosis, as a result of prolongation of EPO signaling. Of interest, this mutation was identified in a family containing a two-time Olympic gold medalist.¹⁰⁴

SOCS Proteins

Another mechanism of growth factor signal termination is mediated by the suppressors of cytokine signaling (SOCS) proteins. The cloning of a STAT-inducible gene, *CIS*,¹⁰⁵ and several additional genes that bear substantial sequence homology,^{106,107} yielded a family of proteins that can directly suppress growth factor receptor-induced signals. The engagement of either HCRs or RTKs leads to STAT activation, as discussed earlier in “The Diversity of Downstream Signals.” One of the transcriptional targets of STATs are the SOCS and PIAS (protein inhibitor of activated STATs) genes (see Fig. 17–2), which, upon transcription and translation, bind to phosphotyrosine residues and inhibit either JAK kinases, STATs, or the phosphorylated receptors themselves, blocking

recruitment of signaling adaptor molecules.¹⁰⁸ Ubiquitin and SUMO (small ubiquitin-like modifier) also play a vital role in SOCS- and PIAS-mediated repression of cytokine signaling.¹⁰⁸ Like for the hematopoietic phosphatases, dysfunction of SOCS proteins has been implicated in malignancy.¹⁰⁹

INHIBITORY SIGNALS

Finally, some signals negatively impact signals derived from other receptors. One example is the interaction of the growth inhibitory signals derived from TGF- β and the growth promoting signals triggered by several hematopoietic growth factors. TGF- β is constitutively expressed in the marrow stroma, and acts to reduce hematopoietic stem cell (HSC) cycling by driving the nuclear localization of a SMAD2–SMAD4 complex, which, in turn, is regulated by an inhibitable nuclear export signal present on the complex. Stem cell factor (SCF), FMS-like tyrosine kinase 3 (Flt-3) ligand, and TPO all induce promote HSC survival and growth, in part through activation of the MAPKs: ERK1 and ERK2. In turn, activated ERK1/2 then phosphorylates several sites on the linker region of SMAD2, inhibiting the nuclear localization of the inhibitory SMAD2/SMAD4 complex, reducing the suppressive effects of TGF- β on the cell cycle.¹¹⁰ Another form of this type of crosstalk between cytokines is illustrated by TPO and interferon (IFN)- α , the latter suppressing megakaryopoiesis driven by the former. By induction of SOCS-1, not usually induced by TPO, IFN- α inhibits TPO-mediated signaling.¹¹¹

SIGNAL COORDINATION AND CROSSTALK

In the foregoing discussion, several examples of the convergence of signaling pathways and receptor crosstalk were summarized. Over the past decade, two types of cell membrane-based supramolecular organizations have been identified: lipid rafts and tetraspanin webs. In their seminal fluid–mosaic model of the cell membrane, Singer and Nicolson posited that integral membrane proteins float in a random array of membrane lipids.¹¹² This model was modified to account for local heterogeneity of the lipid bilayer. Lipid rafts, local concentrations of specific membrane lipids and proteins, are defined by the methods to isolate them—the insoluble components of a cold detergent extraction in which raft components “float” to the top of a density gradient.¹¹³ Upon discovery that many of the proteins present in such rafts were involved in signal transduction, it became apparent that these membrane subdomains could represent a structural basis for communication between seemingly disparate components of the signal transduction apparatus.^{37,114,115}

A second level of membrane-based structural organization of signaling molecules has been elucidated: the tetraspanin-enriched microdomain or “web.” The tetraspanin family of membrane proteins is characterized by four TM domains punctuating two extracellular regions, a CCG motif, and several other conserved cysteine residues in the extracellular domain. The tetraspanins now include more than 30 members,¹¹⁶ most or all of which interact with other cell surface molecules, and have been functionally linked to cell adhesion, migration, differentiation, and signal transduction. Members of this family are thought to act as molecular facilitators of protein–protein interaction by associating with “partners,” the bimolecular complexes then interact with others in a slightly less avid manner, and the complexes loosely associate in microdomains. CD9, CD63, and CD81 are the tetraspanins most closely linked to hematopoietic cell function, are usually found in association with β_1 and β_3 integrins,¹¹⁷ affect many hematopoietic cell types,^{118–120} and act in concert with multiple signaling receptors, kinases, and phosphatases.^{121,122}

CHAPTER 18

HEMATOPOIETIC STEM CELLS, PROGENITORS, AND CYTOKINES

Kenneth Kaushansky

SUMMARY

Blood cell production is an enormously complex process in which a small number of hematopoietic stem cells expand and differentiate into an excess of 10^{11} cells each day. Based on a number of strategies available to the experimental hematologist a hierarchy of hematopoietic stem, progenitor, and mature blood cells is emerging in which each successive developmental stage loses the potential to differentiate into a specific type or class of cells. The characteristics of the stem and progenitor cells that give rise to the cells of the blood are the subject of this chapter, including the roles played by transcription factors and external signals in lineage fate determination, the cytokines and cell adhesion molecules that support cell survival, self-renewal, expansion, and differentiation, and the cell surface properties that allow for their purification, and biochemical and genetic characterization. A thorough understanding of hematopoietic stem and progenitor cells and their supportive microenvironment can provide critical insights into developmental biology of multiple cell systems, favorably impact blood cell development for therapeutic benefit, impact genetic therapy for a number of blood and other human diseases, and potentially provide the tools necessary to allow the regeneration of multiple organs.

Acronyms and Abbreviations: AGM, aorta-gonad-mesonephros; BFU-E, burst-forming unit–erythroid; BFU-MK, burst-forming unit–megakaryocyte; CAFC, cobblestone area-forming cell; CAR, CXCL12–abundant reticular; CFC, colony-forming cell; CFU-E, colony-forming unit–erythroid; CFU-GM, colony-forming unit–granulocyte-macrophage; CFU-MK, colony-forming unit–megakaryocyte; CLP, common lymphoid progenitor; CMP, common myeloid progenitor; EBF, early B-cell factor; ECM, extracellular matrix; EGF, epidermal growth factor; EPO, erythropoietin; EPOR, erythropoietin receptor; FAK, focal adhesion kinase; FL, Flt-3 ligand; G-CSF, granulocyte colony-stimulating factor; G-CSF-R, granulocyte colony-stimulating factor receptor; GM-CSF, granulocyte-macrophage colony-stimulating factor; GM-CSF-R, granulocyte-macrophage colony-stimulating factor receptor; GMP, granulocyte-macrophage progenitor; HSC, hematopoietic stem cell; Ig, immunoglobulin; IL, interleukin; IRF4, interferon regulatory factor 4; LEF, lymphoid-enhancer binding factor; LR, laminin receptor; LTC, long-term culture; LTC-IC, long-term culture-initiating cell; MAPK, mitogen-activated protein kinase; M-CSF, macrophage colony-stimulating factor; MEP, megakaryocyte-erythroid progenitor; MK, megakaryocyte; MSC, mesenchymal stem cell; PI3K, phosphoinositol 3'-kinase; R, receptor; RAG, recombination activating gene; ROS, reactive oxygen species; SCF, stem cell factor; SCL, stem cell leukemia; SDF-1, stromal-derived factor-1; SLAM, signaling lymphocyte activation molecule; TCF, T-cell factor; TGF, transforming growth factor; TPO, thrombopoietin; VCAM, vascular cell adhesion molecule; VLA, very-late antigen.

● AN OVERVIEW OF HEMATOPOIESIS

Blood cell production is an enormous and complex process. Based on the adult blood volume (5 L), the number of each of the blood cell types per microliter of blood, and their circulatory half-life, it can be calculated that each day an adult human produces 2×10^{11} erythrocytes, 1×10^{11} leukocytes, and 1×10^{11} platelets. These numbers can all increase approximately 10-fold in states of blood cell destruction or enhanced need. Over the past four decades experimental hematologists have developed a model of blood cell production in which a hierarchical developmental progression of primitive, multipotential hematopoietic stem cells (HSCs) gradually lose one or more developmental potentials and ultimately become committed to a single cell lineage, which matures into the corresponding blood cell type.¹ Perhaps one of the most compelling arguments supporting this model of hematopoiesis is derived from extensive purification schemes using cell surface markers that yield cells at each predicted developmental stage (Fig. 18–1).² Although hematopoietic development is considered by most investigators as an irreversible stepwise and progressive loss of developmental potentials, studies now suggest that cells undergoing apparent differentiation steps might oscillate between different stages depending on their position in the cell cycle.³ But regardless of the precise relationships between different stages of hematopoietic development, the availability of this model and the data leading to its construction have provided important insights into the biology and clinical uses of hematopoietic stem and progenitor cells. This chapter focuses on our understanding of the molecular basis for blood cell development, beginning with the HSC and its offspring, the lineage-committed progenitor cells.

● DEVELOPMENTAL BIOLOGY OF HEMATOPOIESIS

Blood cell production begins in the yolk sac,⁴ where extraembryonic mesoderm develops into angioblasts and primitive erythroid precursors at day 7 postcoitum of the mouse; cells of the outer layer of the undifferentiated mesoderm at this time flatten and become endothelial cells, and the inner cells round up to become clusters of erythroid precursors,⁵ termed *blood islands* (Chap. 7). Like in the embryo proper, there is much evidence to suggest that these two cells are derived from a common precursor (the hemangioblast).⁶ Once adjacent blood islands begin to coalesce on day 8, the endothelial cells form vascular channels, which by day 8.5 connect with the embryonic vasculature, allowing yolk sac blood cells to exit the blood islands, complete their maturation, and enucleate in the embryonic bloodstream.⁷ In both mouse and man there is a stage of embryonic development where both primitive erythrocytes (as characterized by ζ globin phenotype) and definitive red cells are produced in the yolk sac, although the former appears only very transiently. Although not as well characterized, yolk sac myelopoiesis and thrombopoiesis also occur, perhaps as part of the development of multipotent progenitors that appear by day 8.5 postcoitum. Cells capable of differentiating into multiple cell lineages become recognizable early during yolk sac hematopoiesis.⁸ However, such cells reproducibly engraft only in the marrow of myeloablated embryonic animals and not in adults,⁹ making it unlikely that such cells are true HSCs, although this topic remains controversial. By day 11 postcoitum repopulating HSCs are clearly present in the yolk sac, but the relationship of these cells and the HSCs that are clearly demonstrable a day earlier in a region of the embryonic paraaortic splanchnopleure known as the aorta-gonad-mesonephros (AGM) is not certain. By day 12.5, postcoitum hematopoiesis in the murine yolk sac is eliminated.

Although it was long believed that the developmental origin of the adult mammalian hematopoietic system was the yolk sac, subsequent

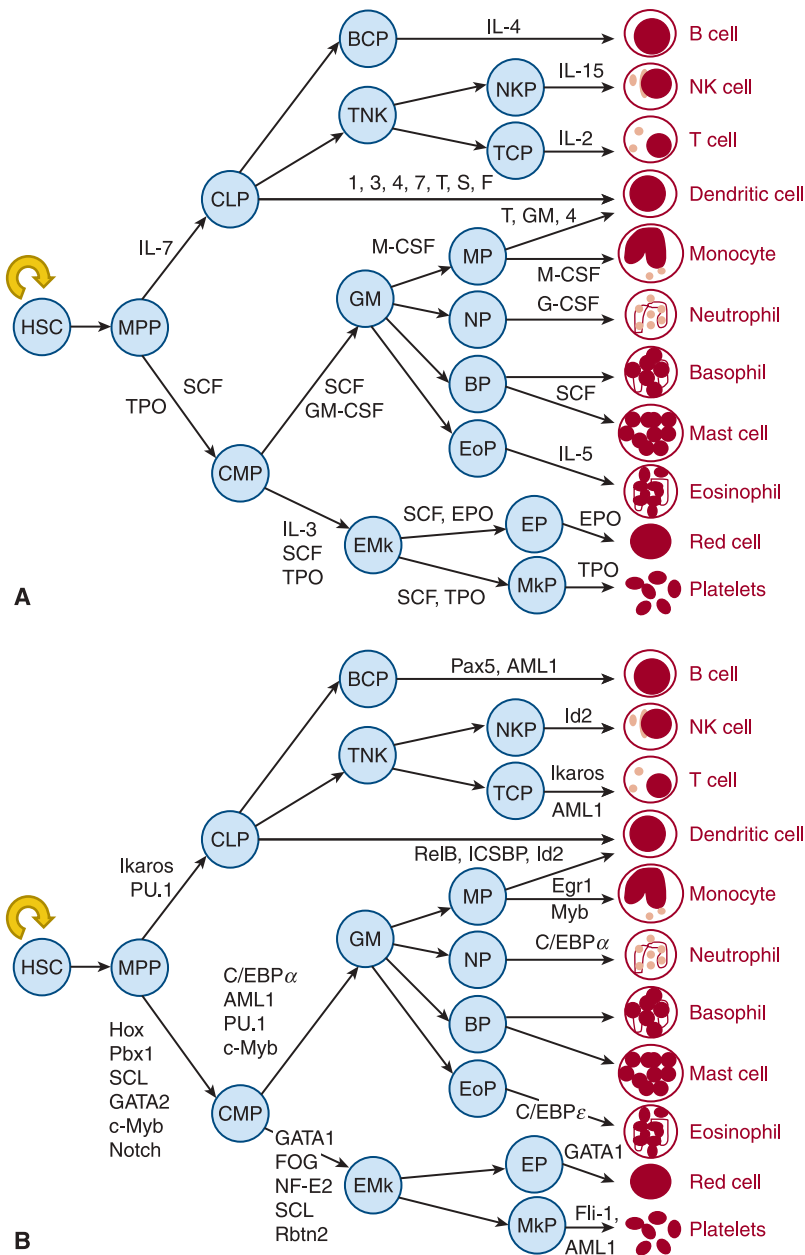

Figure 18-1. The figure displays the hematopoietic progenitors that have been defined by *in vitro* assays or by more complex tissue-based assays. In **(A)** the growth factors for cell survival and proliferation at each corresponding stage of hematopoietic development are shown, and in **(B)** the corresponding transcription factors are illustrated. See text for definitions, except that T,GM,4 represents tumor necrosis factor alpha (TNF- α), GM-CSF and IL-4, and 1,3,4,7,T,S,F represents IL-1, IL-3, IL-4, IL-7, TNF- α , SCF, and Flt3 ligand. Although a single type of macrophage is illustrated, the blood monocyte can differentiate into a plethora of tissue specific macrophage types, including the hepatic Kupffer cell, the brain microglia, and the bone osteoclast (details are provided in Chaps. 67 and 69). Similarly, a single dendritic cell is shown, but of two distinct origins, lymphoid or myeloid (Chap. 20).

research has shown that the first adult-type HSCs are derived from mesodermal cells within the ventral wall of the dorsal aorta of the AGM.¹⁰⁻¹² The AGM remains a source of hematopoiesis between days 9.5 and 11.5 postcoitum in the mouse, and days 30 and 37 in the human.^{13,14} Of interest, the development of hematopoietic cells in this region (as well as in the yolk sac) occurs in a “reverse” direction, that is, single lineage-committed progenitors appear prior to multilineage progenitors, which appear prior to stem cells. This region also has cells that express a number of molecules in common with endothelial cells, including CD34, the transcription factors SCL and GATA-2, and the receptors c-KIT and FLK-1.¹⁵ Moreover, cell culture experiments have established that such cells display combined endothelial and hematopoietic potential, establishing them as “hemangioblasts,” the postulated combined endothelial cell–hematopoietic precursor.¹⁶

Approximately 2 days following the appearance of HSCs in the AGM region, hematopoiesis begins in the murine fetal liver. Careful dissection experiments of the 1970s indicate that fetal liver hematopoiesis

is dependent on an exogenous source of hematopoietic cells,¹⁷ which populate the fetal liver in two waves, consisting of erythroid and multilineage progenitors around day 9 of murine gestation and committed progenitors and true HSCs at day 11.¹⁸ Although there is no direct proof, the temporal appearance of these cell types in the AGM approximately 1 to 2 days prior to their appearance in the fetal liver strongly suggests that the former is the source for populating the latter. In humans the fetal liver becomes the major source of blood cells around 5 weeks of gestation, and the marrow begins to populate with hematopoietic cells at 8 weeks of gestation. Unlike the random pattern of cells seen in the yolk sac, hematopoiesis in the fetal liver is well organized; erythroid cells are usually found in clusters surrounding a central macrophage and CD15+ myelopoietic cells localize mainly around portal triad vessels, although lymphoid precursors fail to demonstrate a specific localization pattern and are randomly found amongst hepatocytes.¹⁹ Up to 50 percent of the fetal liver is composed of hematopoietic cells at days 12 to 14 of murine embryonic life, a proportion that begins to decrease as

hepatocytes replace hematopoietic cells and the latter shift to the marrow, prior to birth.

The final shift in the site of hematopoiesis occurs before birth; although the marrow begins to populate with liver derived hematopoietic cells at day 16 in the mouse and at 8 weeks gestation in the human, it is mostly myeloid in nature and contributes little to the circulating blood until just before birth.²⁰ Hematopoietic stem and progenitor cells circulate in large numbers during fetal life, as clinically witnessed by the use of umbilical cord blood as a rich source of HSCs for transplantation. However, shortly after birth neonatal blood has very few primitive hematopoietic cells, as they begin to home to and lodge in the marrow. Genetic studies reveal that marrow localization of HSCs is dependent on the chemokine CXCL12 (previously known as stromal cell-derived factor [SDF]-1)²¹ as elimination of the chemokine or its receptor (CXCR4) leads to marrow hypoplasia.²² The shifts in localization of hematopoiesis during mammalian development are likely the result of changes both in the cell surface adhesion molecules on hematopoietic stem and progenitors that occur during ontogeny, and the characteristics of stromal cells of the yolk sac, AGM, fetal liver, and adult marrow that provide the microenvironmental support of HSC survival, homing and lodgment, self-renewal, proliferative expansion, and differentiation (Chap. 7).

● THE HEMATOPOIETIC STEM CELL

FUNCTIONAL DEFINITION

Although the concept of a common “mother cell” of all blood elements in the adult dates to Maximov in 1909, and its potential for participation in disease as proposed by Danckhoff in 1916,²³ the basic concepts of a hierarchical organization of stem and progenitor cells leading to mature blood cell production were coalesced by Till and McCulloch using a spleen colony-forming assay, experimentally establishing the existence of multipotential hematopoietic cells.²⁴ The capacity to transplant marrow cells and reconstitute all aspects of hematopoiesis in myeloablated recipients provided an *in vivo* assay for the HSC, but it was not until the development of clonal *in vitro* assays of lineage-committed progenitors that a coherent model of blood cell production began to emerge. The pioneering work of Pluznik and Sachs²⁵ and of Bradley and Metcalf²⁶ provided methods to enumerate and characterize marrow cells committed to the hematopoietic lineage. These investigators independently developed culture conditions that allowed colonies of leukocytes to develop from single progenitors. However, as a result of the more fastidious conditions required for erythropoiesis and megakaryopoiesis *in vitro*, the description of methods to culture these progenitors did not occur for another decade or more.^{27–31} Work using density fractionation, cell sorting, and fluorescent dye exclusion methods has yielded purified populations of stem cells,^{32–36} common myeloid³⁷ and lymphoid³⁸ progenitors, and lineage-restricted hematopoietic progenitors,^{39,40} methods that have greatly advanced our understanding of the cell and molecular biology of blood cell development. Figure 18–1 depicts a working model of this process.

STEM CELL KINETICS

Based on transplantation data indicating that there are a remarkably similar total-body number of HSCs in mice and cats, it has been estimated that all mammals, including humans, possess 2×10^4 stem cells,⁴¹ and because only a small fraction of these are cycling (and therefore contributing to blood cell production) at any given time, it is also clear that daily blood cell development from the few cycling stem cells to produce the approximately 4×10^{11} mature blood cells represents a massive amplification process. However, the capacity of HSCs to contribute to hematopoiesis changes with age (Chap. 9). The number of HSCs

increases with age in some but not all strains of mice.^{42,43} Also, HSC differentiation in aged animals is skewed toward the myeloid rather than lymphoid lineage.⁴⁴ The molecular basis for these changes are undergoing intense study.^{45–48}

Another measure of stem cell kinetics is the time it takes for transplanted marrow cells to repopulate a lethally irradiated animal. Studies using retroviral markers suggest that HSCs can be divided into short-term and long-term repopulating cells, based on the timing of their appearance in the blood following intravenous transplantation (fewer than or more than 3 months following transplantation in mice).⁴⁹ However, a rapidly repopulating stem cell has been identified using a direct marrow injection strategy, a cell capable of generating large numbers of erythroid and myeloid cells within 2 weeks of injection.⁵⁰ Moreover, by transplanting luciferase-labeled single stem cells, a strategy that allows the serial tracking of the cells during life, initially detected foci were found to expand locally, seed other sites in the marrow or spleen, and then recede with different kinetics.⁵¹ From these experimental approaches it is clear that HSCs are heterogeneous.

STEM CELL ASSAYS

Transplantation Assays

Assays of Murine Stem Cells Experimental transplantation in animals affords the clearest estimation of HSC properties as the capacity to durably regenerate all of hematopoiesis in an otherwise lethally irradiated animal remains the gold standard for the field; moreover, the technique can be made quantitative. Typically, either 2×10^5 genetically marked, whole murine marrow cells, or reduced numbers of variably purified cells are infused intravenously into recipient animals who had previously received 90 to 110 cGy of whole-body irradiation. Blood cells and marrow are monitored for hematopoietic recovery in the following weeks and months, and the success of the transplant is measured by survival, and long-range contribution to hematopoiesis in the recipient. The contribution of donor cells to recovery is established by analysis of the posttransplant blood or marrow cells; the most common method of distinguishing donor from residual recipient blood and marrow cells is the use of flow cytometry against isoforms of the cell membrane-bound phosphatase CD45, present on virtually all hematopoietic cells. In a more quantitative embodiment of the strategy, limiting numbers of the genetically distinct cells (e.g., CD45.1+) are mixed with a “just adequate” (for full recovery) number of alternately marked cells (e.g., CD45.2+) and the proportion of CD45.1 to total CD45.1+ plus CD45.2+ cells is assessed following transplantation, yielding a calculation of the number of stem cells in the initial inoculum, an approach termed *competitive repopulation*.⁵² Because there exist both “short-term” and “long-term” repopulating cells, the degree of donor cell chimerism is tested 3 or more months following transplantation, to be certain that only the latter are evaluated. For example, transplantation of megakaryocyte-erythroid progenitor (MEP) cells allows for survival in a lethally irradiated mouse, as these cells allow sufficient time for endogenous recovery of the small number of relatively radio-resistant HSCs in the recipient mouse.⁵³ Consequently, survival alone following cell transplantation is not a sufficient measure of the presence of stem cells in a given population. Thus, with the appropriate caveats, this approach allows an assessment of the numbers or “quality” of HSCs in the test population (i.e., some genetically altered stem cell populations repopulate less robustly than wild-type cells as a consequence of defects in cytokine receptors or other genes that affect the self-renewal, survival, or proliferation of stem cells). Based on the use of these experimental tools, we know most about murine HSCs. Obviously, this approach is not available to assess human HSCs. Instead, a number of alternate experimental approaches have been developed.

Assays of Human Hematopoietic Stem Cells Severely immunocompromised mice can be engrafted by human HSCs, provided their survival can be supported in a strictly controlled animal care environment and that the experiments take place prior to the development of other untoward effects in such animals (e.g., tumor formation). The first assay employing this strategy relies on the combined immunodeficiency created by the severe combined immunodeficiency (SCID) and nonobese diabetic (NOD) genetic mutations.⁵⁴ Subsequently, these mice were found to bear some ability to reject or alter the developmental characteristics of human cell repopulation, leading other investigators to add genetic defects to the NOD-SCID background that improve the engraftment of normal and pathologic human marrow cells, such as NOD-SCID/ β_2 -microglobulin null,⁵⁵ or the most commonly used NOD-SCID/ γ c null,⁵⁶ or by crossing with mice that also express human hematopoietic cytokines.⁵⁷ Such animal models have allowed the assessment of (1) stem cell numbers in human CD34+ cells from mobilized blood or umbilical cord blood,⁵⁸ (2) assessment of the effects of gene therapy vectors,^{59,60} cell-cycle inhibitors,⁶¹ or cytokine cocktails designed to expand stem cell numbers⁵⁸⁻⁶⁴ on the retention of repopulating capacity, or (3) the study of fundamental biologic properties of human HSCs *in vivo*, such as the cell-cycle restriction of repopulating cells.⁶⁵

Surrogate In Vitro Stem Cell Assays

Although *in vivo* assays remain the gold standard, NOD-SCID and more severely immunocompromised mice are difficult to maintain and remain expensive and quite cumbersome methods to assess human HSC quality and quantity. As a result, a number of culture-based methods were developed to more quickly and quantitatively evaluate human HSC function. Generally, each relies on long-term cell growth in culture and other special features to establish their validity as a model of the human HSC.

The ability to grow marrow cells in culture for extended periods of time provided an important tool to explore HSC biology.⁶⁶ In long-term cultures human or murine marrow is incubated in serum-containing medium under defined conditions, and after several weeks the stromal layer that has developed is recharged with fresh marrow cells, which then produce mature blood cells and their progenitors for many months. Cell fractionation studies show that the HSC resides adherent to the stromal cell layer in such cultures,⁶⁷ and that enzymatic disruption of the stromal layer will allow one to reseed a secondary stromal cell layer with the capacity to produce hematopoietic cells for a period of weeks to months, thereby defining an *in vitro* assayable cell termed the *long-term culture-initiating cell* (LTC-IC).⁶⁸ A second assay that was developed based on similar principles is the cobblestone area-forming cell (CAFC), which, when evaluated by phase-contrast microscopy, gives rise to complex colonies of multiple hematopoietic cell types under the stromal cell layer of long-term cultures.⁶⁹ Unfortunately, when careful comparisons are made between these assays and transplantation studies, the true HSCs comprise only a fraction of the repopulating cells found in marrow. Thus, conclusions about stem cell behavior from such *in vitro* assays cannot be considered rigorous.

CELL SURFACE PHENOTYPE

Numerous investigators have used monoclonal antibodies to an increasing number of hematopoietic cell surface proteins to negatively and/or positively enrich for stem and primitive hematopoietic progenitor cells. Although the function of only a few of these stem cell markers is known, it has not impeded their use for research and/or therapeutic benefit. Others have taken advantage of the capacity of primitive hematopoietic cells to extrude fluorescent organic chemicals or on their buoyant density to obtain purified populations of these scarce marrow

cells; most successful stem cell purification strategies employ several such techniques.

The antigenic proteins and glycoproteins that exclusively or predominantly present on HSCs include (1) CD34, a 90- to 110-kDa type I glycoprotein that is postulated to mediate cell adhesion and/or cell-cycle arrest⁷⁰⁻⁷²; (2) CD90 (Thy1),⁷³ a heavily glycosylated glycoposphoinositol-linked protein that participates in T-cell adhesion to stromal cells⁷⁴; (3) CD117 (the c-Kit receptor),⁷⁵ which supports primitive hematopoietic cell survival and proliferation^{76,77}; (4) AA4,³⁴ a murine molecule homologous to the human phagocyte C1q complement receptor⁷⁸; (5) Sca1,⁷⁹ a murine surface molecule shown by knockout studies to be necessary for normal stem cell development⁸⁰; (6) CD133,⁸¹ a 115-kDa pentaspan cell-surface glycoprotein expressed on the apical surface of neuroepithelial and HSCs that has been proposed to function in establishing or maintaining plasma membrane protrusions⁸²; (7) CD164,⁸³ a cell-surface sialomucin that is present in several alternately spliced isoforms and that enhances blood cell homing and inhibits CD34+/CD38- cell proliferation,⁸⁴ and CD150, a member of the signaling lymphocyte activation molecule (SLAM) family of lymphocyte proliferation receptors⁸⁵; and (8) CD110 (the thrombopoietin [TPO] receptor c-Mpl)⁸⁶ present on virtually all repopulating HSCs,⁸⁷ and established to be vital for human HSC physiology as genetic elimination of the receptor leads to congenital amegakaryocytic thrombocytopenia at birth and aplastic anemia shortly thereafter (Chap. 117).

Many or most of the surface membrane proteins found on HSCs are also present on cells that have begun to differentiate toward specific lineages, precluding the exclusive use of positive selection alone for stem cell purification. Thus, a number of stem cell purification strategies include negative selection, based on cell surface markers absent on HSCs but present on mature blood cells and their corresponding unilineage-committed progenitors. Typically, cocktails of negatively selecting antibodies include CD38, HLA-DR, CD3, CD4, CD5, or CD8 for T lymphocytes; CD11b, CD14, or Gr-1 to exclude macrophages and granulocytes; CD10, CD19, CD20, or B220 to eliminate B lymphocytes; and glycophorin A or Ter119 to remove erythroid cells. The products that result from the use of such combinations of negative-selecting antibodies are termed *Lin-* cells.

A particularly difficult problem is presented by separating true HSCs from their progeny committed to the lymphoid or myeloid lineage, but not differentiated beyond that stage. Several studies clarify the cell surface profile of the common lymphoid progenitor (CLP) as *Lin- / interleukin (IL)-7R(receptor) α +/Thy1- / Sca-110^w/c-kit^{low}*³⁷ and the common myeloid progenitor (CMP) as *Lin- / IL-7R α - / c-Kit+/Sca-1-*.³⁶ The cell surface phenotype of human HSCs includes *CD34+/CD38- / KDR(VEGFR2)+/Thy1+/CD133+/Lin-*, although most of these markers require careful clinical assessment before their widespread use in patients can be considered. At present, at least for murine cells, that problem has been solved. The most effective cell sorting method for purifying murine HSC is the E-SLAM approach, negatively selecting for CD48 and positively selecting for CD45, CD201, and CD150. It is estimated that such a cell population is at least 50 percent pure HSC based on single-cell transplantation experiments in mice.

