Toxic effects include necrotic mouth lesions; ulcerations of the esophagus, small intestine, and colon, with abdominal pain, vomiting, and diarrhea; megaloblastic anemia; alopecia; and hyperpigmentation. The drug is excreted by the kidney, so effects and toxicity are prolonged and enhanced if renal function is impaired. Toxicity caused by these folate antagonists is treated with folinic acid (N⁵-formyl FH₄). Folic acid itself is useless in this setting because the blocked reductase cannot convert folate to the active tetrahydro form. Folinic acid is already in the tetrahydro form, so folinic acid is effective despite reductase blockade. The usual dose of folinic acid is 3 to 6 mg/day IM. Larger doses are given in chemotherapy protocols that use folinic acid to rescue patients deliberately treated with otherwise fatal doses of methotrexate. Folinic acid was used intrathecally in a patient in whom a large overdose of methotrexate was accidentally delivered into the subarachnoid space.³⁸¹

Zidovudine (azidothymidine [AZT]) is used for HIV infections (AIDS; Chap. 81).³⁸² Its principal toxic effect is severe megaloblastic anemia. Anemia or neutropenia produced by zidovudine limits use of this drug.³⁸³

HIV infection itself suppresses hematopoiesis, leading to pancytopenia with myelodysplastic features (Chaps. 81 and 87). The blood film shows vacuolated monocytes. Megaloblastosis in HIV infection may result from folate or cobalamin deficiency³⁸⁴ or AZT or trimethoprim toxicity.

Hydroxyurea is used at high doses to treat chronic myelogenous leukemia, polycythemia vera, and essential thrombocythemia, and at lower doses to treat psoriasis, rheumatoid arthritis, and sickle cell disease (Chap. 22). It inhibits conversion of ribonucleotides to deoxyribonucleotides.³⁸⁵ Marked megaloblastic changes are routinely found in the marrow 1 to 2 days after initiating hydroxyurea therapy. These changes are rapidly reversed after the drug is withdrawn. Megaloblastosis as a result of N₂O is discussed in "Acute Megaloblastic Anemia" above.

Long-term use of omeprazole and presumably other H⁺/K⁺-ATPase inhibitors is associated with reduced serum cobalamin levels, presumably because of the ability of these drugs to inhibit parietal cell

function.³⁸⁶ Reduced serum cobalamin levels are not a problem when these drugs are used for short intervals.³⁸⁷

Pemetrexed is an antifolate approved for use in mesothelioma. It also has been used for treatment of non-small cell lung cancer. Like other antifolate agents, pemetrexed can result in a megaloblastic anemia that is treated with cobalamin and folate. Coadministration of the drug with cobalamin and folate also reduces toxicity. Trimethoprim is a FH₂ reductase inhibitor that is designed to act on microbial rather than the mammalian enzyme. Still, in patients with borderline folate status, trimethoprim can precipitate a state of folate deficiency.

MEGALOBlastic ANEMIA IN CHILDHOOD

Megaloblastic anemia in childhood is usually the result of genetic disorders affecting either the cobalamin binding proteins or the enzymes concerned with intracellular trafficking of cobalamin or its conversion to coenzymatically active forms. Several recent reviews have dealt comprehensively with this topic.^{321,388,389}

Defects Involving Cobalamin-Binding Proteins

Several genetic mutations and polymorphisms exist that affect the key binding proteins for cobalamin. Their effects range from being clinically benign to causing severe cobalamin deficiency with megaloblastic anemia and neurologic complications usually manifesting in infancy or early childhood, occasionally in adolescence or early adulthood. In general, the mutations and deletions affecting the encoded proteins cause serious health consequences whereas the polymorphic variants may be totally inconspicuous or result only in a modified likelihood of disease risk.

Cobalamin malabsorption occurs in four childhood conditions associated with a genetic component: (1) cobalamin malabsorption in the presence of normal intrinsic factor secretion, (2) congenital abnormality of intrinsic factor, (3) TC deficiency, and (4) true PA of childhood. The management of cobalamin deficiency in childhood has been comprehensively reviewed.³⁸⁹

Selective Malabsorption of Cobalamin, Autosomal Recessive Megaloblastic Anemia, Imerslund-Gräsbeck Disease Imerslund-Gräsbeck disease³⁹⁰ is an inherited failure of transport of the intrinsic factor-Cbl complex by the ileum, usually accompanied by proteinuria, mostly of albumin.³⁸⁹ It may be the most common cause of cobalamin deficiency in infancy in some populations.³⁹¹ Cobalamin deficiency usually is seen before age 2 years, but may appear earlier or later. Cobalamin malabsorption is not corrected by addition of intrinsic factor. Endogenous intrinsic factor and HCl secretion, TC and HC levels, and gastric and intestinal histology are all normal. Intrinsic factor antibodies are absent. Intrinsic factor-Cbl receptors are present in some but not all patients. The molecular defect responsible for this disease has been elucidated. For the ileal phase of cobalamin absorption, two genes code distinct proteins that form part of the cobalamin-IF receptor (cobalamin-intrinsic factor receptor) complex. The first, which codes for the protein CUBN, is affected by several mutations described in Finnish patients with MGA1.^{95,392} The second, affecting the protein AMN results in a milder MGA1 phenotype and is found in Norwegian patients.^{95,393} Again, several mutations in the gene coding for the AMN protein have been described.⁹⁵ Patients are treated with IM cobalamin. The anemia is corrected, but proteinuria persists.

Congenital Intrinsic Factor Deficiency Congenital intrinsic factor deficiency is an autosomal recessive disease in which parietal cells fail to produce functionally normal intrinsic factor.³⁹⁴ Patients present with irritability and megaloblastic anemia when cobalamin stores (<25 mcg at birth) are exhausted. The disease usually presents at age 6 to 24 months. HCl secretion and gastric histology are normal, proteinuria is not present, and antiintrinsic factor antibodies are absent.³⁹⁵ Abnormal cobalamin absorption is corrected by oral intrinsic factor.³⁹⁶ Treatment consists of standard doses of IM cobalamin.

TABLE 41-5. Drugs That Cause Megaloblastic Anemia

Agents	Comments	Reference
ANTIFOLATES		
Methotrexate	Very potent inhibitor of dihydrofolate reductase	425
Aminopterin	Treat overdose with folinic acid	380
Pyrimethamine	Much weaker than methotrexate and aminopterin	
Trimethoprim	Treat with folinic acid or by withdrawing the drug	426, 427
Sulfasalazine	Can cause acute megaloblastic anemia in susceptible patients, especially those with low folate stores	428
Chlorguanide (Proguanil)		429
Triamterene	Use of folate and cobalamin during pemetrexed treatment reduces toxicity	
Pemetrexed (Alimta)		430
PURINE ANALOGUES		
6-Mercaptopurine	Megaloblastosis precedes hypoplasia, usually mild	431
6-Thioguanine	Responds to folinic acid but not folate	432
Azathioprine		433
Acyclovir	Megaloblastosis at high doses	434
PYRIMIDINE ANALOGUES		
5-Fluorouracil	Mild megaloblastosis	435
Floxuridine (5-fluorodeoxyuridine)		435
6-Azauridine	Blocks uridine monophosphate production by inhibiting orotidyl decarboxylase; occasional megaloblastosis with orotic acid and orotidine in urine	436
Zidovudine (AZT)	Severe megaloblastic anemia is the major side effect	383
RIBONUCLEOTIDE REDUCTASE INHIBITORS		
Hydroxyurea	Marked megaloblastosis within 1–2 days of starting therapy; quickly reversed by withdrawing drug	437
Cytarabine (cytosine arabinoside)	Early megaloblastosis is routine	438
ANTICONVULSANTS		
Phenytoin (diphenylhydantoin)	Occasional megaloblastosis, associated with low folate levels; responds to high-dose folate (1–5 mg/day); how anticonvulsants cause low folate is not understood, but may be related to a drug-induced rise in cytochrome P450	439–441
Phenobarbital		439
Primidone		439
Carbamazepine		442
OTHER DRUGS THAT DEPRESS FOLATES		
Oral contraceptives	Occasional megaloblastosis; sometimes dysplasia of uterine cervix, corrected with folate	443
Glutethimide		
Cycloserine		
H⁺/K⁺-ATPASE INHIBITORS		
Omeprazole	Long-term use causes decreased serum cobalamin levels	386
Lansoprazole		
MISCELLANEOUS		
N ₂ O	See “Acute Megaloblastic Anemia” in text	368
D-Aminosalicic acid	Causes cobalamin malabsorption with occasional mild megaloblastic anemia	444
Metformin		445
Phenformin	Causes cobalamin malabsorption but not anemia	
Colchicine		446
Neomycin		447
Arsenic	Causes myelodysplastic hematopoiesis, sometimes with megaloblastic changes	448

Transcobalamin Deficiency TC deficiency is an autosomal recessive disorder causing a flagrant megaloblastic anemia that generally presents in early infancy.³⁹⁵ The disease is dangerously deceptive because it results from a very severe deficiency of tissue cobalamin, usually with serum cobalamin levels in the normal range because most of the plasma cobalamin is bound to HC resulting in a misleading test result if reliance is placed simply on serum cobalamin measurement. Undiagnosed TC deficiency causes irreversible CNS damage.³⁹⁷ Patients are healthy at birth but over the next few weeks develop signs and symptoms of cobalamin deficiency, such as rapidly progressive pancytopenia, mouth ulcers, vomiting, and diarrhea. Recurrent bacterial infections may occur.³⁹⁵ Neurologic findings are not prominent in the early stages of the disease.³⁹⁷

Serum folate and cobalamin are normal (the latter because most cobalamin is carried by HC). Homocysteine and/or methylmalonic acid levels are elevated in the plasma.³⁹⁸ The marrow is megaloblastic and the cobalamin absorption is usually but not always abnormal and is not corrected by intrinsic factor.³⁹⁹ The diagnosis is made by measuring plasma TC.³⁸⁹ Prenatal diagnosis is possible.⁴⁰⁰ Serum should be obtained prior to treatment because TC levels in normal individuals drop sharply after cobalamin is given. TC deficiency is treated with cobalamin doses sufficiently large to force enough vitamin into the cells to allow normal function. Initial therapy can consist of oral CnCbl or OHCbl 500 to 1000 mcg twice a week, or IM OHCbl 1000 mcg/week. Blood counts and symptoms should be monitored and doses adjusted upward if necessary.

Several single nucleotide polymorphisms in the TC gene have been described and the allele frequency of the most common form (776 C>G) is high in certain populations.^{401,402} HoloTC levels are lower and methylmalonate levels are higher in individuals homozygous for the G allele,^{401,402} suggesting that this genotype may be associated with less-favorable cobalamin status.⁶⁴

Haptocorrin Deficiency Congenital deficiency is not associated with clinically manifested cobalamin deficiency, although the plasma or serum cobalamin levels are well below normal,³⁴⁵ and this is how the condition is recognized. The absence of morbidity in these patients indicates that HCs are not essential for health.

True Juvenile Pernicious Anemia True PA, with gastric atrophy and a defect in intrinsic factor secretion, is exceedingly rare in childhood.⁴⁰³ Patients usually present in their teens with cobalamin deficiency. Serum antiintrinsic factor antibodies usually are present.²⁶⁵ The diagnosis and treatment are the same as for PA in adults.

INBORN ERRORS OF COBALAMIN METABOLISM

Cobalamin is converted to AdoCbl and MeCbl by a complex series of transformations involving several steps.^{388,398,404} Eight disorders affecting this cobalamin transformation pathway have been described, one for each of the steps. Because the molecular causes of these disorders have not yet been fully characterized, the disorders themselves are not named for a defective protein but instead are designated by sequential capital letters preceded by a *cbl* prefix. The disorders can be grouped into three broad clinical syndromes based on the abnormal metabolites in the patient's urine (Table 41–6). These disorders are usually discovered during investigation of infants with unexplained developmental delay, acidosis, anemia, or unexplained neurologic difficulties. Typically they have normal plasma cobalamin levels.

Methylmalonic Aciduria Only (*cblA*, *cblB*, and *cblH*)

In *cblA* and *cblB*, AdoCbl production is impaired but MeCbl production is normal. This may result either from an abnormal methylmalonyl CoA mutase (designated *muto* or *mut*–) or from a defect in activation

TABLE 41–6. Cobalamin Mutant Class Syndromes

Syndrome	Methylmalonic Aciduria	Homocystinuria	Megaloblastic Anemia
<i>cblA</i> , <i>cblB</i> , <i>cblH</i>	+	–	–
<i>cblE</i> , <i>cblC</i>	–	+	+
<i>cblC</i> , <i>cblD</i> , <i>cblF</i>	+	+	±

or production of its cofactor, AdoCbl. The *cblH* variant appears to represent an interallelic variant of *cblA*.⁴⁰⁵ Patients present in infancy with acidosis because they cannot catabolize methylmalonic acid. Symptoms include lethargy and failure to thrive, vomiting, and neurologic problems. Mental retardation is not prominent, and megaloblastic anemia is absent. Most patients respond to 1000 mcg/day of OHCbl or CnCbl, although *muto* and *mut*– patients are unresponsive.

Homocystinuria Only (*Cble* and *Cblg*)

In these disorders, *N*⁵-methyltetrahydrofolate-homocysteine methyltransferase is defective and lacks the capacity to produce MeCbl.⁴⁰⁶ In patients with *cblG*, methionine synthase is missing or defective.⁴⁰⁷ *cblE* results from failure to reactivate methionine synthase that was inactivated by oxidation of its bound cobalamin.⁴⁰⁸ Patients present in infancy with vomiting, mental retardation, and megaloblastic anemia. They have marked homocystinuria and hyperhomocysteinemia without methylmalonic aciduria or methylmalonic acidemia. They respond well to CnCbl 1000 mcg/day or 1000 mcg/week. Infants diagnosed prenatally and treated from birth usually show normal development. On rare occasions, this disorder may first become apparent in adult life.

Methylmalonic Aciduria and Homocystinuria (*Cblc*, *Cbld*, and *Cblf*)

In these disorders, the defect in Cbl transformation affects AdoCbl and MeCbl, probably because reduction of cobalt from Co⁺⁺ to Co⁺ is defective. These patients have both hyperhomocysteinemia and methylmalonic acidemia. The age at initial presentation ranges from early infancy to adolescence. In addition to lethargy and failure to thrive, affected infants present with serious neurologic difficulties. Older patients present with psychological problems, progressive dementia, and motor signs and symptoms. *cblC* disease is the most common of the cobalamin inborn errors. In *cblF* the defect lies in an inability to release cobalamin from lysosomes.⁴⁰⁹ Megaloblastic anemia occurs in about half the cases. Patients respond partially to 1000 mcg/day of OHCbl or CnCbl.

A tentative diagnosis of a cobalamin mutation can be made by demonstrating methylmalonic aciduria and/or homocystinuria in a patient with the clinical findings described above in “Methylmalonic Aciduria Only” or “Homocystinuria Only,” respectively. Establishing a diagnosis requires a specialized laboratory equipped to do cultured fibroblast complementation studies.³⁸⁸ In a patient suspected of having a cobalamin mutation, treatment should be started pending the test results because early high-dose cobalamin treatment is risk-free and may reduce the chance of damage to the CNS. Fetuses with these diseases have been successfully treated *in utero* with very large doses of CnCbl given parenterally to the mother.⁴¹⁰

INBORN ERRORS OF FOLATE METABOLISM

Megaloblastic anemia in infancy has been described in three inherited disorders of folate metabolism.^{30,389,411}

Hereditary Folate Malabsorption

Hereditary folate malabsorption is a rare inherited disorder in which patients cannot absorb folate from the gastrointestinal tract or transport it across the choroid plexus and into the cerebrospinal fluid.^{29,30} The molecular basis for this disorder is caused by abnormalities in the PCFT.²⁹ Patients present with severe megaloblastic anemia, seizures, mental retardation, and other CNS findings.⁴¹² Folate levels are low in the serum and nil in the cerebrospinal fluid. Folate given parenterally has corrected the anemia and seizures in some patients but has had no effect on other CNS symptoms or on the cerebrospinal fluid folate level. Treatment with daily folinic acid by injection maintains the spinal fluid level and can lead to normal development.³⁸⁹

Dihydrofolate Reductase Deficiency

Dihydrofolate reductase deficiency may present isolated megaloblastic anemia within days or weeks after birth. The anemia responds to folinic acid but not to folic acid.⁴¹³

N⁵-Methyltetrahydrofolate–Homocysteine Methyltransferase Deficiency

Decreased methyltransferase activity was described in a liver biopsy from a child with megaloblastic anemia and mental retardation. The anemia failed to respond to folate, cobalamin, or pyridoxal phosphate.⁴¹⁴ The phenotype of this disorder resembles the inborn errors of cobalamin metabolism affecting the methionine synthesis reaction and has not been well characterized as a distinct entity at the molecular level.

Methylene Tetrahydrofolate Reductase Deficiency

In this rare autosomal recessive disorder there is a severe hyperhomocysteinemia and homocystinuria with low plasma methionine. Patients have neurologic and vascular complications but no megaloblastic anemia or methylmalonic aciduria.³⁸⁹ The polymorphic variations in MTHFR have been discussed earlier as well as their influence on disease susceptibility and the influence of the enzyme on the distribution of major folate species toward either methylation or DNA synthetic pathways.

OTHER INBORN ERRORS

Hereditary Orotic Aciduria

Hereditary orotic aciduria is an autosomal recessive disorder of pyrimidine metabolism⁴¹⁵ characterized by megaloblastic anemia, growth impairment, and excretion of orotic acid in the urine. Cobalamin and folate levels are normal.

Lesch-Nyhan Syndrome

The Lesch-Nyhan syndrome is an X-linked disorder of purine metabolism characterized by hyperuricemia, hyperuricosuria, and a neurologic disease with self-mutilation. It is caused by a hypoxanthine–guanine phosphoribosyltransferase deficiency. One patient described had megaloblastic anemia.⁴¹⁶

Thiamine-Responsive Megaloblastic Anemia

Seven children with severe megaloblastic anemia, sensorineural deafness, and diabetes mellitus, all beginning in infancy, have been reported. The anemia responded to thiamine (25 to 100 mg/day). The marrow was reported as myelodysplastic in two patients with the disorder.⁴¹⁷ The gene for this puzzling disorder has been mapped to the long arm of chromosome 1, and the underlying biochemical defect is caused by reduced nucleic acid production through impairment of the thiamine dependent pentose cycle enzyme transketolase that results in cell-cycle arrest and the megaloblastic phenotype.⁴¹⁸ This condition is also discussed in Chap. 44.

OTHER CAUSES OF MEGALOBLASTIC ANEMIA

Congenital Dyserythropoietic Anemia

The congenital dyserythropoietic anemias are lifelong anemias. They often are mild, showing dysplastic changes affecting the red cell line only, most typically multinuclearity of the normoblasts. They appear to result from defects in glycosylation of polylectosaminoglycans linked to membrane proteins and ceramides.⁴¹⁹ Of the three types, two (type I usually⁴²⁰ and type III occasionally⁴²¹) show megaloblastic red cell precursors (Chap. 39).

Refractory Megaloblastic Anemia

Refractory megaloblastic anemia is regarded as a manifestation of some sideroblastic anemias (Chap. 59) and myelodysplastic disorders (Chap. 87).⁴²² The megaloblastic changes are atypical. Dysplastic features are confined to the erythroid series. Giant metamyelocytes and bands are absent from the marrow. A few patients with refractory megaloblastic anemia respond to pharmacologic doses of pyridoxine (200 mg/day),⁴²³ perhaps because of an effect on serine transformylase, which requires both pyridoxine and folate.

Acute Erythroid Leukemia

In acute erythroid leukemia, a variety of acute myelogenous leukemia (Chap. 89)⁴²⁴ nucleated red cells appear on the blood film, there is usually marked anisocytosis and anisochromia, and macrocytes are usually present. The marrow shows pronounced erythroid hyperplasia involving very bizarre looking megaloblast-like red cell precursors, often containing multiple nuclei or nuclear fragments (see Chap. 88, Fig. 88–1) together with increased numbers of blasts. The megaloblastoid erythroid precursors frequently appear vacuolated.

Consideration of the rarer causes of megaloblastic anemia is important when the common and correctable causes resulting from folate or cobalamin deficiencies have been excluded. This is particularly important in the pediatric age group, but also in patients who are refractory to treatment with either folate or cobalamin.

CHAPTER 42

IRON METABOLISM

Tomas Ganz

SUMMARY

Iron is a component of nearly all living organisms. It plays an important metabolic role, particularly in electron transfer reactions. Most of the iron in the human body is incorporated into the hemoglobin of circulating red cells, which contain approximately 1 mg of iron per 1 mL of packed cells. Smaller amounts of iron are present in myoglobin and in many enzymes. Iron is stored within cells inside ferritin and circulates in plasma bound to transferrin. Because little iron is lost from the body under normal circumstances, the iron content of the body is controlled by modulating dietary iron absorption. Iron absorption increases in the presence of iron deficiency and it decreases when there is iron overload. The absorption of inorganic iron involves a ferrireductase and a divalent iron transporter, DMT-1, on the gastrointestinal luminal apical membranes of enterocytes, and ferroportin and hephaestin, located on the basolateral enterocyte membranes, in contact with blood. In contrast to elemental iron, heme iron is absorbed by a distinct pathway, which is still not well understood.

Systemic iron homeostasis is orchestrated by the hepatic peptide hormone hepcidin, which regulates plasma iron concentrations, the absorption

Iron is a key element in the metabolism of nearly all living organisms. Iron is a component of heme, which is the active site of electron transport in cytochromes and cytochrome oxidase involved in mitochondrial energy generation. The heme moiety of hemoglobin and myoglobin binds O_2 , providing the means to transfer O_2 from the lungs to tissues and to store it. Heme is also the active site of peroxidases that protect cells from oxidative injury by reducing peroxides to water or generate microbicidal hypochlorite in granulocytes. DNA synthesis requires the enzyme ribonucleotide reductase to convert ribonucleotides to deoxyribonucleotides. Neither bacteria nor nucleated cells proliferate when the supply of iron is insufficient.

Acronyms and Abbreviations: ABCB10, ATP-binding cassette (ABC) transporter in the inner membrane of mitochondria; ALA synthase, aminolevulinic acid synthase; BMP, bone morphogenetic protein; dcytb, duodenal cytochrome b; DMT, divalent metal transporter; GDF15, growth differentiation factor 15; HFE, human hemochromatosis protein; HRG1, heme transporter; IL, interleukin; IRE, iron-responsive element; IRP, iron-regulatory protein; NADPH, nicotinamide adenine dinucleotide phosphate; Nramp1, natural resistance-associated macrophage protein one; STEAP3, six-transmembrane epithelial antigen of prostate 3; TfR, transferrin receptor.

In the previous edition, this chapter was written by Ernest Beutler and portions of that chapter have been retained.

of dietary iron, and the release of iron from macrophages involved in iron recycling and storage and from hepatocytes that store iron. The cellular iron exporter ferroportin serves as the receptor for hepcidin and is destroyed when the complex is formed. This impairs transport from intestinal mucosal cells, from macrophages and from hepatocytes into the plasma, and lowers iron absorption and release from stores. Hepcidin decreases plasma iron levels by causing iron to be sequestered within cells, predominantly in macrophages or enterocytes, the latter of which are then shed along with their absorbed iron. Once ferric iron enters the plasma, it is bound by transferrin, which, after forming a complex with the transferrin receptor, transports the metal into cells. The transferrin receptor is internalized together with bound transferrin and iron, and the iron is released inside the cell into an acidified vacuole. The transferrin receptor then recycles to the cell surface.

Cellular iron homeostasis is largely achieved through posttranscriptional regulation of key proteins involved in iron transport, storage and utilization. The synthesis of these proteins is regulated by binding of one of the iron-regulatory proteins (IRPs) to iron-responsive elements (IREs) located within stem loop structures of the corresponding messenger ribonucleic acids (mRNAs). IRP-1 is cytoplasmic aconitase that binds to the IRE when it is not complexed with iron and does not bind when iron is present; IRP-2, a closely related protein, is destabilized by the presence of iron. When IRPs bind to IREs at the 5' end of the mRNA, they prevent translation; when they bind at the 3' end, they stabilize the mRNA.

● DISTRIBUTION OF IRON IN THE AVERAGE PERSON

Table 42-1 summarizes the most important iron compartments.

HEMOGLOBIN

Hemoglobin, which is 0.34 percent iron by weight, contains approximately 2 g of body iron in men and 1.5 g in women. One mL of packed erythrocytes contains approximately 1 mg of iron. Because the life span of human erythrocytes is approximately 120 days, every day 1/120 of the iron in hemoglobin is recycled by macrophages and returned to the plasma, from where it is largely delivered to marrow erythroblasts for incorporation into newly synthesized hemoglobin.

STORAGE COMPARTMENT

Iron is stored either as ferritin or as hemosiderin. The former is water-soluble; the latter is water-insoluble. The protein ferritin is composed of 24 similar or identical subunits arranged as 12 dimers forming a dodecahedron that approximates a hollow sphere with a cavity capable of storing up to 4500 Fe atoms as hydrous ferric oxide polymers.^{1,2} The ferritin subunits are of H (heavy) or L (light) type. H subunits have ferroxidase activity, thereby enabling ferritin to take up or release iron quite rapidly. Ferritin that is rich in H subunits takes up iron more readily, but retains it less avidly than does ferritin composed predominantly of L subunits. Much of the storage iron in liver and spleen is in ferritin containing mostly L subunits.

Ferritin is found in virtually all cells of the body and also in tissue fluids. In plasma ferritin is present in minute concentrations. It is glycosylated and largely composed of L subunits. Except under conditions of inflammation, the plasma (serum) ferritin concentration usually correlates with total-body iron stores, making measurement

TABLE 42-1. Iron Compartments in the Average Person*

Compartment	Iron Content (mg)	Total Body Iron (%)
Hemoglobin iron	2000	67
Storage iron (ferritin, hemosiderin)	1000	27
Myoglobin iron	130	3.5
Labile pool	80	2.2
Other tissue iron	8	0.2
Transport iron	3	0.08

*These values represent estimates for an “average” person, that is, 70 kg (154 lb) in weight and 177 cm (70 inches) in height. The values are derived from data in several sources.

of serum ferritin levels important in the diagnosis of disorders of iron metabolism.

The size of the iron storage compartment is quite variable. Normally, in adult men, it amounts to 800 to 2000 mg; in adult women, it is a few hundred milligrams. The mobilization of storage iron from ferritin involves the reduction of Fe^{3+} to Fe^{2+} , its release from the core crystal and its diffusion out of the apoferritin shell. As it passes from cytosol to plasma, it must be reoxidized to Fe^{3+} , either by hephaestin or ceruloplasmin in the cell membrane or by ceruloplasmin in plasma, before it binds to transferrin. Alternatively, iron may be released from ferritin by autophagy followed by lysosomal degradation.³

Hemosiderin is found predominantly in macrophages. Microscopically, in unstained tissue sections or marrow films it appears as clumps or granules of golden refractile pigment. Under pathologic conditions, it may accumulate in large quantities in almost every tissue of the body. Hemosiderin is chemically similar to the iron core of ferritin and may be derived from ferritins whose protein shells have been digested in lysosomes.

MYOGLOBIN

Myoglobin is structurally similar to hemoglobin, but it is monomeric rather than tetrameric: Each myoglobin molecule consists of a heme group nearly surrounded by polypeptide loops of the 154 amino acid protein. It is present in small amounts in all skeletal and cardiac muscle cells, where it may serve as an oxygen reservoir to protect against cellular injury during periods of oxygen deprivation and may scavenge nitric oxide and reactive oxygen species.⁴

LABILE IRON POOL

The existence of a cellular labile iron pool was postulated from studies of the rate of clearance of injected ^{59}Fe from plasma.⁵ Iron leaves the plasma and enters the interstitial and intracellular fluid compartments for a brief time before it is incorporated into heme or storage compounds. Some of the iron reenters plasma, causing a biphasic curve of ^{59}Fe clearance 1 to 2 days after injection. The change in slope defines the size of the labile pool, normally 80 to 90 mg of iron. It is now sometimes considered to be equivalent to the chelatable iron pool.⁶

TISSUE IRON COMPARTMENT

Tissue iron (exclusive of hemoglobin, ferritin, hemosiderin, myoglobin, and the labile compartment) normally amounts to 6 to 8 mg. This includes cytochromes and other iron-containing enzymes. Although a small compartment, it is an extremely vital one and is sensitive to iron deficiency.^{7,8}

TRANSPORT COMPARTMENT

From the standpoint of its total iron content, normally about 3 mg, the transport compartment of plasma is the smallest but the most active of the iron compartments: Its iron, almost entirely carried by transferrin, normally turns over at least 10 times each day. This is the common pathway for interchange of iron between compartments.

Transferrin

Transferrin is a dumbbell-shaped glycoprotein with a Mr of approximately 80 kDa where each of the two globular domains contains a binding cleft for Fe^{3+} .⁹⁻¹¹ Normally, approximately one-third of the transferrin iron-binding sites are occupied by iron. Human plasma normally contains approximately 25 to 45 μM (200 to 360 mg/dL) transferrin, capable of binding 50 to 90 μM iron but carrying only 10 to 30 μM (50 to 180 mcg/dL) iron. Apotransferrin (transferrin devoid of iron) is synthesized by hepatocytes and by cells of the monocyte-macrophage system.^{12,13}

DIETARY IRON

CONTENT

Average American adult men and women ingest 9 to 10 mg and 12 to 14 mg of iron daily, respectively.¹⁴ The amount of iron absorbed by a normal adult male need only balance the small amount that is excreted, mostly in the stool, approximately 1 mg/day.¹⁵ More iron is needed during growth periods or after blood loss. In women, iron absorbed must be sufficient to replace that lost through menstruation or diverted to the fetus or milk during and after pregnancy. Table 42-2 shows the age- and gender-specific recommended dietary allowances for iron.¹⁶

BIOAVAILABILITY

In meat-eaters in Western countries, heme from hemoglobin and myoglobin normally comprises approximately 15 percent of dietary iron but is much more efficiently absorbed than nonheme iron, and promotes the absorption of nonheme iron.¹⁷ The absorption of nonheme dietary iron is strongly affected by iron-binding components of food. Oxalates, phytates, and phosphates complex with iron and retard its absorption, whereas simple reducing substances, such as hydroquinone, ascorbate, lactate, pyruvate, succinate, fructose, cysteine, and sorbitol, increase iron absorption.¹⁸ Iron-fortified cereals are major sources of iron in countries where fortification is practiced, but cooking in iron pots may also provide important exogenous iron.¹⁷ Gastric acid secretion,

TABLE 42-2. Recommended Dietary Allowances (RDAs) for Iron¹⁶

Age	Male	Female	Pregnancy	Lactation
Birth to 6 months	0.27 mg*	0.27 mg*		
7-12 months	11 mg	11 mg		
1-3 years	7 mg	7 mg		
4-8 years	10 mg	10 mg		
9-13 years	8 mg	8 mg		
14-18 years	11 mg	15 mg	27 mg	10 mg
19-50 years	8 mg	18 mg	27 mg	9 mg
51+ years	8 mg	8 mg		

*Adequate intake (AI).

the transit time, and mucus secretion all play roles in iron absorption. Red wine, contrary to popular belief, inhibits iron absorption, probably because of the presence of polyphenols.¹⁹ In mice, alcohol suppresses the response of hepcidin to iron,²⁰ and this may contribute to iron loading that is seen in some alcoholic subjects.

IRON ABSORPTION

Iron normally enters the body through the gastrointestinal tract, mostly through the enterocytes of the duodenum. The amount of iron absorbed is normally tightly regulated according to body needs. Active erythropoiesis and/or iron deficiency increase absorption; iron overload and systemic inflammation decrease absorption. Nevertheless, the amount of iron absorbed increases with the administered dose even though the percentage absorbed decreases (Fig. 42-1). Accidental or deliberate ingestion of large doses of medicinal iron can therefore cause iron intoxication.

MECHANISM OF TRANSPORT ACROSS THE INTESTINAL MUCOSA

Heme Iron

Understanding the mechanism of iron absorption has been made more difficult by the fact that the pathways for the uptake of inorganic iron and of heme by enterocytes are different but seem to merge within the intestinal cell where heme is converted to inorganic iron. How much heme (if any) is exported intact by enterocytes and bound by plasma heme-binding protein hemopexin is not clear, but hemopexin knockout mice show minor retention of iron in duodenal enterocytes without any effect on systemic iron homeostasis,²¹ arguing against a major contribution from this mechanism, at least in mice. Efforts to identify the apical heme import mechanism in enterocytes have not yet been definitive.²²

Ferric Iron

Following the reduction of ferric iron to ferrous iron, in part by duodenal cytochrome b (dcytb) reductase,²³ ferrous iron is transported into

Figure 42-1. The relationship between oral iron dosage and amount of iron absorbed in humans. When the logarithm of the dose is plotted against the logarithm of the amount of iron absorbed, a rectilinear relationship is observed. Thus, at all levels, the greater the dose of iron, the more is absorbed, although the percent of the dose that is absorbed progressively declines. (Reproduced with permission from Mackenzie B, Garrick MD: *Iron Imports. II. Iron uptake at the apical membrane in the intestine.* Am J Physiol Gastrointest Liver Physiol 289(6):G981–G986, 2005.)

the intestinal villus cell by the divalent metal transporter (DMT)-1.^{24,25} How iron transits within the enterocytes is not yet known. Basolateral export of ferrous iron is mediated by ferroportin^{26–28} in association with hephaestin²⁹ and plasma ceruloplasmin³⁰ to oxidize iron to the ferric state. Ferric iron is taken up by plasma apotransferrin. Figure 42-2 illustrates some of the steps that are thought to regulate iron transport across the mucosal cell.

IRON RECYCLING

Role of the Monocyte–Macrophage System

In humans, the destruction and production of erythrocytes generates most of the iron flux in and out of plasma (20 to 25 mg/day recycled in adults compared to 1 to 2 mg/day absorbed). Iron from other cell types is likely also recycled, but this source contributes little to iron flux and has not been studied. Destruction of aged erythrocytes and hemoglobin degradation occur within macrophages (Chap. 32). This proceeds at a rate sufficient to release approximately 20 percent of the hemoglobin iron from the cell to the plasma compartment within a few hours. Approximately 80 percent of this iron is rapidly reincorporated into hemoglobin. Thus, 20 to 70 percent of the hemoglobin iron of nonviable erythrocytes reappears in circulating red cells in 12 days. The remainder of the iron enters the storage pool as ferritin or hemosiderin and then turns over very slowly. In normal subjects, approximately 40 percent of this iron remains in storage after 140 days. When there is an increased iron demand for hemoglobin synthesis, however, storage iron may be mobilized more rapidly.³¹ Conversely, in the presence of infection or another inflammatory process (e.g., ulcerative colitis or malignancy), iron is more slowly reused in hemoglobin synthesis and is associated with anemia (Chap. 37).^{32,33}

Erythrophagocytosis

As human erythrocytes age during their average 120-day life span, they shrink, stiffen, and their membranes accumulate markers of senescence.³⁴ These changes eventually trigger phagocytosis by splenic or hepatic sinusoidal macrophages. Macrophages also take up the products of intravascular hemolysis, including hemoglobin (bound by haptoglobin) and heme (bound by hemopexin), using specific endocytic receptors for the complexes.³⁵ The vesicles involved in phagocytosis and endocytosis must fuse with lysosomes to digest cellular materials or protein complexes and to free heme from hemoglobin. The membrane complex of nicotinamide adenine dinucleotide phosphate (NADPH) cytochrome c reductase, heme oxygenase 1, and biliverdin reductase releases ferrous iron from heme and simultaneously protects erythrophagocytosing macrophages from heme-induced toxicity.³⁶ The subcellular location of the conversion of heme to iron is not known with certainty. Heme oxygenase 1 is mostly located in the endoplasmic reticulum in erythrophagocytic macrophages³⁷ with the catalytic face in the cytosol, and little, if any, heme oxygenase in the phagosomal membrane. Moreover, the phagosomal membrane is enriched in the heme transporter HRG1,³⁸ and macrophage heme has a signaling role in inducing various proteins involved in macrophage iron metabolism, indicating that it may leave the phagosome, and the heme oxygenase-1-mediated release of iron may occur in the cytoplasm. However, the ferrous iron transporter Nramp1, and perhaps DMT-1, may also participate in subcellular iron transport.³⁹ Ultimately, depending on systemic iron requirements, the released ferrous iron is either exported to plasma via ferroportin⁴⁰ or trapped in macrophage cytoplasmic ferritin. By a mechanism potentially important at the low oxygen tensions found in some tissues, plasma ceruloplasmin^{41–43} catalyzes the conversion of ferrous to ferric iron, the form of iron loaded to plasma transferrin for systemic distribution.

Figure 42-2. Schematic of iron uptake from the intestine and transfer to the plasma by an intestinal villus cell. Nonheme dietary iron includes Fe(II) and Fe(III) salts and organic complexes. Fe³⁺ is reduced to Fe²⁺ by ascorbic acid and apical membrane ferrireductases that include duodenal cytochrome b (dcytb). The acid microclimate at the brush-border provides an H⁺ electrochemical potential gradient to drive transport of Fe²⁺ via the divalent metal-ion transporter (DMT-1) into the enterocyte. DMT-1 may also contribute to the absorption of other nutritionally important metal ions (e.g., Mn²⁺). Heme can be taken up by endocytosis, and Fe²⁺ is liberated within the endosome/lysosome, but the molecular identity of proteins involved, including heme carrier protein 1 (HCP1), is yet to be elucidated. Basolateral export of Fe²⁺ may be mediated by ferroportin in association with hephaestin. Fe₂Tf, diferric transferrin; HO, heme oxygenase. (Data from Smith MD, Pannaciuoli IM: Absorption of inorganic iron from graded doses: its significance in relation to iron absorption tests and mucosal block theory. Br J Haematol 4(4):428–434, 1958.)

SYSTEMIC IRON HOMEOSTASIS

The mechanism by which body iron content is regulated by the modulation of iron absorption has been a subject of intense interest for the past 65 years. It has now become clear that intestinal iron absorption, plasma iron concentrations, and tissue distribution of iron are subject to endocrine regulation similar to that of other simple nutrients, for example, glucose or calcium, albeit in a somewhat more complex fashion.

Hepcidin and Ferroportin

Hepcidin, a 25-amino-acid peptide hormone with 4 disulfide bonds,^{44–47} is produced predominantly by hepatocytes and plays a central role in systemic iron homeostasis. Hepcidin regulates plasma iron concentrations by controlling the absorption of iron by the intestinal epithelial enterocytes and its release from iron-recycling macrophages and hepatocytes involved in iron storage. The structural similarity of hepcidin and a class of antimicrobial peptides termed *defensins* suggests that the hormone evolved from the latter to modulate iron homeostasis as a mechanism of body defense against microorganisms. Overexpression of hepcidin results in marked iron-deficiency anemia in mice⁴⁸ and a refractory anemia resembling the anemia of chronic inflammation in humans,⁴⁹ and injection of synthetic hepcidin rapidly lowers plasma iron concentrations.⁵⁰ As many microorganisms are dependent on plasma iron for survival in the circulation, hepcidin can exert host defense. In fact, patients with iron overload and high plasma iron levels are susceptible to such infections, such as with *Yersinia enterocolitica* (Chap. 43).

Hepcidin exerts its iron-regulatory effect by binding to ferroportin, a transmembrane iron-export protein expressed on enterocytes, macrophages, and hepatocytes. Once hepcidin has bound to ferroportin, the ferroportin is internalized and undergoes proteolysis.^{40,51} With membrane ferroportin depleted, iron cannot be exported from the enterocyte, the macrophage or the hepatocyte into the plasma (Fig. 42-3). This results in decreased iron absorption from the gastrointestinal tract and a fall in the plasma iron concentration. Hepcidin production is stimulated by inflammatory cytokines such as interleukin (IL)-6,^{52,53} and the overproduction of hepcidin is one of the factors in the pathogenesis of the anemia of chronic inflammation (Chap. 37).

The regulation of hepcidin production seems to be entirely transcriptional. In humans and laboratory rodents, hepcidin mRNA and plasma hepcidin levels increase in parallel with iron-loading and inflammatory stimuli,^{44,54,55} and are decreased by erythropoietic activity⁵⁶ and iron deficiency.⁵⁷

Regulation of Hepcidin by Iron

Both elevated plasma iron concentrations and increased liver stores are sensed in the intact organism and regulate hepcidin transcription,^{58,59} but the relevant mechanisms are only partially understood. For reasons that are not understood, involving perhaps the complex interactions of hepatocytes with other liver cells, isolated hepatocytes do not show consistently increased hepcidin synthesis after iron treatment, although small effects were observed when the cells were freshly harvested from mice.⁶⁰ Important clues are provided by hereditary disorders in which hepcidin transcription is dysregulated. As indicated in Table 42-3, impairment of the function of several genes is associated with iron overload in humans and in experimental animals. In addition to genes that encode the hormone hepcidin itself and its receptor, ferroportin, or encode proteins primarily involved in iron transport, there are a number of genes whose products are likely to function in

Figure 42-3. Regulation of iron flows into plasma by hepcidin. Ferroportin is the only known transporter that exports iron from cells to plasma (and extracellular fluid). Hepcidin induces ferroportin endocytosis and proteolysis and thereby controls the transfer of iron to plasma from all its major sources: iron-absorbing duodenal enterocytes, iron-storing hepatocytes, and iron-recycling macrophages.

TABLE 42-3. Proteins That Play a Role in Iron Homeostasis in Humans or in Animal Models

Proteins That Affect Iron Homeostasis	Effect of Deficiency or Mutation	References to Human Data	References to Murine Data	Comments
HFE	Parenchymal Fe increased	94	95, 96	Most patients with hereditary hemochromatosis are homozygous for the 845 A→G (C282Y) mutation of this gene. In signaling pathway to hepcidin
Ferroportin (SLC40A1, SLC11A3)	Macrophage Fe increased (loss of function)	97	98	Autosomal dominant, hepcidin receptor, cellular iron exporter
	Parenchymal Fe increased (resistance to hepcidin)	99, 100	101	Autosomal dominant
β_2 -Microglobulin	Parenchymal Fe increased	Unknown	102, 103	Facilitates transport of HFE to membrane
Transferrin	Parenchymal Fe increased	104–106	107, 108	Plasma iron transporter, holotransferrin concentrations regulate hepcidin
Transferrin receptor-1	Lethal; increased CNS Fe	Unknown	109	Mediates cellular iron uptake, essential for erythropoiesis, may be involved in signaling for hepcidin regulation
Transferrin receptor-2	Parenchymal Fe increased	84, 110	111	Signaling for hepcidin regulation
Hephaestin	Fe deficiency	Unknown	29	Sex-linked gene; deletion of exons is cause of <i>sla</i> mouse
Ceruloplasmin	Fe increased	112	42	Brain iron accumulation and neurologic disease
Ferritin H chain	Fe increased	113	Unknown	Dominant IRE mutation
Duodenal cytochrome b (dctyb)	Unknown	Unknown	23	Mild iron restriction under erythropoietic stress
Nramp1 (SLC11A1)	Alters iron distribution in macrophages	Unknown	39	Deficiency increases susceptibility to infection in mice
Nramp2 (DMT-1)	Hypochromic microcytic anemia and hepatic siderosis in people; Fe deficiency in rodents	114, 115	116, 117	Anemia is ameliorated by erythropoietin therapy in humans; same naturally occurring mutations found in the <i>mk</i> mouse and the Belgrade rat
Hepcidin	Parenchymal Fe Increased	118	46, 119	The hormone-regulating iron absorption, plasma iron concentration, and systemic distribution
Hemojuvelin	Parenchymal Fe increased	65	120, 121	Signaling for hepcidin regulation
Tmprss6	Fe deficiency	49	70, 72	Signaling for hepcidin regulation, membrane protease, cleaves hemojuvelin
BMP6	Parenchymal Fe increased	Unknown	122, 123	Necessary for iron regulation in mice
BMP receptor subunit	Parenchymal Fe increased	Unknown	124	Necessary for iron regulation in mice
SMAD4 in the liver	Parenchymal Fe increased	Unknown	125	In signaling pathway for hepcidin regulation
Neogenin	Parenchymal Fe increased	Unknown	126, 127	Necessary for hepcidin regulation

BMP, bone morphogenetic protein; HFE, human hemochromatosis protein; IRE, iron-responsive element.

iron sensing, signal transduction and transcriptional regulation. These include human hemochromatosis protein (HFE), transferrin receptor-2, bone morphogenetic proteins (BMPs), BMP receptor and its signaling pathway, and hemojuvelin, all of which encode proteins that normally stimulate hepcidin transcription to prevent iron overload. In the best-supported model, hepcidin transcription is regulated in an iron-dependent manner by the BMP pathway. Complexes of HFE, transferrin receptor-1, and transferrin receptor-2 may be involved in sensing the concentration of iron-transferrin and interact in as yet unknown manner with the BMP receptor to stimulate the transcription of hepcidin.^{61–64} Hemojuvelin, whose autosomal recessive mutations cause a very severe form of hereditary hemochromatosis, serves as a coreceptor for the BMPs.^{65,66} A soluble fragment of hemojuvelin acts as an inhibitor of the interaction of BMP with the receptor, but it is not

clear whether it has a physiologic regulatory role.^{67,68} Regulation of hepcidin transcription itself is complex, involving the formation of a complex of liver-specific and response-specific transcription factors bound to a distal BMP-RE2/bZIP/HNF4 α /COUP region and to the proximal BMP-RE1/STAT region of the hepcidin promoter, possibly by physical association of the two regions.⁶⁹ A pathway that inhibits the transcription of hepcidin exists as well. Tmprss6 (also called matriptase 2) is a membrane serine protease that inhibits hepcidin transcription, likely by proteolysis of hemojuvelin.^{70,71} This function was discovered when random mutagenesis in mice produced an iron-deficient animal with mutagenized Tmprss6.⁷² Subsequently, humans with mutations of the Tmprss6 orthologue were shown to manifest iron-refractory iron-deficiency anemia that does not respond to oral iron and only partially to parenteral iron therapy.⁴⁹

Regulation of Hepcidin by Erythropoiesis

Intestinal iron absorption is increased severalfold after hemorrhage or erythropoietin administration, and is chronically increased in patients with ineffective erythropoiesis but not in aplastic anemia.⁷³ These observations led to the hypothesis that the marrow generates an “erythroid regulator”⁷³ that modulates intestinal iron absorption. Later studies in mouse models⁵⁶ provided evidence that the erythroid regulator is a marrow-derived suppressor of hepcidin. Erythroferrone is an erythropoietin-induced erythroblast-secreted glycoprotein that acts on hepatocytes to suppress their hepcidin production and is required for rapid suppression of hepcidin after hemorrhage or erythropoietin administration.⁷⁴ It also contributes to hepcidin suppression and iron overload in murine models of β -thalassemia intermedia. Growth differentiation factor 15 (GDF15), a member of the BMP family, may also contribute to pathologic hepcidin suppression in anemias with ineffective erythropoiesis.⁷⁵

Regulation of Hepcidin by Inflammation

Within hours after the onset of systemic infection, plasma iron concentration decreases. The response is thought to contribute to host defense, particularly against microbes with high dependence on environmental iron.⁷⁶ This response, hypoferrremia of inflammation, is also triggered by noninfectious causes of acute and chronic inflammation. Hypoferrremia of inflammation is mediated by cytokine-induced increase in plasma hepcidin concentrations⁵⁴ causing hepcidin-induced sequestration of iron in macrophages. The main human cytokine responsible for hepcidin induction is IL-6^{52,53} acting via the JAK2-STAT3 pathway.⁷⁷⁻⁷⁹

but other cytokines including activin B may also contribute.⁸⁰ Chronic inflammation impairs iron supply to erythropoiesis and combines with other effects of inflammation to cause anemia of inflammation (anemia of chronic disease, see Chap. 37).

TRANSPORT OF IRON

Once an atom of iron enters the blood plasma from dietary iron absorption, it is virtually trapped in the body (Fig. 42-4) and cycles almost endlessly from the plasma to the developing erythroblast (where it is used in hemoglobin synthesis), thence into the circulating blood for approximately 4 months, and then to macrophages. Here it is removed from heme by heme oxygenase and released back into the plasma to repeat the cycle.

The major function of the transport protein transferrin is to move iron from wherever it enters the plasma (intestinal villi, splenic and hepatic sinusoids) to the erythroblasts of the marrow and to other sites of use.

ENDOCYTOSIS OF TRANSFERRIN

Diferic (holo)transferrin binds to the transferrin receptor (TfR)-1 on the cell surface and the holotransferrin-TfR1 complex forms clusters in pits on the cell membrane.⁸¹ The complex is then internalized by endocytosis (Fig. 42-5). Within the cytosol the holotransferrin-TfR1 complex is in a clathrin-coated vesicle. The vesicles fuse with endosomes and become acidified to pH 5 which releases iron from transferrin.

Figure 42-4. The iron cycle in humans. Iron is tightly conserved in a nearly closed system in which each iron atom cycles repeatedly from plasma and extracellular fluid (“plasma”) to the marrow, where it is incorporated into hemoglobin. Then it moves into the blood within erythrocytes and circulates for 4 months. It then travels to phagocytes of the mononuclear phagocyte system (“splenic and other macrophages”), where senescent erythrocytes are engulfed and destroyed, hemoglobin is digested, and iron is released to plasma, where the cycle continues. With each cycle, a small proportion of iron is transferred to storage sites, where it is incorporated into ferritin or hemosiderin, a small proportion of storage iron is released to plasma, a small proportion is lost in urine, sweat, feces, or blood, and an equivalent small amount of iron is absorbed from the intestinal tract. In addition, a small proportion (approximately 10 percent) of newly formed erythrocytes normally is destroyed within the marrow and its iron released, bypassing the circulating blood part of the cycle (ineffective erythropoiesis). The numbers indicate the approximate amount of iron (in mg) in various compartments and fluxes of iron (mg/day) that enter and leave each of these iron compartments in healthy adults who do not have bleeding or other blood disorders.

Figure 42-5. The transferrin cycle. Holotransferrin (Fe^{3+} -Tf) binds to transferrin receptors (TfR1) on the cell surface. The complexes localize to clathrin-coated pits, which invaginate to initiate endocytosis. Specialized endosomes form, and become acidified through the action of a proton pump. Acidification leads to protein conformational changes that release iron from transferrin. STEAP3 (six-transmembrane epithelial antigen of prostate 3) reduces ferric iron to ferrous iron, enabling iron transport out of the endosomes through the activity of the divalent metal transporter-1 protein (DMT-1). Subsequently, apotransferrin (Apo-Tf) and the transferrin receptor both return to the cell surface, where they dissociate at neutral pH. Both proteins participate in further rounds of iron delivery. In nonerythroid cells, iron is stored as ferritin and hemosiderin. (Reproduced with permission from McKie AT: A ferrireductase fills the gap in the transferrin cycle. *Nat Genet* 37(11):1159–1160, 2005.)

Iron-depleted (apo)transferrin and TfR1 remain complexed as they return to the cell membrane, where at neutral pH, apotransferrin separates from its receptor and is released to the interstitial fluid to reenter plasma and take up more iron.

The TfR is a protein consisting of two subunits that are linked by disulfide bonds.⁹ Its aminoterminal is on the cytoplasmic side of the membrane, and its carboxyl-terminus is on the outer surface. Because of the role of TfR1 in the binding and endocytosis of diferric transferrin, control of TfR1 biosynthesis is a major mechanism for regulation of iron metabolism. Synthesis of TfR1 is induced by iron deficiency. Iron inhibits TfR1 synthesis by destabilizing TfR1 mRNA by a mechanism that involves the iron-responsive element (IRE)/iron-regulatory protein (IRP) regulatory system (Fig. 42-6).^{82,83} TfR1 binds to HFE,⁶¹ using a binding site that overlaps that of holotransferrin. According to a current model of iron sensing, high concentrations of holotransferrin would therefore displace HFE from its complex with TfR1, leaving HFE to signal to the BMP receptor complex to increase hepcidin transcription. This model is supported by studies in which the expression of HFE or its binding site on TfR1 are manipulated.⁶¹

A second TfR, TfR2, also endocytic for holotransferrin, is not thought to be involved in delivering iron to cells but its hepatic expression is necessary for normal hepcidin expression and regulation.⁸⁴ TfR2 influences the BMP complex and its signaling pathway to regulate hepcidin transcription but the molecular mechanism of this effect is not yet understood. TfR2 is also expressed in erythroid precursors where it interacts with the erythropoietin receptor and negatively modulates erythropoiesis, perhaps putting a brake on erythrocyte production during iron deficiency.⁸⁵

INTRACELLULAR IRON HOMEOSTASIS

Each cell must regulate its iron uptake and subcellular distribution, both to assure adequate iron for a multitude of cellular enzymes and to prevent excessive iron accumulation that could be injurious or deny adequate iron to other cells. Accordingly, the synthesis of key cellular proteins involved in iron transport, storage, and use is regulated post-transcriptionally by cellular iron concentrations.^{82,83} The mRNA for each of these proteins contains one or several IREs. If the IRE is located at the 5' end of the mRNA, it serves to regulate translation; 3' IREs regulate the stability of the mRNA. Each IRE consists of a stem and loop structure, in which the loop is the nucleotide sequence CAGUG (Fig. 42-7). IRE/IRP-regulated mRNAs include those encoding ferritin, TfR1, aminolevulinic acid (ALA) synthase, transferrin, aconitase, DMT-1, and ferroportin. The ferritin mRNA has, as its IRE, a single stem-loop structure in the 5' (upstream) region. In contrast to the ferritin IRE, there are as many as five stems-loops in the 3' untranslated portion of TfR mRNA. The IREs are targeted by specific RNA-binding proteins, IRPs. IRP-1 is cytoplasmic aconitase with four iron-sulfur clusters and the ability to bind iron, which is required for its aconitase activity; IRP-2 is highly homologous to IRP-1 but differs by the presence of a 73-amino-acid insertion in the N-terminus and a lack of aconitase activity. In the absence of iron, IRP-1 binds to IREs, but in its presence becomes a cytoplasmic aconitase and does not bind IREs. IRP-2 (as well as, to some extent, IRP-1) undergoes ubiquitination and proteasomal degradation in the presence of iron.^{86,87} The effect of binding of IRPs to 5' IREs is to inhibit protein translation; the effect of binding of IRPs to 3' IREs is to increase the stability of the mRNA and thus to enhance the synthesis of the gene product. Figure 42-6 illustrates these relationships for the regulation of synthesis of ferritin and TfR. The net effect of the IRE/IRP system is to balance cellular iron uptake with storage, use, and in some cell types, export of iron.

IRON IN THE ERYTHROBLAST

Once within the developing erythroblast, iron must be transported to mitochondria to be incorporated into heme, or taken up by ferritin within siderosomes. Within the vesicle, STEAP3 (six-transmembrane epithelial antigen of prostate 3) effects the reduction of ferric (Fe^{3+}) to ferrous (Fe^{2+}) iron, and another protein, DMT-1 (the same transporter as in intestinal iron absorption), transports Fe^{2+} into the cytosol, where it is taken up by mitochondria by a complex of mitoferrin-1, ABCB10 (ATP-binding cassette [ABC] transporter in the inner membrane of mitochondria) and ferrochelatase for heme synthesis.⁸⁸ Physical interaction between mitochondria and endosomes ("kiss and run") may also be required.⁸⁹

Mitochondrial Iron

Mitochondria, working together with cellular cytoplasm, supply each cell with heme. Although heme synthesis is important for all cells, erythroblasts synthesize much more heme than any other cell type. The final steps of heme synthesis take place in mitochondria, where iron is inserted into protoporphyrin by the enzyme ferrochelatase. When heme synthesis is impaired, as in lead poisoning or in the sideroblastic anemias (Chap. 59), the mitochondria accumulates excessive amounts of amorphous iron aggregates. The mitochondria can then be stained by the Prussian blue reaction and are seen by light microscopy as a ring of large blue siderotic granules encircling the erythroblast nucleus (ringed sideroblast). In normal, iron-replete marrow, (much smaller) siderotic granules are also demonstrable, scattered in the cytoplasm of about one-third of erythroblasts. These normal siderotic granules are ferritin aggregates located in lysosomal organelles designated siderosomes.⁹⁰ Erythroblasts containing these siderotic granules,

Figure 42-6. The regulation of iron metabolism at the cytoplasmic mRNA level by interaction of iron-regulatory protein (IRP)-1 and the iron-responsive elements (IREs) to apoferritin mRNA (A) and transferrin receptor (TfR) mRNA (B). When the cytoplasmic iron concentration is low (left side of illustration), IRP-1 binds to the IREs of both mRNAs. This represses the translation of apoferritin mRNA, where the IRE is at the 5' end of the mRNA, thereby reducing the amount of apoferritin formed. It stabilizes and increases the translation of TfR mRNA where the IRE is at the 3' end of the mRNA, thereby increasing the amount of TfR formed. Conversely, when there is an abundance of iron in the cytoplasm (right side of illustration), IRP-1 is displaced from both species of mRNA. This results in derepression of apoferritin synthesis and destabilization and degradation of TfR mRNA. (Reproduced with permission from Rouault T, Klausner R: Regulation of iron metabolism in eukaryotes. *Curr Top Cell Regul* 35:1–19, 1997.)

sideroblasts, normally represent 20 to 50 percent of the erythrocyte precursors of the marrow and as visualized by light microscopy. In iron deficiency and in the anemia that accompanies chronic disorders, sideroblasts almost disappear from the marrow. Conversely, in some states of iron overload, they may become more numerous and contain excessive numbers of granules, some of which may be considerably larger than normal.

Mitochondrial Ferritin

Ring sideroblasts contain a ferritin isoform, mitochondrial ferritin (Chap. 59), which is a product of an intronless, IRE-lacking, ferritin gene on chromosome 5q23.1 that is specifically targeted to mitochondria by a 60-amino-acid-leader sequence.¹⁹¹ Mitochondrial ferritin lacks IRE and, thus, is not subject to iron-dependent translational control. Its function appears to be to reduce the labile iron pool and decrease the level of reactive oxygen species. Mitochondrial ferritin has limited tissue expression and is found in high concentrations in the mitochondria

of normal testes and in the sideroblasts of patients with sideroblastic anemia (Chap. 59).⁹²

IRON EXCRETION

The body conserves iron with remarkable efficiency. Most iron loss occurs by way of desquamated intestinal cells in the feces and it normally amounts to approximately 1 mg/day,^{15,93} less than one-thousandth of total-body iron. Exfoliation of skin and dermal appendages and perspiration result in much smaller losses. Even in tropical climates, the loss of iron in sweat is minimal.⁹⁰ Very small amounts of iron are lost in the urine. Lactation may cause excretion of approximately 1 mg iron daily, thus doubling the overall rate of iron loss. Blood loss by normal menstruation contributes to negative iron balance.

Although total daily iron loss is normally approximately 1 mg for males,¹⁵ it averages approximately 2 mg for menstruating women.

Figure 42–7. The stem–loop structure that is the iron-responsive element of apoferritin mRNA. (Reproduced with permission from Hentze MW, Caughman SW, Casey JL, et al: A model for the structure and functions of iron-responsive elements. *Gene* 72(1–2):201–208, 1988.)

Persons with marked iron overload, as in hemochromatosis, may lose as much as 4 mg of iron daily, probably because of the shedding of iron-laden cells, principally macrophages.

CHAPTER 43

IRON DEFICIENCY AND OVERLOAD

Tomas Ganz

SUMMARY

Iron deficiency and iron-deficiency anemia are common nutritional and hematologic disorders. In infants and young children, iron deficiency is most commonly caused by insufficient dietary iron. Rarely, it can result from mutations in *TMPRSS6*, a gene encoding a membrane protease that serves normally as a transcriptional suppressor of the primary negative regulator of iron absorption, hepcidin. In young women, iron deficiency is most often the result of blood loss in menstruation or as a result of blood loss during pregnancy, childbirth, and lactation. In older adults, bleeding is often the cause of iron deficiency, and may originate from the gastrointestinal tract, as from hemorrhoids, peptic ulcer, hiatus hernia, colon cancer, or angiodysplasia; from the genitourinary tract; from uterine leiomyomas or carcinoma, or a renal tumor; or from the pulmonary tree, through chronic hemoptysis caused by infection or malignancy, or as a result of idiopathic pulmonary hemosiderosis. Iron deficiency in infants can result in impairment of growth and intellectual development. The hematologic features of iron deficiency are nonspecific and too often confused with other causes of microcytic anemia such as thalassemias, chronic inflammation, and renal neoplasms. A low serum ferritin concentration is a good indicator of iron deficiency, but ferritin levels are increased by inflammation and can be particularly high in cancer, macrophage activation syndromes, hepatitis, or chronic kidney disease, which may mask the detection of iron deficiency coexisting with the anemia of chronic inflammation. The plasma iron is decreased and the iron-binding capacity increased in severe iron deficiency, but these alterations are not uniformly present in mild iron deficiency, and low plasma iron levels are also characteristic of the anemia of inflammation. Other laboratory tests that are useful include assays for serum transferrin receptor, reticulocyte hemoglobin content, percent hypochromic erythrocytes and erythrocyte zinc protoporphyrin. Diagnosis of iron deficiency, particularly in an adult, obliges the clinician to determine the site and cause of blood loss, and to rectify it whenever possible. Ferrous salts, in doses of 100 to 200 mg of elemental iron daily, are the initial treatment in most patients with iron deficiency. Enteric-coated and prolonged-release preparations should be avoided. Complete correction of anemia is expected in 8 to 12 weeks, depending on patient's age. If this response is not achieved, the patient and the diagnosis require reevaluation. Administration

Acronyms and Abbreviations: BMP, bone morphogenetic protein; cDNA, complementary DNA; DMT, divalent metal transporter; HFE, high iron (*high Fe*)—a mutated protein associated with common hereditary hemochromatosis; HLA, human leukocyte antigen; IL, interleukin; IRE, iron-responsive element; IRP, iron-regulatory protein; MCV, mean corpuscular volume; MRI, magnetic resonance imaging; RDA, recommended daily allowance; RDW, red cell distribution width; TFR, transferrin receptor; TIBC, total iron-binding capacity; UIBC, unsaturated iron-binding capacity.

of iron should be continued for 12 months after correction of anemia, or for as long as bleeding continues. Parenteral iron is used in patients who need more iron than can be delivered by the oral route, patients who do not tolerate oral iron salts, patients with gastrointestinal disease or following certain forms of bariatric surgery, noncompliant patients, and patients undergoing renal dialysis. All current parenteral iron preparations are much less likely to cause serious adverse events than was the case for high-molecular-weight iron dextran used in the past.

At the opposite end of the iron disorder spectrum, iron storage disease (hemochromatosis) can be the result of mutations of genes that are involved in regulation of iron homeostasis or transport, including the genes encoding HFE, transferrin receptor 2, ferroportin, hemojuvelin, and hepcidin. Because iron is not substantially excreted, iron overload commonly results from chronic erythrocyte transfusions for those anemias that are not caused by blood loss or iron deficiency.

Alternatively, iron overload resembling hereditary hemochromatosis can be the result of hyperabsorption of iron induced by ineffective erythropoiesis, including in β -thalassemias, dyserythropoietic anemias, pyruvate kinase deficiency, congenital dyserythropoietic anemias and some sideroblastic anemias. Here iron overload can develop even in the absence of erythrocyte transfusions or the (ill-advised) administration of medicinal iron, but is further aggravated by these events.

The diagnosis of systemic iron overload depends, in large part, upon increased serum ferritin levels accompanied by increased transferrin saturation, which tend to reflect increased iron stores. However, ferritin levels are also increased in patients with chronic inflammation or neoplasia or with the hyperferritinemia cataract syndrome, a disorder caused by mutations in the iron-responsive element of the ferritin light chain. The transferrin saturation is usually increased in patients with hereditary hemochromatosis even when the ferritin level is normal.

Many subjects with genetic hemochromatosis never develop organ dysfunction, those who do, their clinically significant hemochromatosis is characterized by cirrhosis of the liver, darkening of the skin, diabetes, cardiomyopathies, and possibly by arthropathies. Iron deposition is primarily in hepatocytes, with macrophages and intestinal mucosal cells being relatively iron poor. The most common causes of genetic hemochromatosis are mutations of the *HFE* gene. Two common mutations are involved: the c.854G→A (C282Y) and c.187C→G (H63D) substitutions. Increased transferrin saturation values, serum ferritin levels, and iron stores were found in a majority of homozygotes for the C282Y mutation and in many compound heterozygotes for C282Y/H63D or rarely in homozygotes for H63D. However, clinical manifestations even among homozygotes for the C282Y mutation are rare, in contrast to biochemical and/or histologic manifestations of the increased iron levels, which are common. Only a few percent of C282Y homozygous patients develop clinically significant disease, and cofactors including male gender and alcohol intake potentiate disease development. Juvenile hemochromatosis, an earlier onset and more severe type of hemochromatosis with high penetrance is the result of mutations of the hemojuvelin or the hepcidin gene. Ferroportin mutations produced two types of autosomal dominant iron overload. In one of these, the iron is deposited chiefly in macrophages; the other is similar to classical hereditary hemochromatosis with iron deposition in hepatocytes and other parenchymal cells.

Iron can be removed from patients with hereditary hemochromatosis by serial phlebotomy, but in patients with iron-loading anemias iron chelation therapy with either parenteral desferrioxamine infusions or the oral chelators deferasiprone or deferasirox is required.

● IRON DEFICIENCY

DEFINITION AND HISTORY

Iron deficiency is the state in which the content of iron in the body is less than normal. Iron depletion is the earliest stage of iron deficiency, in which storage iron is decreased or absent but serum iron concentration, transferrin saturation, and blood hemoglobin levels are normal. Iron deficiency without anemia is a somewhat more advanced stage of iron deficiency, characterized by absent storage iron, usually low serum iron concentration and transferrin saturation, but without frank anemia. Iron-deficiency anemia, the most advanced stage of iron deficiency, is characterized by absent iron stores, low serum iron concentration, low transferrin saturation, and low blood hemoglobin concentration.

Chlorosis, or “green sickness,” was well known to European physicians after the middle of the 16th century. In France, by the middle of the 17th century, iron salts and other remedies (including, oddly enough, phlebotomy) were used in its treatment. Not long thereafter, iron was recommended by Sydenham as a specific remedy for chlorosis. For the 100 years preceding 1930, iron was used in the treatment of chlorosis, often in ineffective doses, although the mechanism of action of iron and the appropriateness of its use were highly controversial. By the beginning of the 20th century, it had been established that chlorosis was characterized by a decrease in the iron content of the blood and by the presence of hypochromic erythrocytes, but it was not until the classic 1932 studies by Heath, Strauss, and Castle¹ that it was shown that the response of anemia to iron was stoichiometrically related to the amount of iron given and that chlorosis was, indeed, iron deficiency. The history of iron deficiency has been reviewed in greater detail elsewhere.^{2,3}

EPIDEMIOLOGY

Iron-deficiency anemia is the most common anemia worldwide, and is especially prevalent in women and children in regions where meat intake is low, food is not fortified with iron, and malaria, intestinal infections, and parasitic worms are common.⁴⁻⁶ Women with frequent pregnancies may be particularly susceptible. In the United States, iron deficiency is most common in children 1 to 4 years old and in adolescent, reproductive age, or pregnant women.⁷⁻⁹

ETIOLOGY AND PATHOGENESIS

Etiology

Iron deficiency may occur as a result of chronic blood loss, diversion of iron to fetal and infant erythropoiesis during pregnancy and lactation, inadequate dietary iron intake, malabsorption of iron, intravascular hemolysis with hemoglobinuria, diversion of iron to nonhematopoietic tissues like the lung, genetic factors, or a combination of these factors. Of these, gastrointestinal or menstrual blood loss are the most common. As discussed in Chap. 42, the average adult male has approximately 1000 mg of iron in stores, but on average, women have less than half of this amount. The average daily dietary intake of iron is 10 to 12 mg, but much of this is not absorbed, even when absorption is maximal. Blood loss of each milliliter of packed erythrocytes represents 1 mg of iron. Thus chronic daily blood loss greater than 5 mL of erythrocytes will deplete iron reserves over weeks to months, and even if bleeding stops completely, the repletion of lost iron, including the restoration of iron stores (around 1000 mg in the average adult man), will take many months.

Blood Loss

Gastrointestinal Blood Loss In men and in postmenopausal women, iron deficiency is most commonly caused by chronic bleeding from the gastrointestinal tract. Table 43-1 lists the causes of such blood loss.

TABLE 43-1. Sources of Blood Loss

ALIMENTARY TRACT

Telangiectases

Idiopathic pulmonary hemosiderosis

After history and physical examination rule out an obvious bleeding source in the genitourinary or respiratory tracts, evaluation of the gastrointestinal tract¹⁰ is necessary because of the potential that the pathologic process causing the blood loss is life-threatening. In the adult, the most common causes are peptic ulcer, erosion in a hiatal hernia, gastritis (including that caused by alcohol or aspirin ingestion), hemorrhoids, vascular anomalies (such as angiodysplasia), and neoplasms.

Gastritis, Varices, Ulcers, and Inflammation Gastritis as a result of drug ingestion is a common cause of bleeding. Aspirin, indomethacin, ibuprofen, and other nonsteroidal antiinflammatory drugs cause gastritis, but may also cause bleeding by inducing gastric or duodenal ulcers, or lesions in the small intestine¹¹ and even the colon. Gastritis caused by alcohol ingestion¹² can also cause significant blood loss. Chronic blood loss is often the cause of anemia in rheumatoid arthritis (perhaps because of the use of nonsteroidal antiinflammatory medications) and in inflammatory bowel disease.

Chronic blood loss from esophageal or gastric varices can lead to iron-deficiency anemia. Hemorrhoidal bleeding may lead to severe iron-deficiency anemia. Chronic blood loss may result from diffuse gastric mucosal hypertrophy (Ménétrier disease).¹³ Peptic ulcers of the stomach or duodenum are common causes of iron deficiency, and an association between infection with *Helicobacter pylori* and iron-deficiency anemia has been documented in numerous studies.¹⁴ Some of these iron-deficient patients who are infected with *H. pylori* do not respond to oral iron alone, but do respond to eradication of *H. pylori*.¹⁵

Gastric ulceration and bleeding can also occur in disorders of hypergastrinemia, as in Zollinger-Ellison syndrome and pseudo-Zollinger-Ellison syndrome. Although concerns were raised that long-term medical therapy of these disorders with proton pump inhibitors would also cause iron deficiency by raising gastric pH and making iron less soluble, this does not seem to be the case.¹⁶ Anemia that follows subtotal gastrectomy is usually attributed to reduced absorption of dietary iron (see “Malabsorption of Iron” below), but occult intermittent gastrointestinal bleeding from gastrointestinal lesions may also be a contributory factor, and requires endoscopic evaluation.¹⁷

Diaphragmatic Hernia Diaphragmatic (hiatal) hernia is often associated with gastrointestinal bleeding.^{18–20} The frequency of anemia ranges from 8 to 38 percent. Bleeding is much more likely to occur in patients with paraesophageal or large hernias than in those with sliding or small hernias. Mucosal changes cannot always be demonstrated by esophagoscopy or gastroscopy in patients who have had blood loss from hiatus hernia. However, a linear gastric erosion, also called a “Cameron ulcer,” commonly occurs on the crests of mucosal folds at the level of the diaphragm, and appears to be the site of bleeding.²¹

Intestinal Parasitism Hookworms are a major cause of gastrointestinal blood loss in many parts of the world.²²

Vascular Anomalies The lesions of angiodysplasia may occur in any part of the gastrointestinal tract.²³ These tiny vascular anomalies may be the cause of significant blood loss. Endoscopy is usually required for diagnosis, and often needs to be repeated as bleeding can be intermittent. Gastric antral vascular ectasia²⁴ exhibits a characteristic endoscopic appearance (“watermelon stomach”), and is another cause of blood loss. Hemorrhage into the biliary tract is a rare cause of chronic iron-deficiency anemia.²⁵

Tortuous, dilated sublingual venous structures, the cherry hemangiomas commonly seen in the elderly, and the spider telangiectases of chronic liver disease are usually easily distinguished from the lesions of hereditary hemorrhagic telangiectasia. Bleeding from intestinal telangiectases has also been observed in scleroderma²⁶ and in Turner syndrome,²⁷ as a manifestation of bleeding from abnormal blood vessels. Cutaneous hemangiomas (blue rubber bleb nevus) may be associated with hemorrhage from intestinal hemangiomas.²⁸

In hereditary hemorrhagic telangiectasia (Chap. 122), characteristic lesions commonly occur on fingertips, nasal septum, tongue, lips, margins (helices) of ears, oral and pharyngeal mucosa, palms and soles, and other epithelial and cutaneous surfaces throughout the body. Those lesions that occur in the gastrointestinal tract are particularly likely to bleed and to cause iron deficiency.

Meckel Diverticulum Meckel diverticulum is a very common abnormality representing a vestigial remnant of the omphalomesenteric duct. In children, bleeding from this structure accounts for a small proportion of cases of iron-deficiency anemia.²⁹

Genitourinary Tract Heavy menstrual bleeding³⁰ is a very common cause of iron deficiency. The amount of blood lost with menstruation³¹ varies markedly from one woman to another and is often difficult to evaluate by questioning the patient. The average menstrual blood loss is approximately 40 mL per cycle. Blood loss exceeds 80 mL (equivalent to approximately 30 mg of iron) per cycle in only 10 percent of women. The volume of blood lost in the course of one menstrual cycle may be as high as 495 mL in apparently healthy, nonanemic women who do not regard their menstrual flow to be excessive. The amount of menstrual blood lost does not seem to vary markedly from one cycle to another for any given individual. Oral contraceptives reduce menstrual blood loss, but the use of an intrauterine coil for contraception increases menstrual blood loss, especially during the first year of use. Because the daily dietary intake is usually between 10 and 12 mg of iron and only a few milligrams of this can be absorbed, iron balance in many menstruating women is precarious.

Excessive bleeding may be caused by uterine fibroids and malignant neoplasms. Neoplasms, stones, or inflammatory disease of the kidney, ureter, or bladder may cause enough chronic blood loss to produce iron deficiency.

In the absence of hematuria, urinary iron losses as high as 1 mg/day have been reported in rare patients with nephrotic syndrome, some of whom had hypoferremia and hypochromic anemia.³² We found only one report of a patient in whom abnormally high urinary iron loss may have caused anemia without proteinuria or hematuria.³³

Bleeding Disorders Hemostatic defects, particularly those related to abnormal platelet function or number may lead to gastrointestinal bleeding, although unless the thrombocytopenia or platelet dysfunction is severe, gastrointestinal bleeding usually signifies an abnormality in the gastrointestinal tract. Gastrointestinal bleeding is common in von Willebrand disease (Chap. 126), but often because of coexistent peptic ulcer disease. Polycythemia vera is typically associated with iron deficiency as a result either of spontaneous gastrointestinal hemorrhage that commonly occurs in this disorder, or phlebotomy therapy, or both (Chap. 84).

When a patient with a disorder of hemostasis suffers from gastrointestinal bleeding, one must consider the possibility that the bleeding may not be caused by a hemostatic defect alone, but that an anatomic lesion of the gastrointestinal tract may also be present.

Nosocomial (Iatrogenic) Anemia Iatrogenic anemia is particularly prevalent in intensive care units³⁴ where repetitive blood sampling may result in removal of 40 to 70 mL of blood daily, and this iatrogenic phlebotomy can result in iron-deficiency anemia.

The use of extracorporeal dialysis for treatment of chronic renal disease may cause iron deficiency,^{35,36} often superimposed upon the anemia of chronic renal disease (Chap. 37). Patients treated with chronic hemodialysis experience multiple sources of blood loss with the dialysis equipment is a major cause, along with gastrointestinal bleeding, blood sampling and bleeding related to vascular access.

Anemia Incident to Blood Donation Each whole-blood donation removes approximately 200 mg of iron from the body. Lesser amounts of iron are removed in the course of donating platelets or

leukocytes. Potential donors are screened in blood banks, so that those with frank anemia are not phlebotomized. Yet, by the time they are excluded from donation, some blood donors are iron depleted^{37–39} and may readily develop iron-deficiency anemia with relatively small additional blood loss.

Factitious Anemia Factitious anemia as a result of self-inflicted bleeding may present a formidable diagnostic and therapeutic problem. This rare condition has also been called, in literary allusion to a fictitious character, “Lasthénie de Ferjol syndrome” (in Barbey d’Aureville’s gloomy novel, *Une Histoire Sans Nom*), or part of Munchausen syndrome (based on the Rudolf Raspe book, *The Surprising Adventures of Baron Münchhausen*).^{40,41} Most patients are women, and are often employed in a medical setting. There is often a history of numerous blood transfusions. The anemia is chronic and may be severe. The site of induced blood loss is obscure. Hence, patients are subjected to numerous radiographic and endoscopic examinations, usually to no avail. The patients are usually refractory to medical advice and therapy. The patients may be depressed and suicidal; some also suffer anorexia nervosa. Psychiatric care is needed, but often is unsuccessful. Rarely, the outcome of self-bleeding may be fatal.⁴²

Cow’s Milk Anemia Ingestion of whole cow’s milk may induce protein-losing enteropathy and gastrointestinal bleeding in infants,^{43,44} probably on the basis of hypersensitivity or allergy. In four such cases observed endoscopically, erosive gastritis or gastroduodenitis was demonstrated as the probable source of bleeding. At least during the first year of life, children should not be given whole bovine milk, either raw or pasteurized. More protracted heating, as in preparation of infant formulas, eliminates this problem. Intrinsic lesions of the gastrointestinal tract, such as those listed above, may cause bleeding in infants, as well as in older children.

Respiratory Tract Persistent recurrent hemoptysis may lead to iron-deficiency anemia. It may be a result of congenital anomalies of the respiratory tract, endobronchial vascular anomalies, chronic infections, neoplasms, or valvular heart disease. Severe iron-deficiency anemia is a manifestation of idiopathic pulmonary hemosiderosis⁴⁵ and of Goodpasture syndrome (progressive glomerulonephritis with intrapulmonary hemorrhage). In some of these disorders, hemoptysis may not be observed, but sufficient amounts of blood-laden sputum may be swallowed to result in positive tests for occult blood in the stools. Iron deficiency occurs in a large proportion of patients with cystic fibrosis,^{46,47} and occurs even in the absence of hemoptysis, suggesting that inflammatory inhibition of dietary iron absorption and iron loss in purulent sputum could contribute to the deficiency.

Pregnancy and Parturition

Although physiologic decrease in hemoglobin concentration is an expected consequence of hemodilution associated with pregnancy, true iron deficiency frequently results in more severe anemia. In pregnancy, the average iron loss resulting from diversion of iron to the fetus, blood loss at delivery (equivalent to an average of 150 to 200 mg of iron), and lactation is altogether approximately 900 mg; in terms of iron content, this is equivalent to the loss of more than 2 L of blood. Approximately 30 mg of iron may be expended monthly in lactation. Because most women begin pregnancy with low iron reserves, these additional demands frequently result in iron-deficiency anemia. Iron depletion has been reported in some 85 to 100 percent of pregnant women. Iron-deficient mothers are likely to have smaller babies. The incidence of anemia and iron deficiency is lower in women who take oral iron supplementation, daily or intermittently.^{48–51} In regions with endemic malaria, iron supplementation may increase the risk of malaria and some recommend that it be combined with malarial prophylaxis.⁵² Most experts agree that oral iron supplementation during pregnancy is desirable despite side

effects. Increasing safety and convenience of parenteral iron therapy may lead to reevaluation of its role in the prevention and treatment of iron-deficiency anemia of pregnancy.⁵³

Dietary Iron Deficiency

In infants, iron deficiency is most often a result of the use of unsupplemented milk diets, which contain an inadequate amount of iron. During the first year of life, the full-term infant requires approximately 160 mg and the premature infant approximately 240 mg of iron to meet the needs of an expanding red cell mass. Approximately 50 mg of this need is fulfilled by the destruction of erythrocytes that occurs physiologically during the first week of life (Chaps. 7 and 33); the rest must come from the diet. Milk products are very poor sources of iron, and prolonged breast- or bottle-feeding of infants frequently leads to iron-deficiency anemia unless iron supplementation is implemented. This is especially true of premature infants. The European Society for Pediatric Gastroenterology, Hepatology, and Nutrition (ESPGHAN) Committee on Nutrition urges that all infant formulas be iron-fortified⁵⁴; in North America, the use of iron-fortified formula is now generally accepted, but there is controversy about the appropriate level of fortification.⁵⁵ In older children, an iron-poor diet may also contribute to the development of iron-deficiency anemia, particularly during rapid growth periods.

Infants and young women are usually in precarious iron balance, their iron intake being less than 80 percent of the recommended daily allowance (RDA).⁵⁶ Fortification of bread and cereals with ferrous sulfate or metallic iron is commonplace. This practice was suspended in Sweden because of concern for the possibility of increasing iron storage in patients with the hemochromatosis genotype, resulting in increased incidence of iron-deficiency anemia.⁵⁷

The scant iron supply of the American diet places young women and children at particular risk of negative iron balance. Because the adult male needs to absorb only approximately 1 mg iron daily from his diet to maintain normal iron balance, iron deficiency in older men is very rarely caused by insufficient dietary intake alone.

Malabsorption of Iron

Gastric secretion of hydrochloric acid is often reduced in iron deficiency.⁵⁸ Histamine-fast achlorhydria has been found in as many as 43 percent of patients with iron deficiency. Gastric function may improve after correction of the iron deficiency, so that iron deficiency may be both a cause and a result of impairment of gastric iron secretion. However, in persons older than the age of 30 years, the achlorhydria is usually irreversible. Furthermore, when atrophic gastritis coexists with iron deficiency, no improvement in gastric secretory function has followed iron therapy. Autoimmune gastritis, which is often associated with *H. pylori* infection,^{14,15} may play an important role in both iron-deficiency anemia and, in later life, in the development of pernicious anemia.

Intestinal malabsorption of iron is quite an uncommon cause of iron deficiency except after gastrointestinal surgery and in malabsorption syndromes. Ten to 34 percent of patients who have undergone subtotal gastric resection develop iron-deficiency anemia years later. Many such patients have impaired absorption of food iron, caused in part by more rapid gastrojejunal transit and in part by partially digested food bypassing some of the duodenum as a result of the location of the anastomosis. Fortunately, medicinal iron is well absorbed in post-partial gastrectomy patients. Moreover, gastrointestinal blood loss may also play an important role in anemia following gastric resection (see “Gastrointestinal Blood Loss” earlier). In malabsorption syndromes, absorption of iron may be so limited that iron-deficiency anemia develops over a period of years. Celiac disease, whether overt or occult, may be associated with iron-deficiency anemia.^{14,15,59,60}

Intravascular Hemolysis and Hemoglobinuria

Iron-deficiency anemia may occur in paroxysmal nocturnal hemoglobinuria (Chap. 40) and in hemolysis resulting from mechanical erythrocyte trauma from intracardiac myxomas, valvular prostheses (particularly if malfunctioning), or patches (Chaps. 33 and 51). In these disorders, up to 10 mg/day of iron is lost in the urine as hemosiderin and ferritin in desquamated tubular cells and as hemoglobin dimers, an amount sufficient to cause systemic iron deficiency.^{61,62}

Iron deficiency occurs frequently in athletes engaged in a variety of sports (Chaps. 33 and 51), especially female athletes.⁶³ There may be mild anemia. Increased intravascular hemolysis, presumably with some renal loss of iron, may play a role, but gastrointestinal blood loss has also been demonstrated in persons engaged in strenuous athletic pursuits. Hemoglobinuria and hemosiderinuria are also seen in competitive and recreational runners, that is, *march hemoglobinuria* (Chaps. 33 and 51). Strenuous exercise also elicits a rise in serum interleukin (IL)-6 and hepcidin, and this could decrease dietary iron absorption.⁶³

Women soldiers undergoing basic training experience iron depletion as determined by serum ferritin measurements, and this can be partially reversed by iron supplementation.⁶⁴ The etiology may be similar to the iron deficiency seen in athletes.

Genetic Factors

Based on twin studies,⁶⁵ genetic factors play a role in iron deficiency. Mutations in multiple genes, including *HFE* and transferrin, show weak associations with iron stores but only mutations of the membrane serine protease *Tmprss6*⁶⁶ have been identified in genome-wide association studies as genetic factors that cause or predispose to iron deficiency. The genetic syndrome of iron-refractory iron deficiency anemia is mediated by inappropriately increased hepcidin as a result of homozygous or compound heterozygous mutations in *Tmprss6*.^{67–69} Increased hepcidin diminishes iron absorption and causes inappropriate retention of available iron in splenic macrophages and Kupffer cells.

PATHOGENESIS

As iron deficiency develops, different compartments are depleted in iron in an overlapping sequence, as illustrated schematically in Fig. 43–1.

Iron-Containing Proteins

As the body becomes depleted of iron, changes occur in many tissues. Hemosiderin and ferritin virtually disappear from marrow and other storage sites. Hemoglobin synthesis in the marrow decreases, first as a result of fewer erythroblasts,⁷⁰ but eventually also per erythroblast if iron deficiency becomes more severe, resulting in hemoglobin-deficient erythrocytes. The concentration of many other iron-containing proteins is affected, often in an organ-specific manner.⁷¹ Studies in laboratory animals on defined iron-deficient diets are most informative about this process, because human iron deficiency is often confounded by other forms of malnutrition. In such models of severe (pure) iron deficiency, skeletal muscle myoglobin is mildly depleted but cardiac myoglobin is not. Cytochromes and other mitochondrial ferroproteins are depleted but selectively so. Since these classical studies were performed, it has become apparent that the synthesis of many ferroproteins is regulated in an iron-dependent manner, mainly via the iron-responsive element (IRE)/iron-regulatory protein (IRP) system (Chap. 42). The changes in iron-containing proteins may thus be adaptive,⁷² to allow the survival of the organism until more iron becomes available.

Muscular Function and Exercise Tolerance

Decrements in high-intensity exercise performance can be detected even during nonanemic iron deficiency,⁶³ and worsen with increasing

Figure 43–1. Stages in the development of iron deficiency. Early iron deficiency (iron depletion) is usually not accompanied by any abnormalities in blood; at this stage, serum iron concentration is occasionally below normal values and storage iron is markedly depleted. As iron deficiency progresses, development of anemia precedes appearance of morphologic changes in blood, although some cells may be smaller and paler than normal; serum iron concentration is usually low at this time, but it may be normal. With advanced iron depletion, classic changes of hypochromic, microcytic, hypoferrremic anemia become manifest. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

anemia.⁷³ The limitation of high-level exercise by oxygen delivery, and, therefore, hemoglobin content of blood, is well known, and has given rise to surreptitious blood doping and erythropoietin abuse by some athletes. The impairment of performance during nonanemic iron deficiency consists of decreased spontaneous activity (seen in humans and in animal models) and decreased ventilatory threshold, that is, the point at which ventilation starts increasing more rapidly than oxygen consumption.⁷⁴ Other deficits that have been reported include decreased endurance and increased muscle fatigue. The biochemical basis of the deficits associated with nonanemic iron deficiency is not well understood but is attributed to the depletion of iron-containing mitochondrial proteins that are involved in energy metabolism.⁶³ The condition is reversible with iron supplementation.

Neurologic Changes

Iron deficiency is associated with both developmental abnormalities in children and with restless leg syndrome in adults, but in neither case has iron deficiency been established as the primary cause.^{75,76} The substantia nigra is a particularly iron-rich region of the brain and contains dopaminergic neurons that are suspected of involvement in restless leg syndrome. In mouse models of iron deficiency, iron depletion of the substantia nigra is highly strain-dependent,⁷⁷ suggesting that iron deficiency and as yet incompletely characterized genetic variations may cooperate in the pathogenesis of restless leg syndrome by allowing the depletion of iron from susceptible brain regions involved in dopaminergic signaling.⁷⁸

Host Defense and Inflammation

In multiple publications, iron deficiency has been reported to impair various immune functions, but the effects appear minor and inconsistent.⁷⁹ Perhaps surprisingly, the evidence for a narrowly protective and proinflammatory effect of iron deficiency appears stronger. Iron

deficiency decreases the risk and severity of malaria,^{80,81} and iron supplementation may have the opposite effect, especially when not targeted to patients with iron deficiency.^{52,82} The mechanism of this effect is of great interest but not yet well understood.⁸³ There are some indications that iron deficiency may have a proinflammatory effect. In a mouse model, iron deficiency potentiated the systemic effect of lipopolysaccharide in a hepcidin-dependent manner,⁸⁴ and in a mouse model of asthma, iron deficiency promoted allergic inflammation.⁸⁵

Growth and Metabolism

Iron-deficient children have been reported to suffer from growth retardation but it is difficult to isolate the effect of iron deficiency from other nutritional and environmental causes of stunting. Two comprehensive analyses of randomized controlled trials did not detect an effect on growth of iron supplementation alone.^{86,87} Decreased thermoregulation in response to cold exposure is seen in both humans and laboratory models.⁸⁸ It has been attributed to the conflicting effects on blood flow of decreased oxygen content of blood and need to minimize heat loss, as well as the effect of iron deficiency on thyroid function.

Histologic Findings

Severe iron deficiency may lead to histologic changes in various organs. The rapidly proliferating cells of the upper part of the alimentary tract seem particularly susceptible to the effect of iron deficiency. There may be atrophy of the mucosa of the tongue and esophagus,⁸⁹ stomach,⁹⁰ and small intestine.⁹¹ The epithelium of the lateral margins of the tongue is reduced in thickness despite increase in the progenitor compartment. This thinning presumably reflects accelerated exfoliation of epithelial cells.⁹² Buccal mucosa has shown thinning and keratinization of epithelium and increased mitotic activity.^{93,94} However, light microscopic and electron microscopic examination of exfoliated oral mucosal cells showed no aberrations in morphology of nuclei or cytoplasm of the cells of patients with iron-deficiency anemia.⁹⁵ In iron-deficiency anemia resulting from idiopathic pulmonary hemosiderosis, characteristic pathologic changes are found in the lungs, including intense deposition of iron in the littoral cells of the alveoli and interstitial fibrosis.⁴⁵

Widening of diploic spaces of bones, particularly those of the skull and hands,^{96–98} may be a consequence of chronic iron deficiency beginning in infancy. In the skull, this is of the same character as in thalassemia, except that in β -thalassemia major there is maxillary hypertrophy, whereas in severe iron-deficiency anemia maxillary growth and pneumatization are normal.

CLINICAL FEATURES

Clinical Manifestations of Anemia

The anemia in iron-deficient patients can be very severe, with blood hemoglobin levels as low as less than 4 g/dL being encountered in some patients. Severe iron-deficiency anemia is associated with all of the various symptoms of anemia, resulting from hypoxia and the body's response to hypoxia, as described in Chap. 32. Thus, tachycardia with palpitations and pounding in the ears, headache, light-headedness, and even angina pectoris, may all occur in patients who are severely anemic.

Clinical Manifestations That May Be Unrelated to Anemia

The clinical features of iron deficiency encompass nonhematologic effects and symptoms caused by the anemia itself. A number of controlled studies show that various manifestations of iron deficiency can occur in individuals whose hemoglobin is within the accepted normal range.

Decreased Work Performance Objective measurements of work performance and studies using O_2 consumption as an index of work performance have given contradictory results, but a comprehensive review led to the conclusion that severe iron-deficiency anemia (hemoglobin

<8 g/dL) and mild iron deficiency anemia (hemoglobin between 8 and 12 g/dL) led to decreased work performance, primarily as estimated by peak oxygen consumption (VO_2 max) measurements, but the evidence that nonanemic iron deficiency had such an effect was less convincing.⁹⁹ However, in athletes with low ferritin levels but normal hemoglobin levels, iron-supplemented subjects showed an increased VO_2 max without a change in their red cell mass, and in other studies nonanemic subjects treated with iron showed improved performance and/or VO_2 max.⁶³

Infant and Childhood Development It has been proposed that iron deficiency in infants and children is associated with poor attention span, poor response to sensory stimuli, and retarded behavioral and developmental achievement even in the absence of anemia. The causality of these associations is confounded by other coexisting nutritional deficits and socioeconomic deprivation, so reversibility by iron supplementation would be important in establishing causality. However, in systematic meta-analyses, iron supplementation had weak or no effects on these deficits.^{86,100–102}

Hyperactivity Syndromes It has been speculated that there is a relationship between restless legs syndrome, Tourette syndrome, and attention deficit hyperactivity disorder and that iron deficiency contributes to their pathophysiology. Restless legs syndrome, a common nocturnal problem, especially in the elderly, is associated with iron deficiency and is reported to improve on iron therapy, but the beneficial effects are inconsistent and not well predicted by blood ferritin or transferrin saturation.^{75,103,104} In children there may be a relationship between iron deficiency and attention deficit hyperactivity disorder, but the association is inconsistent.¹⁰⁵

Other Neurologic Symptoms Breath holding in children, headaches, and paresthesias have been attributed to iron deficiency but there are no controlled studies to support these impressions. Anecdotal reports of intracranial hypertension with papilledema are buttressed by apparent response to iron therapy.^{106–109} Stroke in children and in adults, possibly triggered by thrombocytosis, is associated with iron-deficiency anemia.^{110–114}

Oral and Nasopharyngeal Symptoms Burning of the tongue has also been described anecdotally in many accounts of iron deficiency, and although this symptom has been observed to diminish with treatment, no controlled studies have been performed. The tongue symptoms could be a result of concurrent pyridoxine deficiency. Although iron deficiency has been proposed as a cause of atrophic rhinitis, the evidence for this is weak.

Dysphagia In the laryngopharynx, mucosal atrophy may lead to web formation in the postcricoid region, thereby giving rise to dysphagia (Paterson-Kelly also known as Plummer-Vinson syndrome).¹¹⁵ If these alterations are of long duration, they may lead to pharyngeal carcinoma. Although it has been generally thought that these changes are secondary to longstanding iron deficiency, this mechanism is not universally accepted. The frequency of the condition is considered to have decreased considerably, and it is remarkably rare in many parts of the world where iron deficiency is common.

Pica The craving to eat unusual substances, for example, dirt, clay, ice, laundry starch, salt, cardboard, and hair, is a well-documented manifestation of iron deficiency and is usually cured promptly by iron therapy.^{116–119}

Hair Loss Although the association of hair loss with iron deficiency is controversial,¹²⁰ low ferritin levels were a risk factor for hair loss in a large multivariate analysis.¹²¹ Remarkably, hair loss sparing the face ("mask mouse") is a sign of iron deficiency in mice.¹²²

Physical Findings

The physical findings in iron-deficiency anemia include pallor, glossitis (smooth, red tongue), stomatitis, and angular cheilitis. Koilonychia

(spoon nails), once a common finding, is now encountered rarely. Retinal hemorrhages and exudates may be seen in severely anemic patients (e.g., hemoglobin concentration of <5 g/dL). Splenomegaly has occasionally been attributed to iron-deficiency anemia, but when it occurs, it is probably from other causes.

LABORATORY FEATURES

In severe, uncomplicated iron-deficiency anemia, the erythrocytes are hypochromic and microcytic; the plasma iron concentration is diminished; the iron-binding capacity is increased; the serum ferritin concentration is low; the serum transferrin receptor (TfR) and erythrocyte zinc protoporphyrin concentrations are increased; and the marrow is depleted of stainable iron. However, the classic combination of laboratory findings occurs consistently only when iron-deficiency anemia is far advanced, when there are no complicating factors such as infection or malignant neoplasms, and when there has not been previous therapy with transfusions or parenteral iron.

Blood Cells

Erythrocytes Anisocytosis is the earliest recognizable morphologic change of erythrocytes in iron-deficiency anemia (Fig. 43-2).¹²³ The anisocytosis is typically accompanied by mild ovalocytosis. As the iron deficiency worsens, a mild normochromic, normocytic anemia often develops. With further progression, hemoglobin concentration, erythrocyte count, mean corpuscular volume (MCV), and mean erythrocyte hemoglobin content all decline together.^{124,125} As the indices change the erythrocytes appear microcytic and hypochromic on stained blood films. Target cells may sometimes be present. Elongated hypochromic elliptocytes may be seen, in which the long sides are nearly parallel. Such cells have been called “pencil cells,” although they more nearly resemble cigars in shape. The red cell indices are consistently abnormal in adults only when iron-deficiency anemia is moderate or severe (e.g., in males with hemoglobin concentrations <12 g/dL or in women with hemoglobin concentrations <10 g/dL) (Fig. 43-3). The distribution of erythrocyte volume (e.g., red cell distribution width [RDW]) is usually increased in established iron-deficiency anemia. The RDW is reported often as the coefficient of variation (in percent) of erythrocyte volume (see “Differential Diagnosis” below).

Leukocytes Leukopenia has been found in some patients with iron-deficiency anemia, but the overall distribution of leukocyte counts in iron-deficient patients seems to be approximately normal.

Platelets Both thrombocytopenia¹²⁶ and, more commonly, thrombocytosis¹²⁷ have been associated with iron deficiency. Platelet

abnormalities correct with iron therapy. Thrombotic complications of iron deficiency have been reported but are very rare.¹²⁸ The etiology of either abnormality is not known. Low-iron-diet-induced iron-deficiency anemia developed in a rat model within 2 weeks, and this was accompanied by sustained 50 percent increase in platelet count with increased platelet size but without significant changes in known megakaryocyte growth factors (thrombopoietin, IL-6 or IL-11). It has been suggested that high erythropoietin levels may stimulate thrombopoietin receptors because the two hematopoietic factors are structurally related, but this does not seem to be the case.¹²⁹

Reticulocytes Reticulocyte count is often mildly increased,¹³⁰ a finding consistent with the increased erythroid activity of the marrow (see “Marrow” below).

Marrow

Because most of the iron in the body is normally in erythrocytes, and iron is not excreted, decrease in erythrocyte mass generally results in increased storage iron. Iron-deficiency anemia is the exception, as iron stores are depleted before the red cell mass is compromised. Thus, evaluation of iron stores should be a sensitive and usually reliable means for the differentiation between iron-deficiency anemia and all other anemias. Decreased or absent hemosiderin in the marrow is characteristic of iron deficiency, and is readily evaluated after staining by the simple Prussian blue method. Stored iron in the macrophages of the marrow can be seen in marrow spicules in marrow sections, or in marrow aspirate films. Iron granules, normally found in the cytoplasm of approximately 30 percent of erythroblasts, become rare but may not be entirely absent.

Evaluation of the amount of iron in marrow macrophages has long been considered the “gold standard” for the diagnosis of iron deficiency. There are, however, technical barriers to the accurate histochemical determination of marrow iron. First, an invasive procedure, marrow aspiration, is required. Second, the differentiation of iron within macrophages from artifacts takes experience and skill. In one study only 74 of 108 cases had been accurately reported.¹³¹ Moreover, misleading results may be obtained in patients who have been transfused or who have been treated with parenteral iron.¹³² The marrow of such patients may contain normal, or even increased, quantities of stainable iron in the face of typical iron-responsive iron-deficiency anemia. In such patients, iron that is seen on marrow examination is not readily available for erythropoiesis. As serum markers of iron deficiency became widely available, the reasons for the primacy of marrow iron estimation have been questioned.¹³³

Figure 43-2. Variability in morphologic diagnosis of iron-deficiency anemia from blood film. As in all deficiency states leading to anemia, the blood film morphology and blood cell changes are a function of the severity of the deficiency. **A.** Normal blood film. Normocytic-normochromic red cells with normal shape. **B.** Mild iron deficiency. Serum iron, ferritin, and transferrin saturation were consistent with mild iron deficiency. Cannot discern if mean red cell size has decreased. There may be a few red cells that have larger central pallor, but that is arguable. A few cells have oval or elliptical shape. **C.** Severe iron deficiency. Serum iron, ferritin, and transferrin saturation were consistent with severe iron deficiency. Note obvious increase in overtly hypochromic cells and higher frequency of microcytes. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

Figure 43-3. Erythrocyte indices in iron-deficiency anemia of adults; data obtained with Coulter Counter, Model S. Normal ranges of indices observed in approximately 500 healthy adults using the same instrument are indicated by shading. The *dashed line* in the *top panel* indicates the more widely accepted lower normal limit of mean corpuscular hemoglobin concentrations (MCHCs) stated in this text. (*Top*) Correlation between venous blood hemoglobin concentration and MCHC. More than half of 62 patients with iron-deficiency anemia had MCHC values clearly in the normal range. (*Bottom*) Correlation between venous blood hemoglobin concentrations and mean corpuscular volume (MCV). Nearly 70 percent of cases exhibited distinct microcytosis. Thus when indices are determined by automated cell-counting methods, the MCV is much more sensitive than is the MCHC in detecting changes of iron deficiency. However, at least 30 percent of cases of iron-deficiency anemia will be misdiagnosed if physicians rely on the erythrocyte indices. (Data from Klee GG: Decision Rules for Accelerated Hematology Laboratory Investigation: Thesis, University of Minnesota.)

Serum Iron Concentration

The serum iron concentration is usually low in untreated iron-deficiency anemia, but may rarely be normal.^{125,134,135} Iron in blood plasma turns over every few hours and constitutes less than 0.1 percent of total body iron in adults, so iron concentrations are readily perturbed by transient changes in iron supply or demand. Physiologically, the serum

iron concentration has a diurnal rhythm; it decreases in late afternoon and evening, reaching a nadir near 9 PM and increases to its maximum between 7 and 10 AM. This effect is rarely of sufficient magnitude to influence diagnosis.¹³⁶ Serum iron levels decrease at about the time of menstrual bleeding^{137,138} regardless of whether the bleeding is physiologic or induced by withdrawal of contraceptive hormonal preparations.

Importantly, the serum iron concentration is reduced in the presence of either acute or chronic inflammatory processes¹³⁹ or malignancy¹⁴⁰ and following acute myocardial infarction.^{141,142} The serum iron concentration under these circumstances may be decreased sufficiently to suggest iron deficiency. Conversely, during chemotherapy of malignancy, the serum iron concentration may be quite elevated, as cytotoxic effects of the drugs on erythroblasts inhibit erythropoiesis and related iron uptake by erythroblasts. This effect is observed from the third to the seventh day after inception of chemotherapy of a variety of tumors.¹⁴³

Normal or high concentrations of serum iron are commonly observed even in patients with iron-deficiency anemia if such patients receive iron medication before blood is drawn for these measurements. Even multivitamin preparations, which commonly contain approximately 18 mg of elemental iron per tablet, can result in this effect. Oral iron medication should be withheld for 24 hours before blood samples are obtained. Parenteral injection of iron dextran may result in a very high serum iron concentration (e.g., 500 to 1000 mcg/dL), at least with some methods,¹⁴⁴ for several weeks. The elevation of serum iron levels after infusion of sodium ferric gluconate or iron sucrose is of much shorter duration.¹⁴⁵

Iron-Binding Capacity and Transferrin Saturation

The iron-binding capacity is a measure of the amount of transferrin in circulating blood. Normally, there is enough transferrin present in 100 mL serum to bind 4.4 to 8.0 μmol (250 to 450 mcg) of iron; because the normal serum iron concentration is approximately 1.8 $\mu\text{mol/dL}$ (100 mcg/dL), transferrin may be found to be approximately one-third saturated with iron. The unsaturated or latent iron-binding capacity (UIBC) is easily measured with radioactive iron or by spectrophotometric techniques. The sum of the UIBC and the plasma iron represents total iron-binding capacity (TIBC). TIBC can also be measured directly. In iron-deficiency anemia, UIBC and TIBC are often increased and serum iron concentrations are decreased so that transferrin saturation of 15 percent or less is usually found. Because transferrin concentration and TIBC are decreased during inflammation, a normal value for transferrin saturation often accompanies a low serum iron concentration in the anemia of chronic inflammation.

Serum Ferritin

Serum ferritin, secreted mainly by macrophages¹⁴⁶ and hepatocytes, contains relatively little iron, yet serum ferritin concentration empirically correlates with total-body iron stores,¹⁴⁷ for reasons that are still obscure. Serum ferritin concentrations of 10 mcg/L or less are characteristic of iron-deficiency anemia. In iron deficiency without anemia, serum ferritin concentration is typically in the range of 10 to 20 mcg/L. An increase in serum ferritin concentration occurs in inflammatory disorders, such as rheumatoid arthritis, in chronic renal disease, and in malignancies.¹⁴⁸ When one of these conditions coexists with iron deficiency, as they often do, the serum ferritin concentration is commonly in the normal range; interpretation of results of this assay then becomes difficult. In patients with rheumatoid arthritis who are anemic, some suggest that concomitant iron deficiency may be suspected when the serum ferritin concentration is less than 60 mcg/L,¹⁴⁹ but such empiric guidelines are unlikely to apply to the full spectrum of severity of inflammation. Increased serum ferritin concentrations are also characteristic

of some malignancies, as well as of acute and chronic liver disease and chronic renal failure.^{150–153} In Gaucher disease, juvenile rheumatoid arthritis, and various macrophage activation syndromes, and in ferroportin disease characterized by massive iron loading of macrophages, the serum ferritin concentration is commonly in the range of thousands of mcg/L and may mask iron deficiency.^{154–158}

Erythrocyte Zinc Protoporphyrin

Erythrocyte protoporphyrin, principally zinc protoporphyrin, is increased in disorders of heme synthesis, including iron deficiency, lead poisoning, and sideroblastic anemias, as well as other conditions.^{159–161} This assay analyzes the fluorescence of erythrocytes and uses small blood samples. It is quite sensitive in the diagnosis of iron deficiency and practical for large-scale screening programs designed to identify children with either iron deficiency or lead poisoning.^{58,159} It does not differentiate between iron deficiency and anemia that accompanies inflammatory or malignant processes.¹⁶²

Serum Transferrin Receptor

The role of TfR in transporting transferrin iron into cells is described in Chap. 42 section “Transport of Iron”. The circulating receptor is a truncated form of the cellular receptor, lacking the transmembrane and cytoplasmic domains of the cellular receptor. It circulates bound to transferrin. Sensitive immunologic methods can detect approximately 5 mg/L of receptor in serum. The levels of circulating TfR mirror the amount of cellular receptor, and therefore are proportional to the number of erythroblasts expressing the receptor. Because receptor synthesis is greatly increased when cells lack iron, the amount of the circulating receptor increases in iron deficiency.^{163,164} In anemia of inflammation, the synthesis of the TfR is suppressed by cytokines and this negates the opposing stimulatory effect of iron restriction, resulting in a lower serum TfR concentration than in pure iron deficiency.¹⁶⁵ This test for iron deficiency has gradually come into clinical use, but the methodology has not yet been standardized, making laboratory-to-laboratory comparisons difficult. A method for performing reproducible assays for the soluble TfR has been standardized.¹⁶⁶ Like the serum ferritin and serum iron, serum TfR assay results may be confounded by poorly understood variations in patients with malignancies; in patients in whom the serum TfR concentration is reduced; and in patients with asymptomatic malaria or thalassemia trait,^{167,168} in whom, in the absence of iron deficiency, it is increased. The ratio of serum TfR to serum ferritin seems to be a useful but not infallible reflection of body iron stores.¹⁶⁹ Moreover, several studies show that the soluble transferrin index calculated as a ratio of the serum TfR/log ferritin (TfR-F Index) may be superior to other means for detection of iron deficiency.^{170–172}

Reticulocyte Hemoglobin Content and Other Novel Erythrocyte Indices

Some automated hematology instruments offer a method for diagnosis of iron deficiency using an assay of hemoglobin content within reticulocytes. This parameter is an indicator of iron restriction of hemoglobin synthesis during 3 to 4 days prior to the test.^{173,174} Percent hypochromic erythrocytes offers a longer term assessment of iron restriction during the preceding few months.^{173,175}

DIFFERENTIAL DIAGNOSIS

Iron-deficiency anemia is characterized by many abnormal laboratory features. Because none of these are unique, a small deviation from normal will detect most cases of iron deficiency (high sensitivity), but

Figure 43–4. Two receiver operator curves. As the specificity increases the sensitivity decreases. The receiver-operator properties of serum ferritin are far from ideal. When the specificity is high (to the left on the abscissa) the sensitivity is low; only when the specificity is low is the sensitivity adequate. The curve that would be obtained with a nearly ideal test for iron deficiency gives high specificity and high sensitivity. In the curve shown, a cutoff value could be found that allows one to identify 75 percent of patients with iron deficiency with a specificity of greater than 90 percent. Unfortunately, no such test exists.

also falsely identify non-iron-deficient subjects as being iron deficient (low specificity). On the other hand, a large deviation from normal will exclude most nondeficient patients (high specificity), but miss many iron-deficient subjects (low sensitivity). This tradeoff is shown graphically in so-called *receiver operator characteristic curves*. These curves are constructed by plotting the sensitivity against the false-positive rate ($1 - \text{specificity}$) at various values of the analyte. Figure 43–4 shows receiver operator characteristic curve for some tests for iron deficiency. The situation is complicated in the case of iron deficiency by the fact that the diagnostic problem faced by the physician is not one of differentiating a patient with iron-deficiency anemia from a normal person, but rather from a patient who has an anemia with a different etiology. It is partly for this reason that a simple algorithm for the diagnosis of iron deficiency does not exist. In a severely anemic patient, microcytosis would have very high specificity and high sensitivity compared to normal, but compared to a patient with thalassemia the specificity would be very low. Similarly, a low serum ferritin level is an excellent test in the general population, but it has relatively little value in patients with chronic renal disease. Another problem that is inherent in evaluating diagnostic tests for iron deficiency is the standard that is applied to decide who is iron deficient and who is not. Marrow iron has served as one “gold standard” but has limitations, as discussed earlier (see “Marrow” earlier). Alternatively, the response to iron therapy serves as a powerful indicator of whose anemia is actually a result of a deficiency of iron. Here, too, there are limitations, in that some iron-deficient patients may fail to respond adequately because of factors such as infection. Lacking an absolute test for iron deficiency, the ability of the physician to use judgment relevant to the particular patient’s circumstances is of paramount importance.

The forms of anemia that must be distinguished from iron-deficiency anemia most frequently include those of thalassemia minor, chronic inflammatory disease, malignancy, chronic liver disease, and chronic renal disease. It is the microcytic anemias that are most likely to be confused with iron deficiency. These include other conditions in which hemoglobin synthesis is impaired,¹⁷⁶ including thalassemias and thalassemia traits, drug- or toxin-induced impairments of heme synthesis, sideroblastic anemias (Chap. 59) and very rare defects in the delivery of iron to erythrocytes or erythrocyte iron uptake and utilization (Table 43–2).

TABLE 43–2. Microcytic Disorders Other Than Iron Deficiency

Mechanisms	Diseases
Impaired globin chain synthesis or highly unstable hemoglobin	β -Thalassemia or trait, α -thalassemia minima or minor, hemoglobin H, hemoglobin E or trait, combinations of above
Drugs or toxins that inhibit heme synthesis	Lead, isoniazid, pyrazinamide, sirolimus
Disorders that impair heme synthesis directly or by decreased iron delivery to erythroblasts, or decreased uptake or utilization of iron by erythroblasts	sideroblastic anemias, erythropoietic porphyrias, atransferrinemia, ²⁰³ aceruloplasminemia, ²⁸⁴ DMT-1 mutations, ²⁰⁷ STEAP3 deficiency ²⁸⁵

DMT, divalent metal transporter; STEAP3, six-transmembrane epithelial antigen of prostate 3.

Thalassemia Minor

In many parts of the world, and in many communities of North America, the frequency of β -thalassemia minor is second only to that of iron deficiency as a cause of hypochromic microcytic anemia (Chap. 48). In African Americans, homozygosity for α -thalassemia-2, that is the state in which only single α -globin gene is present on each chromosome, is a common cause of microcytosis. Approximately 3 percent of African Americans are homozygous for α -thalassemia-2. The condition is associated with only a very modest lowering of the blood hemoglobin level.¹⁷⁷ Heterozygotes may also have microcytosis, although usually they are hematologically normal. Among persons of Mediterranean ancestry both α - and β -thalassemia are very prevalent, particularly the latter. Among Asians, particularly in those from Southeast Asia, β -thalassemia minor, α -thalassemia minor, and hemoglobin E trait, all occur frequently. All are characterized by microcytosis, and none can be distinguished reliably from the others on the basis of erythrocyte morphology or erythrocyte indices alone. In each of these conditions there may be only mild to moderate microcytosis without any other distinctive changes. However, in the majority of patients with α - or β -thalassemia minor, hemoglobin Lepore trait, and hemoglobin E trait, the erythrocyte count is greater than $5 \times 10^{12}/L$ ($5,000,000/\mu L$), despite low hemoglobin concentration.^{178,179} Homozygous hemoglobin E is also characterized by marked hypochromia, microcytosis, abundant target cells, and elevated erythrocyte count, but usually not by more than minimal anemia (Chap. 49).¹⁷⁸

In contrast to the findings in these hemoglobinopathies, erythrocyte counts of $5 \times 10^{12}/L$ ($5,000,000/\mu L$) or higher are relatively uncommon among adults with iron-deficiency anemia.¹⁸⁰ However, erythrocytosis may be seen in children with iron-deficiency anemia or in polycythemia vera patients who have become iron deficient following hemorrhage or therapeutic phlebotomy. Consequently, while the mean MCV is almost always reduced in α - or β -thalassemia minor and in homozygous hemoglobin E, with values of 60 to 70 fL being the rule, values this low are seen only in severe iron-deficiency anemia. In hemoglobin Lepore trait and hemoglobin E trait, only minimal microcytosis is observed.^{178,179,181} Algorithmic rules based on red cell counts, MCV or RDW are not sufficiently reliable for distinguishing iron deficiency from thalassemia in populations with high prevalence of iron deficiency compared to thalassemias.

Mild reticulocytosis, polychromatophilia, and basophilic stippling are more likely to be encountered in β -thalassemia minor, $\delta\beta$ -thalassemia

minor, and hemoglobin Lepore trait than in iron-deficiency anemia, but may be absent in these disorders. The serum iron concentration is usually normal or increased in thalassemic syndromes and is usually low in iron-deficiency anemia. Similarly, examination of marrow iron stores helps to differentiate these disorders. The presence of β -thalassemia trait is substantiated by the demonstration of increased proportions of hemoglobin A₂ and F, or by the presence on electrophoresis of hemoglobin H or Lepore (Chap. 48). At present, the diagnosis of α -thalassemia minor is usually made on the basis of exclusion of other causes of microcytosis, but it can be confirmed by direct demonstration of mutations in α -globin genes by DNA-based techniques.

Iron deficiency may mask concurrent thalassemia. The amounts of both hemoglobin A₂ and hemoglobin H are diminished disproportionately to the reduction in hemoglobin A in the presence of iron deficiency¹⁸² (Chap. 46); however, usually the hemoglobin A₂ level remains above the normal range.

Anemia of Inflammation (Anemia of Chronic Disease)

The anemia of inflammation (Chap. 37) is usually normochromic and normocytic, but hypochromic microcytic anemia occurs in 20 to 30 percent of patients with chronic infections or malignancies.¹³⁹ Thus these disorders cannot be distinguished from iron-deficiency anemia by examination of the blood film. Furthermore, the serum iron concentration is usually decreased in these disorders,¹³⁹ sometimes severely. In uncomplicated iron deficiency, the TIBC is usually increased, whereas in inflammatory and neoplastic diseases it is commonly decreased, but there is considerable overlap among TIBC values of normal subjects, those with iron-deficiency anemia, and those with chronic inflammatory diseases.

Transferrin saturation may be normal in iron-deficiency anemia, and, conversely, low saturation is sometimes observed in chronic inflammation. However, circulating soluble TfRs increase in iron deficiency but not in the anemia of inflammation.¹⁷⁰ The serum ferritin level is usually diminished in iron deficiency, but it is generally increased in chronic inflammatory and neoplastic disorders.¹⁴⁷ Measurement of the ratio of soluble TfR to ferritin has been found to be useful in distinguishing the anemia of chronic inflammation from that of iron deficiency,¹⁷⁰ but meta-analysis of the relevant clinical studies suggested that the ratio may not be better than soluble TfR assay alone at discriminating between iron deficiency anemia and anemia of inflammation.¹⁸³ Examination of the marrow for stainable iron is invasive and requires skilled reading but may be helpful in an occasional patient. Iron staining of marrow macrophages is greatly decreased in amount or absent in iron deficiency anemia and normal or increased in the other disorders. Low serum hepcidin concentrations are characteristic of iron deficiency and high serum hepcidin indicates anemia of inflammation, but this assay is not yet clinically available and its clinical value is unknown. As would be expected from the inhibitory effect of hepcidin on the absorption of iron, high hepcidin levels predict a poor response to oral iron therapy¹⁸⁴ and low incorporation of dietary iron into erythrocytes.¹⁸⁵

Anemia of Chronic Liver Disease

The erythrocytes in the blood film from patients with chronic liver disease may be normochromic and normocytic, macrocytic, or hypochromic. Target cells are frequently present in large numbers. Because the blood film in iron-deficiency anemia may also display these features, differential diagnosis must be based on other observations. Low serum ferritin levels are useful in detecting iron deficiency in the setting of cirrhosis,¹⁸⁶ but normal or even increased serum ferritin does not exclude iron deficiency, especially in the presence of active liver injury.^{186,187}

Anemia of Chronic Renal Disease

Iron deficiency is frequent in patients with chronic renal disease (Chap. 37). Iron-deficiency anemia is particularly difficult to diagnose in patients with chronic renal disease (Chap. 37) where iron delivery to the marrow is inadequate because of coexisting inflammation and because of increased demands from pulsatile erythropoiesis as a result of erythropoiesis-stimulating agents. Because the problem is fairly common, and perhaps because of interest in identifying those patients who can benefit from iron therapy and decreasing their use of erythropoiesis-stimulating agents, a large number of studies have been done to determine the best way to diagnose iron deficiency in patients undergoing extracorporeal dialysis. The diagnostic problem is further complicated by the common occurrence of “functional iron deficiency,”¹⁸⁸ that is, a state in which iron stores are adequate but iron delivery to the marrow is insufficient to meet the increased kinetic requirements of erythropoiesis stimulated by intermittent use of erythropoietin and related agents. If response to intravenous iron therapy is used to diagnose iron deficiency, even many patients with abnormally high ferritins will be iron deficient.^{150,189} High serum ferritins do not preclude a response to IV iron, not even in patients with chronic kidney disease who are not on hemodialysis.¹⁹⁰ Although measurements of reticulocyte hemoglobin and percent of hypochromic erythrocytes show promise as markers of response to iron therapy, there is insufficient evidence that any individual biomarker or combination of biomarkers can reliably predict the response to iron treatment in chronic kidney disease.¹⁹¹

Anemia of Hemolytic Disease

Hemolytic disease can usually be distinguished from iron-deficiency anemia on the basis of the blood film. The marked polychromatophilia, spherocytosis, schistocytes, Heinz bodies, basophilic stippling, and other morphologic features characteristic of various types of hemolysis usually are not seen in iron-deficiency anemia. Furthermore, reticulocytosis is usually marked in hemolytic disorders but minimal or absent in iron-deficiency anemia. However, there are some outstanding exceptions to these generally valid principles.

In unstable hemoglobin disorders, such as hemoglobin H disease or hemoglobin Köln disease, erythrocytic hypochromia may be pronounced. In these disorders, there is moderate reticulocytosis, which helps to differentiate them from iron-deficiency anemia. The serum iron concentration is normal or increased. Chapter 49 discusses the detection of unstable hemoglobins.

When there is chronic intravascular hemolysis, erythrocytes in the blood film may display marked morphologic abnormalities, such as burr cells and schizocytes. Yet because of loss of iron in the urine, iron deficiency may be the dominant cause of the resulting anemia. Evaluation of iron content in marrow aspirates or measurement of serum iron concentration and TIBC may clarify the diagnosis in this form of anemia.

Hypoplastic and Aplastic Anemia

In their early phases, these disorders cannot reliably be differentiated from mild iron-deficiency anemia on the basis of erythrocyte morphology alone (Chap. 35). The reticulocyte count is generally less than 0.5 percent in hypoplastic or aplastic anemia. The presence of neutropenia and thrombocytopenia suggests a diagnosis of aplastic anemia, but mild neutropenia may also occur in iron-deficiency anemia. The serum iron concentration is usually increased in aplastic anemia; and the percentage transferrin saturation is then elevated. Marrow aspiration may produce scant material for cytologic study, and marrow biopsy may be necessary. An iron stain usually reveals increased amounts of hemosiderin in aplastic or hypoplastic anemia. However, if chronic bleeding has occurred, for example, as a consequence of thrombocytopenia, iron stores may be depleted.

Sideroblastic Anemia

In this heterogeneous group of disorders (Chap. 59), the blood findings often simulate those of iron-deficiency anemia. Reticulocytosis is usually absent, and the serum iron concentration and serum ferritin is generally normal or increased. Marrow examination shows characteristic ring sideroblasts and increased amounts of stainable iron.

Congenital Dyserythropoietic Anemia

In the rare congenital dyserythropoietic anemias (Chap. 39), erythrocyte morphologic abnormalities may resemble those of iron deficiency or thalassemia (Chap. 48). In general, in congenital dyserythropoietic anemias, poikilocytosis is very striking and occurs with less reduction in MCV than in iron deficiency or thalassemias. Often, however, such cases are believed to be thalassemic until the marrow is examined.

Megaloblastic Anemia

In pernicious anemia and other types of megaloblastic anemia (Chap. 41), the blood film usually shows changes sufficiently distinctive that there is little difficulty in differential diagnosis. One potential source of error is the change in serum iron concentration that occurs after therapy. In the patient with pernicious anemia or folic acid deficiency, early after starting treatment, the serum iron concentration decreases markedly as iron is used rapidly for hemoglobin synthesis.¹⁹² Thus the finding of a low serum iron concentration in such circumstances should not be taken as evidence of iron deficiency. Iron-deficiency anemia and anemia as a consequence of folic acid or vitamin B₁₂ deficiency may coexist. During the course of treatment, with the rapid increase in the number of red cells, the typical manifestations of severe iron deficiency may develop. The mixture of microcytic-hypochromic and normocytic-normochromic cells has been called *dimorphic anemia* (see “Coexisting Microcytic Anemia” in Chap. 41).

Anemia of Hypothyroidism

The anemia of severe hypothyroidism (myxedema; Chap. 38) is usually normochromic and normocytic and may be accompanied by mild-to-moderate depression of serum iron concentration. Marrow examination may be required to determine whether iron deficiency is present, especially as iron deficiency often complicates myxedema because of menorrhagia, which is common in this disorder.

Therapeutic Trial

In the final analysis, the response to iron therapy is the proof of correctness of diagnosis of iron-deficiency anemia. Furthermore, some physicians or patients may not have access to all the techniques described for diagnosis of iron-deficiency anemia. In this event, the patient's response to therapy may become a primary diagnostic measure. Iron administration in such a therapeutic trial is usually by the oral route, but intravenous iron can be used if there is evidence or strong suspicion of coexisting inflammation, iron malabsorption, or intolerance of oral iron preparations. A therapeutic trial under any circumstances should be followed carefully. If the cause of anemia is iron deficiency, adequate iron therapy should result in reticulocytosis with a peak occurring after 1 to 2 weeks of therapy, although if anemia is mild, the reticulocyte response may be minimal. A significant increase in the hemoglobin concentration of the blood should be evident 3 to 4 weeks later, and the hemoglobin concentration should attain a normal value within 2 to 4 months. Unless there is evidence of continued substantial blood loss, the absence of response to oral or, when appropriate, parenteral iron must be taken as evidence that iron deficiency is not the cause of anemia. Iron therapy should be discontinued and another cause for the anemia sought.

Special Studies to Delineate the Cause of Iron Deficiency

The physician who establishes a diagnosis of iron deficiency resulting from blood loss has the obligation to determine the site and cause of hemorrhage. Examination for fecal occult blood is particularly helpful in determining what additional studies should be carried out. Specimens should be examined on at least 3 days, because bleeding may be intermittent. Occasionally, it is helpful to label the patient's erythrocytes with chromium-51 (^{51}Cr) sodium chromate and to determine quantitatively the amount of blood lost daily. When there is reason to believe that bleeding is from the gastrointestinal tract, roentgenographic and other imaging studies and endoscopic investigation are indicated. The other imaging studies often include gastroscopy, esophagoscopy, colonoscopy, and capsule endoscopy, and, rarely, angiography or scintigraphic studies. Numerous clinical studies indicate that intensive investigation of patients, particularly men and postmenopausal women, reveals unexpected bleeding lesions, many of which are curable or treatable.^{10,193} *H. pylori* infection should be sought, particularly in patients who are iron deficient but who do not seem to respond to therapy.^{14,15} An iron stain of sputum may reveal hemosiderin-laden macrophages when there is intrapulmonary bleeding.

THERAPY

Once it has been established that a patient is deficient in iron, replacement therapy should be instituted. Iron may be administered orally, as simple iron salts; parenterally, as an iron-carbohydrate complex; or, very rarely, as a blood transfusion. In general, the oral route is preferred, but the intravenous route is increasingly used because of the improved safety and convenience of new parenteral iron preparations. In most patients, iron-deficiency anemia is a disorder of long duration and slow progression, and restoration of normal hemoglobin is not urgent unless the patient suffers from acute cardiac problems, in which case blood transfusion is appropriate. There is usually time to wait for normal mechanisms of erythropoiesis to respond to the body's needs and for gradual adjustment of the cardiovascular system to reexpansion of the total circulating erythrocyte volume.

Oral Iron Therapy

Dietary Therapy The patient should be encouraged to eat a diversified diet supplying all nutritional requirements. Nonetheless, it must be emphasized that neither meat nor any other dietary article contains enough iron to be useful therapeutically. Meat contains small amounts of myoglobin and hemoglobin and insignificant amounts of iron in other proteins. Although heme iron is better absorbed than inorganic iron, the quantity of heme iron in meat is actually quite small. In fact, an average (3-ounce) serving of steak provides only about 3 mg of iron, that is, the equivalent of only 3 mL of packed erythrocytes. Provision of sufficient dietary iron to permit a maximal rate or recovery from iron-deficiency anemia might require a daily intake of at least 10 pounds of steak. For these and other reasons, medicinal iron is much superior to dietary iron in the therapy of iron deficiency.

Iron Preparations The pharmaceutical market is glutted with iron preparations in nearly every conceivable form; each promoted to appeal to physician or patient for one reason or another. The following simple principles may help the physician to find a way through this chaos.

1. Each dose of an inorganic iron preparation for an adult should contain between 30 and 100 mg of elemental iron. Doses of this magnitude cause unpleasant side effects relatively infrequently.¹⁹⁴ Smaller doses have been popular in the past, but these may result in a slower recovery of the patient or no recovery at all.
2. The iron should be readily released in acidic or neutral gastric juice or duodenal juice (usually pH 5 to 6), because maximal absorption

occurs when iron is presented to the duodenal mucosa. Enteric-coated and prolonged-release preparations dissolve slowly in any of these fluids. Thus with such preparations the iron that eventually is released may be presented to a portion of the intestinal mucosa in which absorption is least efficient. Some patients who have been treated unsuccessfully with enteric-coated or prolonged-release iron preparations respond promptly to the administration of non-enteric-coated ferrous salts.

3. The iron, once released, should be readily absorbed. Iron is absorbed in the ferrous form; consequently, only ferrous salts should be used.
4. Side effects should be infrequent. This seems not to be a particular problem for any of the common commercially available iron compounds. Despite the claims of pharmaceutical companies, there is no convincing evidence that any one effective preparation is superior in this respect to any other.
5. Inexpensive iron preparations can be as effective as the more costly ones. The use of preparations containing several therapeutic agents is unnecessary and may increase side effects. Physicians should be aware that if ferrous sulfate is prescribed generically, the choice of preparation is left to the pharmacist who may dispense enteric-coated tablets. It is advisable to specify "nonenteric" or to prescribe by brand name a product that is not enteric-coated. Although substances such as ascorbic acid, succinate, and fructose enhance iron absorption, the gain is offset to a large extent by the increase in frequency of side effects, cost of therapy, or both. There is no convincing evidence to support the use of chelated forms of iron or of iron in combination with wetting agents.

Dosage For therapy of iron deficiency in adults, the dosage should be sufficient to provide between 150 and 200 mg elemental iron daily. The iron may be taken orally in three or four doses 1 hour before meals. Infants may be given 6 mg/kg¹⁹⁵ daily in divided doses for therapy, or a daily dose of 12.5 mg daily for prophylaxis of iron deficiency.

Side Effects Mild gastrointestinal side effects occur occasionally in the form of nausea, heartburn, constipation, or changes in the stool consistency. A metallic taste may be experienced. The majority of patients tolerate the usual therapeutic doses of iron without the least side effect. However, there is no doubt that some patients, perhaps 10 to 20 percent, experience symptoms that may be ascribed to the iron preparation and may be dose-dependent. In such cases, reduction of the frequency of administration to 1 tablet a day for a few days may alleviate the symptoms; later, the patient may be able to tolerate treatment in full dosage. It might also be useful to change to another iron preparation, especially one with a different external appearance.

Carbonyl iron has been proposed as an alternative to iron salts, on the assertion that it can be given in large doses with minimal side effects. This substance is actually metallic iron powder, with a particle size less than 5 μm . Because it is insoluble, it is not absorbed until converted to the ionic form. The bioavailability of carbonyl iron has been estimated to be approximately 70 percent of that of an equivalent amount of ferrous sulfate.¹⁹⁶ Oral doses as high as 600 mg three times daily did not produce toxic effects.¹⁹⁶

Widespread iron supplementation in regions where malaria and gastrointestinal infections are highly endemic is associated with increased malaria transmission and childhood mortality, presumably from increased infections.¹⁹⁷ Although there is not yet a consensus on optimal strategy in such settings, it seems reasonable to target iron supplementation to children who are iron-deficient.

Acute Iron Poisoning Acute iron poisoning is usually a consequence of the accidental ingestion by infants or small children of iron-containing medications intended for use by adults. Any potent oral preparation may cause acute iron poisoning, and this serious disorder remains a problem, despite public awareness campaigns and safer

packaging of medications.¹⁹⁸ In the United States, there were nearly 30,000 reported incidents in 2008. The earliest manifestation of iron poisoning is vomiting, usually within 1 hour of the ingestion. There may be hematemesis or melena. Restlessness, hypotension, tachypnea, and cyanosis may develop soon thereafter, and may be followed within a few hours by coma and death but fatal outcomes are now extremely rare. Usually, medical aid is sought early and, with proper treatment, most iron-poisoned children survive. The initial treatment is prompt evacuation of the stomach. In the home, this may be induced by digital stimulation of the pharyngeal gag reflex. If the patient arrives in the emergency room within minutes of ingestion, gastric intubation and lavage should be performed promptly. Whole-bowel irrigation¹⁹⁸ is currently recommended for all heavy metal intoxications. Supportive measures should be used as needed for shock or for metabolic acidosis should these develop. IV desferrioxamine is the agent of choice for specific therapy of hyperferremia, at a maximum rate of 15 mg/kg per hour for 1 hour, then lowered to 125 mg/hour. Improvement often appears several hours to a few days after onset of iron poisoning. Children who survive for 3 or 4 days usually recover without sequelae. However, gastric strictures and fibrosis or intestinal stenosis may occur as late complications.

Parenteral Iron Therapy

Indications As parenteral iron preparations have become safer and easier to administer, the use of parenteral iron is increasing. Established indications for the use of parenteral rather than oral iron include malabsorption, either because of systemic inflammation or gastrointestinal pathology, intolerance to iron taken orally, iron need in excess of an amount that can be absorbed in the intestine, and noncompliance. Parenteral iron administration has an erythropoietin-sparing effect in anemic patients on long-term hemodialysis for chronic renal disease.^{35,199,200} Because of systemic inflammation and possibly other factors, these patients do not appear to respond adequately to oral iron therapy.

Calculating Dosage The amount of iron that needs to be given is readily estimated by noting that 1 mL of red cells contains approximately 1 mg of iron. However, various formulas have been used for estimating total dose required for treatment. Because total blood volume is approximately 65 mL/kg and the iron content of hemoglobin is 0.34 percent by weight, the simplest formula for estimating the total dose required for correction of anemia only is as follows:

$$\begin{aligned} \text{The dose of iron (mg)} &= \text{Whole-blood hemoglobin deficit (g/dL)} \\ &\times \text{Body weight (lb)} \end{aligned}$$

Assuming normal mean hemoglobin concentration of 16 g/dL, a male weighing 170 pounds, whose hemoglobin concentration is 7 g/dL, would require $170 \times (16 - 7) = 1530$ mg iron to correct this anemia. To this should be added a sufficient quantity of iron to replete iron stores, approximately 1000 mg for men and approximately 600 mg for women. Thus a 170-pound male with a hemoglobin concentration of 7 g/dL should receive 2530 mg iron.

Parenteral Iron Preparations Because iron salts are highly toxic when given parenterally, all iron preparations consist of colloidal (nanoparticulate) complex of iron with carbohydrates. To make the iron bioavailable for erythropoiesis and other biologic processes, the iron complexes must be ingested by macrophages and digested so that the administered iron can be gradually delivered to plasma transferrin. Currently available preparations include iron sucrose, low-molecular-weight iron dextran, ferric gluconate, ferumoxytol, ferric carboxymaltose, and iron isomaltoside. High-molecular-weight dextran was associated with anaphylactoid adverse events compared to the other preparations and should therefore be avoided.²⁰¹ The remaining preparations are safe and serious adverse events are extremely rare.²⁰² Although the recommended methods of administration, including the use of test

dosing, the amount of iron per infusion, and infusion rates differ among the preparations, these are not based on comparative studies. Currently available data indicate that the preparations do not significantly differ in safety or efficacy. Premedication to prevent allergic responses was commonly used with the older preparations but it is neither needed nor known to be effective with the newer formulations, and may introduce side effects of its own.

COURSE AND PROGNOSIS

Course

If therapy is adequate, the correction of iron-deficiency anemia is usually gratifying. Symptoms such as headache, fatigue, pica, paresthesia, and burning sensation of the oropharyngeal mucosa may abate within a few days. In the blood, the reticulocyte count begins to increase after a few days, usually reaches a maximum at approximately 7 to 12 days, and thereafter decreases. When anemia is mild, little or no reticulocytosis may be observed. Little change in hemoglobin concentration or hematocrit value is to be expected for the first 2 weeks, but then the anemia is corrected rapidly. The hemoglobin concentration in the blood may be halfway back to normal after 4 to 5 weeks of therapy. By the end of 2 months of therapy, and often much sooner, the hemoglobin concentration should have reached a normal level.

When iron-deficiency anemia does not resolve with oral iron treatment, careful inquiry into the nature, duration, and regularity of iron therapy may reveal a reason for the failure of therapy and permit a gratifying response to be elicited with adequate therapy. Other questions that should be asked in evaluation of such a case are these: (1) Has bleeding been controlled? (2) Has the patient been on iron therapy long enough to show a response? (3) Has the dose of iron been adequate? (4) Are there other factors— inflammatory disease, neoplastic disease, hepatic or renal disease, prior gastrointestinal surgery, concomitant deficiencies (vitamin B₁₂, folic acid, thyroid)—that might retard response? Prominent among these are *H. pylori* infection, autoimmune gastritis, and celiac disease.¹⁵ (5) Is the diagnosis of iron deficiency correct?

Intravenous iron should be effective in patients with established iron deficiency who fail to respond to oral iron after several weeks. Continued loss of blood or, rarely, the genetic disorder iron-refractory iron-deficiency anemia,¹⁵ may account for incomplete response to IV iron.

Prognosis

When the cause of the iron deficiency is a benign disorder, the prognosis is excellent, provided bleeding is controlled or can be compensated for by continual iron therapy. If there is a benign cause of recurrent bleeding that is corrected, such as hiatal hernia, menorrhagia, or hereditary hemorrhagic telangiectasia, oral iron therapy may be continued indefinitely; if the bleeding is especially brisk, supplementation with parenterally administered iron or, rarely, with transfusion may be needed. Continuous iron administration may also be required in patients with iron deficiency secondary to intravascular hemolysis with hemoglobinuria.

IRON STORAGE DISEASE

DEFINITION AND HISTORY

The terms *iron storage disease* and *hemochromatosis* are used to designate an increase of tissue iron resulting in a disease state; *hemosiderosis* denotes an increase of tissue iron stores with or without tissue damage. Classically hemochromatosis has been characterized by bronzing of the skin, cirrhosis, and diabetes, and was once called *bronzed diabetes*. Since the 1970s, usage of the term *hemochromatosis* has expanded well beyond its original meaning. This diagnosis is now commonly applied to persons who have increased body iron as suggested by increased serum

TABLE 43-3. Classification of Hemochromatosis

- I. Hereditary Hemochromatosis
 - A. Classical hemochromatosis (HFE hemochromatosis) (type 1)
 - B. Juvenile hemochromatosis (type 2)
 - 1. Abnormality in hemojuvelin
 - 2. Abnormality of hepcidin
 - C. Transferrin receptor-2 deficiency (type 3)
 - D. Ferroportin abnormalities (type 4)
 - 1. Gain of function (systemic iron overload)
 - 2. Loss of function (macrophage iron overload)
 - E. Ferritin H-chain iron-responsive element mutation
 - F. African iron overload
- II. Secondary Hemochromatosis

ferritin levels, and even to those who merely have the hemochromatosis *HFE* genotype, regardless of the level of their iron stores.

Hemochromatosis may be divided into genetic forms and acquired forms. The former have sometimes been designated as *primary* and the latter as *secondary* forms. The disorder once designated *idiopathic hemochromatosis* and now as *hereditary hemochromatosis* usually is applied to the common genetic form of the disorder, found principally in those of northern European ancestry, and as a result of mutations in the *HFE* gene (type I hemochromatosis). In the United States, this is by far the most common form of the disease. *Juvenile hemochromatosis* from hemojuvelin and hepcidin mutations (type 2), hemochromatosis as a result of TfR-2 mutations (type 3), hemochromatosis caused by ferroportin mutations (type 4), and *African iron overload* are much less common. Table 43-3 classifies hereditary hemochromatosis. *Secondary hemochromatosis* occurs in patients who receive multiple blood transfusions, and in patients with ineffective erythropoiesis, even when they do not receive transfusions.

Systemic iron overload and hepatic iron accumulation similar to hemochromatosis are also characteristic of atransferrinemia²⁰³⁻²⁰⁶ and of human divalent metal transporter (DMT)-1 mutations.^{207,208} A fetal and neonatal disorder termed *neonatal hemochromatosis* is characterized by hepatic and extrahepatic iron deposition and fulminant hepatitis caused by maternal immune response to fetal antigens.²⁰⁹

Iron accumulation in localized sites, particularly the brain, occurs in disorders other than hemochromatosis. Increased quantities of brain iron are characteristic of a ceruloplasminemia, and are found in Alzheimer disease, parkinsonism, Friedreich ataxia, Hallervorden-Spatz syndrome, and multiple system atrophy. Because none of these are primarily hematologic disorders, and because the role of iron deposition in the pathology of the disorders is uncertain, they are not discussed further here.

Hemochromatosis was first described by Trousseau in 1865. The massive accumulation of iron that occurred in this disease was recognized as its hallmark. The ingenious development of serial phlebotomy as treatment for the disease suggested by Finch in 1949, and implemented on a larger scale in 1952,²¹⁰ made it clear that iron accumulation was the most important pathogenetic factor. Alcohol consumption and other environmental factors were also commonly found in patients with hemochromatosis.²¹¹ The existence of a long-suspected hereditary factor was firmly established when the disease was shown tightly linked to the human leukocyte antigen (HLA locus). Surprisingly, the gene proved to be *HFE* (initially named *HLA-H*), one of the many HLA-like genes on chromosome 6.²¹²

The identification of the *HFE* gene made it possible, for the first time, to assess accurately the gene frequency and penetrance of the

HFE mutations. This brought about a fusion of the apparently contrasting views of genetic and environmental causes. The penetrance of the homozygous state is so low that it could be considered an essential risk factor that required other genetic or environmental factors for disease development.²¹³

EPIDEMIOLOGY

The prevalence of mutations of the *HFE* gene is very high. The most significant of these is the c.845 A>G (C282Y) mutation, and with a gene frequency of approximately 0.07 in the northern European population, approximately 5 in 1000 northern Europeans are homozygous for the mutation. The C282Y and S65C mutations are almost entirely confined to individuals with European ancestry. The H63D mutation is more widespread geographically, but is also most common in Europeans. Within Europe the highest gene frequencies of the C282Y mutation are encountered in the southern British Isles and in northern France but other northern Europeans, including Scandinavians, also have high gene frequencies, consistent with Celtic or possibly Viking origin of the mutation.²¹⁴

Although earlier studies attributed nonspecific symptoms in patients to hemochromatosis, large controlled series have shown that most such symptoms are not present in homozygotes for the C282Y mutation at a higher frequency than in controls,²¹⁵⁻²¹⁷ or a borderline increase, at most, invariably in groups of patients who were aware of their diagnosis when answering questions about symptoms. These findings are consistent with the very low prevalence of hemochromatosis reported in autopsy series and in hospital surveys. The prevalence of symptomatic clinical hemochromatosis in northern European populations is probably only approximately 5 in 100,000 individuals. If patients with abnormal liver function tests and/or fibrosis on liver biopsy are included, the number of affected may be severalfold higher.²¹⁸⁻²²¹ The factors that determine whether a patient with the C282Y homozygous genotype develops disease are not well understood. The patient's sex is clearly a modifying factor, with more severe manifestations observed in males, as pregnancy and menstrual losses tend to ameliorate the disease in women. Other genetic factors that might interact with the C282Y homozygous genotype in producing clinically significant iron storage disease have been sought, but not found, except rare instances in which coinheritance of mutations of the hepcidin gene may be responsible. An increased proportion of severely affected patients have a large alcohol intake.^{222,223}

The widespread perception that classical hereditary hemochromatosis frequently led to clinical disease resulted in enthusiasm for population-based screening. However, the cost-to-benefit analysis used was based upon the assumptions that life-threatening disease manifestations will occur in 43 percent of males and in 28 percent of females, estimates that were based upon the prevalence of disease in patients, most of whom had been diagnosed clinically with hemochromatosis. With the realization that the clinical penetrance is much lower, interest in screening the general population for hemochromatosis has largely disappeared.

The prevalence of other forms of hemochromatosis, including juvenile hemochromatosis, hemochromatosis as a result of ferroportin deficiency, and atransferrinemia, is much lower than that the prevalence of classical hereditary hemochromatosis. These forms of hemochromatosis are very rare.

ETIOLOGY AND PATHOGENESIS

Toxicity of Iron

In living organisms, iron associates with proteins to function in oxygen storage and transport and in various metabolic reactions as an electron

donor or electron acceptor. The capacity to catalyze oxidation-reduction reactions appears to cause iron-mediated cellular and tissue injury. One of the pathways that is considered to be of greatest importance is the Haber-Weiss reaction:

The sum of these two reactions is the Fenton reaction:

The hydroxyl radical (HO·) has been implicated in producing damage to polysaccharides, DNA, and enzymes, and in causing lipid peroxidation.²²⁴ Although there is no direct evidence that hydroxyl radical generation is the main pathway of tissue damage in hemochromatosis, this common conjecture seems reasonable. Demonstrating a damaging effect of iron alone on experimental animals has been difficult. Although in mouse models of genetic, parenteral, or dietary iron overload subtle biochemical defects have been documented, frank cirrhotic changes have not been found. In gerbils, parenteral iron overload causes hepatic necrosis, fibrosis, and nodular regeneration, as well as cardiac damage.²²⁵ In rats, iron alone does not cause fibrosis, and alcohol alone causes only minor liver abnormalities. However, administration of both excess iron and alcohol results in fibrosis.²²⁶ These findings in rats are quite consistent with the strong association that has been demonstrated to exist between alcohol ingestion and cirrhosis in patients with the hemochromatosis genotype. In a number of species, including birds, rhinoceros, tapir, fruit bats, and others, iron overload has been observed in zoos or other restricted settings, particularly after a diet other than the animal's native diet is fed.

Iron is stored in ferritin in the cytoplasm of all cells. The multiple isoforms found in human tissues are composed of variable proportions of two subunits: L-ferritin (light) and H-ferritin (heavy).²²⁷ Because free iron is potentially harmful to the cell, it is sequestered and detoxified to the less-soluble ferric form by ferroxidase activity; H-ferritin exerts most of its ferroxidase activity in the cytosol. The mitochondrial ferritin, expressed in the mitochondrial matrix, also has potent ferroxidase activity and is markedly upregulated in sideroblastic anemias.

Causes of Iron Overload

Because body iron content is maintained by regulating absorption, excess body iron can accumulate only when absorption is increased above iron requirements, or when iron is injected into the body, either in the form of medicinal iron or as transfused erythrocytes.

Excessive Iron Absorption A variety of mutations are known to cause increased iron absorption in experimental animals and in man (see Table 43-3 for a summary). Mutations in the genes encoding HFE, hemojuvelin, TfR-2, ferroportin, and hepcidin are all associated with iron overload. The common pathway that causes hyperabsorption of iron is deficiency of hepcidin which allows excessive activity of the iron exporter ferroportin in the duodenum and in macrophages of the reticuloendothelial system. Normally, hepcidin is upregulated when body iron increases. However, this response is blunted or absent in either *Hfe*-, *TfR-2*-, or *Hjv*-deficient mice,²²⁸ or in the human disease,²²⁹⁻²³¹ all of which exhibit disproportionately low hepcidin levels for the degree of iron overload. Although the biochemistry of their interactions is not known, there is increasing evidence that HFE, TfR-2, and hemojuvelin are part of the signaling pathway that regulates hepcidin expression. In autosomal dominant hereditary hemochromatosis (class 4), ferroportin mutations interfere with binding of hepcidin to ferroportin^{232,233} or with the resulting ferroportin endocytosis.

Ineffective Erythropoiesis Anemias with ineffective erythropoiesis commonly cause systemic iron overload with damage to the liver, heart and the endocrine system. Iron storage disease is particularly

common in disorders such as β -thalassemia, hereditary dyserythropoietic anemia, and pyruvate kinase deficiency. The amount of body iron may greatly exceed the quantity that can be accounted for through blood transfusion, and iron overload is common even in patients who are rarely or never transfused.

The iron overload commonly observed in β -thalassemia intermedia and major patients likely results, at least in part, from suppression of the iron-regulatory hormone hepcidin by erythroid factors secreted by massively proliferating erythropoietin-stimulated erythroblasts. Candidate erythroid suppressors of hepcidin include growth differentiation factor 15 (GDF15)²³⁴ and erythroferrone.²³⁵ GDF15 overexpression was also observed in congenital dyserythropoietic anemia.^{236,237}

Transfusion or Iron Therapy Iron overload can be iatrogenic in origin. Because erythrocytes contain 1 mg of iron per milliliter, transfusion of 450 mL of whole blood or of 200 mL of red cells adds 200 mg of total iron to the body, iron that will not be excreted. Thus, a patient who receives 2 units of blood monthly for an anemia that is not a result of blood loss will accumulate 4.8 g of iron per year. If the need for transfusion is occasioned by a disorder in which ineffective erythropoiesis plays a prominent role, the accumulation of iron is even greater. Thalassemia is such a circumstance, and iron overload is the most important cause of death in patients with this disorder (Chap. 48).

The homeostatic mechanisms of the body are such that the inappropriate administration of iron by the oral route is very unlikely to produce clinically significant iron overload. Of the few cases that have been described, all but one were documented before the cloning of the *HFE* gene, raising the possibility that the patients had genetic hemochromatosis that was accelerated by excess iron intake. Documented iron overload after iron injection is even less common and has not been accompanied by demonstrable tissue damage.

Pathology

Affected tissues and organs exhibit a deep brown color. Histologic examination reveals prominent hemosiderin deposition in many tissues and organs.

Liver The liver is often enlarged. After cirrhosis has developed, the organ becomes granular or coarsely nodular. In the liver of patients with classical hemochromatosis, TfR-2 mutations, and in juvenile hemochromatosis, hemosiderin is found primarily in hepatocytes. Kupffer cells are relatively spared. Prior to the development of cirrhosis, the hemosiderin accumulates primarily in periportal hepatocytes and is less toward the central veins. The iron of cirrhotic livers is mostly in the periphery of regenerative nodules. Fibrosis begins periportal, then fibrous septa traverse the lobules. Usually, the distortion of the architecture is not as severe or as uniform as in alcoholic cirrhosis. The cirrhosis of hemochromatosis usually has a micronodular appearance. Iron in bile duct epithelium has sometimes been considered a specific marker for hemochromatosis, but is not reliable. The amount of iron in the liver is always greatly increased. This is apparent on inspection of sections stained for iron with the Prussian blue reaction, and can be quantitated on liver biopsy specimens. An iron concentration of more than 300 $\mu\text{mol/g}$ dry weight (or about 50 $\mu\text{mol/g}$ wet weight) is considered strong evidence for hemochromatosis when factors such as transfusions are eliminated as the cause.

In the original description of African iron overload, the liver pathology was deemed to be indistinguishable from that of classical hemochromatosis, but in newer studies²³⁸ it seems that only some of the affected patients manifest iron storage, primarily in the hepatocytes; some have storage primarily in Kupffer cells. In the case of patients with ferroportin mutations that prevent transport of iron, storage of iron takes place mostly in the Kupffer cells, and fibrosis seems to be absent; ferroportin mutations that prevent interaction with hepcidin, on the

other hand, are associated with hepatocytes iron overload, as is seen in classical hemochromatosis.^{233,239}

Heart Iron accumulates more slowly in the myocardium than in the liver, but the heart is more sensitive to its toxic effects. Myocardial damage is seen when iron loading is rapid, for example, in β -thalassemic patients dying of transfusional iron overload in their 20s and 30s²⁴⁰ prior to effective chelation therapy, and in juvenile hemochromatosis patients who usually present with iron-induced cardiomyopathy and endocrinopathy rather than liver failure.²⁴¹ The myocardium is thickened and the heart is often enlarged; arrhythmias and myocardial failure follows. Accumulation of cardiac iron is the leading cause of death in transfused patients with β -thalassemia major. Patients with transfusion-dependent anemias, such as congenital dyserythropoietic anemia and Diamond-Blackfan syndrome, also develop iron overload-induced cardiomyopathy. In transfused patients with myelodysplastic syndromes, transfusion threshold guidelines of 75 units of blood was suggested as a risk factor of cardiac iron overload but this is not based on firm data. Direct cardiac iron measurement using magnetic resonance imaging predicts cardiac complications and can stratify the risk of subsequent cardiac dysfunction.²⁴² This technique measures the half-life, $T2^*$, of cardiac muscle darkening (with respect to echo time) produced by magnetically active stored cardiac iron.

Marrow The quantity of iron in the marrow of patients with classical hereditary hemochromatosis is only modestly increased, if increased at all. The iron is characteristically distributed into small, equal-size granules, and these are located in endothelial lining cells rather than in macrophages. Indeed, in classical hereditary hemochromatosis, both macrophages²⁴³ and intestinal mucosal cells are iron-poor relative to the overall iron burden.

Genetics

Genetic factors play an important role in the etiology of iron storage disease. This is true not only in the primary forms of the disorder, but also in secondary hemochromatosis, where genetic disorders of erythropoiesis are the most common causes. The genetics of these disorders, including the thalassemias, dyserythropoietic anemias, and red cell enzymopathies, are described in Chaps. 39, 47, and 48. Mutations of several genes that play an important role in iron homeostasis have been found to lead to iron storage disease.²⁴⁴

HFE Mutations The most common cause of hereditary hemochromatosis is a mutation of the *HFE* gene. This HLA-like gene resides on chromosome 6. Three polymorphic mutations have been identified. These are located at nucleotides 187,193, and 845 of the cDNA (complementary DNA) and at the protein level encode the H63D, S65C, and C282Y mutations, respectively. The phenotypic severity of these mutations on iron homeostasis is manifested in the following order: C282Y > H63D > S65C. Hereditary hemochromatosis is essentially an autosomal recessive disorder. Approximately two-thirds of homozygotes for the C282Y and a slightly lower percentage of compound heterozygotes for the C282Y and H63D mutations manifest increased serum transferrin saturations and serum ferritin levels. Individuals heterozygous for either the C282Y or the H63D mutation have, on the average, significantly higher transferrin saturations and serum ferritin levels than do wild-type homozygotes. However, the magnitude of this increase is very low.²⁴⁵ For example, the average transferrin saturation of men with the wild-type genotype is 26.69 percent and heterozygotes for the C282Y mutation have a transferrin saturation averaging 30.63 percent. The effect of the H63D mutation is even less, and that of the S65C mutation barely perceptible.

In spite of the minimal effect of the heterozygous state for *HFE* mutations on iron homeostasis, a number of investigators have proposed that heterozygotes are at increased risk for a variety of disorders.

What has not been taken into account in the studies is that the *HFE* gene is in close proximity to (and therefore likely to be coinherit with) many immune-response genes on chromosome 6; consequently, it is not possible to distinguish the minor effects that *HFE* mutations may have on iron homeostasis from variation in the immune response.

HAMP (Hepcidin) Mutations Mutations of hepcidin are rare, and are associated with severe juvenile hemochromatosis.²⁴⁶

SCL40A1 (Ferroportin) Mutations Mutations of the gene encoding ferroportin cause an autosomal dominant iron storage disease of two types. Gain-of-function mutations, for example the C326S mutation, interfere with hepcidin binding to ferroportin or with the resulting ferroportin endocytosis, so that mutant ferroportin molecules continue exporting iron from enterocytes and macrophages to plasma even in the face of high hepcidin levels²³² that normally cause ferroportin endocytosis and proteolysis. A mouse model of this condition shows that a heterozygous mutation is sufficient to cause severe iron overload but that homozygosity for this mutation is even more severe.²⁴⁷ Loss-of-function mutations are more common and include ferroportin mutations that do not allow ferroportin protein to localize to the cell surface, or prevent transport of iron. Here storage of iron takes place mostly in the Kupffer cells and splenic macrophages, and cirrhosis does not occur. It is not clear why these act in a dominant manner, nor why all of the reported mutations encode amino acid substitutions and none are completely destructive (frameshift or stop codons).^{158,248} An attractive explanation is that these mutations act in a dominant-negative manner, but this mechanism has not yet been supported by convincing biochemical data. A common polymorphism c.744G→T (Gln284His) shows an association with African iron overload,^{238,249,250} but is clearly not present in all patients who manifest this syndrome.

TfR-2 Mutations Mutations of *TfR-2* cause an autosomal recessive disorder that is indistinguishable clinically from the common HFE-related form of hereditary hemochromatosis.^{230,251–253}

Hemojuvelin Mutations Several different mutations of a gene designated as *HFE2* and as *HJV* cause juvenile hemochromatosis.^{231,254–258} Hemojuvelin belongs to the class of glycosylphosphatidylinositol-anchored repulsive-guidance molecules, and may act as a coreceptor for bone morphogenetic proteins (BMPs). BMP receptor is now known to be a key regulator of hepcidin transcription.²⁵⁹

DMT-1 Human Mutations DMT-1 human mutations are all associated with hepatic hemosiderosis^{207,208,260} and most are associated with abnormal liver function tests in addition to microcytic hypochromic anemia. This is in contrast to mice and rats with DMT-1 mutations, as these DMT-1-deficient rodents are iron deficient. This is likely because humans, unlike rodents, can also absorb heme-containing iron, at least to a small degree in a DMT-1 independent manner while the DMT-1 dependent iron utilization by erythroblasts is severely impaired in both humans and rodents.

Animal Models

Naturally Occurring Models

When kept in zoos or other nonnative habitats, a number of animal species, such as myna birds, the toco toucan, Salers cattle, lemurs, and the browsing rhinoceros, are iron-loaded. Rhinoceroses may represent an interesting paradigm for iron storage in captive species. Although the browsing rhinoceros species are iron loaded, grazing species are not, even when kept under similar conditions. It seems likely that because iron is not readily available in the leaves and twigs eaten by the browsing species, these species have evolved to more efficiently take up iron from their diet—more efficiently than needed when fed a zoo diet. Molecular comparisons of iron-regulatory genes in browser versus grazer rhinoceroses identified some promising candidates, but the ultimate cause of the differences in iron handling has not yet been established.²⁶¹

Models Produced by Iron Loading Numerous efforts have been made to create models of hemochromatosis by loading laboratory animals with iron, either by the oral or parenteral route. A few of these appear to simulate the human disease in one respect or another. For example, the iron-loaded gerbil^{262–265} develops heart disease, features of which resemble the human disease. Such models have been used for the study of potential chelating agents.

Targeted Disruption Models Targeted disruption of most of the genes associated with human iron disorders has been achieved. Included are *HFE*,²⁶⁶ *TfR-2*,²⁵² *ferroportin*,²⁶⁷ *hemojuvelin*,^{255,256} and *hepcidin*.²⁶⁸ The targeted disruption of several genes, including those encoding BMP-6,^{269,270} or the components of the BMP receptor,²⁵⁹ caused iron overload in mice, but the equivalent human diseases have not yet been found.

CLINICAL FEATURES

HFE-Related (Type 1) Hereditary Hemochromatosis

Onset The clinical features of the most common form of hereditary hemochromatosis are cirrhosis of the liver, darkening of the skin, cardiomyopathies, and diabetes. These features are only seen in the fully penetrant form of the disease and may depend on additional cofactors such as alcohol consumption. In contrast to the juvenile form of the disease, in which onset is usually in the second or third decade of life, classical hereditary hemochromatosis associated with mutations of the *HFE* gene generally is diagnosed in the fifth or sixth decade of life.

General Symptomatology Many symptoms are attributed to hereditary hemochromatosis, including abdominal pain, weakness, lethargy, fatigue, loss of libido, impotence, and arthropathies. However, all of these symptoms are common in an aging population, and epidemiologic studies show that none of them are more common in patients with the *HFE* hemochromatosis, even those with the biochemical phenotype, than they are in the general population.

Arthropathies The arthropathy of patients with hemochromatosis has characteristic features.^{218,271,272} It is said to tend to begin at the small joints of the hands, especially the second and third metacarpal joints, and that in some cases episodes of acute synovitis may occur, as in calcium pyrophosphate dehydrate deposition arthropathy (pseudogout; chondrocalcinosis). Radiologically, the arthropathy resembles that of osteoarthritis with joint space loss, subchondral cysts, sclerosis, and osteophytosis. The features that have been considered distinctive include the joint distribution, the presence of shape osteophytes emerging from the radial sides of the metacarpal distal epiphysis, and the presence of radiolucent zones in the subchondral area of the femoral head. It is generally recognized that arthritis does not respond to phlebotomy therapy. The possibility that this type of arthritis depends on linkage of *HFE* to other HLA genes is made less likely by the occurrence of similar arthritis in juvenile hemochromatosis,²⁷³ which is genetically independent of the HLA locus. Hip arthritis at an early age was also noted in a family with *hepcidin*-resistant *ferroportin* mutation and iron overload.²³⁹

Liver Patients with hepatic iron overload are at a greatly increased risk of developing a hepatocellular carcinoma, especially when cirrhosis is present.²⁷⁴ Occasional patients with hereditary hemochromatosis have been reported to develop hepatocellular carcinoma even in the absence of cirrhosis suggesting that iron overload could be directly carcinogenic.

Porphyria Cutanea Tarda

Porphyria cutanea tarda is a disease that is well known to be associated with mild iron overload and that responds to phlebotomy treatment (Chap. 58). Numerous studies document that the prevalence of patients with this disorder who also have mutations of the *HFE* gene is considerably increased.²⁷⁵

Juvenile Hemochromatosis

The penetrance of the rare juvenile form of the disease seems to be high and cardiomyopathies and endocrine deficiencies are the major clinical features.²⁷⁶ Joint manifestations were found to be relatively common in patients with juvenile hemochromatosis.²⁷³

African Iron Overload

It is not clear to what extent African iron overload is symptomatic. Among the Bantu, where the disorder was originally described, there are many complicating factors, including malnutrition and high alcohol intake. Among African Americans various associated disorders have been noted, but a cause-and-effect relationship is not clear.

Secondary Hemochromatosis

The clinical findings in patients with hemochromatosis secondary to blood transfusion and/or disorders of erythropoiesis are, in general, indistinguishable from those found in patients with the primary hemochromatosis.²⁷⁷

LABORATORY FEATURES

The main laboratory features of hereditary hemochromatosis are an abnormally high transferrin saturation, and increased serum ferritin level. Five to 10 percent of patients with classical *HFE* hemochromatosis manifest increased liver enzyme levels in the serum. In secondary hemochromatosis, anemia and other manifestations of the underlying disorder are found. Macrocytosis of the erythrocytes is a common feature; this finding seems unrelated to liver disease and its cause is unknown.

Differential Diagnosis

A large number of methods have been introduced that allow the amount of storage iron to be estimated.²⁷⁸ The suspicion that a patient may have primary hemochromatosis is generally raised by an increased serum transferrin saturation, particularly when it is found together with an elevated serum ferritin level. Increased transferrin saturation commonly occurs in patients with chronic liver disease who have no mutations in the *HFE* gene.²⁷⁹ Ferritin is an acute phase protein and levels are elevated in a variety of disorders. Particularly high levels are encountered in patients with macrophage activation syndromes, loss-of-function *ferroportin* mutations, acute hepatitis, Gaucher disease, in some malignancies, and in patients with the hyperferritinemia-cataract syndrome.²⁸⁰ The latter disorder is an uncommon autosomal dominant defect in which a mutation in the 5' IRE of the ferritin light chain prevents binding of the IRPs, resulting in unrestrained constitutive production of the ferritin chains.

Many clinicians have considered a liver biopsy the "gold standard" for the diagnosis of iron overload. The material obtained at biopsy not only provides the opportunity to assess the histopathology of the liver of the patient, but also to quantitate the amount of nonheme iron in the specimen. Dividing the iron content by the patient's age provides an iron index; a value greater than 2 implies the presence of hemochromatosis. Although in some situations liver biopsy may provide useful information, it is an invasive procedure that, although low-risk, is no longer required for the diagnosis of hemochromatosis. Enthusiasm for subjecting every patient with potential hemochromatosis to liver biopsy has diminished with the ready availability of genetic analysis. Moreover, a simple way to determine whether a patient is iron overloaded is to institute a program of phlebotomies. This is an essentially harmless way to determine how much storage iron the body contains. Magnetic resonance imaging (MRI) is also capable of detecting and reliably quantifying the amount of iron in the liver.²⁸¹ For detection of cardiac iron overload, T2* MRI²⁴² is a superior diagnostic approach.

THERAPY

The treatment of hemochromatosis consists of removing the accumulated iron. In the case of patients who are able to mount an erythropoietic response to phlebotomy, removal of blood is generally the treatment of choice. When the patient has marked impairment of erythropoiesis, as in thalassemia and dyserythropoietic anemia, it is necessary to employ chelating agents to remove iron, although occasionally serial phlebotomy will stimulate sufficient erythropoiesis to make it a viable therapy.

Phlebotomy

Each milliliter of packed red cells contains approximately 1 mg of iron. Thus, the removal of 500 mL of blood with a hematocrit of 40 percent removes approximately 200 mg of iron. As the red cell mass is restored to its prephlebotomy size, iron is mobilized from the stores. When the stores have been exhausted the signs of iron deficiency develop, and this is the end point of the initial part of the phlebotomy program. The patient is then followed and a schedule of maintenance phlebotomies is established with the frequency of phlebotomies tailored to maintain the serum ferritin level, the best indicator of body stores, below 100 ng/mL.

The actual volume of blood removed at each phlebotomy depends on the patient's size. Most average-size patients tolerate removal of 500 mL, but patients who weigh 50 kg or less are better treated by the removal of correspondingly smaller volumes of blood. Many patients may complain of symptoms following the first few phlebotomies. Better compliance is achieved if such symptoms are minimized by performing phlebotomies only every 14 days initially, increasing the frequency to weekly phlebotomies once the patient has become accustomed to the procedure and the activity of the marrow has been stimulated so as to replace the lost erythrocytes rapidly. The hematocrit or hemoglobin and the MCV of the red cells should be measured before each phlebotomy is undertaken. If there has been a substantial decrease in the hematocrit or hemoglobin, the phlebotomy should be deferred. The MCV may rise early in the treatment program, but as iron deficiency develops it will fall, signaling that the end point has been reached or is near. The transferrin saturation and serum ferritin level should be measured every 2 or 3 months. When the transferrin saturation is less than 10 percent and the serum ferritin less than 10 ng/mL, phlebotomy should be discontinued and the patient monitored every 4 to 8 weeks. When the serum ferritin is in the 50 to 100 ng/mL range, the maintenance phase should be initiated. Some patients may require phlebotomies monthly to maintain a normal ferritin value, whereas others may only require two or three phlebotomies per year.

Chelation Therapy

Chelation therapy instituted in a timely manner can decrease the potential morbidity caused by iron overload and prolong the life of patients with hereditary chronic iron-loading disorders such as β -thalassemia major or intermedia. It also has a place in the management of some patients with acquired marrow dysplasias provided that the prognosis of the underlying disorder, and the patient's psychological state, justifies the somewhat cumbersome implementation of parenteral chelation. As oral chelating agents become more readily available, the application of chelation therapy to myelodysplastic states may broaden.

Desferrioxamine

Desferrioxamine is a naturally occurring iron-chelating compound elaborated by the microorganism *Streptomyces pilosus*, having evolved to enable the microbe to obtain iron from its environment. One molecule of this chelator binds one atom of iron. Its molecular weight is 560 daltons. The iron complex is excreted into the urine and feces. Urine iron is derived primarily from red cells broken down by macrophages, whereas fecal iron is believed to be from iron chelated in the liver.²⁸²

Desferrioxamine is poorly absorbed from the gastrointestinal tract and must therefore be given parenterally, either by the subcutaneous or intravenous route. Rapid intravenous or intramuscular injection results in the relatively little iron mobilization; instead, it is necessary to administer desferrioxamine by slow intravenous or subcutaneous infusion over a period of 8 to 10 hours. Increasing doses of desferrioxamine result in increased iron excretion, and the usual recommended dose is 30 to 50 mL/kg.^{282,283} Vitamin C (up to 200 mg daily) may be given to enhance iron excretion. The amount of iron excreted will vary from patient to patient and depends to a large extent on the iron burden. Because the treatment is cumbersome and costly, one should be reasonably certain that sufficient good is being accomplished to justify the effort. This can be achieved by measuring urine output of iron after a test desferrioxamine infusion, bearing in mind that urinary excretion may account for only one-third of the iron excreted, fecal excretion accounting for the rest.

Desferrioxamine is usually well tolerated. Minor local reactions, such as local pruritus, induration, or pain at the site of infusion, are not uncommon. Large doses are associated with hearing loss, night blindness and other visual abnormalities, growth retardation, and skeletal changes. At very high doses occasional cases of kidney and lung abnormalities have been reported.²⁸² Approximately 20 percent of patients on desferrioxamine alone will continue to have cardiac iron overload.

Oral Chelating Agents

The inconvenience and high cost of administration with desferrioxamine has stimulated an intensive search for safe, orally active chelating agents. Deferiprone (L-1) is an orally effective bidentate chelating agent; three molecules of deferiprone bind one iron atom. Its molecular weight is only 139 daltons and it is excreted almost entirely in the urine. The usual dose is 75 mg/kg per day divided into three doses. Deferiprone administration is associated with a number of toxic effects, including gastrointestinal disturbances, arthropathy, transient increases in the serum levels of liver enzymes, and zinc deficiency. The main concern has centered on the propensity of the drug to produce neutropenia and agranulocytosis. The latter complication occurs in approximately 1 percent of patients. It appears to be idiosyncratic, is more common in females, and appears to be reversible. Neutropenia with a granulocyte level between 0.5 and $1.5 \times 10^9/L$ (500 and 1500/ μL) occurs in an additional 5 percent of patients. Treatment should be stopped at the first sign of a fall in the leukocyte count.²⁸² It has been suggested that deferiprone may be more effective in removing iron from the heart and desferrioxamine more effective with respect to liver iron accumulations.²⁸³ Preliminary investigations suggest that a combination of desferrioxamine and deferiprone may be more effective than either alone. It has been proposed that deferiprone enters cells and removes their iron and then passes the iron to desferrioxamine.²⁸³ The combination may be particularly useful in patients with heart failure from iron overload where it may decrease mortality, and in patients with endocrinopathies.²⁸³

Deferasirox (ICL670 or Exjade), a tridentate triazole component, is a newer oral iron-chelating agent with a long plasma half-life.²⁸³ At a dose of 30 mg/kg per day, it was found as efficient as desferrioxamine and is generally well tolerated. It has been recommended for patients who are noncompliant with desferrioxamine, and like deferiprone, may be effective at removing cardiac iron. Its main toxicity is renal and hepatic, but it may also cause gastrointestinal hemorrhage.²⁸³ Combination therapy with the two oral chelators is still experimental.

COURSE AND PROGNOSIS

The outlook in this disease has changed to one in which the life span of patients with hemochromatosis is normal or nearly so. This is largely a result of the change in the definition of the disorder. In the early

20th century, the diagnosis was reserved for the rare patient with full-blown bronzed diabetes. Today, the diagnosis is applied to any person found to be homozygous for the C282Y mutation, or, indeed, anyone with an increased transferrin saturation and elevated serum ferritin level. In reality, patients with a diagnosis of hemochromatosis based on genetic and/or biochemical criteria have a normal life span. This is not to suggest that patients do not die of hereditary hemochromatosis; it is simply that the penetrance of the disorder as detected on genetic or biochemical bases is so low that the few deaths that do occur cannot be detected even in very sizable series.

For those patients with classical hereditary hemochromatosis who are clinically affected, it is likely that removal of iron by phlebotomy prevents further complications and prolongs life span. Although controlled studies of the effect of phlebotomy are not ethically feasible, serial observations in patients undergoing phlebotomy suggest that cirrhosis is either stabilized or may, at least in some patients, improve. The course of untreated juvenile hemochromatosis seems much less benign. Cardiac deaths seem to be particularly common,²⁷⁶ and in a few cases cardiac transplantation has been performed successfully, but there are insufficient data concerning this rare disorder to allow one to provide more precise information about the outlook.

Institution of iron chelation has greatly improved outcomes in β -thalassemia major and similar disorders, but the prognosis is grim when iron chelation is not performed (Chap. 48). Death is most frequently a result of cardiac failure but this complication is preventable with modern chelation regimens.

CHAPTER 44

ANEMIA RESULTING FROM OTHER NUTRITIONAL DEFICIENCIES

Ralph Green

SUMMARY

The anemia that results from deficiencies of vitamin B₁₂, folic acid (Chap. 41) or iron (Chap. 43) are, in general, clearly defined and are relatively common. In contrast, characteristics of anemia that may occur with deficiencies of the other vitamins and minerals are poorly defined and relatively rare in humans. When present, they usually exist not as isolated deficiencies of one vitamin or one mineral, but rather, as a combination of deficiencies resulting from malnutrition or malabsorption. In this context, it is difficult to deduce which abnormalities are the result of which deficiency. Studies in experimental animals may not accurately reflect the role of micronutrients in humans. Accordingly, our knowledge of the effects of many micronutrients on hematopoiesis is fragmentary and based on clinical observations and interpretations that may be flawed. Inborn metabolic errors that affect single micronutrient pathways may shed light on specific effects of those micronutrients on hematopoiesis. Daily requirements of some micronutrients are available at: <http://www.nal.usda.gov/fnic/dga/rda.pdf>, and levels normally found in serum, red cells, and leukocytes are shown in Table 44–1.

VITAMIN-DEFICIENCY ANEMIAS

VITAMIN A DEFICIENCY

Chronic deprivation of vitamin A results in anemia similar to that observed in iron deficiency.^{1–4} Mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC) are reduced. Anisocytosis and poikilocytosis may be present, and serum iron levels are low. Unlike iron-deficiency anemia, but similar to anemia of chronic disease, iron stores in the liver and marrow are increased, serum transferrin concentration usually is normal or decreased, and administration of medicinal iron does not correct the anemia. However, there is some evidence to suggest that vitamin A deficiency may result in impaired iron absorption or utilization⁵ and this may be mediated through effects on the expression of genes involved in the regulation of intestinal iron absorption.⁶ The suggestion that vitamin A may facilitate iron absorption⁷ was not confirmed.⁸ Supplementation with vitamin A alone may ameliorate the anemia, although coadministration of vitamin A and iron resulted in a better response than with either nutrient alone.⁹

Acronyms and Abbreviations: MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RDW, red cell distribution width; T₃, triiodothyronine; T₄, thyroxine.

Surveys conducted in developing countries suggest that vitamin A deficiency represents a public health problem among infants, schoolchildren and women of childbearing age.^{10,11} The prevalence of vitamin A deficiency closely coincides with the prevalence of iron deficiency in this demographic setting. However, there is no known causal relationship between the two nutrients beyond both occurring in a setting of generalized malnutrition. Although vitamin A deficiency is recognized to occur in the United States, the relationship between it and anemia is not known.

DEFICIENCIES OF MEMBERS OF THE VITAMIN B GROUP

Isolated nutritional deficiencies of members of the vitamin B group, with the exception of folic acid and vitamin B₁₂, are very uncommon in humans. Evidence linking isolated nutritional deficiencies of pyridoxine, riboflavin, pantothenic acid, and niacin to anemia in patients is inconclusive. In animals, experimentally induced deficiency states are more commonly associated with hematologic abnormalities.

Vitamin B₆ Deficiency

Vitamin B₆ includes pyridoxal, pyridoxine, and pyridoxamine. These components are converted to pyridoxal 5-phosphate, which acts as a coenzyme in decarboxylation and transamination of amino acids and synthesis of aminolevulinic acid, the porphyrin precursor (Chap. 58). Vitamin B₆ deficiency induced in infants is associated with a hypochromic microcytic anemia.¹² A malnourished patient with a hypochromic anemia who failed to respond to iron therapy but subsequently responded to administration of vitamin B₆ has been described.¹³ In some anemic pregnant women who did not respond to iron supplementation alone, vitamin B₆ administration resulted in subsequent improvement in hemoglobin level.¹⁴ Occasionally, patients receiving therapy with antituberculosis agents, such as isoniazid, which interfere with vitamin B₆ metabolism, develop a microcytic anemia that can be corrected with large doses of pyridoxine.¹⁵ Pyridoxine is usually prescribed with isoniazid to prevent such an effect. Some patients with sideroblastic anemias (Chap. 59) respond to administration of large doses of pyridoxine, but these patients are not deficient in this vitamin. A review of more than 200 patients with acquired sideroblastic anemia reported that fewer than 7 percent showed greater than 1.5 g/dL improvement in hemoglobin concentration with pyridoxine treatment.¹⁶ Pyridoxine is involved in many metabolic processes. Derangements in these pathways, sometimes involving anemia, are usually the result of inborn errors affecting the pathways of vitamin B₆ metabolism and specific pyridoxal phosphate-dependent enzymes or inborn errors that lead to accumulation of small molecules that react with pyridoxal phosphate and inactivate it.¹⁷ Other acquired conditions that may influence pyridoxine metabolism include drugs that react with pyridoxal phosphate or affect metabolism, malabsorptive states such as celiac disease, and renal dialysis which leads to increased loss of vitamin B₆ vitamers from the circulation as these vitamers are bound to plasma albumin.¹⁸

Riboflavin Deficiency

Riboflavin deficiency results in a decrease in red cell glutathione reductase activity because this enzyme requires flavin adenine dinucleotide for activation. Glutathione reductase deficiency, induced by riboflavin deficiency, is not associated with hemolytic anemia or increased susceptibility to oxidant-induced injury (Chap. 47).¹⁹ Human volunteers maintained on a semisynthetic riboflavin-deficient diet and fed the riboflavin antagonist, galactoflavin, developed pure red cell aplasia.²⁰ Vacuolated erythroid precursors are evident prior to the development of aplasia. This anemia is reversed specifically by administration of riboflavin. It

TABLE 44-1. Blood Vitamin and Mineral Levels (Adult Values)

Vitamin or Mineral	Serum Level	Plasma Level	Red Cell Level	White Cell Level
Copper	11–24 $\mu\text{mol/L}$		14–24 $\mu\text{mol/L}$	
Folate	7–45 nmol/L		>320 nmol/L	
Riboflavin (B_2)	110–640 nmol/L		265–1350 nmol/L	
Vitamin A	1–3 $\mu\text{mol/L}$			
Vitamin B_6		20–122 nmol/L		
Vitamin C		25–85 $\mu\text{mol/L}$		11–30 attomol/cell
Vitamin E	12–40 $\mu\text{mol/L}$			
Selenium	1200–2000 nmol/L			
Zinc	11–18 $\mu\text{mol/L}$			

Data from Burtis CA and Ashwood EF: *Tietz Textbook of Clinical Chemistry*, 3rd ed. Philadelphia, PA: WB Saunders, 1999.

has been suggested that riboflavin deficiency causes anemia,²¹ possibly by interfering with iron release from ferritin.²⁰ Although the relationship between dietary riboflavin deficiency and anemia is not clear, inadequate riboflavin intake increased the risk of anemia in Chinese adults and was associated with a high probability of anemia when iron intake was low.¹⁶ Thus, poor riboflavin status may interfere with iron handling and contribute to the etiology of anemia when iron intake is low. There is also some evidence to suggest that riboflavin may exert its effects secondarily on other nutrients, such as folate and cobalamin.²²

Pantothenic Acid Deficiency

Pantothenic acid deficiency, when artificially induced in humans, is not associated with anemia.²³

Niacin Deficiency

Pellagra (niacin deficiency) is associated with anemia, which responds to treatment with niacin.²⁴ However, it is not clear whether the anemia is a direct or indirect effect of niacin deficiency.

Thiamine Deficiency

Megaloblastic anemia, responsive to thiamine, occurs in a childhood syndrome in association with diabetes and sensorineural deafness. There is usually profound anemia, megaloblastic changes with or without ringed sideroblasts in the marrow, and occasionally thrombocytopenia.²⁵ Most cases have been reported in patients of Middle and Far Eastern descent. The underlying defect in this condition is in the high-affinity thiamine transporter, which primarily affects synthesis of nucleic acid ribose via the nonoxidative branch of the pentose cycle.²⁶ This decrease in ribose synthesis is a consequence of the thiamine-dependent pentose-cycle enzyme transketolase. Reduced nucleic acid production through impaired transketolase catalysis appears to be the underlying biochemical disturbance that likely induces cell-cycle arrest or apoptosis in marrow cells and leads to thiamine-responsive megaloblastic anemia syndrome in these patients, which responds to life-long administration of oral thiamine (25 to 100 mg/day). The *SLC19A2* gene on chromosome 1q23.3 is implicated in all cases of thiamine-responsive megaloblastic anemia.²⁷ The folate carriers and thiamine transporters evolved from the same family of solute carriers.²⁸

VITAMIN C (ASCORBIC ACID) DEFICIENCY

Although approximately 80 percent of patients with scurvy²⁹ are anemic, attempts to induce anemia in human volunteers by severely restricting

dietary ascorbic acid have been unsuccessful.³⁰ Anemia observed in subjects with scurvy is not simply the result of a deficiency of ascorbic acid, but rather a result of bleeding or deficiency of folic acid.²⁹ Human subjects with scurvy and megaloblastic anemia fail to correct their anemia with vitamin C administration if they are maintained on a folic acid-deficient diet. When folic acid is given to these patients in a dose of 50 mcg/day orally, a prompt hematologic response is observed.³¹

Ascorbic acid, in common with other compounds that contribute to cellular reducing potential, participates in maintenance of dihydrofolate reductase in its reduced, or active, form. Impaired dihydrofolate reductase activity results in an inability to form tetrahydrofolic acid, the metabolically active form of folic acid (Chap. 41). Patients with scurvy and megaloblastic anemia excrete 10-formylfolic acid as the major urinary folate metabolite. Following ascorbic acid therapy, 5-methyltetrahydrofolic acid becomes the major urinary folate metabolite. This observation has led to the suggestion that ascorbic acid prevents the irreversible oxidation of methyltetrahydrofolic acid to formylfolic acid.³² Failure to synthesize tetrahydrofolic acid or protect it from oxidation ultimately results in megaloblastic anemia. Under these circumstances, ascorbic acid therapy produces a hematologic response only if enough folic acid is present to interact with the ascorbic acid.³³ Dietary iron deficiency in children often occurs in association with dietary ascorbic acid deficiency. Iron balance may be compromised by ascorbic acid deficiency because this vitamin serves to facilitate intestinal iron absorption by maintaining iron in a more soluble reduced or ferrous (Fe^{2+}) state. Patients with scurvy, particularly children, may require both iron and vitamin C to correct hypochromic microcytic anemia.³⁴ Vitamin C affects the oxidoreduction involved in compartmental iron release and may stimulate iron mobilization from endosomes, as well as transferrin-dependent iron uptake. Scurvy itself may cause iron deficiency as a consequence of external bleeding. In patients with iron overload from repeated blood transfusions, the level of vitamin C in leukocytes is often decreased because of rapid conversion of ascorbate to oxalate.³⁵ Deferoxamine (desferrioxamine)-induced iron excretion is diminished when stores of vitamin C are reduced, but excretion returns to expected values with vitamin C supplementation.^{36,37} Large doses of ascorbic acid may be harmful in patients with iron overload and should be given only after an infusion of deferoxamine mesylate (Desferal) has been initiated (Chap. 43). The presence of scurvy in patients with iron overload may protect them from tissue damage.³⁸ In scorbutic guinea pigs and Bantu subjects with nutritional vitamin C deficiency and dietary hemosiderosis, iron accumulates in the monocyte-macrophage system rather than in the parenchymal cells of the liver.^{39,40}

VITAMIN E DEFICIENCY

Vitamin E, α -tocopherol, is a fat-soluble vitamin that appears to be an antioxidant in humans. It is not an essential cofactor in any recognized reactions. Nutritional deficiency of vitamin E in humans is extremely uncommon because of the widespread occurrence of α -tocopherol in food. The daily requirement of *d*- α -tocopherol for adults ranges from 5 to 7 mg, but this requirement varies with the polyunsaturated fatty acid content of the diet and the content of peroxidizable lipids in tissues. Hematologic manifestations of vitamin E deficiency in humans are limited to the neonatal period and to pathologic states associated with chronic fat malabsorption.