STEM CELL INTEGRINS

Integrins are a family of heterodimeric single-pass transmembrane proteins (18 α and 8 β subunits form at least 24 different cell surface adhesion receptors in humans) characterized by multiple immunoglobulin (Ig)-like extracellular domains that allow two-way communication between a cell and its environment.⁸⁹ A large number of cell types require contact for survival; *in vitro*, this is usually manifest as integrin-dependent cell adhesion, either to extracellular matrix protein(s) or

to other cells. In such cultures, disruption of adherence causes programmed cell death; for example, endothelial cells undergo apoptosis upon forced detachment *in vitro*, as a result of disruption of multiple integrins.⁹⁰ Integrins also influence the proliferation of cells by affecting the G₁ to S phase transition of the cell cycle.⁹¹ These effects also operate *in vivo*; $\alpha_1\beta_1$ integrin (a component of the $\alpha_1\beta_1$ collagen receptor) null mice have a hypoplastic dermis, and the growth of α_1 -/- fibroblasts on collagen is substantially reduced.⁹²

Hematopoietic stem and progenitor cells express multiple integrins, including $\alpha_4\beta_1$ (also termed *very-late antigen* [VLA] 4), which binds to either vascular cell adhesion molecule (VCAM) 1 or fibronectin, and $\alpha_5\beta_1$ (VLA5), which binds to a region of fibronectin distinct from the $\beta_1\beta_1$ binding domain. Moreover, primitive hematopoietic cells are thought to express integrin $\alpha\text{IIb}\beta_3$, the platelet fibrinogen receptor, based on the death of multiple hematopoietic lineages in mice expressing a suicide transgene under control of the integrin αIIb promoter.⁹³ However, the physiologic significance of this finding is uncertain at present.

The avidity of progenitor cell–integrin interactions can be altered by external effectors; numerous cytokines and chemokines, including cytokines critical for stem cell function (stem cell factor [SCF], TPO, and CXCL12), enhance integrin-mediated binding.^{94–96} Counterreceptors for both integrins, such as VCAM1 and fibronectin (FN), are highly expressed in the marrow matrix and on marrow stromal cells (see “Matrix Proteins” in “The Hematopoietic Microenvironment” later). Integrin-based interactions with the stroma are responsible for homing and retention of stem and primitive progenitor cells in the marrow, as antibodies that interfere with the interaction can mobilize stem and progenitor cells into the blood.⁹⁷ However, it is uncertain whether integrins can influence the survival or growth of HSCs, or affect their ultimate developmental fate.

METABOLIC CHARACTERISTICS

One of the hallmarks of HSCs is their resistance to chemotherapy-induced cytotoxicity. A primary reason for this property is high-level expression of drug efflux pumps of the multidrug resistance class of proteins.⁹⁸ The presence of these verapamil-sensitive efflux pumps has enabled the separation of HSCs based on their low-level retention of various fluorescent markers such as rhodamine 123 and Hoechst 33342, the “Rh^{lo}/Ho^{lo}” population of murine cells and the side population (SP) of cells in human marrow.⁹⁹ However, before such maneuvers can be used for clinical stem cell enrichment procedures, the lack of toxicity of the fluorescent dyes must be confirmed. Nevertheless, such experimental strategies continue to shed important insights into HSC biology.

As a consequence of residing physically removed from the marrow vasculature, the stem cell microenvironment is hypoxic (see “Anatomy” in “Hematopoietic Microenvironment”). The metabolic consequence is that HSCs display a low metabolic state, with most of its ATP generation derived from glycolysis. As the HSC rarely undergoes cell division, it can “afford” the low metabolic state of cells dependent on glycolysis. One of the transcription factors critical for HSC physiology, MEIS1,¹⁰⁰ appears responsible for this metabolic profile, by driving expression of hypoxia-inducible factor (HIF)-1 α , that upregulates expression of the glycolytic enzyme machinery.¹⁰¹ In addition, HIF-1 α also induces pyruvate dehydrogenase kinases (PDK1-4) that prevent mitochondrial pyruvate oxidation by suppressing pyruvate dehydrogenase complex, the first step that fuels the Krebs cycle. Stem cell down-modulation of mitochondrial oxidative phosphorylation acts to reduce the generation of reactive oxygen species (ROS), which is highly toxic to HSCs. It has been suggested that this property, the avoidance of ROS generation, contributes to the longevity of the stem cell pool in any individual.

As HSCs mature into committed progenitors, they migrate toward the marrow vasculature, and into a higher oxygen tension atmosphere. This would appear to be required to gain the additional metabolic rate afforded by oxidative phosphorylation. As one component of this “metabolic switch,” marrow hematopoietic progenitor cells express lower levels of PDKs, reducing PDK-mediated suppression of oxidative phosphorylation seen in HSCs.¹⁰²

CELL-CYCLE CHARACTERISTICS

Adult hematopoietic cells display altered engraftment capacity dependent on their phase in the cell cycle. Using primitive hematopoietic cell populations several investigators have demonstrated that only quiescent G₀/G₁ phase cells engraft into lethally irradiated recipient animals; cells in the S and early G₂ phase display minimal engraftment capacity,^{102,103} a situation that can be experimentally manipulated; elimination of p21, a key cell-cycle progression gene, enhances stem cell expansion.¹⁰⁴ This finding correlates well with findings that the profile of expressed genes in a highly selected population of primitive hematopoietic cells shifts when they are induced from G_{0/1} phase into the cell cycle.¹⁰⁵ However, even though this cell-cycle dependence of engraftment of stem cells is true for adult cells, the corresponding cell populations derived from umbilical cord blood or fetal liver is not cell-cycle dependent.¹⁰⁶ A better understanding of these findings is very likely to shed important new insights into the genes that regulate engraftment.

GENE EXPRESSION PROFILE

It can be argued that the most critical feature of the HSC is its ability to quantitatively balance its three fates—apoptosis, self-renewal, and differentiation—into the mature elements of the blood. Moreover, the undifferentiated cell must express (at the least) the initiating genes responsible for all possible developmental lineages. A useful conceptual framework for this process can be constructed by considering the gene expression profiles of stem and committed hematopoietic progenitors that develop into the multiple hematopoietic differentiation pathways. At each developmental step genes associated with the adopted pathway should remain expressed or be upregulated, while the genes that specify the alternate lineage(s) are likely silenced. A thorough understanding of these gene expression profiles should help to explain the circuitry of specific aspects of hematopoiesis, and of developmental biology in general.

Initial studies using immortalized multipotent hematopoietic cell lines reinforced this conceptual framework; pluripotency is characterized by the expression of multiple genes associated with multiple cell fates.¹⁰⁷ Studies of purified HSCs and lineage-committed progenitors have also strengthened this hypothesis, revealing coexpression of several different lineage-affiliated gene sets in single primitive hematopoietic cells.¹⁰⁸ In contrast, the downstream progenitors of HSCs were found to express only lineage-appropriate transcripts, such as for the granulocyte colony-stimulating factor receptor (G-CSF-R) in granulocyte-macrophage progenitors (GMPs), or β -globin and the erythropoietin receptor (EPOR) in committed erythroid progenitors.³⁶ Similar findings were reported for lymphoid committed cells, although some promiscuity was detected in B-cell progenitors.¹⁰⁹

With these principles established, more ambitious efforts to catalogue all the genes expressed by each stage of hematopoietic development have been made possible by advances in microarray and whole transcriptome sequencing approaches to gene expression.¹¹⁰ On an even broader scale, and as might be expected, comparisons of different types of stem cells (e.g., liver, skin, neural) reveals an overlap in the expressed genes, supporting the hypothesis that the mechanisms responsible for critical stem cell properties, such as self-renewal, are shared among the

cells derived from multiple organs.¹¹¹ This observation also provides a powerful tool to identify such proteins. Such studies have also begun to identify novel genes expressed in HSCs, potentially allowing our better understanding of their role in hematopoiesis.

TRANSCRIPTION FACTOR PROFILE

An important goal of modern cell biology is to provide a molecular explanation for the gene or sets of genes required to orchestrate specific developmental events. Fundamental to this process is an understanding of the proteins present in cells that regulate gene transcription in a lineage-, ontogenic stage-, and developmental level-specific manner. Unlike what is claimed for many organ-specific programs, no single lineage-unique family of master regulators exerts executive control over hematopoiesis. Rather, an assemblage of specific and nonunique factors and signals converge to determine lineage and differentiation patterns. Several transcription factors have been identified in stem cell populations or have been shown to affect stem cell differentiation into the lymphoid and myeloid lineages. In addition to transcription factors that regulate HSC expansion, a number of epigenetic and microRNA changes have been identified that affect gene expression in these cells. The *BMI1* gene encodes a protein that forms part of a polychrome group repressor complex, which represses a number of important target genes including the cell-cycle regulator p16/INK4a, a pathway that regulates HSC function in normal and malignant hematopoiesis.¹¹² In addition, methylation can affect HSC gene expression, as the DNA methyltransferases DNMT3A and DNMT3B affect HSC self-renewal.¹¹³ And microRNA (miRNA) species are regularly being identified that regulate transcription and translation of critical HSC genes. For example, 9 miRNA were overexpressed and 22 downregulated in CD34+/CD38- HSCs compared with CD34+/CD38+ cells. Among the most upregulated miRNAs in the more primitive cells was miR-520h, predicted to target ATP-binding cassette, subfamily G (ABCG2) gene, known to be involved in stem cell maintenance. Transduction of miR-520h into CD34+ cells increased the numbers of several progenitor cell types (colony-forming unit-erythroid [CFU-E], burst-forming unit-erythroid [BFU-E], and colony-forming unit-granulocyte-macrophage [CFU-GM]) as well as the total number of CD34+ cells (reviewed in Ref. 114).

Hematopoietic Stem Cell Self-Renewal and Expansion

Members of the Hox family of transcription factors are important regulators of hematopoietic cell decisions, at least at the level of self-renewal/expansion, based on (1) a similar role in multiple organ systems¹¹⁵; (2) their lineage- and differentiation-stage-specific expression pattern in hematopoietic cells¹¹⁶; (3) disruption of their usual level or pattern of expression that leads to hematologic expansion or malignancies¹¹⁷; and (4) their elimination,¹¹⁸ or elimination of the gene(s) that regulate them,¹¹⁹ which leads to significant defects in hematopoiesis. In addition, members of the extradenticle family of homeodomain-containing proteins serve as cofactors for Hox proteins, altering their cellular localization, DNA-binding affinities, and specificities. Like Hox genes, genetic elimination of some of these cofactor proteins can lead to HSC defects. For example, Pbx1 null mice display greatly reduced numbers of CMPs,¹²⁰ and overexpression or altered expression of MEIS1 is associated with hematologic malignancy.¹²¹

Hematopoietic Stem Cell to Common Lymphoid Progenitor Commitment

The *Ikaros* gene encodes a family of lymphoid-restricted zinc-finger transcription factors related to the *Drosophila* hunchback gene.¹²²

All isoforms of *Ikaros* contain a highly conserved carboxyl-terminal activation domain and two zinc-finger domains that mediate their dimerization. However, only isoforms 1 to 3 of the six known alternatively spliced forms contain more than three of the four N-terminal zinc fingers required for DNA binding to the consensus DNA core motif GGGA.¹²³ The PU.1 gene is 1 of approximately 30 members of the Ets family of transcription factors that bind to the purine-rich sequence 5'-GGAA-3'.¹²² Genetic elimination of the *Ikaros* and PU.1 genes have established their critical role in commitment of HSCs to the lymphoid lineage; fetal stem cells in *Ikaros* -/- mice fail to generate any definitive T- or B-lymphocyte precursors,¹²⁴ and although thymocyte precursors can be identified postnatally, they undergo aberrant differentiation or fail to develop into the CD4, dendritic, and some $\gamma\delta$ T-cell subsets in adult mice. Consequently, *Ikaros* is essential for all of lymphopoiesis early during ontogeny, and for several subsets of lymphocytes later in life. In a similar fashion, PU.1-deficient mice also lack any definitive T- and B-cell precursors in their lymphoid organs at birth (and myeloid cells; see "HSC to CMP Commitment" below),¹²⁵ and if knockout mice are maintained on antibiotics and survive the first 48 hours of life, they begin to develop normal-appearing T cells 3 to 5 days later. In contrast, mature B cells and macrophages remain undetectable in the older mice, indicating absolute tissue dependence for this lineage.

Hematopoietic Stem Cell to Common Myeloid Progenitor Commitment

The SCL (stem cell leukemia) gene encodes one of the transcription factors responsible for the initial stages of myeloid development, a gene first identified at the site of chromosomal rearrangement in a patient with SCL.¹²⁶ SCL belongs to the helix-loop-helix family of transcription factors, which form dimers and bind DNA at consensus E-box motifs (CANNTG).¹²⁷ Although initially identified as a gene rearranged in T-cell acute lymphocytic leukemia, an essential role for SCL in hematopoietic development was established by gene ablation studies, which revealed a complete absence of primitive blood cells and lethality in *scl*-/- embryos at day 9.5 postcoitum.¹²⁸ Consistent with this panhematopoietic phenotype, previous studies showed that SCL is downregulated in differentiating granulocytic and monocytic progenitor cells and that forced expression of the gene in hematopoietic cell lines inhibits cytokine-induced granulocytic and monocytic differentiation.^{129,130} Consistent with their respective roles in promoting stem cell and mature cell survival and proliferation, SCF sustains SCL expression in primary CD34+ cells, maintaining them in an undifferentiated state, whereas granulocyte-macrophage colony-stimulating factor (GM-CSF) downregulates SCL levels and favors granulocyte and monocyte differentiation.^{130,131} Together, these results suggest that SCL expression is required for HSC and CMP maintenance, and that down-modulation of the transcription factor is essential for myeloid differentiation.

The GATA transcription factor family contains six members possessing a highly related DNA-binding domain composed of two conserved zinc-finger motifs.¹³² GATA1 and GATA2 are present in hematopoietic cells, GATA2 is found in the same cells as SCL, with GATA1 expression restricted to latter stages of erythroid/megakaryocytic (MEP) differentiation. Because genetic elimination of GATA2 is lethal as a result of numerous nonhematopoietic defects, and because individual hematopoietic lineage-specific knockouts have not yet been engineered, the role of GATA2 in early hematopoiesis is uncertain. However, like SCL, elimination of GATA2 expression is required for hematopoietic cell maturation.¹³³

As noted above, numerous lines of evidence indicate that HSCs express the TPO receptor, *c-Mpl*, as best exemplified by its expression on all AA4+/Sca+ cells that are capable of long-term hematopoietic repopulation.⁸⁷

Several investigators have shown that the 5' flanking region of the *c-mpl* gene contains a functionally important GATA site and that GATA1 transactivates the gene in hematopoietic cell lines.¹³⁴ Because GATA1 does not appear in hematopoietic cells until they have lost their repopulating capacity, it is possible that GATA2 fulfills this role in HSCs, although there is no evidence yet available establishing that this protein can transactivate the *c-mpl* GATA site.¹³⁵

STEM CELL AGING

While blood cell counts do not change substantially in elderly mammals, a number of alterations are demonstrable in HSCs derived from older individuals. In aged mice, the HSC compartment expands, although each HSC has reduced capacity to expand.¹³⁶ Upon transplantation, aged marrow HSCs display a myeloid skewing, generating reduced numbers of T- and B-lymphoid precursors, that along with thymic involution helps to explain the immune depletion seen in older adults. Similar findings were reported when aged human stem cells were transplanted into immunocompromised mice.¹³⁷ This topic has been reviewed.¹³⁸

THE HEMATOPOIETIC MICROENVIRONMENT

It has been estimated that the concentration of cells within the marrow is $10^9/\text{mL}$; as a result, multiple cell–cell and cell–matrix interactions occur. A major advance in experimental hematology has been the capacity to grow hematopoietic cells in long-term culture. When high concentrations of marrow cells are placed in serum-containing cultures, a stromal cell layer and extracellular proteinaceous matrix form, and when subsequently recharged with fresh marrow cells, these long-term cultures (LTCs) are capable of supporting hematopoiesis for months with simple demidepletion and replacement of culture medium. It is assumed that the cell–cell and cell–matrix interactions that develop in such cultures more closely resemble those found *in vivo*, helping to explain the longevity of such cultures and their capacity to maintain hematopoietic stem and primitive progenitor cells far longer *ex vivo* than do nonstromal cell-containing cultures. The molecular basis for the improved hematopoietic environment of LTCs is thought to rely on stromal cell surface molecules that promote cell–cell contact, prevent programmed cell death, and regulate growth.

The microenvironmental effects on HSCs have far reaching clinical implications as well; our ability to mobilize marrow stem cells for transplantation has greatly changed the way we treat hematologic and other malignancies, and ultimate success in the efforts of experimental hematologists to expand HSCs *ex vivo* with cocktails of cytokines and stromal cells for applications in gene therapy and regenerative medicine will undoubtedly derive only from a thorough understanding of the molecular bases for the interaction of HSCs with their microenvironment (Fig. 18–2).

Marrow stromal cells influence hematopoiesis in a number of ways, by producing several cytokines that positively or negatively affect hematopoietic cell growth,^{139–142} including some, like SCF, that are expressed on their cell surfaces, resulting in enhanced biologic activity.¹⁴³ Stromal cells are the origin of a number of extracellular matrix proteins that either directly affect hematopoietic cells, or do so indirectly by binding growth factors and presenting them in a functional context.¹⁴⁴ They also bear the Jagged/Delta family ligands that stimulate Notch proteins to undergo cleavage and translocation into the nucleus, events that are critical mediators of cell fate decision making,^{145,146} including for hematopoietic cells.¹⁴⁷ Cell–cell interactions mediated by integrins

Figure 18-2. The figure depicts multiple elements of the hematopoietic microenvironment. The niche has two major regions in the marrow, supported by osteoblasts or vascular cells. Several cell types provide cytokines that maintain osteoblasts (Ob), which, in turn, support hematopoietic stem cells (HSC) by secreting CXCL12 and other cytokines. Osteoclasts (Oc) are also shown but are of lesser importance in HSC maintenance, and may inhibit HSC survival/proliferation. Macrophages that express α smooth muscle actin (α SM) support perivascular cells, including the CXCL12 abundant reticular (CAR) cells, that, in turn, provide CXCL12 and SCF (here termed *c-kit ligand* [KitL]) to HSCs. In addition to paracrine support, direct perivascular cell–stem cell contact, through integrins, also support HSCs. (Reproduced with permission from Calvi LM, Link DC: Cellular complexity of the bone marrow hematopoietic stem cell niche. *Calcif Tissue Int* 94(1):112–124, 2014.)

present on hematopoietic cells and counterreceptors on stromal cells are also very important for hematopoiesis.^{65,72} In addition to bringing hematopoietic cells into close proximity to cells producing soluble or cell-bound cytokines, and hence raising the local concentration of these growth promoting proteins, integrin engagement leads to intracellular signaling, usually promoting entry into the cell cycle and preventing programmed cell death.¹⁴⁸ Reflecting the vital and sometimes lineage specific roles of the hematopoietic microenvironment, the extracellular matrix and stromal cells reside in a highly organized structure (Chap. 5).

ANATOMY

Hematopoiesis is highly compartmentalized within areas of red marrow, with erythropoiesis occurring in clusters surrounding a central macrophage,¹⁴⁹ granulocyte development associated with stromal cells,¹⁵⁰ and megakaryopoiesis occurring adjacent to the endothelial sinusoidal cells.¹⁵¹ In the adult marrow, the specialized niche in which HSCs develop into differentiated progeny has been termed the *hematon* by Peault, a structure that includes Str01+ mesenchymal cells, desmin-positive perivascular lipocytes, Flk1+ endothelial cells, macrophages, and hematopoietic progenitors.¹⁵² From these structures can be derived all lineages of committed colony-forming cells (e.g., CFU-GM and BFU-E) and primitive cells that score positive in CAFC assays, LTC-IC, and high proliferative potential colony-forming cell assays (Chap. 5).

One consequence (or perhaps cause) of this anatomical arrangement is that the stem cell microenvironment is quite hypoxia. It is estimated that the O_2 level of the stem cell niche is approximately 5 percent. The HSC response to hypoxia is discussed in “Metabolic Characteristics” above.

STROMAL CELLS

The marrow microenvironment is composed of multiple cell types. Fibroblasts are perhaps the best-studied of the marrow stromal cells, and can bind to primitive hematopoietic cells by engaging cell-surface integrins.¹⁵³ Marrow endothelial cells also support primitive hematopoietic cells, including LTC-IC.¹⁵⁴ The CXCL12-abundant reticular (CAR) cells, which surround the sinusoidal endothelial cells *in vivo*, are also likely to play the critical niche function of the vascular wall.^{155,156} However, based on their ability to increase the number of HSCs when experimentally increased, osteoblasts, which line trabecular bone and reside adjacent to primitive hematopoietic cells,¹⁵⁷ are thought to provide a critical role in serving as the HSC supportive niche.¹⁵⁸ The origin of all of these cell types is thought to reside in the mesenchymal stromal cell (MSC), a functionally defined entity that under specific conditions can be induced to form fibroblasts, endothelial cells, CAR cells, and osteoblasts, amongst others,¹⁵⁹ and hold promise to therapeutically manipulate hematopoiesis.¹⁶⁰ MSCs are discussed more extensively in Chap. 30.

Marrow stromal cells affect HSCs in multiple ways. Each of these cells is known to produce a number of cytokines critical for primitive and mature hematopoietic cell development. For example, although a number of organs produce TPO constitutively,¹⁶¹ marrow stromal cells are induced to produce the hormone in states of thrombocytopenia.^{162,163} Stromal cells produce SCF constitutively in both soluble and membrane bound forms,⁷⁶ and FLT-3 ligand (FL) is produced both constitutively by stromal cells and lymphocytes and can be induced to high levels in the presence of pancytopenia.¹⁶⁴

Besides growth factor production, stromal cells are also known to display counterreceptors for the integrins present on hematopoietic cells, including VCAM-1,¹⁶⁵ interactions that promote cell survival and proliferation in several ways.¹⁶⁶ Osteoblast-derived annexin II serves as an adhesion molecule for HSCs.¹⁶⁷ Stromal cells also elaborate extracellular matrix components, including collagen, laminin, FN, heparins, hyaluronan, and tenascin, which display important effects on HSCs (see “Matrix Proteins” later). These substances, in turn, engage a number of HSC integrins and other cell-surface molecules, and form a solid matrix on which hematopoietic cells firmly attach. Of considerable clinical interest, it appears that interference with cell-matrix interactions,¹⁶⁸ or digestion of the extracellular matrix itself,¹⁶⁹ is involved in mobilizing HSCs by some agents such as granulocyte colony-stimulating factor (G-CSF) and IL-8.

It has long been known that the marrow is innervated by the autonomic nervous system,¹⁷⁰ which influences HSCs in several ways, such as directing HSC trafficking by acting on nestin-positive microenvironmental cells.¹⁷¹ One or more of these functions appear to be critical for HSC homeostasis, as marrow nerve injury impairs hematologic recovery following chemotherapy-induced injury.¹⁷²

Cytokines

The regulation of stem cell survival, proliferation, and differentiation has been difficult to address because of the rarity of stem cells and the requirement that they be assessed using cumbersome transplantation assays. Several cytokines are able to exert effects on HSCs. The pursuit of the cytokines that affect HSCs is of more than pure physiologic interest, as the availability of the right combination of such proteins could allow expansion of the cells for therapeutic use without sacrificing their pluripotent and self-renewal capacities. Three proteins—SCF, FL, and TPO—and their corresponding receptors (c-Kit, Flt3, and c-Mpl, respectively) exert important effects on the number and/or growth of HSCs both *in vitro* and *in vivo* (Table 18-1).

Stem Cell Factor The molecule termed SCF, steel factor, mast cell growth factor, or c-Kit ligand was cloned by several groups based on its

TABLE 18-1. Cytokines and Hormones Active on Stem Cells and Progenitors

Cytokine	Principal Activities
IL-1	Induces production of other cytokines from many cells, works in synergy with other cytokines on primitive hematopoietic cells
IL-2	T-cell growth factor
IL-3	Stimulates the growth of multiple myeloid cell types, involved in delayed type hypersensitivity
IL-4	Stimulates B cell growth and modulates the immune response by affecting immunoglobulin class switching
IL-5*	Eosinophil growth factor and affects mature cell function
IL-6	Stimulates B lymphocyte growth; works in synergy with other cytokines on megakaryocytic progenitors
IL-7*	Principal regulator of early lymphocyte growth
IL-9	Produced by Th2 lymphocytes; costimulates the growth of multiple myeloid cell types
IL-11	Shares activities with IL-11; also affects the gut mucosa
IL-15*	Modulates T lymphocyte activity and stimulates natural killer cell proliferation
IL-21	Affects growth and maturation of B, T, and natural killer cells
SCF*	Affects primitive hematopoietic cells of all lineages and the growth of basophils and mast. Also termed c-Kit Ligand
EPO*	Stimulates the proliferation of erythroid progenitors
M-CSF*	Promotes the proliferation of monocytic progenitors
G-CSF*	Stimulates growth of neutrophilic progenitors, acts in synergy with IL-3 on primitive myeloid cells and activates mature neutrophils
GM-CSF	Affects granulocyte and macrophage progenitors and activates macrophages
TPO*	Affects hematopoietic stem cells and megakaryocytic progenitors
CXCL12	Chemokine that attracts HSCs by binding to the CXCR4 receptor

*Primary regulator of the corresponding cell lineage.

binding to a cell surface receptor encoded by the protooncogene c-Kit,⁷⁶ previously identified as responsible for the severe defects in hematopoiesis, pigmentation, and gametogenesis in W mice. As the phenotype of mice bearing alleles of W was quite similar to those of steel (Sl), but in transplantation studies one strain displayed a stem cell autonomous defect (W) while the other was not (Sl), it had been hypothesized that the two genes represented the receptor for a growth factor and the cytokine itself, respectively, a tenet proven true with the cloning of SCF.

The extracellular domain of c-Kit is composed of five immunoglobulin-like domains, which leads through a typical transmembrane domain to the intracellular domain that bears a split domain-type tyrosine kinase. A single molecule of SCF binds to the first three immunoglobulin domains (D₁D₂D₃) of two c-Kit receptors. The two D₄ domains of a dimeric c-Kit receptor display substantial electrostatic repulsion toward each other, precluding the juxtaposing of the two

transmembrane domains, and by extension, the two intracellular kinase domains. Once SCF binds to c-Kit the affinity for dimer formation overcomes the D4 electrostatic repulsion and the two kinase domains are brought together to initiate signaling.¹⁷³ The intracellular mediators activated by SCF binding to c-Kit include phosphoinositol 3'-kinase (PI3K), mitogen-activated protein kinases (MAPKs), phospholipase C gamma (PLC γ), and c-Src (Chap. 17; reviewed in Ref. 174).

SCF is synthesized by marrow fibroblasts and other cell types. Soluble SCF is a highly glycosylated 36-kDa protein released from its initial site on the cell membrane by proteolytic processing. An alternatively spliced form of SCF messenger RNA (mRNA), that does not encode the cleavage site, remains on the cell membrane, and is a more potent stimulus of c-Kit-receptor-bearing cells.¹⁴⁰ The ratio of soluble to membrane encoding SCF mRNA varies widely in different tissues, ranging from 10:1 in the brain, to 4:1 in the marrow, to 0.4:1 in the testis.

The importance of SCF to hematopoiesis is easily demonstrated; although nullizygous mice (Sl/Sl) are embryonic lethal because of a number of developmental defects, the presence of a partially functional allele (Sl^d) allows compound heterozygotes (Sl/Sl^d) to survive into adulthood, albeit with severe anemia because of diminished numbers/quality of HSCs. In addition to its critical role in the development of embryonic and fetal hematopoiesis, treatment of adult mice with an antibody that neutralizes the SCF receptor, c-Kit, also results in severe pancytopenia, indicating an important hematopoietic role for the receptor/ligand pair throughout life.

When present in culture SCF alone can maintain the long-term repopulating ability of murine Sca-1+/Rh^{lo}/Lin⁻ hematopoietic cells, suggesting that the cytokine can promote the survival of HSCs *in vitro*.¹⁷⁵ However, alone, SCF is only a weak stimulator of cell proliferation, primarily inducing the development of mast cells both *in vitro* and *in vivo*. Nevertheless, in the additional presence of IL-3, IL-6, IL-11, G-CSF, or TPO, SCF exerts profound effects on the generation of hematopoietic progenitor cells of all lineages,¹⁷⁶⁻¹⁷⁸ pointing to primitive hematopoietic cells as critical targets. The molecular mechanisms of such synergy are beginning to emerge.¹⁷⁹ A physical association of c-Kit and EPOR has been detected following SCF stimulation of cells bearing both receptors, an event that is essential for their functional synergy.¹⁸⁰

Flt3 Ligand FL was cloned as the binding partner for the then newly identified novel orphan receptor Flt3,¹⁸¹ a protein most closely related to the receptors for macrophage colony-stimulating factor (M-CSF) (hence the term flt = fms-like tyrosine kinase), and c-Kit. FL is expressed by T lymphocytes and marrow stromal cells.^{164,181} The Flt3 receptor is a 160-kDa cell-surface molecule expressed primarily on primitive hematopoietic cells.¹⁸² Like c-Kit, activation of Flt-3 results in activation of several signaling mediators, including the p85 subunit of phosphatidylinositol 3-kinase, SHP, PLC γ , and a guanosine 5'-triphosphatase (GTPase)-activating protein, activating Ras.¹⁸³ Normal Flt3 signaling also activates the MAPKs extracellular regulated kinase (ERK)-1 and ERK2 but leads to only weak phosphorylation of signal transducer and activator of transcription (STAT)-5, in contrast to an oncogenic form of the receptor, identified in 25 percent of patients with myelodysplastic syndromes or acute myelogenous leukemia.^{184,185} In the leukemic cells of such patients Flt3 bears an internal tandem duplication of the kinase domain, resulting in the constitutive activation of the receptor. Clinically, this is associated with reduced likelihood of patient survival; hence, this observation has led to an attempt to control the growth of such mutant-receptor-bearing cells with specific Flt3 kinase inhibitors,¹⁸⁶ with some success (Chap. 88).