Low-birthweight infants are born with low serum and tissue concentrations of vitamin E. When these infants are fed a diet unusually rich in polyunsaturated fatty acids and inadequate in vitamin E, hemolytic anemia frequently develops by 4 to 6 weeks of age, particularly if iron is also present in the diet.⁴¹ This anemia often is associated with morphologic alterations of the erythrocytes,⁴² thrombocytosis, and edema of the dorsum of the feet and pretibial area.⁴³ Treatment with vitamin E produces a prompt increase in hemoglobin level, a decrease in the elevated reticulocyte count, normalization of red cell life span, and disappearance of thrombocytosis and edema. Modifications of infant formulas have all but eliminated vitamin E deficiency in preterm infants.⁴⁴

Vitamin E deficiency is common in patients with cystic fibrosis who are not receiving daily supplements of a water-soluble form of the vitamin.⁴⁵ Red cell life span in such patients is shortened to an average chromium-51 (⁵¹Cr) half-life of 19 days (normal: approximately 30 days). Severe anemia may be present.⁴⁵ After vitamin E therapy, red cell half-life increases to 27.5 days.⁴⁶

Pharmacologic doses of vitamin E have been employed with apparent success in the absence of vitamin deficiency to compensate for genetic defects that limit erythrocyte defense against oxidant injury. Chronic administration of oral vitamin E 400 to 800 U/day lengthened red cell life span in some,^{47,48} but not all,⁴⁹ studies of patients with hereditary hemolytic anemias associated with glutathione synthetase deficiency or glucose-6-phosphate dehydrogenase deficiency.

Administration of vitamin E (450 U/day for 6 to 36 weeks) to patients with sickle cell anemia significantly reduced the number of irreversibly sickled erythrocytes.⁵⁰ Adult patients with sickle cell anemia have been reported to have significantly lower serum tocopherol values compared with normal controls,^{51,52} and in children with sickle cell anemia, those with vitamin E deficiency have significantly more irreversibly sickled cells than did children without vitamin E deficiency.⁵³

TRACE METAL DEFICIENCY

COPPER DEFICIENCY

Copper is present in a number of metalloproteins. Cytochrome c oxidase, dopamine β -hydroxylase, urate oxidase, tyrosine and lysyl oxidase, ascorbic acid oxidase, and superoxide dismutase (erythrocuprein) are cuproenzymes. More than 90 percent of copper in the blood is carried bound to ceruloplasmin, an α_2 -globulin with ferroxidase activity. Copper is required for absorption and utilization of iron. Copper, in the form of hephaestin,⁵⁴ converts iron to the ferric (Fe^{3+}) state for its transport by transferrin.

Copper deficiency has been described in malnourished children,⁵⁵ and in both infants and adults receiving parenteral alimentation.⁵⁶⁻⁵⁸ There is increasing recognition of copper deficiency associated with anemia occurring as a complication following gastric resection or bariatric gastric reduction surgery.⁵⁹ Copper deficiency is characterized

by anemia, often macrocytic, that is unresponsive to iron therapy; hypoferrremia; neutropenia; and, usually, the presence of vacuolated erythroid and granulocytic precursors in marrow.⁵⁷⁻⁶⁰ The mechanism of neutropenia remains unknown, but there is some evidence that copper deficiency results in inhibition of differentiation and self-renewal of CD34(+) hematopoietic progenitor cells.^{61,62} Iron-containing plasma cells, a decrease in granulocyte precursors and ring sideroblasts have also been reported.^{59,60} Consequently, copper deficiency should enter the differential diagnosis in patients with features of myelodysplastic syndrome, particularly if there is a history of previous gastric surgery (Chap. 87).⁶⁰

Copper deficiency should be considered in the differential diagnosis of a patient with anemia and associated myeloneuropathy suspected of having cobalamin deficiency with subacute combined degeneration of the spinal cord; neurologic findings, most commonly the result of myeloneuropathy, are frequently present.^{63,64}

Radiologic abnormalities generally are present in infants and young children with copper deficiency. These abnormalities include osteoporosis, flaring of the anterior ribs with spontaneous rib fractures, cupping and flaring of long-bone metaphyses with spur formation and submetaphyseal fractures, and epiphyseal separation. These changes are frequently misinterpreted as signs of scurvy.

Copper deficiency with resultant microcytic anemia can be produced by chronic ingestion of massive quantities of zinc. This has been reported in patients using excessive quantities of zinc-containing dental fixatives.^{65,66} Dietary zinc in large doses leads to copper deficiency by impairing copper absorption.^{67,68}

The diagnosis of copper deficiency can be established by demonstrating a low serum ceruloplasmin or serum copper level, but the copper level is thought to be more reliable because ceruloplasmin behaves as an acute-phase protein.⁵⁹ Adequate normal values for the first 2 to 3 months of life are not well defined and normally are lower than the levels observed later in life. Despite these limitations, a serum copper level less than 70 mcg/dL (11 $\mu\text{mol/L}$) or ceruloplasmin level less than 15 mg/dL after age 1 or 2 months can be regarded as evidence of copper deficiency. In later infancy, childhood, and adulthood, serum copper values should normally exceed 70 mcg/dL. Low serum copper values may be observed in hypoproteinemic states, such as exudative enteropathies and nephrosis, and Wilson disease. In these circumstances, a diagnosis of copper deficiency cannot be established by serum measurements alone but requires analysis of liver copper content or clinical response after a therapeutic trial of copper supplementation.

Copper-deficiency anemia and neutropenia are quickly corrected by administration of copper. Treatment of copper-deficient infants consists of administration of approximately 2.5 mg of copper (approximately 80 mcg/kg per day) oral supplementation as a copper sulfate solution.⁶⁹ Intravenous bolus injection of copper chloride also has been used.⁶⁰

ZINC DEFICIENCY

Zinc is required for a large number of zinc metalloenzymes, zinc-activated enzymes, and "zinc finger" transcription factors. Zinc deficiency occurs in a variety of pathologic states in humans, including hemolytic anemias such as thalassemia⁷⁰ and sickle cell anemia.⁷¹ Zinc deficiency with or without an associated copper deficiency has been described in a patient receiving intensive desferrioxamine therapy⁷² and in patients with decreased renal reabsorption of trace minerals.⁷³

Although human zinc deficiency may produce growth retardation, impaired wound healing, impaired taste perception, immunologic abnormalities, and acrodermatitis enteropathica, at present there is no evidence that isolated zinc deficiency produces anemia.

SELENIUM DEFICIENCY

Selenium deficiency occurs in patients who live in areas where the selenium content of the soil is very low⁷⁴ and has been observed in patients receiving total parenteral nutrition.^{75,76} Although this results in a striking decrease in the level of red cell glutathione peroxidase, there do not appear to be any adverse hematologic consequences.

An examination of the relationship between serum selenium and hematologic indices found that low serum selenium was independently associated with anemia among older men and women in the United States.⁷⁷ A similar association has been reported in adolescent girls living in rural Vietnam.⁷⁸

ANEMIA OF STARVATION

Studies conducted during World War II among prisoners of war and conscientious objectors demonstrated that semistarvation for 24 weeks can result in a mild to moderate normocytic normochromic anemia.⁷⁹ Marrow cellularity is usually reduced and is accompanied by a decreased erythroid-to-myeloid ratio. Measurements of red cell volume and plasma volume suggest that dilution is a major factor responsible for a reduction in hemoglobin concentration.

In persons subjected to complete starvation, either for experimental purposes or treatment of severe obesity, anemia was not observed during the first 2 to 9 weeks of fasting.⁸⁰ Starvation for 9 to 17 weeks produced a decrease in hemoglobin and marrow hypocellularity.⁸¹ Resumption of a normal diet was accompanied by reticulocytosis and the disappearance of anemia. It has been suggested that the anemia of starvation is a response to a hypometabolic state with its attendant decrease in oxygen requirements.⁸²

ANEMIA OF PROTEIN DEFICIENCY (KWASHIORKOR)

Even strict vegetarians do not seem to develop hematologic problems related to the absence of animal proteins.⁸³ Vegans may, however, develop vitamin B₁₂ deficiency.⁸⁴ The anemia in this situation is caused by cobalamin insufficiency rather than animal protein insufficiency, and results from the natural occurrence of cobalamin exclusively in foods of animal origin. Kwashiorkor is largely a disease of the underdeveloped world, but occasionally is seen even among the children of educated and well-to-do parents when the children are fed an inappropriate diet.^{85,86}

In infants and children with protein-calorie malnutrition, hemoglobin concentration may fall to 8 g/dL of blood,^{86,87} but some children with kwashiorkor have normal hemoglobin levels, probably because of a decreased plasma volume. The anemia is normocytic and normochromic, but the size and shape of red cells on blood film vary considerably. White blood cells and platelets are usually normal. Marrow is cellular or slightly hypocellular, with a reduced erythroid-to-myeloid ratio. Erythroblastopenia, reticulocytopenia, and marrow containing a few giant pronormoblasts may be found, particularly if the child has an infection. With treatment of the infection, erythroid precursors may appear in the marrow, and reticulocyte count may rise. When nutrition is improved by giving high-protein diets (powdered milk or essential amino acids), reticulocytosis, a slight fall in hematocrit because of hemodilution, and then rises in hemoglobin level occurs. Improvement is very slow, however, and during the third or fourth week, when patients are clinically improved and serum protein levels are approaching normal, another episode of erythroid marrow aplasia may develop. This relapse is not associated with infection, does not respond to antibiotics, and does not remit spontaneously. It may respond to either riboflavin or prednisone.

An abrupt fall in hemoglobin following protein feeding may be an ominous harbinger of an adverse and even fatal outcome and prompt transfusion to restore hemoglobin may be life-saving.⁸⁷ It has been suggested that erythroblastic aplasia may be a manifestation of riboflavin deficiency.⁸⁸

Although plasma volume is reduced to a variable degree in children with kwashiorkor, total circulating red cell volume decreases in proportion to a decrease in lean body mass as protein deprivation reduces metabolic demands. During repletion, an increase in plasma volume may occur before an increase in red cell volume, and anemia may seem to become more severe despite reticulocytosis. In a report from Turkey of patients with protein-energy malnutrition, the major cause of anemia was identified as associated with either iron deficiency or defective utilization of iron.⁸⁹

From study of anemia of protein deficiency in rats, it was deduced that oxygen consumption and, therefore, erythropoietin production are reduced.⁹⁰ Other studies confirmed this observation but related the reduction to calorie deprivation with associated decrease in blood levels of triiodothyronine (T₃) and thyroxine (T₄). As a result, erythropoiesis decreases and reticulocyte count falls. Plasma iron turnover and red cell uptake of radioactive iron are markedly reduced, and red cell volume gradually declines.⁹⁰ Protein deficiency also produces a maturation block at the erythroblast level and slight decrease in the erythropoietin-sensitive progenitor cell pool.⁹¹ If exogenous erythropoietin is provided, normal erythropoiesis is restored despite protein depletion,⁹² an observation that explains the successful use of starved rats in a bioassay for erythropoietin.

Anemia seen in anorexia nervosa shows some features that resemble protein energy malnutrition. Anemia and leukopenia are found in approximately one-third of patients, and 50 percent of these show marrow atrophy with gelatinous transformation of the marrow stroma.⁹³

ALCOHOLISM

Chronic alcohol ingestion is often associated with anemia. This anemia may result from nutritional deficiencies, chronic gastrointestinal bleeding, hepatic dysfunction, or direct toxic effects of alcohol on erythropoiesis. Quite commonly, all these factors work in concert to produce anemia. Pyridoxal phosphate and folate deficiency are common in alcoholics.⁹⁴ Alcohol affects not only red cells, as described here, but also platelet production (Chap. 113).^{95,96}

Macrocytosis is common in chronic alcoholics⁹⁷ and is often associated with megaloblastic anemia. Among hospitalized malnourished alcoholics, it is the most common type of anemia, occurring alone or in combination with ringed sideroblasts in approximately 40 percent of patients.^{98,99} In contrast, megaloblastic anemia is rarely observed in nonhospitalized chronic alcoholics or relatively well-nourished subjects admitted to the hospital for alcohol withdrawal.¹⁰⁰ Anemia, when associated with megaloblastic marrow changes in alcoholics, almost always results from folate deficiency. Iron deficiency often is associated with folate deficiency in alcoholics.¹⁰⁰ In patients with both nutritional deficiencies, the blood film is "dimorphic," with macrocytes, hypersegmented neutrophils, and hypochromic microcytes. This is also the case when folate deficiency coexists with a sideroblastic process.^{98,99} Consequently, the MCV may be normal but, because of marked anisopoikilocytosis, the red cell distribution width (RDW) is elevated.⁶⁴ Although liver disease is frequently present in alcoholics with megaloblastic anemia, it is not responsible for the folate deficiency. Megaloblastic anemia occurs almost exclusively in alcoholics who have been eating poorly. It is seen more commonly in heavy drinkers of wine and whiskey, which contain little or no folate, than in drinkers of beer, which is a rich source of the vitamin.

In addition to folate deficiency, chronic alcoholics frequently demonstrate multiple other micronutrient deficiencies, including thiamine, pyridoxine, and vitamin A, which aggravate the risk of anemia.¹⁰¹ Although decreased dietary folate intake appears to be a necessary factor in the etiology of the megaloblastic anemia, ethanol itself interferes with folate metabolism (Chap. 41).^{102,103}

Macrocytosis, however, does not always indicate the presence of megaloblastic anemia,⁹⁷ reticulocytosis secondary to hemolysis or bleeding, or liver disease. So-called macrocytosis of alcoholism is found in as many as 96 percent of alcoholics.¹⁰⁴ In these patients, the macrocytosis usually is mild, with MCV in the range of 100 to 110 fL, and anemia is usually absent. In the blood film, macrocytes are typically round rather than oval and neutrophil hypersegmentation is not present. The macrocytosis persists until the patient abstains from alcohol. Even then, MCV does not become completely normal for a period of 2 to 4 months in view of the life span of erythrocytes.¹⁰³

Alcohol ingestion for 5 to 7 days produces vacuolization of early red cell precursors, and formation of vacuoles can be observed in *in vitro* marrow cell cultures.^{99,105} These changes disappear promptly when alcohol ingestion is discontinued. Vacuolization with a similar appearance occurs in subjects who are fed a phenylalanine-deficient diet, patients treated with chloramphenicol or pyrazinamide, patients in hyperosmolar coma, and individuals deficient in copper or riboflavin.¹⁰⁴

Two relatively uncommon hematologic complications of alcoholism are Zieve syndrome,^{106,107} consisting of alcohol-induced liver disease, often hyperlipidemia, jaundice, and transient spherocytic hemolytic anemia; and spur cell hemolytic anemia, associated with severe alcohol-induced liver disease often requiring hepatic transplantation for resolution.^{108,109} Chapter 45 discusses these syndromes.

CHAPTER 45

ANEMIA ASSOCIATED WITH MARROW INFILTRATION

Vishnu VB Reddy and Josef T. Prchal

SUMMARY

Myelophthitic anemia is caused by marrow infiltration, typically by metastatic cancer, and by any nonhematopoietic conditions, for example, granulomatous inflammation or fibrosis. It can present with an overt leukoerythroblastic picture or with only a few teardrop-shaped red cells on a blood film. These changes may represent an early spread of the tumor (or other nonhematopoietic tissue) to the marrow or may indicate massive replacement of the marrow space. The diagnosis can be made by standard marrow biopsy. Radioisotope scanning and magnetic resonance imaging, although not very sensitive, can be helpful in locating the biopsy site and can also help in estimating the percentage of involvement of the marrow space.

DEFINITION AND HISTORY

Myelophthitic anemia is the term that has been used to describe diverse pathologic processes, including Fanconi anemia,¹ but currently refers to anemia resulting from the presence of spotty to massive marrow infiltration with abnormal cells or tissue components. Strictly speaking, the blasts of acute leukemia, plasma cells of myeloma, and cells of lymphoma, chronic leukemia, and myeloproliferative neoplasms fit this definition. However, the term *myelophthitic anemia*² is best reserved for marrow replacement by nonhematologic tumors and nonhematopoietic tissue. Minimal to moderate involvement usually does not cause symptoms or hematologic changes. Such infiltration is clinically significant, however, because in patients with an established diagnosis of cancer, it indicates metastatic dissemination of the tumor and usually an advanced stage. Although extensive infiltration may lead to anemia or even pancytopenia, anemia can be frequently accompanied by an elevated leukocyte count, often with immature myeloid cells in the blood. Platelets can be increased, decreased, or normal (megakaryocytic fragments are seen occasionally in the blood film). The findings accompanied by teardrop-shaped red cells (dacrocytes), prematurely released nucleated red cells, and immature myeloid cells is referred to as *leukoerythroblastic reaction* (Chaps. 2, 31, and 86), which generally reflects marrow replacement by tumor or extramedullary hematopoiesis.

ETIOLOGY AND PATHOGENESIS

Tumor metastasis results from the complex interactions between the tumor cells and the surrounding microenvironment. Invasion is the

primary process of metastasis and occurs often as a result of loss of E-cadherin. E-cadherin is a calcium-dependent cell adhesion molecule that likely plays a role in intercellular adhesion and inhibition of invasion by neoplastic cells. The loss of E-cadherin can be caused by many mechanisms, including mutations and gene silencing.³ Dysregulation of calcium influx pathways through stromal interaction molecule (STIM) and calcium-permeable transient receptor potential (TRP) also plays a role in tumor invasive and metastatic behavior.⁴ Many members of the family of matrix metalloproteinases can also participate in the process of tumor cell invasion. Stromal cells, such as tumor-associated macrophages, and growth factors secreted by them, such as fibroblast growth factor, are also known to promote tumor spread.⁵

Table 45–1 lists the most common causes of extensive cellular infiltration of marrow. In myelofibrotic disorders of both primary and secondary origin, the fibrosis/osteosclerosis restricts the available marrow space and disrupts marrow architecture (Chap. 86). The disruption may cause cytopenias with production of deformed red cells, especially poikilocytes and teardrop-shaped cells, and premature release of erythroblasts, myelocytes, and giant platelets. The leukocyte count also may be elevated. Similar abnormalities following marrow replacement by calcium oxalate crystals have been reported.⁶ Anemia seen in metastatic cancer most frequently results from cytokine release leading to anemia of chronic inflammation (Chap. 37), iron deficiency as a result of gastrointestinal or uterine bleeding (Chap. 42), or other nutritional deficiencies (Chaps. 41 and 44). However, marrow replacement causing a myelophthitic anemia as the sole cause of anemia also occurs. The marrow microenvironment is susceptible to implantation of bloodborne malignant cells. Almost all cancers can metastasize to the marrow,^{7–11} but the most common are cancers of the lung, breast, and prostate. Metastatic foci in the marrow can be found in 20 to 30 percent of patients with small cell carcinoma of the lung at the time of diagnosis, and in more than 50 percent of patients at autopsy.^{12,13} Overt leukoerythroblastic blood picture is less common, and its absence is not a reliable indicator that the marrow is not involved.

The characteristic abnormalities observed in patients with myelophthitic anemia may result partly from an attempt for compensatory extramedullary blood formation that generally reflects extramedullary hematopoiesis predominantly from the spleen. A similar picture can be seen when the marrow is replaced by numerous granulomas,^{14,15} for example, sarcoidosis, disseminated tuberculosis, fungal infections, or by macrophages containing indigestible lipids, as in Gaucher and Niemann-Pick diseases (Chap. 72)¹⁶ and in macrophage activation syndrome (MAS).

Marrow necrosis can be an underlying cause of myelophthitic anemia. The morphologic picture, best observed in hematoxylin-and-eosin–stained biopsy of marrow, consists of cell debris and occasional necrotic cells in an eosinophilic amorphous background (Fig. 45–1).¹⁷ Marrow necrosis is generally considered to be very uncommon, accounting for less than 1 percent of marrow biopsies. Metastatic tumors, acute lymphoblastic leukemia (children), and septicemia are generally the underlying cause,^{17,18} but sickle cell disease^{19–21} and arsenic therapy in acute promyelocytic leukemia are other causes.²² Necrotic foci range from small to very extensive (<5 to 90 percent of the biopsy volume). Extensive necrosis often results in inability to perform flow cytometry/molecular analysis satisfactorily. A repeat biopsy at a different site may be needed.^{17,23,24}

Because myelophthitic anemia is so uncommon, only a few rigorous studies of the pathogenesis of anemia in this entity have been conducted. *In vitro* study of hematopoietic progenitors reveals only a moderate decrease of their proportion and proliferative capacity.²⁵ Similar reports of erythropoiesis quantitation by ferroketic studies reveal only a moderate defect (Chap. 32).²⁶ The following confounding factors

Acronyms and Abbreviations: MRI, magnetic resonance imaging; ^{99m}Tc, a radioisotope of technetium; ^{99m}Tc sestamibi, a radioisotope of technetium attached to the sestamibi molecule.

contribute to anemia: elevated hepcidin (Chap. 37) and other factors, including hematopoiesis-inhibiting cytokines released from tumor cells (Chap. 37) and iron (Chap. 42) and folate and cobalamin (Chap. 41) deficiencies. When they are excluded, the finding discussed above suggests that only massive marrow replacement leads to anemia.

CLINICAL FEATURES

Symptoms and signs associated with infiltrative marrow disorders usually are related to the underlying disease. Other symptoms, such as fatigue, often from upregulated cytokines, may also contribute to anemia itself. Some patients are asymptomatic, and the incidental discovery of cytopenias and leukoerythroblastic blood morphology leads to diagnosis of an underlying disorder

LABORATORY FEATURES

BLOOD

The anemia usually is mild to moderate, but it can be severe. White cell and platelet counts may vary, but the most characteristic feature is the morphologic appearance of red cells on the blood film. These cells may show anisocytosis and poikilocytosis, but the presence of teardrop forms and nucleated red cells is particularly suggestive of marrow infiltration (Chap. 31; Fig. 45-2). The combination of nucleated red cells and immature myeloid precursors constitutes the leukoerythroblastic picture that is characteristic of marrow infiltration and extramedullary hematopoiesis. The presence of cancer cells on the blood film occurs occasionally and always indicates marrow invasion (Fig. 45-3).²⁷

MARROW

Marrow biopsy is the most reliable procedure used to diagnose marrow-infiltrative disease and should be performed in all patients with suspected metastatic carcinoma or hematologic features of myelophthitic anemia. Marrow aspiration^{24,28} does not provide a reliable yield of tumor cells and is particularly difficult in primary or secondary myelofibrosis. The inability to aspirate marrow (dry tap) leads to a high degree of suspicion of marrow replacement and accompanying myelofibrosis. Because the diagnostic marrow yield from biopsies depends on the amount of tissue examined, bilateral posterior iliac crest marrow biopsies may be necessary. In patients with metastatic cancer

Figure 45-1. Marrow necrosis. **A.** Low-magnification view of the biopsy showing mostly necrosis (pink area) and focally preserved tumor to the left (blue area). **B.** Higher-magnification view of necrosis with loss of cellular details, granular eosinophilic/pink cell debris.

Figure 45-2. Leukoerythroblastosis. **A.** Blood film containing several nucleated red blood cells (RBCs), few circulating blasts, and RBCs showing severe anisopoikilocytosis. **B.** Corresponding marrow biopsy with reticulin fibrosis (3+) and intrasinusoidal megakaryocytes (*black arrows*).

involving the marrow, the blood CD34-positive cell count can be up to 50 times higher than in patients with metastatic cancer without marrow involvement.²⁹

ISOTOPE AND IMAGING PROCEDURES

Technetium-99m (^{99m}Tc) sestamibi uptake reliably identifies marrow infiltration by Gaucher cells. Sestamibi is a pharmaceutical agent used in nuclear medicine imaging. Magnetic resonance imaging (MRI) is also helpful for defining the severity of marrow replacement and is being used with increasing frequency. This imaging approach is especially useful for following resolution of marrow infiltration in patients with type 1 Gaucher disease who are treated with enzyme-replacement therapy.^{20,30,31} An isotopic bone scan or MRI study showing focal accumulation of radioactive tracers can be helpful in locating a suitable site for biopsy,^{20,32} but a negative study of the area does not exclude the possibility of marrow involvement. On MRI, marrow necrosis characteristically has an extensive, diffuse, geographic pattern of signal abnormality consisting of a central area of variable signal intensity surrounded by a distinct peripheral enhancing rim.²¹

DIFFERENTIAL DIAGNOSIS

The cause of a leukoerythroblastic blood picture is known to occur in a patient with metastatic cancer or overt hematologic malignancy. In the absence of a likely cause after clinical evaluation, the initial approach to diagnosis is the marrow biopsy. Although it is not a very sensitive

technique, with the help of immunocytochemistry and flow cytometry for tumor-specific antigens, its diagnostic sensitivity and specificity increases. MRI or isotopic scanning before the marrow may aid in locating the site of the biopsy. Hematologic disorders causing marrow fibrosis, notably primary myelofibrosis, may mimic a myelophthitic disorder, but the distinctions are usually evident. For example, the patient with primary myelofibrosis invariably has splenic enlargement and the patient with metastatic cancer nearly always does not (Chap. 91). If the myelophthysis is the result of a storage disease or other infiltrative cause, the appropriate chemical tests, as well as marrow biopsy, are helpful in diagnosis. Nucleated red cells and leukocytosis can be seen in acute conditions, including overwhelming sepsis, acute severe hypoxia, postcardiac arrest, and chronic conditions such as thalassemia major, congestive heart failure, and severe hemolytic anemia.

THERAPY, COURSE, AND PROGNOSIS

The goal of treatment is managing the underlying disease. Patients with marrow infiltration caused by cancer should be treated appropriately; however, in some instances the presence of marrow infiltration may not adversely affect the outcome. If treatment is successful, not only the malignant cells but also the reactive fibrosis surrounding metastatic foci may completely disappear. In hormone-refractory prostate cancer, the presence of a leukoerythroblastic picture does not seem to influence survival.³³ However, in most patients with cancers metastatic to the marrow, only short-term survival is a rule.

Figure 45-3. Metastatic tumor in the marrow. **A.** Marrow packed with melanoma cells and displacing normal marrow elements. Tumor cells have characteristic large nuclei with prominent pink nucleoli. **B.** S100 immunohistochemical stain highlights melanoma infiltrates in the marrow.

CHAPTER 46

ERYTHROCYTE MEMBRANE DISORDERS

Theresa L. Coetzer

SUMMARY

The human erythrocyte membrane consists of a lipid bilayer containing transmembrane proteins and an underlying membrane skeleton, which is attached to the bilayer by linker protein complexes. The membrane is critical in maintaining the unique biconcave disk shape of the erythrocyte and enabling it to withstand the circulatory shear stress. The integrity of the membrane is ensured by vertical interactions between the skeleton and the transmembrane proteins, as well as by horizontal interactions between skeletal proteins. Inherited defects of membrane proteins compromise these interactions and alter the shape and deformability of the cells, which ultimately results in their premature destruction and hemolytic anemia. The disorders are typically autosomal dominant and exhibit significant clinical, laboratory, biochemical, and genetic heterogeneity.

Hereditary spherocytosis is a common condition characterized by spherically shaped erythrocytes on the blood film, reticulocytosis, and splenomegaly. The underlying defect is a deficiency of one of the membrane proteins, including ankyrin, band 3, α -spectrin, β -spectrin, or protein 4.2. This weakens the vertical membrane interactions, resulting in loss of membrane and surface area. Spherocytes have diminished deformability, which predisposes them to entrapment and destruction in the spleen. *Hereditary elliptocytosis* is characterized by the presence of elliptical erythrocytes on the blood film. The principal abnormality affects horizontal membrane protein interactions and typically involves α -spectrin, β -spectrin, protein 4.1R, or glycophorin C. The membrane skeleton is destabilized and unable to maintain the biconcave disk shape, which manifests as an elliptical distortion of the cells in the circulation.

Acronyms and Abbreviations: AE1, anion exchanger-1; α^{LELY} , α -spectrin low-expression Lyon; α^{LEPRA} , α -spectrin low-expression Prague; AGLT, acidified glycerol lysis test; ANK, ankyrin; AQP1, aquaporin-1; BCSH, British Committee for Standards in Haematology; BPG, 2,3-bisphosphoglycerate; CD41, congenital dyserythropoietic anemia type II; EMA, eosin 5'-maleimide; 4.1R, erythrocyte isoform of protein 4.1; GLT, glycerol lysis test; GLUT-1, glucose transporter-1; GP, glycophorin; GP-A, -B, -C, -D, -E, various members of glycophorin family; GSSG, oxidized glutathione; HARP, hypobetalipoproteinemia, acanthocytosis, retinitis pigmentosa, and pallidal degeneration syndrome; HE, hereditary elliptocytosis; HPP, hereditary pyropoikilocytosis; HS, hereditary spherocytosis; HSt, hereditary stomatocytosis; MAGUK, membrane-associated guanylate kinase; MARCKS, myristoylated alanine-rich C kinase substrate; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; OF, osmotic fragility; PKAN, pantothenate kinase-associated neurodegeneration; RhAG, Rh-associated glycoprotein; SAO, southeast Asian ovalocytosis; SDS-PAGE, sodium dodecylsulfate polyacrylamide gel electrophoresis; UGT1, uridine diphosphate glucuronosyltransferase 1.

Hereditary pyropoikilocytosis is a rare, severe hemolytic anemia characterized by markedly abnormal erythrocyte morphology caused by defective spectrin. *Southeast Asian ovalocytosis* is largely asymptomatic and is caused by a defect in band 3. The blood film shows large oval red cells with a transverse ridge across the central area. *Acanthocytosis* is typified by contracted, dense erythrocytes with irregular projections, which may be seen in patients with severe liver disease, abetalipoproteinemia, various neurologic disorders, certain aberrant red cell antigens, and postsplenectomy. *Stomatocytosis* is a rare group of inherited disorders associated with abnormal membrane permeability and red cell cation content, which either cause overhydration or dehydration of the cells.

The erythrocyte membrane plays a critical role in the function and structure of the red cell. It is a key determinant of the unique biconcave disk shape and provides the cell with a finely tuned combination of flexibility and durability. These properties enable the erythrocyte to withstand the circulatory shear pressure and allow it to undergo extensive and repeated distortion while negotiating the microvasculature and the spleen, thus ensuring survival during its average 120-day life span. The red cell membrane maintains a nonreactive surface so that erythrocytes do not adhere to the endothelium or aggregate and occlude capillaries. It provides a barrier with selective permeability, which retains vital components inside the cell and permits the efflux of metabolic waste. To facilitate the transfer of carbon dioxide and to maintain pH homeostasis, the membrane exchanges chloride and bicarbonate anions, and it also actively controls the cation and water content of the erythrocyte. The membrane sequesters reducing agents required to prevent oxidative damage to hemoglobin and other cellular components, and it plays a role in regulating metabolism by reversibly binding and inactivating selected glycolytic enzymes.

Abnormalities of the erythrocyte membrane alter the shape of the cell and compromise its integrity and ability to survive the rigors of circulation, which leads to premature destruction and hemolysis. Erythrocyte membrane disorders comprise an important group of hereditary hemolytic anemias, which are classified according to the altered red cell morphology and include hereditary spherocytosis (HS), hereditary elliptocytosis (HE) and related disorders, and the hereditary stomatocytosis (HSt) syndromes. This chapter summarizes our current understanding of the erythrocyte membrane in normal cells followed by a discussion of the underlying molecular defects and their role in the pathophysiology and clinical manifestations of these disorders. The main emphasis is on spherocytosis and elliptocytosis, the two most common and best characterized diseases.

OVERVIEW OF THE ERYTHROCYTE MEMBRANE

The erythrocyte membrane is the most studied plasma membrane and serves as a paradigm for all cellular membranes. Mature erythrocytes are readily accessible; they contain no intracellular organelles, which facilitates the isolation of pure erythrocyte membranes; and “experiments of nature” resulting in abnormal erythrocyte morphology have provided unique opportunities to investigate the function of membrane components. These studies have revealed the primary structure and several important functions of the red cell membrane. Ongoing research, using the latest molecular technologies, continues to yield important insights into our understanding of membrane structure–function relationships, as well as genotype–phenotype correlations.

Figure 46-1. Schematic model of the human erythrocyte membrane. The molecular assembly of the major proteins is indicated. *Vertical* interactions are perpendicular to the plane of the membrane and are represented by the ankyrin and junctional protein complexes that connect the membrane spectrin skeleton to the integral proteins embedded in the lipid bilayer. *Horizontal* interactions occur parallel to the plane of the membrane and involve spectrin tetramers and protein 4.1R. The proteins and lipids are not drawn to scale. b3, Band 3; GPA/GPC, glycophorin A/C; GLUT-1, glucose transporter-1.

The erythrocyte membrane is a complex structure consisting of a relatively fluid lipid bilayer stabilized by an underlying two-dimensional membrane skeleton, which maintains the integrity of the biconcave disk shape of the erythrocyte (Fig. 46-1). The skeleton provides the cell with the strength and flexibility to deform rapidly and repeatedly and thus endure the shear stress encountered in the tiny capillaries of the microcirculation and in the spleen. The lipid bilayer separates the erythrocyte cytoplasm from the external plasma environment and contains phospholipids and cholesterol, as well as integral transmembrane proteins, which are tethered to the skeleton by interactions with linker proteins.

● COMPONENTS OF THE ERYTHROCYTE MEMBRANE

MEMBRANE LIPIDS

The lipid bilayer comprises approximately 50 percent of the membrane mass and contains unesterified cholesterol and phospholipids in approximately equal amounts, with small amounts of glycolipids and phosphoinositides (Chap. 31).^{1,2} Mature erythrocytes are unable to synthesize fatty acids, phospholipids, or cholesterol *de novo*, and they depend on lipid exchange and limited phospholipid repair.³

Cholesterol regulates the fluidity of the membrane and is present in both leaflets, whereas the phospholipids are asymmetrically distributed. The choline phospholipids, phosphatidylcholine and sphingomyelin, are predominantly located in the outer leaflet and play a role in plasma lipid exchange and renewal of membrane phospholipids. Glycolipids carry several important red cell antigens, including A, B, H, and P, and are only found in the external leaflet with their carbohydrate moieties extending into the plasma. The aminophospholipids, phosphatidylserine and phosphatidylethanolamine, as well as phosphatidylinositol are located in the inner leaflet of the lipid bilayer.

This asymmetric distribution of phospholipids is maintained by a dynamic process involving flippase and floppase enzymes, which translocate the aminophospholipids to the inner and outer leaflets, respectively.^{4,5} A scramblase mediates bidirectional movement of phospholipids down their concentration gradient.⁶ Asymmetry of the phospholipids is important for the survival of the erythrocyte since exposure of phosphatidylserine on the outside surface of the cell, as found in sickle cell disease and thalassemia, has several deleterious consequences. It activates the coagulation cascade and may contribute to thromboses⁴; it facilitates adhesion to the vascular endothelium; it provides a recognition signal for macrophages to phagocytose these cells; and it decreases the interaction of skeletal proteins with the bilayer, which destabilizes the membrane.

Lipid rafts have been identified in erythrocytes.⁷ They form detergent-resistant membrane microdomains, enriched in cholesterol and sphingolipids, and are associated with several proteins, including stomatin and flotillin-1 and -2. These rafts play a role in signaling and invasion of malaria parasites.⁸

MEMBRANE PROTEINS

Pioneering studies resolved the major proteins of the red cell membrane by sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE) and numbers from 1 to 8 were assigned to each protein starting with the largest protein, which migrated the slowest (Chap. 31).⁹ Subsequent research revealed minor bands between the major proteins and these were designated with decimals. Analysis of the individual proteins led to the renaming of some of them, such as band 1 and 2, which are now known as α - and β -spectrin, respectively. Technologic advances have enabled an in-depth analysis of the erythrocyte proteome by mass spectrometry, revealing a total of 340 membrane proteins.¹⁰ Table 46-1 summarizes the properties of the major components.

TABLE 46-1. Major Red Cell Membrane Proteins

Band	Protein	Mr (gel)	Mr (calc)	Copies per Cell ($\times 10^3$)	Percentage of Total ^a	Gene Symbol	Chromosomal Localization	Amino Acids	Gene Size (kb)	No. of Exons	Involvement in Hemolytic Anemias

—, Information not available; G3PD, glyceraldehyde 3-phosphate dehydrogenase; HAC, hereditary acanthocytosis; HE, hereditary elliptocytosis; HPP, hereditary pyropoikilocytosis; HS, hereditary spherocytosis; HSt, hereditary stomatocytosis; N, no hematologic abnormalities reported; SAO, southeast Asian ovalocytosis.

^aQuantitation based on scanning of sodium dodecylsulfate polyacrylamide gel electrophoresis of red cell membranes prepared from healthy blood donors. For glycophorins, values indicate the fraction of periodic acid-Schiff–positive material.

^bBands 2.1, 2.2, 2.3, and 2.6 are protein isoforms of erythroid ankyrin, at least some of which are produced by alternative splicing of ankyrin messenger RNA.

^cBecause adducin comigrates with band 3, no numerical band designation is available.

^dNumerous erythroid and nonerythroid isoforms of protein 4.1 produced by alternative splicing have been described. Values correspond to the major erythroid protein 4.1 isoform.

^eBoth dematin and p55 migrate within the 4.9 band.

^fForty thousand dematin trimers are present in one red cell.

^gVariable amounts of band 6 are detected in red cell membranes.

^hDetectable on periodic acid-Schiff–stained gels only.

The membrane proteins are classified as either integral or peripheral based on the ease with which they can be removed from whole red cell membrane preparations in the laboratory. Integral or transmembrane proteins are embedded in the lipid bilayer by hydrophobic interactions and require detergents to extract them. They often protrude from the bilayer and extend into the plasma and/or the interior of the erythrocyte and these structural features correlate with their functions as transport proteins, receptors, signaling molecules, and carriers of red cell antigens.

Peripheral proteins constitute the membrane skeleton and are loosely attached to the cytoplasmic face of the lipid bilayer and can be extracted by high or low salt concentrations or by high pH. Attachment is mediated indirectly by covalent or noncovalent interactions with the cytoplasmic domains of the transmembrane proteins, as well as by direct interactions with the inner leaflet of the lipid bilayer. These associations are dynamic and the affinity of binding is regulated by post-translational modifications of the proteins, including phosphorylation, methylation, glycosylation, or lipid modification (myristoylation, palmitoylation, or farnesylation). Peripheral proteins typically function either as structural proteins and form part of the membrane skeleton or they serve as linker proteins attaching the skeleton to the bilayer.

Many erythrocyte proteins belong to superfamilies and have homologues in nonerythroid cells that are structurally related but are encoded by different genes. This genetic diversity explains why the clinical expression of most (but not all) red cell membrane protein mutations is confined to the erythroid lineage. Several proteins exist in different isoforms, created by tissue- and developmental stage-specific alternative splicing or by the use of alternative initiation codons or promoters. Many of the membrane proteins are large, multifunctional proteins and therefore the position of a mutation determines the functional abnormality and clinical phenotype.

Integral Membrane Proteins

The most abundant and important transmembrane proteins are band 3, which is the anion exchanger (AE1) of the erythrocyte, and the glycoporphins (GPs).

Band 3 The red cell contains approximately 1.2 million copies of AE1, a multifunctional and major integral membrane protein (see Table 46-1). It has a molecular mass of 102 kDa, but migrates as a diffuse band on sodium dodecylsulfate (SDS) gels as a result of heterogeneous N-glycosylation. The 911-amino-acid protein consists of two functional domains; an N-terminal 43-kDa cytoplasmic domain and a 52-kDa transmembrane channel, including a short 33-amino-acid C-terminal cytoplasmic tail¹¹ (Fig. 46-2). The anion exchange domain encompasses 13 α helical transmembrane segments and one nonhelical segment all connected by hydrophilic loops.^{12,13} The short cytoplasmic tail binds carbonic anhydrase II to form a metabolon with the transmembrane domain, enabling the exchange of HCO_3^- and Cl^- anions, which is a critical function of the red cell.¹⁴ The extracellular surface of the transmembrane domain of band 3 carries several antigens, including Diego, I/i, and Wright blood groups.

The N-terminal phosphorylated cytoplasmic domain serves as a major hub for protein-protein interactions, which perform key functions (see Figs. 46-1 and 46-2).¹⁵ It regulates metabolic pathways by sequestering key glycolytic enzymes such as glyceraldehyde-3-phosphate dehydrogenase, phosphoglycerate kinase and aldolase, which are inactive when bound. Phosphorylation at tyrosine 8 prevents binding, which liberates the active enzymes.¹⁶ The cytoplasmic domain interacts with hemoglobin and hemichromes and plays a role in red cell aging¹⁷; it associates with several peripheral membrane proteins, including the erythrocyte isoform of protein (4.1R),^{18,19} protein 4.2,²⁰ and adducin,²¹ as well as phosphatases and kinases. This domain also serves as the major attachment

Figure 46-2. Schematic model of human erythrocyte band 3. The N and C terminal regions of the protein extend into the cytoplasm and provide binding sites for several red cell proteins and enzymes. The transmembrane domain forms an anion exchange channel and consists of 13 α helical segments embedded in the lipid bilayer and one nonhelical segment. Asparagine 642 is linked to complex carbohydrates, which protrude on the exterior of the red cell. Tyrosine 8 is phosphorylated. The domains are not drawn to scale.

site of the membrane to the underlying skeleton through its interaction with ankyrin, which binds to spectrin (see Figs. 46-1 and 46-2).^{22,23}

Band 3 associates with other transmembrane proteins to form macromolecular complexes (see Fig. 46-1).²⁴ This includes the major GP, GPA,²⁵ and the Rh protein complex, consisting of Rh-associated glycoprotein (RhAG), Rh, CD47, LW, and GPB (Chap. 136).²⁴ In addition, band 3 participates in the protein 4.1-based junctional complex of proteins.¹⁹

Band 3 is encoded by the *SLC4A1* gene, which produces different tissue-specific isoforms.^{11,26} The erythroid isoform is controlled by a promoter upstream of exon 1, whereas transcription of the kidney isoform is initiated from a promoter in intron 3, resulting in a protein lacking the first N-terminal 65 amino acids.

Glycophorins GPs are integral membrane glycoproteins composed of an extracellular hydrophilic N-terminal domain, a single α -helical membrane-spanning domain, and a C-terminal cytoplasmic tail. GPA, GPB, and GPE are homologous and are encoded by closely linked genes that arose by duplication of the ancestral GPA gene.²⁷ GPC and GPD are encoded by the same gene but make use of alternate initiation codons.²⁸

GPs have very high sialic acid content and are responsible for most of the external negative charge of red cells, which prevents the adherence of cells to each other and the vascular endothelium. The GPs carry a large number of blood group antigens, including MN, SsU, Miltenberger, En(a-), M^K, and Gerbich (Chap. 136). They also function as receptors for *Plasmodium falciparum*, the most virulent malaria parasite. Within the lipid bilayer of the membrane, GPA interacts with band

3 as part of a macromolecular complex, and may serve as a chaperone for band 3 targeting to the membrane.²⁵ GPC associates with protein 4.1R and p55, thereby providing an additional contact site between the membrane and the skeleton (see Fig. 46-1).¹⁹ These interactions play a role in stabilizing the membrane.

Other Integral Membrane Proteins The Rh-RhAG group of proteins is part of a macromolecular band 3 complex, which stabilizes the membrane. RhAG belongs to the ammonium transporter family of proteins, but its function is controversial. Numerous other proteins are embedded in the lipid bilayer, many of which are implicated in clinical immunohematology and membrane disorders, such as the XK, Kell, Kidd, Duffy, and Lutheran glycoproteins (see Fig. 46-1).^{11,19} Additional integral membrane proteins include ion pumps and channels, such as stomatin, aquaporin, glucose transporter (GLUT-1), and various cation and anion transporters.

Peripheral Membrane Proteins

Underlying the lipid bilayer is the peripheral membrane skeleton, an interlocking network of structural proteins, which plays a critical role in maintaining the shape and integrity of the red cell. The major proteins of the erythrocyte membrane skeleton are spectrin, actin, proteins 4.1R, 4.2, 4.9, p55, and the adducins, which interact in a horizontal plane.

Linker proteins mediate the vertical attachment of the skeleton to integral membrane proteins in the lipid bilayer (see Fig. 46-1). The primary connecting protein is ankyrin, which links spectrin to the cytoplasmic domain of band 3, as well as to the Rh-RhAG complex. Protein 4.1R provides an additional link with GPC and band 3.

Spectrin Spectrin is the major constituent of the erythrocyte membrane skeleton and is present at approximately 240,000 molecules per cell.²⁹ It is a multifunctional protein composed of two homologous but structurally distinct subunits, α and β , encoded by separate genes, which may have evolved from duplication of a single ancestral gene³⁰ (see Table 46-1 and Fig. 46-3). Both α - and β -spectrin contain tandem homologous spectrin repeats that are approximately 106 amino acids long and are folded into three antiparallel helices, A, B, and C. Each repeat is connected to the adjacent repeat by short ordered α -helical linkers (Fig. 46-3).^{31,32} Erythrocyte α -spectrin is a 280-kDa protein comprising 20 complete repeats, an N-terminal partial repeat, a central SH3 domain, and a C-terminal calcium-binding EF hand. The β -spectrin subunit is a 246-kDa polypeptide consisting of 16 complete repeats, an N-terminal actin binding domain, a partial repeat near the C-terminus, and a nonhomologous phosphorylated C-terminus. Mild trypsin treatment of spectrin cleaves the two subunits into distinct structural domains: α I-V and β I-IV. The triple helical structure of the spectrin

Figure 46-3. Schematic model of human erythrocyte α - and β -spectrin. The proteins consist of multiple homologous spectrin repeats of approximately 106 amino acids numbered from the N-terminal. Each repeat is composed of three α helices. Nonhomologous regions include an SH3 domain and calcium-binding EF hands in α -spectrin, a protein 4.1R binding domain, and a C-terminal phosphorylated tail in β -spectrin. The nucleation site indicates the initial region of interaction between α and β monomers to form an antiparallel heterodimer. Spectrin heterodimer self association into tetramers involves helix C of the α 0 partial repeat of α -spectrin and helices A and B of the partial β 17 repeat of β -spectrin to form a complete triple helical repeat. Ankyrin binds to repeats 14 and 15 of β -spectrin. Limited tryptic digestion of spectrin cleaves the proteins into discrete α I-V and β I-IV domains.

repeats renders the molecule highly flexible and enables it to extend and condense reversibly, which provides the red cell with elasticity and durability to withstand the shear stress encountered in the circulation.

The core structure of the erythrocyte skeleton consists of spectrin heterotetramers, which are strong but flexible filaments. Tetramers are assembled from the monomers in a series of events. For initial heterodimer formation, the α - and β -spectrin chains align in an antiparallel fashion and interact with high affinity through long-range electrostatic interactions at a nucleation site, comprising repeats $\alpha 20-21$ and $\beta 1-2$.³³ This triggers the association of the remaining repeats in the two subunits in a zipper-like fashion. Repeats at the N-terminus of α -spectrin (αI domain) and the C-terminus of β -spectrin (βI domain) are the regions involved in heterodimer self-association to form tetramers. Partial repeat $\beta 17$ consists of two helices (A and B) which interact with the single helix C of partial repeat $\alpha 0$ to form a complete triple helical repeat (see Fig. 46-3). The interface of this tetramerization site is dominated by hydrophobic contacts supplemented by electrostatic interactions.³⁴ Phosphorylation of the C-terminal region of β -spectrin beyond the self-association site decreases the mechanical stability of the membrane.

At the opposite tail end of the spectrin tetramers, the N terminus of β -spectrin binds to short F-actin filaments, which is potentiated by 4.1R, to form the core of a junctional complex,³⁵ which links six tetramers together into a hexagonal skeletal network (Fig. 46-4).³⁶ The C-terminal

Figure 46-4. Electron micrograph of the human erythrocyte membrane skeleton. Membrane lipids and transmembrane proteins have been removed and the skeletons were extended during preparation and negative staining to reveal the structure. **A.** Low-magnification image reveals an ordered network of proteins. **B** and **C.** High-magnification image and schematic of the hexagonal lattice showing spectrin tetramers (Sp4) and hexamers (Sp6) or double tetramers (2Sp4). Junctional complexes contain actin filaments and protein 4.1R. Globular ankyrin molecules are bound to spectrin tetramers. (Reproduced with permission from Liu SC et al: *Visualisation of the hexagonal lattice in the erythrocyte membrane skeleton.* J Cell Biol 104(3):527-536, 1987.)

Figure 46-5. Schematic of human erythrocyte ankyrin. The N-terminal domain consists of 24 ANK repeats, which bind to band 3 and the Rh-RhAg complex. The central domain attaches to spectrin. The C-terminal domain varies in different isoforms of ankyrin, which are produced by alternative splicing of the gene. This domain also contains a conserved death domain of unknown function.

EF hand of α -spectrin enhances this spectrin-actin-4.1R interaction.³⁷ Numerous other proteins participate in the junctional complex, including adducin, protein 4.9, p55, tropomodulin and tropomyosin (see Fig. 46-1).¹⁹ Protein 4.1R binds to GPC and band 3, which serves as a secondary attachment site of the skeleton to integral membrane proteins. The main interaction tethering the skeleton to the lipid bilayer is accomplished by ankyrin, which links β -spectrin to band 3 (see Fig. 46-1). The ankyrin binding site is a flexible pocket formed by repeats 14 and 15 of β -spectrin near the C-terminal end of the molecule.^{38,39} Spectrin also interacts with phosphatidylserine on the inner leaflet of the lipid bilayer.

Nonrepeat sequences in spectrin provide the recognition sites for binding to modifiers, including kinases and calmodulin. The functions of spectrin are to maintain the biconcave disk shape of the red cell, regulate the lateral mobility of integral membrane proteins, and provide structural support for the lipid bilayer.

Ankyrin Erythrocyte ankyrin is encoded by the *ANK1* gene, which contains three separate tissue-specific promoters and first exons that are spliced to a common exon 2.⁴⁰ The 206-kDa protein is a versatile binding partner and has three functional domains: an N-terminal 89-kDa membrane-binding domain, that contains sites for band 3 and other ligands; a central 62-kDa spectrin-binding domain, and a C-terminal 55-kDa regulatory domain that is responsible for the different isoforms of the protein, which influence ankyrin-protein interactions (Fig. 46-5).²⁹

The membrane-binding domain contains 24 tandem ankyrin (ANK) repeats, which are stacked into a superhelical array that is coiled into a solenoid. This structure behaves like a reversible spring, which may contribute to the elasticity of the membrane.²² Each 33-amino-acid ANK repeat is highly conserved and forms an L-shaped structure composed of two antiparallel α helices separated by a β hairpin.⁴¹ The ANK repeats are connected by unstructured loops and provide an interface for numerous protein-protein interactions. Erythrocyte ANK repeats specifically bind to band 3 and the Rh-RhAG macromolecular complex.^{19,29}

The spectrin-binding domain contains a small unique subdomain termed *ZU5-ANK*, which has a β -strand core with several surface loops and binds to β -spectrin through hydrophobic and electrostatic interactions.⁴² The regulatory domain contains a highly conserved death domain of unknown function in the red cell. The C-terminal section of the regulatory domain varies in the different isoforms of ankyrin, proteins 2.1 to 2.6, which are created by alternative splicing⁴³ and which exhibit different binding affinities for band 3 and spectrin. Phosphorylation of ankyrin reduces binding to band 3 and spectrin tetramers.

Protein 4.1R The gene encoding protein 4.1 produces diverse isoforms in different tissues and different developmental stages. This diversity is accomplished by the use of alternate first exons under the control of different promoters, and alternate initiation codons. This

Figure 46-6. Schematic of human erythrocyte protein 4.1R. The protein consists of four domains, with the 30-kDa and the 10-kDa domains involved in binding to other red cell membrane proteins. The C-terminal domain has an asparagine residue at position 502 in isoform 4.1a, which is deamidated in older red cells to form aspartic acid and isoform 4.1b.

transcriptional regulation is coupled to complex pre-mRNA splicing events.^{44,45} The erythrocyte isoform, 4.1R, is produced from the downstream initiation codon and contains exon 16, which encodes an essential part of the spectrin-actin binding domain.

Protein 4.1R is a globular phosphoprotein that contains four structural and functional domains of 30 kDa, 16 kDa, 10 kDa, and 22 to 24 kDa (Fig. 46-6). The N-terminal 30-kDa domain is responsible for binding to the cytoplasmic domains of band 3 and GPC, as well as to p55, thereby linking the skeleton to the lipid bilayer.¹⁹ The 10-kDa domain enhances the interaction between spectrin and actin in the junctional complex, which connects spectrin tetramers to each other. The functions of the other two domains are not characterized. Phosphorylation of 4.1R inhibits spectrin-actin-4.1R complex formation and also decreases binding to band 3. Protein 4.1R binds weakly to phosphatidylserine in the lipid bilayer.

Two forms of 4.1R, a and b, are present in red cells, with protein 4.1b predominating in young erythrocytes. The difference between the two isoforms relates to the gradual deamidation of asparagine 502 to aspartic acid in a nonenzymatic, age-dependent manner, which influences the mobility of the protein on SDS gels.⁴⁶

Protein 4.2 Protein 4.2 is a member of the transglutaminase family of proteins,⁴⁷ but it has no enzyme activity as it lacks the critical triad of residues that form the active transglutaminase site. The exact role of protein 4.2 has not been elucidated, but it stabilizes the link between the skeleton and the lipid bilayer. Protein 4.2 interacts with several proteins, including the cytoplasmic domain of band 3, and this binding site has been identified as a hairpin region toward the center of the protein 4.2 molecule.^{11,47} Interactions with the ANK repeats in the membrane-binding domain of ankyrin⁴⁷ and CD47, a component of the Rh complex, have been documented.^{19,47} *In vitro* binding studies have revealed an association of protein 4.2 with 4.1R and spectrin. Protein 4.2 binds calcium adjacent to the spectrin-binding loop suggesting that calcium may regulate this interaction. The protein undergoes posttranslational palmitoylation and myristoylation, which suggests an interaction with the lipid bilayer.⁴⁷

p55 This molecule is a phosphoprotein member of the membrane-associated guanylate kinase (MAGUK) family of proteins.⁴⁸ In the red cell it is found as part of a ternary complex with GPC and 4.1R and it strengthens the link between the skeleton and the bilayer.¹⁹ p55

contains five domains, including an N-terminal PDZ domain, which binds to GPC; an SH3 domain; a central HOOK domain interacting with the 30-kDa domain of 4.1R; a region with tyrosine phosphorylation sites; and a C-terminal guanylate kinase domain (Fig. 46-7).⁴⁸ The protein is extensively palmitoylated, reflecting an interaction with the membrane bilayer.

Adducin Adducin, a calcium/calmodulin-binding phosphoprotein located at the spectrin-actin junctional complex, is composed of $\alpha\beta$ adducin heterodimers, which are structurally similar proteins encoded by separate genes. Adducins contain a 39-kDa globular head region, a small neck region of 9 kDa implicated in oligomerization to form $\alpha_2\beta_2$ heterotetramers, and a 30-kDa cytoplasmic tail with a myristoylated alanine-rich C kinase substrate (MARCKS) phosphorylation domain at the C terminus (Fig. 46-8). The adducin tails cap actin filaments and promote interaction of spectrin and actin.⁴⁹ They also bind band 3 and the GLUT-1, and thus form part of the macromolecular junctional complex linking the spectrin skeleton to the lipid bilayer (see Fig. 46-1).^{21,50} The function of adducin is regulated by calcium-dependent calmodulin binding and differential phosphorylation. A primary deficiency of adducin in human disease has not been described; however, mice with targeted inactivation of α - or β -adducin suffer from compensated spherocytic anemia, suggesting that the adducin mutations may be candidates for recessively inherited hemolytic anemia.⁵¹

Actin and Actin-Binding Proteins The erythrocyte contains β -type actin assembled into short F-actin protofilaments of 14 to 16 monomers. The length of the filaments is regulated by a “molecular ruler” of two rod-shaped tropomyosin molecules, which are bound along the filament, as well as by two tropomodulin molecules, which cap the filaments at the pointed ends.⁵² At the barbed end actin is capped by an adducin heterodimer. Dematin or protein 4.9 is a trimeric phosphoprotein, which bundles the actin filaments,⁵³ but also acts as a linker molecule by binding to the transmembrane GLUT-1.^{21,50}

MEMBRANE ORGANIZATION

The structure of the erythrocyte membrane is determined by multiple protein-protein interactions between (1) integral membrane proteins within the lipid bilayer, (2) peripheral proteins in the skeleton, and (3) linker proteins, which tether the skeleton to the transmembrane proteins (see Fig. 46-1). Protein-lipid interactions within the bilayer or between the anionic phospholipids and the underlying membrane skeleton also play a role in cohesion of the membrane components. By using the cytoplasmic domains of embedded proteins as attachment points, the membrane skeleton not only affixes itself to the lipid bilayer but also influences the topology of the transmembrane proteins and constrains their lateral and rotational mobility.

The membrane skeleton resembles a lattice-like network, with approximately 60 percent of the lipid bilayer directly laminated to the underlying skeleton.³⁶ Electron microscopy of stretched membrane skeletons indicate that the individual proteins can be visualized as a highly ordered meshwork of hexagons (see Fig. 46-4).³⁶ The corners of each hexagon consist of a globular macromolecular junctional complex of proteins, including 4.1R and actin, which interact with spectrin

Figure 46-7. Schematic of human erythrocyte p55. The protein is part of the membrane-associated guanylate kinase family and the kinase domain is close to the C terminus. Adjacent is a tyrosine phosphorylation zone. The central HOOK domain binds protein 4.1R.

Figure 46-8. Schematic of human erythrocyte adducin. The domain structure for α and β adducin is similar. The neck domain is responsible for oligomerization and the tail represents the major binding site for other red cell membrane proteins. MARCKS, myristoylated alanine-rich C kinase substrate.

tetramers, as well as tropomyosin, tropomodulin, adducin, dematin, and p55.^{19,21,50} Spectrin tetramers form the arms of the hexagons, cross-bridging individual junctional complexes. These *horizontal* protein interactions are important in the maintenance of the structural integrity of the cell, accounting for the high tensile strength of the erythrocyte (see Fig. 46-1).

The spectrin/actin skeleton is anchored to the phospholipid bilayer by two major membrane protein complexes: (1) an ankyrin complex that contains transmembrane proteins, band 3, GPA, Rh, and RhAG complex proteins, as well as peripheral proteins ankyrin, protein 4.2, and several glycolytic enzymes, and (2) a distal junctional complex that contains the membrane-spanning proteins band 3, GPC, GLUT-1, Rh, Kell, and XK proteins, in addition to peripheral proteins 4.1R, actin, tropomyosin, tropomodulin, adducin, dematin, and p55. These *vertical* protein-protein interactions are critical in the stabilization of the lipid bilayer, preventing loss of microvesicles from the cells (see Fig. 46-1).

The avidity of these horizontal and vertical interactions is modulated by posttranslational modifications of the participating proteins, especially phosphorylation. The erythrocyte contains multiple protein kinases and phosphatases that constantly phosphorylate and dephosphorylate specific serine, threonine, and tyrosine residues on band 3, β -spectrin, ankyrin, 4.1R, adducin, and dematin, in a dynamic manner, thereby tightly regulating the structural properties of the membrane. Additionally, membrane protein associations are also influenced by a variety of intracellular factors, including calcium, calmodulin, phosphoinositides, and polyanions such as 2,3-bisphosphoglycerate (BPG). Red cell membrane proteins are also subject to a variety of other post-translational modifications, including myristoylation, palmitoylation, glycosylation, methylation, deamidation, oxidation, and limited proteolytic cleavage, but the functional effects of these alterations are generally not known.

● CELLULAR DEFORMABILITY AND MEMBRANE STABILITY

In performing its primary function of oxygen delivery to the tissues, the erythrocyte has to repeatedly negotiate tiny capillaries in the microvasculature, as well as narrow slits in the spleen, which are much smaller than the diameter of the cell. Consequently, it has to undergo extensive distortion and deformation without fragmentation or loss of integrity, and this property of deformability is critical for survival during its average 120-day life span. The structure of the red cell membrane endows the cell with unique material properties, which makes it highly flexible, yet incredibly resilient, and enables a very rapid response to circulatory shear stress.

Elegant biophysical studies have identified three features that regulate the deformability of the cell: (1) the biconcave disk shape, which reflects the cell surface-area-to-volume ratio; (2) the viscoelastic properties of the membrane, which depend on the structural and functional

integrity of the membrane skeleton; and (3) the cytoplasmic viscosity, which is determined primarily by intracellular haemoglobin.⁵⁴

The unique biconcave disk shape of the erythrocyte provides a high ratio of surface area to cellular volume and this excess of membrane is critical for survival of the cell. It enables the red cell to stretch and distort when it passes through the microcirculation and protects it from destruction. To maintain the shape of the cell and to prevent loss of membrane microvesicles, the lipid bilayer and the skeleton have to be in direct contact with each other. The cohesion between the two sections of the membrane depends on protein-protein interactions between transmembrane proteins and peripheral proteins in the vertical plane of the membrane. These contacts are represented by the two macromolecular complexes (ankyrin-band 3 complex and the junctional complex) anchoring the skeleton to the integral proteins. To prevent fragmentation of the membrane and loss of the biconcave disk shape, the structural integrity of the membrane skeleton is critical. In this regard, the horizontal interactions of the peripheral proteins of the junctional complex, mainly 4.1R and actin, which link the tail ends of the spectrin tetramers together, is a major determinant of membrane stability. Spectrin heterodimer self-association, which links the head regions of the spectrin tetramers, is also of paramount importance.

The viscoelastic properties of the membrane are intrinsic features of the spectrin skeleton. The enormous distortion imposed on the cell during passage through the microvasculature is accommodated by the dynamic dissociation of spectrin tetramers into dimers, and subsequent reassociation to restore the original shape once the shear stress is removed.⁵⁵ The lattice structure of the skeleton facilitates this flexibility, as the individual hexagons are either in a compact configuration, with the junctional complexes close to each other and the spectrin tetramers coiled between them, or in an extended configuration, which allows large unidirectional deformation without disruption of the skeleton (see Fig. 46-4). The structure of the spectrin repeats also play a major role in the elasticity of the skeleton. Each triple helical repeat behaves partly as an independently folding unit and has a different thermal stability.⁵⁶ Cysteine labeling studies indicated that shear stress forced the unfolding of the least stable repeats.⁵⁷ These studies highlight the flexibility of the spectrin repeats and support the concept that their unfolding and refolding contributes to the deformability of the membrane. In addition, the elasticity of the ANK repeats may also facilitate the dynamic changes in the membrane during circulatory shear stress.²²

Red cell viscosity is largely determined by the concentration of intracellular hemoglobin, which is tightly regulated to minimize cytoplasmic viscous dissipation during cellular deformation. As the mean cell hemoglobin concentration rises above 37 g/dL, the viscosity increases exponentially, and this compromises the deformability of the cell under increased circulatory shear stress.⁵⁴ The hemoglobin concentration is critically dependent on red cell volume, which is primarily determined by the total cation content of the cell. Numerous membrane pumps and ion channels regulate the transport of sodium and potassium across the membrane (Fig. 46-9).

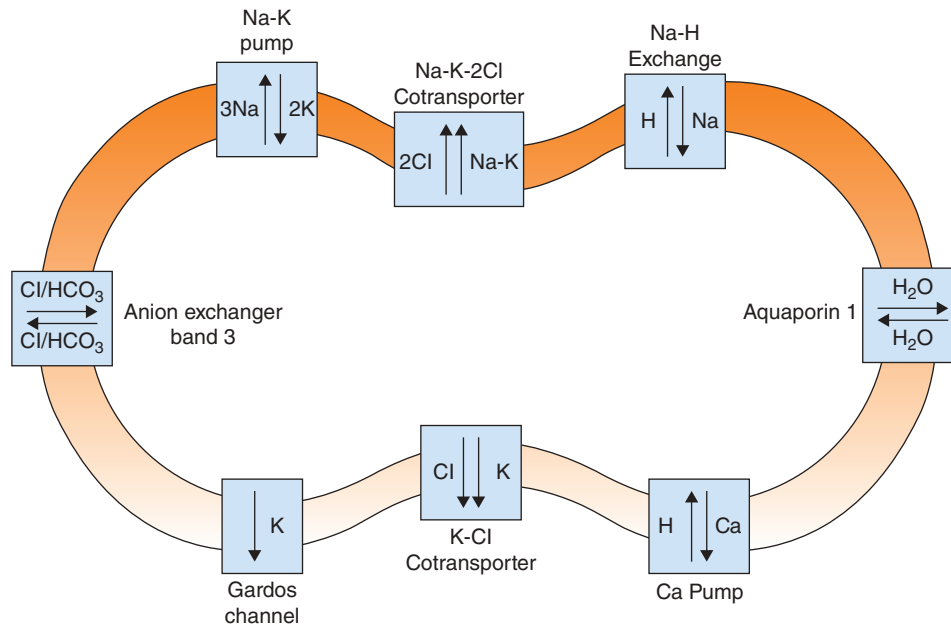

Figure 46–9. Principal ion transport and ion exchange channels and passive permeability pathways of the human erythrocyte.

MEMBRANE PERMEABILITY

The red cell membrane displays selective permeability to cations and anions and it maintains a high potassium, low sodium, and very low calcium content within the cell.⁵⁸ Ion transport pathways in the red cell membrane (see Fig. 46–9) include energy-driven membrane pumps, gradient-driven systems, and various channels. Several transport mechanisms exist for cations, including two energy-driven pumps.⁵⁸ The sodium pump is a Na^+K^+ adenosine triphosphatase (ATPase) that extrudes three sodium ions in exchange for two potassium ions entering the red cell. Calcium is pumped out of the cell by a calmodulin-activated Ca^{2+} ATPase, which protects the cell from deleterious effects of calcium, such as echinocytosis (Chap. 31), membrane vesiculation, calpain activation, membrane proteolysis, and cellular dehydration.⁵⁸ The Ca^{2+} -activated K^+ channel, also called the Gardos channel, causes selective loss of K^+ in response to increased intracellular Ca^{2+} . The Na^+K^+ gradient established by the sodium pump is used by several passive, gradient-driven systems to move ions across the red cell membrane.⁵⁸ The systems include the K^+Cl^- cotransporter, the $\text{Na}^+\text{K}^+\text{2Cl}^-$ cotransporter, and the Na^+H^+ exchanger.

Chloride and bicarbonate anions are readily exchanged through band 3. The red cell is highly permeable to water, which is transported by aquaporin-1 (AQP1),⁵⁹ and glucose is taken up by the glucose transporter.⁶⁰ The membrane also contains an ATP-driven oxidized glutathione (GSSG) transporter and amino acid transport systems.⁵⁸ Larger charged molecules, such as ATP, do not cross the membrane.

RED CELL MEMBRANE DISORDERS

Hemolytic anemias resulting from defects in the erythrocyte membrane comprise an important group of hereditary anemias. The disorders are characterized by altered red cell morphology, which is reflected in the nomenclature of HS, HE, hereditary pyropoikilocytosis (HPP) and southeast Asian ovalocytosis (SAO), which are the most common disorders in this group. Protein studies have identified the underlying membrane abnormalities and advances in molecular biology have

enabled further characterization of these disorders and, in many cases, identification of the causative mutations. These molecular analyses have provided additional information on the pathogenesis of these disorders and important insights into the structure–function relationships of erythrocyte membrane proteins.

As predicted in 1984 by Jiri Palek⁶¹ and confirmed by subsequent studies, protein defects that compromise *vertical* interactions between the membrane skeleton and the lipid bilayer result in destabilization of the bilayer, loss of membrane microvesicles and spherocyte formation; whereas mutations affecting *horizontal* protein interactions within the membrane skeletal network disrupt the skeleton resulting in defective shape recovery and elliptocytes (Table 46–2). Red cell membrane disorders exhibit significant heterogeneity in their clinical, morphologic, laboratory and molecular characteristics.

HEREDITARY SPHEROCYTOSIS

Definition and History

Hereditary spherocytosis is characterized by the presence of osmotically fragile spherical red blood cells on the blood film (Fig. 46–10B). The disorder was first described in 1871 as microcythemia in a case history by two Belgian physicians.⁶²

Epidemiology

HS occurs in all racial and ethnic groups. It is the most common inherited hemolytic anemia in individuals of northern European ancestry, affecting approximately 1 in 2000 individuals in North America and Europe.⁶³ It is also common in Japan and in Africans from southern Africa. Males and females are affected equally.

Etiology and Pathogenesis

The hallmark of HS erythrocytes is loss of membrane surface area relative to intracellular volume, which accounts for the spherical shape and loss of central pallor of the cell (Figs 46–10B and 46–11C). Spherocytes exhibit decreased deformability and are thus selectively retained, damaged and ultimately destroyed in the spleen, which causes the hemolysis

TABLE 46-2. Erythrocyte Membrane Protein Defects in Inherited Disorders of Red Cell Shape

Protein	Disorder	Comment
Ankyrin	HS	Most common cause of typical dominant HS
Band 3	HS, SAO, NIHF, HAC	"Pincered" HS spherocytes seen on blood film presplenectomy; SAO results from 9-amino-acid deletion
β -Spectrin	HS, HE, HPP, NIHF	"Acanthocytic" spherocytes seen on blood film presplenectomy; location of mutation in β -spectrin determines clinical phenotype
α -Spectrin	HS, HE, HPP, NIHF	Location of mutation in α -spectrin determines clinical phenotype; α -spectrin mutations most common cause of typical HE
Protein 4.2	HS	Primarily found in Japanese patients
Protein 4.1	HE	Found in certain European and Arab populations
GPC	HE	Concomitant protein 4.1 deficiency is basis of HE in GPC defects

GPC, glycophorin C; HAC, hereditary acanthocytosis; HE, hereditary elliptocytosis; HPP, hereditary pyropoikilocytosis; HS, hereditary spherocytosis; NIHF, nonimmune hydrops fetalis; SAO, southeast Asian ovalocytosis.

experienced by HS patients. The HS red cell membrane is destabilized by a deficiency of critical membrane proteins, including spectrin, ankyrin, band 3 and protein 4.2, which decreases the vertical interactions between the skeleton and the bilayer, resulting in the release of microvesicles and loss of surface area (Fig. 46-12). It is hypothesized that two mechanisms underlie the membrane loss: (1) in cells with spectrin/ankyrin deficiency, sections of the lipid bilayer and band 3 are not in contact with the skeleton, which will increase the lateral and rotational mobility of band 3, allowing lipid microvesicles containing band 3 to be generated, and (2) in cells with decreased amounts of band 3/protein 4.2, the stabilizing effect of the transmembrane section of band 3 on the lipid bilayer is lost, facilitating the formation of band 3-free microvesicles.¹³

Red Cell Membrane Protein Defects

Analysis of HS red cell membrane proteins by several research groups has revealed quantitative abnormalities of spectrin, ankyrin, band 3, and protein 4.2 in 70 to 90 percent of the cases.^{13,63,64} This spectrum of defects is found worldwide in all the HS cohorts that have been studied; however, the relative frequency of each defect varies with the geographical area and ethnic group. In the United States, parts of Europe, and in Korea, the most common defect is ankyrin deficiency (30 to 60 percent),^{63,65,66} whereas it is relatively uncommon elsewhere in the world (<15 percent). In other parts of Europe^{64,67} and in South Africa (unpublished), band 3 deficiency is the main defect. In Japan, almost half of the HS cases are caused by a decreased amount of protein 4.2, and in Korea and South Africa, this defect is the second most common, but in other populations it is rare (<6 percent).⁶³⁻⁶⁵ The underlying gene mutations have not been investigated in all HS subjects, but the limited research that has been conducted on the defective genes has identified more than 140 different mutations, which are often unique to a family.

Ankyrin Concomitant ankyrin and spectrin deficiency was first described in two patients with severe atypical HS and the primary defect was identified as an ankyrin abnormality.⁶⁸ Subsequent DNA analysis of the *ANK1* gene in patients with typical HS identified several mutations,⁶⁹ and numerous other studies have shown that ankyrin/spectrin deficiency is a common cause of HS. Ankyrin binds to spectrin with high affinity and attaches it to the membrane, which stabilizes the molecule. Because ankyrin is present in limiting amounts, a deficiency of ankyrin causes an equivalent loss of spectrin.

Different types of ankyrin mutations have been identified throughout the gene, indicating that there are several mechanisms that ultimately result in a decreased amount of ankyrin in the membrane. Interestingly, the majority of these mutations are frameshift and nonsense mutations that either result in unstable transcripts that are destroyed by nonsense-mediated mRNA decay or else produce a truncated defective ankyrin molecule.⁶⁶ More than 50 mutations have been documented and they are typically family-specific, although a few recurrent mutations have been described^{69,70} and 15 to 20 percent of mutations are *de novo*.⁶³

Figure 46-12. Pathobiology of hereditary spherocytosis (HS). The primary defect in HS is a deficiency of one of the membrane proteins, which destabilizes the lipid bilayer and leads to a loss of membrane in the form of microvesicles. This reduces the surface area of the cell and leads to spherocyte formation. Red cells with a deficiency of spectrin or ankyrin produce microvesicles containing band 3, whereas a reduced amount of band 3 or protein 4.1R gives rise to band 3-free microvesicles. Spherocytes have decreased deformability and are trapped in the spleen where the membrane is further damaged by splenic conditioning, which ultimately results in hemolysis.

Missense mutations have been documented in all the ankyrin domains and are thought to disrupt normal ankyrin–protein interactions. A few splicing mutations have been identified, including a mutation in intron 16, which created a new splice acceptor site and a complex pattern of aberrant splicing.⁷¹ Both parents were heterozygous for this mutation and the proband was homozygous, indicating that homozygosity for an ankyrin mutation is compatible with life.

Mutations in the erythroid-specific promoter of the *ANK1* gene are common in recessive HS. A dinucleotide deletion impairs the binding of a transcription factor complex, which leads to a reduced number of ankyrin transcripts.⁷² Point mutations in a barrier insulator element of the promoter also decrease transcription of the gene.⁷³

Cytogenetic studies have identified a few ankyrin-deficient HS patients with a contiguous gene syndrome that includes deletion of the ankyrin gene locus at 8p11.2. These patients additionally suffer from dysmorphic features, psychomotor retardation, and hypogonadism.⁷⁴

Band 3 A subset of HS patients present with a band 3 deficiency, typically accompanied by a secondary decrease in protein 4.2, a result of the reduction in protein 4.2 binding sites in the cytoplasmic domain of band 3. The extent of band 3 deficiency in heterozygous patients ranges between 20 and 50 percent, depending on the severity of the mutation, and the compensatory effect of the *in trans* normal allele. Mushroom-shaped “pincer” cells are commonly seen on the blood film of HS patients with a band 3 abnormality.

More than 55 underlying mutations have been described; they are variable and occur throughout the band 3 gene.^{13,66} Null mutations are typically family-specific and are caused by frameshift or nonsense mutations, or, in a few cases, by abnormal splicing, all of which result in truncated nonfunctional proteins or unstable transcripts that are not translated into protein. Missense mutations are common and often occur in several kindred. Highly conserved arginine residues at the internal boundaries of the transmembrane segments of the protein (see Fig. 46–2) are frequently mutated, including residues 490, 518, 760, 808, and 870.^{66,75} The mutations probably interfere with the cotranslational insertion of band 3 into the endoplasmic reticulum and ultimately into the red cell membrane. Short in-frame insertions or deletions have been documented and presumably also impair insertion of the mutant protein into the lipid bilayer.

Mutations in the cytoplasmic domain of band 3 impact on the interaction of band 3 with proteins in the membrane skeleton, or may alter the conformation of the protein rendering it unstable and prone to degradation prior to insertion into the membrane. Some cytoplasmic mutations, such as band 3 Cape Town and band 3 Mondega, are silent in the heterozygous state, but exacerbate the clinical presentation when inherited *in trans* to another mutation.^{76,77}

Spectrin Erythrocytes from HS patients with defects in spectrin or ankyrin are deficient in spectrin. The degree of deficiency correlates with the severity of hemolysis, the response to splenectomy and the ability to withstand mechanical shear stress.^{78,79} Visualization of the membrane skeleton of these red cells revealed a decreased density of the spectrin filaments connecting the junctional complexes.⁸⁰ The causative mutations occur in either α - or β -spectrin genes.

α -Spectrin Defects in α -spectrin are rare and are associated with severe recessive HS. During erythropoiesis α -spectrin is synthesized in a two- to fourfold excess over β -spectrin and heterozygotes thus still produce sufficient α -spectrin to form heterodimers with all the β -spectrin molecules, which will not result in spectrin deficiency. The defect will only be manifested in individuals who are homozygous or doubly heterozygous for mutations in α -spectrin. The mechanism underlying spectrin deficiency has not been fully elucidated, but a low-expression allele or a polymorphism inherited *in trans* to a causative null mutation plays a role. An example of a low-expression allele is

α^{L-EPRA} (low-expression Prague), which produces less than 20 percent of the normal amount of α -spectrin transcripts as a result of a splicing and mRNA processing defect, but does not cause any symptoms even in the homozygous state. However, in combination with another mutation on the other α -spectrin allele, which produces a nonfunctional truncated protein, it causes severe spectrin deficiency and anemia.⁸¹ A polymorphic missense mutation in the α II domain in spectrin Bug Hill has been identified in several patients with spectrin-deficient, recessive HS who carry another uncharacterized α -spectrin gene defect that causes the disease.⁸² Extensive analysis of the α -spectrin gene in a proband with severe nondominant HS revealed a partial maternal isodisomy of chromosome 1, resulting in homozygosity of the 1q23 region containing the maternal *SPTA1* gene, which carried an R891X nonsense mutation.⁸³ Uniparental disomy therefore unmasked a recessive mutation in the mother, which caused severe clinical symptoms in the child.

β -Spectrin The production of β -spectrin polypeptides is the limiting factor in spectrin heterodimer formation and one mutant allele is sufficient to cause spectrin deficiency in autosomal dominant HS. The blood films of these patients typically show a subpopulation of spiculated cells (acanthocytes and echinocytes) in addition to spherocytes.⁶³ Mutations in β -spectrin are found throughout the gene and are mainly null mutations caused by frameshift, nonsense, splicing, and initiator codon defects, which silence the mutant allele.⁸⁴ With a few exceptions the mutations are all kindred-specific. Truncated β -spectrin chains have also been described and are caused by frameshift mutations, in-frame deletions, or exon skipping. These mutations lead to, for example, reduced synthesis of an unstable protein,⁸⁵ or they impair the interaction with ankyrin and thereby the insertion of spectrin into the membrane.⁸⁶ A few missense mutations have been identified, including β -spectrin^{Kissimmee}, which is caused by a mutation in the 4.1R/actin-binding domain of the protein.⁸⁷ The mutant protein is unstable and does not bind to 4.1R, and thus it only interacts weakly with actin, which may explain why these red cells are deficient in spectrin.⁸⁷

Protein 4.2 Protein 4.2 deficiency is common in Japanese patients with recessively inherited HS who exhibit almost a complete absence of the protein.⁶³ Defects in this protein also occur in whites and other population groups, and 13 mutations have been described in the 4.2 gene of individual kindred, including missense mutations and in-frame deletion and insertion of nucleotides. Nonsense, frameshift, and splicing defects result in premature termination of translation and these mutant truncated proteins are not detected on the membrane, indicating that they are unstable and presumably degraded.⁴⁷ Amino acids 306 to 320 are highly conserved and five of the known mutations (three missense and two nonsense) occur in this region, which is adjacent to the hairpin that binds to band 3 in the predicted tertiary structure of protein 4.2.⁸⁸ The only recurrent and most common mutation, protein 4.2 Nippon, is caused by a point mutation that affects mRNA processing.⁸⁹ Patients are either homozygous for this mutation or heterozygous for a second mutation on the other allele.⁴⁷ Mutations have also been identified in individual patients with recessive HS from Europe, Tunisia, and Pakistan. South African kindred with autosomal dominant HS from a deficiency of protein 4.2 have been noted, but the underlying mutations have not been investigated.

Secondary Membrane Defects

The decreased membrane surface area in hereditary spherocytes involves a symmetrical loss of each species of membrane lipid. The relative proportions of cholesterol and phospholipids are therefore normal and the asymmetrical distribution of phospholipids is maintained.

HS red cells exhibit increased cation permeability, presumably secondary to the underlying membrane defect.⁹⁰ The excessive sodium

influx activates the Na⁺-K⁺ ATPase cation pump, which increases ATP turnover and glycolysis. Spherocytes are dehydrated, especially cells obtained from the splenic pulp, but the underlying mechanism has not been clearly defined. The acidic environment of the spleen and oxidative damage by splenic macrophages increase the activity of the K⁺Cl⁻ cotransporter, which may play a role in dehydration. The hyperactive Na⁺-K⁺ ATPase pump may also contribute as three sodium ions are extruded in exchange for two potassium ions, and this loss of monovalent cations is accompanied by the loss of water. Dehydration may also be related to loss of surface area.

Molecular Determinants of Clinical Severity

Affected individuals of the same kindred typically experience similar degrees of hemolysis. However, in some families the clinical expression is variable and this may be influenced by several factors. Low-expression alleles decrease transcription of the gene or influence the expression or incorporation of the protein into the membrane, but there is no phenotypic effect in the heterozygous state because the normal allele compensates for the deleterious effect. However, when inherited with a mutant allele that causes HS, it exacerbates the clinical expression of the disease. Examples of low-expression alleles that influence HS include band 3 Genas, band 3 Mondego, and two α -spectrin alleles, α^{LELY} and α^{LEPRA} .^{77,81,91-94}

Variable penetrance of the defective gene, a *de novo* mutation or a mild form of recessively inherited HS may also influence the clinical severity. Double heterozygosity for two mild band 3 mutations can have an additive effect⁷⁶ and rare cases caused by homozygous defects in band 3 result in severe transfusion-dependent hemolytic anemia or fetal death.^{91,95,96} Coinheritance of other hematologic disorders or Gilbert syndrome, caused by homozygosity for a polymorphism in the promoter of the uridine diphosphate-glucuronosyltransferase (UGT1) gene, can also alter the clinical symptoms.^{63,97,98}

Role of the Spleen

The spleen plays a secondary but important role in the pathophysiology of HS. Spherocytes are retained and ultimately destroyed in the spleen

and this is the primary cause of the chronic hemolysis experienced by HS patients (see Fig. 46-12). The reduced deformability of spherocytes impedes their passage through the interendothelial slits separating the splenic cords of the red pulp from the splenic sinuses. The decrease in red cell deformability is primarily related to a loss of surface area and, to a lesser extent, to an increase in internal viscosity as a result of mild cellular dehydration. *Ex vivo* experiments using perfused human spleens and red cells treated with lysophosphatidylcholine to induce spherocytosis revealed that the degree of splenic retention correlated with the reduction in the surface-area-to-volume ratio.⁹⁹

The spleen is a metabolically hostile environment with a decreased pH, low concentrations of glucose and ATP, and increased oxidants, all of which are detrimental to the red cell. Spherocytes are "conditioned" during erythrostasis in the spleen and become more osmotically fragile and increasingly spherocytic.¹⁰⁰ Exposure to macrophages in the spleen eventually leads to erythrophagocytosis and destruction.

Inheritance

In approximately 75 percent of HS patients, inheritance is autosomal dominant. In the remaining patients, the disorder may be autosomal recessive or result from *de novo* mutations, which is relatively common.^{101,102} Mutations in α -spectrin or protein 4.2 are often associated with recessive HS.

Clinical Features

The clinical manifestations of HS vary widely. The typical clinical picture combines evidence of hemolysis (anemia, jaundice, reticulocytosis, gallstones, splenomegaly) with spherocytosis (spherocytes on the blood film and increased osmotic fragility) and a positive family history. Mild, moderate, and severe forms of HS have been defined according to differences in hemoglobin, bilirubin, and reticulocyte counts (Table 46-3), which can be correlated with the degree of compensation for hemolysis. Initial assessment of a patient with suspected HS should include a family history and questions about history of anemia, jaundice, gallstones, and splenectomy. Physical examination should seek signs such as scleral icterus, jaundice, and splenomegaly.

TABLE 46-3. Classification of Hereditary Spherocytosis

Laboratory Findings	HS Trait or Carrier	Mild Spherocytosis	Moderate Spherocytosis	Moderately Severe Spherocytosis*	Severe Spherocytosis [†]
Hemoglobin (g/dL)	Normal	11-15	8-12	6-8	<6
Reticulocytes (%)	1-2	3-8	± 8	≥10	≥10
Bilirubin (mg/dL)	0-1	1-2	± 2	2-3	≥3
Spectrin content (% of normal) [‡]	100	80-100	50-80	40-80 [§]	20-50
Blood film	Normal	Mild spherocytosis	Spherocytosis	Spherocytosis	Spherocytosis and poikilocytosis
Osmotic fragility					
Fresh blood	Normal	Normal or slightly increased	Distinctly increased	Distinctly increased	Distinctly increased
Incubated blood	Slightly increased	Distinctly increased	Distinctly increased	Distinctly increased	Markedly increased

*Values in untransfused patients.

[†]By definition, patients with severe spherocytosis are transfusion-dependent. Values were obtained immediately prior to transfusion.

[‡]Normal: $245 \pm 27 \times 10^3$ spectrin dimers per erythrocyte.

[§]Spectrin content is variable in this group of patients, presumably reflecting heterogeneity of the underlying pathophysiology.

Adapted with permission from Eber SW, Armbrust R, Schröter W: Variable clinical severity of hereditary spherocytosis: Relation to erythrocytic spectrin concentration, osmotic fragility, and autohemolysis. *J Pediatr* 1990 Sep;117(3):409-416.

Typical Hereditary Spherocytosis Approximately 60 to 70 percent of HS patients have moderate disease, which typically presents in infancy or childhood but may present at any age. In children, anemia is the most frequent finding (50 percent of cases), followed by splenomegaly, jaundice, or a positive family history.^{13,63} No comparable data exist for adults. Hemolysis may be incompletely compensated with mild to moderate anemia (see Table 46-3). The moderate anemia may often be asymptomatic; however, fatigue and mild pallor or both may be present. Jaundice may be intermittent and is seen in about half of patients, usually in association with viral infections. When present, jaundice is acholuric, characterized by unconjugated hyperbilirubinemia without detectable bilirubinuria. Palpable splenomegaly is evident in most (>75 percent) older children and adults. Typically the spleen is modestly enlarged (2 to 6 cm below the costal margin), but it may be massive. No proven correlation exists between the spleen size and the severity of HS. However, given the pathophysiology and response of the disease to splenectomy, such a correlation probably exists.

Mild Hereditary Spherocytosis Approximately 20 to 30 percent of HS patients have mild disease with “compensated hemolysis,” that is, red blood cell production and destruction are balanced, and the hemoglobin concentration of the blood is normal (see Table 46-3).^{63,103} The life span of spherocytes is decreased, but patients adequately compensate for hemolysis with increased marrow erythropoiesis. These patients are usually asymptomatic. Splenomegaly is mild, reticulocyte counts are generally less than 6 percent, and spherocytes on the blood film may be minimal, which complicates the diagnosis. Many of these individuals escape detection until adulthood when they are being evaluated for unrelated disorders or when complications related to anemia or chronic hemolysis occur. Hemolysis may become severe with illnesses that further increase splenomegaly, such as infectious mononucleosis, or may be exacerbated by other factors, such as pregnancy or sustained, vigorous exercise. Because of the asymptomatic course of HS in these patients, diagnosis of HS should be considered during evaluation of incidentally noted splenomegaly, gallstones at a young age, or anemia resulting from parvovirus B19 infection or other viral infections.

Moderately Severe and Severe Hereditary Spherocytosis Approximately 5 to 10 percent of HS patients have moderately severe disease, as evidenced by indicators of anemia that are more pronounced than in typical moderate HS, and an intermittent requirement for transfusions (see Table 46-3). This category includes patients with dominant and recessive HS. A small number (<5 percent) of patients have severe disease with life-threatening anemia and are transfusion-dependent. They almost always have recessive HS. Most have severe spectrin deficiency, which is thought to result from a defect in α -spectrin,^{78,79} but defects in ankyrin or band 3 have also been identified.^{91,96} Patients with severe HS often have irregularly contoured or budding spherocytes or bizarre poikilocytes in addition to typical spherocytes and microspherocytes on the blood film. Added to the risks of recurrent transfusions, patients often suffer from hemolytic and aplastic crises and may develop complications of severe uncompensated anemia, including growth retardation, delayed sexual maturation, and aspects of thalassemic facies.

Asymptomatic Carriers Parents of patients with recessive HS are clinically asymptomatic and do not have anemia, splenomegaly, hyperbilirubinemia, or spherocytosis on the blood films. However, most have subtle laboratory signs of HS (see Table 46-3), including slight reticulocytosis, diminished haptoglobin levels, and slightly elevated incubated osmotic fragility, particularly the 100 percent red cell lysis point, which occurs at a higher sodium chloride concentration in carriers compared to normal subjects.¹⁰³ The acidified glycerol lysis test may also be useful

to detect carriers. In North America and parts of Europe, approximately 1 percent of the population is estimated to be silent carriers.⁶³

Pregnancy and Hereditary Spherocytosis

Most patients do well during pregnancy¹⁰⁴ although anemia may be exacerbated by plasma volume expansion and increased hemolysis. A few patients are symptomatic only during pregnancy. Transfusions are rarely required.

Hereditary Spherocytosis in the Neonate

Jaundice is the most common finding in neonates with HS, present in approximately 90 percent of cases. It may be accentuated by coinheritance of Gilbert syndrome, caused by homozygosity for a polymorphism in the promoter of the *UGT1* gene (Chaps. 33 and 47).^{63,97,98} Less than half of infants are anemic and severe anemia is rare. A few cases of hydrops fetalis from homozygosity or compound heterozygosity for band 3 or spectrin defects have been reported.^{91,105,106}

Complications

Gallbladder Disease Chronic hemolysis leads to formation of bilirubinate gallstones, the most frequently reported complication in up to half of HS patients. Coinheritance of Gilbert syndrome markedly increases the risk of gallstone formation. Although gallstones have been detected in children, they mainly occur in adolescents and young adults.^{13,63} Routine management should include interval ultrasonography to detect gallstones because many patients with cholelithiasis and HS are asymptomatic. Interval ultrasonography allows prompt diagnosis and treatment and prevents complications of symptomatic biliary tract disease, including biliary obstruction, cholecystitis, and cholangitis.

Hemolytic, Aplastic and Megaloblastic Crises Hemolytic crises are the most common and are usually associated with viral illnesses and typically occur in childhood.^{13,63} They are generally mild and characterized by jaundice, splenomegaly, anemia and reticulocytosis. Medical intervention is seldom necessary. During rare severe hemolytic crises, red cell transfusion may be required.

Aplastic crises following virally induced marrow suppression are uncommon but may result in severe anemia requiring hospitalization and transfusion with serious complications, including congestive heart failure or even death.^{13,63} The most common etiologic agent in these cases is parvovirus B19 (Chap. 36). The virus selectively infects erythropoietic progenitor cells and inhibits their growth leading to the characteristic finding of a low number of reticulocytes despite severe anemia. Aplastic crises usually last for 10 to 14 days and may bring asymptomatic, undiagnosed HS patients with compensated hemolysis to medical attention.⁶³

Megaloblastic crises may occur in HS patients with increased folate demands, such as pregnant patients, growing children, or patients recovering from an aplastic crisis. This complication can be prevented with appropriate folate supplementation.

Other Complications Leg ulcers, chronic dermatitis on the legs and gout are rare manifestations of HS, which usually heal rapidly after splenectomy. In severe cases, skeletal abnormalities resulting from expansion of the marrow can occur. Extramedullary hematopoiesis can lead to tumors, particularly along the thoracic and lumbar spine or in the kidney hila, in nonsplenectomized patients with mild to moderate HS.^{13,63} Postsplenectomy, the masses involute and undergo fatty metamorphosis.

HS has been suggested to predispose patients to hematologic malignancies, including myeloproliferative disorders, particularly myeloma, but cause and effect have not been proven. Thrombosis has been reported in several HS patients, usually postsplenectomy. Untreated HS

may aggravate other underlying diseases, such as congestive heart disease and hemochromatosis.^{13,63}

Nonerythroid Manifestations

Clinical manifestations are confined to the erythroid lineage in the majority of patients with HS, but a few exceptions have been observed. Several HS kindred have been reported with cosegregating nonerythroid manifestations, particularly neuromuscular abnormalities including cardiomyopathy, slowly progressive spinocerebellar degenerative disease, spinal cord dysfunction, and movement disorders. Erythrocyte ankyrin and β -spectrin are also expressed in muscle, brain, and spinal cord, which raises the possibility that these HS patients suffer from defects of one of these proteins.¹³

An isoform of band 3 is expressed in the kidney and heterozygous defects of band 3 have been described in patients with inherited distal renal tubular acidosis and normal erythrocytes. This finding is in contrast to most patients with heterozygous mutations of band 3, who have normal renal acidification and abnormal erythrocytes. Kindred with HS and renal acidification defects resulting from band 3 mRNA processing mutations, band 3^{Pribram} and band 3^{Campinas}, have been described.^{107,108} Homozygosity for band 3^{Coimbra}, a V488M missense mutation, resulted in the absence of band 3 and renal tubular acidosis in a severely affected HS infant.⁹¹

Laboratory Features

Laboratory findings in HS are variable, which correlate with the heterogeneous clinical presentation.

Blood Film Erythrocyte morphology in HS is not uniform. Typical HS patients have blood films with easily identifiable spherocytes lacking central pallor (see Fig. 46–10B and 46–11C). Patients with mild HS may present with only a few spherocytes, and at the other end of the spectrum, severely affected patients exhibit numerous dense microspherocytes and bizarre erythrocyte morphology with anisocytosis and poikilocytosis. Blood films from patients with band 3 defects often exhibit “pincered” or mushroom-shaped red cells, whereas spherocytic acanthocytes are associated with β -spectrin mutations. When examining blood from a patient with suspected spherocytosis, a high-quality film with the erythrocytes properly separated and some cells with central pallor in the field of examination are important because spherocytes can be an artifact.

Erythrocyte Indices Most patients have mild to moderate anemia with hemoglobin in the 9 to 12 g/dL range (see Table 46–3). Mean corpuscular hemoglobin concentration (MCHC) is increased (>36 g/dL) because of relative cellular dehydration in approximately half of patients, but all HS patients have some dehydrated cells. Some automated hematology analyzers measure the hemoglobin concentration of individual red cells and a demonstration of a population of hyperdense erythrocytes can be useful as a screening test for HS, especially when combined with an increased red cell distribution width. Mean corpuscular volume (MCV) is usually normal except in cases of severe HS, when MCV is slightly decreased.

Markers of Hemolysis Other laboratory features of HS are markers of ongoing hemolysis. Reticulocytosis, variably increased lactate dehydrogenase, increased urinary and fecal urobilinogen, unconjugated hyperbilirubinemia, and decreased serum haptoglobin reflect hemolysis and increased erythropoiesis (Chaps. 32 and 33). The reticulocyte count may appear to be elevated disproportionately relative to the degree of anemia.

Erythrocyte Fragility Tests Spherocytes have a decreased surface area relative to cell volume and this renders them osmotically fragile. Several laboratory tests exploit this characteristic and are used to diagnose HS. The most common osmotic fragility (OF) test measures lysis

of red cells, either from freshly drawn blood or after incubation of the sample at 37°C for 24 hours, in a range of hypotonic concentrations of sodium chloride. Spherocytes typically swell and burst much more readily than normal biconcave disk-shaped red cells. Other tests based on the same principle measure the rate and extent of cell lysis in buffered glycerol solutions and include the glycerol lysis test (GLT) and the acidified glycerol lysis test (AGLT). These tests, however, have relatively poor sensitivity and do not detect all cases of mild HS or those with small numbers of spherocytes, including patients who had recent blood transfusions.^{63,67,109} These tests may also be unreliable and give normal results in the presence of iron deficiency, obstructive jaundice, or during the recovery phase of an aplastic crisis.⁶³ In addition, these tests do not differentiate HS from other disorders with secondary spherocytosis, such as the autoimmune hemolytic anemias (Chap. 54).

Other fragility tests include the cryohemolysis test, based on the sensitivity of HS red cells to cooling at 0°C in hypertonic conditions, and the autohemolysis test, but these tests also do not detect all cases of HS.¹³ The reduced surface area of spherocytes can be measured by osmotic gradient ektacytometry, but the highly specialized equipment required for this procedure is only available in a few research-oriented laboratories.

Eosin 5'-Maleimide Flow Cytometry Test Eosin 5'-maleimide (EMA) is a fluorescent dye that binds to the transmembrane proteins, band 3, Rh protein, Rh glycoprotein, and CD47.¹¹⁰ Patients with HS exhibit decreased fluorescence compared to controls, irrespective of the underlying defective membrane protein, although not all patients with HS are detected. In addition, lower fluorescence values are also observed in patients with HE, HPP, some red cell enzymopathies, and other abnormalities of band 3, such as congenital dyserythropoietic anemia type II (CDAII; Chap. 39). The sensitivity and specificity of the test vary, depending on the cutoff value of the fluorescence, which differs between laboratories.^{109,111–113}

Molecular Diagnostics Because HS can be caused by mutations in several different genes and because there are very few common mutations, a simple DNA test to diagnose HS is not feasible. Initial analysis of the red cell membrane proteins by quantitative SDS-PAGE is required to identify the underlying defective protein. The sensitivity of this test varies between laboratories and different patient populations, but typically an abnormality is defined in 75 to 93 percent of cases.^{63,64,67} Patients with clinically identified HS and normal SDS-PAGE results may have a slight decrease of 10 to 15 percent in one of the membrane proteins, which may be missed by the densitometric analysis, or they may have an abnormality in a protein that is currently not quantified and not linked to HS, for example, adducin.

Knowledge of the defective protein facilitates subsequent DNA/RNA investigations to characterize the gene defect, although this approach is challenging as the genes causing HS are large and contain many exons. Polymorphisms may be used to identify reduced expression from one allele or loss of heterozygosity because of a null mutation. In families with variable clinical expression of HS, a molecular investigation into low-expression alleles and other modifying genes is useful. A molecular diagnosis is informative in patients with atypical features; severe disease; unclear or recessive inheritance; *de novo* mutations; or undiagnosed hemolytic anemia. Identification of silent carriers and prenatal diagnosis also require molecular testing.

Differential Diagnosis

Clinical features and family history should accompany an initial laboratory investigation comprising a complete blood count with a blood film, reticulocyte count, direct antiglobulin test (Coombs test), and serum bilirubin. Other causes of anemia should be excluded, particularly

autoimmune hemolytic anemia, CDAI and HSt. Further diagnostic tests (discussed in “Laboratory Features” earlier), are not standardized as reflected by a European survey of 25 centers.¹¹⁴ A consistent finding was that all the laboratories used at least two tests to make a final diagnosis, as none of the currently available methods have 100 percent sensitivity. The EMA test was most commonly used. Recent guidelines from the British Committee for Standards in Haematology (BCSH)¹¹⁵ advocate the use of the EMA test or cryohemolysis, but OF is not recommended for routine use.

In neonates, ABO incompatibility should be considered, but its differentiation from HS becomes clear several months after birth. Other causes of spherocytic hemolytic anemia, such as autoimmune hemolysis, clostridial sepsis, transfusion reactions, severe burns, and bites from snakes, spiders, bees, and wasps (Chaps. 52 to 54), should be viewed in the appropriate clinical context. Occasional spherocytes are seen in patients with a large spleen (e.g., in cirrhosis or myelofibrosis) or in patients with microangiopathic anemias (Chap. 51), but differentiation of these conditions from HS does not usually present diagnostic difficulties.

HS may be obscured in disorders that increase the surface-to-volume ratio of erythrocytes, such as obstructive jaundice, iron deficiency (Chap. 43), β -thalassemia trait, or hemoglobin SC disease (Chaps. 48 and 49), and vitamin B₁₂ or folate deficiency (Chap. 41).

Therapy and Prognosis

Splenectomy Splenic sequestration is the primary determinant of erythrocyte survival in HS patients. Thus, splenectomy cures or alleviates the anemia in the overwhelming majority of patients, reducing or eliminating the need for red cell transfusions, which has obvious implications for future iron overload and hemochromatosis-related end-organ damage. The incidence of cholelithiasis is decreased. Postsplenectomy, spherocytosis, and altered OF persist, but the “tail” of the OF curve, created by conditioning of a subpopulation of spherocytes by the spleen, disappears. Erythrocyte life span nearly normalizes, and reticulocyte counts fall to normal or near-normal levels. Changes typical of the postsplenectomy state, including Howell-Jolly bodies, target cells, Pappenheimer bodies (siderocytes), and acanthocytes (Chaps. 2 and 31), become evident on the blood film. Postsplenectomy, patients with the most severe forms of HS still suffer from shortened erythrocyte survival and hemolysis, but their clinical improvement is striking.⁷⁹

Complications of Splenectomy Early complications of splenectomy include local infection, thrombotic complications and in particular hepatic and mesenteric thrombosis, bleeding, and pancreatitis, presumably resulting from injury to the tail of the pancreas incurred during spleen removal. In general, the morbidity of splenectomy for HS is lower than the morbidity of other hematologic disorders. Chapters 5 and 6 discuss the complications of splenectomy.

Indications for Splenectomy In the past, splenectomy, which has a low operative mortality, was considered routine in HS patients. However, the risk of overwhelming postsplenectomy infection and the emergence of penicillin-resistant pneumococci have led to reevaluation of the role of splenectomy in the treatment of HS.¹¹⁶ Considering the risks and benefits, a reasonable approach is to splenectomize all patients with transfusion-dependent severe spherocytosis and all patients suffering from significant signs or symptoms of anemia, including growth failure, skeletal changes, leg ulcers, and extramedullary hematopoietic tumors. Other candidates for splenectomy are older HS patients suffering from vascular compromise of vital organs.

Whether patients with moderate HS and compensated, asymptomatic anemia should undergo splenectomy is controversial. Patients with mild HS and compensated hemolysis can be followed and referred for splenectomy if clinically indicated. Treatment of patients with mild

to moderate HS and gallstones is debatable, particularly because new treatments for cholelithiasis, including laparoscopic cholecystectomy, and endoscopic sphincterotomy, lower the risk of this complication. If such patients have symptomatic gallstones, a combined cholecystectomy and splenectomy can be performed, particularly if acute cholecystitis or biliary obstruction has occurred. No evidence indicates any benefit to performing cholecystectomy and splenectomy separately, as performed in the past.

Because the risk of postsplenectomy sepsis is very high during infancy and early childhood, splenectomy should be delayed until age 5 to 9 years if possible and to at least 3 years if feasible, even if chronic transfusions are required in the interim. No evidence indicates further delay is useful. In fact, further delay may be harmful because the risk of cholelithiasis increases dramatically in children older than 10 years.

When splenectomy is warranted, laparoscopic splenectomy has become the method of choice in centers with surgeons experienced in the technique.¹¹⁷ If desired, the procedure can be combined with laparoscopic cholecystectomy. Laparoscopic splenectomy results in less postoperative discomfort, a quicker return to preoperative diet and activities, shorter hospitalization, decreased costs, and smaller scars. The risk of bleeding increases during the operation and approximately 10 percent of laparoscopic operations (for all causes) must be converted to standard splenectomies. Even very large spleens (>600 g) can be removed laparoscopically because the spleen is placed in a large bag, diced, and eliminated via suction catheters.

Partial splenectomy via laparotomy has been advocated for infants and young children with significant anemia associated with erythrocyte membrane disorders.¹¹⁸ The goal of this procedure is to allow for palliation of hemolysis and anemia while maintaining some residual splenic immune function. Long-term followup data for this procedure have been variable.

Prior to splenectomy, patients should be immunized with vaccines against pneumococcus, *Haemophilus influenzae* type B, and meningococcus, preferably several weeks preoperatively. Use of prophylactic antibiotics postsplenectomy for prevention of pneumococcal sepsis is controversial. Prophylactic antibiotics (penicillin V 125 mg orally twice daily for patients younger than 7 years or 250 mg orally twice daily for those older than 7 years, including adults) have been recommended for at least 5 years postsplenectomy by some and for life by others. The optimal duration of prophylactic antibiotic therapy postsplenectomy is unknown. Presplenectomy and, in severe cases, postsplenectomy, HS patients should take folic acid (1 mg/day orally) to prevent folate deficiency.

Splenectomy Failure Splenectomy failure is uncommon. Failure may result from an accessory spleen missed during splenectomy, from development of splenunculi as a consequence of autotransplantation of splenic tissue during surgery, or from another intrinsic red cell defect, such as pyruvate kinase deficiency (Chap. 47). Accessory spleens occur in 15 to 40 percent of patients and must always be sought. Recurrence of hemolytic anemia years or even decades following splenectomy should raise suspicion of an accessory spleen particularly if Howell-Jolly bodies are no longer found on blood film (Chaps. 2 and 31). Definitive confirmation of ectopic splenic tissue can be achieved by a radiocolloid liver-spleen scan or a scan using ⁵¹Cr-labeled, heat-damaged red cells.

Genetic Counseling

After a patient is diagnosed with HS, family members should be examined for the presence of HS. A history, physical examination for splenomegaly, complete blood count, examination of the blood film for spherocytes, and a reticulocyte count should be obtained for parents, children, and siblings, if available.

HEREDITARY ELLIPTOCYTOSIS AND PYROPOIKILOCYTOSIS

Definition and History

HE is characterized by the presence of elliptical or oval erythrocytes on the blood films of affected individuals (Figs. 46–10D and 46–11F). In 1904, Dresbach, a physiologist at Ohio State University in Columbus, Ohio, published the first description of elliptical red blood cells in one of his students, noticed during a laboratory exercise in which the students were examining their own blood.¹¹⁹ The report elicited controversy because the student died soon thereafter, leading to speculation that he had actually suffered from pernicious anemia. The demonstration of elliptocytosis in three generations of one family established the hereditary nature of this disorder.¹²⁰ A related disorder, HPP is a rare disease first described in 1975 in children with severe neonatal anemia with abnormal poikilocytic red cell morphology reminiscent of that seen in patients suffering from severe burns (Fig. 46–13).¹²¹ The erythrocytes from these patients exhibited increased thermal sensitivity.

Epidemiology and Inheritance

HE has a worldwide distribution but the true incidence is unknown because the disease is heterogeneous and many patients are asymptomatic. In the United States, the incidence is estimated to be 1 in 2000 to 4000 individuals.^{13,122} HE occurs in all racial groups but is more prevalent in individuals of West African descent, possibly because elliptocytes may confer some resistance to malaria.^{123,124} HPP is typically found in patients of African origin, but it has also been diagnosed in subjects of European and Arabic descent.^{122,125,126}

Etiology and Pathogenesis

The primary abnormality in HE and HPP erythrocytes is defective horizontal interactions between components of the membrane skeleton, which weakens the skeleton and compromises its ability to maintain the biconcave disk shape of the red cell during circulatory shear stress. Investigations of erythrocyte membrane proteins in these disorders have identified abnormalities in α - and β -spectrin, protein 4.1, and GPC.¹²² The most common defects occur in spectrin, the main structural protein of the erythrocyte membrane skeleton, and they impair the ability of spectrin dimers to self-associate into tetramers and oligomers, thereby disrupting the skeletal lattice.⁵⁵ Abnormalities in 4.1R diminish the interaction between the tail ends of spectrin tetramers in the junctional complex and thus destabilize the skeleton. Deficiency of GPC/GPD is associated with reduced levels of 4.1R, which presumably is responsible for the elliptocytosis.

When the integrity of the skeleton is compromised, the capacity of the erythrocyte to undergo flow-induced deformation and

rearrangement of the skeleton is reduced. Disruption of the dynamic dissociation and reassociation of spectrin tetramers causes mechanical instability of the membrane, which precludes the recovery of the normal biconcave disk shape of the cell after prolonged and repeated unidirectional axial distortion in the microcirculation.¹²⁷ HE reticulocytes have a normal shape when released into the circulation but the mature red cells become progressively more elliptical as they age and ultimately the abnormal shape becomes permanent.^{13,122} As the severity of the defect increases, poikilocytes are formed and the cells become prone to fragmentation. HPP patients exhibit a combination of horizontal (impaired spectrin tetramer formation) and vertical (spectrin deficiency) defects, with the latter causing microspherocytes and exacerbating the hemolytic anemia.^{128,129}

Red Cell Membrane Protein Defects

Spectrin Mutations that affect spectrin heterodimer self-association are found in the majority of HE patients and in all patients with HPP. This functional defect results in an increased percentage of spectrin dimers relative to tetramers,¹³⁰ which is reflected on a structural level by an abnormal tryptic digest pattern of the protein, whereby the normal peptide is decreased with a concomitant increase in an abnormal peptide of lower molecular weight. Most of the defects affect the 80-kDa α I domain of α -spectrin and of the nine structural variants the most common are Sp $\alpha^{1/74}$, Sp $\alpha^{1/65}$, and Sp $\alpha^{1/46}$ or 50a.¹²⁸

More than 50 mutations have been identified in either α - or β -spectrin genes. The majority of the mutations are missense mutations that substitute highly conserved amino acids or those in close proximity. The abnormal amino acids typically have a different charge, or in the case of glycine or proline substitutions, they disrupt the helical structure of the spectrin repeats, which alter the interactions between α and β subunits. Interestingly, mutations in α -spectrin primarily occur in helix C of the repeats, which highlights the importance of this helix in the triple helical bundle (see Fig. 46–3). Several mechanisms have been identified by which the mutations impair spectrin tetramer formation.

Sp $\alpha^{1/74}$ mutations are mostly missense mutations found at the self-association site, which consists of helix C of the $\alpha 0$ partial spectrin repeat that interacts with helices B and C of β -spectrin partial repeat 17 to form a complete triple helical bundle.³⁴ *In vitro* studies on missense mutations in $\alpha 0$ revealed that the mutant peptides were stable folded structures, similar to wild type, but their binding affinities to β -spectrin peptides were variable. This suggested that their effect on tetramer formation was exerted through defective molecular recognition and disruption of protein-protein interactions at the contact site, rather than an altered structure.¹³¹ These findings contrasted with mutations in the $\beta 17$ repeat of β -spectrin, which perturbed the structural conformation of this partial repeat and the adjacent $\beta 16$ repeat.¹³² Codon 28

Figure 46–13. Blood films from a patient with HPP. **A.** Pre-splenectomy. **B.** Post-splenectomy. Note the prominent micro-poikilocytosis, microspherocytosis, and fragmentation especially after splenectomy. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

A

B

in helix C of $\alpha 0$ has been identified as a mutation “hotspot” since four different point mutations occur in this position, resulting in different amino acid substitutions, and the mutations have also been found in several unrelated kindred.¹³³ Arginine 28 is a highly conserved amino acid and any changes in this position are typically associated with severe HE or HPP.^{133,134} An interesting case of HE $\text{Sp}\alpha^{I74}$ involving an intragenic crossover in the α -spectrin gene and uniparental disomy, together with an underlying R34P mutation, was recently described in a Utah family.¹²⁶

$\text{Sp}\alpha^{I74}$ defects are also caused by mutations in β -spectrin, which presumably expose the αI domain of spectrin to increased tryptic digestion. These abnormalities are all located in partial repeat 17. Missense mutations are found in both helices A and B of the $\beta 17$ repeat, but some in helix A are particularly severe, including spectrin^{Providence}, spectrin^{Cagliari}, and spectrin^{Buffalo}, which cause severe fetal or neonatal anemia and non-immune hydrops fetalis when inherited in the homozygous state.^{105,106,135} Frame-shift mutations and splicing defects predominate in helix B, resulting in truncated spectrin molecules lacking the self-association site.^{13,122,136}

$\text{Sp}\alpha^{I65}$ is a mild defect, even in the homozygous state, because of a duplication of leucine 154 in helix C of the $\alpha 1$ repeat.¹³⁷ It is very common in blacks from West and Central Africa, as well as Arabs in North Africa, suggesting genetic selection, possibly by protecting carriers against *P. falciparum* malaria.^{13,122,123}

$\text{Sp}\alpha^{I46}$ or 50a mutations are distal from the self-association site and usually occur close to the helical linker regions between individual repeats and often involve the substitution of an amino acid with a proline residue, which is a helix breaker.^{13,122} *In vitro* studies on Q471P between repeats 4 and 5 of α -spectrin showed that the mutation uncoupled the repeats and caused cooperative unfolding, which abolished the stabilizing influence of the helical linker on adjacent repeats.¹³⁸ Because β -spectrin has fewer repeats than α -spectrin, the alignment of the heterodimers places $\alpha 4$ and $\alpha 5$ in contact with $\beta 16$ and $\beta 17$, suggesting that unfolding of the mutant spectrin repeats interferes with the self-association site and prevents tetramer formation.¹³⁹ The L260P mutation is in a similar position to Q471P, but is between repeats $\alpha 2$ and $\alpha 3$ of spectrin. When heterodimers are aligned, repeats $\alpha 03$ are not in contact with β -spectrin and they represent an open dimer configuration, which facilitates tetramer formation. Open dimers are in equilibrium with closed dimers whereby $\alpha 0$ to $\alpha 3$ are folded onto $\beta 16$ and $\beta 17$ of the same dimer, thus preventing bivalent tetramer formation.¹³⁹ *In vitro* experiments on the L260P mutation revealed a conformational change, which stabilized the mutant spectrin in the closed dimer configuration and reduced tetramer assembly.¹⁴⁰

Mutations in the αII domain of spectrin implicated in HE are rare. Spectrin^{StClaude} is caused by a single point mutation in intron 19 of α -spectrin,^{141,142} which creates complex splicing events that ultimately impair the function of both α - and β -spectrin, resulting in decreased binding to ankyrin, defective spectrin self-association and spectrin deficiency.¹⁴¹ These membrane abnormalities have profound effects on red blood cell morphology and survival, manifesting as severe HE.

Protein 4.1R Defects in the erythrocyte isoform of protein 4.1 associated with HE are relatively common in some Arab and European populations.¹³ Heterozygotes exhibit partial deficiency of 4.1R, manifesting as mild or asymptomatic HE, whereas homozygotes lack 4.1R and p55, have a reduced content of GPC, and present with severe HE. These red blood cells are mechanically unstable and fragment at moderate shear stress, but the stability can be restored by reconstituting the deficient red cells with 4.1R or the 4.1R spectrin-actin binding domain.¹⁴³ The 4.1R null erythrocytes demonstrate decreased invasion and growth of *P. falciparum* parasites *in vitro*.¹⁴⁴

Mutations in the 4.1R gene often affect the erythroid-specific initiation codon, which abolishes transcription, or else they tend to cluster in the spectrin-actin binding domain where exon deletions or

duplications result in mutant proteins that are smaller or larger than normal.¹²²

Glycophorin C GPC and GPD carry the Gerbich antigens and rare patients with the Leach phenotype are Gerbich-negative and lack both GPs. The underlying mutations are either a 7-kb deletion of genomic DNA or a frameshift mutation.¹⁴⁵ Heterozygous carriers are asymptomatic, with normal red blood cell morphology, whereas homozygous subjects exhibit elliptocytes on the blood film and present with mild HE, presumably as a result of the concomitant partial deficiency of 4.1R.^{13,145}

Molecular Determinants of Clinical Severity

HE patients exhibit marked clinical heterogeneity ranging from asymptomatic carrier to severe, transfusion-dependent anemia. In patients with spectrin heterodimer self-association defects, the resultant increase in spectrin dimers and concomitant decrease in spectrin tetramers, weakens the membrane skeleton and facilitates the formation of elliptocytes under circulatory shear stress. The most important determinants of the severity of hemolysis in these patients are the percentage of spectrin dimers and the spectrin content of the membrane skeleton. These parameters are influenced by the degree of dysfunction of the mutant spectrin, and the gene dose (heterozygote versus homozygote or compound heterozygote).¹²⁸ Genotype-phenotype correlations indicate that the order of clinical severity of αI domain defects is $\text{Sp}\alpha^{I74} > \text{Sp}\alpha^{I46-50a} > \text{Sp}\alpha^{I65}$ and it depends on the position of the mutations within the proteins, as well as the type of mutation. Defects in the spectrin dimer self-association contact site leading to $\text{Sp}\alpha^{I74}$ mutants are the most severe¹²⁸ and, for example, codon 28 mutations, which affect a highly conserved and critical arginine residue, are generally associated with phenotypically severe HE or HPP.¹³³ A more distal mutation such as the duplication of leucine 154, which causes $\text{Sp}\alpha^{I65}$, is phenotypically very mild, even in the homozygous state.¹³⁷ Proline or glycine helix-breaking mutations resulting in $\text{Sp}\alpha^{I46}$ or 50a are more severe even though they are further away from the self-association site.¹³⁸

The clinical expression of HE often varies within the same kindred, despite all the affected individuals carrying the same causative mutation. This heterogeneity is a result of the inheritance of modifier alleles or additional defects. The low-expression α^{LELY} is the most common polymorphism affecting spectrin content and clinical severity. The allele is characterized by an L1857V amino acid substitution, and partial skipping of exon 46 in 50 percent of the α -spectrin mRNA.⁹⁴ The six amino acids encoded by exon 46 are essential for spectrin heterodimer assembly and therefore $\text{Sp}\alpha^{\text{LELY}}$ results in a reduced amount of spectrin, as monomers are rapidly degraded.¹⁴⁶ The $\text{Sp}\alpha^{\text{LELY}}$ allele is clinically silent, even when homozygous, because α -spectrin is normally synthesized in three- to fourfold excess.¹⁴⁷ Inheritance of $\text{Sp}\alpha^{\text{LELY}}$ *in cis* to an elliptocytogenic α -spectrin mutation ameliorates symptoms,¹⁴⁸ whereas inheritance *in trans* causes a relative increase in the mutant spectrin and therefore exacerbates the disease.⁹⁴

Coinheritance of other molecular defects also plays a role in modifying the clinical expression. HPP patients are very severely affected because they are homozygous or doubly heterozygous for spectrin self-association mutations and are also deficient in spectrin.¹²⁹ Several molecular mechanisms have been identified that underlie the spectrin deficiency, including an RNA processing defect¹⁴⁹; reduced α -spectrin mRNA and protein synthesis¹⁵⁰; abnormal splicing resulting in a premature stop codon¹⁵¹; and degradation of α -spectrin.¹⁵⁰ A recent study revealed the complexity of genotype-phenotype interactions in two large Utah families of northern European descent in whom a novel R34P mutation in α -spectrin was associated with three morphologic phenotypes.¹²⁶ This heterogeneity was caused by an intricate interplay and coinheritance of other factors, including $\text{Sp}\alpha^{\text{LELY}}$ *in trans*, reduced transcription from the α -spectrin gene and intragenic crossover.¹²⁶

In neonates the clinical severity of HE can be affected by the weak binding of BPG to fetal hemoglobin leading to an increase in free BPG, which, in turn, destabilizes the spectrin-actin-protein 4.1 interaction.¹⁵² Finally, hemolytic anemia can be exacerbated by several acquired conditions, including those that alter microcirculatory stress to the cells.

Inheritance

HE is typically inherited as an autosomal dominant disorder. *De novo* mutations are rare.¹³⁴ The severity of clinical symptoms is highly variable reflecting heterogeneous molecular abnormalities, as well as the coinheritance of other genetic defects or polymorphisms that modify disease expression. A strong genetic relationship exists between HE and HPP, and parents or siblings of patients with HPP often have typical HE.

Clinical Features

The clinical presentation of HE is heterogeneous, ranging from asymptomatic carriers to patients with severe, life-threatening anemia. The overwhelming majority of patients with HE are asymptomatic and are diagnosed incidentally during testing for unrelated conditions. HPP patients present in infancy or early childhood with a very severe hemolytic anemia.

Asymptomatic carriers who possess the same molecular defect as an affected HE relative but who have normal or near-normal blood films have been identified. The erythrocyte life span is normal, and the patients are not anemic. Asymptomatic HE patients may experience hemolysis in association with infections, hypersplenism, vitamin B₁₂ deficiency, or microangiopathic hemolysis, such as disseminated intravascular coagulation or thrombotic thrombocytopenic purpura. In the latter two conditions, increased hemolysis may result from microcirculatory damage superimposed on the underlying mechanical instability of red cells.

HE patients with chronic hemolysis experience moderate to severe hemolytic anemia with elliptocytes and poikilocytes on the blood film. Red cell life span is decreased and patients may develop complications of chronic hemolysis, such as gallbladder disease. In some kindreds, the hemolytic HE has been transmitted through several generations. In other kindreds, not all HE subjects have chronic hemolysis; some have only mild hemolysis, presumably because another genetic factor modifies disease expression. The blood films of the most severe HE patients with chronic hemolysis exhibit elliptocytes, poikilocytes, fragments and small microspherocytes, reminiscent of HPP.

HPP represents a subtype of common HE, as evidenced by the coexistence of HE and HPP in the same family and the presence of the same molecular defects of spectrin.¹³⁰ HE relatives are heterozygous for an elliptocytogenic spectrin mutation, whereas HPP patients are homozygous or doubly heterozygous and are also partially deficient in spectrin.^{128,129}

Hereditary Elliptocytosis and Pyropoikilocytosis in Infancy

Clinical symptoms of elliptocytosis are uncommon in the neonatal period. Typically, elliptocytes do not appear on the blood film until the patient is 4 to 6 months old. Occasionally, severe forms of HE present in the neonatal period with severe, hemolytic anemia with marked poikilocytosis and jaundice. These patients may require red cell transfusion, phototherapy, or exchange transfusion. Usually, even in severely affected patients, the hemolysis abates between 9 and 12 months of age, and the patient progresses to typical HE with mild anemia. Infrequently, patients remain transfusion dependent beyond the first year of life and require early splenectomy. In cases of suspected neonatal HE or HPP, review of family history and analysis of blood films from the parents usually are of greater diagnostic benefit than other available studies.

A few cases of hydrops fetalis accompanied by fetal or early neonatal death as a result of unusually severe forms of HE have been described.¹⁰⁵ A severely affected hydropic infant salvaged by intrauterine transfusions (Chap. 55) and early exchange transfusion has remained transfusion dependent for more than 2 years.

Laboratory Features

The hallmark of HE is the presence of cigar-shaped elliptocytes on blood films (Figs. 46-10D and 46-11F). These normochromic, normocytic elliptocytes may number from a few to 100 percent. The degree of hemolysis does not correlate with the number of elliptocytes present. Spherocytes, stomatocytes, and fragmented cells may be seen. Osmotic fragility is abnormal in severe HE and in HPP. The reticulocyte count generally is less than 5 percent but may be higher when hemolysis is severe. Other laboratory findings in HE are similar to those of other hemolytic anemias and are nonspecific markers of increased erythrocyte production and destruction. For example, increased serum bilirubin, increased urinary urobilinogen, and decreased serum haptoglobin reflect increased erythrocyte destruction.

HPP blood films exhibit similar features to severe HE, but in addition, they reveal extreme poikilocytosis, some bizarre-shaped cells with fragmentation or budding and often only very few or no elliptocytes (Fig. 46-13). Microspherocytosis is common and MCV is usually low, ranging between 50 to 70 fL. Pyknocytes are prominent on blood films of neonates with HPP. The thermal instability of erythrocytes, originally reported as diagnostic of HPP, is not unique to this disorder because it is also commonly found in HE erythrocytes.

Specialized testing has been used in difficult cases or cases requiring a molecular diagnosis. Tests on isolated membrane proteins include analysis and quantitation of the proteins by SDS-PAGE; extraction of spectrin from the membranes to evaluate the spectrin-dimer-to-tetramer ratio on nonreducing gels, as well as limited tryptic digestion of spectrin followed by SDS-PAGE or two-dimensional gel electrophoresis to identify the defective domain. Ektacytometry may be used to measure membrane stability and deformability. Genomic DNA and/or complementary DNA analyses are used to determine the underlying mutation.

Differential Diagnosis

Elliptocytes may be seen in association with several disorders, including megaloblastic anemias, hypochromic microcytic anemias (iron-deficiency anemia and thalassemia), myelodysplastic syndromes, and myelofibrosis. In these conditions, elliptocytosis is acquired and generally represents less than one-quarter of red cells seen on the blood film. History and additional laboratory testing usually clarify the diagnosis of these disorders. Pseudoelliptocytosis is an artifact of blood film preparation and these cells are found only in certain areas of the film, usually near its tail. The long axes of pseudoelliptocytes are parallel, whereas the axes of true elliptocytes are distributed randomly.

Therapy and Prognosis

Therapy is rarely needed in patients with HE. In rare cases, occasional red blood cell transfusions may be required. In cases of severe HE and HPP, splenectomy has been palliative, as the spleen is the site of erythrocyte sequestration and destruction. The same indications for splenectomy in HS can be applied to patients with symptomatic HE or HPP. Postsplenectomy, patients with HE or HPP exhibit increased hematocrit, decreased reticulocyte counts, and improved clinical symptoms.

Patients should be followed for signs of decompensation during acute illnesses, characterized by acute decrease of hematocrit from nonspecific suppression of erythropoiesis by a concurrent acute event. HE and particularly HPP patients are at increased risk for parvovirus

infection generally requiring short-lasting transfusion support (Chap. 36).¹⁵³ Interval ultrasonography to detect gallstones should be performed. Patients with significant hemolysis should receive daily folate supplementation.

SOUTHEAST ASIAN OVALOCYTOSIS

SAO, also known as Melanesian elliptocytosis or stomatocytic elliptocytosis, is widespread in certain ethnic groups of Malaysia, Papua New Guinea, the Philippines, and Indonesia,¹²³ but is also common in the Cape Coloured population in South Africa.¹⁵⁴ It is characterized by the presence of large oval red cells, many of which contain one or two transverse ridges or a longitudinal slit (Figs. 46–10C and 46–11E).

SAO erythrocytes are rigid and hyperstable because of a structurally and functionally abnormal band 3. SAO band 3 binds tightly to ankyrin, forms oligomers, exhibits restricted lateral and rotational mobility^{155,156} and is unable to transport anions.¹⁵⁷ The underlying molecular abnormality is an in-frame deletion of 27 bp in the band 3 gene resulting in the loss of amino acids 400 to 408 located at the boundary of the cytoplasmic and membrane domains of band 3.¹⁵⁸ The defective SLC4A1 allele also carries a linked band 3^{Memphis} polymorphism, L56E.

SAO is a dominantly inherited trait and homozygosity is postulated to be lethal during embryonic development.¹⁵⁹ A recent case of homozygous SAO has been described where the fetus was kept alive by two intrauterine transfusions and since birth he has been on a monthly transfusion program.¹⁶⁰ Distal renal tubular acidosis was diagnosed at 3 months as a result of the inability of the SAO band 3 to transport anions.

A remarkable feature of SAO erythrocytes is their resistance to infection by several species of malaria parasites. This has been demonstrated by numerous *in vitro* studies, as well as *in vivo* evidence indicating that SAO provides protection against severe malaria and cerebral malaria.^{123,161} Epidemiologic data and the increased prevalence of SAO in populations challenged by malaria suggest a selective advantage of the gene.¹²³ Numerous factors have been implicated in the protective effect, but the precise mechanism of malaria resistance of SAO red cells has not been fully elucidated.

Clinically, the presence on the blood film of at least 20 percent ovalocytic red cells, some containing a central slit or a transverse ridge, and the notable absence of clinical and laboratory evidence of hemolysis are highly suggestive of SAO. Rapid genetic diagnosis can be made by amplifying the defective region of the band 3 gene and demonstrating heterozygosity for the SAO allele containing the 27 bp deletion.

ACANTHOCYTOSIS

Spiculated red cells are classified into two types: acanthocytes and echinocytes. *Acanthocytes* are contracted, dense cells with irregular projections from the red cell surface that vary in width and length (Figs. 46–10F and 46–11G). *Echinocytes* have small, uniform projections spread evenly over the circumference of the red cell (Fig. 46–11B). Diagnostically, the distinction is not critical, and disorders of spiculated red cells are generally classified together. Normal adults may have up to 3 percent spiculated erythrocytes, but care should be taken when preparing and examining the blood film, because spiculated cells, particularly echinocytes, are common artifacts of blood film preparation and blood storage.

Acanthocytes/echinocytes are found in various inherited disorders and acquired conditions. Spiculated cells can occur transiently in several instances, such as after transfusion with stored blood, ingestion of alcohol and certain drugs, exposure to ionizing radiation or certain venoms, and during hemodialysis.¹³ Spiculated cells are commonly seen on the blood films of patients with functional or actual splenectomy, severe liver disease, severe uremia, abetalipoproteinemia, certain inherited neurologic disorders and abnormalities of the Kell blood

group. Occasionally acanthocytes and/or echinocytes may be present in patients with glycolytic enzyme defects, myelodysplasia, hypothyroidism, anorexia nervosa, vitamin E deficiency, and in premature infants.¹³ Individuals with suppressed expression of Lu^a and Lu^b, the major antigens of the Lutheran blood group system, may also exhibit acanthocytes.¹³

The molecular mechanisms whereby acanthocytes are generated have not been fully elucidated. However, alterations in band 3 have emerged as a pivotal causative factor. The abnormal red cell membrane lipid composition and altered lipid distribution between the inner and outer leaflets of the bilayer are only found in some, but not all, of these disorders, implying that they may play a secondary role.¹⁶²

ACANTHOCYTOSIS IN SEVERE LIVER DISEASE

Definition

The anemia in patients with liver disease is often called “spur cell anemia” because of the projections on the red cells. Although only a small number of patients with end-stage liver disease acquire spur cell anemia, these individuals typically account for the majority of cases of acanthocytosis seen in clinical practice.

Etiology and Pathogenesis

The anemia in patients with liver disease is of complex etiology. Common causes include blood loss, iron or folate deficiency, hypersplenism, and marrow suppression from alcohol, malnutrition, hepatitis infection, or other factors. Acquired abnormalities of the red cell membrane may contribute to the anemia in some patients.¹⁶³

In vivo acanthocyte formation in spur cell anemia is a two-step process involving accumulation of free (nonesterified) cholesterol in the red cell membrane and remodeling of abnormally shaped red cells by the spleen.^{13,163} The diseased liver of the patient produces abnormal lipoproteins with excess cholesterol, which is acquired by circulating erythrocytes, increasing their cholesterol content. The cholesterol preferentially partitions into the outer leaflet, increasing the surface area to volume ratio and forming scalloped edges. In the spleen, membrane fragments are lost and the cells develop the characteristic projections of acanthocytes. Cholesterol interacts with band 3 and changes its conformation, which may affect the membrane skeleton and reduce the deformability of the cell,¹⁶² causing it to be trapped and eventually destroyed in the narrow sinusoids of the spleen.

Clinical Features

Spur cell anemia is characterized by rapidly progressive hemolytic anemia with large numbers of acanthocytes on the blood film. Splenomegaly and jaundice become more prominent and are accompanied by severe ascites, bleeding diatheses, and hepatic encephalopathy. Spur cell anemia is most common in patients with alcoholic liver disease, but similar clinical syndromes have been described in association with advanced metastatic liver disease, cardiac cirrhosis, Wilson disease, fulminant hepatitis, and infantile cholestatic liver disease.¹³

Laboratory Features

Most patients have moderate anemia with a hematocrit of 20 to 30 percent, marked indirect hyperbilirubinemia, and laboratory evidence of severe hepatocellular disease. Blood films reveal significant acanthocytosis and in some patients, echinocytes, target cells and microspherocytes, many with very fine spicules, are visible (see Fig. 46–13).

Differential Diagnosis

Spur cell hemolytic anemia should be distinguished from other hemolytic syndromes associated with liver disease, including congestive

splenomegaly, in which patients exhibit chronic, mild hemolysis and occasional spherocytes, and patients with transient hemolytic episodes.

Therapy, Course, and Prognosis

The anemia of spur cell anemia usually is not a significant clinical problem, but it can aggravate pre-existing anemia resulting from, for example, gastrointestinal bleeding, to the point that erythrocyte transfusion is required. The life span of spur cells is markedly decreased because of splenic sequestration, and, as expected, hemolysis abates after splenectomy. However, splenectomy is a dangerous and potentially fatal procedure in these critically ill patients and is generally not recommended.

NEUROACANTHOCYTOSIS

The term *neuroacanthocytosis* describes a heterogeneous group of rare disorders with variable clinical phenotypes and inheritance. The common features are a degeneration of neurons and abnormal acanthocytic erythrocyte morphology. These syndromes may be divided into: (1) lipoprotein abnormalities, which cause peripheral neuropathy, such as abetalipoproteinemia and hypobetalipoproteinemia, (2) neural degeneration of the basal ganglia resulting in movement disorders with normal lipoproteins, such as chorea-acanthocytosis and McLeod syndrome, and (3) movement abnormalities in which acanthocytes are occasionally seen, such as Huntington disease-like 2 (HDL2) and pantothenate kinase-associated neurodegeneration (PKAN).

Abetalipoproteinemia

Definition Abetalipoproteinemia or Bassen-Kornzweig syndrome is a rare autosomal recessive disorder characterized by progressive ataxic neurologic disease, dietary fat malabsorption, retinitis pigmentosa, and acanthocytosis found in people of diverse ethnic backgrounds.¹⁶⁴

Etiology and Pathogenesis This disorder is caused by a failure to synthesize or secrete lipoproteins containing products of the apolipoprotein B (apoB) gene and this leads to changes in the plasma lipid profile.¹⁶⁴ The primary molecular defect is a lack of the microsomal triglyceride transfer protein, which performs an essential step in apoB-containing lipoprotein synthesis.¹⁶⁵ The relative distribution of erythrocyte membrane phospholipids is altered and the phosphatidylcholine content is decreased with a corresponding increase in sphingomyelin. The excess sphingomyelin is preferentially confined to the outer leaflet of the membrane bilayer, where it presumably causes an expansion of this layer and modifies the conformation of band 3, which contributes to the irregularities in cell surface contour.¹⁶² Red cell precursors and reticulocytes have a normal shape and acanthocytosis only becomes apparent as the red cells mature in the circulation, worsening with increasing red cell age.¹⁶⁶

Clinical Features The disorder manifests in the first month of life by steatorrhea. Atypical retinitis pigmentosa, which often results in blindness, and progressive neurologic abnormalities characterized by ataxia and intention tremors develop between 5 and 10 years of age and progress to death in the second or third decade.¹⁶⁶

Laboratory Features Patients usually have mild anemia with normal red cell indices and normal or slightly increased reticulocyte counts.¹⁶⁶ Acanthocytosis is prominent, ranging from approximately 50 to 90 percent of red cells. Despite the red cell lipid abnormalities, the hemolysis is mild and the spleen is normal in patients with abetalipoproteinemia, in contrast to spur cell anemia. There is marked vitamin E deficiency (Chap. 44), which is thought to be a primary stimulus for the neuropathy. Coagulopathy may be observed.¹⁶⁴

Differential Diagnosis The related disorders hypobetalipoproteinemia, normotriglyceridemic abetalipoproteinemia, and chylomicron retention disease are associated with partial production of

apoB-containing lipoproteins or with secretion of lipoproteins containing truncated forms of apoB. Patients with these disorders may experience neurologic disease and acanthocytosis, depending on the severity of the underlying defect.

Therapy, Course, and Prognosis Treatment includes dietary restriction of triglycerides and supplementation with high doses of vitamins A, K, D, and E.¹⁶⁶ Chronic administration of vitamin E can delay or prevent the neurologic symptoms.

Chorea-Acanthocytosis Syndrome

Chorea-acanthocytosis is a rare autosomal recessive movement disorder characterized by atrophy of the basal ganglia and progressive neurodegenerative disease with onset in adolescence or adult life.¹⁶⁷ In some patients, acanthocytosis may precede the onset of neurologic symptoms. The lipoproteins are normal.

Molecular studies have identified approximately 100 mutations in the *VPS13A* gene, which codes for chorein, a protein ubiquitously expressed in the brain and also found in mature red cells.¹⁶⁸⁻¹⁷⁰ It is a member of a conserved protein family involved in trafficking of membrane proteins between cellular compartments, but its role in red cells and the pathogenesis of the disorder and acanthocytes is unknown. The mutations result in the absence or markedly reduced levels of chorein and founder mutations have been identified in Japanese and French-Canadian families.¹⁶⁷

Patients are not anemic, and red cell survival is only slightly decreased. Plasma and erythrocyte membrane lipids, as well as membrane protein composition and content, are normal, but electron microscopy studies revealed structural abnormalities in the skeleton and an uneven distribution of intra-membrane particles. Red cell membrane fluidity is decreased. Increased serine-threonine and tyrosine phosphorylation of band 3, β -spectrin, and β -adducin has been documented.¹⁷¹ In particular, abnormal activation of Lyn kinase results in increased tyrosine phosphorylation of band 3, which alters the association of band 3 with β -adducin and the junctional complex of the skeleton.¹⁷¹ This may lead to localized disruption of the skeleton-membrane interaction, facilitating the formation of protrusions. In one chorea-acanthocytosis kindred a point mutation near the C terminus of band 3 has been identified, which may influence the interaction of band 3 with the skeleton.¹⁷²

McLeod Syndrome

The McLeod phenotype is a rare X-linked defect of the Kell blood group system, whereby cells react poorly with Kell antisera. The XK protein is an integral membrane transport channel protein that is covalently linked to the Kell antigen by disulphide bonds, and mutations in the XK gene cause a deficiency of the XK protein.^{167,170} Male hemizygotes who lack XK have up to 85 percent acanthocytes on the blood film with mild, compensated hemolysis and develop late-onset multisystem myopathy or chorea known as the McLeod syndrome. Female heterozygous carriers may have occasional acanthocytes as a result of mosaicism in X chromosome inactivation. Large deletions involving not only the XK locus at Xp21.1, but also contiguous genes, result in the McLeod syndrome being associated with other diseases, such as chronic granulomatous disease of childhood, retinitis pigmentosa, Duchenne muscular dystrophy, and ornithine transcarbamylase deficiency.

Red cell membrane protein and lipid composition are normal, but the distribution of intramembrane particles is altered and increased phosphorylation of membrane proteins, notably band 3, has been noted, which again implicates band 3 as a key player in the generation of acanthocytes.

Other Neuroacanthocytosis Syndromes

The HDL2 disorder is caused by expanded CGT/CAG trinucleotide repeat mutations in the *junctophilin-3* gene, which encodes a protein involved in junctional membrane structures and calcium regulation.¹⁶⁷ The disease is autosomal dominant and presents with late-onset chorea, parkinsonism, and progressive cognitive defects. Acanthocytes are present in some patients. In one unusual kindred autosomal dominant inheritance of chorea-acanthocytosis with polyglutamine neuronal inclusions was described in association with HDL2. Proteolysis of band 3 was also noted, which could contribute to the altered red cell morphology.^{170,173}

Acanthocytes have been noted in some patients with PKAN (formerly known as Hallervorden-Spatz syndrome) with features of dystonia, dysarthria, and rigidity in childhood, and in HARP syndrome (hypobetalipoproteinemia, acanthocytosis, retinitis pigmentosa and pallidal degeneration). Both conditions are caused by mutations in pantothenate kinase 2, which is involved in synthesis of coenzyme A and phospholipids.^{167,170,174}

Differential Diagnosis of Neuroacanthocytosis with Normal Lipoproteins

Chorea-acanthocytosis, McLeod syndrome, HDL2, and pantothenate kinase disorders present with overlapping neurologic symptoms and

clinical phenotypes and also resemble Huntington disease, which renders the clinical diagnosis difficult. Identification of the underlying gene defects and the availability of molecular tests have markedly improved the diagnostic accuracy. This also provides insight into the underlying pathogenesis and suggests that the affected proteins, which are all linked to membrane structure, may participate in a common pathway that ultimately causes degeneration of the basal ganglia.

HEREDITARY STOMATOCYTOSIS SYNDROMES

The intracellular concentration of the monovalent cations, Na⁺ and K⁺, contribute to erythrocyte volume homeostasis. A net increase in these cations causes water to enter the cells resulting in overhydrated cells or stomatocytes, whereas a net loss dehydrates the cells and forms xerocytes. Disorders of red cell cation permeability are very rare conditions that are inherited in an autosomal dominant fashion with marked clinical and biochemical heterogeneity (Table 46-4).¹⁷⁵

Stomatocytes are cup-shaped red cells characterized by a central hemoglobin-free area (Figs. 46-10E and 46-11D). The molecular mechanism of stomatocyte formation has not been elucidated, but several theories have been postulated. The lipid bilayer hypothesis predicts that agents or abnormalities that expand the inner leaflet will tend to form stomatocytes.¹⁷⁶ Other theories relegate lipids to a secondary role

TABLE 46-4. Heterogeneity of the Hereditary Stomatocytosis Syndromes

	Stomatocytosis (Hydrocytosis)			Intermediate Syndromes		
	Severe Hemolysis	Mild Hemolysis	Cryohydrocytosis	Stomatocytic Xerocytosis	Xerocytosis with High Phosphatidylcholine	Xerocytosis
Hemolysis	Severe	Mild-moderate	Moderate	Mild	Moderate	Moderate

and propose that membrane proteins, specifically band 3, play a major role in regulating the structure of the red cell.¹⁶² Band 3 tetramers are attached to the spectrin skeleton and different configurations of band 3 that either face inward or outward can influence the topography of the skeleton and the shape of the cell.

HEREDITARY XEROCYTOSIS

Definition

Hereditary xerocytosis, also known as dehydrated HSt, is the most common form of the cation permeability defects. It is an autosomal dominant hemolytic anemia characterized by an efflux of K^+ and red cell dehydration. Hereditary xerocytosis is part of a pleiotropic syndrome and patients may also exhibit pseudohyperkalemia and perinatal edema.¹⁷⁷

Etiology and Pathogenesis

The underlying membrane permeability defect is complex and involves a net loss of potassium from the red cells that is not accompanied by a proportional gain of sodium. Consequently, the net intracellular cation content and cell water content are decreased. In some cases, erythrocytes exhibit an increase in phosphatidylcholine and reduced BPG content.¹³

The genetic locus for this disorder was mapped to 16q23–q24.¹⁷⁷ Subsequent refinement of the locus and exome sequencing of several large unrelated multigenerational kindred identified numerous missense mutations in the gene encoding the PIEZO1 protein.^{178,179} Cosegregation of some of the mutations in families with multiple disease phenotypes suggested a correlation between PIEZO and perinatal edema.¹⁷⁸ PIEZO proteins were recently identified as mechanosensory molecules that form part of stretch-activated cation channels. The PIEZO1 protein is present in red cell membranes and two PIEZO1 mutations, R2456H and R2488Q, were demonstrated to regulate a mechanosensitive transduction channel, leading to increased cation transport in erythrocytes.^{178,179}

Clinical Features

Patients may present with symptoms of compensated hemolytic anemia, including jaundice, splenomegaly, and gallstones. Some patients may also exhibit pseudohyperkalemia and perinatal edema and even hydrops fetalis.^{13,177} Variable penetrance is present in this disorder, with significant disparity in clinical symptoms between affected individuals in the same kindred. Patients display a strong tendency to iron overload (Chap. 43).¹⁷⁵

Laboratory Features

The hematologic picture is that of mild to moderate compensated hemolytic anemia (see Table 46–4) with an elevated reticulocyte count. The K^+ content is decreased and the Na^+ content is increased, but the total monovalent cation content is reduced. The MCHC is increased reflecting cellular dehydration and the MCV is frequently mildly increased.¹⁷⁵ Erythrocytes are resistant to osmotic lysis and the bell-shaped curve obtained by osmotic gradient ektacytometry is shifted to the left. Stomatocytes are not a prominent feature on blood films, but some target cells and spiculated cells are seen. In some of the cells, hemoglobin is concentrated (“puddled”) in discrete areas on the cell periphery.

Therapy, Course, and Prognosis

Most patients experience only mild anemia and therapy is not required. The patients should receive folate supplementation and be monitored for complications of hemolysis. Splenectomy does not significantly improve the anemia, which suggests that xerocytes are detected and eliminated in other areas of the reticuloendothelial system. Because of

a markedly high risk of hypercoagulability and life-threatening thrombotic episodes after splenectomy, the procedure is contraindicated.¹³

HEREDITARY STOMATOCYTOSIS/ HYDROCYTOSIS

Definition and History

Hereditary stomatocytosis, also known as hereditary hydrocytosis or overhydrated stomatocytosis, is characterized by a marked passive sodium leak, which causes red cell overhydration and macrocytosis. It is an autosomal dominantly inherited hemolytic anemia. The syndrome was first described in a girl with dominantly inherited hemolytic anemia whose blood film contained stomatocytes.¹⁸⁰ The hallmarks of abnormal cation transport and overhydration of the red cells were discovered subsequently.¹⁸¹

Etiology and Pathogenesis

The red cell membrane of stomatocytes has enhanced permeability toward monovalent cations, especially sodium ions. This marked passive sodium leak into the cell represents the principal lesion in this disorder. The $Na^+-K^+-ATPase$ pump, which normally maintains low intracellular sodium and high potassium concentrations, is stimulated but this increase in active transport, coupled to enhanced glycolysis to provide ATP, is insufficient to overcome the leak.^{175,182}

The overhydrated red cells of some patients lack stomatin, a 31-kDa integral membrane protein, but no gene mutations have been found implying that the absence of the protein is a secondary phenomenon.^{13,175} Stomatin interacts with GLUT-1 and converts it to a dehydroascorbic acid transporter, suggesting that it might be beneficial to inhibit this interaction in stomatocytes, because they require additional glucose for their increased ATP needs.¹⁷⁵

In some stomatocytosis patients, missense mutations causing amino acid substitutions of conserved residues in the transmembrane domain of the RhAG protein, a component of the band 3–Rh–RhAG multiprotein complex in the membrane, have been described.¹⁸³ RhAG is a transport protein that may function as a gas and/or ammonium channel through pore-like structures. The mutations are thought to widen the pores allowing cations to leak through the membrane. A *de novo* missense mutation in the transmembrane domain of band 3 has been described in one patient with stomatocytosis associated with dyserythropoiesis.¹⁸⁴ This changed the transport function of band 3 from an anion exchanger to a cation channel. The tyrosine phosphorylation profile of the stomatocyte membranes revealed increased phosphorylation of band 3 and stomatin, as a result of enhanced activity of the Syk and Lyn tyrosine kinases, suggesting that phospho-signaling pathways involved in cell volume regulation may be perturbed.¹⁸⁴

Clinical Features

Moderate to severe anemia is present. Jaundice and splenomegaly are common, as are complications of chronic hemolysis, such as cholelithiasis. Patients exhibit a tendency for iron overload, independent of transfusion status or splenectomy. No other organ system abnormalities have been noted.^{13,175} A dyserythropoietic phenotype was noted in one patient with mild anemia.¹⁸⁴

Laboratory Features

The blood film reveals striking stomatocytosis and up to 50 percent of red cells may have abnormal morphology (Figs. 46–10E and 46–11D). In addition to the anemia, red cell indices show decreased MCHC and marked macrocytosis, as reflected by an elevated MCV, which can reach 150 fL in some severely affected patients (see Table 46–4). The K^+ content is decreased and the Na^+ content is markedly increased, leading

to elevated total monovalent cation content. The OF of stomatocytes is markedly increased because many of the swollen red cells approach their critical hemolytic volume, which causes a shift of the osmotic gradient ektactometer curve to the right. Red cell deformability is decreased.

Therapy, Course, and Prognosis

The majority of hydrocytosis patients suffer from significant lifelong anemia. They should be monitored for complications of hemolysis, such as cholelithiasis and parvovirus infection, and should receive folate supplementation. The outcome of splenectomy has been variable, but typically it has been beneficial and improved the hemolytic anemia in severely affected patients.¹³ This is expected because stomatocytes expend large amounts of ATP to pump cations in an attempt to avoid osmotic lysis and are, therefore, vulnerable in the metabolically challenging environment of the spleen. However, splenectomy should be carefully considered in patients with this disorder, since they are at high risk of developing hypercoagulability after splenectomy, leading to catastrophic thrombotic episodes.¹³

CRYOHYDROCYTOSIS

The clinical phenotype and biochemical features of some patients with stomatocytes are intermediate between the extremes of hereditary hydrocytosis and hereditary xerocytosis. One of these disorders is cryohydrocytosis in which the mild cation leak is markedly enhanced at low temperatures. It is a very rare condition associated with mild to moderate hemolytic anemia and splenectomy appears to be beneficial.¹⁷⁵ Missense mutations have been found in the transmembrane section of band 3 that cluster between membrane span eight and the last two membrane-spanning domains.^{184–186} *In vitro* studies indicated that the mutant proteins have lost their anion exchange capability and are converted to a nonselective cation channel.^{175,186,187}

Two cases of cryohydrocytosis and stomatin deficiency have been described with mutations in GLUT-1, which abolish the glucose transport function of the protein and create a cation leak.¹⁸⁸

OTHER STOMATOCYTIC DISORDERS

Rh-deficiency syndrome designates rare individuals who either lack all Rh antigens (Rh_{null}) or exhibit markedly reduced (Rh_{mod}) Rh antigen expression. Rh antigens are carried on RhCE and RhD proteins that associate with RhAG and enable the formation of the Rh multiprotein complex in the red cell membrane. The Rh complex is either absent or markedly reduced in patients with Rh deficiency syndrome and they present with mild to moderate hemolytic anemia. Stomatocytes and occasional spherocytes are seen on the blood film and the cells have cation transport abnormalities, which cause dehydration. Hemolytic anemia is improved by splenectomy.^{13,175} Chapter 136 reviews the structure, localization, and functions of the Rh antigens.

Familial deficiency of high-density lipoproteins is a rare condition that leads to accumulation of cholesterol esters in many tissues, resulting in clinical findings of large orange tonsils and hepatosplenomegaly. Hematologic manifestations include moderately severe hemolytic anemia with stomatocytosis. Red cell membrane lipid analyses revealed a low cholesterol content and a relative increase in phosphatidylcholine at the expense of sphingomyelin.¹³

ACQUIRED STOMATOCYTOSIS

Normal individuals have up to 3 percent stomatocytes on blood films. Acquired stomatocytosis is common in alcoholics particularly those with acute alcoholism. Vinca alkaloids, such as vincristine and vinblastine, may induce hemolysis with increased sodium permeability and

stomatocytosis at the doses used for chemotherapy of leukemias and lymphomas.¹⁸⁹ Transient stomatocytosis has been observed in long distance runners immediately after a race. The molecular basis of acquired stomatocytosis is unknown.¹³

CHAPTER 47

ERYTHROCYTE ENZYME DISORDERS

Wouter W. van Solinge and Richard van Wijk

SUMMARY

Red cells possess active metabolic machinery that provides energy to pump ions against electrochemical gradients, to maintain red cell shape, to keep hemoglobin iron in the reduced form, and to maintain enzyme and hemoglobin sulfhydryl groups. The main source of metabolic energy comes from glucose. Glucose is metabolized through the glycolytic pathway and through the hexose monophosphate shunt. Glycolysis catabolizes glucose to pyruvate and lactate, which represent the end products of glucose metabolism in the erythrocyte, because it lacks the mitochondria required for further oxidation of pyruvate. Adenosine diphosphate (ADP) is phosphorylated to ATP, and nicotinamide adenine dinucleotide (NAD)⁺ is reduced to NADH in glycolysis. 2,3-Bisphosphoglycerate, an important regulator of the oxygen affinity of hemoglobin, is generated during glycolysis. The hexose monophosphate shunt oxidizes glucose-6-phosphate, reducing NADP⁺ to reduced nicotinamide adenine dinucleotide phosphate (NADPH). In addition to glucose, the red cell has the capacity to utilize some other sugars and nucleosides as a source of energy. The red cell lacks the capacity for *de novo* purine synthesis, but has a salvage pathway that permits synthesis of purine nucleotides from purine bases. The red cell contains high concentrations of glutathione, which is maintained almost entirely in the reduced state by NADPH through the catalytic activity of glutathione reductase. Glutathione is synthesized from glycine, cysteine, and glutamic acid in a two-step process that requires ATP as a source of energy. Catalase and glutathione peroxidase serve to protect the red cell

Acronyms and Abbreviations: ADA, adenosine deaminase; ADP, adenosine diphosphate; AK, adenylate kinase; AP-1, a transcription factor; 2,3-BPG, 2,3-bisphosphoglycerate; BPGM, bisphosphoglycerate mutase enzyme; CDP, cytidine diphosphate; 2,3-DPG, 2,3-diphosphoglycerate; EMP, Embden-Meyerhof direct glycolytic pathway; FAD, flavin adenine dinucleotide; G6PD, glucose-6-phosphate dehydrogenase; GAPDH, glyceraldehyde phosphate dehydrogenase; GCL, glutamate cysteine ligase; GLUT1, glucose transporter 1; GPI, glucose phosphate isomerase; GR, glutathione reductase; GS, glutathione synthetase; GSH, reduced glutathione; GSSG, oxidized glutathione; *HFE*, the gene associated with hereditary hemochromatosis; HK, hexokinase; KLF1, key erythroid transcription factor; LDH, lactate dehydrogenase; miRNA, microRNA; MRP1, multidrug resistance protein 1; NAD, nicotinamide adenine dinucleotide; NADPH, nicotinamide adenine dinucleotide phosphate (reduced form); nt, nucleotide; P5'N1, pyrimidine-5'-nucleotidase-1; PFK, phosphofructose kinase; *PFKM*, gene encoding muscle subunit of PFK; PGK, phosphoglycerate kinase; PK, pyruvate kinase; *PKLR*, gene encoding PK enzyme activity in red cells and liver; SNP, single nucleotide polymorphism; SOD1, superoxide dismutase type 1; TPI, triosephosphate isomerase; WHO, World Health Organization.

from oxidative damage. The maturation of reticulocytes into erythrocytes is associated with a rapid decrease in the activity of several enzymes. However, the decrease in activities of other enzymes occurs much more slowly or not at all with aging.

Erythrocyte enzyme deficiencies may lead to hemolytic anemia; expression of the defect in other cell lines may lead to pathologic changes such as neuromuscular abnormalities. Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common erythrocyte enzyme defect. In some populations, more than 20 percent of people may be affected by this enzyme deficiency. In the common polymorphic forms, such as G6PD A-, G6PD Mediterranean, or G6PD Canton, hemolysis occurs only during the stress imposed by infection or administration of "oxidative" drugs, and in some individuals upon ingestion of fava beans. Neonatal icterus, which appears largely with the interaction with an independent defect in bilirubin conjugation, is the clinically most serious complication of G6PD deficiency. Patients with uncommon, functionally very severe, genetic variants of G6PD experience chronic hemolysis, a disorder designated hereditary nonspherocytic hemolytic anemia.

Hereditary nonspherocytic hemolytic anemia (HNSHA) also occurs as a consequence of other enzyme deficiencies, the most common of which is pyruvate kinase (PK) deficiency. Glucose phosphate isomerase (GPI), triosephosphate isomerase (TPI), and pyrimidine 5'-nucleotidase (P5'N) deficiency are included among the relatively rare causes of hereditary nonspherocytic hemolytic anemia. In the case of some deficiencies, notably those of glutathione synthetase (GS), TPI, and phosphoglycerate kinase (PGK), the defect is expressed throughout the body, and neurologic and other defects may be a prominent part of the clinical syndrome.

Diagnosis is best achieved by determining red cell enzyme activity either with a quantitative assay or a screening test. Except for the basophilic stippling of erythrocytes that is characteristic, but not specific, of pyrimidine 5'-nucleotidase deficiency, red cell morphology is of little or no help in differentiating one red cell enzyme deficiency from another. A variety of molecular lesions have been defined in most of these enzyme deficiencies. Confirmation of the diagnosis by DNA analysis is recommended: it is necessary for genetic counseling and is helpful in recommendations for treatment, as patients with some enzyme deficiencies (e.g., GPI deficiency) tend to respond favorably to splenectomy whereas others do not (e.g., G6PD deficiency). Some of the defects, such as PK and GPI deficiencies, are transmitted as autosomal recessive disorders, whereas G6PD and PGK deficiencies are X linked.

DEFINITION AND HISTORY

Deficiencies in the activities of a number of erythrocyte enzymes may lead to shortening of the red cell life span. Glucose-6-phosphate dehydrogenase (G6PD) deficiency was the first of these to be recognized and is the most common.

The recognition of G6PD deficiency was the result of investigations of the hemolytic effect of the antimalarial drug primaquine, carried out in the 1950s and described in detail elsewhere.¹⁻³ These early studies defined G6PD deficiency as a hereditary sex-linked enzyme deficiency that affected primarily the erythrocytes, older cells being more severely affected than newly formed ones because of age-dependent decline of mutant enzyme activity. They showed that this enzyme deficiency was very prevalent in individuals of African, Mediterranean, and Asian ethnic origins, but that it could be found in virtually any population. The common (polymorphic) forms of G6PD deficiency were found

to be associated with anemia only under conditions of stress, such as the administration of oxidative drugs, infection, and the neonatal period.

Chronic hemolysis in the absence of a stress occurs in uncommon, functionally severe forms of G6PD deficiency and in patients with a variety of other red cell enzyme deficiencies. Such patients suffer from *hereditary nonspherocytic hemolytic anemia*. Although patients fitting the description of hereditary nonspherocytic hemolytic anemia had been documented earlier, the designation was first introduced by Crosby in 1950.⁴ Dacie and colleagues⁵ subsequently reported several families in which affected members manifested hemolytic anemia from an early age and in whom the osmotic fragility of the red cells was normal. The latter finding was the main feature that distinguished this disorder from hereditary spherocytosis. Thus, defined essentially by exclusion as a hereditary hemolytic anemia that is not hereditary spherocytosis (or without any other major aberration of red cell morphology), it is not at all surprising that hereditary nonspherocytic hemolytic anemia has proven to be extremely heterogeneous both in etiology and in clinical manifestations. Sometimes this disorder is also designated *congenital nonspherocytic hemolytic anemia*, but the name *hereditary hemolytic anemia* is more accurate and is therefore preferable. Although hereditary ovalocytosis, pyropoikilocytosis, and stomatocytosis (Chap. 46), and even thalassemia major and sickle cell disease (Chaps. 48 and 49), are hereditary hemolytic anemias that are also nonspherocytic, they are not included in this category.

Although a deficiency of G6PD was found to be responsible for hemolysis in a few patients with hereditary nonspherocytic hemolytic anemia, in the overwhelming majority of cases the cause remained obscure. In 1954, Selwyn and Dacie⁶ studied autohemolysis (spontaneous lysis of red cells after sterile incubation for 24 to 48 hours at 37°C) in four patients with hereditary nonspherocytic hemolytic anemia and found that in two of them lysis was only slightly increased and was prevented by glucose; these patients were designated as type 1, whereas the others, in whom glucose failed to correct autohemolysis, were classified as type 2. Autohemolysis of the erythrocytes of type 2 patients was modified by the addition of ATP. However, ATP does not penetrate the red cell membrane and instead, its modifying influence was nonspecific exerted chiefly by virtue of its effect on the osmolarity and pH of the suspending solution. These findings suggested to DeGruchy and associates⁷ that patients with type 2 autohemolysis suffered from a defect in ATP generation. This proposal, born of a misunderstanding of red cell biochemistry, turned out to be correct, as one of the major causes of hereditary nonspherocytic hemolytic anemia proved to be a deficiency of the ATP-generating enzyme pyruvate kinase (PK).⁸ PK deficiency was the first of a large number of enzyme defects that have been shown to account for this heterogeneous syndrome.

● EPIDEMIOLOGY

The most common red cell enzyme abnormality is deficiency of G6PD. Its prevalence among white populations ranges from less than 1 in 1000 among northern European populations to 50 percent of the males among Kurdish Jews. The lowest frequencies of G6PD deficiency are found in both North and South America (≤ 1 percent), and highest rates are predicted across the tropical belt of sub-Saharan Africa (15 to 30 percent; Fig. 47-1). The distribution across Asia and Asia Pacific is generally heterogeneous, ranging from virtually absent to relatively high.^{9,10} Although many of the highest frequencies are predicted from sub-Saharan African countries, the very high population densities across Asia infers that the overall population burden is largely focused here. The overall allele frequency of G6PD deficiency across all malaria

endemic countries is predicted to be 8 percent. This corresponds to 220 million affected males and an even greater number of females, although some heterozygous females for this X-chromosome-encoded gene do not have enough deficient erythrocytes to become prone to significant hemolysis.⁹ Details on the distribution of G6PD deficiency among various population groups is presented elsewhere.⁹⁻¹²

The high frequency of G6PD-deficient genes in many populations implies that G6PD deficiency confers a selective advantage. The suggestion that resistance to malaria accounts for the high frequency of G6PD deficiency paralleling the worldwide distribution of malaria is supported by the sheer diversity of variants in the *G6PD* gene. Many of these are found at polymorphic frequencies in genetically isolated populations, suggesting independent selection of each variant.¹¹⁻¹³ Important supporting evidence was obtained from studies in heterozygotes for G6PD A- that showed a higher degree of infestation of G6PD-sufficient cells than of G6PD-deficient cells.¹⁴ Deficient cells infested with malaria parasites may be phagocytosed more efficiently than normal cells.¹⁵ Which G6PD genotypes confer protection from malarial infection is the subject of debate.¹⁶⁻¹⁸ The majority of studies conclude that G6PD deficiency in hemizygous males, and probably also homozygous females, confers significant protection against malarial infection. The nature of protection from the mosaic state of G6PD deficiency in heterozygous females remains to be established.^{18,19}

It has been suggested that a higher prevalence of G6PD deficiency in individuals with sickle cell disease than in the general African population reflects a favorable effect of the enzyme deficiency on the clinical course of the sickling disorders.²⁰ However, studies aimed at investigating the effects of G6PD deficiency on the clinical manifestations of sickle cell disease have produced conflicting results. Some studies found no evidence for any such effect,^{21,22} whereas others reported on lower hemoglobin levels in patients with both disorders, either accompanied²³ or not²⁴ by signs of increased hemolysis.

PK deficiency is the most common cause of hereditary nonspherocytic hemolytic anemia. Based on large-scale mutation analysis, it has been estimated that the population prevalence of PK deficiency among whites is approximately 50 cases per 1 million population.²⁵ Estimates of frequencies of other deficiency alleles, such as those for adenylate kinase, diphosphoglycerate mutase, enolase, triosephosphate isomerase (TPI), and phosphoglycerate kinase (PGK), have been made on large numbers of cord bloods.²⁶ A particularly high incidence of heterozygous TPI deficiency (>4 percent) in Americans of African descent is supported by family studies.²⁷ Because this is not reflected in a correspondingly high birth incidence, the allele might be lethal in the homozygous state.

In addition to the common G6PD mutations, there are mutations in other enzymes that are repeatedly encountered in the population. In PK, the c.1529G>A, p.(Arg510Gln) mutation is the most common mutation in the United States,²⁸ and in northern and central Europe²⁹; the c.1456C>T, p.(Arg486Trp) mutation is prevalent in southern Europe,³⁰ and the c.1468C>T, p.(Arg490Trp) mutation in Asia.³¹ Similarly, the c.315G>C, p.(Glu104Asp) mutation is recurrently encountered in TPI.³² In phosphofructose kinase (PFK) deficiency, one-third of the reported patients are of Jewish origin, and in this population, an intronic splice site mutation, c.237+1G>A, and a single base-pair deletion, c.2003delC, are among the most frequently encountered mutations.³³ In a number of these instances, the existence of each mutation in the context of the same haplotype implies that there has been a *founder effect*, that is, the mutation occurred only once, and all individuals now carrying it are descendants of the person who sustained the original mutation. The expansion of the mutation could represent a selective advantage for heterozygotes, but also may result from random factors or from a selective advantage provided by one or more tightly linked genes.

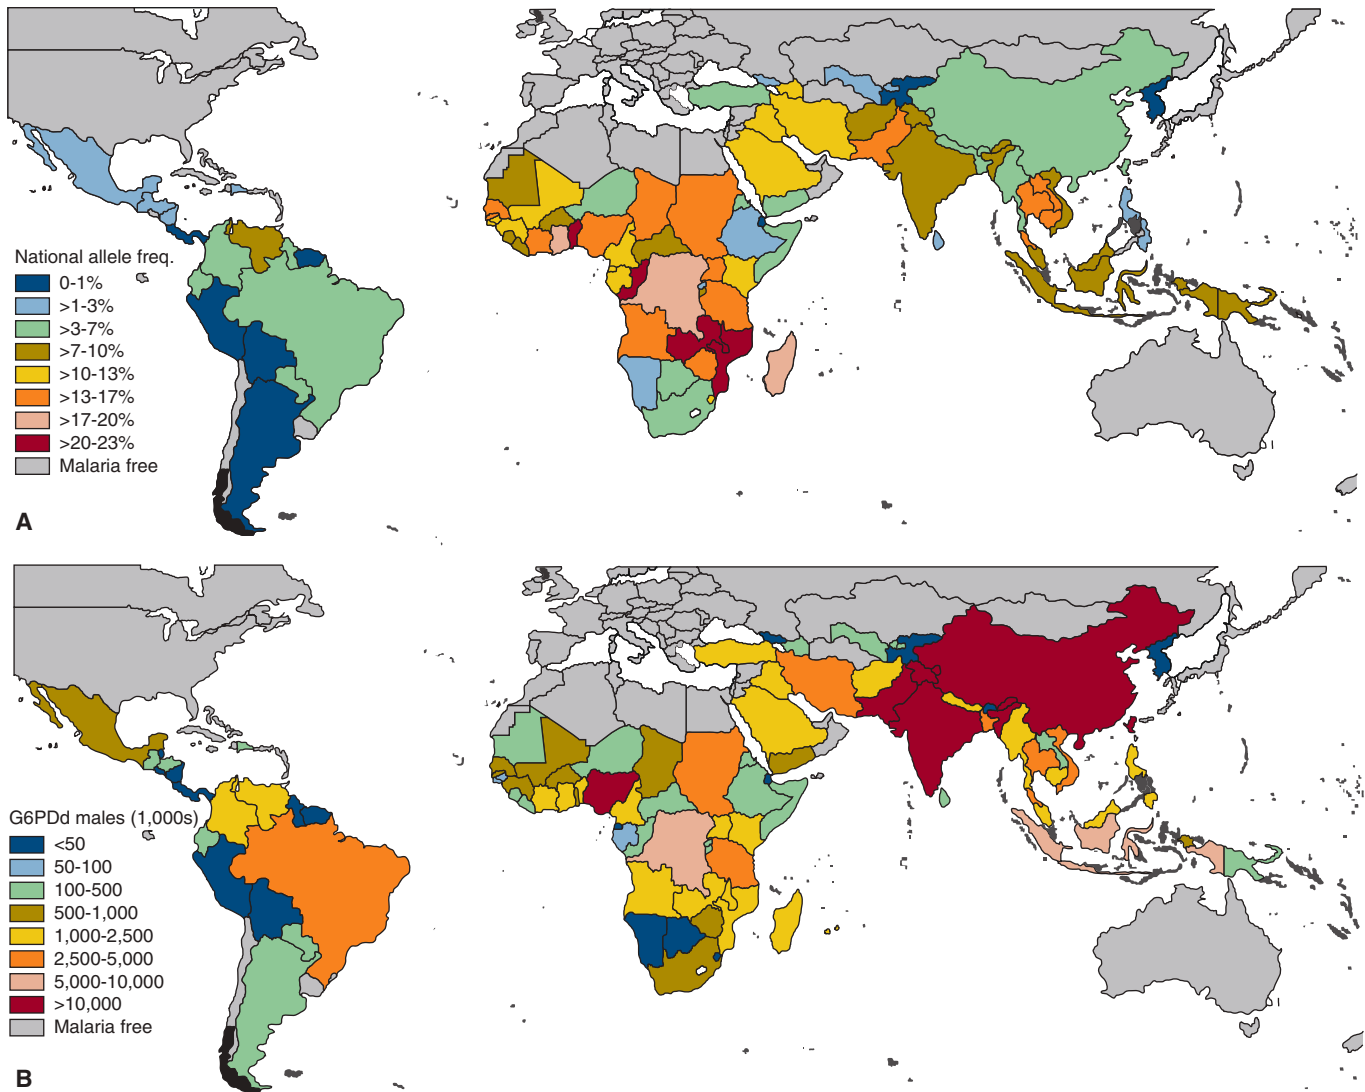

Figure 47-1. Estimated prevalence of glucose-6-phosphate dehydrogenase (G6PD) deficiency. **A.** National-level allele frequencies. **B.** National-level population estimates of G6PD-deficient (G6PDd) males. (Reproduced with permission from Howes RE, Piel FB, Patil AP, et al: G6PD deficiency prevalence and estimates of affected populations in malaria endemic countries: a geostatistical model-based map. *PLoS Med* 2012;9(11):e1001339.)

ETIOLOGY AND PATHOGENESIS

RED CELL METABOLISM

Although the binding, transport, and delivery of oxygen do not require the expenditure of metabolic energy by the red cell, a source of energy is required if the red cell is to perform its function efficiently and to survive in the circulation for its full life span of approximately 120 days. This energy is needed to maintain (1) the iron of hemoglobin in the divalent form; (2) the high potassium and low calcium and sodium levels within the cell against a gradient imposed by the high plasma calcium and sodium and low plasma potassium levels; (3) the sulfhydryl groups of red cell enzymes, hemoglobin, and membranes in the active, reduced form; and (4) the biconcave shape of the cell. If the red cell is deprived of a source of energy, it becomes sodium and calcium logged and potassium depleted, and the red cell shape changes from a flexible biconcave disk. Such a cell is quickly removed from the circulation by the filtering action of the spleen and the monocyte-macrophage system. Even if it survived, such an energy-deprived cell would gradually turn brown as hemoglobin is oxidized to methemoglobin by the very

high concentrations of oxygen within the erythrocyte and would then be unable to perform its function of transporting oxygen and carbon dioxide.

The process of extracting energy from a substrate, such as glucose, and of utilizing this energy is carried out by a large number of enzymes (Table 47-1). Because the red cell loses its nucleus before it enters the circulation and most of its RNA within 1 or 2 days of its release into the circulation, it does not have the capacity to synthesize new proteins to replace those that may become degraded during its life span. The enzymes present in the red cells were formed largely by the nucleated cell in the marrow and, to a lesser extent, the reticulocyte.

Glucose Metabolism

Glucose is the normal energy source of the red cell. It is metabolized by the erythrocyte along two major routes: the glycolytic pathway and the hexose monophosphate shunt. The steps in these pathways are essentially the same as those found in other tissues and in other organisms, including even relatively simple ones such as *Escherichia coli* and yeast. Unlike most other cells, however, the red cell lacks mitochondria and

TABLE 47-1. Activities of Some Red Cell Enzymes

Enzyme	Activity at 37°C IU/g Hgb (mean ± SD)
Acetylcholinesterase	36.93 ± 3.83
Adenosine deaminase	1.11 ± 0.23
Adenylate kinase	258 ± 29.3
Aldolase	3.19 ± 0.86
Bisphosphoglyceromutase	4.78 ± 0.65
Catalase	153,117 ± 2390
Enolase	5.39 ± 0.83
Galactokinase	0.0291 ± 0.004
Galactose-4-epimerase	0.231 ± 0.061
Glucose phosphate isomerase	60.8 ± 11.0
Glucose-6-phosphate dehydrogenase	8.34 ± 1.59
γ-Glutamylcysteine synthetase	1.05 ± 0.19
Glutathione peroxidase*	30.82 ± 4.65
Glutathione reductase without FAD	7.18 ± 1.09
Glutathione reductase with FAD	10.4 ± 1.50
Glutathione-S-transferase	6.66 ± 1.81
Glutathione synthetase	0.34 ± 0.06
Glyceraldehyde phosphate dehydrogenase	226 ± 41.9
Hexokinase	1.78 ± 0.38
Lactate dehydrogenase	200 ± 26.5
Monophosphoglyceromutase	37.71 ± 5.56
NADH-methemoglobin reductase	19.2 ± 3.85(30°)
NADPH diaphorase	2.26 ± 0.16
Nucleoside phosphorylase	359 ± 32
Phosphofructokinase	11.01 ± 2.33
Phosphoglucomutase	5.50 ± 0.62
Phosphoglycerate kinase	320 ± 36.1
Phosphoglycolate phosphatase	1.23 ± 0.10
Phosphomannose isomerase	0.054 ± 0.026
Pyrimidine 5'-nucleotidase	0.138 ± 0.018
Pyruvate kinase	15.0 ± 1.99

hence a citric acid cycle. Only the reticulocytes maintain some capacity for the breakdown of pyruvate to CO₂, with the attendant highly efficient production of ATP. The mature red cell extracts energy from glucose almost solely by anaerobic glycolysis. Before glucose can be metabolized by the red cell, it must pass through the membrane. Transport into the interior of the cell is facilitated by glucose transporter 1 receptor GLUT1, and perhaps regulated by the abundantly expressed membrane protein stomatin; however, the function of this protein is not fully defined.³⁴ In humans, and other mammals that have lost the ability to synthesize ascorbic acid from glucose, GLUT1 also facilitates transport of L-dehydroascorbic acid.³⁴ The red cell membrane contains insulin receptors, but the transport of glucose into red cells is independent of insulin.

Pathways of Glucose Metabolism Direct glycolytic pathway. In the Embden-Meyerhof direct glycolytic pathway (EMP; Fig. 47-2), glucose is catabolized anaerobically to pyruvate or lactate. Although 2 moles of high-energy phosphate in the form of ATP are used in preparing glucose for its further metabolism, up to 4 moles of adenosine diphosphate (ADP) may be phosphorylated to ATP during the metabolism of each mole of glucose, giving a net yield of 2 moles of ATP per mole of glucose metabolized. The rate of glucose utilization is limited largely by the hexokinase and PFK reactions. Both of the enzymes catalyzing these reactions have a relatively high pH optimum and have very little activity at pH levels lower than 7. For this reason, red cell glycolysis is very pH sensitive, being stimulated by a rise in pH. However, at higher than physiologic pH levels, the stimulation of hexokinase and phosphofructokinase activity merely results in the accumulation of fructose diphosphate and triosephosphates, because the availability of nicotinamide adenine dinucleotide (NAD)⁺ for the glyceraldehyde phosphate dehydrogenase (GAPDH) reaction becomes a limiting factor.

Branching of the metabolic stream after the formation of 1,3-bisphosphoglycerate (1,3-BPG) provides the red cell with flexibility in regard to the amount of ATP formed in the metabolism of each mole of glucose. 1,3-BPG may be metabolized to 2,3-bisphosphoglycerate (2,3-BPG), also known as 2,3-diphosphoglycerate (2,3-DPG), thus “wasting” the high-energy phosphate bond in position 1 of the glycerate. Removing the phosphate group at position 2 by bisphosphoglycerate phosphatase results in the formation of 3-phosphoglycerate. Both reactions in this unique glycolytic bypass, known as the *Rapoport-Luebering shunt*, are catalyzed by the erythroid-specific multifunctional enzyme bisphosphoglycerate mutase.³⁵ In mammalian erythrocytes, a separate 2,3-BPG phosphatase activity has been ascribed to multiple inositol polyphosphate phosphatase.³⁶ In contrast to bisphosphoglycerate mutase, multiple inositol polyphosphate phosphatase-1 is able to remove the phosphate at position 3, thereby bypassing the formation of 3-phosphoglycerate. The precise functional significance of multiple inositol polyphosphate phosphatase-1 for human red cell physiology and regulation of 2,3-BPG levels remains to be established.

3-Phosphoglycerate may also be formed directly from 1,3-BPG through the PGK step, resulting in phosphorylation of 1 mole of ADP to ATP. Although metabolism of glucose through the 2,3-BPG step occurs without any net gain of high-energy phosphate bonds in the form of ATP, metabolism through the PGK step results in the formation of two such bonds per mole of glucose metabolized. This portion of the direct glycolytic pathway has been called the *energy clutch*. Regulation of metabolism at this branch point determines not only the rate of ADP phosphorylation to ATP but also the concentration of 2,3-BPG, an important regulator of the oxygen affinity of hemoglobin (Chaps. 49 and 57). The concentration of 2,3-BPG depends on the balance between its rate of formation and degradation by bisphosphoglycerate mutase. Hydrogen ions inhibit the bisphosphoglycerate mutase reaction and stimulate the phosphatase reaction. Thus, red cell 2,3-BPG levels are

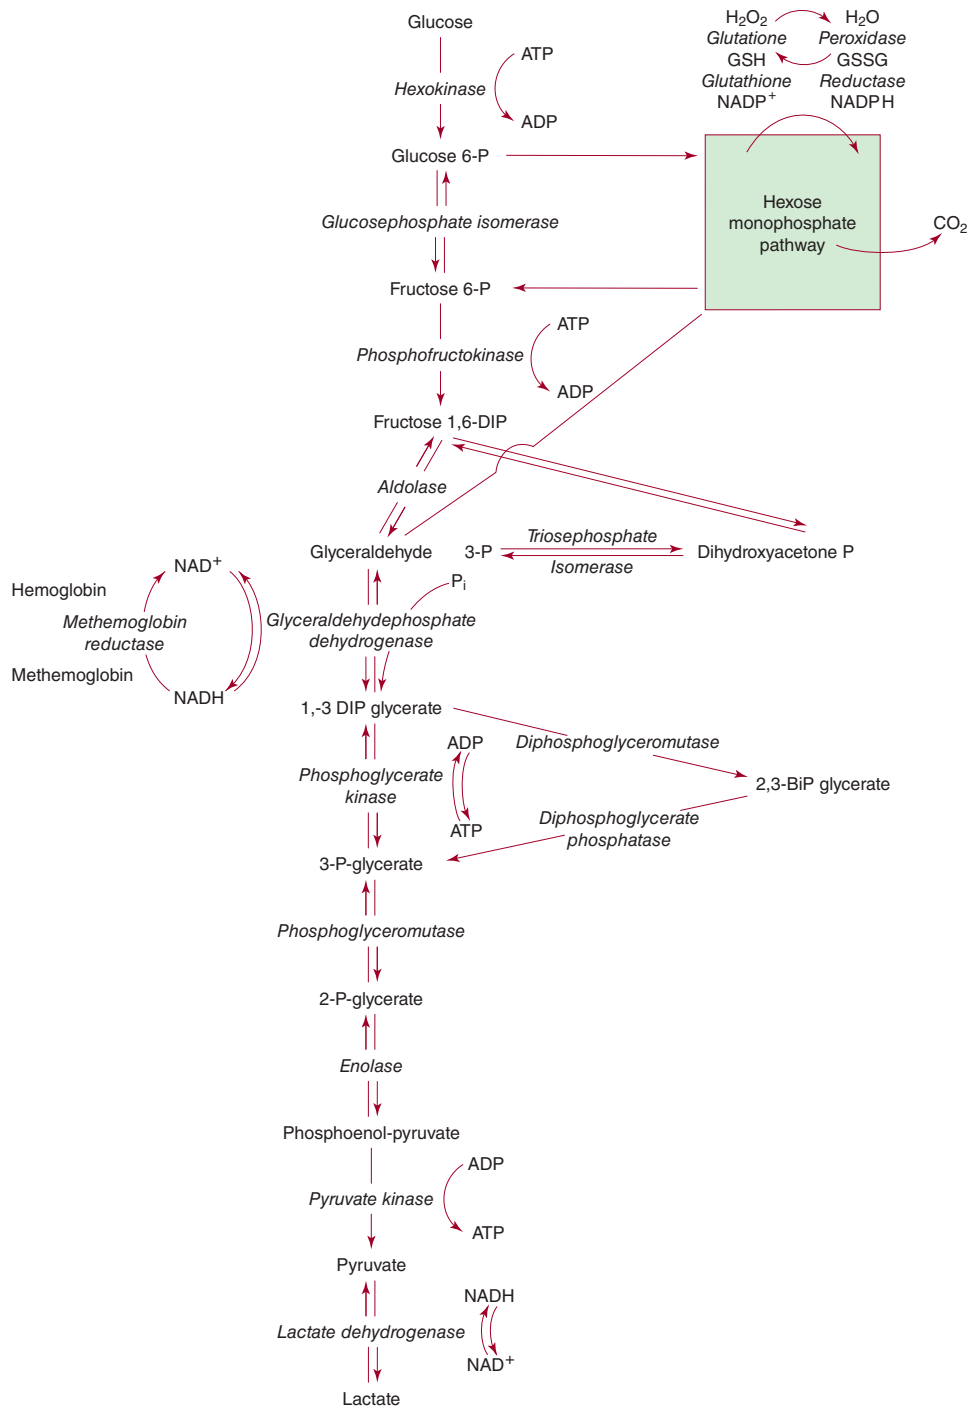

Figure 47-2. Glucose metabolism of the erythrocyte. The details of the hexose monophosphate pathway are shown in Fig. 47-3.

exquisitely sensitive to pH: a rise in pH causes a rise in 2,3-BPG levels, whereas acidosis results in 2,3-BPG depletion. It may be that the ratio of oxyhemoglobin to deoxyhemoglobin also influences 2,3-BPG synthesis by virtue of the fact that only deoxyhemoglobin binds this compound, thus affecting the concentration of free 2,3-BPG that is available for feedback inhibition of the enzymes that lead to its formation. However, the available evidence suggests that the pH is the primary controlling factor.