FL was initially cloned using a soluble form of the receptor to identify ligand-bearing cells.¹⁸⁷ As their receptors bear a number of common structural features, it was not surprising to find that FL shares significant structural homology, as well as biologic properties with both

M-CSF and SCF. Like the other two cytokines, FL displays a 4 α -helix bundle tertiary structure and exists in both membrane-bound and soluble states, the result of alternate splicing of the primary transcript that does or does not include a cleavage site for its release from the cell membrane.¹⁸⁸

Unlike SCF levels that remain relatively static regardless of blood cell counts,⁷⁶ blood concentrations of FL can rise more than 25-fold in response to pancytopenia.¹⁸⁹ Interestingly, only pancytopenia, and not individual lineage deficiencies cause an increase in blood FL concentrations, suggesting that the cytokine is a bona fide regulator of stem or primitive hematopoietic cells. Consistent with this conclusion, transplantation data indicate that HSCs from Flt3-deficient mice do not effectively reconstitute the hematopoietic system,¹⁹⁰ being three- to eightfold less efficient in repopulation as wild-type cells, a conclusion reinforced by its genetic combination with c-Kit mutant mice.¹⁹⁰

Like SCF, FL appears to act on HSCs only in synergy with other hematopoietic cytokines,^{191,192} a finding particularly true for its combination with TPO.^{193,194} In addition, FL is a potent stimulus of B lymphopoiesis and granulocyte-macrophage proliferation and development, particularly of the latter toward the dendritic cell lineage.^{195,196}

Thrombopoietin TPO is a 45- to 70-kDa hormone that was cloned by both traditional biochemical purification and expression cloning strategies based on the use of a then orphan class I cytokine receptor, first identified as the cellular homologue of the murine-transforming oncogene v-mp1.¹⁹⁷ TPO bears extensive sequence homology to erythropoietin (EPO), sharing 20 percent identity and an additional 25 percent similarity. The hormone is produced in several organs, including the liver, kidney, skeletal muscle, and the marrow stroma. Based on murine liver transplantation studies about half of steady-state TPO production occurs in that organ,¹⁹⁸ but in states of thrombocytopenia the marrow stroma increases production substantially.^{160,163} The hormone acts on megakaryocyte (MK) progenitors to enhance their survival and proliferation and on immature MKs to promote their differentiation, but surprisingly not on mature cells during platelet formation.¹⁹⁹ Multiple lines of evidence also indicate that TPO can exert profound effects on the HSC. The hormone also supports the survival of candidate HSC populations, and acts in synergy with IL-3 and SCF to induce these cells into the cell cycle and increase their output of both primitive and committed hematopoietic progenitor cells of all lineages.^{200,201} These properties are also seen *in vivo*. For example, administration of the hormone to myelosuppressed animals leads to more rapid recovery of all hematopoietic lineages, including primitive cells,²⁰²⁻²⁰⁵ and genetic elimination of TPO or its receptor severely reduces the number of marrow stem and progenitor cells of all lineages to 15 to 25 percent of normal values.^{87,206,207} In addition, as noted in "Flt3 Ligand" above, TPO acts in synergy with FL to expand primitive hematopoietic cells in suspension culture, and when used to supplement LTC, the hormone maintained HSC numbers for up to 2 months,²⁰⁷ compared to standard LTCs in which repopulating HSCs are no longer detectable at this time.

The TPO receptor, the product of the cellular protooncogene c-Mpl, is a member of the cytokine receptor family that includes EPO, G-CSF, growth hormone, leptin, and many others. Upon binding TPO, the homodimeric c-Mpl activates its tethered Jak2 kinases, leading to phosphorylation of three of the cytoplasmic domain tyrosine residues. These phosphotyrosine residues then act as docking sites for several secondary signaling molecules, including STATs, MAPKs, and PI3K, ultimately leading to the expression of a number of transcription factors (e.g., homeobox-containing proteins, HIFs) and cell-survival molecules (e.g., BclXL). A more complete discussion of the molecular mechanisms by which TPO affects the HSC is found in Chap. 17.

CXCL12 (Previously Termed Stromal Cell-Derived Factor 1) CXCL12 is produced by a number of the cells that occupy the

hematopoietic microenvironment, and has profound effects on HSC localization to the stem cell niche.²² However, this chemokine is also thought to display direct effects on the survival and proliferation of hematopoietic stem and progenitor cells, both alone and in synergy with other hematopoietic cytokines.^{208,209}

Notch Ligands The human homologue of *Drosophila* Notch was identified as an altered gene product in T-cell leukemia.²¹⁰ The discovery that the hematopoietic microenvironment displays Notch ligands, and that Notch isoforms appear on primitive hematopoietic cells,^{211,212} opened the possibility that Notch affects HSCs. This assertion has been directly proven: The Notch ligands Delta1 and Delta4 expand primitive hematopoietic cells.^{213,214} It is possible that the favorable effect of marrow osteoblasts on HSCs is a result of their expression of Notch ligands, as inhibition of Notch processing blocks the expansion in HSCs seen in mice in which osteoblasts have been experimentally expanded.¹⁵⁸

Wnt Proteins A role for Wnt proteins in hematopoiesis was suggested by their localization at sites of fetal blood cell production and their ability to expand hematopoietic progenitor cells.²¹⁵ Wnt 3a has been shown to expand long-term repopulating HSCs.^{216,217} As Wnt proteins are expressed on primitive hematopoietic cells,²¹⁸ it is also possible that in addition to classical paracrine signaling, Wnts could act in an autocrine fashion in HSC biology.

Transforming Growth Factor β The transforming growth factor (TGF) family of ligands (TGF- β , activins, bone morphogenetic proteins [BMP]) bind to members of the TGF- β receptor family and trigger activation of the SMAD (Sma- and Mad-related protein) group of intracellular mediators.²¹⁹ Unlike the cytokines discussed above, TGF- β members inhibit HSC cycling,^{220,221} and so blunt cell expansion, at least *in vitro*. Nevertheless, the situation *in vivo* is complex; genetic elimination of TGF- β does not alter HSC self-renewal or regeneration *in vivo*,²²² likely because of redundancy in the TGF- β system of ligands.²²³ In contrast, genetic elimination of several of the SMAD proteins disrupts normal HSC homeostasis.^{224,225} Recent data suggests that BMP4 might be the critical member of the TGF family that affects HSC biology.²²⁶

The mechanisms by which these cytokines exert their effects on HSCs are only now beginning to be understood at the molecular level, but it is already clear that effects on the transcription factors that govern HSC survival, self-renewal, and expansion likely play critical roles. It has long been understood that Wnt proteins act to stimulate an increase in intracellular levels of β -catenin, a nascent transcription factor. Upon being liberated from proteasomal degradation in the presence of Wnt, β -catenin translocates to the nucleus and alters transcription of genes displaying the T-cell factor (TCF)/lymphoid-enhancer binding factor (LEF) consensus sequence.²²⁷ Moreover, TGF- β -induced alterations in SMAD protein phosphorylation affects their ability to activate transcription directly.²²⁸ However, most of the cytokine receptors that affect HSCs do not directly affect transcription factors; rather, several cytokines affect signaling pathways that alter the expression, activity, or subcellular localization of HSC transcription factors.

As discussed in "Hematopoietic Stem Cell to Common Myeloid Progenitor Commitment" above, SCL is a helix-loop-helix transcription factor critical for hematopoiesis. SCF enhances the survival of primitive hematopoietic cells in culture by maintaining their expression of SCL,¹³¹ which enhances expression of the SCF receptor c-Kit.²²⁹ Two additional transcription factors that play vital roles in HSC expansion, HOXB4 and HOXA9, are both affected by cytokines. Exogenous expression of HOXB4 to levels only twice normal are associated with a marked and rapid expansion of transduced HSCs on their transplantation into lethally irradiated recipients.¹¹⁶ In both model cell lines and primitive hematopoietic cells TPO doubles the expression of HOXB4, in a p38 MAPK-dependent fashion.²³⁰ Of probably greater significance is the effect of TPO on HOXA9, a gene that also induces rapid expansion of

HSCs on its introduction into these cells, and whose genetic elimination leads to a profound deficit in numbers of HSC *in vivo*.¹¹⁸ Although the hormone fails to affect total cellular levels of HOXA9 in either model cells or primary primitive murine HSC populations, TPO greatly enhances HOXA9 nuclear translocation by inducing expression of its translocation partner, MEIS1, and leading to ERK1/2 MAPK-induced MEIS1 phosphorylation.²³¹

A third mechanism by which cytokines affect HSC expansion is through global inhibitors of signaling. In addition to its direct effects on HSC survival and self-renewal pathways, TPO has been shown to interact with the adaptor protein LNK,²³² which inhibits signaling pathways derived from a broad range of hematopoietic cytokines,^{233,234} including TPO.²³⁵ From these data it appears that TPO and LNK alternately regulate HSC expansion and each other.²³⁶

MATRIX PROTEINS

Fibronectin

FN is a 450-kDa fibril-forming glycoprotein composed of two subunits that is a major component of the hematopoietic microenvironment. FN is produced by both marrow stromal (endothelial cells and fibroblasts) and blood cells,²³⁷ and is implicated in marrow homing of hematopoietic cells.²³⁸ Distinct domains of FN have been identified that interact with different integrins, for example, those for integrin $\alpha_4\beta_1$ and for integrin $\alpha_5\beta_1$.¹⁴⁸ HSCs display multiple integrins and their engagement contributes to cell survival and/or expansion. For example, *ex vivo* culture of human CD34+ cells on FN maintains the repopulating capacity of HSCs, whereas growing the cells in suspension obliterates their ability to repopulate hematopoiesis.²³⁹ FN binding to $\alpha_4\beta_1$ integrins also enhances the generation of large numbers of committed hematopoietic progenitors²⁴⁰ and LTC-IC²⁴¹ from primitive precursors. Multiple molecular mechanisms for the effects of FN on integrin-bearing cells have been identified, and serve as a paradigm for the supportive effects of this entire class of microenvironmental signals.

Integrin engagement by FN triggers a number of intracellular signaling events that affect the cellular cytoskeleton and transcriptional events. Complexes composed of kinases, adaptors, and cytoskeletal components are recruited to sites of integrin engagement, initiated by interactions with integrin cytoplasmic domains.⁸⁹ A critical molecule for integrin-based signaling is paxillin, a 68-kDa protein that contains a number of protein-protein binding domains, and which binds to the cytoplasmic domain of the integrin.²⁴² Additional binding partners also help trigger intracellular signaling, including focal adhesion kinase (FAK) and the closely related Pyk2 kinase. Upon recruitment, FAK and Pyk2 are activated and initiate Tyr phosphorylation of paxillin and other associated molecules, creating additional protein binding sites and activating tethered secondary messenger molecules. One vital signaling pathway downstream of FAK and Pyk2 is PI3K, which is mediated by the association of its regulatory p85 subunit with the adhesion kinases (Chap. 14).²⁴³ FAK also directly activates a pathway that results in upregulation of the cyclin D promoter,²⁴⁴ affecting cell proliferation. Integrin engagement also leads to Src activation, engagement of Grb2, and activation of Ras,²⁴⁵ pathways also activated by SCF and TPO, and potentially providing a mechanism by which diverse extrinsic stimuli of HSCs may converge.

Hyaluronan

Another stromal cell matrix glycoprotein is hyaluronan, which binds to two hematopoietic cell-surface receptors, RHAMM and CD44. Although most CD34+ marrow cells express CD44, only a fraction of them adhere to hyaluronan,²⁴⁶ a process that can be mediated by cytokines, as a result of either increased surface expression of CD44 or an

alteration in its conformation. Consistent with the latter notion, certain epitopes on CD44 have been shown to be inducible,²⁴⁷ and antibodies to CD44 can alter the adherence of CD34+ cells to marrow stroma.²⁴⁸ Nevertheless, other data suggests that RHAMM is the primary receptor for hyaluronan.²⁴⁹ It is also of considerable interest that primitive hematopoietic cells also express hyaluronan, and that it plays an important role in their lodgment in the marrow and subsequent proliferation.²⁵⁰

Heparan Sulfate

LTCs that support hematopoiesis develop a heparan sulfate proteoglycan layer. Immunochemical analysis has shown that marrow stromal cell lines synthesize and secrete numerous members of the syndecan family of heparan sulfate, including glypican, betaglycan, and perlecan.¹⁸ Evidence is accumulating that heparan sulfate-containing proteoglycans may be vital components of the stem cell niche. For example, the structure of the heparan sulfate secreted from stromal cell lines that support long-term hematopoiesis are significantly larger and more highly sulfated than heparan sulfate from nonsupportive stromal cell lines, and when used alone in LTCs, the former can support LTC-IC, whereas desulfated heparan sulfate cannot.²⁵¹

Tenascin

Tenascins are large, extracellular matrix (ECM) glycoproteins found in several tissues, synthesis of which is upregulated in response to tissue regeneration. Tenascins are multimeric proteins composed of numerous modules. For example, tenascin-C is composed of six subunits linked like spokes in a wheel by their C-terminal fibrinogen-like domains, each subunit being composed of multiple epidermal growth factor (EGF)-like and FN type III modules. Two forms of tenascin of molecular mass (Mr) 280 and 220 kDa are also expressed at high levels by marrow stromal cells.²⁵² Marrow cells can adhere to tenascin-C within the fibrinogen-like domain and to two sets of the FN type III-like repeats, and when so engaged, they undergo a proliferative response.²⁵³ Genetic elimination of tenascin leads to modest deficiencies in marrow hematopoietic progenitor cells,²⁵⁴ although as the levels of FN in such mice are also reduced, it is unclear if direct tenascin engagement of hematopoietic cells is responsible, or the defect is a result of the secondary reduction of FN engagement of β_1 integrins.

Laminins

Laminins are heterotrimeric ($\alpha\beta\gamma$) extracellular proteins that regulate cellular function by adhesion to integrin and nonintegrin receptors. At present, 5 α chains, 3 β chains, and 2 γ chains have been characterized, which combine to form at least 12 distinct laminin isoforms.²⁵⁵ Laminins containing γ_2 and either β_1 and α_5 chains are expressed in marrow, but only the latter (laminin-10/11) binds to $\alpha_6\beta_1$ integrin on primitive hematopoietic cell lines²⁵⁶ and to primary human CD34+/CD38- stem and progenitor cells.²⁵⁷ A second, nonintegrin laminin receptor (LR) also binds laminins, as well as other components of the ECM, such as FN, collagen, and elastin, and is composed of an acylated dimer of 32-kDa subunits.²⁵⁸ Although not an integrin, the LR associates with integrins (e.g., integrin $\alpha_6\beta_4$) to modulate laminin binding.²⁵⁹ Functionally, aminin-10/11 facilitates SDF-1 α -stimulated transmigration of CD34+ cells,²⁶⁰ and displays mitogenic activity toward human hematopoietic progenitor cells.²⁵⁵ The nonintegrin LR associates with the GM-CSF receptor (GM-CSF-R) to modulate its signaling properties, down-modulating receptor signaling in the absence of laminin, and releasing the inhibition when bound by its ligand.²⁶¹ This arrangement could provide a novel molecular explanation for how laminins affect cell proliferation; whether this physiology extends to other cytokines that affect HSCs is under investigation.

Collagen Types I, III, V, and VI

Collagen types I, III, IV, and VI have been identified in LTC or *in situ* from marrow sections by a number of methods.^{35,262} Most of the marrow-derived collagen types are assembled into long fibrils, which form the fine, background reticulin staining seen on marrow biopsies, although type IV collagen is assembled into a meshwork seen most commonly as part of basement membranes. Collagens also interact with laminins in the marrow. Collagen types I and VI are strong adhesive substrates for various hematopoietic cell lines and marrow mononuclear cells, including committed myeloid and erythroid progenitors.²⁶² Classic collagen receptors on blood cells are of two types, the β_1 integrins ($\alpha_1\beta_1$ and $\alpha_2\beta_1$) and the nonintegrin glycoprotein VI, present predominantly on platelets.

THE AGING MARROW MICROENVIRONMENT

Like the HSC itself (see “Stem Cell Aging” earlier), the HSC niche undergoes several changes with aging. Although the number of osteoblasts decreases, they generate higher levels of ROS, inducing p38 MAPK signaling, potentially accounting for the reduction in self-renewal capacity of HSCs derived from older mammals. The number of adipocytes increases as a result of the skewed differentiation of aged MSCs; increased adiposity and reduced osteogenesis lead to decreased CXCL12 levels in the aged marrow. This finding could be responsible for altered HSC mobilization in elderly individuals. In contrast, increased levels of the CC-chemokine ligand 5 (CCL5; also known as RANTES [regulated upon activation, normal T-cell expressed and secreted]), in the niche could contribute to the altered myeloid/lymphoid skewing seen in HSCs of older individuals.²⁶³ This topic has been reviewed but clearly requires additional study.¹³⁸

CONTROVERSIES IN HEMATOPOIESIS

LINEAGE FATE DETERMINATION

One of the most contentious issues in hematopoiesis is the origin of stem cell commitment to specific blood cell lineages. Two schools of thought exist: extrinsic and intrinsic control. The former, championed by Metcalf and others,²⁶⁴ argues that cytokines, ECM, or other stimuli instruct the hematopoietic stem or progenitor cell to differentiate into specific cell types. In contrast, Dexter and others²⁶⁵ argue that a hierarchy of transcription factors direct a cell toward a specific lineage, mechanistically explained by a stochastic rise in one or more of a mutually antagonistic set of transcription factors, that drive developmental pathways by enhancing expression of the genes that characterize that pathway, and by interfering with the levels or function of the transcription factors that drive the alternate lineage fate choice.

The Case for Transcription Factors

A strong case has been made for intrinsic control of stem cell lineage determination.²⁶⁵ As Enver and colleagues state: “Simply put, the question is this: Is unilineage commitment the result of a cell-autonomous, internally driven program, or rather is it the consequence of a cell responding to an external, environmentally imposed agenda?” These and several other investigators argue that the stochastic rise in one or another lineage determining transcription factor in the multilineage progenitor leads to its ultimate lineage commitment.

It is abundantly clear that transcription factors can direct lineage commitment in hematopoietic cells. A partial list of transcription factors restricted to specific hematopoietic lineages includes Pax5 (B cells),²⁶⁶ Ikaros (B/T cells),²⁶⁷ PU.1 and C/EBP α (myeloid and B cells),^{268,269} GATA1 (erythrocytes and MKs),^{132,270} Fli1 (MKs),²⁷¹ and C/EBP ϵ (granulocytes).²⁷² A number of loss-of-function studies have

revealed the nonredundant role of these proteins in development of the corresponding cell lineage. For example, genetic elimination of Pax5 eliminates B cells²⁷³; elimination of Ikaros leaves a mouse devoid of fetal T cells, fetal and adult B cells, and their progenitors¹²⁴; and loss of C/EBP α leads to absolute neutropenia.²⁷⁴ Moreover, the exogenous expression of several transcription factors in lineage committed progenitor cells can redirect cell fate. For example, C/EBP α is expressed in myeloid progenitor cells, and introduction of a regulatable C/EBP α gene into purified erythroid progenitors causes their switch to the myeloid lineage.²⁷⁵ In further support of this hypothesis, several lines of evidence have been gathered, including the finding that forced expression of the antiapoptotic gene *bcl₂* in a growth factor-dependent multipotential hematopoietic cell line resulted in growth factor independence and spontaneous differentiation into all of the possible cell lineages that develop when the corresponding growth factor(s) are added to the wild-type cells.²⁷⁶

In addition to providing these and other arguments in favor of a transcription factor–based intrinsic regulatory mechanism of stem cell fate, proponents of the intrinsic hypothesis point to feed-forward switch-like molecular mechanisms in which a stochastic increase in one of a binary set of such transcription factors reduces the level or activity of those transcription factors responsible for alternate cell fates. An example of this physiology is illustrated by the mutually antagonistic effects of the erythroid transcription factor GATA1 and the myeloid transcription factor PU.1; GATA1 acts to inhibit the myeloid activation potential of PU.1,²⁷⁷ and PU.1 blocks the binding of GATA1 to its genetic target sites.²⁷⁸ Thus, when the level of GATA1 stochastically rises above that of PU.1 in a CMP, the granulocyte-macrophage potential would be extinguished and the MEP potential of the cell would march forward, unfettered. Alternately, CMPs in which PU.1 levels rise above that of GATA1 would develop along the myeloid lineages, both through the direct stimulation of myeloid gene expression by PU.1, and indirectly by the blockade of GATA1-mediated erythroid and megakaryocytic gene expression programs.

The Case for Humoral Mediators

Although much evidence has been garnered in favor of an intrinsic mechanism of stem and progenitor cell fate determination, proponents of an extrinsic instructive hypothesis have also generated a large amount of compelling evidence in favor of the importance of extrinsic signals. One illustrative example of the capacity of certain extrinsic signals to impact specific patterns of differentiation is that the exogenous expression of an IL-2R β transgene in CLPs induces their differentiation into myeloid cells.²⁷⁹ Subsequent studies revealed that the presence of the exogenous receptor leads to upregulation of the GM-CSF-R in the CLP, and that exogenous expression of GM-CSF-R could also lead a CLP toward monocyte/macrophage development.² In separate studies, other cytokines were shown to direct myeloid lineage fate determination; compared to the differentiation profile seen when marrow cells were cultured with SCF alone, an antiapoptotic stimulus, the addition of IL-5 greatly enhanced the number of marrow progenitor cells that gave rise to eosinophilic colonies, whereas the addition of TPO induced a predominance of megakaryocytic colonies, without significant changes in the number of apoptotic cells in any of the three culture conditions. These results were interpreted to indicate that while the SCF could keep nearly all progenitor cells alive under the cell culture conditions employed, the second cytokine directed the multilineage progenitors into specific cell fates.²⁸⁰

A number of external signaling events have been found to directly impact the transcriptional apparatus of the cell. For example, as previously noted, two transcription factors that lead to the self-renewal and expansion of HSCs, HOXB4, and HOXA9 are induced to higher levels of expression or to translocate into the nucleus of stem cells in response

to TPO.^{235,236} Moreover, SCL, a transcription factor that when expressed in maturing hematopoietic cells inhibits cytokine-induced granulocytic and monocytic differentiation, maintaining them in an undifferentiated state, is enhanced by SCF and down-modulated by GM-CSF.¹³¹ And the level of *c-Myb*, which determines whether a MEP develops an erythroid or MK fate is affected by TPO, mediated by its induction of miR150.²⁸¹ Thus, strong evidence supporting both extrinsic and intrinsic control of lineage determination has been presented, and like the case for most conflicts in biology, it is most likely that elements of both mechanisms operate in hematopoiesis.

● STEM CELL SURVIVAL, EXPANSION, SELF-RENEWAL, AND DIFFERENTIATION

Like nearly every other cell type, the HSC is subjected to a number of noxious stimuli, and must possess mechanism to survive such insults. Moreover, the regulation of HSC levels is carefully regulated, such as seen following transplantation, through both cell expansion and programmed cell death. The mechanisms that drive HSC survival are beginning to be determined.

A number of cytokines affect cell survival by regulating inhibitors of apoptosis, such as the Bcl proteins. In addition, in response to sublethal DNA damage, cytokines can also act to trigger DNA repair mechanisms. For example, TPO acts to increase the efficiency of DNA-protein kinase-dependent nonhomologous end-joining in response to irradiation or chemotherapy, helping to repair double-stranded DNA breaks.²⁸²

The ability to divide symmetrically to generate identical daughters is a feature of most cells, including HSCs. However, the multipotent stem cell possesses an added ability to undergo asymmetric cell divisions, yielding one committed progenitor daughter and one stem cell daughter, or two differentiating progeny; regulating the balance between symmetric and asymmetric stem cell divisions becomes critical in maintaining proper HSC numbers and in meeting the demand for differentiated cells. The beginnings of the molecular origins of asymmetric division in the HSC are under study.²⁸³

A question related to the previous discussion of whether intrinsic or extrinsic factors determine HSC lineage fate, is whether intrinsic or extrinsic factors determine the possible outcomes for a dividing HSC (two HSC progeny [stem cell expansion], one HSC and one differentiating cell [a self-renewal division], or two differentiating progeny). It is clear that feedback mechanisms exist that govern the size of the stem cell pool, as following myeloablation and transplantation of a limited number of HSCs, the pool expands toward that seen in a normal individual but not beyond, even when subjected to forced overexpression of genes that enhance HSC expansion.²⁸⁴ HSCs do not appear to have a limit on their capacity for expansion; experiments using serial transplantation of marrow cells revealed that even after four such maneuvers the transplantation of a limiting number of HSCs was associated with a 10-fold expansion in the recipient,²⁸⁴ a level of expansion remarkably consistent from one serial transplant to the next. Thus, there does not appear to be an intrinsic limit on HSC expansion that sets the size of the stem cell pool. Rather, evidence from quantitative transplants suggests that there exist both intrinsic and extrinsic controls on the size of the stem cell pool.

Following transplantation the degree to which a limiting number of transplanted HSCs expand depends on the source of the cells; fetal liver cells expand to a far greater degree than a similar number of adult marrow-derived HSCs, indicating that an intrinsic mechanism governs stem cell expansion divisions. However, evidence for an extrinsic mechanism that regulates stem cell expansion also exists, as the transplantation of a smaller number of either fetal liver or adult marrow HSCs

resulted in slower marrow recovery but ultimately greater levels of HSC expansion than did infusion of larger numbers of cells. These results were interpreted to suggest that the more rapid recovery of marrow function associated with the administration of a larger marrow inoculum, with its increased numbers of stem cells, prematurely shut down HSC expansion, calling attention to an extrinsic regulatory mechanism. Moreover, the differences in expansion capacity amongst fetal and adult stem cells might also reflect the influence of extrinsic factors. When adult human marrow cells are transplanted, they retain their stem cell capacity only if quiescent at the time of transfer. In contrast, fetal liver and cord blood stem cells contribute to long-term hematopoiesis regardless of the phase of the cell cycle in which they reside at the time of harvest.²⁸⁶ It is postulated that this latter property of fetal stem cells depends on the fetal hematopoietic microenvironment, making it likely that extrinsic factors play the key role in the decision to self-renew or differentiate. Strong experimental evidence has been generated indicating that stem cell numbers in an individual are governed by the number of hematopoietic niches.²⁸⁷ This data strongly suggests that, at the very least, the availability of stem cell niches places an upper limit upon HSC expansion.

Clues from the developmental biology of lower organisms may also shed important insights into the mechanisms that regulate the decision between symmetric and asymmetric HSC divisions.²⁸⁸ Within the niche of developing *Drosophila* gonadal tissue exist hierarchies of cells. When female gonadal stem cells divide, the cell directly contacting the niche supportive cells remains a stem cell, the daughter that loses contact differentiates and initiates oogenesis. A similar niche architecture also sets the stage for gonadal stem cell retention in the fly testis and in many tissues of many organisms. The developing principle is that a stem cell in contact with the stem cell determining niche stromal cell, or residing in a region of the niche possessing the highest concentration of a stem cell-determining soluble factor, will remain a stem cell, and those removed from contact or soluble factor will differentiate. In such a niche, the axis of stem cell division then determines cell fate; if the axis of cell division is parallel to the front of stem cell-determining contact or soluble mediator gradient, the proximal cell will remain a stem cell while the distal cell differentiates; if the axis of cell division is perpendicular, both cells will remain under the influence of the “stemness” factor(s), and remain stem cells. Consequently, spindle-polarizing signals could be responsible for the fate of the daughters of stem cell division, a focus of much research, but at present, few established mechanisms.

STEM CELL PLASTICITY

A remarkable observation has been repeatedly made in patients who underwent sex-mismatched (male into female) marrow transplantation, suffered subsequent organ damage, and were carefully studied until the time of their death. In such settings, Y chromosome-bearing cells were identified at the site of repair of previous myocardial infarctions, strokes, and other organ damage. These observations suggest that hematopoietic cells can contribute to the replacement of damaged cells of multiple organs. More direct experimentation has lent additional support to this idea; several investigators have found that marrow cells are capable of giving rise to cells of multiple organs, including nerve,^{289,290} liver,^{291,292} skeletal muscle,²⁹³ and cardiac muscle,²⁹⁴ in a process termed *transdifferentiation*. However, direct evidence establishing this conclusion is lacking, as most such studies have assayed only partially purified cell populations that might also contain alternate types of stem cells,²⁹⁵ and almost none have been performed using single cells, a requirement for robust proof of their multipotency. An alternate explanation for the presence of marked hematopoietic cells at nonhematopoietic sites of organ damage has been termed *cell fusion*. It has long been appreciated

that marrow cells (especially macrophages) can fuse with other cells, and spontaneous *in vitro* fusion of embryonic stem cells with marrow-derived cells yields hybrids that display stem cell function^{296,297}; further experimentation is required to prove or disprove the concept of HSC plasticity,³⁰⁰ a proof that will have far reaching implications for regenerative medicine.