Metabolism of glucose by way of the EMP may also yield reducing energy in the form of the reduced form of NAD (NADH). The reduction of NAD⁺ to NADH occurs in the GAPDH step. If NADH is reoxidized

in reducing methemoglobin to hemoglobin, the end product of glucose metabolism is pyruvate. If NADH is not reoxidized by methemoglobin, however, pyruvate is reduced in the lactate dehydrogenase (LDH) step, forming lactate as the final end product of glucose metabolism. The lactate or pyruvate formed is transported from the red cell and is metabolized elsewhere in the body. Thus, the erythrocyte has a flexible EMP that can adjust the amount of ADP phosphorylated per mole of glucose according to the requirement of the cell.

The regulation of red cell glycolytic metabolism is very complex. Products of some reactions may stimulate others. For example, the PK

reaction is exquisitely sensitive to fructose 1,6-diphosphate, the product of PFK. Conversely, other metabolic products may serve as strong enzyme inhibitors. In addition, there is increasing evidence that glycolytic enzymes assemble into enzyme complexes to the interior of the red cell membrane.³⁷ The assembly of these complexes seems to be regulated by the oxygen status of hemoglobin and the phosphorylation status of band 3,^{37,38} suggesting they play a direct role in the regulation of oxygen-dependent changes in glycolytic and pentose shunt fluxes.³⁹

Notably, a number of glycolytic enzymes show additional functional activities. For instance, in addition to its role in glycolysis, glucosephosphate isomerase also functions as a neuroleukin or autocrine motility factor. Another example is enolase, that has been reported to also function as plasminogen receptor.^{40,41} The additional functional activities of these “moonlighting” enzymes could contribute to the complexity of the phenotype of the associated disorder.

Hexose Monophosphate Shunt Not all the glucose metabolized by the red cell passes through the direct glycolytic pathway. A direct oxidative pathway of metabolism, the hexose monophosphate shunt, also functions. In this pathway, glucose-6-phosphate is oxidized at position 1, yielding carbon dioxide. In the process of glucose oxidation, NADP⁺ is reduced to NADPH (reduced NAD phosphate). The pentose phosphate formed when glucose is decarboxylated undergoes a series of molecular rearrangements, eventuating in the formation of a triose, glyceraldehyde-3-phosphate, and a hexose, fructose-6-phosphate (Fig. 47-3). These are normal intermediates in anaerobic glycolysis and thus can rejoin that metabolic stream. Because the glucose phosphate isomerase reaction is freely reversible, allowing fructose-6-phosphate to be converted to glucose-6-phosphate, recycling through the hexose monophosphate pathway is also possible. Unlike the anaerobic glycolytic pathway, the hexose monophosphate pathway does not generate any high-energy phosphate bonds. Its primary function appears to be the formation of NADPH, and, indeed, the amount of glucose passing through this pathway appears to be regulated by the amount of NADP⁺

Figure 47-3. Hexose monophosphate pathway of the erythrocyte: (1) glucose-6-phosphate dehydrogenase, (2) glutathione reductase, (3) phosphogluconate dehydrogenase, (4) ribulose-phosphate epimerase, (5) ribosephosphate isomerase, (6) transketolase, and (7) transaldolase.

that has been made available by the oxidation of NADPH. NADPH appears to function primarily as a substrate for the reduction of glutathione-containing disulfides in the erythrocyte through mediation of the enzyme glutathione reductase, which catalyzes the conversion of oxidized glutathione (GSSG) to reduced glutathione (GSH) and the reduction of mixed disulfides of hemoglobin and GSH.⁴²

Enzymes of Glucose Metabolism

Hexokinase Hexokinase catalyzes the phosphorylation of glucose in position 6 by ATP. It thus serves as the first step in the utilization of glucose, whether by the anaerobic or the hexose monophosphate pathway. Mannose or fructose may also serve as a substrate for this enzyme. Hexokinase is the glycolytic enzyme with the lowest activity. Reticulocytes have much higher levels of hexokinase activity than do mature red cells.^{43,44}

Hexokinase has an absolute requirement for magnesium. It is strongly inhibited by its product, glucose-6-phosphate, and is released from this inhibition by the inorganic phosphate ion^{45,46} and by high concentrations of glucose.⁴⁷ Inorganic phosphate enhances the rate of glucose utilization by red cells. This effect is not exerted through hexokinase but through stimulation of the PFK reaction, resulting in a lowered glucose-6-phosphate concentration within the cell and thus releasing hexokinase from inhibition.⁴⁸ GSSG⁴⁹ and other disulfides, as well as 2,3-BPG,⁵⁰ inhibit hexokinase. The determination of the structures of the human and rat hexokinase isozymes have provided substantial insight into ligand-binding sites and subsequent modes of interaction of these ligands.^{51,52}

The two major fractions of red cell hexokinase (HK) have been designated HK_I and HK_R; the latter fraction being unique to erythrocytes and particularly to reticulocytes.⁵³ Both red cell isozymes are monomers and produced from the hexokinase I gene (*HK1*),⁵⁴ with an apparent molecular weight of 112 kDa.⁵⁵ The *HK1* gene is localized on chromosome 10q22 and spans more than 100 kb. It contains 29 exons,^{56,57} which, by tissue-specific transcription, generate multiple transcripts by alternative use of the 5' exons.^{57,58} Erythroid-specific transcriptional control results in a unique red blood cell-specific mRNA that differs from HK_I transcripts at the 5' end. Consequently, HK_R lacks the porin-binding domain that mediates HK_I binding to mitochondria.⁵⁹ A single nucleotide polymorphism (SNP) in the first intron of HK_R was found to be strongly associated with reduced hemoglobin and hematocrit levels in the European population.⁶⁰ HK deficiency is a rare cause of hereditary nonspherocytic hemolytic anemia.

Glucose Phosphate Isomerase Glucose phosphate isomerase (GPI) catalyzes the interconversion of glucose-6-phosphate and fructose-6-phosphate, the second step of the EMP. The crystal structure of human GPI has been resolved. The enzyme is a homodimer, composed of two subunits of 63 kDa each. The enzyme's active site is composed of polypeptide chains from both subunits, making the dimeric form essential for catalytic activity.⁶¹ Residues that are not in direct contact with the reacting substrate molecule have also been implicated as important for catalytic function of GPI.⁶² The gene encoding GPI (*GPI*) is located on chromosome 19q13.1 and consists of 18 exons, spanning at least 50 kb, with a complementary DNA (cDNA) of 1.9 kb in length.⁶³ GPI deficiency is one of the relatively more common causes of hereditary nonspherocytic hemolytic anemia.

Phosphofructokinase PFK catalyzes the rate-limiting phosphorylation of fructose-6-phosphate by ATP to fructose-1,6-diphosphate. Under intracellular conditions this reaction is nearly irreversible. Therefore PFK is an important regulator of glycolytic flux. The enzyme has a molecular mass of around 340 kDa. Red cell phosphofructokinase exists as five different homo- or heterotetramers comprised of muscle (M) and liver (L) subunits. Each tetramer displays unique properties with respect to catalytic function and regulation. The enzyme requires magnesium

for activity. PFK activity is tightly controlled and subject to regulation by many metabolic effectors. Among the most important activators are ADP, cyclic adenosine monophosphate (cAMP), and fructose-2,6-diphosphate, whereas PFK is inhibited by its substrate ATP, citrate, and lactate.^{64,65} These metabolic effectors exert their effects probably by stabilizing either the minimally active dimeric and fully active tetrameric form of PFK.⁶⁶ PFK activity is also regulated by its binding to calmodulin,⁶⁷ and association of the enzyme with the red cell membrane⁶⁸; in particular, binding to band 3^{69,70} and actin⁷¹ appears to inhibit and stimulate PFK activity, respectively.

A preliminary crystallographic analysis of dimeric wild-type human muscle PFK has been presented.⁷² The gene encoding the 85-kDa M subunit (*PFKM*) is located on chromosome 12q13.3 and spans 30 kb. It contains 27 exons and at least three promoter regions.⁷³ The 80-kDa L-subunit encoding gene (*PFKL*) is located on chromosome 21q22.3; it contains 22 exons and spans more than 28 kb.⁷⁴ Deficiency of PFK is associated with mild hemolytic anemia and with type VII glycogen storage disease (Tarui disease).⁷⁵

Aldolase Aldolase reversibly cleaves fructose-1,6-diphosphate into two trioses. The “upper” half of the fructose-1,6-diphosphate molecule becomes dihydroxyacetone phosphate and the “lower” half becomes glyceraldehyde-3-phosphate. Aldolase is a 159-kDa homotetrameric enzyme comprised of subunits of 40 kDa each.⁷⁶ Three distinct isoenzymes have been identified: aldolase A, B, and C. The 364-amino-acids-long aldolase A subunits are primarily expressed in erythrocytes and muscle cells.⁷⁷ The structure of human aldolase A is known.⁷⁸ Red cell aldolase binds to F-actin⁷⁹ and the N-terminal part of band 3,⁸⁰ which inhibits its activity.⁷⁰ The gene for aldolase A (*ALDOA*) is located on chromosome 16q22–24. It spans 7.5 kb and consists of 12 exons. Several transcription-initiation sites were identified and *ALDOA* pre-mRNA is spliced in a tissue-specific manner.⁸¹ Aldolase deficiency is a very rare cause of hereditary nonspherocytic hemolytic anemia.

Triosephosphate Isomerase TPI is the enzyme of the anaerobic glycolytic pathway that has the highest activity. Its metabolic role is to catalyze interconversion of the two trioses formed by the action of aldolase: dihydroxyacetone phosphate and glyceraldehyde-3-phosphate.⁸² Although equilibrium is in favor of dihydroxyacetone phosphate, glyceraldehyde-3-phosphate undergoes continued oxidation through the action of GAPDH and is thus removed from the equilibrium. TPI is a dimer consisting of two identical 27-kDa subunits of 248 amino acids.⁸³ Several crystal structures have been resolved.^{84,85} These show that the active site is at the dimer interface and a number of critical residues have been identified. Several water molecules, some of which are highly conserved, are an integral part of the dimer interface. There are no isoenzymes known, but three distinct electrophoretic forms can be distinguished as a result of posttranslational modifications.⁸⁶ Red blood cell TPI activity is not red-cell-age dependent. TPI is transcribed from a single gene (*TPI1*), located on chromosome 12p13. The gene spans 3.5 kb and contains 7 exons. Three processed pseudogenes have been identified.⁸⁷ A deficiency of TPI causes hereditary nonspherocytic hemolytic anemia and a severe neuromuscular disorder.

Glyceraldehyde Phosphate Dehydrogenase GAPDH performs the dual functions of oxidizing and phosphorylating glyceraldehyde-3-phosphate, producing 1,3-BPG. In the process, NAD⁺ is reduced to NADH. This enzyme is closely associated with the red cell membrane⁸⁸ where it binds to the N-terminal part of band 3.⁷⁰ Membrane binding influences the activity of GAPDH⁸⁹ thereby possibly regulating glycolytic flux.⁹⁰ Human red blood cell GAPDH has been purified. It is a homotetramer of approximately 150 kDa, composed of 36-kDa subunits, and shows an absolute specificity for NAD⁺.⁹¹ One of the many nonglycolytic functions of GAPDH^{40,41} may include its function as a transferrin receptor.⁹² The crystal structure of human liver GAPDH

reveals a homotetramer, each subunit of which is bound to a NAD⁺ molecule.⁹³ Deficiency of GAPDH seems a rare occurrence without functional consequences.⁹⁴

Phosphoglycerate Kinase PGK effects the transfer to ADP of the high-energy phosphate from the 1-carbon of 1,3-diphosphoglycerate (1,3-DPG) to form ATP. The reaction is readily reversible and can be bypassed by the Rapoport-Luebering shunt. The isoenzyme PGK-1 is ubiquitously expressed in all somatic cells and is a 48-kDa monomeric enzyme of 417 amino acids.⁹⁵ Expression of isozyme PGK-2 has been found in testis.⁹⁶ PGK is composed of two domains. The N-terminal domain binds 3-phosphoglycerate and 1,3-DPG, whereas ADP and ATP bind to the C-terminal domain. For catalysis to occur, the protein needs to undergo a large conformational change (“hinge bending”).^{97–99} The gene encoding PGK (*PGK-1*) is located on the long arm of the X-chromosome (Xq13), spans 23 kb, and is composed of 11 exons. Nonfunctional pseudogenes have been located on chromosome 19 and the X-chromosome.⁹⁶ Deficiency of PGK is a rare cause of nonspherocytic hemolytic anemia, often associated with neuromuscular abnormalities.

Bisphosphoglycerate Mutase The same protein molecule is responsible for both bisphosphoglycerate mutase and bisphosphoglycerate phosphatase activities in the erythrocyte.^{35,100} This enzyme is particularly important because it regulates the concentration of 2,3-BPG of erythrocytes. In its role as a bisphosphoglyceromutase, the enzyme competes with PGK for 1,3-BPG as a substrate. It changes 1,3-BPG to 2,3-BPG, thereby dissipating the energy of the high-energy acylphosphate bond.¹⁰¹ It is inhibited by its product 2,3-BPG and by inorganic phosphate, and it is activated by 2-phosphoglycerate and by increased pH levels. It requires 3-phosphoglycerate for activity. In its role as bisphosphoglycerate phosphatase it catalyzes the removal of the phosphate group from carbon 2 of 2,3-BPG.¹⁰¹ It is inhibited by its product 3-phosphoglycerate and by sulfhydryl reagents. It is most active at a slightly acid pH and is strongly stimulated by bisulfite and phosphoglycolate. Phosphoglycolate, the most potent activator of phosphatase activity, is present in erythrocytes at very low concentrations,¹⁰² but the source of this substance in red cells is unknown.^{103,104} Phosphoglycolate phosphatase, the enzyme that hydrolyzes phosphoglycolate, has also been identified in erythrocytes.¹⁰⁵

Bisphosphoglycerate mutase is a homodimer, with 30-kDa subunits consisting of 258 amino acids. The crystal structure of human bisphosphoglycerate mutase has been determined, providing a rationale for the specific residues that are crucial for synthase, mutase, and phosphatase activity.^{106,107} The gene for bisphosphoglycerate mutase (*BPGM*) has been mapped to chromosome 7q31–34 and it consists of 3 exons, spanning more than 22 kb.

A deficiency of bisphosphoglycerate mutase results in a marked decrease in red cell 2,3-BPG levels. The consequent left shift of the oxygen dissociation curve leads to erythrocytosis/polycythemia (Chap. 57).

Phosphoglycerate Mutase An equilibrium is established between 3-phosphoglycerate and 2-phosphoglycerate by phosphoglycerate mutase.¹⁰⁸ 2,3-BPG acts as an essential cofactor for the transformation. Red blood cell phosphoglycerate mutase is a heterodimer consisting of M and B subunits, encoded by separate genes.¹⁰⁹ Only one well-characterized patient with partial red blood cell monophosphoglycerate mutase deficiency has been described who was homozygous for a p.Met230Ile amino acid change in the B subunit.¹¹⁰ The mutant enzyme was unstable and thus had a short half-life.¹¹¹ Unexpectedly, all glycolytic intermediates were decreased, possibly because of lactate accumulation.¹¹² The exact clinical consequences of this red blood cell enzymopathy remain to be established.

Enolase Enolase is a homodimeric enzyme that establishes an equilibrium between 2-phosphoglycerate and phosphoenolpyruvate.

The reaction is facilitated by the presence of metal ions.¹¹³ Aside from its enzymatic function in the glycolytic pathway, α -enolase (ENO1) has been implicated in numerous diseases, including metastatic cancer, autoimmune disorders, ischemia, and bacterial infection.¹¹⁴ The gene for enolase (*ENO1*) is located on chromosome 1p36.23. Enolase deficiency is extremely rare. Although it has been reported in association with hereditary nonspherocytic hemolytic anemia,^{115,116} a clear cause-and-effect relationship has not yet been firmly established.

Pyruvate Kinase The transfer of phosphate from phosphoenolpyruvate to ADP, forming ATP and pyruvate, is catalyzed by the allosteric enzyme PK. This is the second energy-yielding step of glycolysis. Four PK isoenzymes are present in mammalian tissues: PK-M1 (in skeletal muscle), PK-M2 (in leukocytes, kidney, adipose tissue, and lungs), PK-L (in liver), and PK-R (in red blood cells). The four PK isoenzymes are products of only two genes (*PKLR* and *PKM2*). The PK-M1 and PK-M2 enzymes are formed from the *PKM2* gene by alternative splicing.¹¹⁷ PK-L (the liver enzyme) and PK-R (the erythrocyte enzyme) are products of the *PKLR* gene, transcribed from two different, tissue-specific promoters.^{118,119} There is evidence that other, yet unknown, regulatory elements are involved in *PKLR* gene expression.¹²⁰ *PKLR* consists of 12 exons and spans more than 10 kb. Exon 2, but not exon 1, is present in the processed liver transcript; in the red cell enzyme exon 1, but not exon 2, is represented.¹¹⁹ The red blood cell-specific mRNA is 2 kb in length and codes for a full-length 63-kDa PK-R subunit of 574 amino acids.¹²¹ Red blood cell PK is a heterotetramer comprised of two 62- to 63-kDa and two 57- to 58-kDa subunits, the latter resulting from limited proteolytic cleavage of the full-length subunit.^{122,123} Each subunit of PK-R contains an N domain, A domain, B domain, and C domain (Fig. 47-4).¹²⁴ Domain A is the most highly conserved, whereas the B and C domains are more variable.¹²⁵ The functional role of the N domain is unknown, but it may play a role in enzyme regulation.^{126,127} The active site of PK lies in a cleft between the A domain and the flexible B domain. The C domain contains the binding site for fructose-1,6-diphosphate.

Both intra- and intersubunit interactions are considered to be key determinants of the allosteric response, which involves switching of the PK tetramer from the low-affinity T state to the high-affinity R state.¹²⁸⁻¹³² Red cell PK manifests sigmoid kinetics with respect to phosphoenolpyruvate in the absence of fructose-1,6-diphosphate. Hyperbolic kinetics are observed in the presence of even minute amounts of fructose-1,6-diphosphate,^{122,133} so that at low concentrations of phosphoenolpyruvate the enzyme activity is greatly increased by fructose diphosphate. PK deficiency is the most common cause of hereditary nonspherocytic hemolytic anemia.

Lactate Dehydrogenase LDH catalyzes the reversible reduction of pyruvate to lactate by NADH, the last step in the EMP. The enzyme is composed of H (heart) and M (muscle) subunits. In red cells, the predominant subunit is H. Hereditary absence of the H subunit seems to be a benign condition, usually without clinical manifestations,^{134,135} although one case with hemolysis has been reported.¹³⁶ Absence of the M subunit has been reported as well,¹³⁷ and was unaccompanied by hematologic manifestations. Judging from the origin of the reports, LDH deficiency appears to be most common in Japan, where population surveys show a gene frequency of approximately 0.05 for each deficiency, and several mutations have been identified.¹³⁸

Glucose-6-Phosphate Dehydrogenase G6PD is the most extensively studied erythrocyte enzyme. It catalyzes the oxidation of glucose-6-phosphate to 6-phosphogluconolactone, which is rapidly hydrolyzed to 6-phosphogluconic acid, in the first step of the hexose monophosphate pathway. NADP⁺ is reduced to NADPH in this reaction, generating 1 mole of NADPH. In the erythrocyte, the hexose monophosphate pathway is the only source of NADPH, which is crucial in maintaining high cellular levels of GSH to protect the cell from oxidative stress-induced damage.

The G6PD monomer is composed of 515 amino acids with a calculated molecular weight of approximately 59 kDa.¹³⁹ Aggregation of these inactive monomers into catalytically active dimers and higher forms

Figure 47-4. Ribbon representation of the human erythrocyte pyruvate kinase tetramer. The substrate phosphoglycolate and fructose-1,6-diphosphate are shown in ball-and-stick representation, and colored yellow and gray, respectively. Metal ions in the active site are shown as blue (potassium) and pink (manganese) spheres. Individual subunits are colored lime, cyan, violet, and orange.

requires the presence of NADP⁺ (Fig. 47-5).¹⁴⁰ Hence, NADP⁺ is bound to the enzyme both as a structural component, in the subunit interface, and as one of the substrates of the reaction.¹⁴¹⁻¹⁴³ Under physiologic conditions, the active human enzyme exists in a dimer-tetramer equilibrium. Lowering the pH causes a shift toward the tetrameric form.^{141,144,145}

G6PD is strongly inhibited by physiologic amounts of NADPH¹⁴⁶ and, to a lesser extent, by physiologic concentrations of ATP.¹⁴⁷ It has much higher enzyme-activity in reticulocytes than in mature red cells, especially for the mutant forms of the enzyme.^{43,148} This may complicate diagnosing G6PD deficiency in patients with high reticulocyte counts following a hemolytic episode (see “Laboratory Features” below).

The three-dimensional model of the crystal structure of human G6PD shows that the G6PD monomer is built up by two domains, a N-terminal domain and a large $\beta + \alpha$ domain with an antiparallel nine-stranded sheet. The extensive interface between the two monomers is of crucial importance for enzymatic stability and activity.¹⁴³ The fully conserved amino acids 198 to 205 (Arg-Ile-Asp-His-Tyr-Leu-Gly-Lys) are essential for substrate binding and catalysis.^{143,149-151}

The *G6PD* gene is located on the X-chromosome (Xq28). It spans 18 kb, and consists of 13 exons of which exon 1 is noncoding. Methylation of certain cytidines at the 3' end is believed to have a regulatory function.^{152,153} The 3'-UTR (untranslated region) also harbors putative microRNA (miRNA) target sites, which potentially could have a functional effect on the downregulation of *G6PD* mRNA, thereby affecting the stability of *G6PD* mRNA and translation, or the miRNA regulation process.¹⁵⁴ G6PD deficiency is one of the world's most common hereditary disorders. Many mutations and variants have been reported and studied.^{1,2,155-160}

Phosphogluconolactonase Although 6-phosphogluconolactone is the direct product of the oxidation of glucose-6-phosphate by G6PD and hydrolyzes spontaneously at a physiologic pH, enzymatic hydrolysis is much more rapid and is required for normal metabolic flow through the stimulated hexose monophosphate pathway.^{161,162} Partial deficiency of the enzyme has been observed¹⁶³ and is probably benign.¹⁶⁴

Phosphogluconate Dehydrogenase Phosphogluconate dehydrogenase catalyzes the oxidation of phosphogluconate to ribulose-5-phosphate and CO₂ and the reduction of NADP⁺ to NADPH. Variability of electrophoretic mobility of the enzyme is common in humans and in several animal species.¹⁶⁵ Deficiency of the enzyme has been observed only rarely and appears to be essentially innocuous or possibly associated with mild hemolysis.¹⁶⁶⁻¹⁶⁸

Ribosephosphate Isomerase Ribosephosphate isomerase catalyzes the interconversion of ribulose-5-phosphate and ribose-5-phosphate.

Deficiency of the enzyme has been described as one of the rarest human disorders.¹⁶⁹ It manifests with progressive leukoencephalopathy and neuropathy. No dysfunction of red cells was reported.¹⁷⁰

Ribulose-Phosphate Epimerase Ribulose-phosphate epimerase converts ribulose-5-phosphate to xylulose-5-phosphate. The exact activity of this enzyme in human hemolysates has not been reported but seems to be less than that of ribosephosphate isomerase.

Transketolase Transketolase effects the transfer of two carbon atoms from xylulose-5-phosphate to ribose-5-phosphate, resulting in the formation of the 7-carbon sugar sedoheptulose-7-phosphate and the 3-carbon sugar glyceraldehyde-3-phosphate.¹⁷¹⁻¹⁷³ It can also catalyze the reaction between xylulose-5-phosphate and erythrose-4-phosphate, producing fructose-6-phosphate and glyceraldehyde-3-phosphate. Thiamine pyrophosphate is a coenzyme for transketolase, and the activity of erythrocyte transketolase is used as an index of the adequacy of thiamine nutrition.¹⁷⁴

Transaldolase The conversion of sedoheptulose-7-phosphate and glyceraldehyde-3-phosphate into erythrose-4-phosphate and fructose-6-phosphate is catalyzed by transaldolase.¹⁷⁵ This is another one in the series of molecular rearrangements that leads in the conversion of the 5-carbon sugar formed in the phosphogluconate dehydrogenase step to metabolic intermediates of the EMP. Transaldolase deficiency was first reported in 2001 as a new inborn error of the pentose phosphate pathway.¹⁷⁶ To date, 23 patients from 13 families have been described.^{177,178} It is a pleiotropic metabolic disorder, and patients present in the neonatal or antenatal period with dysmorphic features, hepatosplenomegaly, abnormal liver function, cardiac defects, thrombocytopenia, bleeding tendencies, and anemia. The latter appears to be hemolytic in nature, possibly because of decreased levels of NADPH.^{179,180}

L-Hexonate Dehydrogenase Red cells contain L-hexonate dehydrogenase, an enzyme that has the capacity to reduce aldoses such as glucose, galactose, or glyceraldehyde to their corresponding polyol (i.e., glucose to sorbitol, galactose to dulcitol, and glyceraldehyde to glycerol). NADPH serves as a hydrogen donor for this reaction.¹⁸¹ Aldose reductase is another enzyme that can catalyze this reaction. It is present in red cells,¹⁸² and increased levels have been implicated in diabetic complications, such as retinopathy¹⁸³ and autonomic neuropathy.¹⁸⁴

Utilization of Substrates Other Than Glucose as Energy Sources

The red cell has the capacity to use several other substrates in addition to glucose as a source of energy. Among these are adenosine, inosine, fructose, mannose, galactose, dihydroxyacetone, and lactate.¹⁸⁵ Although in

Figure 47-5. A dimer of human glucose-6-phosphate dehydrogenase. Subunits A and B are colored red and blue. Structural nicotinamide adenine dinucleotide phosphate (NADP⁺) molecules are drawn in ball-and-stick mode and colored dark blue.

the circulation red cells normally rely on glucose as their energy source, the use of other substrates, particularly during blood storage (Chap. 138) and in certain experimental situations, is of interest.

Glutathione Metabolism of the Erythrocyte The red cell contains a high concentration of the sulfhydryl-containing tripeptide GSH. It serves a major role in antioxidant defense, detoxification, and maintenance of thiol status. Reported concentrations range between 0.4 and 3.0 mM, with a terminal half-life ($T_{1/2}$) of approximately 4 days.¹⁸⁷ The wide interindividual range suggests that GSH levels are, at least in part, genetically determined.¹⁸⁸ In its role of defense against oxidative stress GSH is oxidized to glutathione disulfide (GSSG), which can be reverted back to GSH by mediation of glutathione reductase. In addition GSSG can be transported out of the cell.

Glutathione biosynthesis occurs in two ATP-dependent steps:

The first step is rate limiting and catalyzed by glutamate cysteine ligase (GCL) (γ -glutamylcysteine synthetase). Feedback inhibition of GCL by GSH is commonly considered a key regulatory step in GSH homeostasis, but other pathways are likely to play a role in maintaining GSH levels.¹⁸⁹ GCL is a heterodimer composed of a catalytic 73-kDa catalytic subunit (GCLC) and a 31-kDa modifier subunit (GCLM).^{190,191} An intersubunit disulfide bond has been implicated in stabilization and catalytic efficiency of the heterodimer, acting as a cellular redox switch to couple enzyme activity, and consequently GSH levels, with the reduction-oxidation (redox) state of the cell.^{192,193} An alternative model suggests that increased levels of oxidative stress induce the formation of high activity heterodimer complexes from low activity monomeric and holoenzyme forms of the enzyme.¹⁹⁴ GCL subunits are encoded by separate genes, located on chromosome 6p12 (*GCLC*) and 1p22.1 (*GCLM*), respectively. *GCLC* contains 16 exons, encoding for the 637-amino-acids catalytic subunit, whereas *GCLM* contains 7 exons that encode the 274 amino acids of the modifier subunit. A trinucleotide repeat polymorphism in the 5'-UTR affects *GCLC* gene expression and is associated with alterations in GCL activity and GSH levels.¹⁹⁵ GCL deficiency is a very rare cause of hemolytic anemia.

The second step in GSH synthesis is irreversible and mediated by glutathione synthetase (GS). This enzyme is a homodimer composed of 52-kDa subunits,¹⁹⁶ and the crystal structure of human GS has been resolved.¹⁹⁷ There is one gene coding for GS. This 23-kb gene (*GSS*) is located on chromosome 20q11.2 and contains 13 exons, of which the first is noncoding, that code for the 474-amino-acids-long protein. Deficiency of GS is the most common disorder of GSH synthesis and is associated with hemolytic anemia.

One important function of GSH in the erythrocyte is the detoxification of low levels of hydrogen peroxide that may form spontaneously or as a result of drug administration. Hydrogen peroxide is reduced to water through mediation of the enzyme glutathione peroxidase,¹⁹⁸ thereby oxidizing GSH to GSSG (see Fig. 47-7). Several glutathione peroxidases exist but only type 1 appears to be expressed in red blood cells.¹⁹⁹ Glutathione peroxidase is a selenium-containing²⁰⁰ tetrameric enzyme consisting of 21-kDa subunits. A polymorphism affecting the activity of this enzyme, which is most common in persons of Mediterranean descent,²⁰¹ has been described. The consequent decreases in enzyme activity are without clinical effect.²⁰² In agreement with this, complete loss of glutathione peroxidase activity in mice was found to be without any consequences, even at high levels of oxidative stress, thus suggesting that glutathione peroxidase is of minor significance for red cell function.¹⁹⁹

GSH also functions in maintaining integrity of the erythrocyte by reducing sulfhydryl groups of membrane proteins,²⁰³ and glycolytic

enzymes,²⁰⁴ for example, PK.²⁰⁵ In the process of reducing peroxides or oxidized protein sulfhydryl groups, GSH is converted to GSSG, or may form mixed disulfides. Thus, for instance, GSSG has the capacity to inhibit red cell HK,^{49,206} although greater than physiologic levels may be needed for this effect. It may also complex with hemoglobin A to form hemoglobin A₃.²⁰⁷

Glutathione reductase (GR) provides an efficient mechanism for the reduction of GSSG to regenerate GSH, and thus maintaining high intracellular levels of GSH. A mitochondrial and a cytoplasmic isozyme are both produced from the same mRNA, most likely by alternative initiation of translation.²⁰⁸ GR is a homodimer, linked by a disulfide bridge. Each 56-kDa subunit contains four domains, of which domains 1 and 2 bind FAD (flavin adenine dinucleotide) and NADPH, respectively, with domain 4 constituting the interface.²⁰⁹ The protein is encoded by the *GR* gene, located on chromosome 8p21.1. *GR* spans 50 kb, contains 13 exons, and encodes a 522-amino-acids-long protein. GR is a flavin enzyme, and either NADPH or NADH may serve as a hydrogen donor.²¹⁰ In the intact cell, only the NADPH system appears to function.²¹¹ The same enzyme system appears to have the capacity to reduce mixed disulfides of GSH and proteins.⁴² The activity of red cell GR is strongly influenced by the riboflavin content of the diet,²¹² and its activity is used as a biomarker for riboflavin status.²¹³ Correction of partial GR deficiency by riboflavin administration has been reported to ameliorate hemolysis in a case of unstable hemoglobin.²¹⁴ Hereditary deficiency of GR is a very rare disorder and associated with hemolytic anemia.

Red cells also contain thioltransferase that can catalyze GSH-dependent reduction of some disulfides.^{215,216}

Oxidized glutathione is actively extruded from the erythrocyte.^{217,218} GSSG efflux is likely an important regulator of GSH turnover in red blood cells.²¹⁹ The system consists of at least two GSSG-activated adenosine triphosphatases (ATPases) that serve as an enzymatic basis for this transport process.²²⁰ In addition to transporting GSSG, the system appears to have the capacity to transport thioether conjugates of GSH and electrophiles formed by the action of glutathione-S-transferase.^{221,222} Preliminary evidence indicates that multidrug resistance protein 1 (MRP1) may be the exporter protein of both glutathione-S conjugates and GSSG.^{189,223} Erythrocytes contain glutathione-S-transferases rho, sigma, and theta.²²⁴⁻²²⁶ Glutathione-S-transferase catalyzes the formation of a thioether bond between GSH and a variety of xenobiotics. The role of glutathione-S-transferase in the erythrocyte has not been established. It may be that it serves to cleanse the blood of xenobiotics to which the red cell membrane is permeable. Glutathione-S-transferase could conjugate such substances to glutathione, and the detoxified product of conjugation would be transported out of the red cell for subsequent disposal. The enzyme has the capacity to reversibly bind heme, and a possible role in heme transport has been postulated.²²⁷ Deficiency of this enzyme is associated with hemolytic anemia, but a cause-and-effect relationship has not been established.²²⁸

Other Antioxidant Enzymes Superoxide radicals that are formed are converted to hydrogen peroxide by the action of the copper-containing enzyme superoxide dismutase (SOD).²²⁹ Red blood cells contain SOD type 1 (*SOD1*). Mutations in *SOD1* are associated with the dominant disorder familial amyotrophic lateral sclerosis.²³⁰ Patients display no hematologic phenotype. In agreement with this, studies on *SOD1*-deficient mice have shown that a 50 percent reduced SOD activity in red cells is probably sufficient to exert its protective effects.²³¹ *SOD1* null mice are viable, but show elevated levels of oxidative stress that causes regenerative anemia and triggers autoantibody production.²³²

Hydrogen peroxide can be also decomposed to water and oxygen by catalase and peroxiredoxin. Both enzymes are abundantly present in the red blood cell, suggesting an important role in the cell's oxidative defense. Nevertheless, acatalasemia, or catalase deficiency, is a

rare benign condition without hematologic consequences. It has been suggested, though, that it may act as a complicating factor in age and diseases such as diabetes²³³ and oxidative stress-related conditions.²³⁴ Deficiencies of peroxiredoxin 2, the major red cell peroxiredoxin,²³⁵ have not been reported in humans. Peroxiredoxin 2 null mice, however, develop severe hemolytic anemia with Heinz body formation,²³⁶ and show signs of abnormal erythropoiesis.²³⁷ Based on mouse models, it has been postulated that glutathione peroxidase, catalase, and peroxiredoxin each have distinct roles in the scavenging of hydrogen peroxide and antioxidative defense.^{238–240}

Nucleotide Metabolism of the Erythrocyte

Approximately 97 percent of the total nucleotide content of the mature red blood cell consists of interconvertible adenosine phosphates (Chap. 31). Less than 3 percent of total nucleotides are guanosine phosphates. ATP is the most abundant adenosine phosphate (comprising roughly 84 percent of total adenosine ribonucleotides), whereas ADP (14 percent) and adenosine monophosphate (AMP, 1 percent) are present in considerably lower amounts. The interconversion of adenine nucleotides is modulated by adenylate kinase (AK):

By catalyzing the reversible phosphoryl transfer among ATP, ADP, and AMP, AK contributes to cellular adenine nucleotide homeostasis. Red cells contain the AK1 isozyme, which is present in the cytosol as a monomeric enzyme composed of 194 amino acids. The recombinant purified enzyme has a molecular mass of approximately 22 kDa.²⁴¹ The *AK1* gene is localized on chromosome 9q34.1, and consists of 7 exons of which exon 1 is noncoding. AK activity depends on the presence of Mg^{2+} .

ATP serves as a cofactor in a number of reactions, such as the phosphorylation steps mediated by HK and PFK in glycolysis, the synthesis of GSH, and ATPase-dependent function of membrane pumps. Therefore, ATP is crucial in maintenance of the red cell's structure and function. Because the mature red cell is unable to synthesize adenosine phosphates from precursor molecules, it relies on salvage pathways to preserve adenosine ribonucleotides. This is of particular importance for AMP because this adenosine ribonucleotide is at risk of being lost from the adenine pool by dephosphorylation to adenosine and, subsequent, irreversible deamination to inosine by the enzyme adenosine deaminase (ADA). ADA thus plays a regulatory role in the concentration of adenosine ribonucleotides in the red cell. The gene encoding ADA (*ADA*) is located on chromosome 20q13.12. It comprises 12 exons that encode a 363-amino-acid protein.

Deficiency of AK and hyperactivity of ADA are both very rare causes of hereditary nonspherocytic hemolytic anemia.

Additional enzymes of purine metabolism are also present in the red cell. Although disorders of these enzymes are associated with a number of metabolic diseases, their function does not appear to be relevant for the red blood cell as these disorders are without hematologic consequences.²⁴²

Pyrimidine-5'-Nucleotidase-1 Pyrimidine ribonucleotides are found only in trace amounts in the mature red blood cell. They are lost from the cell together with the degradation of ribosomes and RNA during reticulocyte maturation. Pyrimidine-5'-nucleotidase-1 (P5'N1) mediates this loss by catalyzing the dephosphorylation of pyrimidine nucleoside monophosphates into the corresponding nucleosides (cytidine and uridine), which are freely diffusible across the membrane.²⁴³ P5'N1 is specific for pyrimidine nucleotides and does not use purine nucleotides as substrate.²⁴⁴ The enzyme requires Mg^{2+} for its activity, and is inhibited by a number of heavy metals, including Pb^{2+} .²⁴⁵ Like other red blood cell enzymes, P5'N1 activity is much higher in reticulocytes. The enzyme declines in activity during red cell aging.²⁴⁶ P5'N1 also has

phosphotransferase properties, suggesting an additional role of this enzyme in nucleotide metabolism.²⁴⁷ The crystal structure of mouse P5'N1 has been published, providing a framework for understanding the kinetics of both nucleotidase and phosphotransferase activities of human P5'N1.²⁴⁸

P5'N1 is encoded by the *NT5C3A* gene on chromosome 7p14.3. It comprises 11 exons, and produces three distinct mRNAs by alternative splicing. Red cell P5'N1 is translated from the mRNA lacking exons 2 and R.^{249,250} It is a 286-amino-acids-long monomeric protein with an apparent molecular weight of 34 kDa.²⁴⁹

A second P5'N is present in red blood cells, the activity of which is generally measured together with that of P5'N1. This enzyme (P5'N2) is encoded by a separate gene, shows little homology to P5'N1, and is not strictly pyrimidine-specific. It is unable to compensate for deficient function of P5'N1.^{247,251} P5'N1 deficiency is one of the most common causes of hereditary nonspherocytic hemolytic anemia.

Human red blood cells have been found to express low NAD synthesis activity, mediated by nicotinamide mononucleotide adenyltransferase.²⁵² It appears that the predominant isozyme in red blood cells is nicotinamide mononucleotide adenyltransferase-3.²⁵³ Human dysfunction of this enzyme has not been reported but the deficiency in mice blocks glycolysis at the GAPDH step and is associated with hemolytic anemia.²⁵⁴

GENETICS

The great majority of red cell enzyme deficiencies that cause hemolytic anemia are hereditary. Most are inherited as autosomal recessive disorders, but G6PD deficiency and PGK deficiency are X-chromosome-linked. The vast majority of the genes encoding for the red cell enzymes have been identified, making the molecular diagnosis of hereditary red cell enzyme deficiency possible. Occasionally, acquired forms of enzyme deficiencies, particularly PK deficiency, have been encountered, usually in patients with hematologic neoplasia.^{255–259}

ENZYME DEFICIENCIES—BIOCHEMICAL GENETICS AND MOLECULAR BIOLOGY

Table 47–2 lists the erythrocyte enzyme deficiencies shown to cause hemolytic disease. Other red cell enzyme deficiencies (Table 47–3) do not appear to cause hemolysis or other functional abnormality of the erythrocyte.²⁰² For example, acatalasemia, the state in which there is a virtually total absence of red cell catalase, is devoid of hematologic manifestations.²³³ Similarly, red cells without acetylcholinesterase survive normally in most cases.²⁶⁰

The lack of clinical manifestations is not always clearcut. In some instances, hemolytic anemia is reported in some individuals with a given deficiency but not in others. For example, most subjects with LDH deficiency have no anemia, but cases with hemolysis have been reported.¹³⁶ Such ambiguity could result from differences in environmental and genetic factors or from bias of ascertainment. Erythrocyte enzyme assays are usually performed on patients with hemolytic anemia. Thus, a benign enzyme defect may be thought, mistakenly, to cause hemolysis because it is found in a patient with hemolytic anemia caused by an unrelated and undetected defect. Deficiencies of PGK, GS, or AK are usually associated with hereditary nonspherocytic hemolytic anemia, but cases have been reported in which these deficiencies were unassociated with any hematologic manifestations.^{261–263} At times it has been suggested that moderate decreases in the activity of glutathione peroxidase causes hemolytic anemia, but the best available evidence indicates that this enzyme is not ordinarily rate limiting in erythrocyte metabolism and not associated with hemolytic anemia.²⁶⁴

TABLE 47-2. Red Cell Enzyme Abnormalities Leading to Hemolytic Disease

Enzyme	Clinical Features	Inheritance	Red Cell Morphology	Diagnosis (Reference)		Response to Splenectomy*	Approximate Frequency†
				Screening Test	Assay		
Hexokinase	HNSHA	AR	Unremarkable	—	580	++	Rare
Glucose phosphate isomerase	HNSHA; neurologic abnormalities	AR	Unremarkable	580	580	+++	Unusual
Phosphofructokinase	HNSHA and/or muscle glycogen storage disease	AR	Unremarkable	—	580	0	Rare
Aldolase	HNSHA and mild liver glycogen storage; myopathy, mental retardation	AR	Unremarkable	—	580	?	Very rare
Triose-phosphate isomerase	HNSHA and severe neuromuscular disease	AR	Unremarkable	580	580	?	Rare
Phosphoglycerate kinase	HNSHA; myoglobinuria neuromuscular disorder	SL	Unremarkable	—	580	++	Rare
Pyruvate kinase	HNSHA	AR	Usually unremarkable; occasionally contracted echinocytes	580	580	++	Unusual
Glucose-6-phosphate dehydrogenase	HNSHA; drug- or infection-induced hemolysis; favism	SL	Usually unremarkable; rarely "bite cells"	580	580	±	Very common
Glutathione reductase	Drug-sensitive hemolytic anemia and favism	AR	Unremarkable	580	580	?	Very rare
Glutamate cysteine synthetase	HNSHA; drug- or infection-induced hemolysis; neurologic abnormalities	AR	Unremarkable	644	645	?	Very rare
Glutathione synthetase	HNSHA; drug- or infection-induced hemolysis; neurologic defect and 5-oxoprolinuria in some cases	AR	Usually unremarkable	644	645	0	Rare
Pyrimidine 5'-nucleotidase	HNSHA; mental retardation in some cases	AR	Prominent stippling	646	647	0	Unusual
Adenylate kinase	HNSHA	AR	Unremarkable	—	580	?	Rare
Adenosine deaminase (increased activity)	HNSHA	AD	Unremarkable	—	580	?	Very rare

AD, autosomal dominant; AR, autosomal recessive; HNSHA, hereditary nonspherocytic hemolytic anemia; SL, sex-linked; —, not applicable.

*On a scale of 0 to 4+, where 4+ is a complete response. In many cases, data are meager.

†Very common if incidence is >5 percent. Unusual if >100 cases reported. Rare if 10 to 100 cases reported. Very rare if <10 cases reported.

*Recent reports.

TABLE 47-3. Red Cell Enzyme Abnormalities Not Leading to Hemolytic Disease

Enzyme	Clinical Features	Inheritance	Diagnosis Reference Assay	Estimated Frequency*	Reference
6-Phosphogluconate dehydrogenase (complete deficiency)	None	AR	580	Unusual	166–168
6-Phosphogluconolactonase (partial defect)	Probably none	AD	648	Unusual	163
δ-ALA dehydrase	None	AD	649		
Acetylcholinesterase	None	AR	580	Very rare	260
Adenine phosphoribosyl transferase	Kidney stones	AR	650	Rare	651
Adenosine deaminase (decreased activity)	Immunodeficiency	AR	580	Rare	652
AMP deaminase	None	AR	653	Unusual	654
Bisphosphoglycerate mutase	Erythrocytosis	AR	580	Very rare	377, 380
Carbonic anhydrase I	None	AR	655	Rare	656
Carbonic anhydrase II	Osteoporosis	AR		Rare	657
Catalase	Oral ulcers in some types	AR	580	Rare	658
Cytochrome- <i>b</i> ₅ -reductase	Methemoglobinemia; mental retardation	AR	580	Unusual	659
Enolase	HNSHA?	AD?	580	Rare	115, 116
Galactokinase	Cataracts	AR	580	Rare	660
Galactose-1-P-uridyltransferase	Cataracts; mental retardation; liver disease	AR	580	Rare	661
Glutathione peroxidase (partial deficiency)	None	AR and AD ⁶⁶²	580	Very common	580, 662
Glutathione reductase (partial deficiency)	None	Usually not inherited ⁶⁶²	580	Very common	662, 663
Glutathione-S-transferase	HNSHA	?	580	Very rare	228
Glyceraldehyde-3-phosphate dehydrogenase (partial defect)	None	AD	580	Unusual	94
Glyoxalase I	None	AR		Rare	664
Hypoxanthine-guanine phosphoribosyl transferase (HGPRT)	Lesch-Nyhan syndrome (neurologic symptoms and gout)	SL	665	Rare	666
Inosine triphosphatase	None	AR	656	Rare	667
Lactate dehydrogenase	None	AR	580	Rare	135
NADPH diaphorase	None	AR	580	Rare	668
Phosphoglucomutase	None	AR	580	Rare	669
Transaldolase	Liver disease, thrombocytopenia, HNSHA?	AR	670	Rare	175
Uroporphyrinogen 1 synthase	Porphyria	AD	671	Unusual (common in selected populations)	672

AD, autosomal dominant; ALA, aminolevulinic acid; AMP, adenosine monophosphate; AR, autosomal recessive; HNSHA, hereditary nonspherocytic hemolytic anemia; NADPH, nicotinamide adenine dinucleotide phosphate (reduced form); SL, sex-linked.

*Very common if incidence is >5 percent, common if 1 to 5 percent, unusual if 0.01 to 1 percent, rare if <0.01 percent.

Table 47–3 includes deficiencies that may cause hemolytic anemia but for which a cause-and-effect relationship has not been clearly established, such as those of phosphogluconolactonase,¹⁶³ enolase,^{115,116} and glutathione-S-transferase.²²⁸

Patients with unstable hemoglobins (Chap. 49) may present with the clinical picture of hereditary nonspherocytic hemolytic anemia. Hemolytic anemia resulting from abnormalities in the lipid composition of the red cell membrane, particularly increased phosphatidyl choline, occurs rarely (Chap. 46).

Glucose-6-Phosphate Dehydrogenase

The “normal” or wild-type enzyme is designated as G6PD B. Many variants of G6PD have been detected all over the world, associated with a wide range of biochemical characteristics and phenotypes. Accordingly, five classes of G6PD variants can be distinguished based on enzymatic activity and clinical manifestations (Table 47–4).²⁶⁵ Before it became possible to characterize G6PD variants at the DNA level, they were distinguished from each other on the basis of biochemical characteristics, such as electrophoretic mobility, K_m for NADP and glucose-6-P, ability to use substrate analogues, pH activity profile, and thermal stability. To facilitate comparison of variants characterized in different laboratories, international standards for the methodology were established.²⁶⁶ In the case of the common G6PD A– and G6PD Mediterranean mutations, the abnormal enzyme may be synthesized at normal or near-normal rates but has decreased stability *in vivo*.²⁶⁷ The amount of enzyme antigen in the red cells declines concurrently with enzyme activity.²⁶⁸ This suggests that the mutant protein in these variants is rendered unusually sensitive to proteolysis in the environment of the erythrocyte.²⁶⁹ Other mutations also result in the formation of enzyme molecules with decreased enzyme activity²⁶⁸ and with altered kinetic properties,²⁷⁰ some of which may render them functionally inadequate.¹⁵⁸ By far the majority of mutations (85 percent) are missense mutations causing the substitution of a single amino acid.¹⁵⁸ More severe mutations such as frameshift and nonsense mutations have not been found, indicating that some residual activity is required for survival. In agreement with this, targeted deletion of G6PD in the mouse causes embryonic lethality.²⁷¹

Detailed biochemical and genetic characteristics of some 400 putatively distinct G6PD variants and more than 200 different mutations have been tabulated.^{155,160} Table 47–4 lists common G6PD variants that have reached polymorphic frequencies in certain populations.

African Variants Among persons of African descent, a mutant enzyme G6PD A+, with normal activity is polymorphic. It migrates electrophoretically more rapidly than the normal B enzyme, has substitution of Asn to Asp at codon 126, resulting from nucleotide change c.376A>G.²⁷² G6PD A– is the principal deficient variant found among people of African origin. The red cells contain only 5 to 15 percent of the normal amount of enzyme activity; however because of the instability of the enzyme, the age-dependent decline of the activity renders old red cells severely deficient and susceptible to hemolysis. These two electrophoretically rapid variants are common in African populations have in common a nucleotide substitution at cDNA nucleotide 376 that produces the amino acid substitution responsible for the rapid electrophoretic mobility. Most samples with G6PD A– manifest an additional *in cis* G>A mutation at cDNA nucleotide 202 (c.202G>A; p.Val68Met), which accounts for its *in vivo* instability.²⁷³ Less commonly, the additional mutation is at a different site (c.680G>T or c.968T>C).²⁷³ Thus G6PD A– arose in an individual who already had the G6PD A+ mutation. However, the ancestral human sequence has been deduced to be that of G6PD B, both by showing that this is the sequence of the chimpanzee,²⁷⁴ our nearest relative, and by analysis of linkage disequilibrium.²⁷⁵ Although it has been suggested that only the interaction of p.Val68Met and p.Asn126Asp invariably results in G6PD A– deficiency,²⁷⁶ the

c.202G>A mutation has been found in a patient to cause deficiency without the presence of the mutation at cDNA nucleotide (nt) 376.²⁷⁴

Variants in the Mediterranean Region Among white populations, G6PD deficiency is most common in Mediterranean countries. The most common enzyme variant in this region is G6PD Mediterranean.^{270,277} The enzyme activity of the red cells of individuals who have inherited this abnormal gene is barely detectable. Other variants are also prevalent in the Mediterranean region, including G6PD A– and G6PD Seattle (see Table 47–4).

Variants in Asia A great many different variants have been described in Asian populations. Some of these proved to be identical at a molecular level (e.g., G6PD Gifu-like, Canton, Agrigento-like, and Taiwan-Hakka all have the same mutation at cDNA nt 1376 [see Table 47–4]). DNA analysis shows that more than 100 different mutations are found in various Asian populations.^{160,278}

Variants Producing Hereditary Nonspherocytic Hemolytic Anemia Some mutations of G6PD result in chronic hemolysis without, but exacerbated by, precipitating causes. These variants are class I mutants (World Health Organization [WHO] class 1).²⁶⁵ From a functional point of view, these mutations are more severe than the more commonly occurring polymorphic forms of the enzyme, such as G6PD Mediterranean and G6PD A–. On a molecular level, such variants are often caused by mutations located in exons 10 and 11, encoding the subunit interface, or affect residues that bind the structural NADP molecule.^{143,158} There are, however, exceptions to this rule.^{28,279–281} The clinical severity of these variants can be quite variable.²⁸²

G6PD deficiency has also been encountered in the rat, dog,²⁸³ mouse,²⁸⁴ and horse.²⁸⁵ G6PD deficiency in mice has been rescued by stable *in vivo* expression of the human *G6PD* gene in hematopoietic tissues by a gene transfer approach.^{271,286}

Pyruvate Kinase

PK deficiency is the second most common enzyme disorder in glycolysis and the most common cause of nonspherocytic hemolytic anemia.²⁸⁷ Like G6PD deficiency, the disease is genetically heterogeneous, with different mutations causing different kinetic changes in the enzyme that is formed. There are even cases in which the activity of PK as measured *in vitro* is higher than normal, but a kinetically abnormal enzyme is responsible for the occurrence of hemolytic anemia.²⁸⁸ Kinetic characterization and analysis of PK mutants is considerably more complex than analysis of G6PD mutants. Most PK-deficient patients are compound heterozygous for two different (missense) mutations, rather than homozygous for one. Assuming that stable mutant monomers are synthesized, up to seven different tetrameric forms of PK may be present in compound heterozygous individuals, each with distinct structural and kinetic properties. This complicates genotype-to-phenotype correlations in these individuals as it is difficult to infer which mutation is primarily responsible for deficient enzyme function and the clinical phenotype.^{289,290} More than 230 mutations in the *PKLR* gene encoding the red cell PK have been identified. Seventy percent of these mutations are missense mutations affecting conserved residues in structurally and functionally important domains of PK. There appears to be no direct relationship between the nature and location of the substituted amino acid and the type of molecular perturbation.¹²⁴ Hence, the nature of the mutation has relatively little predictive value with respect to the severity of the clinical course and the phenotypic expression of identical mutations can be strikingly different in patients.^{29,289–291}

Apart from decreased red blood cell survival ineffective erythropoiesis because of increased numbers of apoptotic cells is implicated as one of the pathophysiologic features of PK deficiency.^{292,293} In particular, glycolytic inhibition by mutation of *PKLR* has been suggested to augment oxidative stress, leading to proapoptotic gene expression.²⁹³

Data from Mason, P. J., Bautista, J. M., and Gilsanz, F. G6PD deficiency: The genotype-phenotype association. *Blood reviews*. 21: 267-283, 2007 and Minucci, A., Moradkhani, K., Hwang, M. J., et al. Glucose-6-phosphate dehydrogenase (G6PD) mutations database: Review of the "old" and update of the new mutations. *Blood cells, molecules & diseases* 48: 154-165, 2012.

PK deficiency may be also caused by mutations not directly involving the *PKLR* gene as demonstrated by a deficiency of PK being one of the key features of severe congenital hemolytic anemia caused by mutations in the key erythroid transcription factor KLF1.²⁹⁴

There is evidence that PK deficiency provides protection against infection and replication of *Plasmodium falciparum* in human erythrocytes,^{295,296} an effect possibly mediated by reduced ATP levels in PK-deficient red blood cells.²⁹⁷ This suggests that PK deficiency may confer a protective advantage against malaria in human populations in areas where this disease is endemic. In agreement with this, population studies on sub-Saharan African populations indicate that malaria is acting as a selective force in the *PKLR* genomic region.^{298–300}

PK deficiency has also been recognized in mice, dogs, and multiple breeds of domestic cats.³⁰¹ In all these animals, the deficiency causes severe anemia and marked reticulocytosis, closely resembling human PK deficiency. Basenji dogs with PK deficiency completely lack PKLR enzymatic activity and, instead, only the PK-M2 isozyme is expressed in their red blood cells.³⁰² A unique feature of PK deficiency in dogs is the progressive development of myelofibrosis and osteosclerosis. Marrow fibrosis may occur in response to damage caused by iron overload,³⁰³ although factors associated with marked erythropoiesis have also been proposed to play a role.³⁰⁴ Gene therapy approaches have been employed to cure PK deficiency in dogs.³⁰⁵ PK-deficient mice show delayed switching from PK-M2 to PK-R, resulting in delayed onset of the hemolytic anemia.³⁰⁶ PK deficiency in mice has been rescued by expression of the human PK-R isozyme in murine hematopoietic stem cells.^{307,308}

Other Enzyme Deficiencies

Hexokinase Deficiency Nineteen families with HK deficiency have been described as of the time of this writing^{309–311} and only four patients have been characterized at the molecular level.^{310–313} Two of these patients were homozygous, either for a highly conserved substitution in the enzyme's active site³¹³ or a lethal out-of-frame deletion of exons 5 to 8 of *HK1*.³¹⁰ In one patient a regulatory mutation was identified in the putative erythroid-specific promoter. *In vitro*, this mutation disrupted binding of the AP-1 transcription factor complex, leading to strongly decreased gene expression.³¹¹

In mice, a mutation designated *downeast anemia* causes severe hemolytic anemia with extensive tissue iron deposition and marked reticulocytosis, representing a mouse model of generalized HK deficiency.³¹⁴

Glucosephosphate Isomerase Deficiency Glucosephosphate isomerase deficiency is second to PK deficiency in frequency, with respect to glycolytic enzymopathies. To date, approximately 55 families with glucosephosphate isomerase deficiency have been described worldwide.^{315–320} Most of these patients are compound heterozygous for mutations that partially inactivate the enzyme. Most of the 31 *GPI* mutations reported to date are missense mutations. Mapping of these mutations to the crystal structure of the human enzyme and recombinant expression of genetic variants has provided considerable insight in the molecular mechanisms causing hemolytic anemia in this disorder.^{321,322} The majority of the mutations disrupt key interactions that contribute directly or indirectly to the architecture of the enzyme's active site.³²¹ In rare cases, GPI deficiency also affects nonerythroid tissues, causing severe neuromuscular symptoms and granulocyte dysfunction.^{323–328} The finding that GPI also functions as a neuroleukin,³²⁹ an autocrine motility factor,³³⁰ a nerve growth factor,³³¹ and a differentiation and maturation mediator³³² has led to the hypothesis that the mutation-dependent loss of cytokine function of GPI could account for the neuromuscular symptoms.³³³ An alternative explanation involves disturbed glycerolipid biosynthesis in GPI deficiency, which could have significant effects on membrane formation, membrane function, and axonal migration.^{334,335}

Homozygous GPI-deficient mice exhibit hematologic features resembling that of the human enzymopathies. In addition, other tissues are also affected, indicating a reduced glycolytic capability of the whole organism.³³⁶ Complete loss of GPI in mice is embryonically lethal.³³⁷

Phosphofruktokinase Deficiency Because red cells contain both PFK M and L subunits, mutations affecting either gene (*PFKM* or *PFKL*) will lead to a partially reduced red cell enzyme activity in PFK deficiency. Mutations in the *PFKM* gene cause PFKM deficiency or glycogen storage disease VII (Tarui disease).³³⁸ The disease is characterized predominantly by mild to severe myopathy, in particular exercise intolerance, cramps, and myoglobinuria. The associated hemolysis is usually mild but may be absent. As of this writing, there has been only one reported case in which an unstable L subunit was identified. This patient exhibited no signs of myopathy or hemolysis.⁷⁵ Approximately 100 cases of PFK deficiency have been reported as of this writing, and 23 mutant *PFKM* alleles are reported. Approximately half of the reported mutations are missense mutations, the remaining mutations mostly affect splicing. Intriguingly, PFK-deficient Ashkenazi Jews share two common mutations: a G>A base change affecting the donor splice site of intron 5 (c.237+1G>A) and a single base deletion in exon 2 (c.2003delC).^{33,339} The mode of action by which missense mutations cause disease is largely unknown.^{33,340–347}

PFK deficiency in dogs³⁰¹ is characterized by the association of hemolytic crises with strenuous exercise.³⁴⁸ *Pfkm* null mice show exercise intolerance, reduced life span, and progressive cardiac hypertrophy, suggesting that Tarui disease should be considered as a complex systemic disorder rather than a muscle glycogenesis.^{349,350}

Aldolase Deficiency At the time of this writing, only six patients with red cell aldolase deficiency had been described, four of whom were characterized at the DNA level. All displayed moderate chronic hemolytic anemia, either by itself³⁵¹ or accompanied by myopathy,^{352,353} rhabdomyolysis,³⁵⁴ psychomotor retardation,³⁵² or mental retardation.^{77,352}

Triosephosphate Isomerase Deficiency TPI deficiency is characterized by hemolytic anemia, often accompanied by neonatal hyperbilirubinemia requiring exchange transfusion. In addition, patients display progressive neurologic dysfunction, increased susceptibility to infection, and cardiomyopathy.³⁵⁵ Most affected individuals die before the age of 6 years, but there are remarkable exceptions.³⁵⁶ TPI deficiency is the most severe disorder of glycolysis. Key in the pathophysiology of the severe neuromuscular disease is the formation of toxic protein aggregates: accumulation of the substrate dihydroxyacetone phosphate results in elevated levels of the toxic methylglyoxal, leading to the formation of terminal glycation of proteins, whereas mutation-induced changes in the quaternary structure of TPI lead to the formation of an aggregation-prone protein.^{357,358} Therefore, it has been suggested that TPI deficiency represents a conformational rather than a metabolic disease.³⁵⁷

Approximately 40 patients and 19 different mutations have been reported in TPI deficiency.^{355,358–363} The most common mutation is the p.(Glu104Asp) amino acid change which is detected in approximately 80 percent of patients, all descendants from a common ancestor.³⁶⁴ Studies on recombinant mutant TPI show that the p.(Glu104Asp) does not affect catalysis. Instead, the mutation disrupts a conserved network of buried water molecules, which prevents efficient formation of the active TPI dimer, causing its dissociation in inactive monomers.⁸⁵

TPI-null mice die at an early stage of development.³⁶⁵ Hemolytic anemia characterizes the only viable mouse model of TPI deficiency.³⁶⁶ Studies on a *Drosophila* model recapitulating the neurologic phenotype of TPI deficiency³⁶⁷ suggests that loss of an isomerase-independent function of TPI underlies the neuropathogenesis in TPI deficiency.³⁶⁸

Phosphoglycerate Kinase Deficiency PGK deficiency is one of the relatively uncommon causes of hereditary nonspherocytic

hemolytic anemia. Mutations in the X chromosome-linked gene may cause mild to severe chronic hemolysis, neurologic dysfunction, and myopathy.³⁶⁹ Approximately 40 patients with PGK deficiency have been reported.^{369,370} Most patients manifest either hemolytic anemia in combination with neurologic symptoms, including mental retardation, seizures, progressive decline of motor function, and developmental delay, or isolated myopathy.^{370–372} The combination of all clinical manifestations is a rare event, described in only 2 families.^{373,374} Splenectomy has been reported to be beneficial but does not correct the hemolytic process.^{341,369} Marrow transplantation has been performed to prevent the manifestation of severe neurologic symptoms.³⁷⁵

Twenty-two unique mutations have been identified.^{370,371} Most of these mutations (80 percent) are missense mutations. Most of the encoded amino acid changes heavily affect the protein's thermal stability and to a different extent catalytic efficiency.^{371,376} In an attempt to correlate the genotype to the phenotype, it was found that amino acid changes grossly impairing protein stability but moderately affecting kinetic properties were associated mostly with hemolytic anemia and neurological symptoms. Mutations perturbing both catalysis and heat stability were associated with myopathy alone, whereas mutations faintly affecting molecular properties of PGK correlated with a wide range of clinical symptoms.³⁷⁶ Yet, the precise reason for the different clinical manifestations of mutations of the same gene remains unknown, suggesting the involvement of yet unknown alternate function of this enzyme, environmental, metabolic, genetic and/or epigenetic factors.^{372,376}

Bisphosphoglycerate Mutase Deficiency Bisphosphoglycerate mutase deficiency is a very rare disorder. Only three affected families have been characterized. Bisphosphoglycerate mutase deficiency appears to be inherited as an autosomal recessive disorder. However, some heterozygous relatives have had a borderline high hemoglobin concentration,^{377,378} and in one single affected patient only one mutation was identified.³⁷⁹ Erythrocytosis was the predominant feature of the clinically normal probands, likely resulting from reduced 2,3-BPG levels³⁸⁰ and, consequently, the increased oxygen affinity of hemoglobin (Chap. 57).

Glutamate Cysteine Ligase Deficiency GCL deficiency is associated with mild hereditary nonspherocytic hemolytic anemia that may be fully compensated. Drug- and infection-induced hemolytic crises may occur as a consequence of strongly reduced GSH levels. As of this writing, eight cases of GCL deficiency had been described, belonging to six unrelated families.^{381–388} In approximately half of the patients with GCL deficiency, the hemolytic anemia was accompanied by impaired neurological function.³⁸⁸ Six patients have been characterized at the molecular level and five different mutations have been reported.^{385–388} In all these cases, the causative mutation affected the catalytic subunit of GCL. The clinically observed mutations have been mapped to a homology model of the human enzyme, based on the crystal structure of GCL of *Saccharomyces cerevisiae*, thus explaining the molecular basis of GSH depletion as a result of GCL deficiency.¹⁹² Complementary expression studies in mice showed that these GCL mutations impair glutathione production by reducing the activity of the catalytic subunit of GCL. Addition of the modifier subunit was able to largely restore enzymatic activity, thereby underscoring the critical role of GCLM.³⁸⁹ Complete deficiency of GCLC has shown to be lethal in mice,^{390,391} whereas GCLM-null mice are viable and show no overt phenotype despite strongly reduced GSH levels, including a reduction of more than 90 percent in red blood cells.³⁹² Upon exposure to oxidative stress, however, red blood cells from such mice undergo massive hemolysis with fatal outcome.³⁹³

Glutathione Synthetase Deficiency GS deficiency³⁹⁴ is the most common abnormality of red cell glutathione metabolism. Three distinct clinical forms of GS deficiency can be distinguished,³⁹⁵ most likely reflecting different mutations or epigenetic modifications in the GS

gene.³⁹⁶ Patients with mild GS deficiency display mild hemolytic anemia as their only symptom. In contrast, patients with a moderate deficiency usually present in the neonatal period with metabolic acidosis, 5-oxoprolinuria, and mild to moderate hemolytic anemia. In addition to these symptoms, patients with the third and most severe type develop progressive neurologic symptoms such as psychomotor retardation, mental retardation, seizures, ataxia, and spasticity. 5-Oxoprolinuria results from accumulation of γ -glutamylcysteine because of decreased feedback inhibition of GCL by the decreased levels of GSH.³⁹⁷ Importantly, 5-oxoprolinuria may have other causes.^{398,399} Experiments in rats show that acute administration of 5-oxoproline induces oxidative damage in the brain, a mechanism that may be involved in the neurologic symptoms of severe GS deficiency.⁴⁰⁰

The diagnosis of GS deficiency has been established in more than 70 patients from 50 families,^{396,397,401,402} of whom approximately 25 percent died in childhood.⁴⁰¹ Thirty-two mutations are identified as being associated with GS deficiency. Based on the nature of the mutation, and taking into account GS activity and GSH levels it seems possible to predict a mild versus a more severe phenotype.³⁹⁶ The structural effects of a number of missense mutations have been determined.¹⁹⁷

A long-term followup study showed that early diagnosis, correction of acidosis, and early supplementation with antioxidants vitamins C and E improve survival and long-term outcome.³⁹⁵ For these reasons it has been argued that GS deficiency should be included in the newborn screening program.⁴⁰¹

Complete deficiency of GS has shown to be lethal in mice, whereas heterozygous animals survive with no distinct phenotype.⁴⁰³

Glutathione Reductase Deficiency Only two families with hereditary GR deficiency have been described and characterized.^{404,405} The complete absence of GR in the red cells of members of one family was associated with only rare episodes of hemolysis, possibly caused by fava beans. GR deficiency was caused by homozygosity for a large genomic deletion. GR deficiency in the other family was caused by compound heterozygosity for a nonsense mutation, and a missense mutation affecting a highly conserved residue. GR in red cells was undetectable, but some residual activity was found in the patient's leucocytes.⁴⁰⁴

In vitro studies on members of one of the GR deficiency families has provided experimental evidence that GR deficiency may protect from malarial infection by enhancing phagocytosis of ring-infected red blood cells.⁴⁰⁶

Adenylate Kinase Deficiency AK deficiency has been reported in 12 unrelated families and 7 different mutations have been identified.^{263,407–412} In all but one case,^{263,413} the deficiency was associated with moderate to severe hemolytic anemia. In some of the patients, mental retardation and psychomotor impairment was also observed.^{410,414} Studies on a number of recombinant proteins revealed strongly altered catalytic properties or protein stability resulting from mutation.²⁴¹ In contrast, patient's cells sometimes displayed considerable residual enzymatic activity. The activation of expression of other isozymes, that is, AK2 and AK3, has been proposed as one of the factors contributing to this apparent discrepancy.⁴¹²

Adenosine Deaminase Hyperactivity An increased activity of ADA is associated with hereditary nonspherocytic hemolytic anemia. It is the only red cell enzyme disorder that is inherited in an autosomal dominant disorder.⁴¹⁵ Adenosine deaminase hyperactivity results in depletion of red cell ATP.^{415,416} Few cases with a 30- to 70-fold increase in activity have been described. The molecular mechanism of this disorder has not been identified but the markedly increased amounts of ADA mRNA in affected individuals indicate that the red blood cell-specific overexpression occurs at the mRNA level,⁴¹⁷ causing an overproduction of a structurally normal enzyme.⁴¹⁸ ADA hyperactivity probably results from a *cis*-acting mutation in the vicinity of the ADA gene.⁴¹⁹

Figure 47-6. Prominent basophilic stippling in pyrimidine-5'-nucleotidase-1 (P5'N1) deficiency.

For reasons that are not understood, milder elevations of red cell ADA activity (two- to sixfold) are also increased in most, but not all, patients with Diamond-Blackfan anemia.¹⁸⁶ Deficiency of ADA is associated with severe combined immunodeficiency (Chap. 80). In this disorder, large quantities of deoxyadenine nucleotides, not normally present in erythrocytes, accumulate.

Pyrimidine 5'-Nucleotidase Deficiency Pyrimidine 5'-nucleotidase deficiency is the most frequent disorder of red cell nucleotide metabolism and a relatively common cause of mild-to-moderate hemolytic anemia.⁴²⁰⁻⁴²² More than 100 patients have been reported, but because of the relatively mild phenotype many patients may remain undetected. Deficient enzyme function leads to the accumulation of pyrimidine nucleotides. This results in prominent stippling on the blood film, the hallmark of this disorder (Fig. 47-6).²⁴⁴ Hence, P5'N1 deficiency is the only red cell enzyme deficiency in which red cell morphology is helpful in establishing the diagnosis. The precise mechanism leading to premature destruction of P5'N1-deficient red cells is unknown. Some proposed pathophysiologic mechanisms have related the accumulation of pyrimidine nucleotide to alterations of the red cell membrane due to increased levels of cytidine diphosphate (CDP)-choline and CDP-ethanolamide,⁴²³ decreased pentose phosphate shunt activity,⁴²⁴⁻⁴²⁶ chelation of Mg^{2+} ions that serves as a cofactor for a number of enzymes,⁴²⁷ decreased phosphoribosyl pyrophosphate synthetase activity,^{428,429} increased activity of pyrimidine nucleoside monophosphate kinase,⁴³⁰ increased levels of GSH,⁴³¹ and competition with reactions that require ADP or ATP.⁴³² However, clear cause-and-effect relationships have not been established.

As of this writing, 27 different mutations have been reported in *NT5C3A* in association with P5'N1 deficiency.^{420,433,434} Most patients were found to be homozygous for a specific mutation. The majority of mutations concern frameshift or nonsense mutations, deletions, or mutations that affect splicing. Functional analysis of reported missense mutations was studied using recombinant mutant proteins. These rendered contrasting results between the substantial changes in kinetic behavior and thermostability and the actual residual enzymatic activity in patient's red cells, probably due to compensation by upregulation of other nucleotidases.⁴³⁵ Of interest is the observation that none of the

reported missense mutations affect residues of the catalytic site, suggesting that the reduced catalytic efficiency and/or instability result from secondary effects related to conformational changes.²⁴⁸

Acquired deficiency of P5'N1 may result from lead poisoning. Structural studies have shown that Pb^{2+} specifically binds within the active site, in a different position than Mg^{2+} but with much higher affinity.²⁴⁸ Because simultaneous binding of Mg^{2+} and Pb^{2+} is not possible, Pb^{2+} outcompetes Mg^{2+} , thereby preventing this essential cofactor from binding, thus abolishing catalytic activity. P5'N1 activity is also inhibited in β -thalassemia and related disorders that result in excess α -globin chains, such as hemoglobin E, probably from oxidative damage induced by excess α -globin chains.^{436,437}

MECHANISM OF HEMOLYSIS

G6PD Deficiency

The life span of G6PD-deficient red cells is shortened under many circumstances, particularly during drug administration and infection. The exact reason for this is not known.

Drug-Induced Hemolysis

Drug-induced hemolysis in G6PD-deficient cells is generally accompanied by the formation of Heinz bodies, particles of denatured hemoglobin, and stromal protein (Chap. 49), formed only in the presence of oxygen.⁴³⁸ Together with the inability to protect their GSH against drug challenge, this suggests that a major component of the hemolytic process is the inability of G6PD-deficient cells to protect sulfhydryl groups against oxidative damage.² The mechanism by which Heinz bodies are formed and become attached to red cell stroma has been the subject of considerable investigation and speculation. Exposure of red cells to certain drugs results in the formation of low levels of hydrogen peroxide as the drug interacts with hemoglobin.⁴³⁹ In addition, some drugs may form free radicals that oxidize GSH without the formation of peroxide as an intermediate.⁴⁴⁰ The formation of free radicals of GSH through the action of peroxide or by the direct action of drugs may be followed either by oxidation of GSH to the disulfide form (GSSG) or complexing of the glutathione with hemoglobin to form a mixed disulfide. Such mixed disulfides are believed to form initially with the sulfhydryl group of the β -93 position of β -globin.⁴⁴¹ The mixed disulfide of GSH and hemoglobin is probably unstable and undergoes conformational changes exposing interior sulfhydryl groups to oxidation and mixed disulfide formation. Globin chain separation into free α and β chains also occurs.⁴⁴² Once such oxidation has occurred, hemoglobin is denatured irreversibly and will precipitate as Heinz bodies. Normal red cells can defend themselves to a considerable extent against such changes by reducing GSSG to GSH and by reducing the mixed disulfides of GSH and hemoglobin through the GR reaction.⁴² However, the reduction of these disulfide bonds requires a source of NADPH. Because G6PD-deficient red cells are unable to reduce $NADP^+$ to NADPH at a normal rate, they are unable to reduce hydrogen peroxide or the mixed disulfides of hemoglobin and GSH. Moreover, because catalase contains tightly bound NADPH⁴⁴³ that is required for activity, the lack of freely available NADPH generation may, in addition, impede disposal of hydrogen peroxide by the catalase-dependent pathway.⁴⁴⁴ When such cells are challenged by drugs, they form Heinz bodies more readily than do normal cells. Cells containing Heinz bodies encounter difficulty in traversing the splenic pulp⁴⁴⁵ and are eliminated relatively rapidly from the circulation. Figure 47-7 summarizes a plausible scenario of the metabolic events that leads to red cell damage and eventually destruction. However, it has been shown that in mice, targeted disruption of the gene encoding glutathione peroxidase has little effect on oxidation of hemoglobin of murine red cells challenged with peroxides.¹⁹⁹ In addition,

Figure 47-7. Reactions through which hydrogen peroxide is generated and detoxified in the erythrocyte. In glucose-6-phosphate dehydrogenase (G6PD) deficiency and related disorders, inadequate generation of nicotinamide adenine dinucleotide phosphate (reduced form) (NADPH) results in accumulation of GSSG and probably of hydrogen peroxide (H₂O₂). The accumulation of these substances leads to hemoglobin denaturation, Heinz body formation, and, consequently, to decreased red cell survival. GR, glutathione reductase; GSH, reduced glutathione; GSH-Px, glutathione peroxidase; GSSG, glutathione disulfide (oxidized glutathione); HbO₂, oxyhemoglobin; NADP, nicotinamide adenine dinucleotide phosphate; Sup Dismut, superoxide dismutase.

catalase-null mice show negligible antioxidant function of catalase in oxidant injury.⁴⁴⁶ If such murine models reflect the situation in man, then different pathways requiring GSH, such as the thioredoxin, and/or peroxiredoxin reactions, may be important.^{446,447}

The formation of methemoglobin frequently accompanies the administration of drugs that have the capacity to produce hemolysis of G6PD-deficient cells.⁴⁴⁸ The heme groups of methemoglobin become detached from the globin more readily than do the heme groups of oxyhemoglobin.⁴⁴⁹ It is not clear whether methemoglobin formation plays an important role in the oxidative degradation of hemoglobin to Heinz bodies or whether formation of methemoglobin is merely an incidental side effect of oxidative drugs.^{450,451}

Infection-Induced Hemolysis

The mechanism of hemolysis induced by infection or occurring spontaneously in G6PD-deficient subjects is not well understood. The generation of hydrogen peroxide by phagocytizing leukocytes may play a role in this type of hemolytic reaction.⁴⁵¹

Favism

Substances capable of destroying red cell GSH have been isolated from fava beans,⁴⁵² but scientific evidence that these components (i.e., divicine and isouramil) are indeed responsible for hemolysis is lacking. Favism occurs only in G6PD-deficient subjects, but not all individuals in a particular family may be sensitive to the hemolytic effect of the beans. Nonetheless, some tendency toward familial occurrence has suggested that an additional genetic factor may be important.⁴⁵³ The observation of increased excretion of glucaric acid⁴⁵⁴ led to the suggestion that a defect in glucuronide formation might be present. Specific genotypes

of the acid phosphatase gene have been attributed to a decrease in the *f* isoforms of this tyrosine phosphatase and, consequently, low GSH levels.⁴⁵⁵ Immunologic factors do not seem to play a role in favism.⁴⁵⁶ Increased levels of red cell calcium^{457,458} and consequent “cross-bonding” of membranes may occur. Other membrane alterations that have been described are oxidation and clustering of membrane proteins, hemichrome binding to the internal face of the membrane, destabilization of the membrane, and the release of microvesicles.^{459–462}

Icterus Neonatorum

G6PD-deficient neonates are at increased risk of developing severe icterus neonatorum. The icterus is frequently unaccompanied by changes in hematologic indices reflective of a hemolytic process.^{463–465} The reason for this discrepancy is unclear. Icterus probably results principally from inadequate processing of bilirubin by the immature liver of G6PD-deficient infants. The demonstrated increase in carboxyhemoglobin levels, indicative of increased heme catabolism, suggests, however, that shortening of red cell life span also plays a role.⁴⁶⁶ A predisposing factor for severe jaundice in G6PD deficiency is mutation of the uridine diphosphoglucuronate glucuronosyltransferase-1 gene (*UGT1A1*) promoter,⁴⁶⁷ or, in Asia, the c.211G>A coding mutation.⁴⁶⁸ In adults, these mutations are associated with Gilbert syndrome. The limited data available on liver G6PD in deficient adults⁴⁶⁹ suggest that a considerable degree of deficiency may be present. If such a deficiency also is present in infants, it may play a role in impairing the borderline ability of infant livers with the *UGT1A1* promoter defect to catabolize bilirubin, in particular when a hemolytic process is set off because of contact with environmental factors, for example, neocytolysis (Chap. 33) certain drugs, naphthalene containing mothballs, etc. However, it is becoming apparent that modulation of bilirubin metabolism and serum bilirubin levels is under complex genetic control,⁴⁷⁰ and coexpressing of mutations in other genes, for example, *SLCO1B3*,⁴⁷¹ may contribute further to the bilirubin production-conjugation imbalance in G6PD-deficient individuals.⁴⁷²

Deficiencies of Other Enzymes of the Hexose Monophosphate Shunt and of Glutathione Metabolism

Deficiencies of glutamate cysteine synthetase, GS, and GR are associated with a decrease in red cell GSH levels. The generally mild hemolysis that occurs in these disorders probably has a pathogenesis similar to the hemolysis that occurs in G6PD deficiency. Other defects of the hexose monophosphate shunt and associated metabolic pathways are not associated with hemolysis (see Table 47-3).

Other Enzyme Deficiencies

How deficiencies of enzymes other than those of the hexose monophosphate pathway result in shortening of red cell life-span remains unknown, although it has been the object of much experimental work and of speculation. It is often believed that ATP depletion is a common pathway in producing damage to the cell leading to its destruction,⁴⁷³ but the evidence that this is the case is not always compelling.⁴⁷⁴ Nevertheless, it seems reasonable to assume that a red cell, deprived of a source of energy becomes sodium and calcium logged and potassium depleted, and the red cell shape changes from a flexible biconcave disk. Such a cell is quickly removed from the circulation by the filtering action of the spleen and the monocyte-macrophage system. Even if it survived, such an energy-deprived cell would gradually turn brown as hemoglobin is oxidized to methemoglobin by the very high concentrations of oxygen within the erythrocyte. Calcium has been proposed to play a central role. In particular, malfunction of ATP-dependent calcium transporters could lead to increased intracellular calcium levels that could affect red cell membrane proteins (i.e., protein 4.1), the lipid bilayer, volume regulation, metabolism, and redox state preservation, consequently leading

to proteolysis, oxidation, irreversible cellular shrinkage, phosphatidyl exposure and premature clearance.⁴⁷⁵ In agreement with this, PFK deficiency has been shown to result in increased calcium levels, accompanied by volume loss and metabolic dysregulation.^{476,477}

It is possible that, at least in some cases, alteration of the levels of red cell intermediate metabolites interferes with synthesis of cell components in early stages of development of the cell. In agreement with this, the lack of pyruvate has been implicated in the ineffective maturation of erythroid progenitors in PK-deficient mice.⁴⁷⁸

CLINICAL FEATURES

COMMON FORMS OF GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

Individuals who inherit the common (polymorphic) forms of G6PD deficiency, such as G6PD A- or G6PD Mediterranean, usually have no clinical manifestations. The major clinical consequence of G6PD deficiency is hemolytic anemia in adults and neonatal icterus in infants. Usually the anemia is episodic, but some of the unusual variants of G6PD may cause nonspherocytic congenital hemolytic disease (see “Variants Producing Hereditary Nonspherocytic Hemolytic Anemia” above). In general, hemolysis is associated with stress, most notably drug administration, infection, and, in certain individuals, exposure to fava beans.

Drug-Induced Hemolytic Anemia

Table 47-5 is an evidence-based^{3,479} list of drugs and other chemicals that are predicted to precipitate hemolytic reactions in G6PD-deficient individuals, and drugs that are innocuous when given in normal doses,

TABLE 47-5. Drugs That Can Trigger Hemolysis in G6PD-Deficient Individuals

Category of Drug	Predictable Hemolysis	Possible Hemolysis
Antimalarials	Dapsone	Chloroquine
	Primaquine	Quinine
	Methylene blue	
Analgesics/ Antipyretic	Phenazopyridine	Aspirin (high doses)
		Paracetamol (Acetaminophen)
Antibacterials	Cotrimoxazole	Sulfasalazine
	Sulfadiazine	
	Quinolones (including nalidixic acid, ciprofloxacin, ofloxacin)	
	Nitrofurantoin	
Other	Rasburicase	Chloramphenicol
	Toluidine blue	Isoniazid
		Ascorbic acid
		Glibenclamide
		Vitamin K
		Isosorbide dinitrate

but may be hemolytic when given in excessive doses. A case in point is ascorbic acid, which does not cause hemolytic anemia in normal doses but which can produce severe, even fatal, hemolysis at doses of 80 g or more intravenously.⁴⁸⁰⁻⁴⁸² Some drugs, such as chloramphenicol, may induce mild hemolysis in a person with severe, Mediterranean-type G6PD deficiency,⁴⁸⁴ but not in those with the milder A- or Canton⁴⁸⁵ types of deficiency. Furthermore, there appears, to be a difference in the severity of the reaction to the same drug of different individuals with the same G6PD variant. For example, red cells from a single G6PD-deficient individual were hemolyzed in the circulation of some recipients who were given thiazolsulfone, but their survival was normal in the circulation of others.⁴³⁸ Sulfamethoxazole, which was clearly hemolytic in experimental studies, does not appear to be a common cause of hemolysis in a clinical setting.⁴⁸⁶ Undoubtedly, individual differences in the metabolism and excretion of drugs influence the extent to which G6PD-deficient red cells are destroyed.^{487,488}

Several animal models have been developed to serve as a screening platform for the determination of hemolytic toxicity of pharmacologic agents in G6PD deficiency.^{489,490-492}

Typically, an episode of drug-induced hemolysis in G6PD-deficient individuals begins 1 to 3 days after drug administration is initiated.⁴⁹³ Heinz bodies appear in the red cells, and the hemoglobin concentration begins to decline rapidly.⁴⁹⁴ As hemolysis progresses, Heinz bodies disappear from the circulation, presumably as they or the erythrocytes that contain them are removed by the spleen. In severe cases, abdominal or back pain may occur. The urine may turn dark or even black. Within 4 to 6 days, there is generally an increase in the reticulocyte count, except in instances in which the patient has received the offending drug for treatment of an active infection as infection depresses erythropoiesis (Chap. 37). Because of the tendency of infections and certain other stressful situations to precipitate hemolysis in G6PD-deficient individuals, many drugs have been incorrectly implicated as a cause. Other drugs, such as aspirin, have appeared on many lists of proscribed medications because very large doses could slightly reduce the red cell life span. It is important to recognize that such drugs do not produce clinically significant hemolytic anemia. Advising patients not to ingest these drugs may not only deprive patients of potentially helpful medications, but will also weaken their confidence in the advice that they have received. Most G6PD-deficient patients, after all, have taken aspirin without untoward effect and are likely to distrust an advisor who counsels them that the ingestion of aspirin will have catastrophic effects.

In the A- type of G6PD deficiency, the hemolytic anemia is self-limited⁴⁹⁵ because the young red cells produced in response to hemolysis have nearly normal G6PD levels and are relatively resistant to hemolysis.⁴⁹⁵ The hemoglobin level may return to normal even while the same dose of drug that initially precipitated hemolysis is administered. In contrast, hemolysis is not self-limited in the more severe types such as Mediterranean deficiency.⁴⁹⁶

Hemolytic Anemia Occurring During Infection

Anemia often develops rather suddenly in G6PD-deficient individuals within a few days of onset of a febrile illness. The anemia is usually relatively mild, with a decline in the hemoglobin concentration of 3 or 4 g/dL. Hemolysis has been noted particularly in patients suffering from hepatitis A and B, cytomegalovirus, and pneumonia, and in those with typhoid fever.⁴⁹⁷⁻⁴⁹⁹ The fulminating form of the disease occurs particularly frequently among G6PD-deficient patients who are infected with Rocky Mountain spotted fever.⁵⁰⁰ Jaundice is not a prominent part of the clinical picture, except where hemolysis occurs in association with infectious hepatitis.^{501,502} In that case, it can be quite intense. Presumably because of the effect of the infection, reticulocytosis is usually absent, and recovery from the anemia is generally delayed until after the

active infection has abated. In rare cases, G6PD deficiency may present as transient aplastic crisis caused by viral infection.^{503,504}

Favism

Favism is potentially one of the gravest clinical consequences of G6PD deficiency. It occurs much more commonly in children than in adults, and occurs almost exclusively in persons who have inherited variants of G6PD that cause severe deficiency (most frequently associated with the Mediterranean variant), but rarely has the disorder been noted in patients with G6PD A-.⁵⁰⁵ The onset of hemolysis may be quite sudden, having been reported to occur within the first hours after exposure to fava beans. More commonly, the onset is gradual, hemolysis being noticed 1 to 2 days after ingestion of the beans.⁵⁰⁶ The urine becomes red or quite dark, and in severe cases shock may develop within a short time. Care should be taken to avoid acute renal failure. The oxidative stress causes membrane changes in erythrocytes, leading to extravascular hemolysis (in addition to the intravascular destruction).³ Sometimes the patient or parent does not realize that fava beans have been ingested, as they may be incorporated into foods such as Yew Dow, eaten by the Chinese,⁵⁰⁷ or falafel, eaten in the Middle East. Occasionally ingestion of other foodstuffs, such as unripe peaches⁵⁰⁸ or a spiced Nigerian barbecued meat known as red suya,⁵⁰⁹ has been reported to precipitate hemolysis. The toxic constituents of the fava beans are transmitted into the milk of breastfeeding mothers, putting affected babies at risk.⁵¹⁰

Neonatal Icterus

Although serious, the clinical consequences of drug-induced hemolysis, favism, or chronic hemolytic anemia are usually not devastating, and death from favism is a very rare event. The most serious consequence of G6PD deficiency is icterus neonatorum.⁴⁶³ G6PD-deficient neonates are an estimated three to four times more at risk for hyperbilirubinemia and phototherapy than G6PD-adequate neonates,⁵¹¹ depending on population groups and geographic area.⁵¹² Jaundice commences in the immediate perinatal period, and is usually evident by 1 to 4 days of age, similar to physiologic jaundice, but is seen at a later time than in blood group alloimmunization.⁵¹³ The jaundice may be quite severe and, if untreated, may result in kernicterus. Reports indicate an overrepresentation of G6PD deficiency among cases of kernicterus relative to the frequency of in the background population, also in countries with a low overall frequency of G6PD deficiency.⁴⁷² Thus, G6PD deficiency is a preventable cause of mental retardation,⁵¹⁴⁻⁵¹⁶ and this aspect of the disorder has considerable public health significance. Neonatal screening for G6PD deficiency has been associated with a decrease in the number of cases of kernicterus.⁴⁷²

Nonspherocytic Hemolytic Anemia

As described, the anemia in G6PD deficiency is usually episodic and acute, but some sporadic variants of G6PD may cause nonspherocytic congenital hemolytic disease, exacerbated by oxidative stress. Affected individuals have a history of severe neonatal jaundice, and features of chronic hemolysis (see “Variants Producing Hereditary Nonspherocytic Hemolytic Anemia” above). The hemolysis is mainly extravascular.