HEMATOPOIETIC PROGENITORS

The loss of one or more developmental potentials of the HSC results in a progenitor committed to any number of specific hematopoietic cell lineages. Besides the loss of pluripotency, committed hematopoietic progenitors display a number of characteristics that differ from their parents, including the lack of capacity for self-renewal, a higher fraction of cells traversing the cell cycle, reduced ability to efflux foreign substances, and a change in their surface protein profile. On the genetic level, the transition of HSCs to committed progenitors is marked by the downregulation of a large number of HSC-associated genes and progressive upregulation of a limited number of lineage-specific genes. This section highlights some of the features of specific lineage-committed progenitors that allow for their purification, characterization, and, potentially, their manipulation for therapeutic benefit. Details of the morphologic, biochemical, and genetic aspects of the differentiation of each of these progenitors is found in the chapters corresponding to their mature blood cell types.

PROGENITOR CELL ASSAYS

Assays for most hematopoietic progenitor cells consist of marrow or (occasionally) blood cells, either unfractionated or purified to varying degrees, a semisolid support (either methylcellulose or agar, which prevents cellular migration), and a source of hematopoietic growth factors. The cultures are incubated in a humidified environment at 37°C for 2 to 7 days for murine cells, or 5 to 14 days for human cells, during which time the vast majority of the cells that began culture as mature blood cells die, allowing the few hematopoietic progenitors present to proliferate and differentiate into mature blood cells. As the cells in such culture systems are immobilized by the semisolid supporting matrix, all of the progeny in the resultant colonies are derived from a single progenitor, allowing one to retrospectively determine the developmental capacity of that cell, termed a *colony-forming cell* (CFC) or *unit* (CFU). The requirement for a source of hematopoietic growth factors was initially fulfilled by using cellular underlayers containing fibroblasts, lymphocytes, or monocytes, or tissue culture medium conditioned by a variety of normal and neoplastic cellular sources, but essentially all the requisite growth factors are now available in purified recombinant form. Despite substantial progress in our understanding of the developmental requirements of committed hematopoietic progenitors, we still do not have an adequate *in vitro* colony-forming assay for some well-characterized hematopoietic progenitor cells (e.g., those committed to the T lymphocytic or natural killer [NK] cell lineages) that still require more complex assays (e.g., fetal thymus explant assay).

CHARACTERISTICS OF SPECIFIC PROGENITOR CELL TYPES

Lymphoid Progenitors

Common Lymphoid Progenitors The existence of a population of cells committed to all lymphoid lineages but devoid of myeloid capacity was theorized to exist based on a number of analyses. For example, patients with adenosine deaminase deficiency, or mice with genetic elimination of the γ_c receptor, the signaling kinase JAK3, or the transcription factor Ikaros, lack T and B lymphocytes and have few, if any, myeloid defects,

arguing that the defects in these disorders might affect a CLP; however, this does not prove the existence of a cell common for all. Work using cell sorting for CD10+/CD34+/Thy-/c-Kit-/Lin- human marrow cells revealed the capacity to develop into T, B, NK, and lymphoid dendritic cell progenitors,²⁹⁸ but the report did not demonstrate a common progenitor capable of giving rise to each lineage on a clonal level.

More recent work, based upon the importance of IL-7 for all single-lineage lymphoid progenitor cells, and on the severe lymphopenia seen when the gene was eliminated in mice,²⁹⁹ has indicated that the IL-7R marks a CLP that can be used in flow cytometry to isolate a population of IL7R+/Lin-/Thy-/Sca^{lo}/Kit^{lo} cells that engrafts all of lymphopoiesis but no myeloopoiesis in congenic mice.³⁷ For example, the injection of 2000 such CD45.1+ cells plus 1 × 10⁵ whole-marrow CD45.2+ cells into lethally irradiated CD45.2 recipients lead to 3 to 20 percent CD45.1+ B and T lymphocytes, which disappear after approximately 6 months. In contrast, this strategy never results in the appearance of CD45.1+ myeloid cells. When limiting dilution studies were performed, approximately 1 in 20 such cells could give rise to short-term B-lymphopoiesis when injected intravenously, and an equal number could give rise to T-lymphopoiesis when injected into the thymus. In colony-forming assays using IL-7, SCF, and FL, approximately 20 percent of such cells gave rise to pre-B and pro-B cell colonies *in vitro*. Thus, given the low likelihood of proper homing when injected into mice, it is almost certain that the CLP exists and is IL7R+/Lin-/Thy-/Sca^{lo}/Kit^{lo}. When a genetic expression analysis was performed comparing HSCs to CLPs, the latter demonstrated a down-modulation of many molecules associated with HSCs, such as the cell-surface receptors c-Mpl, β_1 -integrin, and Tie2, and the transcription factors HOXA9 and EGR1, and upregulation of the IL-7R and the recombination activating protein recombination activating gene (RAG) 2.³⁰⁰

T Lymphocyte/NK Cell, T Lymphocyte, and NK Cell Progenitors

Simple colony-forming assays for mixed T/NK cell progenitors have not been developed, but the existence of the bipotent progenitor can be inferred from studies in which CD44+CD25-Fc γ R/III- fetal thymic cells are cultured with genetically marked, deoxyguanosine treated fetal thymic lobes under 70 percent oxygen at 37°C. Without cytokine supplementation, such cultures yield primarily CD3+/Thy1+ T cells, but if IL-2 plus IL-15 are added, the NK cell potential (CD3-/NK1.1+) of these cells is realized, and if IL-7 is also added, the number of single cells that yield cells of both lineages increases significantly.³⁰¹ As this type of readout is possible from single day 12 fetal thymus cells, such studies establish that bipotent T/NK cell progenitors exist.

E box-binding proteins consisting of HEB, E2-2, and the E2A gene products E12 and E47 form a distinct subgroup within the large family of basic helix-loop-helix transcription factors.³⁰² Heterodimers or homodimers form between family members through their helix-loop-helix (HLH) region, and through their basic regions bind to canonical E-box DNA sequences and thereby affect gene expression, including T-cell targets such as CD4³⁰³ and the pre-T α ,³⁰⁴ and assist in recombination of the $\gamma\delta$ T-cell receptors.³⁰⁵ It is now clear that E2A is required for the transition from the bipotent T/NK progenitor to committed T-cell progenitors as its genetic elimination leads to preservation of the former but elimination of the latter.³⁰¹

Another important subgroup of HLH proteins is the Id family, which contain an HLH region but lack a DNA binding domain, thereby acting as a sink for functional HLH proteins and thus negatively regulating the function of E proteins.³⁰⁶ Id proteins appear to be essential for NK cell development, as genetic elimination of Id2 leads to a profound loss of NK cell progenitors³⁰⁷ and forced overexpression of Id3 leads to a shift of T/NK cells preferentially into the NK cell lineage.³⁰⁸

It is also clear that Notch activation plays a vital role in T-cell lineage commitment from the CLP. Overexpression of active Notch1

directs marrow stem cells into immature CD4+/CD8+ T cells and inhibits B-lymphocyte development.³⁰⁹ Overexpression of Notch1 in RAG-deficient precursors also results in differentiation to the T-cell lineage, although only to the immature CD4-/CD8- stage, indicating that Notch cannot substitute for pre-T-cell-receptor signaling.³¹⁰

B-Lymphocyte Progenitors B-cell progenitors include the pro-B cell, the earliest cell irreversibly committed to the lineage, which are CD34+/CD10+/CD38+/CD19+/CD20+, the pre-B cell, which displays the initial stages of immunoglobulin rearrangement, expresses immunoglobulin heavy chains in their cytoplasm and are CD34-/CD10+/CD19+/CD20+/CD38-, and immature B cells which begin immunoglobulin light-chain production, express cell-surface IgM, and are CD10+/CD19+/CD20+. Pro-B cells can be detected in a simple colony-forming assay.³¹¹ Normally, B-cell precursor development occurs in contact with the hematopoietic microenvironment, mediated by precursor cell integrin $\beta_1\beta_1$ and stromal cell VCAM or matrix FN. A number of cytokines affect B-cell progenitor proliferation,³¹² including IL-7,³¹³ insulin-like growth factor (IGF)-1,³¹⁴ SDF-1,³¹⁵ and SCF,³¹⁶ although based on genetic knockout studies, B cells are absolutely dependent only on IL-7²⁹⁹ and SDF-1.²²

A number of cytokines also inhibit B-cell precursor development, including interferon (IFN) α/β ,³¹⁷ IFN- γ ,³¹⁸ IL-4,³¹⁹ and TGF- β .³²⁰ The role of these and other inhibitory cytokines in B lymphopoiesis is complex, as in some situations a cytokine can inhibit one stage and stimulate another stage of development, and some might act indirectly.

A number of transcription factors are required for mature B cell function, including PU.1, nuclear factor- κ B (NF- κ B), early B-cell factor (EBF), interferon regulatory factor 4 (IRF4), and Oct2, many of which bind to the promoters and enhancers involved in immunoglobulin gene expression. In contrast to these relatively later stage effects, E2A is required for commitment to the lineage.³²¹ The marrow of E2A-deficient mice is devoid of CD19 B cells, as well as most B-cell lineage-specific genes, including RAG1/2, Pax5, EBF, and VpreB. Moreover, no immunoglobulin rearrangement is detectable, and there are no IL-7 responsive cells. Reintroduction of E2A into the marrow cells of null mice reconstitutes pre-B-cell development.³²²

E2A sits upon a hierarchy of B-cell lineage-specific genes and transcription factors³²³; E2A directly regulates the expression of RAG1, λ 5, D-J_H, V-J κ , and the transcription factor EBF, the latter, in turn, regulating VpreB, mb-1, D-J_H, V-J κ , and the transcription factor Pax5, which, in turn, regulates CD19 and LEF1 and shuts down genes associated with alternate lineages, such as M-CSF-R (monocytic), myeloperoxidase (neutrophilic), GATA1 (MEP), and pT α (T lymphocytic). As noted earlier in the section "Notch Ligands", a critical condition for B-cell commitment is the absence of Notch signaling.

Myeloid Progenitors

Common Myeloid Progenitors Flow cytometry has also been extensively used to purify myeloid progenitors; an IL-7R-/Lin-/c-Kit+/Sca1- population of murine marrow cells, which by virtue of being Sca1- excludes HSCs, develop into all myeloid lineages.³⁶ Based on expression of CD34 and the Fc γ RII/III, three distinct subpopulations can be identified by further flow cytometry, IL-7R α -/Lin-/c-Kit+/Sca1-/CD34+/FcRy^{lo}, IL-7R α -/Lin-/c-Kit+/Sca1-/CD34-/FcRy^{lo}, and IL-7R α -/Lin-/c-Kit+/Sca1-/CD34+/FcRy^{hi}. When tested in colony-forming assays in the presence of SCF, FL, IL-11, IL-3, GM-CSF, EPO, and TPO, each cell population yielded distinct mature cell types.³⁶ IL-7R α -/Lin-/c-Kit+/Sca1-/CD34+/FcRy^{lo} cells give rise to all myeloid colony types, including CFU-Mix, BFU-E, CFU-megakaryocyte (CFU-MK), MEP, CFU-GM, CFU-granulocyte (CFU-G), and CFU-macrophage (CFU-M), consistent with that expected for the CMP. In contrast, IL-7R α -/Lin-/c-Kit+/Sca1-/CD34+/FcRy^{hi} cells form

only CFU-M⁻, CFU-G⁻, and CFU-GM⁻-derived colonies in response to any of the growth factors, alone or in combination, and thus represent granulocyte/macrophage lineage-restricted progenitors (GMP). Finally, IL-7R α -/Lin-/c-Kit+/Sca-1-/CD34-/FcR γ ^{lo} cells form only BFU-E⁻, CFU-MK⁻, and mixed megakaryocyte-erythroid colonies, leading to their designation as MEP. To demonstrate their capacity to differentiate *in vivo*, limiting numbers of each cell population were transplanted into congenic mice; in such studies, cell fate outcomes corresponded strictly with those of the *in vitro* colony assays. For example, 6 days after injection of 5000 CMPs, both donor-derived Gr-1+/Mac-1+ myelomonocytic cells and TER119+ erythroid cells were detectable in recipients. In contrast, when 5000 GMPs were transplanted, only Gr-1+/Mac-1+ cells were recovered, and only for a transient period of time. Likewise, MEPs reconstituted only TER119+ cells in similar experiments, and the genetically marked progeny from each of these progenitor populations disappear within 4 weeks of transplantation, indicating their limited self-renewal capacity.

Erythroid/Megakaryopoietic, Erythroid, and Megakaryopoietic Progenitors Culture conditions necessary for *in vitro* erythropoiesis have been known for nearly 35 years,^{324,325} with colony morphologies ranging from small compact clusters of 20 to 50 erythrocytes developing with 2 to 5 days in murine and human marrow plasma clot cultures (CFU-E), to large highly complex colonies containing up to thousands of cells taking from 7 to 14 days to develop in methylcellulose or agar (BFU-E). The cytokine requirement for the former is simple—EPO, whereas a cytokine that stimulates earlier cells, such as IL-3 or SCF, is required for the latter progenitor cell type.

Culture conditions that support the proliferation of MK progenitors have been established for both mouse and humans.^{29,31} Using either methylcellulose, agar, or a plasma clot, two colony morphologies that contain exclusively MKs have been described. The CFU-MK is a cell that develops into a simple colony containing from 3 to 50 mature MKs, larger, more complex colonies that include satellite collections of MKs and contain up to several hundred cells are derived from the burst-forming unit–megakaryocyte (BFU-MK). Because of the difference in their proliferative potential and by analogy to erythroid progenitors, BFU-MK and CFU-MK are thought to represent primitive and mature progenitors restricted to the MK lineage. And like their erythroid counterparts, the cytokine requirements for CFU-MK are simple: TPO stimulates the growth of 75 percent of all CFU-MK, with IL-3 being required along with TPO for the remainder,⁷⁷ whereas IL-3 or SCF is required alone with TPO for more complex, larger MK colony formation from their more primitive progenitors.

Progenitors for erythrocytes and MKs display many common features: they share a number of transcription factors (SCL, GATA1, GATA2, NF-E2), cell-surface molecules (TER119), and cytokine receptors (for IL-3, SCF, EPO, and TPO), and most erythroid and MK leukemia cell lines display, or can be induced to display, features of the alternate lineage.³²⁶ Moreover, the cytokines most responsible for development of these two lineages—EPO and TPO—are the two most closely related proteins in the hematopoietic cytokine family,¹⁴⁸ and display synergy in stimulating the growth of progenitors of both lineages.⁷⁷ For these and other reasons it has been postulated that erythropoiesis and megakaryopoiesis share a common progenitor cell,³²⁷ a hypothesis now established³⁶ with the identification of IL-7R α -/Lin-/c-Kit+/Sca-1-/CD34-/FcR γ ^{lo} cells.

Like other primitive hematopoietic cells, bipotent MEP progenitors resemble small lymphocytes but can be distinguished by a specific pattern of cell-surface protein display. As noted above, MEPs are IL-7R α -/Lin-/c-Kit+/Sca-1-/CD34-/FcR γ ^{lo}. Cells committed to the MK lineage then begin to express CD41 and CD61 (integrin α Ib β ₃), CD42 (glycoprotein Ib), and glycoprotein V. Those that are committed

to the erythroid lineage begin to express CD41 and the transferrin receptor (CD71), and as they mature lose CD41 expression but express the thrombospondin receptor (CD36), glycophorin, and, ultimately, globin.³²⁸ These and other cell-surface markers provide experimental hematologists several strategies to purify committed MK^{39,329} and erythroid³³⁰ progenitors. Another useful method to identify megakaryoblasts is histochemical staining for von Willebrand factor, and in rodents, acetylcholinesterase.³³¹

The transcription factors expressed by erythroid and MK progenitors that allow for their commitment to the lineage are becoming increasingly well understood. GATA1 is an X-linked gene encoding a 50-kDa polypeptide that contains two zinc fingers required for DNA binding.²⁷⁰ Genetic elimination of the transcription factor established the critical role of this transcription factor in hematopoiesis; GATA1^{-/-} mice are embryonic lethal as a consequence of failure of erythropoiesis,³³² and MK-specific elimination of GATA1 leads to severe thrombocytopenia as a consequence of dysmegakaryopoiesis.³³³ GATA1 acts in concert with another protein that affects transcription without binding to DNA, friend of GATA (FOG).³³⁴ The importance of this interaction to megakaryopoiesis is clear: several different mutations of the site on GATA1 responsible for FOG binding lead to congenital thrombocytopenia.³³⁵

The Ets family of transcription factors includes about 30 members that bind to a purine box sequence, proteins that interact in both positive and antagonistic ways. For example, PU.1, initially termed Spi-1 based on its association with spleen focus-forming virus-induced erythroleukemias, blocks erythroid differentiation, although it appears important for MK development.³³⁶ Moreover, the Ets factor Fli-1 is essential for megakaryopoiesis³³⁷ and mutations in the transcription factor are also associated with congenital thrombocytopenia in man.²⁷¹

Granulocyte/Monocytic, Granulocyte, and Monocytic Progenitors As noted above, GMPs (CFU-GM) are IL-7R α -/Lin-/c-Kit+/Sca-1-/CD34+/FcR γ ^{hi}, reflecting their beginning differentiation toward phagocytic cells (i.e., FcR γ -positive). In the human, GMP are CD34+/CD33+/CD13+ markers, which are of clinical significance. For example, CD33 is also termed Siglec-2, a member of a family of sialic-acid-binding surface membrane proteins of the immunoglobulin superfamily that are involved in cell–cell interactions and signaling. Although the role of CD33 is not yet known with certainty, it has become a therapeutic target because of its high-level expression on the blasts of several forms of acute myelogenous leukemia³³⁸; the use of gemtuzumab ozogamicin, in which a humanized anti-CD33 monoclonal antibody has been fused to *N*-acetyl-gamma calicheamicin 1,2-dimethyl hydrazine dichloride, a potent antitumor antibiotic, has resulted in a complete remission rate of 15 to 20 percent as a single agent in patients with relapsed disease.³³⁹ These initial successes have prompted its testing in earlier stage disease along with other active agents.³⁴⁰ When marrow grafts are purged of CD33-bearing cells durable engraftment occurs, but is often quite delayed, indicating that CD33 is not present on the HSC, but that the presence of GMPs in a transplantation product is vital for rapid engraftment.

CD13 is also termed *aminopeptidase N*, an ectopeptidase present in many organs other than the marrow, a member of a family of proteases that play an important role in cell growth by virtue of their cleavage of biologically important peptides, in some cases inactivating, and in some cases activating them, and by serving a cell adhesive function as well. CD13 is present on early hematopoietic cells, including myeloid and lymphoid lineage progenitors, but disappears from the latter class of cells and its expression rises as monocytes mature. Although it functions to scavenge peptides in the intestinal brush border and degrade endorphins and enkephalins in the synaptic cleft, its role in hematopoiesis is less clear, although IL-8 is a substrate of its proteolytic activity.

Once bipotent GMPs differentiate, they further restrict their developmental potential. Monocytic progenitors are characterized by a predominance of PU.1, whereas granulocytic cells by members of the C/EBP family—C/EBP α and C/EBP ϵ —are vital for the expression of neutrophil and eosinophil granule proteins.^{272,341} A recent study suggests that the developmental decision of a bipotent GMP into each of the two lineages might be mediated by alterations in the relative levels of PU.1 and C/EBP expression³⁴²; haploinsufficiency of PU.1 (PU.1+/-) results in a reduction in CFU-M frequency in the marrow and an increase in CFU-G levels, even ameliorating the neutropenia seen in G-CSF null mice. Moreover, by increasing expression of C/EBP α , a transcription factor that drives granulocytic differentiation, G-CSF further influences the choice between the granulocytic and monocytic lineages. However, it is also clear that PU.1 plays an important role in both lineages, and it is likely that additional investigation will yield new insights into the molecular mechanisms that establish the ordered process we term *myelopoiesis*.

CHAPTER 19

THE INFLAMMATORY RESPONSE

Jeffrey S. Warren and Peter A. Ward

SUMMARY

The acute inflammatory response is characterized by a rapid but relatively short-lived localized increase in blood flow, an increase in microvascular permeability and the sequential recruitment of different types of leukocytes. Acute inflammation may be followed by “chronic” inflammation and a superimposed series of reparative processes (e.g., angiogenesis, production of extracellular matrix, parenchymal regeneration and scar formation). The early hemodynamic changes at a site of inflammation establish low shear conditions that enable marginated leukocytes to engage in low-affinity selectin-mediated rolling interactions with activated endothelial cells. In response to locally produced soluble and cell surface mediators, endothelial cells and rolling leukocytes sequentially express several sets of complementary adhesion molecules that include selectins, integrins, and members of the immunoglobulin superfamily. Leukocyte and endothelial cell adhesion molecules mediate the high-affinity adhesive interactions necessary for leukocyte emigration from the vascular space along chemotactic gradients. Analogous, temporally regulated, soluble mediators and cellular adhesion molecules also orchestrate succeeding monocyte- and lymphocyte-rich chronic inflammatory responses. This paradigm is modulated by a vast network of surface-active and soluble inflammatory mediators. Recruited leukocytes and cells indigenous to the anatomic site of inflammation both play critical roles in host defense, resolution of inflammation and tissue repair.

HISTORY

The sentinel clinical features of acute inflammation—*rubor*, *calor*, *tumor*, and *dolor*—have been recognized for at least 5000 years.¹ Dr. John Hunter, the renowned late 18th-century Scottish surgeon, observed that the inflammatory response is not a disease *per se* but

Acronyms and Abbreviations: ADAM, a disintegrin and metalloproteinase; BPI, bacterial permeability-increasing protein; CAP37, cationic antimicrobial protein; DARC, Duffy antigen receptor for chemokines; CD, cluster of differentiation; eNOS, endothelial nitric oxide synthase; HEV, high-endothelial venule; HPETE, hydroperoxyeicosatetraenoic acid; ICAM, intercellular adhesion molecule; IFN, interferon; Ig, immunoglobulin; IL, interleukin; iNOS, inducible nitric oxide synthase; LT, leukotriene; $LTB_4/C_4/D_4/E_4$, leukotriene $B_4/C_4/D_4/E_4$; MadCAM, mucosal addressin cell adhesion molecule; MASP, mannan-binding lectin-associated serine protease; MBL, mannan-binding lectin; NADPH, nicotinamide adenine dinucleotide phosphate (reduced); NO, nitric oxide; PAF, platelet-activating factor; PARs, proteinase-activated receptors; PNAd, peripheral node addressin; PSGL-1, P-selectin glycoprotein ligand-1; RGD, arginine-glycine-aspartic acid peptide sequence; TACE, tumor necrosis factor- α converting enzyme; TNF, tumor necrosis factor; VCAM, vascular cell adhesion molecule; VLA, very-late antigen.

rather a nonspecific and salutary response to a variety of insults. Through his microscopic examinations of transparent vital membrane preparations, German pathologist Julius Cohnheim concluded that the inflammatory response is fundamentally a vascular phenomenon. Phagocytosis was described late in the 19th century by Elie Metchnikoff and his colleagues at the Pasteur Institute. Morphologic studies, using both live animals and fixed histologic preparations, transformed our understanding of inflammation and led to the currently held concepts of inflammation-associated hemodynamic alterations, *acute* inflammation and *chronic* inflammation.^{1,2} During the past 5 decades, the modern techniques of biochemistry, tissue culture, monoclonal antibody production, recombinant DNA technology, and the genetic manipulation of isolated cells and whole animals have enabled a more detailed understanding of the cellular and molecular mechanisms which underpin the inflammatory response, the active resolution of inflammation, and the transition to tissue repair and restitution. These studies, in concert with “experiments of nature,” such as chronic granulomatous disease (Chap. 66) and the leukocyte adhesion deficiency disorders (Chap. 66), have permitted the formulation of complex, yet elegant, models of acute and chronic inflammation and led to the promise of incisive therapeutic approaches. A large array of human diseases is marked by either defects in the development of the inflammatory response or the deleterious effects of the inflammatory response itself.

GENERAL CHARACTERISTICS OF INFLAMMATION

It is useful to consider inflammation as an acute or chronic (persistent) process. *Acute* inflammation lasts from minutes to several days and is characterized by pronounced local hemodynamic and microvascular changes and leukocyte accumulation.^{2,3} The acute inflammatory response is consistently marked by microvascular leakage and the accumulation of neutrophils. The four cardinal signs of acute inflammation, alluded to above, can be accounted for within the physiologic parameters of inflammation. The systemic effects of inflammation, particularly acute inflammation, account for the familiar clinical findings of fever, acute-phase response and altered sensorium. In turn, *sepsis* is a systemic inflammatory response syndrome that occurs in response to infection; *severe sepsis* is sepsis complicated by acute organ dysfunction; and *septic shock* is sepsis complicated by either fluid resuscitation-resistant hypotension or by hyperlactatemia.⁴

The *chronic* inflammatory response, which lasts much longer and is more varied in its effects, is marked by growth of new capillaries and proliferation of resident fibroblasts.^{2,3} Cellular infiltrates typically include monocytes and lymphocytes, but there are many variations in the cellular composition, anatomic distribution and tempo of development of chronic inflammatory lesions. Chronic inflammatory processes can be classified according to these variations. For example, granulomatous inflammation is a chronic process marked by nodular aggregates of mononuclear phagocytes that have become “transformed” into epithelioid histiocytes, so-called because of their similar appearance to epithelial cells.² Granulomas may be distributed along blood vessels (e.g., angiocentric), along upper airways (e.g., bronchocentric), or randomly throughout the interstitium or parenchyma of an organ. Granulomas may vary morphologically. Tuberculous granulomas often contain areas of caseous necrosis while sarcoidosis-associated granulomas are often cellular and exhibit fibrosis but usually without areas of necrosis.² Other chronic inflammatory processes are marked by a preponderance of eosinophils or plasma cells. In contrast to the more stereotyped appearance of an acute inflammatory lesion, the particular appearance of a chronic inflammatory lesion can sometimes provide insight into its cause (e.g.,

caseating granulomas in tuberculosis, eosinophil-rich infiltrates in a parasitic infection and plasma cell-rich infiltrates in viral hepatitis).

Superimposed upon acute and chronic inflammatory responses is *repair*.^{2,5} Resolution or termination of the inflammatory response is an important step in the pathway to repair; it occurs through a complex set of regulated processes.⁵ Repair, which may entail the regeneration of parenchymal cells damaged as the result of an insult *per se* or as “bystanders” to the inflammatory response, is characterized by the growth of new capillaries (angiogenesis) and the activation of fibroblasts which produce extracellular matrix molecules (e.g., scar tissue). In some circumstances an inflammatory response is self-limited (e.g., sunburn), whereas in other situations the response may persist for many years (e.g., tuberculous granulomas). The elimination or persistence of an insult has a major influence on outcome—whether ongoing chronic inflammation, complete regeneration or scar formation. There is great complexity in terms of the networks of proinflammatory and anti-inflammatory soluble mediators (e.g., cytokines) and the phenotypes, as well as the functional and regulatory roles of both indigenous cells and recruited inflammatory cells in inflammation, resolution and repair.^{2,3,5–7}

This chapter first addresses acute inflammation, which encompasses localized changes in blood flow, alterations in microvascular permeability and neutrophil exudation.^{2,3} In addition to hemodynamic changes, inflammation encompasses endothelial cell activation, low-affinity leukocyte–endothelial adhesion, high-affinity or stationary leukocyte–endothelial adhesive interactions, leukocyte emigration, leukocyte activation, and the subsequent dampening and resolution of the inflammatory response. The highly regulated migration of leukocytes from the vasculature into sites of inflammation and of lymphocytes through secondary lymphoid tissues and, in turn, into sites of microbial invasion, are pivotal to host defense in the contexts of inflammation and immunity.^{2,3,6} This extraordinary complexity of regulatory processes that control inflammation is exemplified by, but not limited to, proinflammatory cytokines (e.g., tumor necrosis factor [TNF]- α , interleukin [IL]-1 β , IL-6) that drive inflammation, countered by rises in anti-inflammatory cytokines (e.g., IL-4, IL-10, IL-11, IL-13, transforming growth factor [TGF]- β , IL-1ra) and soluble cytokine receptors) that dampen inflammatory responses (see “Cytokines and Chemokines”).^{2,7} Both the termination of an inflammatory process and the transition from an active inflammatory milieu to a wound-healing, tissue-remodeling environment are actively regulated processes. The concept of “active” termination of the inflammatory response, including the roles of chemokine depletion, neutrophil apoptosis, resolvins and protectins, and the shift from interferon (IFN)- γ -driven “classical M1” macrophages to IL-4/IL-13-driven “alternative M2” macrophages, is introduced at the end of the first section of this chapter (M1 and M2 Macrophages). The section “Regulators of the Inflammatory Response” of this chapter introduces (and where appropriate, reiterates) the vast array of soluble and surface-active mediators that regulate both acute and chronic inflammatory responses, as well as some aspects of resolution. These mediators include substances that range from short-lived reactive oxygen and nitrogen intermediates to entire regulatory systems (e.g., complement and coagulation). Many mediators of inflammation have become targets for therapeutic interruption strategies. See section “Chronic Inflammation and Repair.” This chapter provides a framework for understanding the basic processes of inflammation while promoting an appreciation for the highly complex and integrated nature of the regulated inflammatory response.