Effects on Other Tissues

In the common variants of G6PD, such as G6PD A- and Mediterranean, and even in most of the severely deficient variants, there is usually no demonstrated defect in leukocyte number or function.⁵¹⁷ However, there have been reports of isolated instances of leukocyte dysfunction associated with rare, severely deficient variants of G6PD.^{280,281,518-522} Patients with G6PD deficiency do not have a bleeding tendency, and studies of platelet function have yielded conflicting results.^{523,524} Occasionally, cataracts have been observed in patients with variants of G6PD

that produce nonspherocytic hemolytic anemia,⁵²⁵⁻⁵²⁷ or in neonatal patients.⁵²⁸ The incidence of senile cataracts may be increased in G6PD deficiency,^{529,530} but this remains controversial.^{531,532} Small studies from the Middle East are suggestive that decreased G6PD activity may predispose to the development of diabetes.⁵³³⁻⁵³⁵

A number of studies reported on acute rhabdomyolysis in patients with G6PD deficiency, suggesting that this condition could predispose to muscle damage,⁵³⁵⁻⁵⁴⁰ probably through the depletion of NADPH.⁵⁴¹ Others however, have demonstrated that G6PD-deficient individuals can participate in various physical activities, even high-intensity muscle damaging activities⁵⁴² without a negative impact on muscle function and redox status.^{543,544}

Although claims have been made that an association exists between various kinds of G6PD deficiency and cancer,^{545,546} the relationship between G6PD status and cancer is not clear as epidemiologic studies have not demonstrated any difference in risk for cancers between G6PD-deficient and normal patients.⁵⁴⁷⁻⁵⁴⁹ Some role for G6PD in carcinogenesis may be conceivable, though, given the finding that mutation of p53 abolishes the direct binding of this major tumor-suppressor gene to G6PD, thereby enhancing hexose monophosphate shunt flux and tumor cell biosynthesis.⁵⁵⁰

Population studies are needed to better elucidate the postulated effects of G6PD deficiency on the development of cardiovascular disease.^{278,551}

ENZYME DEFICIENCIES OTHER THAN GLUCOSE-6-PHOSPHATE DEHYDROGENASE

Most patients with hereditary nonspherocytic hemolytic anemia manifest only the usual clinical signs and symptoms of chronic hemolysis. The degree of anemia in this group of disorders varies widely. In some cases of very severe PK deficiency, scarcely any deficient cells survive in the circulation, and only transfused cells are found or steady-state hemoglobin levels as low as 5 g/dL are encountered. Other patients with hereditary nonspherocytic hemolytic anemia may manifest compensated hemolysis with a normal steady-state hemoglobin concentration. Chronic jaundice is a common finding, and splenomegaly is often present. Gallstones are common. As in other forms of chronic hemolytic anemia, ankle ulcers may be present.^{552,553} Pregnancy has been thought to precipitate hemolysis in patients with PK deficiency, perhaps even in heterozygotes.⁵⁵⁴⁻⁵⁵⁶ In PK deficiency, the increased 2,3-BPG levels may ameliorate the anemia by lowering the oxygen-affinity of hemoglobin. Some PK-deficient patients present with hydrops fetalis.⁵⁵⁷

In the case of some enzyme defects, characteristic nonhematologic systemic manifestations may be present, and these may be the only sign of the enzyme deficiency. For example, patients with PFK deficiency may have type VII muscle glycogen storage disease. In some patients with this defect, hemolysis is present without muscle manifestations, but in others both muscle abnormalities and hemolysis occur.⁵⁵⁸ Glutathione synthetase deficiency may be associated with 5-oxoprolinuria and neuromuscular disturbances, and such abnormalities may occur either with⁵⁵⁹ or without hematologic abnormalities.²⁶² On the other hand, some patients with GS deficiency manifest only the hematologic abnormalities.³⁸² Spinocerebellar degeneration was documented in the first case of glutamate cysteine synthetase described,^{381,384} but was not present in subsequently investigated patients.^{382,383} Patients with TPI deficiency nearly always manifest serious neuromuscular disease, and most of the patients who inherit this abnormality die in the first decade of life,^{560,561} but there are exceptions, as only one of two brothers with the same genotype manifested neurologic disease (see “Genetic Modifiers of the Phenotypes” below).^{562,563} Neurologic symptoms have also been noted in patients with deficiencies of glucosephosphate isomerase

and PGK.^{333,564} Myoglobinuria has been encountered in patients with PGK,^{261,565} aldolase,³⁵² and G6PD deficiency.⁵³⁹ Table 47–2 summarizes the clinical features of enzyme deficiencies causing nonspherocytic hemolytic anemia.

GENETIC MODIFIERS OF THE PHENOTYPES

The clinical phenotype of both acute and chronic hemolysis can be modified by coinherited (although unrelated) other defects of the red cells. Combined deficiencies of, for example, GPI and G6PD,³¹⁶ of PK and band 3,^{566–568} of PK and α -thalassemia,⁵⁶⁹ and of PK and G6PD⁵⁷⁰ have been documented.

The inheritance of polymorphic *UGT1A1* promoter alleles exacerbates the icterus both in neonates and in adults with G6PD deficiency (see also “Mechanism of Hemolysis” above).⁴⁷² Overt iron overload and iron-related morbidity in PK deficiency has been attributed to coinheritance of mutations in *HFE*, the gene associated with hereditary hemochromatosis.⁵⁷¹

A striking example of complex interplay defining the differences between the genotype and the phenotype was described in a Hungarian family with TPI deficiency. Two adult germline-identical compound heterozygous brothers displayed strikingly different phenotypes. Both had the same severe decrease in TPI activity and congenital hemolytic anemia, but only one suffered from severe neurologic disorder. Studies aimed at the pathogenesis of this differing phenotype indicated functional differences between the two brothers in lipid environment of the red cell membrane proteins influencing the enzyme activities,⁵⁶² as well as differences in *TPI1* mRNA expression, and protein expression levels of prolyl oligopeptidase, the activity decrease of which has been reported in well-characterized neurodegenerative diseases.⁵⁷²

The variety of clinical features associated with the various enzymopathies, regardless of the underlying molecular mechanism, do unequivocally demonstrate that the phenotype of hereditary red blood cell enzymopathies, is not solely dependent on the molecular properties of mutant proteins but rather reflects a complex interplay between physiologic, environmental, and other (genetic) factors. Putative phenotypic modifiers include differences in genetic background, concomitant functional polymorphisms of other glycolytic enzymes (many enzymes are regulated by their product or other metabolites), posttranslational modification, ineffective erythropoiesis, and different splenic function. As an example, persistent expression of the PK-M2 isozyme has been reported in the red blood cells of patients (and animals) with severe PK deficiency.^{29,573} The survival of these patients, though not in all cases may be enabled by this compensatory increase in PK activity.⁵⁷⁴

LABORATORY FEATURES

Varying degrees of anemia and reticulocytosis are the main hematologic laboratory features of patients with hereditary nonspherocytic hemolytic anemia. Heinz bodies often are found in the erythrocytes of G6PD-deficient patients undergoing drug-induced hemolysis. In the absence of hemolysis, the light-microscopic morphology of G6PD-deficient red cells appears to be normal. Differences in the texture of the membrane of the cells have, however, been observed under electron microscopy.⁵⁷⁵ When a hemolytic drug is administered to a G6PD-deficient patient, Heinz bodies (Chap. 31) develop in the erythrocytes immediately preceding and in the early phases of the hemolytic episode. If the hemolytic anemia is very severe, spherocytosis and red cell fragmentation may be seen in the stained film. Despite the fact that “bite cells” may be noted in the blood of a G6PD-deficient patient undergoing drug-induced hemolysis, the association with G6PD deficiency is doubtful because such cells are usually lacking in acute hemolytic

states of patients with common G6PD variants or in G6PD-deficient patients with chronic hemolysis. Moreover, “bite cells” have been noted in G6PD-replete patients.^{576,577}

The presence of small, densely staining cells has often been noted in the blood films of patients with hereditary nonspherocytic hemolytic anemia with defects other than G6PD deficiency. Particularly when manifesting an echinocytic appearance, such cells have been thought to be common in PK deficiency. In one reported case,⁵⁷⁸ spectacular numbers of such cells were observed. However, cells of this type are seen in many blood films both from patients with other glycolytic enzyme deficiencies and from those with other disorders and it is hazardous to attempt to make an enzymatic diagnosis on the basis of such findings. Basophilic stippling of the erythrocytes is prominent in most patients with pyrimidine 5'-nucleotidase deficiency but is on itself an unspecific finding, and may not be apparent in blood that has been collected in ethylenediaminetetraacetic acid anticoagulant. Leukopenia occasionally is observed in patients with hereditary nonspherocytic hemolytic anemia, possibly secondary to splenic enlargement. Other laboratory stigmata of increased hemolysis may include increased levels of serum bilirubin, decreased haptoglobin levels, and increased serum LDH activity (Chap. 33). Reticulocytosis is frequently observed, which may result in increased mean corpuscular volume of erythrocytes. In PK deficiency, splenectomy increases reticulocyte counts even further because in particular the younger PK-deficient red blood cells are preferentially sequestered by the spleen.⁵⁷⁹ Also in P5'N1 deficiency reticulocytes tend to be higher in splenectomized patients compared to non-splenectomized patients.⁴²⁰

Diagnosis of red cell enzyme deficiencies usually depends on the demonstration of decreased enzyme activity either through a quantitative assay or a screening test.^{580–583} Assay of most of the enzymes generally is carried out by measuring the rate of reduction or oxidation of nicotinamide adenine nucleotides in an ultraviolet spectrophotometer, and a number of screening tests that depend upon the development or loss of fluorescence have been devised.⁵⁸⁴

However, difficulties arise when the patient has been transfused so that the blood drawn represents a mixture of the patient's own cells and those obtained from the blood bank. Under the circumstances, DNA analysis may prove invaluable, because the DNA is extracted from blood leukocytes and transfused leukocytes do not persist in the circulation. Alternatively, density fractionation has been applied to isolate fractions of patient's red cells, in which an enzyme deficiency can be detected.⁵⁸⁵

Although detection of G6PD deficiency in the healthy, fully affected (hemizygous) male can be achieved readily through either assay or screening tests, difficulties arise when a patient with G6PD deficiency of the A- type has undergone a hemolytic episode. As the older, more enzyme-deficient cells are removed from the circulation and are replaced by young cells, the level of the enzyme begins to increase toward normal. Under such circumstances, suspicion that the patient may be G6PD deficient should be raised by the fact that enzyme activity is not increased, even though the reticulocytes count is elevated.^{586,587} It is helpful to perform DNA mutational analyses, carry out family studies, or to wait until the circulating red cells have aged sufficiently to betray their lack of enzyme.

Even greater difficulties are encountered in attempting to diagnose heterozygotes for G6PD deficiency.⁵⁸⁸ Because the gene is X linked, a population of normal red cells coexists with the deficient cells. This may mask the enzyme deficiency when screening tests are used. Even enzyme assays carried out on erythrocytes of heterozygous females frequently may be in the normal range. Here DNA mutational analyses and histochemical methods that depend upon individual red cell enzyme activity may be useful.^{589,590} In addition, the ascorbate cyanide test,⁵⁹¹ in which screening is carried out on a whole-cell population rather than

on a lysate, may be more sensitive than the other screening procedures. Prenatal diagnosis of G6PD deficiency is also possible using DNA mutational analyses approach.

Testing for red cells enzyme deficiencies is best done in specialized laboratories. Specimens can be shipped by mail to reference laboratories. As a rule, whole-blood specimens are suitable and can best be sent at 4°C as some enzymes, notably PFK, are relatively unstable.⁵⁸⁰ Blood from a healthy volunteer should be shipped with the patient sample to serve as a shipping control. Exceptions are assays for phosphorylated sugar intermediates, 2,3-BPG, and nucleotide intermediates, which are unstable in freshly drawn blood and require immediate deproteinization in perchloric acid.

Several aspects should be kept in mind when interpreting test results. First, care must be taken to remove leukocytes and platelets in assays such as for PK, as these cells contain PK activity, obscuring a deficiency in the red cells. Second, one should be aware of the already mentioned red cell age dependency of, for example, PK, HK, and G6PD. The measurement of these enzymes simultaneously can give an idea about red cell age and relative deficiencies. If patients received blood transfusions, interpreting results from red cell enzyme assays is generally not possible because the presence of donor erythrocytes will obscure any deficiencies. Some mutant enzymes also display a normal activity *in vitro*, whereas *in vivo* severe hemolysis can occur, reflecting the differences between optimal circumstances *in vitro* and the *in vivo* cellular environment. More sophisticated assays to measure, for example, heat instability and kinetics, have to be used in those cases. Interpretation can be particularly challenging in newborn patients given the differences in red cell energy metabolism and enzymatic activities between adults and newborn infants.⁵⁹²⁻⁵⁹⁶ Molecular diagnosis is now available for all red cell enzyme deficiencies.

DIFFERENTIAL DIAGNOSIS

Drug-induced hemolytic anemia resulting from G6PD deficiency is similar in its clinical features and in certain laboratory features, to drug-induced hemolytic anemia associated with unstable hemoglobins (Chap. 49). Other enzyme defects affecting the pentose-phosphate shunt, such as a deficiency of GS, also may mimic G6PD deficiency. The diagnosis of hemoglobinopathies can be excluded by performing a stability test,⁵⁹⁷ hemoglobin electrophoresis or DNA sequence analysis. These are normal in G6PD deficiency. Some of the screening tests, particularly the ascorbate cyanide test,⁵⁹¹ may give positive results in the above-named disorders, but a G6PD assay or the fluorescent screening test will be positive only in G6PD deficiency. In addition, defects of the erythrocyte membrane should be excluded (Chap. 46), but these cytoskeletal and other membrane defects are generally associated with characteristic morphologic abnormalities, that makes them easy to differentiate from hemolysis because of enzyme defects.

Physicians often attempt to establish the cause of hereditary nonspherocytic hemolytic anemia on the basis of the appearance of red cells on a blood film. In reality, red cell morphology is helpful only in the diagnosis of pyrimidine 5'-nucleotidase deficiency because of the characteristic stippling of the red cells that is observed in that disorder. The appearance of Heinz bodies suggests the possible presence of an unstable hemoglobin, or defective GSH metabolism. They are more likely to be present after splenectomy.

Because the laboratory diagnosis of these disorders may entail considerable expenditure of time and effort, it is prudent to perform the simplest tests for the most common causes of hereditary nonspherocytic hemolytic anemia first. Accordingly, it is useful to carry out screening tests^{580,582} for G6PD and PK activity and an isopropanol stability test to detect an unstable hemoglobin (Chap. 49). If prominent

stippling of erythrocytes is present, examination of the ultraviolet spectrum of a perchloric acid extract of the erythrocytes, reflecting the ratio between pyrimidine and purine nucleotide content, may help to establish the diagnosis of pyrimidine 5'-nucleotidase deficiency.⁵⁹⁸ Beyond these relatively simple procedures it is probably rarely useful to pick and choose individual enzyme assays on the basis of family history or clinical manifestations. Rather, it is usually appropriate to submit a blood sample to a reference laboratory that has the capability of performing all the enzyme assays listed in Table 47-3. Preferably, the suspicion of a specific enzyme disorder causing hereditary nonspherocytic hemolytic anemia is confirmed by DNA sequence analysis. This also enables prenatal diagnosis which has already been achieved for some of enzymatic defects.⁵⁹⁹⁻⁶⁰⁷

Notably, in an estimated 70 percent of cases of suspected hereditary nonspherocytic hemolytic anemia no enzymatic abnormality is found.^{608,609} Current promising approaches such as red cell proteome analysis⁶¹⁰⁻⁶¹² and/or the use of next-generation sequencing technologies⁶¹³ may aid in a better and more comprehensive understanding of the etiology of this disorder.

THERAPY

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

G6PD-deficient individuals should avoid drugs that are predicted to induce hemolytic episodes (see Table 47-5). However, it is important to realize that such patients are able to tolerate most drugs. Unfortunately, in the past, a number of case reports incorrectly suggested that some drugs had hemolytic potential that subsequently were shown to be safe (see Table 47-5, possible hemolysis). Although it is possible that some of these may be hemolytic in some patients or under some circumstances, this is unlikely, and G6PD-deficient patients should not be deprived of the possible benefit of these drugs.

If hemolysis occurs as a result of drug ingestion or infection, particularly in the milder A- type of deficiency, transfusion usually is not required. If, however, the rate of hemolysis is very rapid, as may occur, for example, in favism, transfusions of packed cells may be useful. Good urine flow should be maintained in patients with hemoglobinuria to avert renal damage. Infants with neonatal jaundice resulting from G6PD deficiency may require phototherapy or exchange transfusion; in areas in which G6PD deficiency is prevalent, care must be taken not to give G6PD-deficient blood to such newborns.⁶¹⁴ A single dose of Sn-mesoporphyrin, a potent inhibitor of heme oxygenase, has been advocated to eliminate the need for phototherapy.⁶¹⁵ Patients with hereditary nonspherocytic hemolytic anemia resulting from G6PD deficiency usually do not require any therapy. Splenectomy is often ineffective, although some improvement has been reported in a number of cases following removal of the spleen.^{264,616} In most cases, the anemia is not very severe, but in some instances frequent transfusions have been necessary.^{617,618} The antioxidant properties of vitamin E have been tested in G6PD-deficient subjects, and a slight but statistically significant reduction in hemolysis was observed.^{619,620} These results could not be confirmed in other studies.^{621,622} It has been suggested that desferrioxamine decreases hemolysis.^{623,624} Inhibition of histone acetylation by histone deacetylase inhibitors has been shown to increase G6PD gene transcription in erythroid progenitor cells and restore G6PD deficiency.⁶²⁵

OTHER ENZYME DEFICIENCIES

Most patients with hereditary nonspherocytic hemolytic anemia secondary to red cell enzymopathies do not require therapy, other than blood transfusion during hemolytic periods, if the anemia needs

clinically to be corrected. There are patients with PK deficiency who need to be transfused continually. Chronic transfusion therapy usually requires iron chelation if of sufficient iron load. Patients with TPI deficiency generally die as children, not because of the severity of the anemia but because of the severe neuromuscular effects of the enzyme deficiency. It has been proposed that the exogenous replacement of TPI might be useful for the treatment of this deficiency,⁶²⁶ but no clinical trials have been carried out. PK deficiency⁶²⁷ and PGK deficiency³⁷⁵ have been treated successfully by stem cell transplantation, but this is still only very rarely done. Studies are underway to improve gene therapy in PK deficiency.^{305,307,308} In PK deficiency, erythroid cells have been treated *ex vivo* with glycolytic intermediates to correct for metabolic dysfunction.⁶²⁸ Preliminary evidence indicates that small molecule activation of mutant PK may be able to restore glycolytic pathway activity and normalize red cell metabolism in PK deficiency.⁶²⁹ The jaundice of glucose-phosphate isomerase deficiency has been treated by the administration of phenobarbital.⁶³⁰

The principal decision that the physician must make regarding patients with hereditary nonspherocytic hemolytic anemia is whether or not they require a splenectomy. This decision is not made easily as the response is unpredictable, and some patients who fail to respond may develop serious thrombotic complications, resulting thrombocytosis is often exaggerated when splenectomy does not ameliorate the hemolysis. The recommendation that is made should be based upon the following considerations: (1) severity of the disease, (2) family history of response to splenectomy, (3) the underlying defect, and (4) perhaps the need for cholecystectomy. Because it is unusual to obtain more than a partial response to splenectomy, this procedure should probably be reserved for patients whose quality of life is impaired by their anemia. The operation needs to be particularly considered for patients who need frequent transfusion and for those who require gallbladder surgery, in which splenectomy might be carried out as part of the same procedure. The best guide to the likely efficacy of splenectomy is probably the response to splenectomy of other affected family members. Unfortunately, such information is only occasionally available. The physician must therefore rely upon the experience of other patients with hereditary nonspherocytic hemolytic anemia of similar etiology to serve as a guide. However, even as the large group of patients with hereditary nonspherocytic hemolytic anemia represents a heterogeneous population, so individuals with a single enzymatic lesion, such as PK deficiency, are heterogeneous. Each family is likely to be afflicted with a distinct mutant enzyme, and the various mutants may differ both with respect to clinical manifestations and with respect to response to splenectomy. Some of the available information regarding response to splenectomy of patients with hereditary nonspherocytic hemolytic anemia has been reviewed²⁶⁴ and is summarized in Table 47–2.

Glucocorticoids are of no known value in this group of disorders. Folic acid is often given, as in other patients with increased marrow activity, but without proven hematologic benefit. In the absence of iron deficiency, iron is contraindicated. Iron overload is a complication in this group of disorders, particularly in connection with PK deficiency,^{289,571,631,632} even in nontransfused patients.⁶³³ The iron overload is probably multifactorial (Chap. 43), involving chronic hemolysis, ineffective erythropoiesis, splenectomy, coinheritance of hereditary hemochromatosis gene (*HFE*) mutations, growth differentiation factor-15, and hepcidin levels.^{571,634,635}

COURSE AND PROGNOSIS

Hemolytic episodes in the A– type of deficiency are usually self-limited, even if drug administration is continued. This is not the case in the more severe Mediterranean type of deficiency.⁶³⁶ In patients with hereditary

nonspherocytic hemolytic anemia resulting from G6PD deficiency, gallstones may occur.⁶³⁷ During periods of infections or drug administration, anemia may increase in severity. Otherwise, the hemoglobin level of affected subjects remains relatively stable.

Nearly all patients with drug- or infection-induced hemolysis recover uneventfully. Favism must be considered, by comparison, a relatively dangerous disease. The most serious complication of G6PD deficiency is neonatal icterus. If not recognized early and properly treated, it can lead to kernicterus (see “Clinical Features” above).

In one large population study, a decreasing incidence of G6PD deficiency was noted with increasing age of the population,⁶³⁸ but no such change was observed in another.²² Although age stratification might represent evidence of a shorter life span for individuals with the A– deficiency, other factors are more likely explanations. Examination of the health records of more than 65,000 U.S. Veterans Administration males failed to reveal any higher frequency of any illness in G6PD-deficient compared to nondeficient subjects.⁶³⁹ Furthermore, it appears that there are no indications that G6PD-deficient individuals should systematically be excluded from serving as blood donors,⁶⁴⁰ or hematopoietic stem cell donor.⁶⁴¹ In view of the benign nature of the common types of G6PD deficiency, community-based population screening is not recommended. However, screening for G6PD deficiency of all patients admitted to the hospital may be useful in anticipating hemolytic reactions and in understanding them if they occur; however, this recommendation has not been submitted to rigorous analysis and is controversial because of low likelihood of any preventable hemolysis. This is particularly prudent if a drug such as dapsone or rasburicase, known to cause hemolysis in G6PD-deficient individuals, is to be given.^{483,642} Study of family members of patients with this X chromosome-linked enzyme deficiency can be helpful in providing appropriate counseling to affected individuals.

The diagnosis of hereditary nonspherocytic hemolytic anemia has been made as late as the seventh decade,²⁰² and the disease can be fatal in the first few years of life. TPI deficiency appears to have the worst prognosis of all of the known defects that cause this disorder. With few exceptions, patients with this deficiency have died by the fifth or sixth year of life, usually of cardiopulmonary failure. PK deficiency, too, can be fatal in early childhood; the PK mutation prevalent among the Amish of Pennsylvania produces particularly severe disease.⁶⁴³ Unless the affected homozygous children have their spleens removed, the disorder is commonly lethal. In PK deficiency, compound heterozygotes and homozygotes can suffer of major side effects as a result of the chronic hemolysis and the burden of repeated transfusions and iron chelation. In general, however, hereditary nonspherocytic hemolytic anemia is a relatively mild disease and most affected individuals lead a relatively normal life, apparently without much compromise of life span.

CHAPTER 48

THE THALASSEMIAS: DISORDERS OF GLOBIN SYNTHESIS

David J. Weatherall

SUMMARY

The thalassemias are the commonest monogenic diseases in man. They occur at a high gene frequency throughout the Mediterranean populations, the Middle East, the Indian subcontinent, and Myanmar, and in a line stretching from southern China through Thailand and the Malay peninsula into the island populations of the Pacific. They are also seen commonly in countries in which there has been immigration from these high-frequency populations.

There are two main classes of thalassemias, α and β , in which the α - and β -globin genes are involved, and rarer forms caused by abnormalities of other globin genes. Some extremely rare congenital and acquired thalassemia that have intact globin genes are caused by either mutations of nonglobin genes or factors yet to be elucidated. All thalassemias have in common an imbalanced rate of production of the globin chains of adult hemoglobin, excess α chains in β -thalassemia and excess β chains in α -thalassemia. Several hundred different mutations at the α - and β -globin loci have been defined as the cause of the reduced or absent output of α or β chains. The high frequency and genetic diversity of the thalassemias is related to past or present heterozygote resistance to malaria.

The pathophysiology of the thalassemias can be traced to the deleterious effects of the globin-chain subunits that are produced in excess. In β -thalassemia, excess α chains cause damage to the red cell precursors and red

cells and lead to profound anemia. This causes expansion of the ineffective marrow, with severe effects on development, bone formation, and growth. The major cause of morbidity and mortality is the effect of iron deposition in the endocrine organs, liver, and heart, which results from increased intestinal absorption and the effects of blood transfusion. The pathophysiology of the α -thalassemias is different because the excess β chains that result from defective α -chain production form β_4 molecules, or hemoglobin H, which is soluble and does not precipitate in the marrow. However, it is unstable and precipitates in older red cells. Hence, the anemia of α -thalassemia is hemolytic rather than dyserythropoietic.

The clinical pictures of α - and β -thalassemia vary widely, and knowledge is gradually being amassed about some of the genetic and environmental factors that modify these phenotypes.

Because the carrier states for the thalassemias can be identified and affected fetuses can be diagnosed by DNA analysis after the ninth to tenth week of gestation, these conditions are widely amenable to prenatal diagnosis. Currently, marrow transplantation is the only way in which they can be cured. Symptomatic management is based on regular blood transfusion, iron chelation therapy, and the judicious use of splenectomy. Experimental approaches to their management include the stimulation of fetal hemoglobin synthesis and attempts at somatic cell gene therapy.

DEFINITIONS AND HISTORY

In 1925, Cooley and Lee¹ first described a form of severe anemia that occurred early in life and was associated with splenomegaly and bone changes. In 1932, George H. Whipple and William L. Bradford² published a comprehensive account of the pathologic findings in this disease. Whipple coined the phrase *thalassic anemia*^{3,4} and condensed it to *thalassemia*, from $\theta\alpha\lambda\alpha\sigma\sigma\alpha$ (“the sea”), because early patients were all of Mediterranean background. The true genetic character of the disorder became fully appreciated after 1940. The disease described by Cooley and Lee is the homozygous state of an autosomal gene for which the heterozygous state is associated with much milder hematologic changes. The severe homozygous condition became known as *thalassemia major*. The heterozygous states, thalassemia trait, were designated according to their severity as *thalassemia minor* or *minima*.^{3,5-7} Later, the term *thalassemia intermedia* was used to describe disorders that were milder than the major form but more severe than the traits.

Thalassemia is not a single disease but a group of disorders, each resulting from an inherited abnormality of globin production.⁷ The conditions form part of the spectrum of diseases known collectively as the *hemoglobinopathies*, which can be classified broadly into two types. The first subdivision consists of conditions, such as sickle cell anemia, that result from an inherited structural alteration in one of the globin chains. Although such abnormal hemoglobins may be synthesized less efficiently or broken down more rapidly than normal adult hemoglobin, the associated clinical abnormalities result from the physical properties of the abnormal hemoglobin (Chap. 49). The second major subdivision of the hemoglobinopathies, the thalassemias, consists of inherited defects in the rate of synthesis of one or more of the globin chains. The result is imbalanced globin chain production, ineffective erythropoiesis, hemolysis, and a variable degree of anemia.

Several monographs describe the historical aspects of thalassemia in greater detail.^{5,7}

Acronyms and Abbreviations: AATAAA, the polyadenylation signal site; ATR-16, α -thalassemia chromosome 16-linked mental retardation syndrome; ATR-X, α -thalassemia X-linked mental retardation syndrome; *BCL11A*, B-cell lymphoma/leukemia oncogene important for γ - to β -globin switching; CAP site, a DNA site located in or near a promoter; DNase I, an enzyme used to detect DNA-protein interaction; GATA-1, a transcription factor essential for productive erythropoiesis; H₂FO₂, hereditary persistence of fetal hemoglobin; HS, hypersensitive site to DNase I treatment; IVS, intervening sequence of a gene (i.e., an intron); KLF1, erythroid Kruppel-like factor; LCR, locus control region; MCS, multispecies conserved sequences; NFE-2L1, “nuclear factor, erythroid 2” is a transcription factor essential for productive erythropoiesis; PHD region, known as plant homeodomain is a DNA region with zinc finger motif commonly deleted in ATR-X α -thalassemia; RFLP, restriction fragment length polymorphism; TATA box, a DNA sequence (*cis*-regulatory element) found in the promoter region of genes.

DIFFERENT FORMS OF THALASSEMIA

Thalassemia can be defined as a condition in which a reduced rate of synthesis of one or more of the globin chains leads to imbalanced globin-chain synthesis, defective hemoglobin production, and damage to the red cells or their precursors from the effects of the globin subunits that are produced in relative excess.^{7,8} Table 48–1 summarizes the main varieties of thalassemia that have been defined with certainty.

The β -thalassemias are divided into two main varieties. In one form, β^0 -thalassemia, there is no β -chain production. In the other form, β^+ -thalassemia, there is a partial deficiency of β -chain production. The hallmark of the common forms of β -thalassemia is an elevated level of hemoglobin A₂ in heterozygotes. In a less-common class of β -thalassemias, heterozygotes have normal hemoglobin A₂ levels. Other rare forms include varieties of β -thalassemia intermedia that are inherited in a dominant fashion, that is, heterozygotes are severely affected, and there is a variety in which the genetic determinants are not linked to the β -globin gene cluster.^{7,9,10}

The $\delta\beta$ -thalassemias are heterogeneous. In some cases, no δ or β chains are synthesized. Originally, these disorders were classified according to the structure of the hemoglobin F produced, that is, $^{\epsilon}\gamma^{\wedge}\gamma(\delta\beta)^0$ - and $^{\epsilon}\gamma(\delta\beta)^0$ -thalassemia. This classification is illogical. The

conditions are best described by the globin chains that are defectively synthesized, that is, simply $(\delta\beta)^{+-}$, $(\delta\beta)^{0-}$, and $(^{\wedge}\gamma\delta\beta)^{0-}$ -thalassemia.^{7,10} In the $(\delta\beta)^{+-}$ -thalassemias, an abnormal hemoglobin is produced that has normal α chains combined with non- α chains consisting of the N-terminal residues of the δ chain fused to the C-terminal residues of the β chain. These fusion variants, called the *Lepore hemoglobins*, show structural heterogeneity.

The δ -thalassemias^{7,10} are characterized by reduced output of δ chains and hence reduced hemoglobin A₂ levels in heterozygotes and an absence of hemoglobin A₂ in homozygotes. They are of no clinical significance except that, when inherited with β -thalassemia trait, the level of hemoglobin A₂ is reduced to the normal range.

A disorder characterized by defective ϵ -, γ -, δ -, and β -chain synthesis has been defined at the clinical and molecular level.^{7,10} The homozygous state for this condition, $\epsilon\gamma\delta\beta$ -thalassemia, presumably is not compatible with fetal survival. It has been observed only in heterozygotes.

Hereditary persistence of fetal hemoglobin (HPFH) is a heterogeneous condition characterized by persistent fetal hemoglobin.^{7,9,10} It is classified into deletion and nondeletion forms. The deletion forms of HPFH can be classified, like $\delta\beta$ -thalassemia, as $(\delta\beta)^0$ HPFH and then subdivided according to the particular population in which this occurs and its associated molecular defect. In effect, the deletion forms of HPFH are very similar to β -thalassemia except for more efficient γ -chain synthesis and, therefore, less chain imbalance and a milder phenotype. The homozygous state is associated with mild thallemic changes. In fact, the β -thalassemias and deletion forms of HPFH form a clinical continuum. The nondeletion forms of HPFH also are heterogeneous. In some cases, they are associated with mutations that involve the β -globin gene cluster and in which there is β -chain synthesis *cis* to the HPFH determinant. These conditions are subdivided into $^{\epsilon}\gamma\beta^+$ HPFH and $^{\wedge}\gamma\beta^+$ HPFH. Again, they often are subclassified according to the population in which they occur, for example, Greek HPFH, British HPFH, and so on. Finally, a heterogeneous group of HPFH determinants is associated with very low levels of persistent fetal hemoglobin, the genetic loci of which, at least in some cases, are not linked to the β -globin gene cluster.

Because α chains are present in both fetal and adult hemoglobins, a deficiency of α -chain production affects hemoglobin synthesis in fetal and in adult life. A reduced rate of α -chain synthesis in fetal life results in an excess of γ chains, which form γ_4 tetramers, or hemoglobin Bart's. In adult life, a deficiency of α chains results in an excess of β chains, which form β_4 tetramers, or hemoglobin H. Because there are two α -globin genes per haploid genome, the genetics of α -thalassemia is more complicated than that of β -thalassemia. There are two main groups of α -thalassemia determinants.^{7,10} First, in the α^0 -thalassemias (formerly called α -thalassemia 1), no α chains are produced from an affected chromosome; that is, both linked α -globin genes are inactivated. Second, in the α^+ -thalassemias (formerly called α -thalassemia 2), the output of one of the linked pair of α -globin genes is defective. The α^+ -thalassemias are subdivided into deletion and nondeletion types. Both the α^0 -thalassemias and deletion and nondeletion forms of α^+ -thalassemia are extremely heterogeneous at the molecular level. There are two major clinical phenotypes of α -thalassemia: the hemoglobin Bart's hydrops syndrome, which usually reflects the homozygous state for α^0 -thalassemia, and hemoglobin H disease, which usually results from the compound heterozygous state for α^0 - and α^+ -thalassemia.

Because the structural hemoglobin variants and the thalassemias occur at a high frequency in some populations, the two types of genetic defect can be found in the same individual. The different genetic varieties of thalassemia and their combinations with the genes for abnormal hemoglobins produce a series of disorders known collectively as the *thalassemia syndromes*.⁷

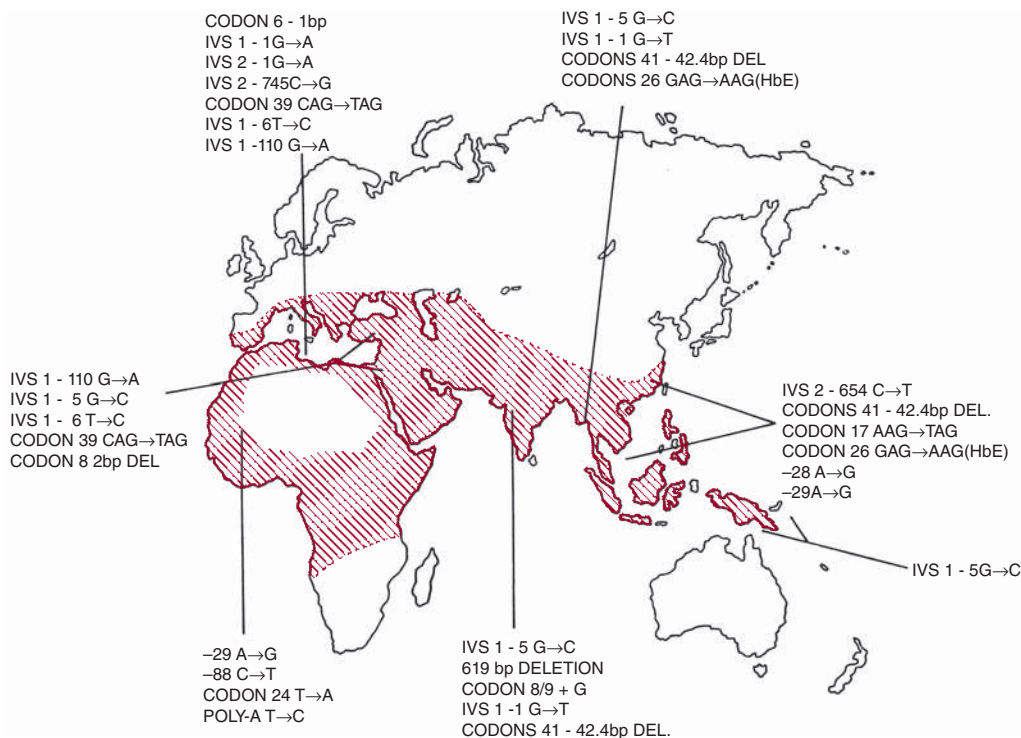

Figure 48-1. World distribution of β -thalassemia.

● EPIDEMIOLOGY AND POPULATION GENETICS

The β -thalassemias are distributed widely in Mediterranean populations, the Middle East, parts of India and Pakistan, and throughout Southeast Asia (Fig. 48-1).^{7,11,12} The disease is common in Tajikistan, Turkmenistan, Kyrgyzstan, and the People's Republic of China. Because of the extensive migration from areas of high gene frequency such as the Mediterranean region (e.g., Italy, Greece), Africa, and Asia to the Americas, the α - and β -thalassemia genes and clinical disease are relatively common, especially in North, but also South, America. The β -thalassemias are rare in Africa, except for isolated pockets in West Africa, notably Liberia, and in parts of North Africa. However, β -thalassemia occurs sporadically in all racial groups and has been observed in the homozygous state in persons of pure Anglo-Saxon heritage. Thus, a patient's racial background does not preclude the diagnosis.

The $\delta\beta$ -thalassemias have been observed sporadically in many racial groups, although no high-frequency populations have been defined. Similarly, the hemoglobin Lepore syndromes have been found in many populations, but, with the possible exceptions of central Italy, Western Europe, and parts of Spain and Portugal, these disorders have not been found to occur at a high frequency in any particular region.

The α -thalassemias occur widely throughout Africa, the Mediterranean countries, the Middle East, and Southeast Asia (Fig. 48-2).^{7,11,12} The α^0 -thalassemias are found most commonly in Mediterranean and Oriental populations, but are extremely rare in African and Middle Eastern populations. However, the deletion forms of α^+ -thalassemia occur at a high frequency throughout West Africa, the Mediterranean, the Middle East, and Southeast Asia. In United States, approximately 30 percent of Americans of African descent carry the gene α^+ -thalassemia. Up to 80 percent of the population of some parts of Papua New Guinea are carriers for the deletion form of α^+ -thalassemia. How common the nondeletion forms of α^+ -thalassemia are in any particular populations

is uncertain, but they have been reported quite frequently in some of the Mediterranean island populations and in the Middle Eastern and Southeast Asian populations. Because the hemoglobin Bart's hydrops syndrome and hemoglobin H disease require the action of an α^0 -thalassemia determinant, these disorders are found at a high frequency only in Southeast Asia and in parts of the Mediterranean region. The α -chain termination mutants, such as hemoglobin Constant Spring, seem to be particularly common in Southeast Asia. Approximately 4 percent of the population in Thailand are carriers.

In 1949, J.B.S. Haldane¹³ suggested that thalassemia had reached its high frequency in tropical regions because heterozygotes are protected against malaria.¹³ Although many population studies have tested this

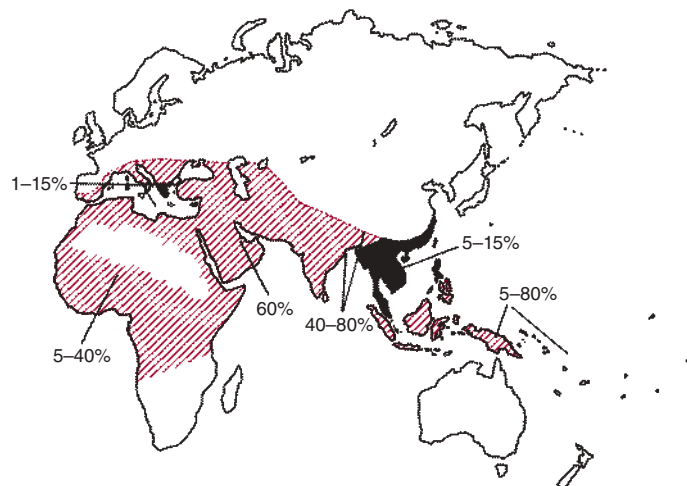

Figure 48-2. World distribution of α^+ - (hatched areas) and α^0 -thalassemia (shaded areas).

hypothesis, elucidation of some of the extremely complex population genetics underlying polymorphic systems such as the thalassemias has been possible only with the advent of recombinant DNA technology.

In each of the high-frequency areas for the β -thalassemias, a few common mutations and varying numbers of rare mutations are seen (see Fig. 48-1). Furthermore, in each of these regions the pattern of mutations is different, usually found in the context of different haplotypes in the associated β -globin gene cluster.^{11,14,15} Similar observations have been made in the α -thalassemias (see Fig. 48-2).^{7,11} These studies suggest the thalassemias arose independently in different populations and then achieved their high frequency by selection. Although some movement of the thalassemia genes may have resulted from drift, independent mutation and selection undoubtedly provide the overall basis for their world distribution. Early studies in Sardinia, showing that β -thalassemia is less common in the mountainous regions where malarial transmission is low, supported Haldane's suggestion that β -thalassemia reached its high frequency because of protection against malarial infections.¹⁶ For many years these data remained the only convincing evidence for a protective effect. However, later studies using malaria endemicity data and globin-gene mapping showed a clear altitude-related effect on the frequency of α -thalassemia in Papua New Guinea. In addition, a sharp cline (a gradual change of species phenotype over a geographical area) in the frequency of α -thalassemia has been found in the region stretching south from Papua New Guinea through the island populations of Melanesia to New Caledonia. This is mirrored by a similar gradient in the distribution of malaria.¹⁷ The effect of drift and founder effect in these island populations has been largely excluded by showing that other DNA polymorphisms have a random distribution through the region, with no evidence of a cline similar to that characterizing the distribution of α -thalassemia and malaria.

Firm evidence for protection of individuals with mild forms of α^+ -thalassemia against *Plasmodium falciparum* malaria has been provided. In a case-control study performed in Papua New Guinea, the homozygous state for α^+ -thalassemia offered approximately 60 percent protection against hospital admittance because of serious complications of malaria, notably coma or profound anemia.¹⁸ Similar levels of protection by α -thalassemia against *P. falciparum* malaria have been found in several different African populations.¹⁹ However, it is becoming clear that there are complex genetic epistatic interactions between protective polymorphisms of this kind. For example, although α -thalassemia and the sickle cell trait both offer strong protection against *P. falciparum* malaria, in those who inherit both traits, the protection is canceled out and they are fully susceptible to the disease.²⁰ Interactions of this type will have an important effect on the gene frequency of protective polymorphisms in countries in which more than one exists in the same population.

There is growing evidence that both immune and cellular mechanisms may underlie these protective effects of different red cell polymorphisms against malarial infection. Followup studies of cohorts of babies with α -thalassemia suggest that, in the first year of life, they are more prone to *Plasmodium vivax* and *P. falciparum* malaria. Because there is evidence for cross-immunization between these two species, it is possible that this effect induces early immunization that may result in babies with α -thalassemia being more resistant to *P. falciparum* malaria later in life.²¹ At the cellular level there is no evidence that α -thalassemia has any effect on the rates of parasite invasion and growth in red cells. However, parasitized α -thalassemic red cells are more susceptible to phagocytosis *in vitro*, and are less able than normal cells to form rosettes, an *in vitro* phenomena whereby uninfected cells bind to infected cells that is strongly associated with severity of infection, and express low levels of complement receptor 1, which is required for rosette formation.²² These highly complex immune and cellular interactions are discussed in detail

in reviews.^{19,23,24} Although there are less data of this kind available for the β -thalassemias, there is strong indirect evidence that their high frequency has also been maintained by protection against *P. falciparum* malaria.

● ETIOLOGY AND PATHOGENESIS

GENETIC CONTROL AND SYNTHESIS OF HEMOGLOBIN

The structure and ontogeny of the hemoglobins are reviewed in Chaps. 7 and 49, respectively. Only those aspects with particular relevance to the thalassemia problem are discussed here.

Human adult hemoglobin is a heterogeneous mixture of proteins consisting of the major component hemoglobin A and the minor component hemoglobin A₂, which constitutes approximately 2.5 percent of the total. In intrauterine life, the main hemoglobin is hemoglobin F. The structure of these hemoglobins is similar. Each consists of two separate pairs of identical globin chains. Except for some of the embryonic hemoglobins (see below), all normal human hemoglobins have one pair of α chains. In hemoglobin A, the α chains are combined with β chains ($\alpha_2\beta_2$), in hemoglobin A₂ with δ chains ($\alpha_2\delta_2$), and in hemoglobin F with γ chains ($\alpha_2\gamma_2$).

Human hemoglobin shows further heterogeneity, particularly in fetal life, and this has important implications for understanding the thalassemias and for approaches to their prenatal diagnosis. Hemoglobin F is a mixture of molecular species with the formulas $\alpha_2\gamma_2^{136\text{Gly}}$ and $\alpha_2\gamma_2^{136\text{Ala}}$. The γ chains containing glycine at position 136 are designated $^G\gamma$ chains. The γ chains containing alanine are called $^A\gamma$ chains. At birth, the ratio of molecules containing $^G\gamma$ chains to those containing $^A\gamma$ chains is approximately 3:1. The ratio varies widely in the trace amounts of hemoglobin F present in normal adults.

Before week 8 of intrauterine life, three embryonic hemoglobins—Gower 1 ($\xi_2\varepsilon_2$), Gower 2 ($\alpha_2\varepsilon_2$), and Portland ($\xi_2\gamma_2$)—are present. The ξ and ε chains are the embryonic counterparts of the adult α and β and γ and δ chains, respectively. ξ -Chain synthesis persists beyond the embryonic stage of development in some of the α -thalassemias. Persistent ε -chain production has not been found in any of the thalassemia syndromes. During fetal development, an orderly switch from ξ - to α -chain and from ε - to γ -chain production occurs, followed by β - and δ -chain production after birth.

Figure 48-3 shows the different human hemoglobins and the arrangements of the α -gene cluster on chromosome 16 and the β -gene cluster on chromosome 11.

Globin Gene Clusters

Although some individual variability exists, the α -gene cluster usually contains one functional ξ gene and two α genes, designated α_2 and α_1 . It also contains four pseudogenes: $\psi\xi_1$, $\psi\alpha_1$, $\psi\alpha_2$, and θ_1 .^{9,10} These four pseudogenes are remarkably conserved among different species. Although it appears to be expressed early in fetal life, its function is unknown. It likely does not produce a viable globin chain. Each α gene is located in a region of homology approximately 4 kb long, interrupted by two small nonhomologous regions.²⁵⁻²⁷ The homologous regions are believed to result from gene duplication, and the nonhomologous segments are believed to arise subsequently by insertion of DNA into the noncoding regions around one of the two genes. The exons of the two α -globin genes have identical sequences. The first intron in each gene is identical. The second intron of α_1 is nine bases longer and differs by three bases from that in the α_2 gene.²⁷⁻²⁹ Despite their high degree of homology, the sequences of the two α -globin genes diverge in their 3' untranslated regions 13 bases beyond the TAA stop codon. These differences provide

Figure 48-3. Genetic control of human hemoglobin (Hgb). The main globin gene clusters are located on chromosomes 11 and 16. At each stage of development, different genes in these clusters are activated or repressed. The different globin chains directed by individual genes are synthesized independently and combine in random fashion as indicated by the arrows.

an opportunity to assess the relative output of the genes, an important part of the analysis of the α -thalassemias.^{30,31} Production of α_2 messenger RNA appears to exceed that of α_1 by a factor of 1.5 to 3. $\psi\xi_1$ and ξ_2 genes also are highly homologous. The introns are much larger than those of α -globin genes. In contrast to the latter, IVS-1 is larger than IVS-2. In each ξ gene, IVS-1 contains several copies of a simple repeated 14-bp sequence that is similar to sequences located between the two ξ genes and near the human insulin gene. The coding sequence of the first exon of $\psi\xi_1$ contains three base changes, one of which gives rise to a premature stop codon, thus making $\psi\xi_1$ an inactive pseudogene.

The regions separating and surrounding the α -like structural genes have been analyzed in detail. Of particular relevance to thalassemia is the polymorphic nature of this gene cluster.³² The cluster contains five hypervariable regions: one downstream from the α_1 gene, one between the ξ and $\psi\xi$ genes, one in the first intron of both the ξ and $\psi\xi$ genes, and one 5' to the cluster. These regions consist of varying numbers of tandem repeats of nucleotide sequences. Taken together with single-base restriction fragment length polymorphisms (RFLPs), the variability of the α -globin gene cluster reaches a heterozygosity level of approximately 0.95. Thus, each parental α -globin gene cluster can be identified in the majority of persons. This heterogeneity has important implications for tracing the history of the thalassemia mutations.

Figure 48-3 shows the arrangement of the β -globin gene cluster on the short arm of chromosome 11. Each of the individual genes and their flanking regions have been sequenced.³³⁻³⁶ Like the α_1 and α_2 gene pairs, the γ_G and γ_A genes share a similar sequence. In fact, the γ_G and γ_A genes on one chromosome are identical in the region 5' to the center of the large intron yet show some divergence 3' to that position. At the boundary between the conserved and divergent regions, a block of simple sequence may be a "hot spot" for initiation of recombination events that lead to unidirectional gene conversion.

Like the α -globin genes, the β -gene cluster contains a series of single-point RFLPs, although in this case no hypervariable regions have been identified.^{37,38} The arrangement of RFLPs, or haplotypes, in the β -globin gene cluster falls into two domains. The 5' side of the β gene, spanning approximately 32 kb from the ϵ gene to the 3' end of the $\psi\beta$ gene, contains three common patterns of RFLPs. The region encompassing about 18 kb to the 3' side of the β -globin gene also contains three common patterns in different populations. Between these regions is a sequence of about 11 kb in which there is randomization of the 5' and 3' domains; hence, a relatively higher frequency of recombination can occur.³⁸ The β -globin gene haplotypes are similar in most populations but differ markedly in individuals of African origin. These findings suggest the haplotype arrangements were laid down very early during evolution. The findings are consistent with data obtained from mitochondrial DNA polymorphisms pointing to the early emergence of a relatively small population from Africa with subsequent divergence into

other racial groups.³⁹ Again, they are extremely useful for analyzing the population genetics and history of the thalassemia mutations.

The regions flanking the coding regions of the globin genes contain a number of conserved sequences essential for their expression.^{28,33} The first conserved sequence is the TATA box, which serves accurately to locate the site of transcription initiation at the CAP site, usually about 30 bases downstream. It also appears to influence the rate of transcription. In addition, two so-called upstream promoter elements are present. A second conserved sequence, the CCAAT box, is located 70 or 80 bp upstream. The third conserved sequence, the CACCC homology box, is located further 5', approximately 80 to 100 bp from the CAP site. It can be either inverted or duplicated. These promoter sequences also are required for optimal transcription. Mutations in this region of the β -globin gene cause its defective expression and these findings provide the foundation for understating regulation of other human genes. The globin genes also have conserved sequences in their 3' flanking regions, notably AATAAA, which is the polyadenylation signal site.

Regulation of Globin Gene Clusters Figure 48-4 summarizes the mechanism of globin gene expression. The primary transcript is a mRNA precursor containing both intron and exon sequences. During its stay in

Figure 48-4. Expression of a human globin gene.

the nucleus, it undergoes a good deal of processing that entails capping the 5' end and polyadenylation of the 3' end, both of which probably serve to stabilize the transcript (Chap. 10). The intervening sequences are removed from the mRNA precursor in a complex two-stage process that relies on certain critical sequences at the intron–exon junctions.

The method by which globin gene clusters are regulated is important to understanding the pathogenesis of the thalassemias. Many details remain to be determined, but studies performed over the last few years have provided at least an outline of some of the major mechanisms of globin gene regulation.^{7,9,40–42}

Most of the DNA within cells that is not involved in gene transcription is packaged into a compact form that is inaccessible to transcription factors and RNA polymerase. Transcriptional activity is characterized by a major change in the structure of the chromatin surrounding a particular gene. These alterations in chromatin structure can be identified by enhanced sensitivity to exogenous nucleases. Erythroid lineage-specific nuclease-hypersensitive sites are found at several locations in the β -globin gene cluster, which vary during different stages of development. In fetal life, these sites are associated with the promoter regions of all four globin genes. In adult erythroid cells, the sites associated with the γ genes are absent. The methylation state of the genes plays an important role in their ability to be expressed. In human and other animal tissues, the globin genes are extensively methylated in nonerythroid organs and are relatively undermethylated in hematopoietic tissues. Changes in chromatin configuration around the globin genes at different stages of development are reflected by alterations in their methylation state.

In addition to the promoter elements, several other important regulatory sequences have been identified in the globin gene clusters. For example, several enhancer sequences thought to be involved with tissue-specific expression have been identified. Their sequences are similar to the upstream activating sequences of the promoter elements. Both consist of a number of “modules,” or motifs, that contain binding sites for transcriptional activators or repressors. The enhancer sequences are thought to act by coming into spatial apposition with the promoter sequences to increase the efficiency of transcription of particular genes. It now is clear that transcriptional regulatory proteins may bind to both the promoter region of a gene and to the enhancer. Some of these transcriptional proteins, GATA-1 and NFE-2, for example, appear to be largely restricted to hematopoietic tissues.⁴⁰ These proteins may bring the promoter and the enhancer into close physical proximity, permitting transcription factors bound to the enhancer to interact with the transcriptional complex that forms near the TATA box. At least some of these hematopoietic gene transcription factors likely will be developmental-stage specific.

Another set of erythroid-specific nuclease-hypersensitive sites is located upstream from the embryonic globin genes in both the α - and β -gene clusters. These sites mark the regions of particularly important control elements. In the case of the β -globin gene cluster, the region is marked by five hypersensitive sites to DNase I treatment (HS) (an enzyme used to detect DNA-protein interaction).⁴⁰ The most 5' site (HS5) does not show tissue specificity. HS1 through HS4, which together form the locus control region (LCR), are largely erythroid-specific. Each of the regions of the LCR contains a variety of binding sites for erythroid transcription factors. The precise function of the LCR is not known, but it is undoubtedly required to establish a transcriptionally active domain spanning the entire globin gene cluster. The α -globin gene cluster also has a major regulatory element of this kind, in this case HS40.⁴¹ This forms part of four highly conserved noncoding sequences, or multispecies conserved sequences (MCSs), called MSC-R1–R4; of these elements only MSC-R2, that is HS40, is essential for α -globin gene expression. Although deletions of this region inactivate the entire α -globin gene

cluster, its action must be fundamentally different from that of the β -globin LCR because the chromatin structure of the α -gene cluster is in an open conformation in all tissues.

Some forms of thalassemia result from deletions involving these regulatory regions. In addition, the phenotypic effects of deletions of these gene clusters are strongly positional, which may reflect the relative distance of particular genes from the LCR and HS40.

Developmental Changes in Globin Gene Expression

One particularly important aspect of human globin genes is regulation of the switch from fetal to adult hemoglobin. Because many of the thalassemias and related disorders of the β -globin gene cluster are associated with persistent γ -chain synthesis, a full understanding of their pathophysiology must include an explanation for this important phenomenon, which plays a considerable role in modifying their phenotypic expression.

The complex topic of hemoglobin switching has been the subject of several extensive reviews.^{7,42} β -Globin synthesis commences early during fetal life, at approximately 8 to 10 weeks' gestation. β -Globin synthesis continues at a low level, approximately 10 percent of the total non- α -globin chain production, up to approximately 36 weeks' gestation, after which it is considerably augmented. At the same time, γ -globin chain synthesis starts to decline so that, at birth, approximately equal amounts of γ - and β -globin chains are produced. Over the first year of life, γ -chain synthesis gradually declines. By the end of the first year, γ -chain synthesis amounts to less than 1 percent of the total non- α -globin chain output. In adults the small amount of hemoglobin F is confined to an erythrocyte population called *F cells*.

How this series of developmental switches is regulated is not clear. The process is not organ specific but is synchronized throughout the developing hematopoietic tissues. Although environmental factors may be involved, the bulk of experimental evidence suggests some form of “time clock” is built into the hematopoietic stem cell. At the chromosomal level, regulation appears to occur in a complex manner involving both developmental stage-specific *trans*-activating factors and the relative proximity of the different genes of the β -globin gene cluster to LCR. Some of the elements involved in the stage-specific regulation of human globin genes have been identified. KLF1 (erythroid Kruppel-like factor), a developmental stage-enriched protein, activates human β -globin gene expression and is involved in human γ - to β -globin gene switching.⁴³ More recently BCL11A and MYB have also been identified as being involved in this process.⁴²

Fetal hemoglobin synthesis can be reactivated at low levels in states of hematopoietic stress and at higher levels in certain hematologic malignancies, notably juvenile myeloid leukemia. However, high levels of hemoglobin F production are seen consistently in adult life only in the hemoglobinopathies.

MOLECULAR BASIS OF THE THALASSEMIAS

Once cloning and sequencing of globin genes from patients with many different forms of thalassemia were possible, the wide spectrum of mutations underlying these conditions became clear. A picture of remarkable heterogeneity has emerged. For more extensive coverage of this topic, the reader is referred to several monographs and reviews.^{7,9,10,44–46}

β -THALASSEMIA

β -thalassemia is extremely heterogeneous at the molecular level.⁷ More than 200 different mutations have been found in association with the β -thalassemia phenotype.⁷ Broadly, they fall into deletions

of the β -globin gene and nondeletional mutations that may affect the transcription, processing, or translation of β -globin messenger (Table 48-2 and Fig. 48-5). Each major population group has a different set of β -thalassemia mutations, usually consisting of two or three mutations forming the bulk and large numbers of rare mutations. Because of

this distribution pattern, only approximately 20 alleles account for the majority of all β -thalassemia determinants (see Fig. 48-1).

Gene Deletions

At least 17 different deletions affecting only the β genes have been described. With one exception, the deletions are rare and appear to be isolated, single events. The 619-bp deletion at the 3' end of the β gene is more common,⁴⁸ but even that is restricted to the Sind and Gujarati populations of Pakistan and India, where it accounts for approximately 50 percent of β -thalassemia alleles.⁴⁸ The Indian 619-bp deletion removes the 3' end of the β gene but leaves the 5' end intact. Many of the other deletions remove the 5' end of the gene and leave the δ gene intact.⁴⁹⁻⁵³ Homozygotes for these deletions have β^0 -thalassemia. Heterozygotes for the Indian deletion have increased hemoglobin A₂ and F levels identical to those seen in heterozygotes for the other common forms of β -thalassemia. Heterozygotes for the other deletions all have unusually high hemoglobin A₂ levels.⁷ Increased δ -chain production results from increased δ -gene transcription *in cis* to the deletion, possibly as a result of reduced competition from the deleted 5' β gene for transcription factors.

Other Transcriptional Mutations

Several different base substitutions involve the conserved sequences upstream from the β -globin gene.⁷ In every case, the phenotype is β^+ -thalassemia, although considerable variability exists in the clinical severity associated with different mutations of this type. Several mutations, at positions -88 and -87 relative to the mRNA CAP site, for example,^{54,55} are close to the CCAAT box, whereas others lie within the TATA box homology.⁵⁶⁻⁵⁹

Some mutations upstream from the β -globin gene are associated with even more subtle alterations in phenotype. For example, a C→T substitution at position -101, which involves one of the upstream promoter elements, is associated with "silent" β -thalassemia, that is, a completely normal ("silent") phenotype that can be identified only by its interaction with more severe forms of β -thalassemia in compound heterozygotes.⁶⁰ A single example of an A→C substitution at the CAP site (+1) was described in an Asian Indian who, despite being homozygous for the mutation, appeared to have the phenotype of the β -thalassemia trait.⁶¹

Upstream regulatory mutations confirm the importance of the role of conserved sequences in this region as regulators of the transcription of the β -globin genes and provide the basis for some of the mildest forms of β -thalassemia, particularly those in African populations, and for some varieties of "silent" β -thalassemia.

RNA-Processing Mutations

One surprise about β -thalassemia has been the remarkable diversity of the single-base mutations that can interfere with the intranuclear processing of mRNA.

Figure 48-5. Classes of mutations that underlie β -thalassemia. C, CAP site; FS, frameshift; I, initiation site; NS, nonsense mutation; POLY A, polyA addition site mutation; PR, promoter; SPL, splicing mutation. For a complete list see ref. 304.

Figure 48–6. Activation of cryptic splice sites in exon 1 as the cause of β^+ -thalassemia, hemoglobin E, and hemoglobin Knossos. The similarities between the 5' splice region of intron 1 and the cryptic splice region in exon 1 are shown in *capitals*.

The boundaries of exons and introns are marked by invariant dinucleotides, GT at the 5' (donor) and AG at the 3' (receptor) sites. Single-base changes that involve either of these splice junctions totally abolish normal RNA splicing and result in the β^0 -thalassemia phenotype.^{7,62–66}

Highly conserved sequences involved in mRNA processing surround the invariant dinucleotides at the splice junctions. Different varieties of β -thalassemia involve single-base substitutions within the consensus sequence of the IVS-1 donor site.^{55,58,63–69} These mutations are particularly interesting because of the remarkable variability in their associated phenotypes. For example, substitution of the G in position 5 of IVS-1 by C or T results in severe β^+ -thalassemia.⁵⁵ On the other hand, a T \rightarrow C change at position 6, found commonly in the Mediterranean region,⁷⁰ results in a very mild form of β^+ -thalassemia. The G \rightarrow C change at position 5 has also been found in Melanesia and appears to be the most common cause of β -thalassemia in Papua New Guinea.⁷¹

RNA processing is affected by mutations that create new splice sites within either introns or exons. Again, these lesions are remarkably variable in their phenotypic effect, depending on the degree to which the new site is utilized compared with the normal splice site. For example, the G \rightarrow A substitution at position 110 of IVS-1, which is one of the most common forms of β -thalassemia in the Mediterranean region, leads to only approximately 10 percent splicing at the normal site and hence results in a severe β^+ -thalassemia phenotype.^{72,73} Similarly, a mutation that produces a new acceptor site at position 116 in IVS-1 results in little or no β -globin mRNA production and the β^0 -thalassemia phenotype.⁷⁴ Several mutations that generate new donor sites within IVS-2 of the β -globin gene have been described.^{55,68}

Another mechanism for abnormal splicing is activation of donor sites within exons (Fig. 48–6). For example, within exon 1 is a cryptic donor site in the region of codons 24 through 27. This site contains a GT dinucleotide. An adjacent substitution that alters the site so that it more closely resembles the consensus donor splice site results in its activation, even though the normal site is active. Several mutations in this region can activate this site so that it is utilized during RNA processing, with the production of abnormal mRNAs.^{75–78} Three of the substitutions—A \rightarrow G in codon 19, G \rightarrow A in codon 26, and G \rightarrow T in codon 27—result in reduced production of β -globin mRNA and an amino acid substitution so that the mRNA that is spliced normally is translated into protein. The abnormal hemoglobins produced are hemoglobins Malay, E, and Knossos, respectively, all of which are associated with a β -thalassemia phenotype, presumably as a result of reduced overall output of normal mRNA (Fig. 48–6). A variety of other cryptic splice mutations within introns and exons have been described.⁴⁴

Another class of processing mutations involves the polyadenylation signal site AAUAAA in the 3' untranslated region of β -globin

mRNA.^{79–81} For example, a T \rightarrow C substitution in this sequence leads to only one-tenth the normal amount of β -globin mRNA and hence the severe β^+ -thalassemia phenotype.⁷⁹

Mutations Causing Abnormal Translation of Messenger RNA

Base substitutions that change an amino acid codon into a chain termination codon, that is, nonsense mutations, prevent translation of the mRNA and result in β^0 -thalassemia. Many substitutions of this type have been described.^{7,44} For example, a codon 17 mutation is common in Southeast Asia,^{82,83} and a codon 39 mutation occurs at a high frequency in the Mediterranean region.^{84,85}

The insertion or deletion of one, two, or four nucleotides in the coding region of the β -globin gene disrupts the normal reading frame and results, upon translation of the mRNA, in the addition of anomalous amino acids until a termination codon is reached in the new reading frame. Several frameshift mutations of this type have been described.^{7,44} Two mutations—the insertion of one nucleotide between codons 8 and 9 and a deletion of four nucleotides in codons 41 and 42—are common in Asian Indians.⁶³ The latter deletions are found frequently in different populations in Southeast Asia.⁸³

An unusual β^+ -thalassemia was described in a patient from the Czech Republic in whom a full-length L1 transposon was inserted into the second intron of β -globin, creating a β^+ -thalassemia phenotype by an undefined molecular mechanism.⁸⁶

Dominantly Inherited β -Thalassemia

Families in which a picture indistinguishable from moderately severe β -thalassemia has segregated in mendelian dominant fashion have been reported sporadically.^{87,88} Because this condition often is characterized by the presence of inclusion bodies in the red cell precursors, it has been called *inclusion body β -thalassemia*. However, because all severe forms of β -thalassemia have inclusions in the red cell precursors, the term *dominantly inherited β -thalassemia* is preferred.^{7,89} Sequence analysis has shown that these conditions are heterogeneous at the molecular level, but that many involve mutations of exon 3 of the β -globin gene. The mutations include frameshifts, premature chain termination mutations, and complex rearrangements that lead to synthesis of truncated or elongated and highly unstable β -globin gene products.^{7,89–93} The most common mutation of this type is a GAA \rightarrow TAA change at codon 121 that leads to synthesis of a truncated β -globin chain.⁹⁴ Although an abnormal β -chain product from loci affected by mutations of this type is unusual, many of these conditions are designated as hemoglobin variants.

The reason why mutations occurring in exons 1 and 2 produce the classic form of recessive β -thalassemia whereas the bulk of the dominant thalassemias result from mutations in exon 3 has become clearer. In the former case, very little abnormal β -globin mRNA is found in the

cytoplasm of the red cell precursors, whereas exon 3 mutations are associated with full-length but abnormal mRNA accumulation. The different phenotypes of these premature termination codons have been suggested to reflect a phenomenon called *nonsense-mediated RNA decay*, a surveillance system to prevent transport of mRNA coding for truncated peptides. Presumably this process is active in the case of exon 1 or 2 mutations, in which affected mRNAs are degraded, but is not active in the case of exon 3 mutations.^{95–97} A complete list of the mutations that underlie the dominant β -thalassemias is given in reference 44.

Unstable β -Globin Variants

Some β -globin chain variants are highly unstable but are capable of forming a viable tetramer. The resulting unstable hemoglobins may precipitate in the red cell precursors or in the blood, giving rise to a spectrum of conditions ranging from dominantly inherited β -thalassemia to a hemolytic anemia similar to the anemia associated with other unstable hemoglobins. The first unstable hemoglobin to be described was hemoglobin Indianapolis.⁹⁸ Its structure was characterized by DNA analysis performed on stored autopsy material; however, the original description proved to be incorrect.⁹⁹

Silent β -Thalassemia

A number of extremely mild β -thalassemia alleles are either silent or almost unidentifiable in heterozygotes (see Table 48–2). Some alleles are in the region of the promoter boxes of the β -globin gene, but others involve the CAP sites or the 5' or 3' untranslated regions.^{7,44} These alleles usually are identified by finding a form of β -thalassemia intermedia in which one parent has a typical thalassemia trait and the other parent appears to be normal but, in fact, is a carrier of one of the mild β -thalassemia alleles.

β -Thalassemia Mutations Unlinked to the B-Globin Gene Cluster

Several family studies suggest the existence of mutations that result in the β -thalassemia phenotype but do not segregate with the β -globin genes¹⁰⁰; however, their molecular basis has not been determined. Further evidence for the existence of novel mutations of this type can be found in reference 7.

Variant Forms of β -Thalassemia

In several forms of β -thalassemia, the hemoglobin A₂ level is normal in heterozygotes. Some cases result from “silent” β -thalassemia alleles, whereas others reflect the coinheritance of β - and δ -thalassemia.⁷

$\delta\beta$ -THALASSEMIA

The $\delta\beta$ -thalassemias are classified into the $(\delta\beta)^+$ - and $(\delta\beta)^0$ -thalassemias (Table 48–3). The $(\delta\beta)^0$ -thalassemias are further divided into $(\delta\beta)^0$ -thalassemia, in which both the δ - and β -globin genes are deleted, and $(^A\gamma\delta\beta)^0$ -thalassemia, in which the $^A\gamma$, δ , and β genes are deleted. Because many different deletion forms of $\delta\beta$ -thalassemia have been described, they are further classified according to the country in which they were first identified (Table 48–3).

$(\delta\beta)^0$ - and $(^A\gamma\delta\beta)^0$ -Thalassemia

Nearly all these conditions result from deletions involving varying lengths of the β -globin gene cluster. Many different varieties have been described in different populations (see Table 48–3), although their heterozygous and homozygous phenotypes are very similar.⁷ Rare forms of these conditions result from more complex gene rearrangements. For example, one form of $(^A\gamma\delta\beta)^0$ -thalassemia, found in Indian populations, does not result from a simple linear deletion but rather from a complex

rearrangement with two deletions, one affecting the $^A\gamma$ gene and the other the δ and β genes. The intervening region is intact but inverted.¹⁰¹ Figure 48–7 illustrates some of these conditions.

$(\delta\beta)^+$ -Thalassemia

The $(\delta\beta)^+$ -thalassemias usually are associated with the production of structural hemoglobin variants called Lepore.¹⁰² Hemoglobin Lepore contains normal α chains and non- α chains that consist of the first 50 to 80 amino acid residues of the δ chains and the last 60 to 90 residues of the normal C-terminal amino acid sequence of the β chains. Thus,

Figure 48-7. Some deletions responsible for the β - and $\delta\beta$ -thalassemias and hereditary persistence of fetal hemoglobin. For a complete list see reference 304.

the Lepore non- α chain is a β -fusion chain. Several different varieties of hemoglobin Lepore have been described—Washington-Boston, Baltimore, and Hollandia—in which the transition from δ to β sequences occurs at different points.⁷ The fusion chains probably arose by nonhomologous crossing over between part of the δ locus on one chromosome and part of the β locus on the complementary chromosome (Fig. 48-8). This event results from misalignment of chromosome pairing during meiosis so that a δ -chain gene pairs with a β -chain gene instead of with its homologous partner.¹⁰³ Figure 48-8 shows such a mechanism should give rise to two abnormal chromosomes: the first, the Lepore chromosome, will have no normal δ or β loci but simply a $\delta\beta$ fusion gene. Opposite the homologous pairs of chromosomes should be an anti-Lepore ($\beta\delta$) fusion gene and normal δ and β loci. A variety of anti-Lepore-like hemoglobins have been discovered, including hemoglobins Miyada, P-Congo, Lincoln Park, and P-Nilotic.⁷ All the hemoglobin Lepore disorders are characterized by a severe form of $\delta\beta$ -thalassemia. The output of the γ -globin genes on the chromosome with the $\delta\beta$ fusion gene is not increased sufficiently to compensate for the low output of the $\delta\beta$ fusion product. The reduced rate of production of the $\delta\beta$ fusion chains

of hemoglobin Lepore presumably reflects the fact that its genetic determinant has the δ gene promoter region, which is structurally different from the β -globin gene promoter and is associated with a reduced rate of transcription of its gene product.

$\delta\beta$ -Thalassemia-Like Disorders Resulting from Two Mutations in the β -Globin Gene Cluster

A heterogeneous group of nondeletion $\delta\beta$ -thalassemias has been described, most resulting from two mutations in the $\epsilon\gamma\delta\beta$ -globin gene cluster (see Table 48-3). Strictly speaking, they are not all $\delta\beta$ -thalassemias, but they often appear in the literature under this title because their phenotypes resemble the deletion forms of $(\delta\beta)^0$ -thalassemia. In the Sardinian form of $\delta\beta$ -thalassemia, the β -globin gene has the common Mediterranean codon 39 nonsense mutation that leads to an absence of β -globin synthesis. The relatively high expression of the γ gene in *cis* gives this condition the $\delta\beta$ -thalassemia phenotype because of a point mutation at position -196 upstream from the γ gene (see “Hereditary Persistence of Fetal Hemoglobin” below). The phenotypic picture, in which heterozygotes have 15 to 20 percent hemoglobin F and

Figure 48-8. Mechanisms for the production of the Lepore and anti-Lepore hemoglobins. Hgb, hemoglobin.

normal hemoglobin A_2 levels, is identical to that of $\delta\beta$ -thalassemia.¹⁰³ Another condition having the β -thalassemia phenotype, with greater than 20 percent hemoglobin F in heterozygotes, has been described in a Chinese patient in whom defective β -globin chain synthesis appears to result from an A→G change in the ATA sequence in the promoter region of the β -globin gene.¹⁰⁴ The increased γ -chain synthesis, which appears to involve both $G\gamma$ and $A\gamma$ *cis* to this mutation, remains unexplained. A disorder originally called $\delta\beta$ -thalassemia has been described in the Corfu population.^{105,106} The condition results from two mutations in the β -globin gene cluster: first, a 7201-bp deletion that starts in the δ -globin gene, IVS-2, position 818 to 822, and extends upstream to a 5' breakpoint located 1719 to 1722 bp 3' to the $\psi\beta$ -gene termination codon; and second, a G→A mutation at position 5 in the donor site consensus region of IVS-1 of the β -globin gene. The output from this chromosome consists of relatively high levels of γ chains with very low levels of β chains. The condition resembles $\delta\beta$ -thalassemia in the homozygous state, with almost 100 percent hemoglobin F, traces of hemoglobin A, but no hemoglobin A_2 . Heterozygotes have only slightly elevated hemoglobin F levels, with a phenotype similar to "normal $A_2\beta$ -thalassemia."

$\epsilon\gamma\delta\beta$ -THALASSEMIA

These rare conditions¹⁰⁷⁻¹¹³ result from long deletions that begin upstream from the β -gene complex 55 kb or more 5' to the ϵ gene and terminate within the cluster (see Fig. 48-7). In two cases, designated Dutch^{110,111} and English,¹¹² the deletions leave the β -globin gene intact, but no β -chain production occurs even though the gene is expressed in heterologous systems.

The molecular basis for inactivation of the β -globin gene *cis* to these deletions was clarified by the discovery of the LCR approximately 50 kb upstream from the $\epsilon\gamma\delta\beta$ -globin gene cluster (see "Genetic Control and Synthesis of Hemoglobin" above). Removal of this critical regulatory region seems to completely inactivate the downstream globin gene complex. The Hispanic form of $\epsilon\gamma\delta\beta$ -thalassemia¹¹³ results from a deletion that includes most of the LCR, including four of the five DNase-1-hypersensitive sites. These lesions appear to close down the chromatin domain that usually is open in erythroid tissues and delay replication of the β -globin genes in the cell cycle. Thus, although they are rare, the lesions have been of considerable importance because analysis of the

Dutch deletion first pointed to the possibility of a major control region upstream from the β -like-globin gene cluster and ultimately led to the discovery of the β -globin LCR.

HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN

This heterogeneous group of conditions produces phenotypes very similar to those of the $\delta\beta$ -thalassemias, except that defective β -chain production appears to be almost, but in some forms not completely, compensated by persistent γ -chain production. These conditions are best classified into deletion and nondeletion forms (Table 48-4). In the past, the conditions were classified into pancellular and heterocellular varieties, depending on the intercellular distribution of fetal hemoglobin. However, this subdivision now appears to bear little relevance to their molecular basis and probably relates more to the particular level of fetal hemoglobin and how its cellular distribution is determined.⁷

The deletion forms of HPFH are heterogeneous (see Fig. 48-7). The two African varieties result from extensive deletions of similar length (<70 kb) but with staggered ends, differing phenotypically only in the proportions of $G\gamma$ and $A\gamma$ chains produced.¹¹⁴ Another type of HPFH results from misalignment during crossing over between the $A\gamma$ - and β -globin genes, resulting in production of $A\gamma\beta$ fusion genes (see Fig. 48-8) that combine with α chains to form the hemoglobin variant called hemoglobin Kenya.^{115,116} Hemoglobin Kenya is associated with an increased output of hemoglobin F, although at a lower level than in the deletion forms of HPFH. A theory that adequately explains the phenotypic differences between $\delta\beta$ -thalassemia and the deletion forms of HPFH has not been developed.⁷

The nondeletion determinants of HPFH can be classified into those that map within the β -globin gene cluster and those that segregate independently. The former are subdivided into $G\gamma\beta^+$ and $A\gamma\beta^+$ varieties, indicating persistent $G\gamma$ - or $A\gamma$ -chain synthesis in association with β -globin production directed by the β gene *cis* (on the same chromosome) to the HPFH determinant. Analysis of the overexpressed γ genes revealed in each case a single-base substitution in the region immediately upstream from the transcription start site.^{7,117-120} Clustering of these substitutions and lack of similar changes in normal γ genes suggest they are responsible for persistent hemoglobin F production (Fig. 48-9). This region

of DNA likely is involved in binding of *trans*-acting proteins involved in the normal developmental repression of γ -gene expression, either by decreasing the affinity for an inhibitory factor normally present in adult life or by increasing the affinity for a factor promoting gene expression. The most common of these conditions are Greek $^A\gamma\beta^+$ HPFH and a form of $\zeta\gamma\beta^+$ HPFH, which has been found in several different African populations. If the upstream point mutations associated with persistent γ -chain production occur on the same chromosome as β -globin genes

that carry β^0 -thalassemia mutations, the clinical phenotype is converted from HPFH to $\delta\beta$ -thalassemia, albeit with different hemoglobin A_2 levels.

In some cases, other nondeletional forms of HPFH have been related to small structural changes in the β -globin gene cluster (see Table 48-4). Although strictly speaking not a true form of HPFH, because even in homozygotes it may not be associated with increased hemoglobin F levels, the T→C polymorphism at position -158 to the $\zeta\gamma$ -globin gene¹²¹ might be associated with an increased output of hemoglobin F under conditions of erythropoietic stress.

Other forms of HPFH are characterized by the persistence of low levels of fetal hemoglobin production distributed in a heterocellular manner. In all populations studied, a small proportion of individuals have an increased amount of hemoglobin F and F cells, that is, red cells that can be detected when blood films are treated with antibodies against hemoglobin F. Although this condition originally was called the Swiss form of HPFH because it was first recognized in Swiss army recruits,¹²² it is observed in every racial group. Using a variety of genetic approaches, it has become clear that a number of genes may be involved in the generation of heterocellular HPFH, including loci at Xp22.2-p22.3, 6q23, 8q, and 2p15¹²³⁻¹²⁸; the latter linkage has been identified as the oncogene *BCL11A*. The mechanism whereby these different loci affect the level of F cells in normal individuals and increase their levels in conditions like thalassemia and sickle cell anemia remain to be determined, but their coinheritance with these conditions may have an extremely beneficial effect of their associated phenotypes.¹²⁹

δ -THALASSEMIA

Several point mutations and deletions that reduce δ -globin synthesis have been described. They are summarized in reference 7.

α -THALASSEMIA

Table 48-5 summarizes the different classes of α -thalassemia mutations. The α -globin gene haplotype can be written $\alpha\alpha$, indicating the α_1 and α_2 genes, respectively. A normal individual has the genotype $\alpha\alpha/\alpha\alpha$. A deletion involving one ($-\alpha$) or both ($--$) α genes can be further classified based on its size, written as a superscript; thus, $-\alpha^{3.7}$ indicates a deletion of 3.7 kb including one α gene. When the sizes of the deletions are not established, a superscript describing their geographic or family origin is useful; thus, $--^{MED}$ describes a deletion of both α genes first identified in individuals of Mediterranean origin. In thalassemia haplotypes in which both genes are intact, that is, nondeletion lesions, the nomenclature $\alpha^{ND}\alpha$ is given, with the superscript ND indicating the gene is thalassemic. However, when the precise molecular defect is known, as in hemoglobin Constant Spring, for example, $\alpha^{ND}\alpha$ can be replaced by the more informative $\alpha^{CS}\alpha$. The molecular pathology and population genetics of the α -thalassemias have been the subject of several extensive reviews.^{7,41,45,130,131}

α^0 -Thalassemia

Many deletions that involve both α genes, and therefore abolish α -chain production from the affected chromosome, have been described (Fig. 48-10).⁷ Several of the 3' breakpoints fall within a 6- to 8-kb region at the 3' end of the α -globin complex, suggesting this represents a breakpoint cluster region with a high level of recombination.¹³² In at least five of the deletions, the 5' breakpoints also appear to cluster. This gives rise to a situation in which the 5' breakpoints are located approximately the same distance apart and in the same order along a chromosome as their respective 3' breakpoints. It is possible that such staggered deletions arise from illegitimate recombination events that delete an integral number of chromatin loops as they pass through their nuclear attachment

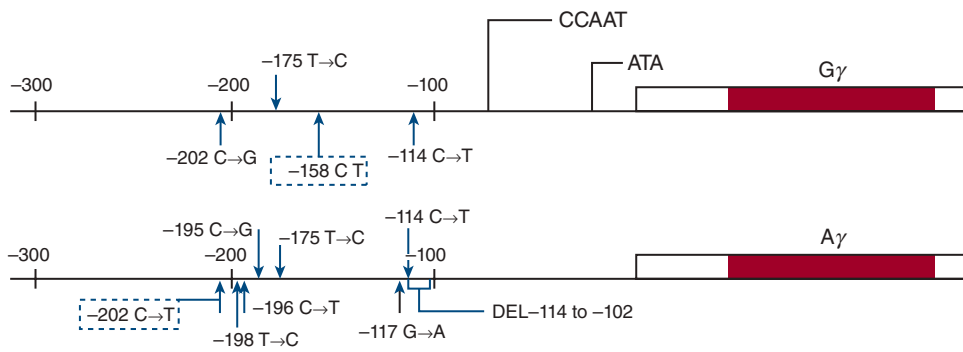

Figure 48-9. Some upstream point mutations associated with hereditary persistence of fetal hemoglobin.

points during replication. This mechanism has also been suggested to underlie some of the deletion forms of HPFH. One of these deletions ($-\text{MED}$) involves a more complex rearrangement that introduces a new piece of DNA bridging the two breakpoints in the α -gene cluster. This new sequence originates upstream from the α cluster and appears to

have been replicated into the junction in a manner suggesting that the upstream segment of DNA also lies at the base of a replication loop. At least some of these deletions seem to have arisen by recombination events between Alu repeat sequences.

Several other mechanisms for the generation of α^0 -thalassemia have been identified. In one case of unusual genetic interest, a long (>18 kb) deletion that removes the α_1 gene and the region downstream was identified in which the α_2 gene remains intact but is completely inactivated, giving the α^0 -thalassemia phenotype. Although the inactive α_2 gene retains all its local and remote *cis*-regulatory elements, its expression is completely silenced and its CpG island is completely methylated as a result of transcription of antisense RNA expressed from a locus that had been juxtaposed to the α_2 gene because of the large deletion.^{133,134} In some cases, this condition results from a terminal truncation of the short arm of chromosome 16 to a site 50 kb distal to the α -globin genes.¹³⁵ It is interesting that the telomeric consensus sequence (TTAGGG)_n has been added directly to the site of the break. Because this mutation is stably inherited, telomeric DNA alone appears sufficient to stabilize the broken chromosome end. This observation raises the possibility that other genetic diseases result from chromosomal truncations.

Several deletions have been identified that appear to downregulate α -globin genes by removing the α -globin LCR (HS40).^{7,136,137} In each case, the α -globin genes are left intact, although in one the 3' breakpoint is found between the ξ and $\psi\xi$ genes, thus removing the ξ gene. These deletions appear to completely inactivate the α -globin gene complex, just as deletions of the β -globin LCR inactivate the entire β -gene complex. Such deletions have not been observed in the homozygous state, presumably because they would be lethal.

α^+ -Thalassemia Gene Deletions

The most common forms of α^+ -thalassemia ($-\alpha^{3,7}$ and $-\alpha^{4,2}$) involve deletion of one or the other of the duplicated α -globin genes (see Figs. 48-10 and 48-11).

Each α gene is located within a region of homology approximately 4 kb long, interrupted by two nonhomologous regions. The homologous regions are believed to have resulted from an ancient duplication event and to have subsequently subdivided, presumably by insertions and deletions, to give three homologous subsegments referred to as X, Y, and Z (see Fig. 48-11). The duplicated Z boxes are 3.7 kb apart, and the X boxes are 4.2 kb apart. Misalignment and reciprocal crossover between these segments at meiosis can give rise to chromosomes with either single ($-\alpha$) or triplicated (aaa) α -globin genes. Such an occurrence between homologous Z boxes deletes 3.7 kb of DNA (rightward deletion). A similar crossover between the two X blocks deletes 4.2 kb of DNA (leftward deletion $-\alpha^{4,2}$).¹³⁸ The corresponding triplicated α -gene arrangements are referred to as $aaa\alpha^{\text{anti-3.7}}$ and $\alpha^{\text{anti-4.2}}$.¹³⁹⁻¹⁴¹ More detailed analysis of these crossover events indicates they occur more commonly in the Z box. At least three different $-\alpha^{3,7}$ deletions have been found,

Mechanisms for production of the common deletion forms of α^+ -thalassemia. **A.** Normal α -globin gene cluster showing the homology boxes X, Y, and Z. **B.** Rightward crossover through the Z boxes, giving rise to the 3.7-kb deletion and a chromosome with three α -globin genes. **C.** Leftward crossover through the Z boxes, giving rise to a 4.2-kb deletion and a chromosome containing three α genes.

depending on exactly where the crossover occurred.¹⁴² These deletions are designated $-\alpha^{3.7I}$, $-\alpha^{3.7II}$, and $-\alpha^{3.7III}$, respectively. Other, rarer deletions of a single α gene have been observed.⁷

Nondeletion α -Thalassemia

Because expression of the α_2 gene is two to three times greater than expression of the α_1 gene, the finding that most of the nondeletion mutants discovered to date affect predominantly α_2 gene expression is not surprising. Presumably this is ascertainment bias because of the greater phenotypic effect of these lesions. It also is possible that defective expression of the α_2 gene has come under greater selective pressure.

Like the β -thalassemia mutations, α -thalassemia mutations⁷ can be classified according to the level of gene expression they affect (see Table 48-5). Several processing mutations have been identified. For example, a pentanucleotide deletion includes the 5' splice site of IVS-1 of the α_2 -globin gene. This mutation involves the invariant GT donor splicing sequence and thus completely inactivates the α_2 gene.¹⁴³ A second mutant of this type, found commonly in the Middle East, involves the poly-A addition signal site (AATAAA \rightarrow AATAAG) and downregulates the α_2 gene by interfering with 3' end processing.^{144,145}

A second group of nondeletion α -thalassemias results from mutations that interfere with translation of mRNA.⁷ Several mutations involve the initiation codon.¹⁴⁶⁻¹⁴⁹ In one case, for example, the initiation codon

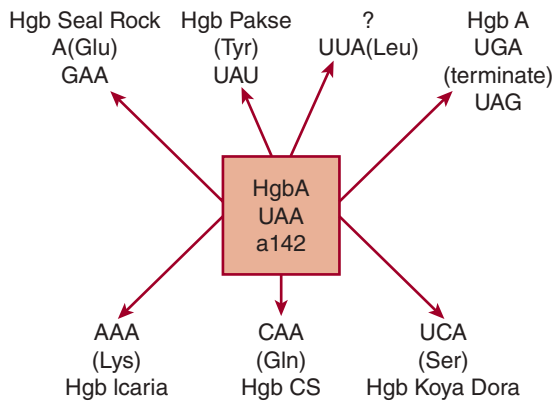

Figure 48–12. Point mutations in the α -globin gene termination codon. Hgb, hemoglobin; Hgb CS, hemoglobin Constant Spring;

is inactivated by a T→C transition.¹⁴⁶ In another case, efficiency of initiation is reduced by a dinucleotide deletion in the consensus sequence around the start signal.¹⁴⁹ Five mutations that affect termination of translation and give rise to elongated α chains have been identified: hemoglobins Constant Spring, Icaria, Koya Dora, Seal Rock, and Pakse.⁷ Each mutation specifically changes the termination codon TAA so that an amino acid is inserted instead of the chain terminating (Fig. 48–12). This process is followed by read-through of mRNA that is not normally translated until another “in-phase” stop codon is reached. Thus, each of these variants has an elongated α chain. The “read-through” of α -globin mRNA that usually is not utilized likely reduces its stability.¹⁵⁰ Several nonsense mutations occur, for example, one in exon 3 of the α_2 -globin gene.¹⁵¹ Finally, several mutations occur that cause α -thalassemia by producing highly unstable α -globin chains, including hemoglobins Quong Sze,¹⁵² Suan Doc,¹⁵³ Petah Tikvah,¹⁵⁴ and Evanston.¹⁵⁵ A complete list of nondeletion α -thalassemia alleles is given in reference 45.

Interactions of α -Thalassemia Haplotypes

Many α -thalassemia haplotypes have been described, and potentially more than 500 interactions are possible!¹⁷ These phenotypes result in four broad categories: (1) normal, (2) conditions characterized by mild hematologic changes but no clinical abnormality, (3) hemoglobin H disease, and (4) hemoglobin Bart’s hydrops fetalis syndrome. The heterozygous states for deletion or nondeletion forms of α^+ -thalassemia either cause extremely mild hematologic abnormalities or are completely silent. In populations where α -thalassemia is common, the homozygous state for α^+ -thalassemia ($-\alpha/-\alpha$) can produce a hematologic phenotype identical to that of the heterozygous state for α^0 -thalassemia ($-/-\alpha\alpha$), that is, mild anemia with reduced mean cell hemoglobin and mean cell volume values.

Hemoglobin H disease usually results from the compound heterozygous state for α^0 -thalassemia and either deletion or non-deletion α^+ -thalassemia. It occurs most frequently in Southeast Asia ($-_{SEA}/-\alpha^{3,7}$) and the Mediterranean region (usually $-_{MED}/-\alpha^{3,7}$).

The hemoglobin Bart’s hydrops fetalis syndrome usually results from the homozygous state for α^0 -thalassemia, most commonly $-_{SEA}/-_{SEA}$ or $-_{MED}/-_{MED}$. A few infants with this syndrome who synthesized very low levels of α chains at birth have been reported. Gene-mapping studies suggest these cases result from interaction of α^0 -thalassemia with nondeletion mutations ($\alpha\alpha^{ND}$).

Unusual Forms of α -Thalassemia

Some unusual forms of α -thalassemia are completely unrelated to the common forms of the disease that occur in tropical populations. These

conditions, which can occur in any racial groups, include α -thalassemia associated with mental retardation or leukemia. Their importance lies with the diagnostic problems they may present and, more importantly, the light that elucidation of the α -thalassemia pathology may shed on broader disease mechanisms.

Molecular Pathology of the α -Thalassemia Mental Retardation Syndrome

The first descriptions of noninherited forms of α -thalassemia associated with mental retardation suggested the lesions involving the α -globin gene locus were acquired in the paternal germ cells and that their molecular pathology might help elucidate the associated developmental changes.¹⁵⁶ Two separate syndromes of this type now are evident. In one group of patients, long deletions involve the α -globin gene cluster and remove at least 1 Mb.¹⁵⁷ This condition can arise in several ways, including unbalanced translocation involving chromosome 16, truncation of the tip of chromosome 16, and loss of the α -globin gene cluster and parts of its flanking regions by other mechanisms. These findings localize a region of approximately 1.7 Mb in band 16p13.3 proximal to the α -globin genes as being causative of mental handicap.⁴¹

The second group is characterized by defective α -globin synthesis associated with severe mental retardation and a relatively homogeneous pattern of dysmorphology.¹⁵⁸ Extensive structural studies have shown no abnormalities of the α -globin genes. These chromosomes direct the synthesis of normal amounts of α -globin in mouse erythroleukemia cells, suggesting that α -thalassemia results from deficiency of a *trans*-activating factor involved in regulation of the α -globin genes. This condition is encoded by a locus on the short arm of the X chromosome.¹⁵⁹ *ATR-X*, the gene involved, is a DNA helicase with many features of a DNA-binding protein. Many different mutations of this gene have been identified in different families with the *ATR-X* (α -thalassemia X-linked mental retardation) syndrome.^{131,160} Studies have identified a plant homeodomain (PHD) region and an adenosine triphosphatase (ATPase)/helicase domain.¹⁶¹ Because patients with *ATR-X* syndrome show defective methylation of recombinant DNA arrays and related defects, this condition likely is one of a growing list of disorders that result from disordered chromatin remodeling.^{162,163}

α -Thalassemia and Myelodysplasia

The hematologic findings of hemoglobin H disease or mild α -thalassemia occasionally are observed in elderly patients with myeloid leukemia or the myelodysplastic syndrome. Earlier studies suggested this finding resulted from an acquired defect of α -globin synthesis in which the α -globin genes were completely inactivated in the neoplastic hemopoietic cell line.¹⁶⁴ The molecular basis for this observation now is known to reside in a variety of different mutations involving *ATR-X*.^{41,165} The relationship of these somatic mutations of *ATR-X* to the neoplastic transformation remains to be determined. The molecular defect of other cases of acquired α -thalassemia, such as that seen in variable combined immunodeficiency,¹⁶⁶ also remains to be defined.

● PATHOPHYSIOLOGY

Almost all the pathophysiologic features of the thalassemias can be related to a primary imbalance of globin-chain synthesis. This phenomenon makes the thalassemias fundamentally different from all the other genetic and acquired disorders of hemoglobin production and, to a large extent, explains their extreme severity in the homozygous and compound heterozygous states (Fig. 48–13).

The anemia of β -thalassemia has three major components. First, and most important, is ineffective erythropoiesis with intramedullary destruction of a variable proportion of the developing red cell

Figure 48–13. Pathophysiology of β -thalassemia. HgbF, hemoglobin F; RBC, red blood cell.

precursors. Second is hemolysis resulting from destruction of mature red cells containing α -chain inclusions. Third are the hypochromic and microcytic red cells that result from the overall reduction in hemoglobin synthesis.

Because the primary defect in β -thalassemia involves β -chain production, synthesis of hemoglobins F and A_2 should be unaffected. Fetal hemoglobin production *in utero* is normal. The clinical manifestations of thalassemia appear only when the neonatal switch from γ - to β -chain production occurs. However, fetal hemoglobin synthesis persists beyond the neonatal period in nearly all forms of β -thalassemia (see “Persistent Fetal Hemoglobin Production and Cellular Heterogeneity” below). β -Thalassemia heterozygotes have an elevated level of hemoglobin A_2 . The elevated level appears to reflect not only a relative decrease in hemoglobin A as a result of defective β -chain synthesis but also an absolute increase in the output of δ chains both *cis* and *trans* to the mutant β -globin gene.⁷

Because α chains are shared by hemoglobins F, A, and A_2 , there is no increase in hemoglobin F in the α -thalassemias. The excess γ and β chains formed as a result of defective α -chain production produce soluble homotetramers (see “Mechanisms and Consequences of Erythroid Precursor Damage and Red Cell Damage” below). Hence there is less ineffective erythropoiesis than in β -thalassemia and the major cause of anemia is hemolysis and poorly hemoglobinized red cells.

IMBALANCED GLOBIN-CHAIN SYNTHESIS

Measurements of *in vitro* globin-chain synthesis in the blood or marrow of patients with different types of thalassemia^{167,168} and family studies that allow examination of the action of thalassemia genes in patients

who also inherited α - or β -globin structural variants^{7,9} provide a clear picture of the action of the thalassemia determinants. In homozygous β -thalassemia, β -globin synthesis is either absent or markedly reduced. The result is excessive production of α -globin chains. α -Globin chains are incapable of forming a viable hemoglobin tetramer, so the chains precipitate in red cell precursors. The resulting inclusion bodies can be demonstrated by both light and electron microscopy.^{169,170} In the marrow, precipitation can be seen in the earliest hemoglobinized precursors and throughout the erythroid maturation pathway.¹⁷¹ These large inclusions are responsible for intramedullary destruction of red cell precursors and hence for the ineffective erythropoiesis characterizing all the β -thalassemias. A large proportion of the developing erythroblasts are destroyed within the marrow in severe cases.¹⁷² Any red cells that are released are prematurely destroyed by mechanisms that are considered below in “Mechanisms and Consequences of Erythroid Precursor and Red Cell Damage.” β -Thalassemia heterozygotes also have imbalanced globin-chain synthesis, but the magnitude of α -chain excess is much less and presumably can be resolved by the proteolytic enzymes of the red cell precursors.¹⁷³ Notwithstanding, a mild degree of ineffective erythropoiesis occurs.

Although there is marked globin-chain imbalance in the severe α -thalassemias,^{7,167} the excess γ and β chains form homotetramers that do not precipitate in the red cell precursors to the same extent as excess α chains in β -thalassemia. Hence the pathophysiology of anemia is fundamentally different between the two conditions.

MECHANISMS AND CONSEQUENCES OF ERYTHROID PRECURSOR AND RED CELL DAMAGE

Damage to the red cell membrane by the globin-chain precipitation process occurs by two major routes: generation of hemichromes (Chap. 49) from excess α chains with subsequent structural damage to the red cell membrane, and similar damage mediated through the degradation products of excess α chains.^{7,174–176} The degradation products of free α chains—globin, heme, hemin (oxidized heme), and free iron—also play a role in damaging red cell membranes. Excess globin chains bind to different membrane proteins and alter their structure and function. Excess iron, by generating oxygen free radicals, damages several red cell membrane components (including lipids and protein) and intracellular organelles. Heme and its products can catalyze the formation of a variety of reactive oxygen species that can damage the red cell membrane. These changes are reflected in an increased rate of apoptosis of red cell precursors.¹⁷⁷ The red cells are rigid and underhydrated, leak potassium, and have increased levels of calcium and low, unstable levels of ATP. Damage to the red cells can also be mediated by the presence of rigid inclusion bodies during passage of the red cells through the spleen.

The consequences of excess non- α -chain production in the α -thalassemias are quite different. Because α chains are shared by both fetal and adult hemoglobin (Chaps. 6 and 48), defective α -chain production is manifest in both fetal and adult life. In the fetus, it leads to excess γ -chain production; in the adult, it leads to an excess of β chains. Excess γ chains form γ_4 homotetramers or hemoglobin Bart’s¹⁷⁸; excess β chains form β_4 homotetramers or hemoglobin H.¹⁷⁹ The fact that γ and β chains form homotetramers is the reason for the fundamental difference in the pathophysiology of α - and β -thalassemia. Because γ_4 and β_4 tetramers are soluble, they do not precipitate to any significant degree in the marrow, and therefore the α -thalassemias are not characterized by severe ineffective erythropoiesis. However, β_4 tetramers precipitate as red cells age, with the formation of inclusion bodies. Thus, the anemia of the more severe forms of α -thalassemia in the adult results from a shortened

survival of red cells consequent to their damage in the microvasculature of the spleen as a result of the presence of the inclusions. In addition, because of the defect in hemoglobin synthesis, the cells are hypochromic and microcytic. Hemoglobin Bart's is more stable than hemoglobin H and does not form large inclusions.

Although, as is the case in β -thalassemia, excess globin chains cause damage to the red cell membrane, the mechanisms are different in the two forms of the disease. As described in "Etiology and Pathogenesis" above, in β -thalassemia, excess α chains result in mechanical instability and oxidative damage to a variety of membrane proteins, notably protein 4.1. However, in α -thalassemia, the membranes are hyperstable, and no evidence of oxidation or dysfunction of this protein is present. Furthermore, the state of red cell hydration is different in α -thalassemia. Accumulation of excess β chains results in increased hydration. These differences in the pathophysiology of membrane damage between α - and β -thalassemia are discussed in detail in references 7 and 174 to 176.

Another factor exacerbates the tissue hypoxia of the anemia of the α -thalassemias. Both hemoglobin Bart's and hemoglobin H show no heme-heme interaction and have almost hyperbolic oxygen dissociation curves with very high oxygen affinities. Thus, they are not able to liberate oxygen at physiologic tissue tensions; in effect, they are useless as oxygen carriers.⁷

As a consequence, infants with high levels of hemoglobin Bart's have severe intrauterine hypoxia. This is the major basis for the clinical picture of homozygous α^0 -thalassemia, which results in the stillbirth of hydropic infants late in pregnancy or at term. Oxygen deprivation is reflected by the grossly hydropic state of the infant, presumably as a result of increased capillary permeability, and by severe erythroblastosis. Deficient fetal oxygenation probably is responsible for the enormously hypertrophied placentas and possibly for the associated developmental abnormalities that occur with the severe forms of intrauterine α -thalassemia.⁷

PERSISTENT FETAL HEMOGLOBIN PRODUCTION AND CELLULAR HETEROGENEITY

Children with severe thalassemia have an increased level of hemoglobin F that persists into childhood and later.^{7,10} In the β^0 -thalassemias, hemoglobin F is the only hemoglobin produced, except for small amounts of hemoglobin A₂. Examination of the blood using staining methods specific for hemoglobin F shows that it is heterogeneously distributed among the red cells.⁷ Persistent hemoglobin F production is not a major feature of the more severe forms of α -thalassemia.

The mechanism of persistent γ -chain synthesis in the thalassemias is incompletely understood. Normal adults have small quantities of hemoglobin F that are heterogeneously distributed among the red cells. Cells with demonstrable hemoglobin F are called *F cells*. One important mechanism for high hemoglobin F levels in the blood of patients with β -thalassemia is cell selection.^{7,180-183} The major cause of ineffective erythropoiesis and shortened red cell survival in β -thalassemia is the deleterious effect of excess α chains on erythroid maturation in the marrow and on the survival of red cells in the blood. Therefore, red cell precursors that produce γ chains are at a selective advantage. Excess α chains combine with γ chains to produce hemoglobin F; therefore, the magnitude of α -chain precipitation is less. Differential centrifugation experiments¹⁸¹⁻¹⁸³ and *in vivo* labeling studies¹⁸⁰ have shown that populations of red cells with relatively large amounts of hemoglobin F are more efficiently produced and survive longer in the blood. The blood of patients with homozygous β -thalassemia shows remarkable cellular heterogeneity with respect to red cell survival, such as populations of cells containing predominantly hemoglobin A that are destroyed very

rapidly in the spleen and elsewhere, cells with a much longer survival that contain relatively more hemoglobin F, and populations of intermediate age and hemoglobin constitution.^{7,182}

Although cell selection is probably the main reason for the increased levels of hemoglobin F in the red cells in β -thalassemia, other mechanisms may also be involved. In any form of "stress erythropoiesis," that is, rapid erythroid proliferation, there is a tendency for a relative increase in γ -chain production. Furthermore, as discussed in "Hereditary Persistence of Fetal Hemoglobin" above, several genes or chromosomal locations have been defined in which polymorphisms are involved in the increased basal production of γ chains and a relative increase in the number of F cells in the blood. The interaction of these different loci appear to be responsible for high levels of hemoglobin F production in β -thalassemia and sickle cell anemia with the production of milder phenotypes.^{125-128,184} However, biosynthesis studies indicate that marrow expansion and the selective survival of F-cell precursors and their progeny are the major factors in hemoglobin F production in hemoglobin E/ β -thalassemia.¹⁸³

Because a reciprocal relation exists between γ - and δ -chain synthesis, the red cells of β -thalassemia homozygotes containing large amounts of hemoglobin F have relatively low hemoglobin A₂ levels.⁷ Thus, the measured percent hemoglobin A₂ in these individuals is the average of a very heterogeneous cell population. This finding probably accounts for the extreme variability in hemoglobin A₂ levels found in homozygotes for this disorder. A further consequence of the persistence of hemoglobin F in β -thalassemia is the high oxygen affinity of the red cells.

CONSEQUENCES OF COMPENSATORY MECHANISMS FOR THE ANEMIA OF THALASSEMIA

The profound anemia of homozygous β -thalassemia and the relatively high oxygen affinity of hemoglobin F combine to cause severe tissue hypoxia. Because of the high oxygen affinity of hemoglobins Bart's and H, a similar defect in tissue oxygenation occurs in the more severe forms of α -thalassemia. The major adaptive response to hypoxia is increased erythropoietin production. It has been found that in severely anemic children with hemoglobin E β -thalassemia, age and hemoglobin levels are independent variables in erythropoietin response and that for a given hemoglobin level there is a relatively high erythropoietin in very young children.¹⁸⁵ These observations provide an explanation for the rather unstable phenotype of many intermediate forms of β -thalassemia during early childhood. The major effect of these very high levels of erythropoietin production is expansion of the dyserythropoietic marrow. The results are deformities of the skull and face and porosity of the long bones.⁷ Extramedullary hematopoietic tumors may develop in extreme cases. Apart from the production of severe skeletal deformities, marrow expansion may cause pathologic fractures and sinus and middle ear infection as a result of ineffective drainage.

Another important effect of the enormous expansion of the marrow mass is the diversion of calories required for normal development to the ineffective red cell precursors. Thus, patients severely affected by thalassemia show poor development and wasting. The massive turnover of erythroid precursors may result in secondary hyperuricemia and gout and severe folate deficiency.

The effects of gross intrauterine hypoxia in homozygous α^0 -thalassemia have been described. In the symptomatic forms of α -thalassemia (e.g., hemoglobin H disease) that are compatible with survival into adult life, bone changes and other consequences of erythroid expansion are seen, although less commonly than in β -thalassemia.

SPLENOMEGALY: DILUTIONAL ANEMIA

Constant exposure of the spleen to red cells with inclusions consisting of precipitated globin chains gives rise to the phenomenon of “work hypertrophy.” Progressive splenomegaly occurs in both α - and β -thalassemia and may worsen the anemia.^{7,10} A large spleen acts as a sump for red cells, sequestering a considerable proportion of the red cell mass. Furthermore, splenomegaly may cause plasma volume expansion, a complication that can be exacerbated by massive expansion of the erythroid marrow. The combination of pooling of the red cells in the spleen and plasma volume expansion can exacerbate the anemia in both α - and β -thalassemia.

ABNORMAL IRON METABOLISM

β -Thalassemia homozygotes that are anemic manifest increased intestinal iron absorption that is related to the degree of expansion of the red cell precursor population. Iron absorption is decreased by blood transfusion.^{7,10} Increased absorption causes a steady accumulation of iron, first in the Kupffer cells of the liver and the macrophages of the spleen and later in the parenchymal cells of the liver. Most patients homozygous for β -thalassemia require regular blood transfusion; thus, transfusional siderosis adds to the iron accumulation. Iron accumulates in the endocrine glands,^{7,186} particularly in the parathyroids, pituitary, pancreas, skin leading to increased pigmentation, liver, and, most important, in the myocardium.^{7,187} Iron accumulation in the myocardium leads to death by involving the conducting tissues or by causing intractable cardiac failure. Other consequences of iron loading include diabetes, hypoparathyroidism, hypothyroidism, and abnormalities of hypothalamic–pituitary function leading to growth retardation and hypogonadism.^{7,186} Recent work on the mechanisms of hepcidin downregulation in association with marrow hypertrophy provides a much better understanding of the mechanisms of iron loading in diseases like thalassemia and may provide new therapeutic options for the future (Chap. 43 and Ref. 188).

Accurate information is available regarding the levels of body iron, as reflected by hepatic iron, at which patients are at risk for serious complications of iron overload.^{7,189} These studies, which extrapolate data obtained from patients with genetic hemochromatosis, suggest that patients with hepatic iron levels of approximately 80 μmol of iron per gram of liver, wet weight (~15 mg of iron per gram of liver, dry weight), are at increased risk for hepatic disease and endocrine organ damage. Patients with higher body iron burdens are at particular risk for cardiac disease and early death (Chap. 43).

Disordered iron metabolism is less common in the adult forms of α -thalassemia. The milder degree of anemia, fewer transfusions, and the less marked erythroid expansion of the marrow are likely explanations.

The mechanisms whereby iron, and in particular non-transferrin-bound iron mediate tissue damage, and recent evidence about the central role of hepcidin in the abnormal regulation of iron absorption in disorders like thalassemia are discussed in Chap. 42.

INFECTION

All forms of severe thalassemia appear to be associated with an increased susceptibility to bacterial infection.⁷ The reason is not known. The relatively high serum iron levels may favor bacterial growth. Another possible mechanism is blockade of the monocyte–macrophage system as a result of the increased rate of destruction of red cells. No consistent defects in white cell or immune function have been reported, and high serum iron levels as an important factor remain to be unequivocally demonstrated. The one exception is infection with *Yersinia enterocolitica*, a normally nonvirulent pathogen that can produce its

own siderophore and hence can thrive in iron excess. Transfusion-dependent patients with thalassemia are at particular risk for blood-borne infections including hepatitis B, hepatitis C, HIV/AIDS, and, in some parts of the world, malaria.

COAGULATION DEFECTS

The increasing knowledge about the potential hypercoagulable state in some forms of thalassemia has been reviewed in detail.^{174–176,190} Evidence indicates that patients, particularly after splenectomy and with high platelet counts, may develop progressive pulmonary arterial disease as a result of platelet aggregation in the pulmonary circulation. Furthermore, using thalassemic red cells as a source of phospholipids, enhanced thrombin generation has been demonstrated in a prothrombinase assay. The procoagulant effect of thalassemia cells appears to result from increased expression of anionic phospholipids on the red cell surface (Chap. 33). Normally, neutral or negatively charged phospholipids are confined to the inner leaflet of the red cell membrane, an effect that is mediated by the action of aminophospholipid translocase, an enzyme sometimes known as flippase. In effect, this enzyme flips aminophospholipids that are diffused to the outer leaflet back to the inner leaflet (Chaps. 31 and 46). The current belief is that these aminophospholipids in thalassemic red cells are moved to the outer leaflet, thus providing a surface on which coagulation can be activated. Other nonspecific changes in the coagulation pathway and its antagonists have been observed in patients with different forms of thalassemia.

There is increasing evidence that, as in the case of sickle cell anemia (Chap. 49), the hemolytic component of the anemia of β -thalassemia is associated with the release of hemoglobin and arginase resulting in impaired nitric oxide availability and endothelial dysfunction with progressive pulmonary hypertension.¹⁹¹ There may be other contributions to this complication including increased coagulability and local structural damage to the lungs relating to excess iron deposition.

CLINICAL HETEROGENEITY

The pathophysiologic mechanisms described above provide the basis for the remarkably diverse clinical findings in the thalassemia syndromes.^{7,192} All the manifestations of β -thalassemia can be related to excess α -chain production. Thus, any mechanism that reduces the excess of α chains should reduce the clinical severity of the disease. Several elegant “experiments of nature” have shown that this reasoning is true and, incidentally, have confirmed that globin-chain imbalance is the major factor determining the severity of the thalassemias.

Coinheritance of α -thalassemia can reduce the severity of the more severe forms of β -thalassemia.^{193,194} The effect is much more marked in individuals who are homozygotes or compound heterozygotes for different forms of β^+ -thalassemia. β^0 -Thalassemia homozygotes who have inherited α -thalassemia seem to be protected little, if at all.

Severe β -thalassemia can be modified by the coinheritance of genetic determinants for enhanced production of γ chains. Several determinants may be involved. For example, inheritance of a particular RFLP haplotype in the region 5' to the β -globin gene may be an important factor.^{195,196} This particular β -globin gene haplotype is associated with a single base change, C \rightarrow T, at position –158 relative to the $^G\gamma$ -globin gene, an alteration that creates a cleavage site for the restriction enzyme XmnI.¹²¹ An excess of individuals homozygous for T (XmnI+ +) with the phenotype of thalassemia intermedia exist compared with thalassemia major in different populations.^{196–198} Whether this polymorphism is the only factor that increases hemoglobin F production in these cases is not absolutely clear. As discussed under “Hereditary Persistence of Fetal Hemoglobin” above, it is now clear that there are

loci on chromosomes 2, 6, and 8, and possibly the X chromosome, at which polymorphisms are involved in the elevation of fetal hemoglobin synthesis and that their coinheritance may significantly modify the phenotype of different forms of β -thalassemia.

Some mutations that cause β -thalassemia are associated with a mild phenotype because they result in only modest reduction of β -chain production.⁷ For example, mutations at positions -29 and -88 are associated with mild β^+ -thalassemia in Africans. Similarly, particularly mild phenotypes are commonly found with a base substitution at position 6 in IVS-1 and at position -87 in the 5'-flanking region of the β -globin gene in Mediterranean populations. The homozygous state for the IVS-1 position 6 mutation usually produces an extremely mild form of β -thalassemia. When these "mild" mutations are coinherited with more-severe β -thalassemia determinants, the compound heterozygous states are characterized by a more severe form of thalassemia intermedia. Other forms of thalassemia intermedia are associated with the homozygous state for $\delta\beta$ -thalassemia, the various interactions of β -thalassemia with $\delta\beta$ -thalassemia, and heterozygous β -thalassemia of the severe variety or in association with triplicated α -gene loci.^{7,10,198} These complex interactions are the subject of several extensive reviews.¹⁹⁸⁻²⁰⁰

These mechanisms for the phenotypic variability of the β -thalassemias represent only the beginning of our understanding of the genetic diversity of these conditions. Hence, defining a series of genetic modifiers that act at different levels is useful.¹⁹² Primary modifiers represent the diversity of mutations at the β -globin gene locus. Secondary modifiers are those, such as α -thalassemia and increased hemoglobin F production, that directly modify the relative degree of the imbalanced globin chain output. However, an increasing number of tertiary modifiers, that is, genetic diversity, have an important effect on the complications of the disease. These include loci involved in iron, bone, and bilirubin metabolism and in determining resistance of susceptibility to infection. Furthermore, phenotypic diversity may reflect different degrees of adaptation to anemia and the effect of the environment. These complex issues have been reviewed¹⁹² and are illustrated in Fig. 48-14. Several extensive reviews of the pathophysiology of the intermediate forms of β -thalassemia in different populations are available.^{199,200}

The α -thalassemias, particularly hemoglobin H disease, show considerable clinical diversity. Some of this variability can be related to particular genotypes,^{7,41} but the reasons for the heterogeneity of these disorders is not clear.

CLINICAL FEATURES

β - AND $\delta\beta$ -THALASSEMIAS

The most clinically severe form of β -thalassemia is thalassemia major. A milder clinical picture, characterized by a later onset and either no transfusion requirement or at least fewer transfusions than are required to treat the major form of the illnesses, is designated *β -thalassemia intermedia*. *β -Thalassemia minor* is the term used to describe the heterozygous carrier state for β -thalassemia. More extensive accounts of the clinical features of these conditions are given in two monographs.^{7,9}

β -THALASSEMIA MAJOR

The homozygous or compound heterozygous state for β -thalassemia, thalassemia major, produces the clinical picture first described by Cooley and Lee¹ in 1925. Affected infants are well at birth. Anemia usually develops during the first few months of life and becomes progressively more severe. The infants fail to thrive and may have feeding problems, bouts of fever, diarrhea, and other gastrointestinal symptoms. The majority of infants who develop transfusion-dependent homozygous β -thalassemia present with these symptoms within the first year of life.

Figure 48-14. Different levels of modification of the β -thalassemia phenotype. COL, various genes involved in collagen metabolism; CO-selection, indicates variable selection of genes involved in susceptibility to infection along with different thalassemia genes; HFE, gene for hereditary hemochromatosis; Hgb F, hemoglobin F; ICAM, intercellular adhesion molecule; OR, estrogen receptor; TNF, tumor necrosis factor; UGT1A1, uridine diphosphate-glucuronyltransferase; VDR, vitamin D receptor. (Adapted with permission from Weatherall DJ: *Phenotype-genotype relationships in monogenic disease: lessons from the thalassaemias*. *Nat Rev Genet* 2(4):245-255, 2001.)

A later onset suggests the condition will develop into one of the intermediate forms of β -thalassemia (see "Pathophysiology" above).

The course of the disease in childhood depends almost entirely on whether the child is maintained on an adequate transfusion program.^{7,9} The classic textbook picture of Cooley anemia describes the disease as it was seen before these children could be maintained with relatively normal hemoglobin levels by regular blood transfusions. If adequate transfusion is possible, children grow and develop normally and have no abnormal physical signs. Few of the complications of the disorder occur during childhood. The disease presents a problem only when the effects of iron loading resulting from ineffective erythropoiesis and from repeated blood transfusions become apparent at the end of the first decade. Children who are treated with an adequate iron chelation regimen develop normally, although some of them remain short in height.

An inadequately transfused child develops the typical features of Cooley anemia. Growth is stunted. With bossing of the skull and overgrowth of the maxillary region, the face gradually assumes a "mongoloid" appearance. These changes are associated with a characteristic radiologic appearance of the skull, long bones, and hands (Fig. 48-15). The diploe widens, with a "hair on end" or "sun ray" appearance and a lacy trabeculation of the long bones and phalanges. Gross skeletal deformities can occur. The liver and spleen are enlarged, and the pigmentation of the skin increases. Many features of a hypermetabolic state, as evidenced by fever, wasting, and hyperuricemia, may develop.

The clinical course is characterized by severe anemia with frequent complications. These children are particularly prone to infection, which

Figure 48-15. Radiologic appearances of the hands in homozygous β -thalassemia. The scattered lucent areas in the bones of the fingers reflect the marked expansion of marrow in distal areas.

is a common cause of death. Spontaneous fractures occur commonly as a result of the expansion of the marrow cavities with thinning of the long bones and skull. Maxillary deformities often lead to dental problems from malocclusion. Formation of massive deposits of extramedullary hematopoietic tissue may cause neurologic complications. With the gross splenomegaly that may occur, secondary thrombocytopenia and leukopenia frequently develop, leading to a further tendency to infection and bleeding. Splenectomy is frequently performed to reduce transfusion frequency and severe thrombocytopenia; however, postsplenectomy infections are particularly common.⁷ Bleeding tendency may be seen in the absence of thrombocytopenia. Epistaxis is particularly common. These hemostatic problems are associated with poor liver function in some cases. Chronic leg ulceration may occur but is more common in thalassemia intermedia.

Children who have grown and developed normally throughout the first 10 years of life as a result of regular blood transfusion begin to develop the symptoms of iron loading as they enter puberty, particularly if they have not received adequate iron chelation.^{7,9} The first indication of iron loading usually is the absence of the pubertal growth spurt and failure of the menarche. Over the succeeding years, a variety of endocrine disturbances may develop, particularly diabetes mellitus, hypogonadotropic hypogonadism, and growth hormone deficiency. Hypothyroidism and adrenal insufficiency also occur but are less common.^{7,186} Toward the end of the second decade, cardiac complications arise, and death usually occurs in the second or third decade as a result of cardiac siderosis.¹⁸⁷⁻¹⁸⁹ Cardiac siderosis may cause an acute cardiac death with arrhythmia, or intractable cardiac failure. Both of these complications can be precipitated by intercurrent infection.

Even the adequately transfused child who has received chelation therapy may suffer a number of complications. Bloodborne infection, notably with hepatitis B or C,²⁰¹ HIV,²⁰² or malaria,²⁰³ is extremely common in some populations, although the frequency is decreasing with the use of widespread blood-donor screening programs. Delayed puberty and growth retardation are common and probably reflect hypogonadotropic hypogonadism and damage to the pituitary gland.^{201,204}

Osteoporosis is being recognized increasingly and may, at least in part, be a reflection of hypogonadism.²⁰¹

β -THALASSEMIA INTERMEDIA

The clinical phenotype of patients designated as having thalassemia intermedia is more severe than the usual asymptomatic thalassemia trait but milder than transfusion-dependent thalassemia major.^{7,199,200} The syndrome encompasses disorders with a wide spectrum of disability. At the severe end, patients present with anemia later than patients with the transfusion-dependent forms of homozygous β -thalassemia and are just able to maintain a hemoglobin level of approximately 6 g/dL without transfusion. However, their growth and development are retarded. The patients become seriously disabled, with marked skeletal deformities, arthritis, and bone pain; progressive splenomegaly; growth retardation; and chronic ulcerations above the ankles. At the other end of the spectrum, patients remain completely asymptomatic until adult life and are transfusion independent, with hemoglobin levels as high as 10 to 12 g/dL. All varieties of intermediate severity are observed. Some patients become disabled simply from the effects of hypersplenism. Intensive studies of the molecular pathology of this condition have provided some guidelines about genotype-phenotype relationships that are useful for genetic counseling (Table 48-6).

Overall, the clinical features of the intermediate forms of β -thalassemia are similar to the features of β -thalassemia major. At the severe end of the spectrum, particularly in cases of growth retardation, patients should be treated with regular transfusion. However, a number of important complications, including progressive hypersplenism, occur in patients with milder forms. Clinically significant iron loading

TABLE 48-6. Genotypes of Patients with β -Thalassemia Intermedia

Mild forms of β -thalassemia	
Homozygosity for mild β^+ -thalassemia alleles	
Compound heterozygosity for two mild β^+ -thalassemia alleles	
Compound heterozygosity for a "silent" or mild and more-severe β -thalassemia allele	
Inheritance of α - and β -thalassemia	
β^+ -Thalassemia with α^0 -thalassemia ($-/-\alpha\alpha$) or α^+ -thalassemia ($-/\alpha\alpha$ or $-/\alpha$)	
β^+ -Thalassemia with genotype of Hgb H disease ($-/-\alpha$)	
β -Thalassemia with elevated γ -chain synthesis	
Homozygous β -thalassemia with heterocellular HPFH	
Homozygous β -thalassemia with homozygous $\epsilon\gamma$ 158 T \rightarrow C change (some cases)	
Compound heterozygosity for β -thalassemia and deletion forms of HPFH	
Compound heterozygosity for β -thalassemia and β -chain variants	
Hgb E/ β -thalassemia	
Other interactions with rare β -chain variants	
Heterozygous β -thalassemia with triplicated or quadruplicated α -chain genes (aaa or $aaaa$)

as a result of increased absorption is seen even in patients with infrequent transfusions (Chap. 43). Iron overload results in frequent diabetes and endocrine disturbances, typically by fourth decade of life. A high incidence of pigment gallstones, skeletal deformities, bone and joint disease, leg ulcers, and thrombotic tendency, particularly after splenectomy, is observed.⁷

Hematologists should be aware that in patients heterozygous for rare forms of β -thalassemia, a phenotype of thalassemia intermedia that results in the clinical constellation of autosomal dominant thalassemia (discussed in “Pathophysiology” above) is encountered on rare occasions.

β -THALASSEMIA MINOR

The heterozygous state for β -thalassemia is usually identified during family studies of patients with more severe forms of β -thalassemia, population surveys, or, most frequently, by the chance finding of the characteristic hematologic changes during a routine study. There is an extensive literature on this condition,⁷ some of which suggests that affected individuals may have symptoms of anemia and, not infrequently, splenomegaly, while other studies suggest that the condition is completely symptomless and palpable splenomegaly does not occur. Surprisingly, none of these studies have been controlled. A controlled study reported that individuals with the β -thalassemia trait suffer from fatigue and other symptoms indistinguishable from those with mild anemias from other causes. There was no difference in the frequency of palpable splenomegaly between the thalassemic and control groups.²⁰⁵ The trait not infrequently causes a moderately severe anemia of pregnancy, in some cases requiring transfusion. Some β -thalassemia carriers have increased iron stores, although this is most often a result of inappropriate iron therapy based on a misdiagnosis. In countries where there is a relatively high frequency of genetic determinants for hemochromatosis, the possibility of their coinheritance should be borne in mind if a patient with β -thalassemia trait with an unusually high plasma iron or serum ferritin level is encountered.

α -THALASSEMIAS

Hemoglobin Bart's Hydrops Fetalis Syndrome

This disorder is a frequent cause of stillbirth in Southeast Asia. Infants either are stillborn between 34 and 40 weeks' gestation or are born alive but die within the first few hours.^{7,206} Pallor, edema, and hepatosplenomegaly are seen. The clinical picture resembles hydrops fetalis as a result of Rh blood group incompatibility. Massive extramedullary hemopoiesis and enlargement of the placenta are noted at autopsy. A variety of congenital anomalies have been observed.

The rescue of a few infants with this syndrome by prenatal detection and exchange transfusion has been reported. These babies have grown and developed normally, although they are blood transfusion-dependent.^{207,208}

This condition is associated with a high incidence of maternal toxemia of pregnancy and difficulties at the time of delivery because of the massive placenta.²⁰⁶ The reason for placental hypertrophy is unknown, although severe intrauterine hypoxia is suspected because a similar phenomenon is observed in hydrops infants with Rh incompatibility.

Hemoglobin H Disease

Hemoglobin H disease was described independently in the United States and in Greece in 1956.^{209,210} The clinical findings are variable. A few patients are affected almost as severely as patients with β -thalassemia major, but most patients have a much milder course.^{7,211} Lifelong anemia with variable splenomegaly occurs; bone changes are unusual.

As discussed earlier in “Etiology and Pathogenesis,” a few attempts have been made to correlate the genotype with the phenotype of hemoglobin H disease. In general, as expected, patients with a nondeletion form of α -thalassemia affecting the predominant α_2 gene interacting with an α^0 -thalassemia determinant $\alpha^{\text{ND}}\alpha/-$, or $\alpha^{\text{ConstantSpring}}\alpha/-$, for example, have higher hemoglobin H levels, a greater degree of anemia, and a more severe clinical course than patients with the $-/-\alpha$ genotype.²¹²⁻²¹⁵

Milder Forms of α -Thalassemia

Because two α -globin genes exist per haploid genome, a wide spectrum of different conditions with overlapping phenotypes result from their various interactions.⁷ The carrier states for the deletion and nondeletion forms of α -thalassemia, $-\alpha/\alpha\alpha$ and $\alpha^{\text{ND}}\alpha/\alpha\alpha$, are symptomless. Similarly, the homozygous states for the deletion forms of α^+ -thalassemia, $-\alpha/-\alpha$, and the heterozygous state for α^0 -thalassemia, $-/-\alpha\alpha$, are symptomless, although they are associated with mild anemia and red cell changes. On the other hand, the homozygous states for the nondeletion forms of α -thalassemia, $\alpha^{\text{ND}}\alpha/\alpha^{\text{ND}}\alpha$, are associated with an extremely diverse series of phenotypes. As mentioned in “Interactions of α -Thalassemia Haplotypes” above in “Etiology and Pathogenesis,” they sometimes result in the clinical picture of hemoglobin H disease. In other patients, they are associated with only mild hypochromic anemia.⁷ The homozygous states for the chain termination mutants, notably hemoglobin Constant Spring, constitute a special case because they produce a particularly characteristic phenotype. In this case, moderate hemolytic anemia with splenomegaly are seen.^{7,216,217}

α -Thalassemia and Mental Retardation

The clinical phenotype of these conditions is heterogeneous. In cases associated with chromosomal deletion (tip of chromosome 16; ATR-16 [α -thalassemia chromosome 16-linked mental retardation syndrome]), the clinical defects vary with the extent of chromosomal defect; only α -thalassemia and mental retardation are constant.¹⁵⁷ To some extent this clinical variation is related to the length of the associated deletions; those which extend for 2000 kb involve the genes that are involved in tuberous sclerosis and polycystic kidney disease. In these cases the latter dominate the clinical picture, but there mental retardation and α -thalassemia are also associated.

The clinical phenotype in the second group of these disorders, which are caused by mutations of ATR-X, includes skeletal abnormalities, dysmorphic face, neonatal hypotonus, genital abnormalities, and a variety of less-constant features, in addition to mental retardation and α -thalassemia.¹⁵⁸

$\epsilon\gamma\delta\beta$ -Thalassemia

The clinical picture varies with the stage of development.⁷ Neonates may be significantly anemic and require transfusions. In contrast, children and adults with this condition are asymptomatic. They have the clinical and laboratory picture of heterozygous β -thalassemia, with the exception of a normal hemoglobin A₂ level. The reason for this discrepancy of developmental differences of the clinical phenotype has not been identified. The homozygous state is assumed to be lethal.

LABORATORY FEATURES

β -THALASSEMIA MAJOR

Hemoglobin levels at presentation may range from 2 to 3 g/dL or even lower.⁷ The red cells show marked anisopoikilocytosis, with hypochromia, target cell formation, and a variable degree of basophilic stippling (Fig. 48-16). The appearance of the blood film varies, depending on whether the spleen is intact. In nonsplenectomized patients, large

Figure 48-16. Blood films in β -thalassemia. **A.** β -Thalassemia minor. Anisocytosis, poikilocytosis, hypochromia. Occasional spherocytes and stomatocytes. **B.** Scanning electron micrograph of cells in **(A)** showing more detail of the poikilocytes. Small lymphocyte on the left. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

poikilocytes are common. After splenectomy, large, flat macrocytes and small, deformed microcytes are frequently seen. The reticulocyte count is moderately elevated, and nucleated red cells nearly always are present in the blood. These red cell forms may reach very high levels after splenectomy. The white cell and platelet counts are slightly elevated unless secondary hypersplenism occurs. Staining of the blood with methyl violet, particularly in splenectomized subjects, reveals stippling or ragged inclusion bodies in the red cells.¹⁶⁹ These inclusions can nearly always be found in the red cell precursors in the marrow. The marrow usually shows erythroid hyperplasia with morphologic abnormalities of the erythroblasts, such as striking basophilic stippling and increased iron deposition. Iron kinetic studies indicate markedly ineffective erythropoiesis, and red cell survival usually is shortened. Populations of cells with very short survival and longer-lived populations of cells are seen. The latter contain relatively more fetal hemoglobin. An increased level of fetal hemoglobin, ranging from less than 10 percent to greater than 90 percent, is characteristic of homozygous β -thalassemia. No hemoglobin A is produced in β^0 -thalassemia. The fetal hemoglobin is heterogeneously distributed among the red cells. Hemoglobin A₂ levels in homozygous β -thalassemia may be low, normal, or high. However, expressed as a proportion of hemoglobin A, the hemoglobin A₂ level almost invariably is elevated. Differential centrifugation studies indicate some heterogeneity of hemoglobin F and A₂ distribution among thalassaemic red cells, but their level in whole blood gives little indication of their total rates of synthesis.

In vitro hemoglobin synthesis studies using marrow or blood show a marked degree of globin-chain imbalance. Marked excess of α -chain

over β - and γ -chain production is always observed. Other aspects of the laboratory findings in this condition, including red cell survival, iron absorption, ferrokinetics, erythrokinetics, and the consequences of iron loading, were discussed earlier (see "Etiology and Pathogenesis" above).

The examination of siblings, parents, and children can be very important in confirming the diagnosis by finding the abnormalities in other family members, and the examining physician should make every effort to obtain a complete blood count in family members. With the exception of higher hemoglobin levels, the hematological changes in β -thalassemia intermedia are similar to those in β -thalassemia major (Fig. 48-17).

β -THALASSEMIA MINOR

Hemoglobin values of patients with β -thalassemia minor usually range from 9 to 11 g/dL. The most consistent finding is small, poorly hemoglobinized red cells (see Fig. 48-16), resulting in mean cell hemoglobin (MCH) values of 20 to 22 pg and mean corpuscular volume (MCV) values of 50 to 70 fL. The red cell count is usually normal or elevated and the hemoglobin and hematocrit is usually slightly below normal; however, the red cell indices are particularly useful in screening for heterozygous carriers of thalassemia in population surveys. The marrow in heterozygous β -thalassemia shows slight erythroid hyperplasia with rare red cell inclusions. Megaloblastic transformation as a result of folic acid deficiency occurs occasionally, particularly during pregnancy. A mild degree of ineffective erythropoiesis is noted, but red cell survival is normal or nearly normal. The hemoglobin A₂ level is increased to

Figure 48-17. **A.** Thalassemia intermedia. Blood films. Marked anisocytosis, poikilocytosis with elliptical, oval, tear-drop-shaped, and fragmented red cells. Target cells. **B.** Postsplenectomy. Morphology similar to that in **(A)** but with a nucleated red cell, coarsely stippled cell in center of field, and large and numerous platelets, indicative of the changes superimposed by splenectomy. 3.5 to 7.0 percent. The level of fetal hemoglobin is elevated in approximately 50 percent of cases, usually to 1 to 3 percent and rarely to greater than 5 percent.

α -THALASSEMIAS

Hemoglobin Bart's Hydrops Fetalis Syndrome

In infants with the hydrops fetalis syndrome, the blood film shows severe thalassemic changes with many nucleated red cells. The hemoglobin consists mainly of hemoglobin Bart's, with approximately 10 to 20 percent hemoglobin Portland. Usually no hemoglobin A or F is present, although rare cases that seem to result from interaction of α^0 -thalassemia with a severe nondeletion form of α^+ -thalassemia show small amounts of hemoglobin A.

Hemoglobin H Disease

The blood film shows hypochromia and anisopoikilocytosis. The reticulocyte count usually is approximately 5 percent. Incubation of the red cells with brilliant cresyl blue results in ragged inclusion bodies in almost all cells. These bodies form because of precipitation of hemoglobin H *in vitro* as a result of redox action of the dye. After splenectomy, large, single Heinz bodies are observed in some cells (Fig. 48–18). These bodies are formed by *in vitro* precipitation of the unstable hemoglobin H molecule and are seen only after splenectomy. Hemoglobin H constitutes between 5 and 40 percent of the total hemoglobin. Traces of hemoglobin Bart's may be present, and the hemoglobin A₂ level usually is slightly subnormal.

α^0 -Thalassemia and α^+ -Thalassemia Traits

The α^0 -thalassemia trait is characterized by the presence of 5 to 15 percent hemoglobin Bart's at birth.⁷ This hemoglobin disappears during maturation and is not replaced by a similar amount of hemoglobin H. An occasional cell with hemoglobin H inclusion bodies may appear after incubation with brilliant cresyl blue. This phenomenon is often used as a diagnostic test for the α -thalassemia trait. However, the test is difficult to standardize and requires much experience to be useful. In adult life, the red cells of heterozygotes have morphologic changes of heterozygous thalassemia with low MCH and MCV values. The electrophoretic pattern is normal. Globin-synthesis studies show a deficit of α -chain production, with an α -chain-to- β -chain production ratio of approximately 0.7.

The α^+ -thalassemia trait ($-\alpha/\alpha$) is characterized by a mild reduction in MCH and MCV values although in some cases there are normal values, 1 to 2 percent of hemoglobin Bart's at birth in some but not all cases, and a slightly reduced α -chain-to- β -chain production ratio of approximately 0.8; thus, this genotype often is referred to as *silent carrier*. Extensive studies comparing the level of hemoglobin Bart's at birth with a DNA analyses demonstrated that there is no detectable hemoglobin Bart's in a significant number of newborns who are heterozygous for α^+ -thalassemia.^{218,219} Globin gene synthetic ratios can be distinguished from normal only by studying relatively large numbers of samples and comparing the mean α -to- β ratio with that of normal control subjects. This approach is not reliable for diagnosing individual cases of the α^+ -thalassemia trait, and, unfortunately, no reliable method of diagnosis is available except for DNA analysis.

Figure 48–18. Hemoglobin H disease (α -thalassemia). Blood films. **A.** Note hypochromic red cells, anisocytosis, target cells, poikilocytes, including tear-drop-shaped red cells. **B.** Wet preparation stained with crystal violet. Inclusions in red cells (Heinz bodies) usually attached to membrane. **C.** Postsplenectomy. Note reduction in poikilocytes and frequency of target cells, a change consistent with hemoglobin H disease and enhanced by postsplenectomy effects. A nucleated red cell is in this field, reflecting an increase in their prevalence in the blood after splenectomy. **D.** Blood incubated for 90 minutes with brilliant cresyl blue. Numerous hemoglobin H intracellular precipitates (precipitates of excess β -globin chains). The frequent crenation is an artifact of the incubation conditions. Homozygous State for Nondeletion Types of α -Thalassemia

The homozygous state for nondeletion forms of α -thalassemia involving the dominant (α_2) globin gene causes a more severe deficit of α chains than do the deletion forms of α^+ -thalassemia. In some cases, the homozygous state produces hemoglobin H disease.

The homozygous state for hemoglobin Constant Spring or other chain-termination mutations is associated with moderately severe hemolytic anemia in which, for reasons not explained, no hemoglobin H is present but small amounts of hemoglobin Bart's persist into adult life. The homozygous states for the other nondeletion forms of α^+ -thalassemia are associated with hemoglobin H disease. In the homozygous state for hemoglobin Constant Spring, the blood picture shows mild thalassemic changes with normal-size red cells.^{216,217} The hemoglobin consists of approximately 5 to 6 percent hemoglobin Constant Spring, normal hemoglobin A₂ levels, and trace amounts of hemoglobin Bart's. The remainder is hemoglobin A.

The heterozygous state for hemoglobin Constant Spring shows no hematologic abnormality. The hemoglobin pattern is normal except for the presence of approximately 0.5 percent hemoglobin Constant Spring. The latter can be observed on alkaline starch-gel electrophoresis as a faint band migrating between hemoglobin A₂ and the origin. It is best seen on heavily loaded starch gels and is easily missed if other electrophoretic techniques are used (Fig. 48-19). In the newborn, usually 1 to 3 percent hemoglobin Bart's is present in the cord blood.

Homozygous State for Deletion Forms of α^+ -Thalassemia

The homozygous state for deletion forms of α^+ -thalassemia is characterized by a thalassemic blood picture with 5 to 10 percent hemoglobin Bart's at birth and hematologic findings similar to those in α^0 -thalassemia heterozygotes in adult life. In general, the $-\alpha^{4,2}$ deletion is associated with a more severe phenotype than is the $-\alpha^{3,7}$ deletion.⁷

DIFFERENTIAL DIAGNOSIS

The clinical and hematologic findings in homozygous β -thalassemia and hemoglobin H disease are so characteristic that the diagnosis usually is not difficult. Figure 48-20 shows a simple flowchart for laboratory investigations of a suspected case.

In early childhood, distinguishing the thalassemias from the congenital sideroblastic anemias may be difficult, but the marrow appearances in the latter are quite characteristic. Because of the high

Figure 48-19. Hemoglobin (Hgb) Constant Spring. Starch gel electrophoresis of 1,2, normal adult; 3,4, compound heterozygotes for hemoglobin Constant Spring and α^0 -thalassemia with hemoglobin H disease; 5, normal adult; and 6, compound heterozygote for α^0 -thalassemia and hemoglobin Constant Spring.

hemoglobin F levels encountered in juvenile chronic myelogenous leukemia, this disorder may superficially resemble β -thalassemia. However, the finding of primitive cells in the marrow, the absence of elevated hemoglobin A₂ levels on hemoglobin electrophoresis, the decrease in carbonic anhydrase in juvenile chronic myelogenous leukemia, and characteristic *in vitro* responses of myeloid progenitors *in vitro* to granulocyte-monocyte colony-stimulating factor (Chap. 87) readily differentiate this disorder from β -thalassemia.

LESS-COMMON FORMS OF THALASSEMIA

$(\delta\beta)^0$ -Thalassemia

The homozygous state for $\delta\beta$ -thalassemia is clinically milder than Cooley anemia and is one form of thalassemia intermedia.²²⁰⁻²²² Only hemoglobin F is present; hemoglobins A and A₂ are not produced. Heterozygous $\delta\beta$ -thalassemia is hematologically similar to β -thalassemia minor.⁷ The fetal hemoglobin level is higher (range: 5 to 20 percent), and the hemoglobin A₂ value is normal or slightly reduced. As in β -thalassemia, the fetal hemoglobin is heterogeneously distributed among the red cells, thus distinguishing this disorder from HPFH (Fig. 48-21).

Heterozygosity for both β -thalassemia and $\delta\beta$ -thalassemia results in a condition clinically similar to but milder than Cooley anemia. The hemoglobin consists largely of hemoglobin F, with a small amount of hemoglobin A₂. This finding is seen because the associated β -thalassemia gene has usually been the β^0 variety. $\delta\beta$ -Thalassemia has also been observed in individuals heterozygous for hemoglobin S or C.⁷

$(\delta\beta)^+$ -Thalassemia and Hemoglobin Lepore Disorders

The hemoglobin Lepore disorders have been described in the homozygous state and in the heterozygous state, either alone or in association with β - or $\delta\beta$ -thalassemia, hemoglobin S, or hemoglobin C.^{7,9,223} In the homozygous state, approximately 20 percent of the hemoglobin is of the Lepore type and 80 percent is fetal hemoglobin. Hemoglobins A and A₂ are absent. The clinical picture is variable. Some cases are identical to transfusion-dependent homozygous β -thalassemia; others are associated with the clinical picture of thalassemia intermedia. In the heterozygous state, the findings are similar to those of β -thalassemia minor. The hemoglobin consists of approximately 10 percent hemoglobin Lepore, with a reduced level of hemoglobin A₂ and a slight but consistent increase in fetal hemoglobin level. The Lepore hemoglobins have been found sporadically in most racial groups. In the majority of cases, chemical analysis has shown that these hemoglobins are identical to hemoglobin Lepore Washington-Boston. Hemoglobin Lepore Hollandia and Lepore Baltimore have been observed in only a few patients.^{7,223}

HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN

The current knowledge about the molecular pathology of HPFH was described earlier in "Etiology and Pathogenesis." Table 48-4 summarizes the currently accepted classification and nomenclature of this complex group of conditions. The different forms of HPFH are of very little clinical importance except that they may interact with thalassemia or the structural hemoglobin variants.

$(\delta\beta)^0$ Hereditary Persistence of Fetal Hemoglobin

Homozygotes for $(\delta\beta)^0$ HPFH have 100 percent hemoglobin F. Their blood shows mild thalassemic changes, with reduced MCH and MCV values very similar to those observed in heterozygous β -thalassemia. Similarly, they have imbalanced globin chain production, with ratios in the range of those observed in β -thalassemia heterozygotes.²²⁴ Heterozygotes have approximately 20 to 30 percent hemoglobin F, slightly

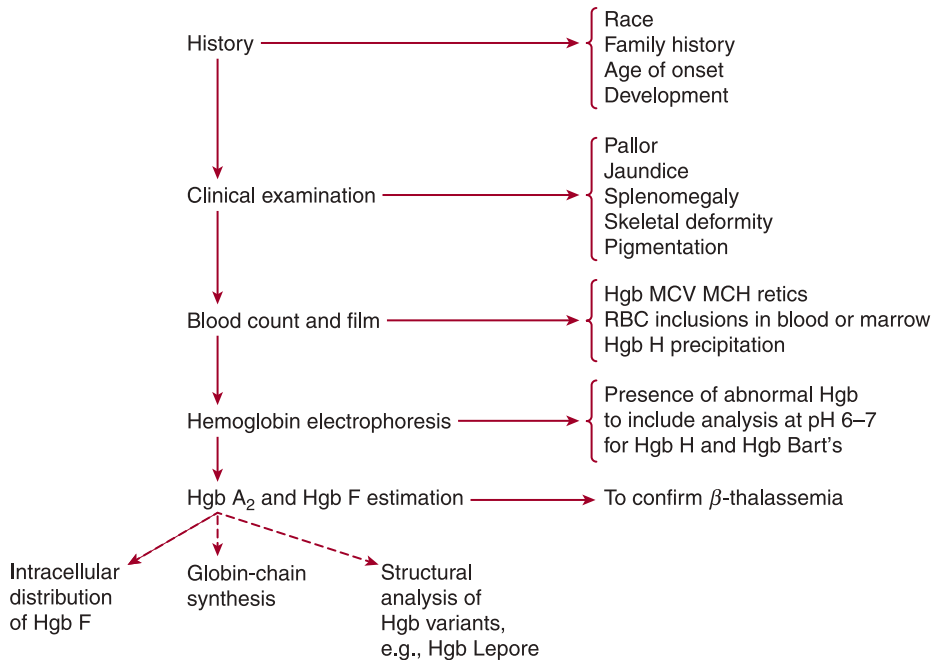

Figure 48-20. Flowchart showing an approach to diagnosis of the thalassemia syndromes. Hgb, hemoglobin; MCV, mean corpuscular volume; RBC, red blood cell count.

reduced hemoglobin A₂ values, and completely normal blood pictures. Thus, this condition appears to be an extremely well-compensated form of $\delta\beta$ -thalassemia in which the output of γ chains almost but not entirely compensates for the complete absence of β and δ chains. The different molecular forms of this condition show no difference in phenotype except in the proportion of $^{\text{C}}\gamma$ chains. The African forms of ($\delta\beta$)⁰ HPFH have been found in association with hemoglobins S and C or with β -thalassemia (Chap. 49). These compound heterozygous states are associated with little clinical disability.⁷

Nondeletion Types of Hereditary Persistence of Fetal Hemoglobin

Many nondeletion forms of HPFH associated with point mutations upstream from the γ -globin genes have been described (see Table 48-4). $^{\text{C}}\gamma\beta^+$ HPFH has been found in the heterozygous and compound heterozygous states with β -globin chain variants in African populations. No associated clinical or hematologic findings have been reported. Compound heterozygotes for $^{\text{C}}\gamma\beta^+$ HPFH and hemoglobins S or C produce 45 percent of the abnormal hemoglobin, approximately 30 percent hemoglobin A, and approximately 20 percent hemoglobin F containing only $^{\text{C}}\gamma$ chains.^{225,226}

The most common form of nondeletion HPFH is $^{\text{A}}\gamma\beta^+$ HPFH, which is found in Greeks.²²⁷⁻²²⁹ In the homozygous state, no clinical or hematologic abnormalities are noted. The hemoglobin findings are characterized by approximately 25 percent fetal hemoglobin and reduced hemoglobin A₂ levels of approximately 0.8 percent.²³⁰ Heterozygotes, who also are hematologically normal, have 10 to 15 percent hemoglobin F, almost all of the $^{\text{A}}\gamma$ variety. Compound heterozygotes with β -thalassemia have high hemoglobin F levels and a clinical picture that is only slightly more severe than the β -thalassemia trait.

In the British form of $^{\text{A}}\gamma\beta^+$ HPFH²³¹ heterozygotes have approximately 5 to 12 percent hemoglobin F, whereas homozygotes have approximately 20 percent. No associated hematologic abnormalities are seen, although surprisingly in this form of nondeletion HPFH the hemoglobin F seems to be unevenly distributed among the red cells.

A heterogeneous group of conditions is associated with persistent production of small amounts of hemoglobin F in adult life. They are

categorized under the general heading of *heterocellular HPFH*. Their clinical importance is that, when they are coinherited with different forms of β -thalassemia, they may lead to greater output of hemoglobin F and, hence, to a milder phenotype. This type of interaction should be suspected when one parent of a patient with β -thalassemia intermedia has an unusually high level of hemoglobin F for the β -thalassemia trait. Similarly, unaffected lateral relatives or other family members with slightly elevated hemoglobin F levels may be found.

β -THALASSEMIA ASSOCIATED WITH β -CHAIN STRUCTURAL HEMOGLOBIN VARIANTS

The most clinically important associations of β -thalassemia with β structural hemoglobin variants are sickle cell thalassemia, hemoglobin C thalassemia, and hemoglobin E thalassemia (Chap. 49). In addition, many interactions of β -thalassemia with rare structural variants have been reported.^{7,9,10}

Sickle cell thalassemia^{7,232,233} occurs in parts of Africa and in the Mediterranean, particularly Greece and Italy. It also has been observed in the Middle East and parts of India. The clinical consequences of carrying one gene for hemoglobin S and one gene for β -thalassemia depend entirely on the type of β -thalassemia mutation. The interaction between the sickle cell gene and β^0 -thalassemia is characterized by a clinical disorder that is very similar to sickle cell anemia. Similarly, the interaction of the sickle cell gene with the more severe forms of β^+ -thalassemia associated with marked reduction in β -globin synthesis yields a similar clinical phenotype. On the other hand, the interaction of the sickle cell gene with very mild forms of β^+ -thalassemia may be quite innocuous.²³³ The latter disorder is characterized by mild anemia associated with splenomegaly and a hemoglobin composition of approximately 60 to 70 percent hemoglobin S, 25 percent hemoglobin A, and an elevated level of hemoglobin A₂. In all these interactions, one parent shows the sickle cell trait, and the other parent shows the β -thalassemia trait.

Hemoglobin C thalassemia is a mild hemolytic disorder associated with splenomegaly.^{7,9,10} Again, the hemoglobin pattern varies depending on whether the thalassemia gene is the β^+ or β^0 type. This relatively innocuous condition has been recorded mainly in North Africa, but

C

Figure 48–21. Acid elution preparations of blood films from (A) $\delta\beta$ -thalassemia, (B) hereditary persistence of fetal hemoglobin, and (C) artificial mixture of fetal and adult red cells. The dark cells contain hemoglobin F. Hemoglobin F is resistant to acid elution.

it also is found in West Africa. It is characterized by a mild hemolytic anemia and splenomegaly with a blood picture showing the numerous target cells characteristic of all the hemoglobin C disorders.

Hemoglobin E thalassemia, which occurs at a high frequency in the eastern half of the Indian subcontinent and throughout Southeast

Asia, is one of the most important hemoglobinopathies in the world population.^{7,9,10,234–240} As mentioned earlier in “Etiology and Pathogenesis,” hemoglobin E is synthesized at a reduced rate and hence produces the clinical phenotype of a mild form of β -thalassemia. Hence, when hemoglobin E is inherited with β -thalassemia—and most often this is a β^0 - or severe β^+ -thalassemia mutation in Southeast Asia and India—a marked deficit of β -chain production results, with the clinical picture of severe β -thalassemia. Hemoglobin E thalassemia shows a remarkable variability in clinical expression,^{234–238} ranging from a mild form of thalassemia intermedia to a transfusion-dependent condition clinically indistinguishable from homozygous β -thalassemia. The reasons for this variability of expression are not understood, although some of the factors involved are identical to those that modify other forms of β -thalassemia.^{239,240}

In more-severe cases of hemoglobin E thalassemia, severe anemia with growth retardation, leg ulcers, bone deformity, marked tendency to infection, iron loading, and variable splenomegaly and hypersplenism are seen. Large tumor masses composed of extramedullary erythropoietic tissue may cause a variety of compression syndromes, including a clinical picture that closely mimics a cerebral tumor. Another curious picture that seems to be restricted to splenectomized patients is an obliterative occlusion of the pulmonary vasculature that is believed to result from an extremely high platelet count.²⁴¹

The clinical course and complications in transfusion-dependent patients are similar to those observed in homozygous β -thalassemia. In the milder forms, the main complications are progressive hypersplenism, organ damage as a result of progressive iron loading from an increased rate of absorption, extramedullary erythropoietic tumor masses, bone disease, and infection. The blood picture shows a typical thalassemic pattern. The hemoglobin consists of E, F, and A_2 . Usually no hemoglobin A is present because the β^0 -thalassemias are particularly common in the parts of the world where hemoglobin E is found.

Newer studies emphasize the complex interactions between genetic factors,^{239,240} differences in adaptation to anemia, particularly in early life (see “Pathophysiology” above), and the environment, notably proneness to malarial infection, that underlie the widely differing and unstable phenotypes of patients with hemoglobin E β -thalassemia.^{238,239}

β -THALASSEMIA WITH NORMAL HEMOGLOBIN A_2 LEVEL

Rare forms of β -thalassemia are seen in which heterozygotes have normal hemoglobin A_2 levels. Their main clinical importance is that they can be confused with the more severe forms of α -thalassemia in the heterozygous state and therefore may cause difficulties in genetic counseling and prenatal diagnosis. Based on hematologic studies, two main classes of “normal hemoglobin A_2 β -thalassemia”—sometimes called types 1 and 2—are seen.²⁴² Type 1 is the “silent” form of β -thalassemia. Type 2 is heterogeneous, with many cases representing the compound heterozygous state for β -thalassemia and δ -thalassemia.

“Silent” β -thalassemia^{7,243} is characterized by no hematologic changes in heterozygotes. Several mild forms of β -thalassemia that underlie this phenotype are described (see Refs. 44 and 45). Although this condition can be partly identified by demonstrating a mild degree of globin-chain imbalance, with α -to- β synthesis ratios of approximately 1.5:1, it can only be diagnosed with certainty by DNA analysis. Compound heterozygotes for this condition and β^0 -thalassemia have a mild form of β -thalassemia intermedia.

Normal hemoglobin A_2 β -thalassemia type 2 in heterozygotes is indistinguishable from typical β -thalassemia with elevated hemoglobin A_2 levels.²⁴² The homozygous state has not been described. The compound heterozygous state for this gene and for β -thalassemia with

raised hemoglobin A_2 levels is characterized by a clinical picture of severe transfusion-dependent β -thalassemia. Family data obtained in Italy and Sardinia suggest this condition represents the compound heterozygous state for both β -thalassemia and δ -thalassemia.^{244,245} Most of the δ -thalassemias have been observed *trans* to β -thalassemia. However, the form of δ -thalassemia resulting from loss of an A in codon 59 occurs on the same chromosome as the hemoglobin Knossos mutation, which is associated with a mild form of β -thalassemia.²⁴⁶ This finding explains the normal level of hemoglobin A_2 associated with this condition, which is the most common form of normal hemoglobin A_2 β -thalassemia in the Mediterranean region.

Several other conditions, mentioned earlier in this chapter in “Etiology and Pathogenesis,” are associated with a phenotype that is indistinguishable from normal A_2 β -thalassemia. These conditions include the heterozygous states for the Corfu form of $\delta\beta$ -thalassemia and $\epsilon\gamma\delta\beta$ -thalassemia.

OTHER UNUSUAL FORMS OF β -THALASSEMIA

The clinical features of the dominant β -thalassemias resemble the features of thalassemia intermedia.⁷ Moderate anemia and splenomegaly are seen, with a blood picture showing thalassemic red cell changes. The marrow shows erythroid hyperplasia with well-marked inclusion bodies in the red cell precursors. The latter may be seen in the blood after splenectomy. Hemoglobin analysis shows hemoglobins A and A_2 are present, and the hemoglobin F level is not usually elevated much higher than that seen in β -thalassemia trait. Hemoglobin A_2 levels are always raised.

Other unusual varieties of β -thalassemia include those categorized by unusually high hemoglobin F or A_2 levels. Most of these conditions result from deletions involving the β -globin gene and its promoter region. For example, the so-called Dutch²⁴⁷ form of β -thalassemia is associated with unusually high hemoglobin F levels in heterozygotes and high hemoglobin A_2 levels. Several other conditions of this type, which result from different-size deletions, have been reported (see Ref. 7).

δ^0 -THALASSEMIA

δ^0 -Thalassemia causes a complete absence of hemoglobin A_2 in homozygotes and a reduced hemoglobin A_2 level in heterozygotes.²⁴⁸ It is of no clinical significance except for its effect of reducing hemoglobin A_2 levels in β -thalassemia heterozygotes.

$\epsilon\gamma\delta\beta$ -THALASSEMIA

This heterogeneous condition has been observed only in the heterozygous state in a few families.^{7,108,109} It is characterized by neonatal hemolysis and, in adult life, by the hematologic picture of heterozygous β -thalassemia with normal hemoglobin A_2 levels.

α -THALASSEMIA IN ASSOCIATION WITH α - AND β -CHAIN HEMOGLOBIN VARIANTS

Several α -globin structural variants are caused by single amino acid substitutions at α -chain loci on chromosomes that carry only a single α -chain gene. Individuals who inherit variants of this type and an α^0 -thalassemia determinant have a form of hemoglobin H disease in which the hemoglobin consists of the α -chain variant hemoglobin and hemoglobin H. Well-documented examples include hemoglobin QH disease ($-/-\alpha^Q$),^{249,250} hemoglobin G Philadelphia H disease ($-/-\alpha^G$),^{251,252} and hemoglobin Hasharon H disease ($-/-\alpha^{\text{Hash}}$).²⁵³ Many examples of the coexistence of the homozygous or heterozygous states for β -chain hemoglobin variants and different α -thalassemia determinants have

been reported.^{7,9,10} Particularly well-characterized disorders include the various interactions of α^0 - and α^+ -thalassemia with hemoglobin E^{7,234} and hemoglobin S (Chap. 49).^{254,255} Carriers for these hemoglobin variants who also have the α^0 - or α^+ -thalassemia traits have thalassemic red cell indices and unusually low levels of the abnormal hemoglobin. Individuals with sickle cell anemia who have α -thalassemia show thalassemic red cell changes, more persistent splenomegaly, and lower hemoglobin F values than do patients without the thalassemia genes.

● THERAPY, COURSE, AND PROGNOSIS

The only forms of treatment available for thalassemic children are regular blood transfusions, iron chelation therapy in an attempt to prevent iron overload, judicious use of splenectomy in cases complicated by hypersplenism, and a good standard of general pediatric care.^{7,9,256} Marrow transplantation has an important role in selected cases (Chap. 23).

TRANSFUSION

Children with β -thalassemia who are maintained at a hemoglobin level of 9.5 to 14.0 g/dL grow and develop normally. They do not develop the distressing skeletal complications of thalassemia.^{7,256} Maintaining a lower hemoglobin level than this range without any deleterious effects on development and with the added advantage of reducing the level of iron loading may be possible. This regimen maintains a mean pre-transfusion level that does not exceed 9.5 g/dL.²⁵⁷ A transfusion program should not be started too early, and it should be initiated only when the hemoglobin level is too low to be compatible with normal development. If transfusion is started too soon, thalassemia intermedia may be missed, and the child may be transfused unnecessarily. Usually blood transfusions are given every 4 weeks on an outpatient basis. To avoid transfusion reactions, washed, filtered, or frozen red cells should be used so that the majority of the white cells and plasma-protein components are removed (Chap. 138).

IRON CHELATION

Every child who is maintained on a high-transfusion regimen ultimately develops iron overload and dies of siderosis of the myocardium. Therefore, such children must be started on a program of iron chelation within the first 2 to 3 years of life.²⁵⁶ Deferoxamine (desferrioxamine) was the first chelating agent of proven long-term value for treatment of thalassemia. It is best administered by an 8- to 12-hour overnight pump-driven infusion in the subcutaneous tissues of the anterior abdominal wall.^{258,259} Chelation therapy should commence by the time the serum ferritin level reaches approximately 1000 mcg/dL. In practice, this level usually is seen after the 12th to 15th transfusion. To prevent toxicity, infants must not be overchelated when the iron burden is still low. The initial dose usually is 20 mg/kg 5 nights per week, with 100 mg of oral vitamin C (200 mg in older children and adults) on the day of infusion, after the infusion has been initiated.²⁵⁹ Some evidence and widespread opinion indicate ascorbate precipitates cardiomyopathy in these patients if it is given before deferoxamine infusion is started.^{260,261} In patients who are heavily iron loaded, particularly those patients with cardiac or endocrine complications, the body iron stores can be effectively lowered by continuous intravenous infusion of deferoxamine at a dose of up to 50 mg/kg body weight. The procedure usually entails insertion of an intravenous delivery system.

Extensive experience with the use of deferoxamine and its toxic effects has been reported.¹⁸⁹ No serious complications occur other than local erythema and painful subcutaneous nodules at the site of infusions and extremely rare severe allergic reactions. These reactions can

be controlled, at least in part, by including 5 to 10 mg hydrocortisone in the infusion. Probably of greatest concern is neurosensory toxicity, which has been documented in up to 30 percent of cases. Toxicity causes high-frequency hearing loss that may become symptomatic.^{262,263} In a few cases, the toxicity did not respond to discontinuation of the drug, and permanent hearing loss resulted. Ocular toxicity has been reported.²⁶² Symptoms include visual failure, night and color blindness, and field loss. Reversal of symptoms after discontinuation of the drug has been reported. Deferoxamine may cause bone changes and growth retardation, sometimes associated with bone pain. Body measurements characteristically show a reduced crown-pubis-to-pubis-heel ratio.²⁶⁴ These changes may be associated with radiologic abnormalities of the vertebral column. These complications can be prevented by exercising extreme care in monitoring patients receiving long-term deferoxamine therapy. Young children or individuals from whom most of the iron has been removed by chelation are at particularly high risk. Formal audiometry and ophthalmologic examinations at 6-month intervals are recommended.

Because of the practical difficulties of a nightly subcutaneous infusion of deferoxamine there has been an intensive search for effective oral chelating drugs. Two of these agents are currently available, deferiprone (Ferriprox, L1) and deferasirox. The extensive literature on these agents has been reviewed.²⁶⁵⁻²⁶⁷ Deferiprone is administered at a dosage of 75 mg/kg in three daily doses. Unfortunately there have been limited numbers of long-term trials comparing its efficacy with deferoxamine, but overall it appears to be less effective than deferoxamine at maintaining safe body iron levels. Its administration is accompanied by a number of complications, the most important of which is neutropenia and, in some cases, agranulocytosis with some fatalities. Hence it is recommended that patients receiving this agent have a weekly white cell count. It also causes arthritis which varies in severity and between different ethnic groups. However, by virtue of its membrane-crossing capacity it has been suggested that it may be more effective in removing cardiac iron (Chap. 43). Unfortunately, to date, all the studies that suggest that it may reduce the frequency of cardiac complications in transfusion-dependent thalassemics have been retrospective and there are no long-term controlled data available. It is currently suggested that it should be used in combination with desferrioxamine, particularly for its cardiac-iron sparing effect; again, long-term prospective data are required.

The initial studies of deferasirox were promising²⁶⁶ and suggested that this agent in doses of 5 or 10 mg/kg per day, or higher in those who are heavily iron-loaded, was as effective as desferrioxamine in containing adequate hepatic iron levels. Preliminary clinical studies also showed that this agent may be effective for removing excess cardiac iron. Recent followup data have confirmed these early observations.²⁶⁷ The most frequent adverse reactions to deferasirox included gastrointestinal disturbances, transient rashes, and a nonprogressive increase in serum creatinine. It is still too early to be sure about the overall effectiveness of this agent, however, or to assess its long-term safety.

Because of the extremely well-documented data showing long-term survival of patients adequately treated with deferoxamine,²⁶⁸⁻²⁷⁰ this agent is still recommended as a first-line choice for management of transfusion-dependent thalassemia. However, particularly in view of problems of compliance and the promising trial results of deferasirox, this drug is also being used increasingly as a first line form of treatment. Further long-term follow up data regarding its efficacy are still required however.

Careful monitoring of the degree of iron accumulation during chelation therapy is absolutely vital. The simplest approach, particularly in countries where most sophisticated technology is not available, is a regular estimation of the serum ferritin level, which should be

maintained at less than 1500 mcg/L. The value of hepatic iron concentration assessment was discussed earlier in "Abnormal Iron Metabolism." Newer noninvasive approaches to assessing body iron burden have been developed. There is now strong evidence that, with adequate calibration, the measurement and mapping of liver iron concentrations using magnetic resonance imaging (MRI) is an extremely effective approach for the regular assessment of the effectiveness of chelation therapy.²⁷¹ Similarly, there have been advances in the noninvasive estimation of myocardial iron using T2* MRI. Evidence obtained using this approach suggests that there may be a variable correlation between hepatic and cardiac iron concentrations.²⁷² Clearly functional cardiologic studies should be combined with assessment of cardiac iron levels, particularly the ejection fraction, pulmonary artery pressure, and other parameters of cardiac activity. The true value of these new approaches to assessing myocardial iron levels and function still require further study by prospective controlled trials.

Increasing evidence indicates children maintained at a high hemoglobin level do not develop hypersplenism.⁷ However, enlargement of the spleen with increased transfusion requirements occurs commonly in patients maintained at a lower hemoglobin level. Splenectomy should be performed if transfusion requirements increase dramatically or pain develops because of the size of the spleen. Because of the risk of overwhelming pneumococcal infections, splenectomy should not be performed in children younger than age 5 years. Patients should receive a pneumococcal vaccine prior to the procedure. They then should be placed on prophylactic oral penicillin after the operation. *Haemophilus influenzae* type B and meningococcal vaccines also are recommended.

Children with severe thalassemia are still prone to other infections. Presentation with abdominal pain, diarrhea, and vomiting should always suggest an infection with a member of the *Yersinia* class of bacteria. Empirical treatment should start immediately with either an aminoglycoside or a cotrimoxazole. Transfusion-transmitted virus infection is common in some populations. All chronically transfused patients should be tested annually for hepatitis C, hepatitis B, and HIV. Patients with serologic evidence of chronic active hepatitis should be considered for treatment.

As mentioned earlier in "Abnormal Iron Metabolism," subtle endocrine deficiencies are increasingly recognized, particularly those associated with growth retardation and hypogonadism. These patients require expert endocrinologic assessment and replacement therapy when appropriate.

STEM CELL TRANSPLANTATION

By 1997, more than 1000 marrow transplants had been performed at three centers in Italy.²⁷³⁻²⁷⁶ Based on this experience and on later data,⁷ the prognosis evidently depended on the adequacy of iron chelation up to the time of transplantation. Hence, patients were divided into three classes: class I patients had a history of adequate iron chelation and neither liver fibrosis nor hepatomegaly; class II patients had one or two of these characteristics; and class III patients had all three characteristics. Among children in class I who had undergone transplantation early in the course of the disease, disease-free survival was assessed at 90 to 93 percent at 5 years, with a 4 percent risk of mortality related to the procedure. For class II patients, the intermediate-risk group, the survival and disease-free survival rates were 86 percent and 82 percent, respectively. For class III, the high-risk group, the survival and disease-free survival rates were 62 percent and 51 percent, respectively. Apart from the immediate complications of severe infection in the posttransplantation period, most of the problems were related to development of acute or chronic graft-versus-host disease. The overall frequency of mild to severe grades ranges from 27 to 30 percent.²⁷⁷ Modification of

preparative drug regimens has reduced the frequency of drug toxicity. The occurrence of mixed chimerism may be a risk factor for graft-versus-host disease. No case of hematologic malignancy has been observed in the longest followup of patients between 15 and 20 years after transplantation. Recent experience has fully confirmed these pioneering studies²⁷⁸ and suggests that patients without matched donors could benefit from haploidentical mother-to-child transplantation. The current status of blood stem cell therapy is discussed further in Chap. 23.

GENERAL CARE

Management of thalassemia requires a high standard of general pediatric care. Infection should be treated early. If the diet is deficient in folate, supplements should be given. Supplementation probably is unnecessary in children maintained on a high-transfusion regimen. Particular attention should be paid to the ear, nose, and throat because of chronic sinus infection and middle-ear diseases resulting from bone deformity of the skull. Similarly, regular dental surveillance is essential because poorly transfused thalassemic children have a variety of deformities of the maxilla and poorly developed teeth. In the later stages of the illness, when iron loading becomes the major feature, endocrine replacement therapy may be necessary. Symptomatic treatment for metabolic bone disease and cardiac failure also may be needed.

THERAPIES OF SPECIAL TYPES OF THALASSEMIA

Hemoglobin H disease usually requires no specific therapy, although splenectomy may be of value in cases associated with severe anemia and splenomegaly.^{7,9,10} Because splenectomy may be followed by a higher incidence of thromboembolic disease than occurs in splenectomized children with β -thalassemia,⁷ the spleen should be removed only in cases of extreme anemia and splenomegaly. Oxidant drugs should not be given to patients with hemoglobin H disease. The management of symptomatic sickle cell thalassemia follows the lines described for sickle cell anemia (Chap. 49).

Thalassemia intermedia presents a particularly complex therapeutic problem. Whether a child with a steady-state hemoglobin level of 6 to 7 g/dL should be transfused is difficult to determine with certainty. Probably the best compromise is to watch such children very closely during the first years of life. If they grow and develop normally and no signs of bone changes are evident, they should be maintained without transfusion. If, however, their early growth pattern is retarded or their activity is limited because of their anemia, they should be placed on a regular transfusion regimen. If hypersplenism plays a role in their anemia as the children grow older, splenectomy should be performed. Because many of these patients have significant iron loading from the gastrointestinal tract, regular estimations of serum iron and ferritin should be obtained and chelation therapy instituted when appropriate.

EXPERIMENTAL APPROACHES TO TREATMENT

Two main experimental approaches are being pursued in the search for more effective therapy of the thalassemias: (1) reactivation or augmentation of fetal hemoglobin production and (2) somatic gene therapy.

The main rationale for employing agents that have been used in attempts to increase hemoglobin F production is based on the observation that patients recovering from cytotoxic drug therapy or during other periods of erythroid expansion may reactivate hemoglobin F synthesis. In addition, the observation that butyrate analogues might have a stimulating effect on hemoglobin F production has led to a number of studies of their potential for management of thalassemia. A number of clinical trials have been performed.^{279–282} Agents that have been used

include various cytotoxic drugs, erythropoietin, and several different butyrate analogues. Overall, these agents, used alone or in combination, have produced some small effects on fetal hemoglobin production, but the results of these trials have been disappointing. Some notable exceptions were seen, however, particularly several cases of homozygosity or compound heterozygosity for hemoglobin Lepore in which use of either a combination of sodium phenylbutyrate and hydroxyurea or hydroxyurea alone produced a spectacular rise in hemoglobin F production. In the case of two homozygotes for hemoglobin Lepore, the necessity for further transfusion was eliminated.²⁸³ This finding raises the intriguing possibility that certain mutations, possibly deletions of the β -globin gene cluster, are more susceptible to this type of approach. Recent progress in searching for genetic targets for modifying fetal hemoglobin synthesis has been reviewed recently.⁴²

The other experimental approach involves somatic gene therapy. Currently, the therapy is mainly directed at gene transfer into potential hematopoietic stem cells using retroviral vectors.²⁸⁴ Other approaches also are being taken, including attempts at the restoration of normal splicing in cases of splicing mutations²⁸⁵ and use of *trans*-splicing ribozymes to correct β -globin gene transcripts.²⁸⁶ However, studies using murine models with recombinant lentiviral vectors suggest that sustained, high-level globin gene expression may be possible, at least in this experimental system.^{287,288} There continues to be slow progress toward somatic-cell gene therapy as applied to the hemoglobin disorders,²⁸⁹ with at least one apparent success and future plans for several clinical trials.

PROGNOSIS

The prognosis for patients with severe forms of β -thalassemia who are adequately treated by transfusion and chelation has improved dramatically over the years. Three large studies investigated the influence of effective long-term desferrioxamine use on the development of cardiac disease.^{268–270} In one study, patients who had maintained sustained reduction of body iron, as estimated by a serum ferritin level less than 2500 mcg/L over 12 years of followup, had an estimated cardiac disease-free survival rate of 91 percent. This finding is in contrast to patients in whom most determinations of serum ferritin level exceeded this value, in whom the estimated cardiac disease-free survival rate was less than 20 percent. In a second study, the relationship between survival and total-body iron burden was measured directly using hepatic storage iron values. Patients who had maintained hepatic iron concentrations of at least 15 mg of iron per gram of liver, dry weight, had a 32 percent probability of survival to age 25 years. No cardiac disease developed in patients who maintained hepatic iron levels below this threshold. These and other studies provide unequivocal evidence that adequate transfusion and chelation are associated with longevity and good quality of life. On the other hand, poor compliance or unavailability of chelating agents still are associated with a poor prospect of survival much beyond the second decade.

PREVENTION

In parts of the world where the incidence of thalassemia is high, the disease places an immense economic burden on society. For example, if all the thalassemic children born in Cyprus were treated by regular blood transfusions and iron-chelating therapy, it was estimated that within 15 years the total medical budget of the island would be required to treat this single disease.²⁹⁰ Clearly, this approach was not feasible, so considerable effort was directed toward developing programs for prevention of the different forms of thalassemia.

The goal of prevention can be achieved in two ways. The first is prospective genetic counseling, that is, screening total populations while

the children still are at school and warning carriers about the potential risks of marriage to another carrier. Few data are available about the value of programs of this type; a pilot study in Greece was unsuccessful.²⁹¹ Because it is believed this approach will not be successful in many populations, considerable effort has been directed toward developing prenatal diagnosis programs.

Prenatal diagnosis for prevention of thalassemia entails screening mothers at the first prenatal visit, screening the father in cases in which the mother is a thalassemia carrier, and offering the couple the possibility of prenatal diagnosis and termination of pregnancy if both mother and father are carriers of a gene for a severe form of thalassemia. Currently, these programs are devoted mainly to prenatal diagnosis of the severe transfusion-dependent forms of homozygous β^+ or β^0 -thalassemia. Considerable experience has also been gained in prenatal diagnosis of mothers at risk for having a fetus with the hemoglobin Bart hydrops syndrome, considering the distress caused by a long and difficult pregnancy and the obstetric problems resulting from the birth of a hydropic infant with a massive placenta.

The first efforts at prenatal detection of β -thalassemia used fetal blood sampling and globin-chain synthesis analysis carried out at approximately week 18 of pregnancy. Despite the technical difficulties involved, the method was applied successfully in many countries and resulted in a reduced birth rate of infants with β -thalassemia.²⁹² The technique is associated with a low maternal morbidity rate, a fetal mortality rate of approximately 3 to 4 percent, and an error rate of 1 to 2 percent. Its main disadvantage is that it must be carried out relatively late in pregnancy. For this reason, efforts turned to first trimester prenatal diagnosis.

DNA technology has enabled diagnosis of important hemoglobin disorders *in utero* by fetal DNA analysis. Although analysis can be carried out on DNA derived from amniotic fluid, the approach has drawbacks because, again, it must be done relatively late in pregnancy, and often amniotic fluid cells must be grown in culture to obtain a sufficient amount of DNA.²⁹³ However, DNA can be obtained as early as week 9 of pregnancy by chorionic villus sampling. Although the safety of this technique remains to be fully evaluated and limb reduction deformities may occur when the procedure is carried out very early in pregnancy (9 or 10 weeks), chorionic villus sampling has become the major method for prenatal diagnosis of the thalassemias based on subsequent experience with the technique.^{7,293–297}

Remarkable advances in DNA technology have provided a variety of methods for the direct identification of mutations in fetal DNA.⁷⁷ Even in families with extremely rare mutations, rapid DNA sequencing technology allows a diagnosis to be made very rapidly. The error rate using these different approaches varies, mainly depending on the experience of the particular laboratory; low rates, less than 1 percent, are reported from most centers. Potential sources of error include maternal contamination of fetal DNA and nonpaternity.

The application of this new technology has caused a major reduction in the birth rate of infants with thalassemia throughout the Mediterranean region and the Middle East, and in parts of the Indian subcontinent and Southeast Asia. Several approaches continue to be explored in an attempt to avoid the use of invasive procedures like chorion villous sampling. A variety of methods are being used to harvest fetal DNA from fetal cells in maternal blood or from maternal plasma^{298,299} and there are increasing numbers of attempts at preimplantation diagnosis of thalassemias.^{300,301} There is every expectation that some of these approaches will reach the clinic in the near future.³⁰²

THALASSEMIA AS A GLOBAL HEALTH PROBLEM

The remarkable advances in the diagnosis, prevention, and treatment of the thalassemias described in this chapter are only relevant to the richer

countries of the world. In many developing countries in which there is a very high frequency of thalassemia, there are very limited facilities for their diagnosis and management. Because many of these countries are going through the epidemiologic transition, which involves improvements in nutrition, cleaner water supplies, and better public health services, babies with serious forms of thalassemia who previously would have died of infection or profound anemia are now surviving to present for treatment.

Approaches to the better control and management of the thalassemias in developing countries have been reviewed.^{303,304} They include the development of partnerships between centers in the developed and developing countries for training workers in this field, and, once these partnerships are developed, for the further evolution of partnerships between those developing countries where there is knowledge and expertise of the field with those where no knowledge or facilities exist. Without organizations along these lines, the thalassemias will continue to cause the premature death of hundreds of thousands of infants worldwide.

CHAPTER 49

DISORDERS OF HEMOGLOBIN STRUCTURE: SICKLE CELL ANEMIA AND RELATED ABNORMALITIES

Kavita Natrajan and Abdullah Kutlar

SUMMARY

Hemoglobinopathies are the most common inherited red cell disorders worldwide. Among these disorders, sickle cell syndromes and thalassemias constitute a major public health problem. A glutamic acid to valine substitution at the sixth amino acid of the β -globin chain of human hemoglobin (HbA) results in formation of sickle hemoglobin (HbS). Sickle cell disease results from homozygosity for this mutation, or from a compound heterozygosity for sickle hemoglobin and β -thalassemia or another β -globin variant such as HbC, HbD, HbE, or HbO_{Arab}. The sickle mutation renders the hemoglobin molecule insoluble upon deoxygenation; thus red blood cells containing deoxy HbS polymer are rigid and have impaired rheologic properties. The downstream effects of the sickling process include: membrane changes leading to potassium loss and cellular dehydration, interaction of sickle hemoglobin with microvascular endothelium, neutrophils, and monocytes, hemolysis, nitric oxide depletion, release of inflammatory proteins and activation of coagulation. These processes lead to a hemolytic anemia, an inflammatory state, painful vasoocclusive episodes, and damage to multiple organ systems with a resultant shortened life expectancy.

Acronyms and Abbreviations: ACS, acute chest syndrome; ADMA, asymmetric dimethylarginine; AHSCT, allogeneic hematopoietic stem cell transplantation; BMP, bone morphogenic protein; 2,3-BPG, 2,3-bisphosphoglycerate; CO₂, carbon dioxide; CSSCD, Cooperative Study of Sickle Cell Disease; eNOS, endothelial nitric oxide synthase; Hb, hemoglobin; HbAS, sickle cell trait; HbF, fetal hemoglobin; HbS, sickle hemoglobin; HbSC, sickle cell–HbC disease; HIF, hypoxia-inducible factor; HLA, human leukocyte antigen; HPLC, high-performance liquid chromatography; IL, interleukin; iNKT cells, invariant natural killer T cells; K⁺, potassium; LDH, lactate dehydrogenase; MCHC, mean cell hemoglobin concentration; MCV, mean corpuscular volume; MPs, microparticles; MRI, magnetic resonance imaging; NO, nitric oxide; NT-pro-BNP, N-terminal pro–brain natriuretic peptide; O₂, oxygen; P₅₀, point at which hemoglobin is one-half saturated with oxygen; PCV7, pneumococcal polyvalent conjugate 7; PH, pulmonary hypertension; PIGF, placenta growth factor; P₀₂, partial pressure of oxygen; R state, relaxed oxy; SCD, sickle cell disease; SCT, stem cell transplantation; sPLA₂, secretory phospholipase A₂; STOP, Stroke Prevention Trial in Sickle Cell Disease; T state, tense, deoxy; TCD, transcranial Doppler; TF, tissue factor; TGF- β , transforming growth factor-beta; TNF- α , tumor necrosis factor-alpha; UDP, uridine diphosphate; UGT1A1, UDP glucuronosyltransferase 1 family; VOE, vasoocclusive episode; VTE, venous thromboembolism.

There is considerable heterogeneity in the severity of the disease; the best known modifier of the disease is an elevated level of fetal hemoglobin (HbF), which exerts a potent antisickling effect. Concomitant α -thalassemia is also a modifier, which leads to a decrease in hemolysis. There is an interest in nonglobin genetic modifiers of sickle cell disease. Over the past 3 decades, advances in supportive care and implementation of disease-modifying therapies, such as anti- γ to β -globin switching therapies, which result in increased HbF and less HbS synthesis, and have led to an increase in life expectancy. Hydroxyurea has emerged as an effective disease-modifying agent that has been approved by the FDA for use in adults with sickle cell disease. Although its main mechanism of action is to enhance HbF production, other effects such as a decrease in neutrophils, platelets, and decreased expression of adhesion molecules contribute to its efficacy. Novel antiswitching agents, most notably, DNA methyltransferase 1 inhibitors (5'-azacytidine and decitabine) and histone deacetylase inhibitors (butyrate derivatives and others) are now in clinical trials. Evolving therapies include antiadhesive therapies to prevent interaction of sickle cells with microvascular endothelium, antiinflammatory approaches, and modulation of hemoglobin–oxygen affinity to prevent sickling. To date, the only curative therapy remains allogeneic hematopoietic stem cell transplantation.