ACUTE INFLAMMATION

HEMODYNAMIC CHANGES

The hemodynamic changes that occur early in acute inflammation include arteriolar vasodilatation and localized increases in microvascular permeability (Fig. 19–1). In many circumstances, arteriolar

vasodilation follows a rapid and transient period of vasoconstriction.^{2,3} Arteriolar vasodilation results in increased blood flow, thus explaining the familiar redness and warmth that characterize a site of acute inflammation. The increase in blood flow, coupled with increases in microvascular permeability, results in hemoconcentration and increased local viscosity. These hemodynamic changes are critical to subsequent leukocyte emigration because selectin-mediated low-affinity rolling leukocyte–endothelial adhesive interactions occur only under such conditions of low shear force. Experimental studies using *in vitro* flow chambers and transparent vital membrane preparations in live animals indicate that selectin-mediated leukocyte–endothelial rolling adhesive interactions cannot occur in the face of the shear forces that exist under conditions of normal blood flow velocity. Increased microvascular permeability leads initially to protein-poor transudation followed by protein-rich plasma exudation, another characteristic of acute inflammation.² Microvascular leakage occurs through a variety of temporally regulated mechanisms, including rapid, reversible, and short-lived venular endothelial cell contraction attended by widening of intercellular junctions; so-called endothelial cell retraction, which is less-well understood but involves long-lived cytokine-mediated cytoskeletal changes; direct endothelial injury and disruption by physical trauma; leukocyte-mediated endothelial cell injury; and leakage via new capillaries that do not yet possess completely “closed” intercellular junctions.² Increases in rate of transcytosis by which plasma constituents cross endothelial cells in vesicles or vacuoles (vesiculovacuolar organelles) occur in neoplastic blood vessels and may play a role in inflammation.^{2,8} Alterations in local blood flow occur at the level of arterioles, the key to vascular resistance and regulated largely by the autonomic nervous system, nitric oxide (NO) (formerly called endothelium-derived relaxing factor), vasoactive peptides, and eicosanoids. A variety of soluble mediators can induce increases in microvascular permeability through several of the above-mentioned mechanisms.

LEUKOCYTES

The recruitment of leukocytes into a site of inflammation is a fundamental characteristic of the inflammatory response.^{2,3,9} The orchestrated recruitment of particular types of leukocytes into specific tissues, whether sites of acute inflammation, in the course of physiologic lymphocyte recirculation through lymph nodes or in the cellular immune response to microbial invasion, is referred to as *homing*.³ The general mechanisms of leukocyte homing are similar, but the leukocytes and particular mediator molecules vary. For example, neutrophils bind and traverse postcapillary venules in acute inflammation, naïve T lymphocytes bind and traverse lymph node high-endothelial venules (HEVs) in lymphocyte recirculation, and effector and memory T lymphocytes bind and traverse postcapillary endothelial cells in sites of chronic infection.³ The importance of white blood cells in host defense is highlighted in patients with either numerical leukocyte deficiencies or functional defects. Leukocytes are critical because of their central role in the phagocytosis and killing or containment of microbes and in the digestion of necrotic tissue debris. Leukocyte-derived products, such as proteolytic enzymes and reactive oxygen intermediates, contribute to tissue injury.

Leukocyte Adhesion and Transmigration

Vascular stasis that results from the hemodynamic changes of early acute inflammation leads to displacement of leukocytes from the central axial column of circulating blood cells to positions along the endothelial surface. This process, margination, is enhanced under conditions of slow blood flow.^{2,3} Leukocytes adhere transiently and weakly to the endothelial surface. Vital membrane preparations and flow chamber studies using endothelial cell monolayers and suspensions of purified leukocytes have revealed that cells “tumble and roll” along the

Figure 19-1. Early hemodynamic events in acute inflammation. Vascular dilatation, increased microvascular permeability, fluid transudation, and leukocyte recruitment and emigration occur after a transient period of arteriolar vasoconstriction. (Modified with permission from Cotran RS, Kumar V, Collins T, Robbins SL (eds): *Robbins Pathologic Basis of Disease, 6th ed.* Philadelphia, PA: Saunders/Elsevier, 1999.)

endothelial surface.¹⁰ Transient, weak, rolling neutrophil–endothelial adhesive interactions occur within minutes of initiation of an acute inflammatory response and can, depending upon the time point within the evolution of an inflammatory response, involve neutrophils, lymphocytes, monocytes, basophils, or eosinophils. Leukocyte–endothelial cell-rolling adhesive interaction is a specific and necessary step that precedes high-affinity, or so-called stationary adhesion and emigration.^{9–11} Early rolling adhesive interactions are mediated largely by selectins and their carbohydrate-rich counterreceptors.^{2,3,9,10} In turn, the cell-surface expression of selectins (and other intercellular adhesion molecules) is regulated by locally produced proinflammatory mediators.^{9–11}

Selectins contain an extracellular N-terminal carbohydrate-binding region that is homologous to mammalian lectins, an epidermal growth factor-like domain, a series of complement regulatory domains, and a lipophilic transmembrane domain (Table 19-1).^{2,3,9,10} P-selectin is expressed by endothelial cells and platelets, E-selectin by endothelial cells, and L-selectin by most white blood cells. P-selectin is constitutively synthesized and stored in endothelial intracytoplasmic granules (Weibel-Palade bodies).⁹ When endothelial cells are exposed to histamine, thrombin, platelet-activating factor (PAF) or tissue factor, preformed P-selectin is rapidly (within minutes) translocated to the

endothelial surface where it engages marginated leukocytes via carbohydrate moieties that contain sialic acid residues (e.g., P-selectin glycoprotein ligand-1 [PSGL-1]).^{2,3,10,12} This transient, low-affinity, binding interaction accounts in part for the early rolling interactions (Fig. 19-2). The development of single knockout mice (i.e., lacking individual selectins [P-/-; E-/- or L-/-], double knockout mice (e.g., E-/- and P-/-), and even triple knockout mice, has confirmed that leukocyte rolling can be almost completely accounted for by selectins.^{13,14} Exposure of endothelial cells to TNF- α or IL-1 β results in new protein synthesis-dependent expression of E-selectin, a response that occurs within 1 to 2 hours and peaks at 4 to 6 hours.^{2,3,9} As in the case of P-selectin-mediated leukocyte adhesion, E-selectin-mediated adhesion occurs via a series of sialylated and fucosylated carbohydrate moieties related to the sialyl Lewis X and sialyl Lewis A blood group antigens, but found on leukocytes (Table 19-1).^{9,10} Selectin counterreceptors consist of several different mucin-like glycoproteins coated with various sialyl moieties. L-selectin is constitutively expressed by leukocytes, participates in neutrophil and monocyte binding to activated endothelium in inflammatory sites, lymphocyte–endothelial cell homing (e.g., lymphocyte homing to lymph nodes via HEVs), leukocyte–leukocyte adhesive interactions via sulfur-containing mucin-like glycoproteins, and is cleaved from

TABLE 19–1. Adhesion Molecules in Inflammation

Family	Structure	Members	Tissue Distribution	Counterreceptor*
Selectin	N-terminal lectin domain, epidermal growth factor domain, multiple complement regulatory repeats, transmembrane, and short cytoplasmic tail	P-selectin	Endothelium, platelets	PSGL-1, SLe ^x glycoprotein
		E-selectin	Endothelium	PSGL-1, SLe ^x glycoprotein
		L-selectin	Leukocytes	PNAds: GlyCAM-1, MadCAM-1, CD34
Immunoglobulin superfamily	Multiple immunoglobulin domains, transmembrane region and cytoplasmic tail	ICAM-1	Endothelium, other cells	CD11a/CD18
		ICAM-2		CD11b/CD18
		ICAM-3		
		VCAM-1	Endothelium	VLA-4
		CD31 (PECAM)	Endothelium	CD31
Integrin (β_2 ; leukocyte)	Heterodimers: distinct α subunits with common β subunits	CD11a/CD18 (LFA-1)	Neutrophils, monocytes, macrophages, and lymphocytes	ICAM-1
				ICAM-2
				ICAM-3
		CD11b/CD18 (Mac-1)	Neutrophils, monocytes, and macrophages	ICAM-1, iC3b, LPS, and fibronectin
VLA-4	Monocytes and lymphocytes	VCAM-1 and fibronectin		

CD, cluster of differentiation; ICAM, intercellular adhesion molecule; LFA-1, leukocyte function-associated antigen-1; LPS, lipopolysaccharide; PECAM, platelet endothelial cell adhesion molecule; PSGL-1, P-selectin glycoprotein ligand-1; SLe^x, sialyl Lewis X; VCAM, vascular cell adhesion molecule; VLA, very-late antigen.

*"Counterreceptor" refers to a complementary moiety to which a receptor specifically binds. For example, P-selectin binds to PSGL-1.

cells by means of "shedase" enzymes such as a disintegrin and metalloproteinase (ADAM)-17 (TNF- α converting enzyme [TACE]) when the leukocyte is activated (see Table 19–1).^{3,15} The relevant mucin-like glycoprotein counter-receptors on HEVs are collectively referred to as peripheral node addressins (PNAds) and include mucosal addressin cell adhesion molecule (MadCAM)-1, GlyCAM-1, and CD34.^{3,15} L-selectin shedding facilitates leukocyte emigration by allowing the weakly adherent white blood cell to detach from the endothelium. Low-affinity rolling adhesive interactions set the stage for β -integrin- and immunoglobulin superfamily mediated high-affinity adhesive interactions and leukocyte transmigration.^{2,3,9}

Weak selectin-mediated rolling and high-affinity stationary adhesive interactions are not temporally or mechanically completely discrete. For example, TNF- α and IL-1 β both induce E-selectin, which is not expressed by quiescent cells, and both increase endothelial expression of intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1, which are constitutively expressed in

low cell-surface densities.^{2,3} ICAM-1 is involved in the recruitment of all types of leukocytes and VCAM-1 is involved in the recruitment of chronic inflammatory leukocytes (lymphocytes, monocytes, eosinophils, and basophils).^{2,3,9} ICAM-1 binds to β_2 (leukocyte) integrins, which are heterodimeric structures that contain one species of α chain (e.g., CD11a, CD11b, CD11c, CD11d) and a common β chain (CD18).¹⁶ VCAM-1 binds to β_1 integrins (e.g., very-late antigen [VLA]-4/ $\alpha_4\beta_1$) (see Table 19–1).^{2,3} Activated endothelial cells secrete PAF and CXCL8 (IL-8), which activate overlying selectin-bound leukocytes.^{2,3,9,16} Individual leukocyte CD11a/CD18 (LFA-1) heterodimers undergo a transient conformational change and groups of CD11a/CD18 molecules form multimolecular clusters.^{2,3,9} Both the conformational change in CD11a/CD18 and the clustering contribute to increases in binding affinity to endothelial ICAM-1.^{3,16} CD11b/CD18 (Mac-1) binds ICAM-1, ICAM-2, and iC3b (see section "Complement"), the latter of which opsonizes complement-coated particulates. CD11c/CD18 also binds to iC3b and initiates phagocytosis, but plays a lesser role in

Figure 19–2. Leukocyte–endothelial adhesive interactions. Early in the acute inflammatory response, marginated leukocytes engage in transient, low-affinity, selectin-mediated rolling adhesive interactions with endothelial cells. As the response evolves, activated leukocytes and endothelial cells engage in high-affinity, β_2 -integrin- and immunoglobulin superfamily mediated adhesive interactions. A variety of chemotactic factors trigger the motive force for leukocyte emigration.

neutrophil adhesion than do CD11a/CD18 and CD11b/CD18. Intercellular adhesion molecules are found on a variety of cell types other than endothelial cells. The roles of CD11c/CD18, CD11d/CD18, and ICAM-3 in leukocyte–endothelial adhesion are less-well established. β_1 -Integrins, notably VLA-4, are found primarily on chronic inflammatory leukocytes (e.g., lymphocytes, monocytes, basophils, and eosinophils) and mediate leukocyte binding via VCAM-1.^{2,3,9} β_1 -Integrin–mediated adhesive interactions occur via arginine-glycine-aspartic acid peptide sequences (RGDs) displayed by VCAM-1, as well as on exposed surfaces of matrix molecules (e.g., fibronectin). β_2 -Integrin–ICAM-1 and β_1 -integrin–VCAM-1–mediated adhesive interactions occur later (hours to days) in the inflammatory response than do selectin-mediated interactions.

β_1 - and β_2 -integrins are clearly important in leukocyte recruitment into sites of acute and chronic inflammation. Eighteen different integrin α subunits, eight integrin β subunits, and 24 *in vivo* heterodimer combinations have been identified in mammals.¹⁷ In addition to leukocyte–endothelial cell adhesion interactions, integrins function in a variety of other cell–cell and cell–extracellular matrix interactions. A large number of integrin-targeted small molecule, peptide, and designer antibodies have been developed for therapeutic applications.¹⁷ Inflammatory–immunologic diseases treated with integrin antagonists include, among others, multiple sclerosis, Crohn disease, and age-related macular degeneration.

High-affinity stationary adhesive interactions precede leukocyte transmigration across the endothelium into the subjacent interstitium. The functional importance of complementary leukocyte–endothelial adhesive interactions has been clarified by *in vitro* binding studies and *in vivo* studies that have employed neutralizing antibodies directed against adhesion molecules, pharmacologic antagonists of adhesion molecules, and knockout mice.^{2,3} The functional importance of leukocyte integrins (CD11a/CD18, CD11b/CD18, CD11c/CD18) has also been highlighted by clinical and experimental observations in patients with rare genetic leukocyte adhesion deficiencies (Chap. 66).

β_2 -Integrin ICAM-1 and ICAM-2, as well as β_1 -integrin (VLA-4) VCAM-1, induce adhesive interactions that lead to cytoskeletal reorganization in leukocytes that flatten and spread out on the endothelial surface, extend pseudopodia between endothelial cells, and migrate along extravascular chemotactic gradients. Most leukocytes exit the vascular space between adjacent endothelial cells (paracellular transmigration). Paracellular transmigration depends not only on integrin–ligand interactions but also on CD31 (PECAM-1 [platelet–endothelial cell adhesion molecule-1]) expressed on both leukocytes and endothelial cells, and transient reversible disassembly of tight interendothelial vascular endothelial (VE)–cadherin junctional complexes.¹⁸ There is evidence that leukocytes can also exit the vascular space via a less-well-characterized transcellular pathway.

Leukocyte Chemotaxis and Activation

Leukocytes bound tightly to endothelium emigrate from the vascular space into the interstitium by extending pseudopods between intercellular junctions (see Fig. 19–2).¹⁸ Secreted neutral proteases such as elastase, cathepsin G, and proteinase 3, play a role in the passage or “invasion” of leukocytes through the subendothelial extracellular matrix. Collagenases are particularly important in leukocyte transmigration through basement membranes. A variety of matrix metalloproteinases, produced by several cell types, participate in leukocyte migration, and also play roles in resolution of inflammation and tissue remodeling. Leukocyte emigration and subsequent movement through the interstitium follow chemical concentration gradients; processes facilitated by binding interactions between leukocyte integrins and complementary sites on extracellular matrix molecules (e.g., fibronectin).⁹ A wide variety of

soluble mediators can provide the motive trigger for this process.^{2,3,19} Chemotactic factors for neutrophils include peptides derived from bacteria (e.g., *N*-formyl peptides), complement-derived peptides (e.g., C5a), cell membrane-derived chemotactic lipids (e.g., PAF), and cytokines and chemokines produced by a variety of cell types (e.g., CXCL8 [IL-8] from endothelial cells).^{2,3,19} Chemotactic factors vary with respect to their specificity for different types of leukocytes. For example, C5a and *N*-formyl peptides both induce neutrophil and monocyte chemotaxis, and CXCL8 [IL-8] induces neutrophil chemotaxis, whereas CCL2 (monocyte chemoattractant protein [MCP]-1) induces chemotactic responses in monocytes and a specific subset of memory T lymphocytes.³ The Th17 subset of CD4 T-helper lymphocytes secretes IL-17 and IL-22 which participate in the recruitment of neutrophils.³ (There are several species of IL-17, including homodimers IL-17A–IL-17F as well as heterodimeric species.²⁰) Each of these chemotactic factors activates “target” cells by engaging specific cell surface receptors, which, in turn, are linked to the contractile cell motility apparatus.^{3,19}

In addition to chemotaxis, soluble and cell-surface mediators induce leukocyte activation manifested by a wide array of changes in cellular function (e.g., leukocyte integrin upregulation and increased binding affinity [e.g., CD11b/CD18], selectin shedding [e.g., L-selectin], lysosome degranulation, and initiation of the respiratory burst). There have been great advances in understanding of the biochemical pathways involved in chemotaxis, cell activation, and degranulation.²¹ Although there are many nuances in the signal transduction pathways involved in these processes, several themes have emerged. Cell surface receptors are activated by specific ligands (e.g., C5a, leukotriene B₄ [LTB₄], CXCL8 [IL-8] and receptor activation is transduced via specific G proteins and membrane-associated phospholipases, which leads to mobilization of intracellular calcium, influx of extracellular calcium and phosphorylation of series of cytosolic proteins.¹⁹ Rare genetic diseases linked to receptor and effector defects (e.g., IFN- γ receptor defects and nicotinamide adenine dinucleotide phosphate [reduced form] [NADPH] oxidase defects) have provided insight into leukocyte function and the importance of such specific activities in host defense (Chap. 66).

A principal result of neutrophil and monocyte recruitment is provision of large numbers of activated leukocytes that can release lytic substances and reactive oxygen and nitrogen intermediates needed to destroy foreign invaders, and a vehicle to contain foreign particulates through phagocytosis. Some recruited monocytes differentiate into macrophages and recruited effector and memory lymphocytes play pivotal roles in the adaptive immune response.^{3,6} The products and functions of activated inflammatory cells are at once salutary because they contain and destroy invaders and deleterious because they cause tissue damage. The roles of neutrophil apoptosis (programmed cell death) in the termination of acute inflammatory responses and IFN- γ –driven M1 macrophages and IL-4/IL-13–driven M2 macrophages in the transition of an inflammatory milieu to a wound-healing or tissue-remodeling milieu are discussed in “M1 and M2 Macrophages”.

Leukocyte activation, especially of neutrophils and mononuclear phagocytes, results in the secretion of microbicidal peptides (e.g., defensins, bactericidal permeability-increasing protein [BPI], cationic antimicrobial protein [e.g., CAP37]) and lytic enzymes (e.g., myeloperoxidase, elastase, cathepsin G).^{5,21,22} The release of such granular constituents is accompanied by the generation of reactive oxygen and nitrogen intermediates (e.g., O₂⁻, H₂O₂, NO), the generation of arachidonate metabolites (e.g., leukotrienes and prostaglandins) and the production of other proinflammatory mediators (see section “Regulators of the Inflammatory Response”).^{21,22} In some circumstances these mediators are released into phagolysosomes where they contribute to the destruction of engulfed microbes, while in other circumstances they are secreted into the extracellular milieu where

they amplify the inflammatory response and cause tissue damage. The various types of neutrophil granules (primary azurophilic, secondary specific, tertiary gelatinase-containing, and secretory vesicles) are released in a differentially coordinated fashion.^{21,22}

An important recently formulated concept is that of the “inflammasome,” a cytosolic multiprotein complex that is formed in a variety of leukocytes and leads to the generation of IL-1 β via activated caspase-1-mediated cleavage of pro-IL-1 β .²³ Inflammasome formation can be induced by a wide variety of microbial products (e.g., lipopolysaccharide) as well as by other proinflammatory molecules (e.g., urate crystals, damage-associated molecular patterns also known as “alarmins”).²³ Pathogens can activate immune cells via several classes of pattern-recognition receptors, including C-type lectin receptors, toll-like receptors (TLRs), retinoic acid-inducible gene (RIG) 1-like cytosolic receptor and nucleotide-binding oligomerization domain (NOD)-like receptors.^{23,24}

Effective phagocytosis involves three distinct steps: (1) recognition and attachment, (2) engulfment, and (3) degradation (killing in the case of microbes) of the ingested material.^{21,22} Phagocytosis is greatly enhanced when particles (e.g., bacteria) are coated with opsonins, which, in turn, function as ligands for leukocyte surface receptors. The major opsonins include the Fc domains of immunoglobulin (Ig) G and IgM and the complement-derived fragments C3b and iC3b, which are generated via activation of the complement cascades and covalently bound to the surfaces of nearby large molecules and particles (e.g., microbes). There are a variety of Fc receptors (Fc γ RI, Fc γ RII, Fc γ RIIIB, etc.) and complement receptors (e.g., CR1, CR3, CR4) that specifically engage their respective opsonins when the latter coat foreign particulates.⁶ In addition to facilitating receptor-mediated phagocytosis of opsonized particles, Fc receptors trigger cell activation with the attendant release of granular constituents and the generation of reactive oxygen intermediates.⁶ Other important recognition molecules expressed by leukocytes include integrins, the C1q receptor, mannose receptors, scavenger receptors and TLRs.^{6,24,25} Mannose receptors bind to mannose and fucose moieties, which are present on some microbes but not mammalian cells; scavenger receptors bind to a variety of microbes, as well as to oxidized and acetylated low-density lipoproteins; and TLRs bind to a variety of microbial moieties including endotoxins (lipopolysaccharide) and prokaryotic nucleic acids (e.g., double-stranded RNA).^{6,24,25} Humans express at least nine species of TLR, some of which are expressed on external cell surfaces and others on the inner surfaces of endosomes.^{24,25} Some enhanced phagocytic reactions occur independently of opsonins. The engulfment, degradation, and oxidative burst triggered as the result of engagement of FcR is enhanced by the concurrent engagement of complement receptors. In some circumstances, engulfment is enhanced by the simultaneous binding of the leukocyte to specific extracellular matrix molecules (e.g., fibronectin) or soluble cytokines. Engulfment results in the formation of phagosomes, which fuse with lysosomes to form phagolysosomes in which foreign particles are oxidized and degraded. Numerous mechanisms for killing and/or degradation of microbes have been elucidated (Table 19–2). Although these mechanisms are classified as either oxygen-dependent or oxygen-independent, both types of processes may be involved in the destruction of a given microorganism, and a given microorganism may vary greatly in its susceptibility to various mechanisms of destruction.^{6,21,22} Extracellular release of reactive oxygen and nitrogen intermediates, lysosomal enzymes, lipid mediators, and cationic proteins can all contribute to inflammation-related tissue injury.

As noted above, acute inflammation may be followed by chronic inflammation and a superimposed series of reparative processes that can result in resolution or scar formation. Resolution of inflammation was long viewed to be a passive process that included a poorly understood decline in concentrations of proinflammatory mediators

TABLE 19–2. Killing and Degradation of Microorganisms in Phagocytes

Oxygen-Dependent		Oxygen-Independent
Superoxide anion	(O ₂ ⁻)	Arachidonate metabolites (prostaglandins, leukotrienes)
Hydrogen peroxide	(H ₂ O ₂)	Platelet-activating factor
Hydroxyl radical	(HO•)	Lysosomal proteases
Singlet oxygen	(¹ O ₂)	Lactoferrin
N-chloramines	(R-NHC1, R-NCl ₂)	Lysozyme
Hypohalous acids	(HO-X)	Cationic proteins (e.g., bactericidal permeability-increasing protein, major basic protein, defensins)
Nitric oxide	(NO)	
Peroxynitrite	(ONOO ⁻)	

and cells.⁵ It has become clear that the balance between a proinflammatory and an antiinflammatory milieu is regulated by networks of proinflammatory mediators (e.g., proinflammatory cytokines: TNF- α , IL-1 β , IL-6) and antiinflammatory mediators (e.g., antiinflammatory cytokines: IL-4, IL-10, IL-11, IL-13, TGF β , IL-1ra, and soluble cytokine receptors). Clearance of inflammatory cells and mediators is an active process that encompasses leukocyte apoptosis, inactivation and sequestration of proinflammatory chemokines, and egress of leukocytes from sites of inflammation.⁵ Detailed serial biochemical analyses of inflammatory exudates by liquid chromatography-mass spectroscopy have, along with structure-function analyses and *in vivo* animal studies, elucidated the identities of “resolvins” and “protectins,” lipids derived from omega-3 polyunsaturated fatty acids that facilitate resolution of inflammation.^{5,26,27} The recognition of functionally distinguishable macrophages as “classical, IFN- γ -driven M1” phenotype and “alternative, IL-4/IL-13-driven M2” phenotype has provided insight into the transition of an active inflammatory milieu to a wound-healing or tissue-remodeling milieu.^{5,28,29,28} It has become clear that there are several different macrophage phenotypes, a reflection of the great complexity of the transition from active inflammation to resolution and remodeling. Insight into actively regulated termination of inflammation as well as the transition from active inflammation to resolution and remodeling has provided for new therapeutic strategies.

ACUTE-PHASE RESPONSE

The acute-phase response is a stereotyped host response to insults that include trauma, tissue damage, and infection.³ TNF- α , IL-1 β , and IL-6 are consistently produced regardless of trigger. As discussed throughout, these soluble cytokines mediate several proinflammatory processes. (Proinflammatory cytokines TNF- α , IL-1 β , IL-6, and antiinflammatory cytokines are further discussed in “Cytokines and Chemokines.”) TNF- α , IL-1 β and IL-6 act on the hypothalamus to increase the body temperature set point, resulting in fever. Because they are produced endogenously and induce fever in the context of a systemic host response, these mediators have sometimes been referred to as “endogenous pyrogens.” Exogenous pyrogens (e.g., endotoxin or lipopolysaccharide) originate from outside the host but induce TNF- α , IL-1 β , and IL-6. The downstream effects of these cytokines are responsible for several familiar clinical manifestations of infection, including fever, altered

sensorium, and the production of fibrinogen, serum amyloid protein, C3, C4, and C-reactive protein by hepatocytes and other cell types. The biochemical fingerprints of an acute-phase response are revealed through several widely available laboratory tests (C-reactive protein measurement, serum protein electrophoresis). Severe, overwhelming infections attended by high serum concentrations of endotoxin can induce very high concentrations of TNF- α , IL-1 β , and IL-6.⁴ High concentrations of TNF- α are directly responsible for several of the key manifestations of severe sepsis and septic shock (e.g., cardiac suppression, intravascular thrombosis, capillary leakage and insulin resistance).^{3,4}

Interruption of TNF- α has been a therapeutic strategy in localized inflammatory conditions like the joint inflammation (and destruction) of rheumatoid arthritis and bowel wall inflammation in Crohn disease and ulcerative colitis, as well as in severe sepsis and septic shock.³⁰ Anti-TNF- α therapy (via engineered monoclonal antibodies [infliximab and adalimumab] that neutralize TNF- α as well as inhibitory soluble TNF receptors [etanercept]) has been effective in conditions such as rheumatoid arthritis and inflammatory bowel disease, but not in severe sepsis or septic shock in humans.^{4,30} Major adverse events associated with anti-TNF- α therapies include an increased risk of mycobacterial infection, development of autoantibodies (but not autoimmune disease), and injection site inflammation.³⁰ There have been isolated reports of cytopenias, skin cancer and worsened congestive heart failure.³⁰

RESOLUTION OF INFLAMMATION

Since the advent of morphologic examinations of tissue from inflammatory lesions, it has been recognized that resolution of acute inflammation is marked by the disappearance of neutrophils and the engulfment of cellular debris by recruited monocytes and tissue macrophages. It has been relatively recent that resolution of inflammation has been understood to be an active process.⁵ Key aspects of resolution include: (1) cessation of neutrophil influx effected by chemokine inactivation and sequestration; (2) neutrophil apoptosis; (3) functional polarization or switching of macrophages from a proinflammatory (M1) to a wound-healing and tissue-remodeling (M2) phenotype; and (4) the rapid, localized generation of proresolution lipid mediators that include lipoxins, resolvins, and protectins.⁵

INACTIVATION AND SEQUESTRATION OF CHEMOKINES

As described in the preceding section, neutrophil influx into an inflammatory site is in part mediated by locally generated chemokines. The actions of proinflammatory chemokines are terminated as a result of their cleavage into inactive fragments and through sequestration or removal from participation by binding to indigenous nonfunctional decoy receptors or to locally generated decoy receptors. Examples include the cleavage of neutrophil-directed CXC-chemokines within a critical ELR motif by macrophage-derived matrix metalloproteinase 12 and matrix metalloproteinase cleavage of the monocyte-directed CC-chemokine, CCL7.^{5,31} Cleaved CCL7 can still bind its cognate receptors, CCR1, CCR2, and CCR3, but these cells are not mobilized by the truncated version of CCL7.⁵

Chemokine receptors that lack an intact highly-conserved DRY motif, which normally links the receptor to key signal transduction molecules, function as decoy receptors. The best understood of these are the “Duffy antigen receptor for chemokines” (DARC) and D6.⁵ DARC is expressed by endothelial cells at sites of leukocyte egress and binds both CC and CXC chemokines. Functional studies reveal that disruption of DARC leads to increased neutrophil recruitment into sites of inflammation. D6 binds several different CC chemokines, thus rendering them

ineffective. Chemokine decoy receptors can also be derived *in situ* from previously active receptors in sites of inflammation. IL-10 facilitates maintenance of CCR1, CCR2, and CCR5 expression, but induces the functional inactivity of these receptors thus hastening the resolution of inflammation.

NEUTROPHIL APOPTOSIS

Contrary to a long-held belief that extravascular neutrophil life spans are fixed, recent studies suggest that neutrophil life spans can be modulated by local mediators.⁵ Low concentrations of macrophage-derived TNF- α and Fas-ligand prolong neutrophil life span, whereas high concentrations of the same ligands lead to shortened life spans.⁵ The latter results in neutrophil apoptosis via phosphoinositide 3-kinase-triggered oxygen metabolite generation and Btk-NADPH-modulated pathways. Other local regulators of neutrophil apoptosis include oxygen tension-modulated hypoxia-inducible factor 1 α and granulocyte-macrophage colony-stimulating factor (GM-CSF).⁵

In turn, apoptotic neutrophils attenuate inflammation via the secretion of annexin A1, which inhibits the recruitment of additional neutrophils as well enhances neutrophil apoptosis and phagocytosis by macrophages.⁵ Lactoferrin, a neutrophil secondary granule protein, also inhibits neutrophil recruitment and induces apoptosis following its release into the inflammatory milieu. (The effect of lactoferrin on neutrophil survival is influenced by its degree of iron saturation.) Macrophage ingestion of apoptotic neutrophils is called “efferocytosis,” a process directed by distinct “find me” and “eat me” signals.⁵ “Find me” signals include the nucleotides ATP and uridine triphosphate (UTP), fractalkine (CX₃CL1), lysophosphatidylcholine and sphingosine-1-phosphate (S-1-P). The corresponding counterreceptors for these “find me” signals include P2Y2 receptors, CX₃CR1, G2A, and S-1-P₁₋₅ receptors, respectively. This set of “find me/eat me” ligand receptor pairs fits within a larger set of apoptotic cell-efferocyte interactions. In some cases, apoptotic cell “find me” molecules are expressed as a function of apoptosis *per se*, whereas in other cases, existing surface molecules are either modified or linked with mediators that facilitate recognition and ingestion by efferocytes.

M1 AND M2 MACROPHAGES

It was recognized during the 1980s and 1990s that various cytokines can differentially modulate macrophage function.⁵ From original specific observations of an IFN- γ -activated macrophage phenotype and an IL-4-activated macrophage phenotype, emerged the concept of “classical, IFN- γ -activated, M1” macrophages and “alternative, IL-4-activated, M2” macrophages.⁵ Such macrophages are sometimes described as being “polarized” by IFN- γ , IL-4, or other mediators. Several different activated macrophage “phenotype signatures” have been elucidated, a recognition that has led to a series of designations with “M1” and “M2” representing the most extreme differences.⁵ There are several M2 subtypes.⁵ IFN- γ -activated macrophages (M1) produce tissue-toxic radicals (e.g., NO) and proinflammatory cytokines (e.g., TNF- α), whereas M2 macrophages produce less NO and more IL-10 and TGF- β , the latter being important mediators of wound healing and/or tissue-remodeling.⁵ Insight into the role of tissue macrophages in the resolution of active inflammation and the transition to wound-healing and tissue-remodeling has helped foster the concept of inflammation as an actively regulated response.

LIPID REGULATORS: RESOLVINS AND PROTECTINS

The transition from peak acute inflammation, marked by maximum concentrations of neutrophils, toward resolution, is accompanied by

marked changes not only in the local cytokine–chemokine milieu, but also in the lipid milieu. Specifically, there is a shift from high local concentrations of proinflammatory prostaglandins and leukotrienes to antiinflammatory lipoxins, resolvins, and protectins. Basic lipoxin biochemistry is outlined later in the section “Inflammatory Lipids”. Resolvins and protectins, derived from omega-3 polyunsaturated fatty acids, each encompass several classes of related molecules.^{5,26,27} The synthesis of both resolvins and protectins occurs through enzymatic pathways; the mediators themselves exert their effects through specific receptors on neutrophils, macrophages and dendritic cells.^{5,26,27} Antiinflammatory mechanisms exerted by resolvins and protectins are diverse and include enhancement of macrophage-mediated clearance of apoptotic neutrophils, upregulation of cell-surface CCR5 which sequesters proinflammatory chemokines, and the shift of biochemical pathways toward an antiinflammatory phenotype.^{3,26,27} The identification and characterization of both resolvins and protectins has laid the groundwork for new therapeutic strategies to modulate inflammation.^{5,26} Efficacy of several “proresolving lipids” has been reported in animal models of inflammation.⁵ Resolvin E1, a synthetic resolvin analogue (RX-100045), and LXA4-based compounds are under investigation in several human inflammatory diseases.⁵

REGULATORS OF THE INFLAMMATORY RESPONSE

The foregoing sections have provided a conceptual framework for the inflammatory response, specifically, the hemodynamic alterations, mechanisms of specific leukocyte–endothelial adhesive interactions, chemotaxis, leukocyte activation, phagocytosis, intracellular microbial killing mechanisms, active termination/resolution of the acute inflammatory response, and the contributions of M1 and M2 macrophages to inflammation and tissue repair. The many steps that constitute this paradigm are regulated by soluble mediators produced by endothelial cells and leukocytes at a site of inflammation, by other resident cells (e.g., tissue macrophages, fibroblasts, mast cells) and as byproducts of bloodborne proteins (e.g., complement system, coagulation cascade; Table 19–3). There are many examples of “crosstalk” among regulatory systems (e.g., proteinase-activated receptors), complex regulatory networks (e.g., proinflammatory and antiinflammatory cytokine balance), and pleiotropism exhibited by individual mediators (e.g., TNF- α and IL-1 β).

REACTIVE OXYGEN INTERMEDIATES

Since the early 1970s it has been recognized that activated phagocytes exhibit a transient but marked increase in oxygen consumption and the mechanistically coupled generation of reduced oxygen metabolites.³² Although small quantities of reactive oxygen intermediates are produced as byproducts of several metabolic pathways, the chief source is the leukocyte cytosol and membrane-associated NADPH oxidase, an enzyme complex that is defective in most patients with chronic granulomatous disease (Chap. 66). Reactive oxygen intermediates include superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), hydroxyl radical ($HO\cdot$), and singlet oxygen (1O_2).³² These reduced oxygen products play a major role in intraphagolysosomal killing of microorganisms, and when released extracellularly, are directly or indirectly responsible for a variety of proinflammatory processes, including endothelial cell lysis, extracellular matrix degradation, activation of latent proteolytic enzymes (collagenase, gelatinase), inactivation of antiproteases, interaction with metabolites of L-arginine, and generation of chemotactic factors from arachidonic acid and the complement component, C5.³³ In addition to their role in endothelial cytotoxicity, reactive oxygen intermediates are cytotoxic to fibroblasts, erythrocytes, tumor cells and

TABLE 19–3. Inflammatory Mediator Systems

Mediator System	Source	Major Actions
Reactive oxygen intermediates (O_2^- , H_2O_2 , HOX, HO)	Leukocytes, endothelial cells	Tissue damage through cytolysis, matrix degradation, activation of complement, and generation of chemotactic lipids
Reactive nitrogen intermediates (NO, ONOO $^-$, NO $_2^-$, NO $_3^-$)	Monocytes, macrophages, lymphocytes, endothelial cells	Cytostasis of cells, inhibition of DNA synthesis, inhibition of mitochondrial respiration, and formation of OH
Lysosomal granule constituents (proteases, lysozyme, lactoferrin, cationic proteins)	Neutrophils, monocytes	Tissue damage through proteolysis, matrix degradation, and catalysis of oxidant-generating reactions
Cytokines and chemokines (TNF, IL-1, IL-8, MCP-1, etc.)	Monocytes, macrophages, and endothelial cells	Cell activation, induction of adhesion, chemotaxis, fever, and acute-phase response
Platelet-activating factor	Leukocytes, endothelial cells	Vascular permeability and cell activation
Arachidonic acid metabolites (prostaglandins, 5-HPETE, leukotrienes)	Cell membranes (endothelial cells, platelets, leukocytes)	Coagulation, vasodilation, vascular permeability, cell activation, and chemotaxis
Kinins (bradykinin, kallikrein)	Plasma	Pain, vascular permeability, and vasodilation
Vasoactive amines (serotonin, histamine)	Platelets, mast cells, and basophils	Vascular permeability, induction of adhesion
Complement	Plasma, macrophages	Chemotaxis, vascular permeability, and cell activation
Coagulation	Plasma	Chemotaxis, vascular permeability, and complement activation

5-HPETE, 5 hydroperoxyeicosatetraenoic acid; IL, interleukin; MCP-1, monocyte chemoattractant protein-1; TNF, tumor necrosis factor.

many types of parenchymal cells.³³ Implicated biochemical mechanisms include lipid peroxidation, formation of carbonyl moieties and nitrosylation products, intracellular enzyme inactivation, protein oxidation, and oxidant-mediated DNA damage. Reactive oxygen intermediates (e.g., O_2^-) can also undergo reactions with reactive nitrogen intermediates (e.g., NO; see “Reactive Nitrogen Intermediates” below) to generate toxic NO derivatives.³³ Within limits, host cells are protected by antioxidant defense systems (e.g., superoxide dismutase, catalase, reduced glutathione).³³

REACTIVE NITROGEN INTERMEDIATES

Described in 1980 as “endothelium-derived relaxing factor,” NO is the soluble, gaseous, short-acting biosynthetic product of L-arginine, O_2 , NADPH, and NO synthase (NOS).³⁴ As suggested by its original name, NO mediates vascular smooth muscle relaxation. NO binds to the heme moiety of guanylyl cyclase to trigger the generation of intracytoplasmic

cyclic guanosine monophosphate (cGMP) and, through the activation of a series of kinases, induces smooth-muscle relaxation and vasodilation.³⁵ Three different forms of NOS have been characterized: endothelial (eNOS), neuronal (nNOS), and inducible (iNOS).³⁵ Nitric oxide can be produced either constitutively (eNOS, nNOS) or induced (iNOS) in a wide variety of cell types (e.g., endothelial cells, neurons, macrophages, respectively). Nitric oxide produced by eNOS plays a particularly important role in the localized regulation of vascular tone, whereas NO derived from nNOS is important in neuronal signal transduction. NO also plays important roles in the inhibition of smooth-muscle proliferation and in inflammation. The roles of NO in inflammation include inhibition of cell-mediated inflammation, reduction in platelet aggregation and adhesion, and as a regulator of leukocyte recruitment. Specifically, NO produced by cytokine-iNOS reduces leukocyte recruitment into sites of inflammation. NO can react with reactive oxygen intermediates to form both reactive oxygen and nitrogen species (e.g., $\text{NO} + \text{O}_2^- \rightarrow \text{NO}_2^- + \text{HO}\bullet$); it can inhibit DNA synthesis; it can directly kill microbes and tumor cells; and it can inactivate cytosolic glutathione and other sulfhydryl enzymes. NO and its generating enzymes, eNOS, nNOS, and iNOS, represent a regulatory system that has varied effects on the inflammatory response depending upon location and setting.

LYSOSOMAL GRANULE CONSTITUENTS

The activation of neutrophils, monocytes and macrophages results in the release, either through exocytosis or as the result of cell death, of a wide variety of proinflammatory mediators that have important roles in the inflammatory response. Neutrophils contain three major types of granules and also secretory vesicles (Chap. 60). Large, primary (azurophilic) granules contain myeloperoxidase, lysozyme, a variety of cationic proteins, defensins, phospholipase, acid hydrolases and neutral proteases (e.g., proteinase 3, collagenases, elastase). Smaller, secondary (specific) granules contain lactoferrin, lysozyme, type IV collagenase, subunits of NADPH oxidase and the β_2 -integrin, CD11b/CD18. Tertiary granules contain gelatinase, subunits of NADPH oxidase and CD11b/CD18. Acid proteases function most efficiently within phagolysosomes where the pH is low, whereas neutral proteases can function efficiently within extracellular inflammatory exudates. Lysosomal granule constituents contribute to the inflammatory response and tissue injury through a wide array of mechanisms (e.g., degradation of extracellular matrix, proteolytic generation of chemotactic peptides and catalysis of reactive oxygen metabolite generation).

CYTOKINES AND CHEMOKINES

Cytokines are proteins that exhibit a variety of proinflammatory and antiinflammatory effects. They are produced by many cell types and modulate the function of other cell types. Individual cells may produce many different cytokines, and an individual cytokine may exert a wide variety of effects; they are pleiotropic.^{2,3,6} In addition to their important roles in regulating various aspects of the immune response (e.g., lymphocyte activation, proliferation, and differentiation), many cytokines participate in innate immunity (e.g., TNF- α , IL-1 β , IL-6, type I interferons), mediate the acute-phase response (TNF- α , IL-1 β , IL-6), activate inflammatory cells (e.g., IFN- γ) and participate in hematopoiesis (e.g., IL-3, granulocyte-monocyte colony-stimulating factor, granulocyte colony-stimulating factor, macrophage colony-stimulating factor).^{2,3} Among the most thoroughly characterized cytokines are TNF- α and IL-1 β , which are structurally dissimilar but share many biologic activities and can function as autocrine, paracrine and endocrine mediators of inflammation (Table 19-4).^{2,3} TNF- α and IL-1 β are produced by various cell types and are pleiotropic. Particularly important functions in inflammation include endothelial, leukocyte and fibroblast activation.

Induction of IL-1, IL-6, IL-8
Procoagulant phenotype
Inhibition of fibrinolysis
Leukocyte adherence
Fibroblast activation
Proliferation
Collagen synthesis
Collagenase and protease induction

Elevated local (and sometimes systemic) concentrations of TNF- α , IL-1 β , and IL-6 are consistently observed during the development of an inflammatory response. Based on their roles in the systemic acute-phase response and in the orchestration of important localized mechanistic steps in inflammation (e.g., induction of endothelial leukocyte adhesion molecules, phagocyte activation, procoagulant mediator induction), these mediators are prototypic “proinflammatory” cytokines. Their expression is regulated by nuclear factor κB (NF κB). NF κB is a transcription factor that exists as a heterodimer complexed with I κB (inhibitor κB) in the cytosol of many different cells types.^{3,6} When cells are activated by various microbial products, viruses, reactive oxygen intermediates, cytokines, and chemotherapeutic agents, I κB is phosphorylated before it dissociates from NF κB heterodimers. Unbound NF κB translocates into the cell nucleus where it participates in the upregulation of as many as 200 different genes, including TNF- α , IL-1 β and IL-6.

The proinflammatory cytokines and their activities are counterbalanced by a wide variety of “antiinflammatory” cytokines, including IL-4, IL-10, IL-11, IL-13, TGF β , IL-1ra, and several soluble cytokine receptors.^{2,3,7} IL-4, a 20-kDa peptide produced by CD4 Th2 cells, inhibits IL-1 β synthesis and induces IL-1ra (IL-1 receptor antagonist). Soluble IL-1ra binds IL-1 β (and IL-1 α), preventing their binding to IL-1 receptors. IL-10 is also secreted by CD4 Th2 cells (and regulatory T cells, monocytes, and macrophages). Acting through its cognate receptor, IL-10 suppresses the expression of proinflammatory cytokines, adhesion molecules, chemokines, and cell-surface activation molecules of neutrophils, monocytes, macrophages, and T lymphocytes.⁷ IL-10 also induces the shedding of TNF- α receptors, which then function as soluble TNF- α antagonists. IL-11, IL-13, and TGF β also each exert a set of activities that counter the proinflammatory actions of TNF- α , IL-1 β , and IL-6. Recognition of the many counterbalancing actions between proinflammatory and antiinflammatory cytokines has led to the concept of “proinflammatory-antiinflammatory cytokine balance.” This concept is the basis for rational therapeutic strategies to manipulate or “reset” this balance.

TNF- α , IL-1 β , and IL-6 are key proximate mediators of the “acute-phase response.” Stimuli such as bacterial endotoxin (lipopolysaccharide), exotoxins, immune complexes and physical stimuli (e.g., heat or

trauma) can induce macrophages (and other cell types) to secrete TNF- α , IL-1 β , and IL-6.^{2,3,7} In turn, TNF- α , IL-1 β , and IL-6 mediate fever, somnolence, increased production of proteins such as α_1 -antitrypsin (α_1 -antiprotease) and α_2 -macroglobulin, and decreased production of proteins such as albumin and transferrin. As noted, the acute-phase response is a stereotyped host metabolic response to a wide variety of insults. In addition to the systemic acute-phase response, TNF- α and IL-1 β induce endothelial activation marked by increases in leukocyte adherence and a procoagulant state, leukocyte activation marked by cytokine secretion, and fibroblast activation marked by proliferation, collagen synthesis, and collagenase production.^{2,3,7} These actions are critical components of inflammation and wound healing; they exemplify the linkage between the inflammatory response and the coagulation system.

TNF- α , originally identified as “cachexin or cachectin” because of its role in the systemic wasting that accompanies some chronic infections and cancer, can induce cytokine production in a variety of cells.^{2,3} TNF- α can induce neutrophil activation and the expression of adhesion molecules on endothelial cells. In contrast to IL-1 β , TNF- α also possesses potent cytotoxic activities for some types of cells. Both IL-1 β and TNF- α are produced in response to endotoxemia and both can mediate a systemic shock-like response.

IL-1 β , which exhibits a wide variety of biologic activities, was initially termed *endogenous pyrogen* because of its ability to induce temperature elevation and the acute-phase response.^{2,3,6} IL-1 β is relevant to acute inflammation because of its ability to induce cytokine production in monocytes, macrophages, fibroblasts and endothelial cells. IL-1 β can also induce NOS.³⁶ As noted previously, IL-1 β can activate endothelial cells, resulting in the expression of adhesion molecules and a procoagulant phenotype.^{2,3,6}

IL-6 participates in the acute-phase response through the induction of proinflammatory mediators production by hepatocytes, via the differentiation of CD4 T lymphocytes that produce IL-17 and through the induction of marrow neutrophil production.^{2,3} IL-6 is produced by a variety of cell types following activation by TNF- α , IL-1 β , and pathogen-associated molecular patterns (PAMPs) such as lipopolysaccharides (endotoxin), mannans, flagellin, and microbial nucleic acids.^{3,6}

Chemokines, or “intercrines,” are small proteins, which, in addition to many of the general properties of cytokines, exhibit prominent chemotactic activities.^{3,6,37} Chemokines are grouped into four classes based on the amino acid sequence positions of conserved cysteine (C) residues in mature peptides.^{6,37} The four classes include CC, CXC, XC, and CX₃C chemokines. There are four families of corresponding chemokine receptors: CCR, CXCR, XCR, and CX₃CR, respectively. Nomenclature

of chemokines is based on the locations of N-terminal cysteine residues whereby “CC” indicates two adjacent residues, “CXC” indicates two cysteine residues separated by one intervening amino acid, and so on. Individual chemokines contain the letter “L” for ligand, followed by individual numbers (e.g., CCL1, CCL2, CCL3, etc.); more than 40 have been identified. The two most studied subfamilies include the alpha, or “CXC” chemokines, and the beta, or “CC” chemokines. Alpha chemokines, of which IL-8 (CXCL8) is the prototype, consistently exhibit neutrophil chemotactic activity, whereas the beta, or “CC” chemokines, of which MCP-1 (CCL2) is the prototype, exhibit monocyte chemotactic activity (Table 19–5).^{37,38} Both *in vitro* and *in vivo* studies have provided insight into the roles of chemokines in inflammation. For example, MCP-1 knockout mice (MCP-1 $-/-$) exhibit reductions in monocyte influx into sites of experimentally induced peritonitis and delayed-type hypersensitivity.³⁹ Complementary studies using knockout mice devoid of the MCP-1 receptor CCR2 do not form typical granulomas.³⁹ These types of studies, as well as many that have employed specific chemokine-neutralizing antibodies or soluble chemokine receptor antagonists, have provided valuable insight into the pathophysiology of inflammation. Seemingly contradictory experimental results suggest that leukocyte recruitment mechanisms are multiple, overlapping or redundant, and not completely understood. Chemokine receptors noted above (CCR, CXCR, etc.) activate leukocytes through membrane receptors (sometimes called “serpentine” receptors) that contain seven transmembrane domains and are linked to cytosolic heterotrimeric G proteins.^{3,6}

INFLAMMATORY LIPIDS

Lipid mediators of inflammation, commonly derived from cell membrane precursor molecules, can act either intracellularly or extracellularly, the latter in a short-lived, localized manner.⁴¹ Arachidonic acid, a 20-carbon polyunsaturated fatty acid (5,8,11,14-eicosatetraenoic acid) derived either from dietary sources or by conversion from linoleic acid, is maintained in cell membranes as an esterified phospholipid. Three families of inflammatory mediators derived from arachidonic acid are generated via the cyclooxygenase and lipoxygenase pathways. Arachidonic acid is released from membrane phospholipids via cellular phospholipases such as phospholipase A₂. Phospholipase activation is triggered by mechanical/physical or chemical stimuli. Arachidonic acid can be metabolized via the cyclooxygenase pathway to prostaglandins (e.g., PGG₂, PGH₂, PGD₂, PGE₂, PGF₂), prostacyclin (PGI₂) or thromboxane (TXA₂).⁴¹ Prostacyclin mediates vasodilation and the inhibition of platelet aggregation; thromboxane has the opposite effects; and PGD₂, PGE₂, and PGF₂ mediate vasodilation and edema. Activation

TABLE 19–5. Chemokines

Family	Members	Abbreviation(s)	Primary Target Cell(s)
α -Chemokines (CXC)	Interleukin-8	IL-8	Neutrophils
	Platelet factor 4	PF4	Neutrophils
	Melanocyte growth-stimulatory activity	MGSA or GRO α	Neutrophils
	Neutrophil-activating peptide-2	NAP-2	Neutrophils
	γ -Interferon-inducible protein	γ -IP-10	Neutrophils
β -Chemokines (CC)	Monocyte chemoattractant protein-1	MCP-1/MCAF or JE	Monocytes, basophils
	Regulated on activation, normal T-cell expressed and presumably secreted	RANTES	Monocytes, eosinophils, basophils
	Macrophage inflammatory protein-1 α	MIP-1 α	Monocytes, eosinophils
	Macrophage inflammatory protein-1 β	MIP-1 β	Monocytes

of the lipoxygenase pathway results in the synthesis of 5-hydroperoxyeicosatetraenoic acid (5-HPETE), which is a potent chemoattractant of neutrophils and can be enzymatically modified to yield a series of other leukotrienes. LTB_4 induces neutrophil chemotaxis, aggregation, degranulation, and adherence, while LTC_4 , LTD_4 , and LTE_4 trigger smooth-muscle constriction, increases in vascular permeability and bronchoconstriction.⁴¹ Members of both of these families of lipid-derived mediators and their catabolites have been detected in inflammatory exudates. There are two important branches within the lipoxygenase pathway.^{41,42} Lipoxins (A_4 [LXA_4] and B_4 [LXB_4]) are generated via the 12-lipoxygenase branch of the lipoxygenase pathway in conjunction with a unique transcellular biosynthetic pathway.⁴² Neutrophils generate LTA_4 via the 5-lipoxygenase pathway branch; in turn, lipoxins (LXA_4 and LXB_4) are generated through the action of platelet 12-lipoxygenase on neutrophil LTA_4 . Prevention of neutrophil-platelet binding interrupts this pathway. Lipoxins inhibit neutrophil chemotaxis and adhesion to endothelium.⁴² As noted above, resolvins and protectins each encompass several molecular species—all derived from omega-3 polyunsaturated fatty acids.^{26,27}

PAF is a potent proinflammatory lipid produced by a variety of cell types, including neutrophils, monocytes, endothelial cells and IgE-sensitized basophils.⁴³ Derived from the cell membrane constituent, choline phosphoglyceride, PAF is an acetyl glycerol ether phosphocholine that is synthesized following the activation of phospholipase A_2 . PAF triggers platelet aggregation and degranulation, increases vascular permeability, and promotes leukocyte accumulation and activation. *In vivo* studies using specific PAF antagonists have suggested a role for PAF in a variety of acute inflammatory lesions.⁴³

KININS

The kinin system is activated by contact activation of clotting factor XII (Hageman factor) (Chaps. 113 and 114).⁴⁴ Activation of the kinin system results in the generation of bradykinin, a nine-amino-acid vasoactive peptide. Bradykinin possesses several activities, including the capacity to increase vascular permeability, induce smooth-muscle contraction, trigger vasodilation, and cause pain.⁴⁴ Activated Hageman

factor (factor XIIa), also known as the prekallikrein activator, converts plasma prekallikrein to kallikrein. In turn, kallikrein cleaves high-molecular-weight kininogen to produce bradykinin. Models of septic shock reveal decreases in plasma kininogen that parallel decreases in peripheral arterial resistance.⁴⁴

VASOACTIVE AMINES

Histamine and serotonin (5-hydroxytryptamine) are low-molecular-weight vasoactive amines. Histamine is contained in mast cell and basophil granules, whereas platelets are a chief source of serotonin.⁴⁵ Localized release of histamine results in wheal formation as a consequence of increases in vascular permeability. Histamine induces the formation of reversible openings in endothelial tight junctions, triggers the formation of prostacyclin by endothelial cells and induces NO release from the endothelium. In addition, histamine, like thrombin, can induce the rapid upregulation of endothelial P-selectin.⁴⁵ Serotonin, acting through receptors on vascular smooth-muscle cells, is responsible for vasoconstriction, whereas interaction with endothelial receptors results in vasodilation (via release of NO) and increased permeability.² Release of histamine and serotonin from mast cells and platelets can be triggered by IgE-mediated type I hypersensitivity reactions, directly by C3a or C5a, and directly by neutrophil granule-derived cationic proteins.

COMPLEMENT

The complement system, including its soluble and cell membrane-associated regulators, consists of nearly two dozen plasma proteins that give rise to mediators of chemotaxis, increased vascular permeability, opsonic activity, phagocyte activation, and cytolysis.⁴⁶ In a manner analogous to coagulation, the complement system is activated through a cascade of proteolytic cleavage reactions. There are three convergent pathways (Fig. 19–3). The first of these, the “classical pathway,” is initiated primarily (but not exclusively) by complement-fixing immune complexes (IgG subclasses 1 to 3 and IgM), whereas the second, the “alternative pathway,” is triggered by a variety of substances that include

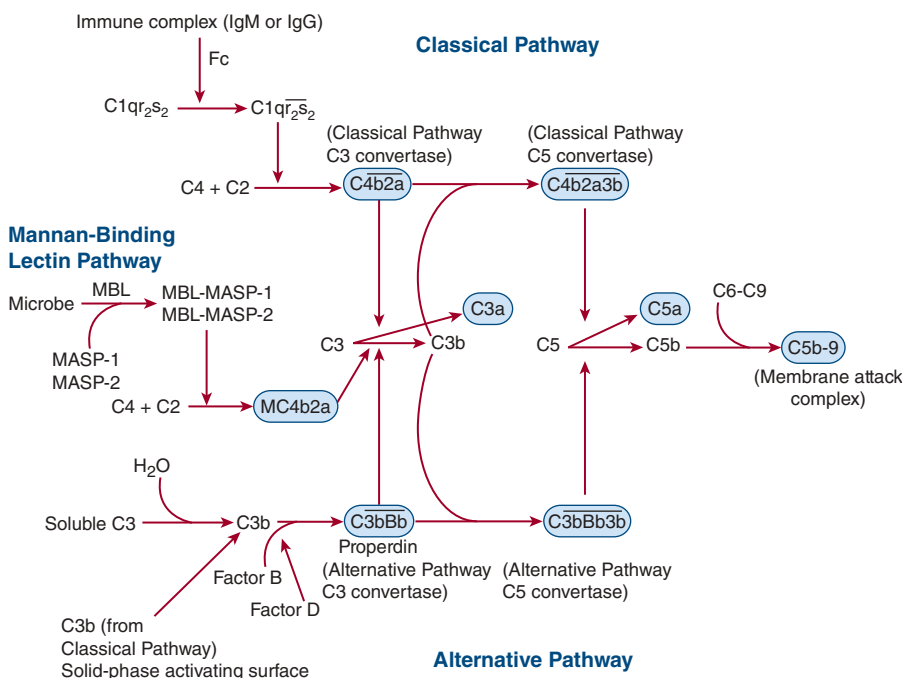

Figure 19–3. The complement system. The complement system consists of a series of soluble and surface-associated mediators that are functionally organized into the classical, alternative, and mannan-binding lectin (MBL) pathways. The three pathways of complement converge and lead to the production of the pore-forming membrane attack complex. The classical pathway is most often activated by IgG- and IgM-containing immune complexes, the alternative pathway can be activated by a variety of carbohydrate-coated particulates, and the MBL pathway also by various carbohydrate-coated surfaces. In all three cases, complex multicomponent enzyme complexes, called C3 and C5 convertases, are formed. A variety of soluble proinflammatory peptide fragments (e.g., C3a, C5a) are generated as a result of complement activation.

IgA aggregates, endotoxin, cobra venom factor, and polysaccharide moieties found on some bacterial and fungal cell walls. The third pathway, the “mannan-binding” lectin (MBL) pathway, is activated when MBL binds to a microorganism coated with certain carbohydrate moieties (e.g., mannans). Upon binding, MBL activates MBL-associated serine proteases (e.g., MASP-1, MASP-2) which function in a manner analogous to C1r and C1s of the classical pathway. MBL recognizes carbohydrate moieties infrequently present in mammalian hosts, thus constituting a system for recognizing foreign particulates. As such, the alternative and MBL pathways are considered to be part of the innate system of host defense.⁶ The classical pathway is initiated by the fixation of C1 (C1q_rs₂) by the Fc portion of surface-bound IgG or IgM immunoglobulins. Activated C1 (C1q_rs₂) cleaves C2 and C4, which leads to the formation of the “classical pathway” C3 convertase, C4b2a. Activation of the alternative pathway results in the formation of an “alternative pathway” C3 convertase following direct cleavage of C3 and subsequent interactions of C3b with factors B and D in the presence of Mg²⁺. The resulting complex, C3bBb, is stabilized by properdin, leading to the stable C3 convertase, C3bBbP. C3 convertases generated via any of the three pathways efficiently cleave C3 to form C3a and C3b.

These enzymatic reactions exhibit high activity levels, thus serving to dramatically amplify the cascade. C3b can bind to either the classical or alternative pathway C3 convertase to form a C5 convertase, which cleaves C5 into C5a and C5b. C5a is released into the fluid phase, like C3a, whereas C5b combines first with C6 and then C7 to form C5b-7, which, in turn, binds with C8 and multiple C9 molecules to form C5b-9, the membrane attack complex. In addition to the cell-activating and cytolytic activities of C5b-9, individual complement cleavage products and complexes mediate a variety of specific and potent proinflammatory activities.⁴⁶ These functions, combined with the rapid amplification in numbers of complement-derived mediators, emphasize the vital role of complement in acute inflammation. The most important activation products of complement appear to be C5a, a major chemotactic factor, and the anaphylatoxins (C3a, C4a, C5a), of which C3a is the most abundant. C5b-9 is a major cytotoxic product, provided that this complex is assembled on the surface of a susceptible cell (e.g., bacterium).

A series of soluble and cell membrane-associated complement proteins play important roles in the regulation of the complement cascade.⁴⁶ The pivotal regulator of the proximal arm of classical pathway is C1 esterase inhibitor (C1E-INH), a serine protease inhibitor that covalently bonds to the activated esterase subunits of the C1qrs complex thus preventing activation of the downstream zymogen cascade.⁴⁶ Defects in C1E-INH, from genetic defects or those acquired (e.g., neutralizing antibodies against C1E-INH), can result in angioedema. Angioedema can manifest in a variety of ways including as life-threatening laryngeal soft tissue swelling.

COAGULATION SYSTEM

The coagulation system is reviewed in detail in Chaps. 113, 114, and 116. The interrelationships among the coagulation system and several inflammatory mediator systems are important in the context of host defense and the pathophysiology of septic shock.⁴ Activation of the clotting cascade results in the generation of fibrinopeptides which increase vascular permeability and are chemotactic for leukocytes. Thrombin and tissue factor induce endothelial expression of P-selectin, resulting in increased neutrophil adhesion.¹² In addition, plasmin is responsible for the activation of Hageman factor, which then can activate the kinin system and can cleave C3 into its active components.⁴⁴ It can also generate “fibrin-split” or “fibrin-degradation” products. The induction of tissue factor in endothelial cells exposed to TNF- α and IL-1 β further links the coagulation system to the inflammatory response.

PROTEINASE-ACTIVATED RECEPTORS

Proteinase-activated receptors (PARs) define an important general mechanism that links several seemingly disparate regulatory systems involved in inflammation.⁴⁷ PARs subsume a G-protein-coupled receptor subfamily defined by a common activation mechanism.⁴⁷ Individual PARs include an N-terminal extracellular domain, seven transmembrane helices connected by three intracellular and three extracellular loops, and linkage to cytosolic G-protein-mediated signal transduction pathways.⁴⁷ PARs are activated when extracellular proteinases cleave the N-terminal extracellular domain at a specific site which results in the creation of a “tethered ligand.” The tethered ligand is the residual, now unmasked N-terminal portion of the PAR; it interacts with the nearby nontruncated extracellular PAR domain and activates the receptor. The PAR family possesses of four members: PAR₁, PAR₂, PAR₃, and PAR₄. The extracellular domain of each PAR possesses several potential cleavage sites. For example, the canonical PAR₁ tethered ligand sequence created after cleavage by thrombin is the amino acid sequence, SFLLRN.⁴⁷ A wide variety of proteinases that are pivotal in inflammation, thrombosis, hemostasis, and wound healing (as well as in development and cancer progression) can activate PARs. PAR₁, PAR₃, and PAR₄ are susceptible to cleavage by thrombin. Other coagulation system-related proteinases, such as factor Xa, activated protein C, plasmin, and kallikreins can also activate PAR₁. Likewise, PAR₁ can also be activated by matrix metalloproteinase-1, neutrophil elastase, and neutrophil proteinase-3. Various proteinases cleave the N-terminal extracellular domain of PARs at different, yet specific, sites. Examples of PAR activation relevant to inflammation include thrombin-induced CCL2 expression in osteoblasts and PAR₂ and PAR₄ activation in animal models of arthritis. A goal of rational therapeutic design is to target crosstalk interactions using paired drugs or bifunctional agents. Although no PAR-targeting compounds have yet come into clinical use, this is a promising area.⁴⁷

● CHRONIC INFLAMMATION AND REPAIR

The chronic inflammatory response and repair processes are, like the acute inflammatory response, highly regulated. By definition, “chronic” inflammation connotes a process that lasts at least several days and more often, weeks to months, sometimes years. Chronic inflammation is characterized by the recruitment of mononuclear cells including lymphocytes, monocytes and plasma cells, as well as by the proliferation of new capillaries (angiogenesis) and increases in the deposition of extracellular matrix. Replacement of damaged tissue by new small blood vessels and extracellular matrix constitutes a fundamental aspect of chronic inflammation and, simultaneously, is an integral part of wound healing and repair. The recruitment of this wide variety of cell types is achieved by complex interactions among cytokines, chemokines and indigenous cells. Great advances in understanding of angiogenesis and extracellular matrix molecule metabolism have been made in recent years.

Chronic inflammation can be caused by persistent infections with a wide variety of microorganisms (e.g., *Treponema pallidum*, *Mycobacterium tuberculosis*). In contrast to highly virulent organisms that trigger acute pyogenic infections (e.g., *Streptococcus pneumoniae*, *Haemophilus influenzae*), organisms that induce chronic inflammation typically exhibit relatively low intrinsic toxicity, are poorly cleared and may provoke a delayed-type hypersensitivity reaction. Chronic inflammation is also triggered by long-term exposure to insoluble exogenous particles (e.g., carbon dust, silica).² The initiation of other chronic inflammatory processes such as atherosclerosis and autoimmune diseases (e.g., rheumatoid arthritis, systemic lupus erythematosus) is less well understood, but it is clear that a variety of environmental factors (e.g., diet in atherosclerosis) and genetic factors (e.g., human leukocyte

antigen [HLA]-linked susceptibility in rheumatoid arthritis) are important. The characteristics of individual chronic inflammatory responses are dependent on the location of the injury and the type of injurious agent. As noted throughout this chapter, the recruitment of mononuclear cells into an inflammatory lesion is governed by the same general paradigm that orchestrates the recruitment of neutrophils into sites of acute inflammation. Unlike most acute conditions, chronic inflammatory processes are sometimes marked by a relatively specific morphology (e.g., granuloma formation in tuberculosis, eosinophil infiltration in parasitic infections) and by the coexistence of tissue repair (i.e., angiogenesis and extracellular matrix production).

A key cell type in chronic inflammatory processes is the macrophage.^{3,5} Tissue macrophages are derived primarily from circulating blood monocytes and can adopt relatively specific functions based on their differentiation in selected body sites (e.g., hepatic Kupffer cells, alveolar macrophages, central nervous system microglia). In the setting of chronic inflammation, tissue macrophages can be activated by immunologic means (IFN- γ secreted by antigen-activated CD4 T lymphocytes) and by nonimmunologic means (microbial endotoxin, extracellular matrix proteins and foreign particulates; Chap. 67). In turn, activated macrophages enlarge, become more metabolically active, exhibit enhanced phagocytosis and secrete a large array of mediators.^{3,5} Mediators secreted by activated macrophages include proteases, reactive oxygen and nitrogen intermediates, coagulation factors, arachidonic acid-derived lipids and cytokines. These mediators, as detailed in preceding sections, participate in inflammation. Activated macrophages also secrete collagenases that participate in tissue remodeling, angiogenic factors (e.g., fibroblast growth factor) and profibrogenic growth factors (fibroblast growth factor, TGF- β , platelet-derived growth factor).^{3,5} Consequently, activated tissue macrophages participate in inflammation *per se*, tissue remodeling, angiogenesis and fibrosis.

Although macrophages play a central role in all facets of chronic inflammation, other cell types are also important. Lymphocytes (both B and T cells) are recruited into chronic inflammatory lesions via leukocyte-endothelial adhesive interactions and via chemotactic mechanisms analogous to those involved in neutrophil recruitment. Antigen-activated CD4 Th1 lymphocytes produce IFN- γ , which, as discussed above, is an important activator of tissue macrophages.³ Activated CD4 Th2 lymphocytes produce a variety of proinflammatory mediators that are involved in lymphocyte activation (e.g., IL-2) and in immune regulation (e.g., IL-5 in IgE production).³

Eosinophils and mast cells also play important roles in some types of chronic inflammation. Mast cells, which tend to be distributed along small blood vessels, possess high-affinity Fc ϵ RI receptors for IgE.⁴⁸ Engagement of mast cell-bound IgE triggers degranulation that leads to histamine and arachidonic acid-derived lipid release (Chap. 63). Eosinophils are characteristically formed in IgE-mediated allergic reactions and in parasitic infections (Chap. 62). Eotaxin, a CC chemokine, binds to and activates eosinophils via CCR3.^{3,48} Recruited eosinophils secrete various granule proteins that help kill parasites, but which can also cause tissue damage. As inferred above, the histopathologic appearance of many chronic inflammatory lesions can provide insight into their pathogenesis and cause. A variety of poorly degraded, intrinsically low toxicity agents can induce granulomatous inflammation (e.g., *M. tuberculosis*).⁴⁹ Many parasites induce an eosinophilic response (e.g., *Toxocara canis*). Finally, the induction of tissue remodeling, angiogenesis and fibrosis can contribute to both tissue damage and repair, and can also suggest underlying etiology (e.g., lung fibrosis associated with asbestos). The tremendous advances in understanding of the inflammatory response hold great promise for the future of both diagnostics and therapeutics.

CHAPTER 20

INNATE IMMUNITY

Bruce Beutler

SUMMARY

The innate immune system provides immediate protection against infection and serves an essential antigen-presenting role that allows the adaptive immune response to occur during the days and weeks that follow. The sensory apparatus that allows detection of infectious microbes has been deciphered in large part, and it is now known that Toll-like receptors, NOD-like receptors, RIG-I-like helicases, C-type lectin receptors, and cytosolic sensors of DNA, most notably cyclic guanosine monophosphate/adenosine monophosphate synthetase, permit recognition of specific molecules of microbial origin. Much has also been learned of the biochemical events that follow activation of these sensors. Susceptibility to infection in humans is strongly heritable, and among the many loci that influence it, those that encode proteins vital to the innate immune response are of central importance. Moreover, autoinflammatory and autoimmune diseases are dependent upon the activation of innate immune signaling pathways.

Acronyms and Abbreviations: BIR, baculovirus inhibitor of apoptosis repeat; CARD, caspase activating and recruitment domain; CD, cluster of differentiation; cGAS, cyclic AMP/GMP synthetase; CTLA, cytotoxic T-lymphocyte antigen; DAI, DNA-dependent activator of IRFs; ERK, extracellular signal-regulated kinase; FADD, Fas-associated death domain; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; I κ B, inhibitor of κ B; IKK, I κ B kinase; IL, interleukin; IPAF, ice-protease activating factor; IPS-1, IFN- β promoter stimulator 1; IRAK, interleukin-1 receptor-associated kinase; IRF, interferon response factor; JAK, Janus kinase; JNK, c-Jun N-terminal kinase; LPS, lipopolysaccharide; LRR, leucine-rich repeat; MAL, MyD88 adaptor-like; MDA5, melanoma differentiation-associated gene 5; MDP, muramyl dipeptide; MyD88, myeloid differentiation primary response 88; NACHT, a nucleotide-binding domain present in NAIP, CIITA, HET-E, and TP-1; NADPH, nicotinamide adenine dinucleotide phosphate; NBS, nucleotide binding sequence; NEMO, NF- κ B essential modulator; NF- κ B, nuclear factor- κ B; NK, natural killer; NLR, NOD-like receptor; NOD, nucleotide-binding oligomerization domain; PAR-2, proteinase-activated G-protein-coupled receptor; PRAT4A, protein associated with TLR4; PYD, pyrin domain; RIG-I, retinoic acid inducible gene 1; RIP, receptor-interacting protein; RHL, RIG-I-like helicase; ROS, reactive oxygen species; SARM, sterile- α and armadillo motif; SOCS-1, suppressor of cytokine signaling 1; STAT, signal transducer and activator of transcription; STING, stimulator of interferon genes; TAK-1, transforming growth factor- β -activating kinase 1; TBK1, TANK-binding kinase 1; TIR, Toll/interleukin-1 receptor; TLR, Toll-like receptor; TNF, tumor necrosis factor; Tpl2, tumor progression locus 2; TRAF, TNF receptor-associated factor; TRAM, TRIF-related adaptor molecule; TRIF, Toll/interleukin-1 receptor (TIR) domain-containing adaptor inducing IFN- β ; UCM, upregulation of costimulatory molecules.

● INNATE IMMUNITY VERSUS ADAPTIVE IMMUNITY

In humans, as in all mammals, resistance to microbial infection is based partly upon lymphocytes, which yield highly specific responses to microbial antigens: either the production of antibodies or the expansion of T-cell clones that are directly cytotoxic to infected cells (Chaps. 75 and 76). This, the *adaptive* immune response, is a recent fixture in evolution, witnessed only in vertebrates and traceable to the development of a mechanism for recombination of genomic DNA that arose approximately 450 to 500 million years ago, operating on genes encoding proteins with immunoglobulin domains in some lineages and on genes encoding proteins with leucine-rich repeats in other lineages.^{1,2} A more fundamental type of immunity, known as *innate* immunity, is represented in one form or another in all multicellular organisms. For this reason, a great deal of progress in the innate immunity field has come from the study of model animals such as *Drosophila melanogaster*, and model plants such as *Arabidopsis thaliana*. Despite the vast evolutionary divergence of these organisms from *Homo sapiens*, these species use defensive proteins and signaling pathways that are ancestrally related to those represented in humans.

Like the adaptive immune system, the innate immune system is endowed with a means of detecting microbes, destroying them, and at the same time, exercising self-tolerance. These mechanisms are far older than the analogous adaptive mechanisms and as a consequence are more refined. Although it is sometimes termed the “primitive” immune system, the innate immune system is both sophisticated and highly effective. Moreover, adaptive immunity is largely dependent upon innate immunity in the sense that antigen presentation and adaptive immune activation depend upon innate immune cells.

Innate immunity, which acts immediately to protect the host in the event of microbial inoculation, fills a temporal gap that would otherwise exist in the global immune response. Days or weeks are required for an effective adaptive immune response to develop when the naïve host encounters a new pathogen. During this time, innate immunity alone protects the host. Indeed, innate immunity is objectively more important than adaptive immunity. In a nonsterile environment, survival would be impossible without it (Table 20-1).

● TYPES OF INNATE IMMUNITY

Innate immunity embraces a large number of host resistance mechanisms, which may be divided into cellular and noncellular components, and also into afferent and effector components. Noncellular components of innate immunity include antimicrobial peptides, which selectively disrupt microbial cell membranes, complement, components of which also disrupt cell membranes, and the proteins hemopexin and haptoglobin, which deny iron to invasive microbes. Cellular components include myeloid cells (granulocytes, monocyte/macrophages, mast cells, and dendritic cells) and lymphoid cells (natural killer [NK] cells and NKT cells). As such, it can be seen that despite their recent evolutionary origin, some lymphoid cells have been coopted to serve in the innate immune system rather than the adaptive immune system. Many other cells are also endowed with some degree of innate (often “cell-autonomous”) immune function. For example, fibroblasts can sense viral infection and respond with interferon (IFN) production.

Once initiated, the innate immune response runs its course in a preprogrammed fashion, proceeding from microbe sensing all the way through to microbial killing, making division into “afferent” and “effector” functions somewhat arbitrary. Nonetheless, the proteins

TABLE 20–1. Comparisons between Innate and Adaptive Immunity

	Innate Immunity	Adaptive Immunity
Sensing mechanism	TLRs, NK receptors; NLRs, RLHs, fMLP receptor	Immunoglobulins, T-cell receptors
Cellular components	Macrophages, dendritic cells, granulocytes, mast cells, NK cells	T cells, B cells
Efferent mechanisms	Cytokine production, inflammatory response, phagocytosis, pathogen killing	Antibody production, cytokine production, cell killing
Purpose	Alert other innate and adaptive immune cells to pathogen presence; directly kill pathogen; encourage the development of an adaptive immune response	Assist in efficacy of innate immune response, produce highly specific ligands for pathogens
Time scale of response	Quick (maximal in minutes to hours)	Slow (maximal in days to weeks)
Specific memory	No	Yes
Phylogeny	Ancient (all multicellular organisms)	Recent (vertebrates only)

fMLP, *N*-formyl-methionyl-leucyl-phenylalanine; NK, natural killer; NLR, NOD (nucleotide-binding oligomerization domain)-like receptor; RLH, RIG (retinoic acid inducible gene)-I-like helicase; TLR, Toll-like receptor.

responsible for microbial recognition, signaling, and the development of a transcriptional response within innate immune cells are generally considered “afferent” components; the cytokines that mediate the response and the cellular weaponry that is used to destroy viruses and bacteria may be considered “effector” components.

The remainder of this chapter emphasizes the afferent arm of cellular innate immunity, as the effector mechanisms (neutrophil-mediated

killing, complement, and antimicrobial peptides) are covered in other chapters. Our understanding of innate immune responses has improved dramatically as forward and reverse genetic methods have been used to dissect the signaling pathways that permit host recognition of microbes. The initial interactions between molecules of microbes and molecules of the host that trigger an innate immune response have been studied in great detail over the past decade. The afferent pathways are each capable of activating responses that partly overlap with one another.

MICROBE RECOGNITION BY THE TOLL-LIKE RECEPTORS

Discovery of the Mammalian Toll Like Receptors as the Primary Sensors of the Innate Immune System

The Toll-like receptors (TLRs) collectively mediate the recognition of most microbes. Ten TLRs are encoded in the human genome. The molecular specificity of nine of these TLRs has been established, at least in part. Although publications can be found to suggest that some of the TLRs (notably TLRs 2 and 4) detect dozens of molecules, the evidence favoring most of these interactions is slender, and a conservative viewpoint is preferred; hence, [Table 20–2](#) presents only those interactions that are deemed certain.

The microbe-sensing function of the mammalian TLR was discovered as a result of inquiry into the mechanism of endotoxin sensing. Endotoxin (later identified as lipopolysaccharide [LPS]) was first described by Pfeiffer as a toxic component of *Vibrio cholerae* more than 100 years ago.³ Its chemical structure was established many years later (reviewed in Ref. 4), and a toxic “lipid A” moiety of LPS was synthesized artificially in 1985 and found to have full biologic activity.⁵ The identity of the LPS receptor was established in 1998, through the positional cloning of *Lps*, a locus that was known to be required for all cellular responses to endotoxin, and for the effective clearance of Gram-negative bacterial infections⁶ in laboratory mice. In LPS-unresponsive mice, the *Tlr4* locus was shown to be mutationally altered or deleted.⁷ It had previously been recognized that Toll, a *Drosophila* protein also known for its developmental effects,⁸ was required for the innate immune response to fungal infection in flies.⁹ Hence, the

TABLE 20–2. Toll-Like Receptors, Microbial Specificities, and Transducers

TLR	Known Macromolecular Associations	Ligand(s)	Adapter Use	Refs.
1	TLR2	Tri-acyl lipopeptides	MyD88, MAL	12, 137–139
2	TLRs 1 or 6, or homodimer	Lipopeptides, lipoteichoic acid, zymosan, protozoal GPI	MyD88, MAL	11

dsRNA, double-stranded RNA; GPI, glycosylphosphatidylinositol; LPS, lipopolysaccharide; MAL, MyD88 adaptor-like; MyD88, myeloid differentiation 88; ssRNA, single-stranded ribonucleic acid; TRAM, TRIF-related adaptor molecule; TRIF, Toll/interleukin-1 receptor (TIR) domain-containing adaptor inducing IFN- β .

discovery of an LPS-sensing function for TLR4, a homologue of Toll, made evolutionary sense.

Other molecules of microbial origin (for example, di- and triacylated lipopeptides and lipoproteins, lipoteichoic acid, unmethylated DNA bearing CpG dinucleotides in a particular context, flagellin, and double-stranded RNA [dsRNA]) were known to elicit responses qualitatively similar to those elicited by LPS. The other TLR paralogs seemed excellent candidate receptors for these molecules. Reverse genetic methods established that each of these molecules is indeed recognized by a particular TLR or heteromeric combination of TLRs.^{10–14} Moreover, genetic complementation analyses have shown that at least some microbial ligands directly engage the TLRs in order to elicit a signal.^{15,16} On the other hand, other molecules enhance the signal, and also participate in ligand recognition. Dectin-1 is a type II transmembrane C-type lectin that recognizes glucans present in the cell walls of fungi, signals via spleen tyrosine kinase (Syk) and the Card9/Bcl-10/MALT1 complex to activate nuclear factor- κ B (NF- κ B),^{17,18} and enhances TLR2/6 signaling.¹⁹ Similarly, proteinase-activated G-protein-coupled receptor (PAR-2) signaling enhances TLR4 responses to LPS.²⁰ Other examples include the binding of cluster of differentiation (CD) 14 to LPS²¹ which augments LPS responses,²² as well as the enhancement of responses to bacterial diacylglycerides by CD36.²³ It is likely that these accessory molecules form complexes with the TLRs, which are responsible for transducing the signal across the cell membrane. TLR4 exists in a tight complex with MD-2, a small secreted protein that is required for TLR4 to reach the cell surface and required for LPS sensing as well.²⁴

Structure of the Toll-Like Receptors

The TLRs are single-spanning transmembrane proteins with leucine-rich repeat (LRR) motifs in their extracellular domains and a characteristic TIR (Toll/interleukin [IL]-1 receptor) motif in their cytoplasmic domains. The TIR domain is based on an ancient protein fold²⁵ evident in cytosolic plant disease resistance proteins (where it often is represented together with a nucleotide binding sequence [NBS] and/or LRR motifs), in proteins of the IL-1 and IL-18 receptor family, in the adapter proteins that carry signals from TLRs, and in the TLRs themselves.

The structure of the TLR2/1, 2/6, 3, 4, 5, and 8 ectodomains has been determined by x-ray crystallography, which showed a horseshoe-shape characteristic of LRR-containing proteins. TLRs form homodimers or heterodimers induced by the simultaneous binding of ligands to LRRs of distinct receptor chains. The nature of the ligand-receptor interaction has also been determined for several of the above receptors, and appears to be different in each individual case (Fig. 20–1). To activate TLR4, LPS interacts with MD-2, which has a hydrophobic pocket that accommodates the lipid A moiety of LPS.^{26,27} TLR2/1 heterodimers are “crosslinked” by the engagement of two acyl chains by TLR1 and a single acyl chain by TLR2.²⁸ TLR3 molecules bind a linear, negatively charged dsRNA oligonucleotide, which triggers activation.²⁹

TLRs 3, 7, 8, and 9 are believed to be intracellular. Little (TLR3) or no (TLRs 7 and 9) surface expression can be detected, and tagged versions of the molecules are found to reside within the interior of transfected cells.³⁰ The ectodomains of these TLRs project into endocytic vesicles and there detect foreign molecules rather than within the

Figure 20–1. Structures of Toll-like receptors (TLRs) and their ligands. TLR2-TLR6-Pam₂CSK₄ lipopeptide (3A79), TLR2-TLR1-Pam₃CSK₄ lipopeptide (2Z7X), TLR3-dsRNA (3CIY), TLR4-MD2-LPS (3FXI), TLR5 (3J0A), and TLR8-R848 (3W3L) are shown. Side view (upper panels) and top view (lower panels) are shown. Protein Databank ID numbers are indicated in parentheses. Figures were generated with UCSF Chimera. dsRNA, double-stranded RNA.

extracellular space. TLRs 3, 7, 8, and 9 are trafficked from the endoplasmic reticulum (ER) to endosomal compartments via the secretory pathway, and depend on the aid of chaperones to do so. For example, UNC93B1, a 12-transmembrane spanning ER protein, directly binds and is necessary for TLRs 3, 7, and 9 to gain access to the endosomal compartment.³¹ UNC93B1 is believed to escort these molecules, and perhaps others, to their destination in the cell.³² PRAT4A (encoded by *TNRC5*) serves a critical role in chaperoning multiple TLRs to their destination,³³ while the ER chaperone protein, gp96 (also called GRP94 or HSP90B1) is critical for all TLR maturation (Fig. 20-2).³⁴ Proteolysis of TLR7 and 9 is known to occur in the endolysosome, and at least for TLR9, this cleavage increases ligand binding and is necessary for activating downstream signaling pathways.^{35,36} In plasmacytoid dendritic cells, TLR7 and TLR9 are further trafficked from endosomes to lysosome-related organelles; this trafficking is necessary for the abundant production of type I IFN for which these cells are specialized.^{37,38} The

adaptor protein complex 3 (AP-3), which directs subcellular trafficking through the secretory pathway, and the peptide/histidine transporter 1 (PHT1) are necessary for TLR7 and TLR9 trafficking to lysosome-related organelles.

Toll/Interleukin-1 Receptor Adapter Signaling

The signaling events initiated by the TLRs are increasingly complex and have been studied in great detail [reviewed in Refs. 39 and 40]. Figure 20-3 illustrates the pathways as they are presently understood. It must be recognized that not all TLRs operate within the same cells, nor are all cells equivalent in their responses to TLR ligation. Notably, macrophages and conventional (myeloid) dendritic cells respond to different stimuli than do lymphoid cells, or plasmacytoid dendritic cells (which are specialized for type I IFN production). Moreover, some cells not usually regarded as “professional” components of the innate immune system are capable of responding to TLR ligands in one way or another.

Figure 20-2. The Toll-like receptors (TLRs). The TLRs exist in homo- or heterodimeric form and are capable of sensing diverse molecules derived from pathogenic organisms. TLRs 1, 2, 4, 5, and 6 are located at the cell surface, while TLRs 3, 7, and 9 are located in the endosome. All TLR maturation is dependent on the chaperone protein gp96 in the endoplasmic reticulum (ER). Two other ER proteins, PRAT4A and UNC93B1, play important roles in TLR trafficking. PRAT4A is necessary for TLRs 1, 2, 4, 7, and 9 responses, while UNC93B1 is required for TLRs 3, 7, and 9 trafficking. At the cell surface, a TLR4 complex composed of TLR4, MD2, and CD14 specifically binds to lipopolysaccharide (LPS) and vesicular stomatitis virus glycoprotein G (VSV-G). The TLR2/6 heterodimer, along with CD36 and CD14, recognizes diacylated lipopeptides and lipoteichoic acid (LTA). The TLR1/2 heterodimer senses triacylated lipopeptides (PAM₃CSK₄), and TLR5 recognizes flagellin. TLR7 is able to bind to single-stranded RNA, TLR9 to CpG DNA, and TLR3 to double-stranded RNA. Proteolysis of both TLR7 and TLR9 by lysosomal cysteine proteases including cathepsins and asparagine endopeptidase occurs in the endolysosome, and at least in the case of TLR9, is required for function. Abbreviations are as used in the text.

Figure 20–3. Overview of Toll-like receptor (TLR) signaling pathways. Shown are the activating events downstream of TLR activation that ultimately lead to the induction of thousands of genes including those encoding tumor necrosis factor (TNF) and type I interferon (IFN), which are critical in activating innate and adaptive immune responses. TLR4 activation is shown as a prototypical model. Once TLR complexes recognize a specific molecule, they recruit combinations of adaptor proteins (MyD88 [myeloid differentiation primary response 88], TRIF [Toll/interleukin-1 receptor domain-containing adaptor inducing IFN- β], TRAM [TRIF-related adaptor molecule], MAL [MyD88 adaptor-like]) and initiate activation of downstream signaling molecules. See text for details of MyD88-dependent and TRIF-dependent signaling. When bound to vesicular stomatitis virus glycoprotein G (VSV-G), TLR4 can signal through TRAM to induce interferon response factor (IRF) 7 activation, a process that is partially dependent on TRIF (not shown). K63 and K48 ubiquitination are represented by *chained circles*. Proteins that are degraded are shown with a *dotted outline*. LP2, lipopeptide 2; LTA, lipoteichoic acid. PAM₃CSK₄ is a triacyl lipopeptide. Phosphorylation events are represented by *P*-labeled circles. Abbreviations are as used in the text.

A total of five TIR adapter proteins are encoded in the human genome. These adapters are MyD88 (myeloid differentiation primary response 88), MAL (MyD88 adaptor-like; also known as TIRAP), TRIF (Toll/interleukin-1 receptor domain-containing adaptor inducing IFN- β ; also known as TICAM1 and first identified by a mutant allele known as *Lps2*), TRAM (TRIF-related adaptor molecule; also known as TICAM2), and SARM (sterile- α and armadillo motif). The function of SARM remains unknown, and it is the most distantly related paralog among the adaptors. However, the four remaining adapters have well-defined roles in signal transduction. All four of these adapters are required for normal signaling from the LPS receptor, TLR4; MyD88 and MAL act in concert with one another, and TRIF and TRAM act together, so that two primary branches of the LPS signaling pathway diverge at the level of the receptor.^{41,42} In contrast, TRIF alone serves TLR3 signaling; MyD88 and MAL (but neither TRIF nor TRAM) serve TLR2; and MyD88 alone serves TLRs 7, 8, and 9. Mutational inactivation of MyD88 creates a severe immunodeficiency state in mice and humans,^{43,44} and compound homozygosity for mutations affecting both MyD88 and TRIF causes immunodeficiency that is still more severe, in which animals are essentially unable to sense the presence of most microbes.⁴²

Two main branches of signaling, dependent on MyD88 or TRIF, mediate the effects of TLR activation in conventional dendritic cells, macrophages, and fibroblasts (see Fig. 20–3). The MyD88-dependent pathway is used by all TLRs except TLR3, as mentioned above. MyD88 is believed to assemble into a helical complex called the Myddosome upon receptor activation, engaging the serine kinases IRAK (interleukin-1 receptor-associated kinase) 4 and IRAK2 or IRAK1 through death domain interactions.⁴⁵ Signaling proceeds via phosphorylation of IRAK2 or IRAK1 by IRAK4. No comparable structural data illuminate the function of MAL, TRIF, or TRAM proteins, but it is clear that TRIF can directly engage TLR3.⁴⁶ The activated Myddosome recruits the E3 ubiquitin ligase tumor necrosis factor (TNF) receptor-associated factor (TRAF) 6, a cellular scaffold protein that coordinates the recruitment of several other protein kinases. MyD88 also interacts with TRAF3; however, degradative K48-linked ubiquitination of TRAF3 by cIAP1/2 during MyD88-dependent TLR signaling is necessary for the activation of mitogen-activated protein kinases (MAPKs) and production of inflammatory cytokines.⁴⁷ In conjunction with the E2 ubiquitin-conjugating enzyme 13 (Ubc13) and the Ubc-like protein Uev1a, TRAF6 adds chains of K63-linked polyubiquitin to itself, as well as inhibitor of κ B ($\text{I}\kappa\text{B}$) kinase γ (IKK γ ; also called NEMO [NF- κ B essential modulator]) and to TRAF2 (reviewed in Ref. 48). Transforming growth factor- β -activating kinase 1 (TAK-1) forms a complex with TAB1, TAB2, and TAB3, is recruited to the TRAF6 complex, and phosphorylates IKK β , which in complex with IKK α and IKK γ phosphorylates $\text{I}\kappa\text{B}$ (an inhibitor of the p65 form of NF- κ B), leading to its K48-ubiquitin-mediated degradation.⁴⁸ Nuclear translocation of homo- or heterodimers composed of p65 and/or p50 NF- κ B ensues. NF- κ B drives the transcription of hundreds of genes encoding proteins that form the inflammatory response. Mitochondrial reactive oxygen species (ROS) are also produced in macrophages as a result of TLR4, TLR2, and TLR1 activation; this antibacterial response depends on the translocation of TRAF6 to mitochondria to engage and ubiquitinate a protein called ECSIT, which functions in mitochondrial respiratory chain assembly.⁴⁹

At the same time, the IKK complex activated by TAK-1 phosphorylates the p105 form of NF- κ B and MAP3K8 (also known as Tpl2), proteins that form a complex in which MAP3K8 is inactive under basal conditions. This leads to the degradation of p105 NF- κ B, and to the activation of MAP3K8.^{50,51} MAP3K8 phosphorylates and activates MEK1 and MEK2, while independently MEK3 and MEK6 are activated by TAK-1.⁴⁰ The MEKs activate MAPK family members, including extracellular signal-regulated kinase (ERK) 1 and ERK2, c-Jun N-terminal kinase

(JNK), and p38 kinases. These kinases trigger the activation of other transcription factors, including c-Jun, which together with c-Fos forms the transcription factor AP1, and members of the cyclic adenosine monophosphate (AMP) response element-binding protein (CREB) family.

The TRIF-dependent TLR signaling pathway is activated by TLR3 and TLR4, and results in the induction of type I IFNs as well as inflammatory response genes (see Fig. 20–3). Upon receptor activation, TRIF interacts with TRAF3, which recruits TANK-binding kinase 1 (TBK1) and IKK ϵ (both distantly homologous to the IKKs).^{52,53} This complex engages and phosphorylates interferon response factor (IRF) 3, an interaction that may be mediated by phosphatidylinositol-5-phosphate generated by PIKfyve.⁵⁴ IRF3 dimerizes and translocates to the nucleus to activate transcription of type I IFN genes with the aid of deformed epidermal autoregulatory factor-1 (DEAF-1).⁵⁵ Two other IRF proteins, IRF1 and IRF7, also activate type I IFN genes, but in response to signaling from TLR7 and TLR9 particularly in plasmacytoid dendritic cells.^{56,57} Activation of IRF3 and IRF1 can initiate expression of the IFN- β gene.^{58,59} IFN- β mediates antiviral effects, and is also required for the upregulation of costimulatory proteins (e.g., CD40, CD80, and CD86) that enhance the activation of an adaptive immune response. Hence, the adjuvant effects of LPS and dsRNA are dependent upon the type I IFN receptor.⁶⁰ IRF7 induces the expression of the IFN α genes.^{59,61} Both α and β IFNs bind to the type I IFN receptor rendering similar if not identical biological responses.

To induce inflammatory response genes, TRIF recruits receptor-interacting protein (RIP) 1 following its polyubiquitination by the E3 ligase Pellino.⁶² RIP1 interacts with the TRAF6/TAK-1 complex leading to NF- κ B activation following the pathway described above for MyD88-dependent signaling. For reasons that remain unclear, the heteromeric MyD88/MAL complex is incapable of driving type I IFN gene expression.

Countervailing Influences in Toll/Interleukin-1 Receptor Adapter Signaling

IRAK-M, a homologue of IRAKs 1, 2, and 4, is an inhibitor of TIR domain signaling and may participate in feedback inhibition of signaling known as “endotoxin tolerance.”⁶³ In addition, suppressor of cytokine signaling 1 (SOCS-1) inhibits signal transduction from the Janus kinase (JAK)/signal transducer and activator of transcription (STAT) pathway (Chap. 17) activated by type I IFN, one of the key cytokines elicited in the course of an innate immune response.⁶⁴ A20 and CYLD, both deubiquitination enzymes, remove the K63 ubiquitin tails from TRAF6, NEMO, and RIP, inhibiting the activation cascade.⁴⁸ Still more distally, inhibition of signaling via antiinflammatory cytokines (such as IL-10 or transforming growth factor [TGF]- β) acts to limit responses initiated by the TLRs.

SENSORS OF THE NUCLEOTIDE-BINDING OLIGOMERIZATION DOMAIN-LIKE RECEPTOR FAMILY

An extensive family of proteins defined by their motif structure has recently been recognized for its participation in innate immune responses to intracellular microbes as well as noninfectious inflammatory stimuli, including, for example, uric acid crystals and aluminum hydroxide particles. Collectively called the nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs), the proteins contain CARD (caspase activating and recruitment domain), Pyrin, or BIR (baculovirus inhibitor of apoptosis repeat) domains followed by nucleotide-binding NACHT domains and LRR domains arranged in tandem, and have been assigned to several subfamilies (Fig. 20–4).⁶⁵ Mutations within different representatives of the family produce dominant or semidominant inflammatory diseases. In some cases there is

Figure 20-4. Domain structure of nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs). The various members of the NOD-like receptor family are grouped into subfamilies based on domain structure and homology by the Human Genome Gene Nomenclature Committee (HGNC), although sometimes domain classifications and homologies remain unclear. The leucine-rich repeat (LRR) domain contains variable numbers of LRR repeats. Abbreviations are as used in the text.

limited penetrance and strong dependence upon the presence of mutations in other genes. For example, *NOD2* mutations have been clearly shown to enhance the likelihood of Crohn disease⁶⁶ and cause Blau syndrome,⁶⁷ while distinct *NLPR3* mutations are the proximal cause of cold-induced autoinflammatory syndrome (CIAS1), chronic neurologic cutaneous and articular (CINCA) syndrome, or neonatal onset multi-system inflammatory disease (NOMID).⁶⁸⁻⁷⁰ Mutations in the structurally related *MEFV* (pyrin-encoding) gene are responsible for familial Mediterranean fever.⁷¹ Pyrin has been shown to interact with the adaptor protein PSTPIP1 (proline serine threonine phosphatase-interacting protein 1). Mutations in the gene encoding this protein also cause an inflammatory disorder, pyogenic arthritis, pyoderma gangrenosum and acne (PAPA) syndrome.⁷²

The inflammatory potential of the NLR superfamily is exerted through two signaling pathways: the “inflammasome” pathway and the “NOD1/2” pathway. Each is less fully elucidated at present than the TLR signaling pathways. Moreover, each likely interacts with the TLR signaling pathways and in the case of the inflammasome, is dependent upon the TLR signaling for full expression of activity.

The Inflammasome Pathway

The “inflammasome” pathway (Fig. 20-5) is induced by at least three proteins, and possibly others. Ice-protease activating factor (IPAF/NLRC4; encoded by *CARD12*), NACHT domain-, LRR-, and pyrin domain (PYD) containing protein 1 (NLRP1, also known as CARD7), and NLRP3 (also known as cryopyrin) each trigger the inflammasome response. Diverse cellular perturbations probably lead to activation of IPAF, NLRP1, and NLRP3. Cytosolic flagellin introduced via type III or type IV bacterial secretion systems activates IPAF.⁷³ Anthrax lethal factor and muramyl dipeptide (MDP, a product of bacterial cell walls)

introduced via pore-forming toxins activate NLRP1.^{74,75} Peptidoglycan (PGN), MDP, lipopeptides, nucleic acids, uric acid crystals, alum, and other foreign substances activate NLRP3.⁷⁶⁻⁸⁰ Full activation of NLRP3 depends upon a drop in cytosolic potassium concentration, mediated in part by the potassium exporting channel P2X7. Activation of P2X7 recruits the gap junction channel Pannexin-1 (Panx-1), allowing entry of bacterial products and other molecules into the cell.⁸¹ Although it is not clear that the inducers have direct contact with the NLRPs or IPAF, the latter undergo oligomerization (mediated by the NACHT domain). They then signal either directly (in the case of IPAF) or via adapter proteins (ASC in the case of NLRP1, and both ASC and CARDINAL in the case of NLRP3) to activate the cytosolic cysteine proteases caspase-1 and/or caspase-5. Activation occurs through CARD interactions. Homodimeric caspase-1 and caspase-5 act to convert the inflammatory cytokine pro-IL-1 β into its active form. Importantly, inflammasome signaling does not initially activate expression of the IL-1 β encoding gene. However, TLR signaling, which activates NF- κ B, or signaling by IL-1 β itself, can do so.⁶⁵

IL-1 β signals via its receptor to activate a signaling pathway very similar to those used by the TLRs, dependent upon MyD88 and the downstream signaling cascade components described earlier in this chapter in the section “Toll/Interleukin-1 Receptor Adapter Signaling”. As such, IL-1 β may be viewed as an endogenous ligand that elicits a response similar to those elicited by microbial ligands. This signal may initially be induced by a focal infection operating in conjunction with a noninfectious inflammatory stimulus.

The Nucleotide-Binding Oligomerization Domain Pathway

NOD1 (CARD4) and NOD2 (CARD15) proteins have been mentioned as sensors of γ -D-glutamyl diaminopimelic acid (DAP) and MDP,

Figure 20-5. Inflammasome complexes formed by NLRP1 (NALP1), NLRP3 (NALP3), and NLRC4 (IPAF [ice-protease activating factor]). In the absence of activating signals, NOD-like receptors (NLRs) are present in the cytosol in inactive conformations. The SGT1/HSP90 chaperone complex associates with and keeps NLRP3 in an activation-ready state. Upon activation, binding and hydrolysis of ATP results in oligomerization and inflammasome formation. NLRP1 and NLRP3 engage procaspase-1 through adaptor proteins (ASC or ASC/CARDINAL for NLRP3), while NLRC4 is able to bind procaspase-1 directly. NLRP1 is also able to engage procaspase-5. This engagement leads to the autoproteolytic maturation of the caspases, which then cleave the pro forms of inflammatory cytokines to their biologically active forms. Protein domains shown are the same as in Fig. 20-4.

respectively, both components of microbial cell walls. They are believed to detect intracellular bacteria or fragments thereof.⁸²⁻⁸⁴ NOD2 has been strongly implicated in the pathogenesis of Crohn disease through linkage disequilibrium mapping and sequence analysis,⁶⁶ but mutations of NOD2 cause disease with low penetrance, suggesting the importance of other genetic and environmental factors. No clear disease association has been defined for NOD1. The NOD proteins do not form the core of inflammasomes, although recent data suggests that NOD2 is able to associate with NLRP1 and caspase-1 upon stimulation with MDP.⁸⁵ In response to microbial stimuli, the NOD proteins oligomerize and signal via TRAF2, TRAF5, and TRAF6 to cause K63 ubiquitination of RICK2 (also known as RIP2, or CARDIAK), a protein with a domain structure similar to receptor interacting protein (RIP), known for its involvement in TNF signal transduction. RICK2 activates TAK-1, and by way of TAK-1, elicits the activation of both NF- κ B and the mitogen-activated protein (MAP) kinase cascade, leading to activation of the transcription factor AP1 (Fig. 20-6).

SENSORS OF THE RIG-I-LIKE HELICASE PATHWAYS

While TLRs are capable of detecting nucleic acids within the endosomal compartment and do make an essential contribution to the detection of some viruses (notably herpesviruses), other viruses are detected chiefly or entirely by cytosolic receptors. Among these, the RIG-I-like helicases (RLHs), including retinoic acid inducible gene I (RIG-I), melanoma differentiation-associated gene 5 (MDA5), and LGP2, are the best known sensors and are believed to undergo direct interaction with nucleic acids to initiate a response. RIG-I and MDA5 sense specific viruses; for example, viruses detected by RIG-I include influenza A, Sendai, and vesicular stomatitis viruses, and MDA5 detects encephalomyocarditis and murine hepatitis viruses.⁸⁶ RLH proteins have RNA helicase domains (involved in binding nucleic acids), as well as a regulatory domain (RD) that has been implicated in inhibiting downstream signaling,⁸⁷ but is also necessary for RNA sensing.^{88,89} Both RIG-I and

Figure 20–6. The nucleotide-binding oligomerization domain (NOD) 1/2 signaling pathways. Upon sensing PGN-derived motifs in the cytosol (γ -D-glutamyl diaminopimelic acid [DAP] and muramyl dipeptide [MDP]), NOD1 and NOD2 oligomerize and form complexes with the serine/threonine kinase RICK2. Signaling through tumor necrosis factor receptor–associated factors (TRAFs, which are E3 ubiquitin ligases) results in K63 ubiquitination (*chained circles*) of RICK2, and transforming growth factor- β -activating kinase (TAK)-1 recruitment. Activation of the TAK-1 complex leads to I κ B kinase (IKK) and MKK activation, resulting in signaling cascades similar to those activated in response to TLR ligands. Caspase activating and recruitment domain (CARD) 9 is important for p38 activation downstream of NOD2. NOD-like receptor (NLR) protein domains shown are the same as in Fig. 20–4. Phosphorylation events are represented by P-labeled *circles*. Abbreviations are as used in the text.

MDA5 have more proximal CARD domains involved in signaling, whereas LGP2 does not. On this basis it was initially believed that LGP2 might have an inhibitory function.⁹⁰ However, it appears to contribute to sensing in a positive manner, and may augment RIG-I and MDA5 signaling.^{89,91,92}

Although TLR3 can detect dsRNA and its synthetic analogue poly I:C, the dominant sensor of poly I:C (long polymers in particular) *in vivo* is MDA5⁹³; shorter poly I:C polymers are better detected by RIG-I. RIG-I is able to form stable complexes with dsRNA molecules containing blunt ends or 5'-overhangs, while dsRNA with 3'-overhangs

are unwound by its helicase activity.⁸⁸ RIG-I additionally recognizes single-stranded RNA (ssRNA) molecules, distinguishing them from host RNA by detecting 5'-triphosphate structures such as are found in ssRNA from the influenza virus.^{94,95} RIG-I must be activated by T-cell receptor interacting molecule 25 (TRIM25), a host resistance factor that ubiquitinates RIG-I (K63 linkages).

Upon virus recognition the RLHs initiate signaling, leading to type I IFN and inflammatory cytokine production dependent, respectively, upon IRF and NF- κ B activation. RLHs signal by CARD domain-mediated interaction with mitochondrial antiviral signaling protein (MAVS; also known as IPS-1, VISA, or CARDIF), an integral protein of the mitochondrial outer membrane with a CARD domain that projects into the cytoplasm.⁹⁶⁻⁹⁹ Upon activation by RIG-I interaction, MAVS forms prion-like polymeric fibers that induce the formation of similar aggregates by untouched MAVS molecules, which thereby gain competence to

activate IRF3.¹⁰⁰ MAVS, in its active form, is capable of triggering three different signaling pathways. One pathway mimics the TNF signaling pathway, and includes the adaptor protein TRADD, Fas-associated death domain protein (FADD), RIP1, caspase-8 and caspase-10, and leads to IKK complex and NF- κ B activation. A second pathway recruits TRAF6 and MEKK1, leading to activation of the MAP kinases and AP1. These two pathways are responsible for inflammatory cytokine production. The third pathway entails activation of TBK1 and IKK ϵ , and leads to the activation of IRF3 and IRF7, with ensuing type I IFN production (Fig. 20-7).

A pathway for responses to cytoplasmic double-stranded DNA (dsDNA) has also been identified in mammalian cells (see Fig. 20-7).^{101,102} Cyclic adenosine monophosphate (AMP)/guanosine monophosphate (GMP) synthetase (cGAS) is an enzyme allosterically activated by binding to dsDNA, whereon it synthesizes cyclic GMP:AMP (cGAMP). cGAMP activates stimulator of IFN genes (STING),¹⁰³ a

Figure 20-7. Cytosolic sensors and signaling pathways. Retinoic acid inducible gene I (RIG-I) and melanoma differentiation-associated gene 5 (MDA5) respond to different viral infections, recognizing single-stranded RNA (ssRNA) and double-stranded RNA (dsRNA), respectively. RIG-I also detects short dsRNA sequences. LGP2 is able to bind to dsRNA, and appears to modulate RIG-I and MDA5 signaling. Full RIG-I activity requires K63 ubiquitination (*chained circles*) by T-cell receptor interacting molecule 25 (TRIM25). RIG-I and MDA5 activate mitochondrial antiviral signaling protein (MAVS), which interacts with a complex containing receptor-interacting protein 1 (RIP1), Fas-associated death domain (FADD), and tumor necrosis factor (TNF) receptor-associated death domain (TRADD), as well as with TNF receptor-associated factor (TRAF) 6, and TRAF3. Association of FADD with procaspase 8 or procaspase 10 results in cleavage to the mature, active caspase 8 or caspase 10, which go on to activate nuclear factor (NF)- κ B. Recruitment of TRAF6 leads to activation of the mitogen-activated protein (MAP) kinase pathway and AP1, while K63-ubiquitinated TRAF3 activates interferon response factor (IRF) 3 and IRF7 through the kinases I κ B kinase (IKK) ϵ and TANK-binding kinase (TBK). The latter also associate with TRAF family member-associated NF- κ B activator (TANK), NAK-associated protein 1 (NAP1), and similar to NAP1 TBK1 adaptor (SINTBAD). MAVS is negatively regulated by the autophagy conjugate Atg12-Atg5, and potentially by NLRX1, while RIG-I is negatively regulated by the IFN-inducible ubiquitin ligase RNF125 (K48 linkage) and the deubiquitinase A20. The TRAF3-dependent pathway is negatively controlled by the deubiquitinase DUBA. The peptidyl-prolyl-isomerase Pin1 triggers phosphorylated IRF3 ubiquitination and degradation. dsDNA is sensed by cyclic adenosine monophosphate (AMP)/guanosine monophosphate (GMP) synthetase (cGAS), which synthesizes cGAMP from ATP and guanosine triphosphate (GTP). cGAMP binds and activates STING (stimulator of interferon genes), which recruits TBK1 to phosphorylate IRF3. STING also activates the IKK complex. dsDNA can also be sensed by DNA-dependent activator of IRFs (DAI). STING also associates with RIG-I (not shown). The caspase activating and recruitment domains (CARDs) are indicated by *rust-colored rectangles*, helicase domains by *white rectangles*, RD domains by *green rectangles*. NLRX1 domains are the same as in Fig. 20-4 except for the unclassified domain, which is shown inserted into the mitochondrial membrane. Phosphorylation events are represented by P-labeled circles. Unknown signaling pathway(s) are represented by a dotted arrow. Abbreviations are as used in the text.

penta-spanning ER membrane protein that undergoes a conformational change leading to the activation of TBK1 to phosphorylate IRF3, which dimerizes and translocates to the nucleus to induce type I IFNs. STING also activates the IKK complex, leading to degradation of $\text{I}\kappa\text{B}$ and release of $\text{NF-}\kappa\text{B}$ to enter the nucleus and induce other cytokines. A putative cytosolic DNA sensor DAI (for DNA-dependent activator of IRFs) has also been described. DAI contains DNA binding domains and enhances DNA-mediated induction of type I IFNs *in vitro*.¹⁰⁴ However, the role of DAI as a sensor of cytoplasmic DNA appears to be redundant.¹⁰⁵

Both the RLH-MAVS pathway and the cGAS-STING pathway become activated in B cells when they are stimulated by type 2 T-cell-independent antigens, such as pneumococcal vaccine (PPSV23).¹⁰⁶ These pathways sense the induction of endogenous retroviruses, leading to sustained B-cell activation and an immunoglobulin (Ig) M response.

KEY EFFECTOR CYTOKINES IN THE INNATE IMMUNE RESPONSE

Cells of the innate immune system exhibit a measure of autonomy (e.g., neutrophils directly engulf and destroy pathogens), but also initiate the adaptive immune response to microbes and summon “reinforcements” to the site of infection. These functions depend upon the production of cytokines, too numerous to describe in this chapter. However, a few of the key mediators are listed here.

Tumor Necrosis Factor- α

A homotrimeric cytokine that is made by many cells, TNF is synthesized in greatest amounts by mononuclear phagocytes that have been exposed to LPS or other TLR-activating stimuli. It was recognized as a key endogenous mediator of endotoxicity,¹⁰⁷ and later, as a mediator of other forms of inflammation (including sterile inflammation, as observed in rheumatoid arthritis and cancer, Crohn disease, ankylosing spondylitis, and psoriasis). The TNF signaling pathway depends upon two receptors, involves $\text{NF-}\kappa\text{B}$ activation, and is ancestrally related to the *Drosophila* *Imd* (immunodeficiency) pathway for recognition of Gram-negative bacteria.¹⁰⁸ The ancient phylogenetic origins of TNF signaling, its large representation in distant species, the therapeutic efficacy of TNF neutralization in the diseases just mentioned, and the immunocompromising effects of TNF and TNF receptor mutations in animals all suggest that TNF is one of the most important of the cytokines utilized by the innate immune system for effective containment of infection.

Interleukin-1 α and β

Once known as pleiotropic inflammatory cytokines, IL-1 α and IL-1 β , two distantly related ligands that share the same set of receptors, are produced in response to innate immune stimuli and evoke fever, swelling, and neutrophil adhesion in the region of an infectious nidus. The type I IL-1 receptor, responsible for most or all of the agonist activity of the IL-1 proteins, has two chains, each of which is endowed with a cytoplasmic TIR domain. The receptor complex signals via MyD88 and no other adapters are known to be required. IL-1 signaling may act as an amplification mechanism that augments the primary infectious signal, and transmits awareness of infection to cells that lack the innate immune sensors required for detection of microbes.

Interleukin-6

Signaling via a receptor that uses the JAK/STAT pathway, IL-6 activates many elements of the “acute phase response”; that is, hepatic production of fibrinogen, serum amyloid A protein, and C-reactive protein. It also has thrombopoietic activity, both directly (minor effect) and through its stimulation of thrombopoietin production (major effect) (Chap. 11),

which stimulates platelet production, often consumed in the course of a serious infection.

Interleukin-12

A cytokine made in abundance by dendritic and other cells in response to TLR stimulation, IL-12 activates the production of IFN- γ by lymphoid cells, which, in turn, increases the microbicidal activity of mononuclear phagocytes. Unlike most cytokines, IL-12 is a heterodimeric protein, and the IL-12 p40 subunit is subject to induction, whereas the p35 subunit is synthesized constitutively. Mutations of the genes encoding IL-12 or its receptor, or IFN- γ or its receptor, are known to cause relatively severe susceptibility to infection by mycobacteria and other intracellular infections. Hence the IL-12/IFN- γ feedback loop is considered one of the most important innate/adaptive immune interactions.

Chemokines

A family of small proteins, highly redundant in receptor specificity and organized into CC and CXC subfamilies, the chemokines are induced by primary microbial stimuli and by TNF and IL-1. Binding to G-protein-coupled receptors, they exhibit phagocyte chemotactic activity (Chaps. 61 and 68), and are believed to contribute to the egress of neutrophils from blood into infected tissue.

Granulocyte Colony-Stimulating Factor and Granulocyte-Macrophage Colony-Stimulating Factor

The central hematopoietic response is attuned to events in the peripheral tissues, and granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) promote the production and release of granulocytes and monocytes to cope with an infectious challenge. These cytokines are produced by macrophages, endothelial cells and fibroblasts in direct response to TLR signaling (Chap. 61), and also in response to secondary cytokines such as TNF. They signal via JAK/STAT-coupled receptors.

Interferons

Type I IFNs (IFN- α and IFN- β) are expressed immediately in response to LPS, dsRNA, or unmethylated DNA, and have broad activity in the containment of viral infections. LPS-induced type I IFN production depends upon TLR4 and the adapters TRIF and TRAM. dsRNA-induced type I IFN depends upon TLR3 and TRIF (but not TRAM). Unmethylated CpG motifs in DNA stimulate type I IFN production that depends upon MyD88. Although many cells are induced into an antiviral state as the result of IFN stimulation, NK cells, which are specialized for the elimination of virus-infected targets, are particularly dependent upon type I IFN signaling (Chap. 77),¹⁰⁹ and require it for the elimination of specific pathogens such as cytomegalovirus.¹¹⁰ The type I IFNs are also involved in protection against bacterial infection,¹¹¹ and type I IFN signaling has been shown to be important to the development of endotoxic shock.¹¹² Plasmacytoid dendritic cells are a particularly important source of type I IFN.¹¹³

Type II IFN (IFN- γ) has less antiviral activity than type I IFN, is produced by T cells in response to IL-12 receptor stimulation, and is crucial for the elimination of intracellular pathogens such as mycobacteria, which reside within macrophages of the infected host.

THE ACTIVATION OF ADAPTIVE IMMUNITY

The adjuvant effect of microbes has been known since the classic studies of Lewis and Loomis¹¹⁴ who coined the term “allergic irritability” to describe the augmented production of antibodies against a

protein antigen in guinea pigs infected with *Mycobacterium tuberculosis*. Freund and McDermott¹¹⁵ demonstrated that heat-killed mycobacteria were capable of eliciting an exaggerated antibody response as well when coadministered with a protein antigen, indicating that molecular components of microbes (rather than infection *per se*) were responsible for adjuvanticity. LPS was shown to be endowed with adjuvant activity in 1955,¹¹⁶ and by 1975 the *Lps* locus was shown to be required for this effect of LPS (as it is required for all other cellular effects of LPS).¹¹⁷ By deduction, the positional cloning of *Lps* thus revealed the essential role of TLR4 in LPS-mediated adjuvanticity.⁷

Activation of an adaptive immune response to a specific antigen has long been known to depend upon two signals that occur in the course of antigen presentation. First, the T-cell receptor must be activated. In addition, costimulatory molecules upregulated on the antigen-presenting cell (e.g., CD40, CD69, CD80, and CD86) are known to interact with receptors (or in some cases ligands) on the T cell. An exchange of signals occurs over a period of approximately 12 hours,¹¹⁸ ultimately leading to autonomous expansion of the T-cell clone and, in turn, activation of specific B cells. Some of these signals are well characterized. For example, CD80 and CD86 both engage CD28 and cytotoxic T-lymphocyte antigen (CTLA) on the T-cell surface, and abrogation of signaling via these costimulatory receptors is known to substantially attenuate the adaptive immune response.¹¹⁹

Upregulation of costimulatory molecules (UCM) is therefore essential, although not by itself sufficient, for activation of the adaptive immune response. LPS depends upon TRIF (and specifically, upon TRIF-mediated type I IFN gene expression) to elicit UCM^{42,60,120}; absent TRIF, LPS cannot exert an adjuvant effect. TRAM is also required for UCM.⁴¹ Although MyD88 does not elicit UCM, it does contribute to LPS-induced adjuvanticity in an experimental setting.⁶⁰ It is likely that IL-12, a cytokine that is largely MyD88-dependent, also contributes to the adjuvant effect, along with other proteins yet to be identified.

Even though several publications initially suggested that TLR signaling is required for adaptive immune responses to occur, it has been observed that mice lacking all TLR signaling are quite capable of mounting adaptive immune responses, including antibody responses and recall responses to defined antigens administered with diverse adjuvants.¹²¹ It is now evident that there is much redundancy in adaptive immune responses, and several innate immune pathways can independently trigger such responses.

● DISEASES CAUSED BY INNATE IMMUNE DEFECTS

Premature death from infection is strongly heritable in humans.¹²² Defects of the innate immune sensing apparatus are expected to cause hypersusceptibility to infection in humans as they clearly do in mice, and specific examples of such mutations have recently come to light including the NLR disorders discussed above (see “Sensors of the NOD-Like Receptor Family”). Missense mutations of TLR4 that are rare among the normal white population are quite common in patients with systemic meningococcal disease, and have been assigned a role in susceptibility on this basis.¹²³ A nonsense mutation of TLR5 was found to be overrepresented in patients who developed Legionnaire disease as compared to a comparably exposed population that remained disease-free.¹²⁴ Mutations of IRAK4 and MyD88 create susceptibility to suppurative Gram-positive infections.^{44,125} In humans, both TLR3¹²⁶ and UNC93B1¹²⁷ mutations cause susceptibility to recurrent Herpes simplex virus encephalitis, and presumably to other diseases as well.

On the effector side, examples of immunocompromise from innate immune defects are far better known, and include diseases caused by

mutations affecting IFN- γ ,¹²⁸ IL-12¹²⁹ and its receptor,^{130,131} defects of granule formation,¹³² and defects of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase.¹³³

● THE GENERAL STRATEGY OF INNATE IMMUNE RESPONSES AND THE CONCEPT OF FORWARD FEEDBACK LOOPS IN AUTOIMMUNITY