Sickle trait, the heterozygous state for sickle hemoglobin, affects approximately 8 percent of Americans of African descent, and with rare exceptions is asymptomatic. HbC is associated with target cells and spherocytes in the blood film and splenomegaly. HbD disease is essentially asymptomatic. HbE is very common in Southeast Asia, and because of large population movements from this area, it has become a prevalent hemoglobinopathy in other regions of the world. HbE is a thalassemic variant and its coinheritance with β^0 -thalassemia mutations can result in severe transfusion-dependent thalassemia major. Unstable hemoglobin variants appear as rare, sporadic cases and are characterized by a Heinz body hemolytic anemia. Variants that alter the oxygen affinity of the Hb molecule lead to erythrocytosis (high oxygen affinity variants) or anemia (low oxygen affinity variants) and are rare causes of these syndromes.

● THE STRUCTURE AND FUNCTION OF NORMAL HEMOGLOBIN

The red protein hemoglobin (Hb) serves to transport oxygen from the lungs to the tissues and carbon dioxide (CO₂) from the tissues to the lungs. Hb also binds the physiologically important nitric oxide (NO) molecule. The protein has evolved to perform its gas transport functions in a highly efficient manner. The oxygen affinity of Hb permits nearly complete saturation with oxygen in the lungs, as well as efficient oxygen unloading in the tissues because of its sigmoid oxygen dissociation curve. This curve results from the fact that Hb is a four-subunit, allosteric molecule; its conformation, and hence the oxygen affinity, changes as each successive molecule of oxygen is bound. Hb also plays an important role in acid–base balance: deoxyhemoglobin binds protons and oxyhemoglobin releases protons. Regulation of the oxygen dissociation curve to meet the needs of the body is remarkable. Hypoxic tissues become acidotic acutely, and the protons released produce a shift in the oxygen dissociation curve that enables more oxygen to be delivered to the tissue. However, longer-term acidosis or alkalosis (as occurs at high altitudes) is counteracted by modulation of red cell 2,3-bisphosphoglycerate (2,3-BPG), serving to decrease hemoglobin–oxygen affinity (Chap. 47).

Normal mammalian Hbs contain two pairs of related polypeptide chains: one chain of each pair is α or α -like and the other is non- α (β , γ ,

or δ). The α -chains of all human Hbs encountered after early embryogenesis are the same. The non- α chains include the β -chain of normal adult Hb ($\alpha_2\beta_2$), the γ -chain of fetal Hb ($\alpha_2\gamma_2$), and the δ -chain of the minor adult Hb (HbA₂ [$\alpha_2\delta_2$]), which accounts for 2.5 percent of the Hb of normal adults. Chapter 48 discusses the regulation of production of the globin chains.

Certain residues in the amino acid sequence of each polypeptide chain appear to be critical to stability and function. Such residues are usually the same (invariant) in α or β chains. The NH₂-terminal valines of the β chains are important in 2,3-BPG interactions. The C-terminal residues are important in the salt bridges that characterize the unliganded

molecules. Areas of contact between chains and between heme and globin tend to contain invariant residues. The non- α (β , γ , δ , or ϵ) chains are all 146 amino acids in length. The γ -chain of fetal Hb (HbF) differs from the β -chain by 39 residues. The γ genes are duplicated: one codes for glycine ($^G\gamma$) and the other for alanine ($^A\gamma$)⁷ at residue 136, giving rise to two kinds of γ chains. In addition, a common polymorphism, the substitution of threonine for isoleucine, is frequently found at residue 75 of the $^A\gamma$ -chain.

Approximately 75 percent of the amino acids in α and β chains are in a helical arrangement. All Hbs studied have a similar helical content (Fig. 49-1A). Eight helical areas, lettered A to H, occur in the β chains.

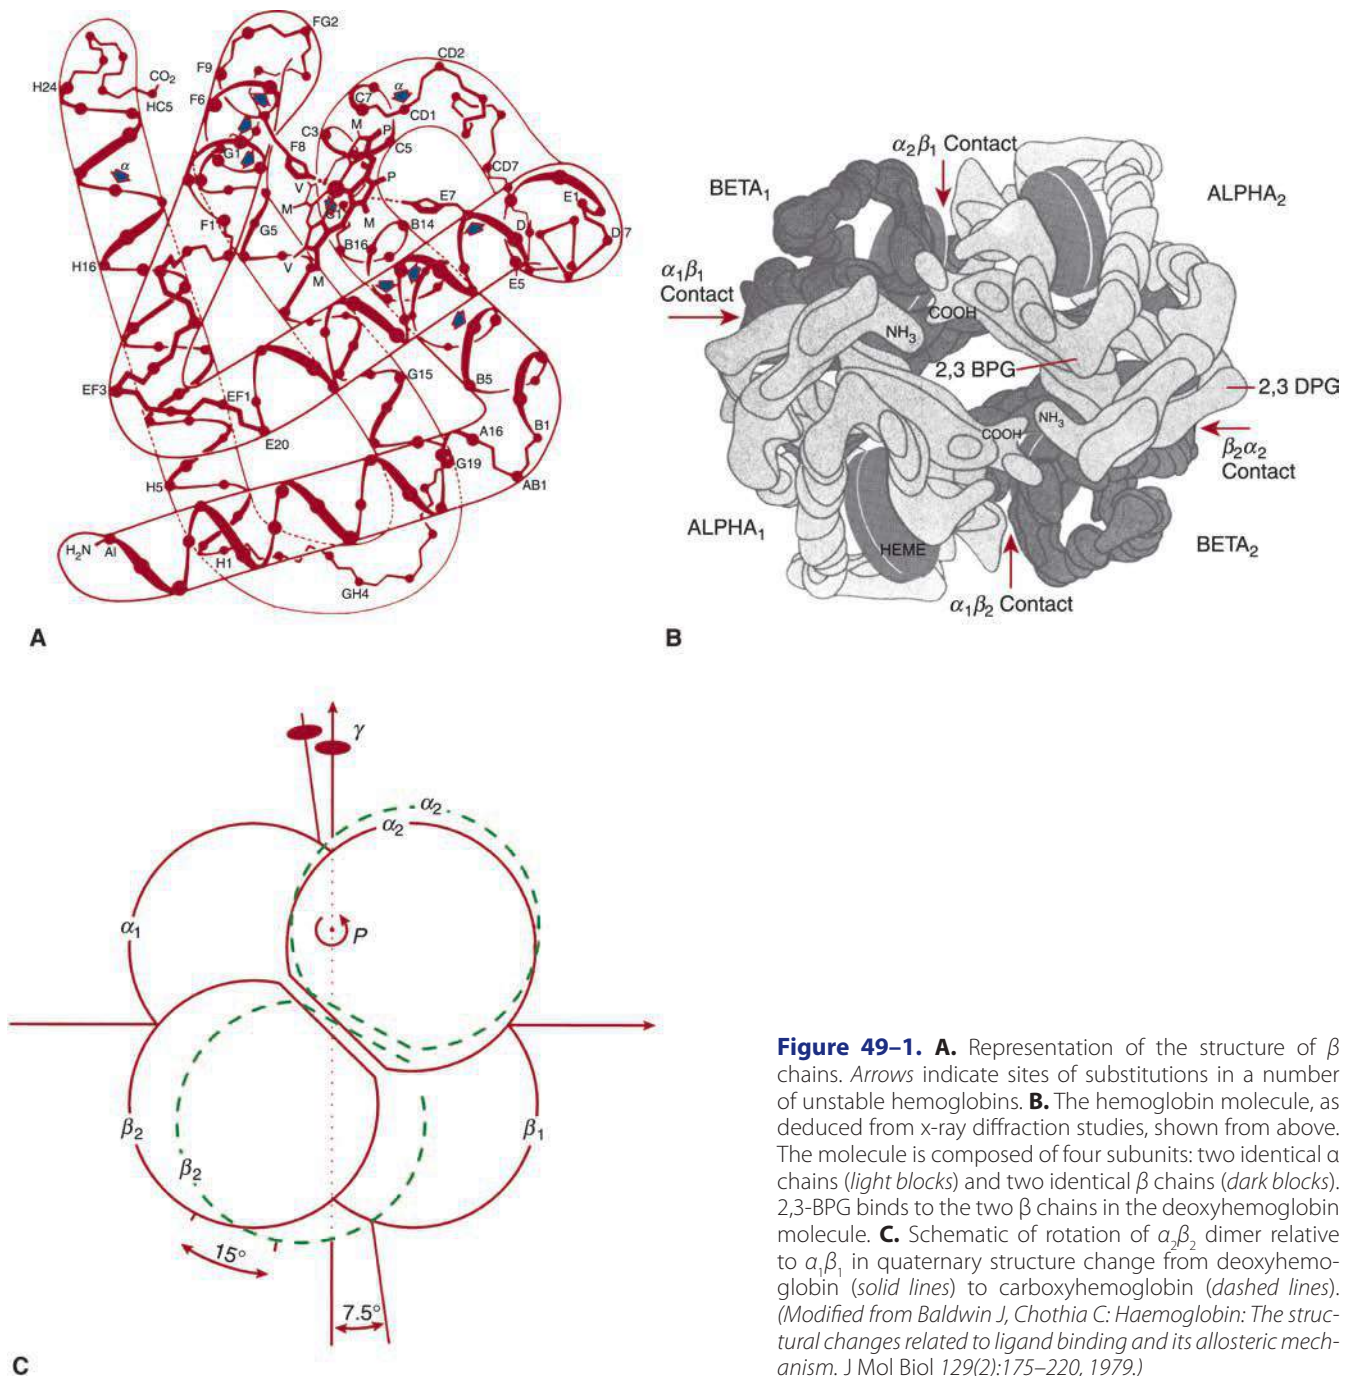

Figure 49-1. **A.** Representation of the structure of β chains. Arrows indicate sites of substitutions in a number of unstable hemoglobins. **B.** The hemoglobin molecule, as deduced from x-ray diffraction studies, shown from above. The molecule is composed of four subunits: two identical α chains (light blocks) and two identical β chains (dark blocks). 2,3-BPG binds to the two β chains in the deoxyhemoglobin molecule. **C.** Schematic of rotation of $\alpha_2\beta_2$ dimer relative to $\alpha_1\beta_1$ in quaternary structure change from deoxyhemoglobin (solid lines) to carboxyhemoglobin (dashed lines). (Modified from Baldwin J, Chothia C: Haemoglobin: The structural changes related to ligand binding and its allosteric mechanism. *J Mol Biol* 129(2):175-220, 1979.)

Figure 49-2. **A.** Structure of heme (ferroprotoporphyrin IX). **B.** Heme group and its environment in the unliganded α -chain. Only selected side chains are shown; the heme 4-propionate is omitted. (Reproduced from Gelin BR, Lee AW, Karplus M: Hemoglobin tertiary structural change on ligand binding. *J Mol Biol* 25;171(4):489–559, 1983.)

Hb nomenclature specifies that amino acids within helices are designated by the amino acid number and the helix letter, whereas amino acids between helices bear the number of the amino acid and the letters of the two helices. Thus, residue EF3 is the third residue of the segment connecting the E and F helices, whereas residue F8 is the eighth residue of the F helix. Alignment according to helical designation makes homology evident: Residue F8 is the proximal heme linked histidine, and the histidine on the distal side of the heme is E7.

Figure 49-1B show the tertiary structure of the α and β chains. The prosthetic group of Hb is heme (ferroprotoporphyrin IX); Fig. 49-2A shows its structure. The heme group is located in a crevice between the E and F helices in each chain (Fig. 49-2B). The highly polar propionate side chains of the heme are on the surface of the molecule and are ionized at physiologic pH. The rest of the heme is inside the molecule, surrounded by nonpolar residues except for two histidines. The iron atom is linked by a coordinate bond to the imidazole nitrogen (N) of histidine F8. The E7 distal histidine, on the other side of the heme plane, is not bonded to the iron atom, but is very close to the ligand-binding site.

The sigmoid oxygen dissociation curve is a function of the change of the conformation of the molecule from the liganded to the unliganded state (Table 49-1). In the deoxy state, the Hb tetramer is held together by intersubunit salt bonds (Fig. 49-3) and intersubunit hydrophobic contacts (see Fig. 49-1B), in addition to a certain number of hydrogen bonds. In deoxyhemoglobin, 2,3-BPG is situated in the central cavity between the two β chains (see Fig. 49-1B). The change in conformation of the Hb molecule is brought about by a complex, coordinated series of changes in the structure of the molecule as heme binds oxygen. The oxygen dissociation curve can be linearized by a transformation known as the Hill plot:

$$\log[y/(1 - y)] = \log K + n \log P_{O_2}$$

TABLE 49-1. Nomenclature of Hemoglobin Quaternary Structures

Liganded (Oxygen Bound)	Unliganded (Reduced)
Oxy	Deoxy
R-state	T-state
Relaxed	Tense
High affinity	Low affinity

where K is an empiric overall constant without physicochemical basis. The slope n is taken as a convenient measure of cooperativity. Values of n in noninteracting Hbs that exhibit hyperbolic, not sigmoid, oxygen dissociation curves (e.g., myoglobin) are approximately 1. In a normal tetrameric Hb with four oxygen-reactive sites, the maximum value for n is 4.0; however, n values of 2.7 to 3.0 are found in normal Hb.

The point at which the Hb is one-half saturated with oxygen (P_{50}) is the usual measurement of oxygen affinity. It depends upon pH (the Bohr effect), temperature, and 2,3-BPG concentration. In common practice, P_{50} is standardized at 37°C and pH 7.20. P_{50} of freshly drawn blood is approximately 26.7 torr under standard conditions, but the partial pressure of oxygen (P_{O_2}) of Hb from which 2,3-BPG has been removed is only approximately 13 torr. Although fetal and newborn red cells have 2,3-BPG levels similar to those of adults, their oxygen dissociation curve is left shifted (increased oxygen affinity) with a P_{50} of approximately 23 torr because HbF does not react as strongly with 2,3-BPG as does HbA.

Figure 49-3. Salt bridges in deoxyhemoglobin (* = ionizable group less protonated at pH 9.0 than at pH 7.0). These groups account for 60% of the alkaline Bohr effect. The remainder is due to α H5 His. (Data from Perutz MF, Wilkinson AJ, Paoli M, et al: The stereochemical mechanism of the cooperative effects in hemoglobin revisited, *Annu Rev Biophys Biomol Struct* 1998;27:1–34.)

● NOMENCLATURE OF ABNORMAL HEMOGLOBINS

Following the molecular characterization of HbS by Ingram and colleagues in 1956, there has been a rapid and exponential increase in the number of variant or “abnormal” Hbs.¹ This number now exceeds 1000. A detailed description of variant Hbs, their chemical and functional properties, and population distribution can be found on the Globin Gene Server website (<http://globin.cse.psu.edu/>). Initially, newly described variants were designated by letters of the alphabet (e.g., HbC, HbD, HbE, HbJ). When the letters of the alphabet were exhausted, the practice of naming the variant Hbs after the geographic location where they were first described was adapted (e.g., Hb_{Köln}, Hb_{Zürich}). Variants with electrophoretic or functional properties similar to previously described abnormal Hbs were designated with the letter and the geographic location (e.g., HbD_{Punjab}, HbE_{Saskatoon}, HbM_{Hyde Park}). Some alphabetic designations were also used to indicate electrophoretic properties of certain variants; for example, there are a number of HbDs (D_{Punjab}, D_{Iran}, D_{Ibadan}). All of these variants share the electrophoretic properties of HbS-like mobility on alkaline (cellulose acetate) electrophoresis, whereas they move with HbA at acidic pH (citrate agar electrophoresis). Similarly, HbEs have HbC-like mobility on alkaline electrophoresis and move with HbA on citrate agar electrophoresis.

The vast majority of Hb variants arise as a result of single nucleotide mutations, leading to an amino acid change in either α -, β -, δ -, or γ -globin subunits of the Hb tetramer resulting in variants of HbA (α or β), HbA2 (δ), or HbF (γ). Other mechanisms include small deletions or insertions, elongated chains, and fusions (for a detailed description of Hb variants and associated clinical syndromes, see “Other Abnormal Hemoglobins” below).

The coinheritance of HbS with some other variant Hbs or β -thalassemia mutations results in a number of sickling syndromes. In the United States, the most common sickling disorder is homozygous HbS (HbSS, sickle cell anemia), which is now commonly referred to as sickle cell disease (SCD). This is followed by sickle cell-HbC disease (HbSC), sickle cell- β^+ -thalassemia (HbS- β^+ -thalassemia), and sickle cell- β^0 -thalassemia (HbS- β^0 -thalassemia). Other rarer forms include HbSD_{Punjab}, HbSO_{Arab}, HbS_{Lepore}, and HbSE diseases. Coinheritance of a large number of β -chain variants with HbS does not result in a symptomatic sickling disorder; rather, they are clinically and hematologically indistinguishable from sickle cell trait (HbAS).

HbC is found in 17 to 28 percent of West Africans, particularly east of the Niger River in the vicinity of North Ghana. The selective factors that account for this high prevalence are unknown at present, but HbC probably confers some resistance to infection with malaria. The prevalence of HbC among Americans of African descent is 2 to 3 percent. Sporadic cases also have been reported in other populations, including Italians and Afrikaners.

HbD_{Punjab}, which is now recognized to be identical with HbD_{Los Angeles} because both have the structure $\alpha_2\beta_2121$ Glu→Gln, also interacts with HbS in forming aggregates in the deoxy conformation. HbD has been found in many parts of the world, including Africa, northern Europe, and India.

HbE is so prevalent that it may be the most common abnormal Hb or second in prevalence only to HbS. HbE is found principally in Burma, Thailand, Laos, Cambodia, Malaysia, and Indonesia. In some areas, HbE is found with a carrier rate of 30 percent. On the other hand, it is not prevalent among Chinese. Studies of restriction length polymorphisms in the β -globin cluster indicate the HbE mutation has arisen several times independently. It, too, probably confers some resistance to infection with malaria.

● SICKLE CELL DISEASE

DEFINITION AND HISTORY

The first case of SCD, reported in 1910, was that of a dental student from Grenada, Walter Clement-Noel, studying in Chicago. Dr. James Herrick and his intern, Dr. Ernest Irons, were in charge of Mr. Noel's care between 1904 and 1907, during which time he had several bouts of fever and cough and a history of leg ulcers, jaundice, and exercise intolerance. Herrick and Irons made astute clinical observations and prepared blood films and photomicrographs of nucleated red blood cells and of red cells having a “slender sickle shape” (Fig. 49–4).² During the next decade, two more cases of this unusual anemia were reported. In 1915, Cook and Meyer raised the question of a genetic basis for the disorder based on the family history of the third reported case. In 1917, Victor Emmel used *in vitro* culture to show that sickle red cells represented a physical alteration of morphologically normally appearing red cells and were not released from the marrow as sickle cells.³ He also demonstrated that morphologically normal red cells of the father of a patient became sickle shaped after *in vitro* culture. Vernon Mason, who reported the fourth case in 1922, coined the term *sickle cell anemia* after observing the similarities between all the cases reported up to that time. In 1923, Sydenstricker and Huck noted “latent-sicklers” among relatives of the diagnosed patients, confirming and expanding on Emmel's finding. In 1927, Hahn and Gillespie showed that sickling was related to low oxygen tension and low pH. In 1933, Diggs distinguished the difference of symptomatic cases called sickle cell anemia, from asymptomatic cases that were termed *sickle cell trait*, and he found that approximately 8 percent of Americans of African descent had the sickle cell trait.⁴

Figure 49–4. Peculiar elongated and sickle-shaped red cells from the first report of sickle cell anemia with depiction of sickle cells. (Reproduced with permission from Herrick JB: Peculiar elongated and sickle-shaped red corpuscles in a case of severe anemia. Arch Intern Med 6:517, 1910.)

Irving Sherman, while a medical student at Johns Hopkins, showed that sickled red cells were birefringent under a polarizing microscope and that this finding was reversible with oxygenation of the cells. This observation ultimately led Linus Pauling to study sickle Hb after being advised of this property of sickle cell by William Castle, a noted research hematologist. Indeed, in 1949, Pauling and his colleagues demonstrated electrophoretic differences between Hbs from normal, sickle cell trait, and sickle cell anemia subjects and hypothesized that there must be chemical differences, thus establishing sickle cell anemia as the first molecular disease described. In the late 1950s, Hunt and Ingram sequenced the globin peptide and linked the abnormality to a change in the amino acid composition of the β -globin chain (replacement of glutamic acid by valine at residue 6). In 1977, Marotta and coworkers showed that the corresponding change in codon 6 of the β -globin gene was GAG \rightarrow GTC. The discovery of a variant fragment in HbS versus HbA during restriction endonuclease mapping of amniotic fluid cells by Y. W. Kan paved the way for antenatal diagnosis of SCD and opened the way for modern genetics using recombinant DNA technology.⁵

The history of sickle cell anemia serves as an inspiring reminder of the power of clinical and laboratory observations, and in an era of mechanistic basic science research, serves to highlight the importance of bedside to bench and bench to bedside research integration.^{6–9}

EPIDEMIOLOGY

The observation that sickle cell trait may have a survival advantage against some environmental factors was first suggested by Dr. Alan Raper in East Africa in 1949. Drs. Mackey and Vivarelli suggested that the environmental influence might be malaria. It was subsequently noted that blood from sickle cell trait persons contained less malarial parasites and that the sickle trait conferred some protection against malaria in early childhood. Data suggest that sickle trait is maximally protective against severe malaria as opposed to asymptomatic parasitemia or mild disease.¹⁰ The mechanism of such a protection has been the matter of much debate. Plausible mechanisms include selective sickling of parasitized red blood cells, resulting in more effective removal by the monocyte-macrophage system, and inhibitory effect on parasite growth by increased red cell potassium loss, decreased red cell pH, and increased endothelial adherence of parasitized sickle red cells.

Thus, the prevalence of sickle cell anemia closely mirrors the worldwide distribution of falciparum malaria; however, as a result of migration of peoples to the industrialized Western countries, SCD has become more prevalent in areas where malaria is not endemic.

The World Health Organization estimated in 2006 that 5 percent of the world population carries a gene for a hemoglobinopathy. Sickle cell anemia is highly prevalent in sub-Saharan and equatorial Africa with lesser but significant prevalence in the Middle East, India, and the Mediterranean region. Incidence of SCD in sub-Saharan African countries ranges between 1 and 2 percent, which translates into approximately 500,000 cases per year. In the Jamaican cohort study, newborn screening in 100,000 consecutive vaginal deliveries resulted in the finding of sickle cell trait in 10 percent of newborns.¹¹

In the United States, the Centers for Disease Control and Prevention estimates that sickle cell anemia is present in 1 in 500 livebirths among Americans of African descent; 1 in 12 American of African descent have the trait, and approximately 100,000 Americans largely of African descent live with the disease. In Americans of Hispanic descent, the rate of SCD is 1 in 36,000 livebirths. Accurate population statistics of SCD are difficult to obtain in the United States because of a lack of standardized data collection and central reporting.¹²

As of 2002, in the United States, more than one billion dollars are spent per year on hospitalizations for SCD.¹³ Data from a single

state Medicaid program estimated a lifetime cost of care of \$500,000 per patient with SCD. In this patient population, cost increased with increasing age, including cost of non-SCD health issues. The majority of the costs were for inpatient healthcare utilization.¹⁴

Previously, speculation existed as to whether the sickle mutation arose once and gained worldwide distribution or whether the mutation had arisen independently in different regions of the world. The non-random association of restriction endonuclease polymorphisms in the β -globin cluster define the β -globin haplotype. The β -globin gene cluster yields five distinct haplotypes associated with sickle cell mutations (Chap. 9).^{15–17} Four of the five patterns occur in Africa and are designated as the Senegal, Benin, Bantu, and Cameroon haplotypes, whereas the fifth arose on the Indian subcontinent.¹⁸ These findings indicate that the sickle mutation arose independently at five different times.

PATHOPHYSIOLOGY

The *sine qua non* of sickle cell anemia is a Glu \rightarrow Val substitution in the sixth amino acid of the β -globin gene. However, the pathophysiologic processes that result in the clinical phenotype extend beyond the red cell (Fig. 49–5). There is marked clinical heterogeneity from one patient to another and in the same patient over time. The heterogeneity for the same genotypic abnormality therefore implies that a multitude of other factors must contribute to the pathology of sickle cell anemia. The pathology is now far removed from the simplistic theory of hypoxia-induced microvascular occlusion. Sickle cell anemia is a chronic inflammatory state punctuated by acute increase in inflammation wherein the endothelium, neutrophils and monocytes, platelets, coagulation pathways, several plasma proteins, adhesion molecules, and derangements in NO metabolism interact in concert with the abnormality in Hb polymerization described several decades ago (Fig. 49–6). Abnormal adenosine signaling and activation of invariant natural killer T (iNKT) cells have been implicated in disease pathophysiology. Added to that are the complex differences in tissue-specific vascular beds and differences in various parts of the vasculature in the same organ. Also, variation in several genes other than the β -globin gene that modify the milieu in which organ damage occurs may play a role.

The pathophysiology of sickle cell anemia is described in separate sections; however, because no single, dominant pathway explains the multitude of manifestations, no single therapeutic modality serves to abrogate all of the pathology. Most experiments are in isolation in animal models or relatively simplistic experimental conditions with few *in vivo* studies in humans and thus do not replicate the complexity of this disorder.

Hemoglobin Polymerization

Aggregation of deoxy HbS molecules into polymers occurs when aggregates reach a thermodynamically critical size. This process is termed *homogenous nucleation*, and the smallest aggregate formed that favors polymer growth is called the critical nucleus.^{19–24} Addition of subsequent deoxy HbS molecules to already formed polymers is termed *heterogenous nucleation*, which results in polymer branching. Polymer growth is, therefore, an exponential process wherein there is a delay time between presence of deoxy HbS molecules and polymer formation. This delay time is inversely proportional to the concentration of HbS molecules. Polymer formation alters the rheologic properties of the red cell.

The quaternary structure of oxy HbS cannot maintain axial and lateral hydrophobic contacts unlike that in the deoxygenated state, thus explaining the unsickling phenomenon upon reoxygenation.^{25–28} The sickling process that is initially reversible with oxygenation of deoxy HbS eventually leads to the formation of sickle-shaped red cells that

Figure 49-5. Schema summarizing the pathophysiology of sickle cell anemia. K⁺, potassium; NO, nitric oxide; PS, phosphatidylserine; RBC, red blood cell; ROS, reactive oxygen species; TF, tissue factor; WBC, white blood cell; XO, xanthine oxidase.

fail to return to their normal discoid shape with oxygenation because of membrane damage imparted by repeated cycles of sickling and unsickling in the circulation. These cells are then termed *irreversibly sickled cells*. The rate and extent of polymerization is dependent on several factors, including intracellular Hb concentration, presence of Hbs other than HbS, blood oxygen saturation, pH, temperature, and 2,3-BPG levels.²⁹ Microvascular occlusion by sickle red cells containing polymers is favored by prolonged transit times through the microcirculation, rapid deoxygenation and increased numbers of dense sickle red cells that contain polymers even at oxygen saturation levels found in the arterial circulation.^{29–32} Arguments against HbS polymerization as the major determinant of sickle cell pathophysiology include lack of clinically significant events despite constant sickling of red cells, the association of neutrophilia with vasoocclusive episodes (VOEs), and clinical features that imply macrovascular rather than microvascular perturbation, for example, large-vessel stroke.³³

Cellular Dehydration

Membrane injury in HbSS red cells results in impaired cation homeostasis with decreased ability to maintain intracellular potassium concentrations. The calcium-activated potassium (K⁺) channel (Gardos channel), potassium-chloride cotransport channel, and a sickling-induced nonselective cation leak pathway have been implicated in sickle red cell dehydration. The net result is loss of intracellular potassium and water resulting in cellular dehydration.^{34–39} This change effectively increases the red cell Hb concentration, favoring sickling.

Hemolysis and Nitric Oxide Scavenging

NO is a key component of the vascular endothelium that has vasodilatory, antiinflammatory, and antiplatelet properties.⁴⁰ NO is a soluble gas synthesized from L-arginine by endothelial nitric oxide synthase (eNOS).⁴¹ Red cell L-arginase released as a consequence of sickle red cell hemolysis converts arginine to ornithine, thereby limiting L-arginine availability for NO synthesis. Decreased NO production because of elevated levels of endogenous nitric oxide synthase (NOS) inhibitors, especially asymmetric dimethylarginine (ADMA) and reduced L-arginine, have been documented in SCD especially during VOE.^{42–46} Reduced plasma arginine levels and elevated ADMA levels also result in NOS coupling causing production of reactive oxygen species rather than NO.^{47,48} Chronic hemolysis with release of plasma free Hb results in scavenging of NO with consequent endothelial dysfunction, which may favor sickle cell adherence.^{49,50}

Abnormal Cell Adhesiveness

Seminal work by several groups showed that sickle red cells adhere to stimulated endothelium unlike their normal counterparts.^{51,52} Newly released red cells, called *reticulocytes*, express high levels of adhesion molecules, integrin $\alpha_4\beta_1$, and CD36, and are more adherent than dense sickle red cells.^{53,54} Increased endothelial reticulocyte adhesion as compared to dense red cell adhesion is thought to be secondary to deformable red cells adhering to the endothelium behind which the dense red cells are trapped, leading to microvascular occlusion.²⁹ Other molecules involved in sickle red cell-endothelium interactions include vascular

Figure 49-6. Electron micrograph of negatively stained fiber of HgS and the structure deduced by three-dimensional image reconstruction. The reconstructed fiber is presented as ball models, with each ball representing a HgS tetramer. The models are presented as the outer sheath (*left*), the inner core (*center*), and a combination of both inner and outer filaments (*right*). (Reproduced with permission from the University of Texas Medical Branch.)

cell adhesion molecule (VCAM)-1, integrin $\alpha_v\beta_3$, P-selectin, P-selectin glycoprotein ligand (PSGL)-1, E-selectin, Lutheran blood group antigen, and thrombospondin.⁵⁵⁻⁶⁰ The site of adhesion is purported to be the postcapillary venule at which site sickle red cells appear to interact with white cells adherent to the endothelium rather than engaging the endothelium directly.³¹

Neutrophilia is an adverse prognostic factor in sickle cell anemia. Because of their larger size, adherent leukocytes cause a greater decrease in vessel caliber than red cells. Diapedesis occurs in postcapillary venules, a site of vasoocclusion in sickle cell anemia.^{31,61-63} Neutrophil integrin $\alpha_M\beta_2$ microdomains capture sickle red cells causing vascular occlusion in sickle cell mouse models. Monocytes are also highly activated in sickle cell anemia, and they promote increased endothelial activation by increased production of tumor necrosis factor (TNF)- α and interleukin (IL)-1 β .⁶⁰ Expression of leukocyte adhesion molecules, L-selectin, and integrin $\alpha_M\beta_2$, are associated with a severe clinical phenotype.^{61,64}

Inflammation and Chronic Vasculopathy

Sickle cell anemia is characterized by chronic leukocytosis, abnormal activation of neutrophils and monocytes, and an increase in several proinflammatory mediators including TNF- α , IL-6, and IL-1 β . Several

adhesion molecules are upregulated, including VCAM, selectins, integrins, the acute phase reactants C-reactive protein, secretory phospholipase A₂ (sPLA₂), and coagulation factors are activated.⁶⁴⁻⁷⁶ Placental growth factor (PIGF) released from erythrocytes activates monocytes to produce inflammatory cytokines and upregulates endothelin-1 signaling via the endothelin B receptor. Endothelin-1 is a potent vasoconstrictor and upregulation is associated with adverse outcomes in SCD. Placental growth factor has independently been shown to be correlated with disease severity as well.^{77,78} Hemin has been demonstrated to activate PIGF in mice via the erythroid Kruppel-like factor; consequently, PIGF may play an important role in the pathophysiology of iron overload as well.⁷⁹ It is an open question whether inflammation is caused by abnormally adhesive red cells to the vascular endothelium or whether inflammation causes abnormal red cell adhesiveness. It is likely both occur, given that red cell adhesiveness incites endothelial activity, and infection-induced inflammation precipitates clinically significant vascular events in patients.

The vascular beds in sickle cell anemia display changes akin to atherosclerotic vascular disease: large vessel intimal hyperplasia and smooth muscle proliferation.^{80,81} However, the characteristic lipid laden plaques of atherosclerotic vascular disease are not present.⁶⁴

Ischemia–Reperfusion Injury

Akin to other disease states, such as myocardial infarction, resolution of vasoocclusion results in reperfusion injury characterized by increased oxygen free radical formation via activation of xanthine oxidase, generation of oxidant stress, lipid peroxidation, upregulation of cellular adhesion molecules, and nuclear factor- κ B, a key player in the inflammatory process.^{64,82,83} iNKT cells propagate the inflammatory cascade in ischemia reperfusion injury and are increased and activated in patients with SCD. Agonists to adenosine 2A receptor (A_{2A}R) on iNKT cells downregulate their activation and attenuate inflammation in mouse models of SCD.⁸⁴

Activation of the Coagulation System

The initiator of coagulation, tissue factor (TF), is elevated in patients with sickle cell anemia.^{40,74,85-87} Microparticles (MPs) expressing TF derived from monocytes, macrophages, neutrophils and endothelial cells have been described in SCD.^{58,68,74,88} Conflicting results exist in the literature on the presence and contribution of TF bearing MPs. There is a lack of correlation between TF bearing MPs and procoagulant activity in SCD. Erythrocyte and platelet MPs are TF-negative and are the major component of MPs in SCD. Activation of the intrinsic pathway of coagulation by TF-negative, red cell, and platelet MPs through a phosphatidylserine-dependent mechanism appears to be the major contributor of MP-dependent coagulation activation in SCD. Perivascular TF interaction with plasma coagulation factors made possible by increased vascular permeability and phosphatidylserine exposure on the surface of red cells secondary to repeated cycles of sickling provide an impetus for the coagulation process.⁸⁹ Heightened thrombin generation, platelet activation, and decreased protein C and S levels favor a procoagulant state.^{69,90,91} Increased plasma levels of D-dimers, thrombin–antithrombin complexes, prothrombin fragment 1.2, and plasmin–antiplasmin complexes are indicative of increased thrombin-mediated coagulation with subsequent fibrinolysis.⁹² Plasma from sickle cell patients contains increased ultralarge von Willebrand factor multimers as a result of increased endothelial cell secretion and impaired cleavage by ADAMTS13 (a disintegrin and metalloprotease with a thrombospondin type 1 motif member 13).⁹³

Adenosine Signaling

Cellular stress leads to the degradation of adenine nucleotides, resulting in the generation of adenosine. Adenosine homeostasis is maintained

by two enzymes: adenosine kinase, which phosphorylates adenosine to adenosine monophosphate and adenosine deaminase, which converts adenosine to inosine. Adenosine signals through four different receptors that have differing functions. Signaling via the $A_{2A}R$ expressed on most leukocyte and platelets results in an antiinflammatory effect; however, signaling via the $A_{2B}R$ was shown to cause priapism in SCD mice via hypoxia-inducible factor (HIF)-1-mediated decrease of phosphodiesterase 5. Signaling via $A_{2B}R$ also leads to increased 2,3-BPG in red cells causing decreased oxygen binding affinity of Hb, which promotes sickling. Pegylated adenosine deaminase treatment of sickle mice resulted in decreased hemolysis and hypoxia reoxygenation injury.^{94,95}

SICKLE CELL TRAIT

Inheritance of only one HbS allele is termed *sickle cell trait* (HbAS). An estimated 300 million people carry the trait worldwide.⁹⁶ The percentage of HbA is always higher (~60 percent) than HbS (~40 percent) in sickle cell trait.

HbAS is considered a generally asymptomatic state with HbA in the cell preventing sickling except in the most unusual circumstances. HbAS cells sickle at O_2 tension of approximately 15 torr.⁹⁷

Plasma myeloperoxidase and red cell sickling have been reported to increase during exercise with fluid restriction in HbAS subjects.⁹⁸ Plasma levels of VCAM-1 are higher in HbAS subjects and remain elevated following exercise compared to normal controls or HbAS with concomitant α -thalassemia, which is suggestive of subtle microcirculatory dysfunction in this population.⁹⁹ Skeletal muscle capillary structures are different in HbAS subjects compared to controls. There is a 30-fold increased risk of sudden death in black army recruits with HbAS.¹⁰⁰ Although controversial, in 2009 the National Collegiate Athletic Association recommended mandatory testing for HbAS for all its student athletes.¹⁰¹

Renal abnormalities are among the most common manifestations of HbAS. Anoxia, hyperosmolarity, and low pH of the renal medulla predisposes to sickling. Microscopic or gross hematuria from renal papillary necrosis is usually painless. Renal neoplasm or stones should be excluded in those with persistent gross hematuria. Isosthenuria may be seen in and may contribute to exercise induced rhabdomyolysis and sudden death.¹⁰² Renal medullary carcinoma is a rare but serious complication of HbAS. Risk of urinary tract infection is higher in females with HbAS, especially during pregnancy. End-stage renal disease occurs at an earlier age for HbAS patients with polycystic kidney disease and HbAS may contribute to erythropoietin resistance.¹⁰³

Splenic infarction occurs under extreme environmental conditions in persons with HbAS; most resolve spontaneously.^{104,105} Caution and immediate intervention is also warranted in those HbAS individuals who develop traumatic hyphema.¹⁰⁶ The risk of venous thromboembolism is increased twofold in HbAS subjects compared to those without the trait. The risk appears to be greater for pulmonary embolism than for deep vein thrombosis.^{101,105} HbAS patients do not have increased perioperative morbidity or mortality. The life span of patients with HbAS is normal.¹⁰⁷

LABORATORY FEATURES

Sickle cell anemia is characterized by a laboratory profile of evidence of hemolytic anemia with increases in lactate dehydrogenase (LDH), indirect bilirubin, reticulocyte count, and a decrease in serum haptoglobin. Anemia is usually normochromic, normocytic with a steady-state Hb level between 5 and 11 g/dL.^{1,108} The red cell density is increased with a normal mean cell Hb concentration (MCHC).¹⁰⁹ Serum erythropoietin level is decreased relative to the degree of anemia.¹¹⁰ Elevated neutrophil and platelet levels are observed even in asymptomatic patients reflective of persistent low-grade inflammation.^{111–113}

Plasma tocopherol and zinc levels are low.^{114–116} Serum ferritin is increased, especially in iron overloaded patients. Elevated brain natriuretic peptide is seen in patients with pulmonary hypertension (PH) and congestive heart failure. Morphologically, classic sickle red cells are seen on blood film examination, and the marrow shows erythroid hyperplasia.

Sickle cell anemia can be accurately diagnosed with high-performance liquid chromatography (HPLC) and isoelectric focusing.¹¹⁷ Rapid methods, such as solubility testing and sickling of red cells using sodium metabisulfite, are less-reliable tests.¹¹⁸ Polymerase chain reaction is the method of choice for prenatal diagnosis.¹¹⁹ No HbA is found in patients with HbSS, HbSC, or HbS β^0 diseases. Varying amounts of HbA (depending on the severity of the β -thalassemia mutation) are found in HbS- β^+ -thalassemia subjects.

COURSE AND PROGNOSIS

Mortality from SCD in the United States has declined since 1968, coinciding with the introduction of pneumococcal polyvalent conjugate 7 (PVC7) vaccine. Comparison of mortality rates between 1979 to 1998 and 1999 to 2009 showed a 61 percent decrease in infants, 67 percent in children ages 1 to 4 years, and 35 percent decrease in children ages 5 to 19 years. Transition from pediatric to adult medical care showed an increased mortality trend with similar rises in rates during the decades of comparison.¹²⁰ Average life expectancy of patients with HbSS disease in the United States is 42 and 48 years for males and females, respectively.¹²¹ In Jamaica, the population has a median survival of 53 years and 58 years for men and women, respectively, with 44 percent of individuals born prior to 1943 still living as of 2009.¹²² As the sickle cell population ages, causes of death change from an infectious etiology to those related to end-organ damage, such as renal failure.

CLINICAL FEATURES AND MANAGEMENT

The reader is referred to the National Institutes of Health, National Heart, Lung and Blood Institute's guidelines from 2002 for an extensive review on the topic; revised guidelines were released in the fall of 2014 at <http://www.nhlbi.nih.gov/health-pro/guidelines/sickle-cell-disease-guidelines/>.¹²³ General approaches to SCD management and pain management are described separately (Table 49–2).

Sickle Cell Crises

The typical course for a sickle cell patient is that of periods of relatively normal functioning despite chronic anemia and ongoing vasoocclusion, punctuated by periods of increased pain, and serial changes in various laboratory parameters that is termed "a sickle cell crisis." Crises have typically been classified as VOs, aplastic crises, sequestration crises, and hyperhemolytic crises.

Vasoocclusive Crises The hallmark of SCD is the VOE. It is the most common clinical manifestation but occurs with varying frequency in different individuals. It results from increasing vasoocclusion causing tissue hypoxia, which manifests as pain. Vasoocclusion may affect any tissue, but patients typically have pain in the chest, lower back, and extremities. Abdominal pain may mimic acute abdomen from other causes. Different patients display different patterns of painful sites during a VOE, but each patient's recurrences usually mimic the same pattern of pain. Fever is often present, even in the absence of infection. Episodes may be precipitated by dehydration, infection, and cold weather although in about most cases no precipitating factor is found.¹²⁴

Figure 49–7 illustrates the phases of VOs.¹²⁵ Crises requiring readmission within 1 week occur in approximately 20 percent of patients after hospital discharge.¹²⁵

TABLE 49–2. Pathophysiologic Mechanisms and Potential Therapeutic Targets in Sickle Cell Disease

Pathophysiology/Complication	Therapeutic Interventions
Sickle hemoglobin (HbS) polymerization	Fetal hemoglobin (HbF) induction
Cellular dehydration	Gardos channel inhibition Potassium-chloride cotransport channel inhibition
Adhesion to endothelium	
Red blood cell	Antiselectin Antiintegrin
White blood cell	Antiselectin Intravenous immunoglobulin Hydroxyurea (HU)
Inflammation	Nuclear factor- κ B inhibition Immunomodulatory drugs HU Statins
Nitric oxide (NO) scavenging	NO donor (NO, HU, tetrahydrobiopterin) Phosphodiesterase 5 inhibition Modulation of hemolysis
Coagulation	Tissue factor inhibition Antiplatelet therapy Anticoagulation
Hyposplenism/infection	Penicillin prophylaxis
Ischemia–reperfusion	Xanthine oxidase inhibition Myeloperoxidase inhibition
Iron overload	Chelation

The characterization of crisis phases has implications for clinical research, especially in pain management, wherein interventions early in the course of a crisis could result in better outcomes for patients.

Aplastic Crises Aplastic crises in sickle cell anemia result when there is a marked reduction in red cell production in the face of ongoing hemolysis, causing an acute, severe drop in Hb level. The characteristic laboratory finding is a reticulocyte count less than 1 percent. The most common causative agent is parvovirus B19, which attaches to the P antigen receptor on erythroid progenitor cells, causing a temporary arrest in red cell production (Chap. 36). Recurrent aplastic crises by parvovirus B19 are rare because of the development of protective antibodies. Other rare complications associated with parvovirus B19 include acute splenic and/or hepatic sequestration, acute chest syndrome, marrow necrosis, and renal dysfunction. Patients usually recover within 2 weeks; however, those with severe symptomatic anemia need red cell transfusion. Siblings of SCD patients with parvovirus infections should be monitored closely for aplastic crisis given high secondary attack rates (>50 percent). Patients need to be isolated from pregnant individuals given increased risk of hydrops fetalis with parvovirus B19 infection.¹²⁶

Sequestration Crises This type of crisis is characterized by sudden, massive pooling of red cells, typically in the spleen and less

commonly in the liver.¹²⁷ Splenic sequestration is typically seen in children (younger than 5 years of age) prior to autoinfarction of the spleen, but can be seen in adults with HbSC disease or HbS- β -thalassemia with persisting splenomegaly.^{128–130} A minor sequestration episode is usually accompanied by a Hb of more than 7 g/dL, and a major episode usually is one in which the Hb is less than 7 g/dL or the Hb has decreased by 3 g/dL from baseline.¹³¹

Acute splenic and hepatic sequestration crises can present with rapidly enlarging spleen or liver, pain, hypoxemia, and hypovolemic shock. Treatment consists of red cell transfusion. Transfusion carries the risk of hyperviscosity when the sequestration crisis resolves and the sequestered red cells are returned to the general circulation. Splenic sequestration crisis has a high rate of recurrence, especially in children. Splenectomy to prevent recurrence is debated in very young children. Some report chronic red cell exchange transfusion as a means of delaying splenectomy until the child is older while others did not see any benefit to this treatment. Patients younger than 2 years of age can be placed on chronic transfusion until they are older, at which time splenectomy should be considered. Splenectomy is recommended after the first episode of life-threatening splenic sequestration crisis or chronic hypersplenism. Partial splenectomy and emergency splenectomy during a crisis is not recommended. Parental education is important for early recognition of the problem so they can seek medical care promptly.¹²⁶

Hyperhemolytic Crisis The term *hyperhemolytic crisis* is used to describe the occurrence of episodes of accelerated rates of hemolysis characterized by decreased blood Hb, increasing reticulocytes, and other markers of hemolysis (hyperbilirubinemia, increased LDH). Hyperhemolysis can occur during resolution of a VOE, at which time irreversibly sickled and dense red cells are rapidly destroyed, as well as from an acute or delayed hemolytic transfusion reactions.^{126,132}

Pain Control

Patients with SCD have acute pain, chronic pain, or both. As a symptom, pain is often underrated in its intensity and undertreated by caregivers, especially inexperienced physicians. Patients are often perceived as drug-seekers or drug addicts, when in fact less than 10 percent of patients are addicted, a number comparable to other disease states. Unsatisfactory relief of pain drives patients to behaviors that appear to healthcare givers as signs of addiction—a state termed *pseudoaddiction*. A study comparing sickle cell anemia patients who use the emergency department frequently or infrequently found significant impairment in quality of life and increased markers of disease severity in those who use the emergency department frequently, dispelling the myth that frequent emergency department use indicates narcotic-addicted individuals when, in fact, they may have more severe disease.^{3,133–137} The landmark *Pain in Sickle Cell Epidemiology Study* revealed that adult SCD patients have pain at home approximately 55 percent of the time, which contrasts sharply to pain studies in children, who report at-home pain approximately 9 percent of the time.^{138,139}

Acute pain is managed with opioids, nonsteroidal antiinflammatory drugs, acetaminophen, or a combination of these medications. Immediate pain assessment and frequent reassessment with appropriate application of medications until pain relief is obtained is important. For adults and children weighing more than 50 kg, morphine can be started at a dose of 0.1 to 0.15 mg/kg. The hydromorphone dose should be 0.015 to 0.020 mg/kg intravenously. These are recommended doses for opioid-naïve patients and are at the lower end of the dosing range.^{123,140,141} The use of meperidine has declined because of neurologic side effects, especially in patients with renal failure, who are at risk for the serotonin syndrome in conjunction with use of other medications.^{142–144} However, the use of morphine is not benign and concerns of increased association of acute chest syndrome, dysphoria, and neuroexcitatory

Figure 49-7. A typical profile of the events that develop during the evolution of a severe sickle cell painful crisis in an adult in the absence of overt infection or other complications. Such events are usually treated in the hospital with an average stay of 9 to 11 days. Pain becomes most severe by day 3 of the crisis and starts decreasing by day 6 or 7. The Roman numerals refer to the phase of the crisis: I indicates prodromal phase; II, initial phase; III, established phase; and IV, resolving phase. Dots on the x-axis indicate the time when changes became apparent; and dots on the y-axis, the relative value of change compared with the steady state indicated by the horizontal dashed line. Arrows indicate the time when certain clinical signs and symptoms may become apparent. Values shown are those reported at least twice by different investigators; values that were anecdotal, unconfirmed, or that were not reported to occur on a specific day of the crisis are not shown. CPK, creatinine phosphokinase; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; HDW, hemoglobin distribution width; ISC, irreversibly sickled cells; LDH, lactate dehydrogenase; RBC DI, red cell deformability index; RDW, red cell distribution width; SAA, serum amyloid A. (Reproduced with permission from SK Ballas, K Gupta, P Adams-Graves: *Sickle cell pain: A critical reappraisal*. Blood 120(18):3647–3656, 2012.)

side effects have been raised.¹²⁵ Prior use of opioid therapy should be taken into consideration when deciding initial opioid doses as patients may be tolerant and require higher doses. Caution should be exercised with nonsteroidal antiinflammatory drugs and acetaminophen if there is renal or hepatic dysfunction. Patients with acute pain are better managed in a setting dedicated to sickle cell patients.¹⁴⁵ A multidisciplinary approach is needed for pain management, especially if chronic pain is present.^{146,147} Opioid side effects should be anticipated and managed. Antidepressants, anticonvulsants, and clonidine can be used for neuropathic pain. Occasionally, severe, unrelenting pain may require red cell transfusion to decrease sickle Hb below 30 percent in the blood.¹⁴⁸

There is a paucity of data regarding optimal management of pain in SCD. A randomized trial of optimizing patient controlled analgesia strategy was closed because of poor accrual.¹⁴⁹ A trial looking at NO inhalation for treatment of VOE did not show improvement in pain.¹⁵⁰

Pulmonary Manifestations

Acute Chest Syndrome The acute chest syndrome (ACS) is a constellation of signs and symptoms in patients with SCD that includes a new infiltrate on chest radiograph defined by alveolar consolidation

but not atelectasis, chest pain, fever, tachypnea, wheezing, or cough, and hypoxia (Fig. 49-8).¹⁵¹ However, respiratory findings on clinical examination in the absence of radiographic findings should trigger high suspicion for ACS and warrants close monitoring. ACS is the leading cause of mortality in patients with SCD.¹²¹ Etiology varies depending on age, with viral and bacterial infections dominating in the pediatric age group and fat embolization resulting from marrow necrosis during VOE dominating in adults.^{152,153} Important pathogens include *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, *Streptococcus pneumoniae*, *Staphylococcus aureus*, parvovirus B19, respiratory syncytial virus, and influenza. Regardless of the triggering factor, the pathogenesis of ACS involves increased intrapulmonary sickling, intrapulmonary inflammation with increased microvascular permeability, and alveolar consolidation. ACS can rapidly evolve with bilateral infiltrates and consolidation leading to acute respiratory failure requiring intubation and ventilatory assistance.

Independent risk factors for respiratory failure are age older than 20 years, platelet count less than $20 \times 10^9/L$, multilobar lung involvement, and a history of cardiac disease.¹⁵² Thrombocytopenia is an independent predictor of neurologic complications during hospitalization

Figure 49–8. Anteroposterior view of chest radiograph depicting bilateral, patchy, lung infiltrates in a 30-year-old female with sickle cell disease and evolving acute chest syndrome.

for ACS, which was seen in 22 percent of adult patients in the National Acute Chest Syndrome study.¹⁵⁴

The treatment of ACS includes oxygenation, incentive spirometry, adequate pain control to avoid chest splinting, antimicrobial therapy that always covers atypical bacteria and influenza when indicated, avoidance of overhydration, use of bronchodilators, and red cell transfusion to decrease intrapulmonary sickling.^{152,155–160} The use of glucocorticoids may attenuate the course of ACS; however, its use is not well established and readmission rates for VOE after ACS resolution are increased.¹⁵³ sPLA₂ has been recognized as a predictor of ACS; however, a clinical trial investigating early transfusion based on sPLA₂ elevation closed because of poor accrual. Hydroxyurea therapy should be offered to all patients with a history of ACS because it reduces the incidence by 50 percent in adults and 73 percent in children.¹⁶¹

Pulmonary Hypertension PH, defined by a resting mean pulmonary arterial pressure of 25 torr or higher on right-heart catheterization, is seen in 6 to 11 percent of SCD patients. An elevated tricuspid regurgitant velocity of 2.5 m/s has a positive predictive value of 25 percent for PH in SCD and is seen in one-third of these patients. PH, as defined by right-heart catheterization, elevated tricuspid regurgitant jet velocity of 2.5 m/s or higher, and a serum N-terminal pro-brain natriuretic peptide (NT-pro-BNP) level of 160 pg/mL or higher, confers an increased mortality risk.¹⁶²

Abnormalities in NO metabolism, hemolysis, and inflammation contribute to the pathophysiology of PH.¹⁶² Parenchymal lung disease from repeated episodes of ACS and thromboembolism are other causal factors.

Clinical symptoms of PH include fatigue, dizziness, and dyspnea on exertion, chest pain, and syncope. These may be unrecognized as being related to PH, as PH is often undiagnosed in patients with SCD.

PH should be treated following guidelines set for the treatment of primary PH unrelated to SCD. Two trials looking at bosentan (endothelin receptor antagonist) in SCD patients closed because of sponsor withdrawal. A trial of sildenafil was halted early because of increased incidence of VOE. Patients who have venous thromboembolism in the setting of PH should be considered for indefinite anticoagulation.

Hydroxyurea should be offered to all patients with any of the risk factors for increased mortality described above.¹⁶²

Asthma, Abnormal Pulmonary Function Tests, and Airway Hyperreactivity. Asthma is a common comorbidity with higher-than-average prevalence in patients with SCD and is associated with increased risk of ACS, VOE, stroke, and mortality. Airway hyperreactivity as evidenced by a positive bronchodilator response on pulmonary function testing, irrespective of baseline function, and in response to cold air or methacholine challenge, is seen in approximately two-thirds of SCD patients. Inflammation, hypoxemia, and increased oxidative stress associated with asthma may contribute to the vasculopathy of SCD.¹⁶³

Pulmonary function tests collected as part of the Cooperative Study of Sickle Cell Disease (CSSCD) revealed abnormalities in 90 percent of the 310 patients, with the majority having restrictive lung disease.

Asthma treatment follows general treatment guidelines as in the non-SCD populations.^{164,165}

Cardiac Manifestations

Anemia in SCD results in an elevated cardiac output secondary to an increased stroke volume with minimal increase in heart rate.^{166,167} Clinical manifestations of a hyperdynamic circulation include a forceful precordial apical impulse, systolic and diastolic flow murmurs, and tachycardia that may increase during periods of increased hemodynamic stress. Diastolic left ventricular dysfunction may begin in early childhood and is an independent risk factor for death, with even greater risk of mortality in those having PH. Left ventricular hypertrophy is common and progressive with age; left ventricular dysfunction is a late event. Myocardial infarction is an underrecognized problem in SCD. Epicardial coronary artery disease is rare; microvascular ischemia is likely causative. Sudden cardiac death has been reported in 40 percent of patients in an autopsy series.^{168–170} Previously sudden cardiac death was ascribed to narcotic overdose; currently, it is thought to be secondary to cardiopulmonary causes in the majority of cases. QTc prolongation, atrial and ventricular arrhythmias, nonspecific ST-T wave changes are common in SCD patients. Patients presenting with chest pain should have a thorough evaluation to rule out cardiac disease. Cardiac magnetic resonance may be a good modality to image microvascular flow and quantitate cardiac iron overload.^{171,172} Blood pressure in patients with SCD is significantly lower than age-, sex-, and race-matched controls, partly secondary to anemia.¹⁷³ Relative hypertension is associated with end-organ damage. Diuretics may be used, keeping in mind that SCD patients have obligate hyposthenuria and are prone to dehydration, which can precipitate a VOE.

Central Nervous System

Originally thought to be a small vessel disease, stroke in SCD is a macrovascular phenomenon with devastating consequences that affects approximately 11 percent of patients younger than 20 years of age.^{174,175} Risk is highest in the first decade of life followed by a second smaller peak after age 29 years. Ischemic stroke is most common in children and older adults, whereas hemorrhagic stroke predominates in the third decade of life.¹⁷⁵ Recurrent stroke is most common in the first 2 years following the primary event.¹⁷⁶ Silent infarcts, defined as an increased T2 signal abnormality on magnetic resonance imaging (MRI), begins in infancy and has a cumulative incidence of 37 percent by age 14 years. They occur in watershed areas of the brain, are not predicted by abnormal transcranial Doppler (TCD) velocity, and may progress despite chronic transfusion.^{177–180} There is evidence of neurocognitive decline in asymptomatic adults despite having normal brain imaging that is attributed to anemia and hypoxemia.¹⁵⁴

Cerebral blood flow is significantly increased in SCD because of chronic anemia and hypoxemia, but does not increase further in

response to increased hypoxic stress, thereby predisposing to ischemia.^{181,182} Stenosis of large vessels, especially of the circle of Willis, without the classic atherosclerotic plaque occurs in conjunction with a multitude of other factors, including chronic hemolysis, deranged NO metabolism and impaired vascular autoregulation, and can lead to stroke.¹⁸² Rare causes of cerebral vascular disease include fat embolization and venous sinus thrombosis. Moyamoya type fragile collaterals have been reported in more than one-fifth of patients with prior stroke, possibly leading to hemorrhagic stroke in later life.^{183–188}

Risk factors for ischemic stroke include transient ischemic attack, recent or recurrent ACS, nocturnal hypoxemia, silent infarcts, hypertension, elevated lactic dehydrogenase, and leukocytosis, whereas anemia, neutrophilia, the use of glucocorticoids, and recent transfusion are independent risk factors for hemorrhagic stroke, especially in children.^{175,189–195} Sickle cell genotypes other than HbSS carry a lower risk, as do patients with HbS- α -thalassemia.^{175,196,197} The best predictor of stroke risk, however, is an increased blood flow velocity in major intracranial arteries on TCD ultrasonography.¹⁹⁷ Blood flow velocities less than 170 cm/s are considered normal. Velocities between 170 and 200 cm/s are termed *conditional*, and velocities of greater than 200 cm/s are considered high and are associated with a 10-fold increase in ischemic stroke in children 2 to 16 years of age.

There is an increased frequency of stroke among siblings of patients with SCD than would be expected by chance alone, raising the possibility of other modifier genes contributing to stroke risk.¹⁸³ The TNF (-308) G/A promoter polymorphism is associated with increased large-vessel stroke risk as is the IL-4-receptor gene 503 S/P variant, although it did not reach statistical significance. The clinical features of stroke in SCD encompass the classic findings of stroke in other disorders, including, but not limited to, hemiparesis, seizures, coma, paresthesias, headaches, and cranial nerve palsies. Neurocognitive deficits in IQ, memory, language, and executive function have been demonstrated.^{154,198}

Imaging approaches for acute stroke are the same as those for non-SCD patients and includes MRI and magnetic resonance angiography.

Prevention of Primary Stroke Based on the results from the Stroke Prevention in Sickle Cell Disease (STOP) Study, it is recommended that asymptomatic children with HbSS disease older than two years of age should be screened for stroke risk using TCD.¹⁹⁷ Those with high TCD velocities should be offered a chronic red cell transfusion program for primary stroke prevention. Repeat TCD screenings should be done every 3 to 12 months even in patients who have normal or conditional baseline velocities, because they can evolve into a higher-risk category. Despite obstacles to TCD screening, clinical practice changes based on the STOP study translated into declining stroke rates since 1991.^{199,200}

Prevention of Secondary Stroke Patients with SCD who present with a stroke and are not on chronic transfusion should be placed on a transfusion program to prevent secondary strokes. Exchange transfusion may be preferable to periodic red cell transfusion, not only to avoid iron overload, but also to further reduce stroke risk. In a retrospective study, children who received periodic transfusion had a five-fold higher relative risk of a recurrent stroke compared to those on an exchange transfusion regimen.²⁰¹ Despite chronic transfusions, patients may have a recurrent stroke, especially in patients with HbS greater than 30 percent.²⁰² Hydroxyurea was shown to decrease high and conditional TCD velocities in more than 90 percent of patients studied.²⁰³ However, a randomized trial comparing transfusions with iron chelation to hydroxyurea with phlebotomy showed a 10 percent stroke rate in the hydroxyurea arm, thus establishing transfusion as the preferred preventive strategy.²⁰⁴

Anticoagulation therapy has not been studied in patients with SCD and, therefore, no recommendations can be made. Treatment guidelines

for intracranial hemorrhage are as those for non-SCD-related intracranial hemorrhage; role of transfusion is less clear in SCD especially when cause of intracranial hemorrhage is unclear. Patients with moyamoya disease who have a particularly poor outcome may benefit from revascularization using encephaloduroarteriosyngiosis.^{205,206}

Genitourinary Systems

Renal Failure Sickling of HbSS erythrocytes in the hypoxic, acidic, and hypertonic environment of the renal medulla, oxidative stress, increase in prostaglandins and endothelin-1 in the kidney, and abnormalities of the renin angiotensin system contribute to the pathophysiology of renal disease in SCD.²⁰⁷ The incidence of renal failure varies between 4 and 20 percent.^{208–211} Dehydration is the most common cause of acute renal failure in SCD. Isosthenuria is highly prevalent in SCD, may increase the risk of dehydration, and is irreversible.²¹² Glomerular hypertrophy, focal and segmental glomerular sclerosis, and hemosiderin deposition in proximal renal tubular epithelium have been described; however, no single lesion is pathognomonic of sickle cell nephropathy. Cystatin C is an accurate marker of glomerular filtration and therefore is preferable to serum creatinine in estimating renal function.^{213,214} Glomerular hyperfiltration, microalbuminuria, and macroalbuminuria occur sequentially in SCD patients starting in infancy and increasing in frequency with age.^{122,161,215} Incidence of microalbuminuria is greater than 60 percent in those over age 35 years.²¹³ End-stage renal disease requiring dialysis carries a poor prognosis and is associated with a median survival of 4 years.²¹⁶

Angiotensin-converting enzyme inhibitors decrease proteinuria and hyperfiltration in SCD; however, large-scale studies are needed to characterize the magnitude of the benefit. Treatment of renal disease follows principles used for non-SCD kidney pathology and includes effective blood pressure control, avoidance of nephrotoxic agents, and treatment of urinary tract infection. A relative decrease in serum erythropoietin levels, proportionate to the degree of anemia is observed; however, erythropoietin treatment, with its resultant increase in Hb may cause an increase in VOEs because of an increase in blood viscosity.²¹³

Renal tubular acidosis type IV, secondary to decreased potassium and hydrogen ion in the distal tubule can cause disproportionate acidosis and hyperkalemia in patients with declining renal function.²¹³

Hematuria is discussed in the section on sickle cell trait.

Priapism Priapism is prevalent in at least 35 percent of male patients with SCD with devastating psychological consequences; true prevalence may be higher as it is often underreported.^{217–219} The mean age of episodes is 15 years and two-thirds of patients have “stuttering priapism” a term used for episodes that last less than 3 hours.²²⁰ Derangements in NO metabolism and adenosine signaling are thought to be the major contributors to priapism in SCD.⁹⁴ Greater than 95 percent of priapism is the “low-flow” type resulting from ischemia, is painful, and is a medical emergency.²²¹

Aspiration of the corpus cavernosa followed by epinephrine injections, exchange transfusion, and α and β agonists have all been used, but data regarding efficacy are sparse. α -Agonists, etilefrine 50 mg, and ephedrine 15 to 30 mg per day, seem to reduce the incidence of stuttering priapism.²²² Hormonal therapies, including antiandrogens and luteinizing hormone-releasing hormone, reduce nocturnal erections but are associated with loss of libido.²²¹ Transfusion therapy has resulted in neurologic sequelae termed “the ASPEN syndrome” (Association of Sickle Cell Disease, Priapism, Exchange Transfusion) and is thought to be secondary to hyperviscosity; care, therefore, must be taken not to increase the hematocrit beyond 30 percent.²²³ In recalcitrant cases, a shunt is performed but results in permanent impotence.²²² A penile prosthesis is used to ameliorate sexual dysfunction.

Nocturnal Enuresis Nocturnal enuresis is prevalent in 25 to 33 percent of the pediatric sickle cell population, which is higher compared

to that of age-matched controls.^{224–226} It tends to decrease with age but is still prevalent in adults. Social and environmental factors, decreased functional bladder capacity, and decreased arousal during sleep appear to be contributing factors.

Musculoskeletal System

VOE is commonly manifested by marrow infarction causing musculoskeletal pain, swelling at involved sites, fever, and leukocytosis. Marrow hypercellularity is thought to predispose to this phenomenon by causing a decrease in local blood flow and oxygenation.

Dactylitis Dactylitis is a painful swelling of digits of the hands and feet (“hand-foot syndrome”). It occurs early in infancy as hematopoietic marrow is still present in these bones at this age. Most episodes resolve within in 2 weeks.^{227–230} Epiphyseal infarction can result in joint pain and swelling mimicking septic arthritis. Use of hydroxyurea in the BABY HUG trial resulted in significant reduction of rate of dactylitis.¹⁶¹

Osteomyelitis, Septic Arthritis, and Bone Infarction Impaired cellular and humoral immunity together with infarction of bone contribute to this complication with an estimated prevalence of 12 percent. Atypical serotypes of *Salmonella*, *S. aureus*, and Gram-negative bacilli are the principal infectious offenders. No single lab or imaging test reliably differentiates osteomyelitis from infarction.^{227,229,231–235} Culture results may be nondiagnostic as patients usually receive antibiotics on presentation with fever; therefore, the presence of leukocytes in bone and joint aspirates should evoke a high suspicion for osteomyelitis.¹²⁶ Septic arthritis tends to occur in joints involved with avascular necrosis, also seen following hip arthroplasty. Multiple joints may be involved. An elevated C-reactive protein should raise suspicion for septic arthritis and prompt intervention with appropriate antibiotics as needed to prevent joint deterioration and collapse.²²⁷ Vertebral body infarctions with subsequent collapse causes the classic “fish mouth” appearance of vertebrae on radiographs of the spine.

Osteopenia and Osteoporosis Osteopenia and osteoporosis are prevalent (30 to 80 percent) in patients with sickle cell anemia, with a predilection for the lumbar spine. Presence of avascular necrosis with local bone remodeling may lead to false-negative results on a bone mineral density test at the femoral neck.¹²⁶ Fractures of the long bones are commonly underdiagnosed and self-reported rates of fractures in young adults with SCD are high. Etiology of osteoporosis is multifactorial with hypogonadism, hypothyroidism, nutritional deficiencies, and iron overload interfering with osteoblast function being the major causes.^{126,236–238} More than 50 percent of patients are vitamin D deficient with the majority (>80 percent) having less-than-optimal levels. High doses of vitamin D supplementation have resulted in improvement in chronic pain and higher levels of physical activity.²³⁹

Avascular Necrosis Vasoocclusion resulting in infarction of articular surfaces of long bone occurs most commonly in the femur followed by the humerus. It was previously thought to occur with increased frequency in HbSC disease as opposed to patients with HbSS. However, with increased longevity of HbSS patients, its prevalence is greater in patients with HbSS.^{240–242} As per the CSSCD estimates, 50 percent of patients by age 33 years will have avascular necrosis of the femoral head (Fig. 49–9). The presence of concurrent deletional α -thalassemia ($-\alpha^{3-7}$) and a history of frequent VOEs are classic risk factors for avascular necrosis. Other risk factors include male gender, higher Hb concentration, low fetal Hb, and vitamin D deficiency.^{126,243,244} Polymorphisms in *BMP6*, *ANNEXIN A₂*, and *KLOTHO* genes are associated with avascular necrosis.²⁴⁵

Patients present with chronic joint pain with progressive decrease in range of motion of affected joints. Multiple joints are commonly involved.²⁴⁶ The vast majority of untreated patients will progress to femoral head collapse within 5 years.^{247,248}

Figure 49–9. Avascular necrosis of the right hip in a 31-year-old female with sickle cell disease depicting a patchy lucency and sclerosis and irregular contour of the femoral head and loss of the joint space.

Avascular necrosis has been treated with a number of modalities including core decompression, osteotomy, bone grafting, surface arthroplasty, and joint replacement. Two randomized trials in avascular necrosis compared core decompression and physical therapy versus physical therapy alone and did not show a difference in outcome between the two arms; however, followup was short, a significant number of stage III hip joints were included in one study, and sample size was limited.²⁴⁹ In our experience, core decompression is a useful option in early stage avascular necrosis. Several studies associate total hip replacement in SCD with a higher rate of orthopedic and medical complications. However, other studies show a lower rate of orthopedic complications. Structural bone diseases in SCD make joint replacement challenging.^{250–252} Hydroxyurea and chronic transfusion therapy have not been shown to reduce the risk of avascular necrosis.²⁴³

Leg Ulcers

Leg ulcers occur in 2 to 40 percent of cases with SCD and varies geographically with the highest rate being reported in Jamaica.^{1,253} In the United States, leg ulcers are seen in 4 to 6 percent of patients with SCD and are most common in patients older than 10 years of age.²⁵⁴ They occur on the lower extremities, especially on the malleoli, and cause chronic pain and disability. Venous stasis is a predisposing factor while coinheritance of α -thalassemia appears to have a protective effect. The relationship between hydroxyurea use and increased occurrence of leg ulcers is controversial.²⁵⁵ Polymorphisms in *KLOTHO*, *TEK*, and several other genes in the transforming growth factor (TGF)- β and bone morphogenic protein (BMP) pathways are associated with leg ulcers.²⁴⁵ Once established, ulcers are recalcitrant and significantly impair quality of life.²⁵⁶

Treatment of leg ulcers is largely empiric. Leg elevation, bed rest when practical and feasible, wet-to-dry dressings, gentle debridement, Unna boots, and treatment of infection and topical or systemic antibiotics are commonly used. The peptide encoding integrin-interaction site of many extracellular matrix proteins (RGD peptide) enhanced healing of the ulcers in preliminary studies, but, unfortunately, it never came to

clinical practice because of nonmedical reasons.²⁵⁷ Increases in HbF and transfusions occasionally hasten healing of leg ulcers.²⁵⁸

Hepatobiliary Complications

Chronic liver abnormalities in SCD are frequent and of different etiologies that include vasoocclusion, transfusional iron overload, pigmented gallstones with bile duct obstruction, acute or chronic cholecystitis, viral hepatitis, and cholestasis.^{259,260} Common clinical manifestations include right upper quadrant pain, fever, hepatomegaly, nausea, and vomiting. Bilirubin levels from chronic hemolysis are usually not above 6 mg/dL, with a majority of it being the indirect fraction.²⁶¹ Because some degree of aspartate transaminase elevation is seen with hemolysis, alanine transaminase elevation is a more accurate marker of liver injury.

Vasoocclusion involving the hepatic sinusoids was seen in 39 percent of patients in one study, while previous reports of vasoocclusion involving the liver, termed *acute sickle hepatic crisis*, has been reported in 10 percent of patients. The differing prevalence is the result of varying criteria used to include biochemical and clinical abnormalities.²⁶² Acute hepatic sequestration crisis characterized by a rapidly enlarging, tender liver and hypovolemia is akin to splenic sequestration but much rarer. It requires prompt treatment with red cell transfusion. Severe intrahepatic cholestasis with serum bilirubin levels as high as 100 mg/dL is a catastrophic situation needing exchange transfusion for resolution; synthetic liver function is lost as characterized by low serum albumin and coagulation protein abnormalities; renal impairment may occur. A more benign form of cholestasis has been described, which resolves with conservative measure.^{263–268}

Chronic hemolysis results in an increased burden on the heme catabolic pathway leading to increased unconjugated bilirubin and formation of pigmented gallstones. The incidence of gallstones increases with age, with a reported prevalence of 50 percent at 22 years of age.^{269–271} The number of uridine diphosphate (UDP) glucuronosyltransferase 1 family (UGT1A1) promoter (TA) repeats (the polymorphism associated with Gilbert syndrome) is strongly associated with increased incidence of gallstones and bilirubin levels while coinherited α -thalassemia (Chap. 48) decreases bilirubin levels in patients with SCD.²⁷² Laparoscopic cholecystectomy is recommended in symptomatic patients with cholelithiasis. The treatment of asymptomatic patients with positive findings on abdominal ultrasonography is more controversial. In the Jamaican cohort study, only 7 percent of patients with positive ultrasonograms had symptoms suggestive of biliary tract disease and needed a cholecystectomy. However, patients in the United States appear to be more symptomatic, with the majority of gallbladders removed after only a positive ultrasonogram have pathologic evidence of cholecystitis.²⁶⁹ Asymptomatic patients with negative screening ultrasonograms should be observed; however, timing and frequency of screening has not been standardized.

Ophthalmic Complications

The microvasculature of the retina with relative hypoxemia facilitates “sickling” akin to several other vascular beds. Microcirculatory obstruction occurs followed by neovascularization and arteriovenous aneurysms. Hemorrhage, scarring, and retinal detachment leading to blindness are the sequelae. Changes occur at the periphery, thereby sparing central vision at earlier stages. The term *sickle cell retinopathy* encompasses nonproliferative and proliferative changes.

Nonproliferative changes include “salmon-patch” hemorrhages, peripheral retinal lesions termed “black sunbursts,” and iridescent spots, whereas neovascularization is characteristic of proliferative changes, giving a pattern of vascular lesions resembling a marine invertebrate and is termed as “sea fans.”²⁷³

Increased levels of plasma and intraocular vascular endothelial growth factor have been documented in proliferative sickle cell

retinopathy, as have angiopoietin-1 and -2 and von Willebrand factor. Pigment epithelium derived factor, an angiogenesis inhibitor, is increased as well, especially in nonviable “sea fans.”^{274–276}

Proliferative sickle cell retinopathy may differ from other proliferative retinopathies in that spontaneous regression of neovascularization can occur in up to 60 percent of cases.^{277,278} The Jamaican cohort study reported an annual incidence of 0.5 cases per 100 HbSS subjects versus 2.5 cases per 100 HbSC subjects. Prevalence was greater in HbSC subjects as well, with a 43 percent rate in the third decade versus 14 percent for those with HbSS. However, there was a 32 percent incidence of spontaneous regression. Irreversible visual loss occurred only in 2 percent of HbSC subjects up to 26 years of age observed at time of the study.²⁷⁷

Central retinal artery occlusion is rare in HbSS disease.²⁷⁹ Conjunctival vascularity is decreased in SCD patients compared to controls with further decreased vascularity and decreased conjunctival red cell velocities during vasoocclusion.^{280–283}

An orbital compression syndrome characterized by fever, headache, orbital swelling, and visual impairment secondary to optic nerve dysfunction can occur in SCD. Orbital marrow infarction is a common cause.²⁸⁴

All patients with sickle hemoglobinopathies should have a yearly ophthalmology examination beginning in childhood. The examination should be carried out by an ophthalmologist and should include slit-lamp examination of the anterior chamber and detailed retinal visualization including a fluorescein angiography in addition to visual acuity.

The evaluation and treatment of proliferative sickle retinopathy is complicated by the fact that spontaneous regression may occur. Laser photocoagulation remains the most commonly performed procedure for this finding. Traumatic hyphema needs urgent optical referral because increased sickle red cells can cause obstruction of outflow channels, resulting in acute glaucoma. This vascular obstruction may cause decrease in retinal and optic nerve perfusion causing further visual problems. Unresolved vitreous hemorrhage and retinal detachment may need surgical intervention. Exchange transfusion to keep HbA at more than 50 percent is recommended. Central retinal artery occlusion needs urgent exchange transfusion and an ophthalmology consultation.^{277,285–287} Orbital compression syndrome is treated with glucocorticoids with the addition of antibiotics if concomitant infection cannot be ruled out.¹²⁶

Splenic Complications

Functional asplenia defined as impaired mononuclear phagocyte system functions in the spleen occurs in 86 percent of infants with SCD.²⁸⁸ It is defined by the presence of Howell-Jolly bodies and absence of ^{99m}Tc (99m-technetium) splenic uptake, even in the presence of a palpable spleen. Slow blood flow in the red pulp of the spleen sets the stage for increased red cell sickling. Repeated splenic infarctions lead to “autosplenectomy.” As a consequence, patients are prone to microbial infections, especially with encapsulated microorganisms such as *S. pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*. Hypertransfusion early in childhood, prior to age 7 years, may lead to reversal of functional asplenia. Marrow transplantation and hydroxyurea have resulted in reversal of functional asplenia in some older subjects. Splenic sequestration occurs in young children.^{289–293}

Management during Pregnancy

Differing morbidity and mortality rates have been reported in pregnant women with SCD, some of which is attributed to geographic location and access to healthcare. Although the CSSCD data showed low rates of pregnancy loss and mortality, other studies have shown an increased mortality of 10 to 100 orders of magnitude greater as compared to non-SCD patients.^{285–290} Preterm delivery occurs in 30 to 50 percent of SCD

patients and two-thirds will have infants with birth weights less than the 50th percentile.^{294,295} There is an increased frequency of VOs reported during pregnancy. In a study looking at pregnancy outcomes in SCD patients compared to non-SCD patients with comorbidities, patients with SCD displayed a significantly increased incidence of venous thromboembolism (VTE), nonhemorrhagic obstetric shock (defined as pulmonary thromboembolism, amniotic fluid embolism, acute uterine inversion, and sepsis), and infection, despite being significantly younger.^{296,297} Other studies have shown similar findings, especially the fivefold increased risk of VTE in this population.^{295,297,298}

Given increased risk of preeclampsia and eclampsia, patients should have close monitoring of blood pressure and proteinuria after 20 weeks of gestation. Fetal nonstress and umbilical artery Doppler studies should be undertaken after 28 weeks to identify patients who might benefit from early delivery. Studies examining prophylactic red cell transfusions in pregnancy have shown mixed results. Patients should be transfused to a Hb concentration of less than 6 g/dL, because abnormal fetal oxygenation and death have been reported below this Hb level in non-SCD populations. Otherwise, patients should be transfused based on guidelines for the nonpregnant patient with SCD.²⁹⁴ Based on data from animal models and small reports of spontaneous abortion or fetal death, the use of hydroxyurea is not recommended during pregnancy and breastfeeding.^{299,300} Hydroxyurea may decrease spermatogenesis and therefore male patients may need to stop the drug temporarily when their partners are trying to conceive. Narcotics administered for relief of pain have not been shown to cause fetal harm, but babies of mothers exposed to narcotics during pregnancy should be monitored for the neonatal abstinence syndrome.²⁹⁴

Despite increased concern for VTE, given insufficient data, contraception advice is similar as for women without SCD.³⁰¹

Management of and Prevention of Infection

Patients with SCD are predisposed to infections for a variety of reasons, including functional asplenia and defective neutrophil responses.^{302–306} The magnitude of this problem was highlighted in 1971 in a landmark paper by E. Barrett-Connor.³⁰⁶ Functional asplenia results in susceptibility to encapsulated microorganisms, particularly to *S. pneumoniae*, especially in children younger than 5 years of age. The CSSCD data reported an eight-per-100-patient-years rate of invasive bacterial infection in children younger than 3 years of age.³⁰⁷

Given the high incidence of infection, especially in childhood, infection prevention and rapid diagnosis of established infections is of paramount importance.^{308,309} The pneumococcal vaccine (PCV7) can be administered in infancy with effective immunologic response prior to 2 years of age; the American Academy of Pediatrics recommends it be administered at ages 2, 4, 6, 8, and 12 to 15 months. The PCV7 vaccine decreases invasive pneumococcal disease by as much as 80 to 90 percent.³¹⁰ The pneumococcal polysaccharide vaccine, PPV23, covers more serotypes but is not immunogenic prior to 24 months and response lasts for 3 years. The first dose is recommended at 24 months with additional doses 3 to 5 years later.^{309,311–314} Nonvaccine covered strains of *S. pneumoniae* are emerging as important pathogens; therefore, prompt referral of patients with suspected infection to a healthcare facility is important.³¹⁵

Oral penicillin prophylaxis is recommended at a dose of 125 mg twice a day for children between 0 and 3 years of age and at 250 mg twice a day for children between 3 and 5 years of age.³¹⁶ Penicillin prophylaxis beyond 5 years is recommended only for patients with recurrent pneumococcal infections or who have had surgical splenectomy. Patients allergic to penicillin are offered erythromycin.

The meningococcal vaccine covers most invasive isolates of *N. meningitidis* and is recommended by the American Academy of Pediatrics.³¹⁷ Standard pediatric immunizations protecting against

H. influenzae and hepatitis B virus should be given. Influenza virus vaccine should be given annually because viral respiratory infection favors invasive bacterial infection.

Parents and caregivers of children should be educated to recognize infections and to seek medical attention early. Diagnosis of established infections varies by site and offending agent. For invasive pneumococcal disease, ceftriaxone remains the drug of choice despite concerns of immune-mediated hemolysis. Infections seen classically in SCD patients include salmonella osteomyelitis and pneumonia caused by atypical bacteria like *Chlamydia* and *M. pneumoniae*, which need to be treated with the appropriate antibiotics.

The spectrum of infectious complications in adults may be different. One study reported data on blood infections in adults.³⁰² Pneumococcal infections were rare. *S. aureus* was the predominant organism. Patients with *S. aureus* had a predilection for bone-joint infection. Those with indwelling venous catheters and a severe disease course appeared to have a high risk for bloodstream infections.

Although the sickle trait confers resistance to malaria, protection is not complete and severe disease and deaths from malaria have been reported in SCD patients. Malaria chemoprophylaxis is recommended for all patients living in or traveling to endemic regions.^{318,319}

Management during Anesthesia and Surgery

Patients with SCD should have careful monitoring of Hb concentration, hydration, oxygen, and metabolic studies in the perioperative period. Acute chest syndrome and VOE occur with higher frequency in the perioperative period. Increased age is associated with increased complications.^{320–322} Transfusion to keep Hb levels approximately 10 g/dL is recommended. Although a prior randomized trial showed no benefit in decreasing SCD-related complications between patients transfused aggressively to a mean HbS of less than 30 percent versus those transfused to a total Hb of 10 g/dL with mean HbS percent of 59, more recent data show reduction in clinically important events, especially serious complications, in the preoperative transfused group prior to low and moderate risk surgery.^{202,323} Care should be taken to avoid transfusion-induced hyperviscosity.

MODIFIERS OF DISEASE SEVERITY

Some patients have a mild course with few problems related to SCD, and survive into the sixth or seventh decade. In contrast, some patients have a difficult course with multiple complications, frequent hospitalizations, severe organ damage, and a significantly shortened life expectancy.^{324,325} Inheritance of α -thalassemia trait and a high HbF are two factors that ameliorate many complications of SCD. Genome-wide association studies revealed three major loci associated with HbF levels: The β -globin locus on chromosome 11, an intergenic region between *HBSIL* and *MYB* genes on chromosome 6, and the *BCL11* gene on chromosome 2.³²⁶ Repression of *BCL11A* results in increased γ -globin gene expression and, consequently, in increased HbF. The exact mechanism of how *BCL11A* silences γ -globin expression is unclear; its expression seems to be controlled by an erythroid specific transcription factor, *KLF1* with decreased expression of *BCL11A* upon knockdown of *KLF1* gene transcript.^{326,327}

Inheritance of α -thalassemia and HbF level do not account for all of the clinical diversity of SCD. The completion of the human genome project has provided the impetus to study polymorphisms in candidate genes as potential modifiers of disease severity. Association of polymorphisms in candidate genes and different features of SCD such as stroke,^{328–330} ACS,³³¹ bilirubin levels and cholelithiasis,^{332–335} avascular necrosis,²⁴⁵ priapism,³³⁶ and leg ulcers,²⁵³ as well as HbF levels,^{337–342} and HbF response to hydroxyurea,³⁴³ have been studied in different groups of patients.

Polymorphisms in the TGF- β -BMP pathway, a ubiquitous signaling pathway that is involved in many cellular processes and pathways, have emerged as recurrent findings in many of these studies. Some of the associations have functional consequences; the association of bilirubin levels in polymorphisms in the *UGT1A1* gene promoter is such an example. The 7TA repeat in the promoter leads to a decreased activity of this enzyme and hence a decrease in glucuronidation of bilirubin. Thus, the association of this polymorphism with higher bilirubin levels can be understood. On the other hand, the mechanisms by which polymorphisms in the ubiquitous TGF- β -BMP pathway are associated with various complications of SCD are unknown, and thus a causal relationship cannot yet be established. Functional studies of these variants and genomewide association studies are expected to provide a better insight into genetic modulation of the phenotype of SCD.

GENERAL MANAGEMENT OF SICKLE CELL DISEASE

Pharmacotherapeutics to Increase Fetal Hemoglobin Levels

The observation that HbF results in ameliorating the phenotype of SCD led to research focused on HbF modulation as a therapy for SCD. The γ -chains of HbF are excluded from the deoxy HbS polymer; thus the presence of HbF in sickle red cells exerts a potent antisickling effect. This effect has also been supported by clinical observations; the manifestations of SCD do not become apparent in the first few months of life until the switch from γ -chain production to β -chain production is almost complete in the postnatal period. Additionally, the phenotypes of some compound heterozygous states with HbS and other inherited globin disorders that lead to increased expression of HbF in the adult life ($\delta\beta$ -thalassemias, hereditary persistence of HbF) are very mild (Chap. 47). In fact, compound heterozygotes for HbS and deletional hereditary persistence of HbF, in which there is continued high levels of HbF expression (30 to 35 percent) uniformly distributed in all red cells (pancellular), are clinically asymptomatic and hematologically normal. In the late 1970s, further evidence in support of the ameliorating effect of high HbF came from the observation of Saudi Arabian sickle cell anemia patients who had few, if any, symptoms of SCD, had mild anemia, and were not diagnosed until adult age.³⁴⁴ These individuals had HbF levels in the 20 to 25 percent range as opposed to the African patients or American patients of African descent, the majority of whom had HbF levels of approximately 5 percent. Similar patients were reported from India, and this genetic propensity for high HbF production in SCD patients was linked to a unique β -globin gene cluster haplotype (Saudi Arabian-Indian) that is distinct from those found in Africa. These observations paved the way for intense investigations on the cellular and molecular mechanisms of the fetal to adult (γ to β) switch during the perinatal period and the search for “antiswitching” agents, agents that would facilitate retaining elevated HbF levels. The observation that there is a transient increase in HbF production during recovery from marrow aplasia or suppression provided the rationale for the use of myelosuppressive agents as *antiswitching* therapy (Table 49-3). Antiswitching indicates a mechanism to prevent the switch from γ -globin chains to β -globin chains.

Hydroxyurea Although many myelosuppressive agents have been studied in primates and some have been used in a small number of patients, only one of these, hydroxyurea, has been used, starting in the early 1980s, in large-scale clinical trials. This is largely attributable to its excellent oral bioavailability, relatively short half-life (important from the standpoint of rapid reversibility of toxicity), no evidence that its use leads to an increase in cancer prevalence, and few side effects.

Hydroxyurea is the only FDA-approved agent for the treatment of SCD. It is a ribonucleotide reductase inhibitor and is S-phase specific

TABLE 49-3. Antiswitching Therapies

Drug	Mechanism
Hydroxyurea	Myelosuppression Antiinflammatory Nitric oxide donor Increased cyclic guanosine monophosphate
Decitabine	DNA methyltransferase 1 inhibition, i.e., hypomethylation
5'-Azacitidine	DNA methyltransferase 1 inhibition, i.e., hypomethylation
Butyrate derivatives	Histone deacetylase inhibition
Histone deacetylase inhibitors	Histone deacetylase inhibition
Immunomodulatory drugs	P38 mitogen-activated protein kinase pathway

in the cell cycle. The mechanism by which hydroxyurea increases HbF synthesis is not fully understood; it has been postulated that the myelosuppressive effect leads to the recruitment of early erythroid progenitors that have retained their fetal (γ) globin synthesis capability, giving rise to the production of red cells with a higher HbF content. Some studies show that hydroxyurea acts as a NO donor and increases HbF synthesis via the cyclic guanosine monophosphate (cGMP) pathway.³⁴⁵ Others suggest it works by reducing the neutrophil count, thereby reducing the contributions of neutrophils to the abnormal vascular adhesion of sickle red cells. It has several other actions that explain its efficacy in SCD other than increasing HbF. These include decrease in platelets and reticulocytes, improvement in red cell hydration, and a decrease in red cell adhesiveness to the vascular endothelium (Fig. 49-10).³⁴⁶⁻³⁴⁸

In the landmark Multicenter Study of Hydroxyurea, hydroxyurea was shown to decrease frequency of painful crises, ACS, hospitalizations, and blood transfusions. Followup showed a 40 percent decrease in mortality in patients randomized to the drug.^{160,349} Hydroxyurea is recommended in patients with three or more VOEs or history of ACS. It can be started at a dose of 15 mg/kg given as a single daily dose and escalated by 5 mg/kg per day every 8 weeks until toxicity or a maximum dose of 35 mg/kg is reached. *Maximum tolerated dose* is defined as the dose that targets an absolute neutrophil count of 2 to 4 $\times 10^9/L$ and absolute reticulocyte count 100 to 200 $\times 10^9/L$.^{350,351} Periodic monitoring of blood cell counts and serum chemistries, especially in the first year of treatment is important. Maximal effect on HbF may not be seen until 6 to 12 months of therapy is completed. The dose should be decreased in renal failure. Although not proven to have teratogenic or leukemogenic potential in SCD patients, it is recommended that it not be used in pregnant or breastfeeding patients. Concerns about detrimental effect on spermatogenesis have also been raised based on studies in mice.³⁵²⁻³⁵⁵

Patients receiving hydroxyurea who die while on treatment are likely to be older when therapy is initiated, more anemic, likely to have Bantu or Cameron β -globin gene haplotypes, and have impaired renal function.³²⁴

Several studies have now been published on the use of hydroxyurea in infants and children. Therapy can begin between 6 and 9 months of age, is safe and well tolerated with improved growth rates, preserves organ function, and the additional benefits as seen in adults.^{161,351,356,357}

Other Fetal Hemoglobin-Inducing Agents Although significant advances have been made in understanding the basic mechanism(s) of the perinatal switch from γ - to β -globin synthesis, this knowledge is

Figure 49-10. Blood film from SCD patients: effect of hydroxyurea therapy. **A.** Blood film before therapy. Note frequent sickled cells. **B.** Marked decrease in sickle cells with therapy. (Reproduced with permission from Dr. Scott Drury and Dr. Elizabeth Manaloor, Department of Pathology, Medical College of Georgia.)

far from complete. Certain epigenetic mechanisms (histone deacetylation and DNA methylation) are involved in the silencing of the γ -globin genes postnatally. This has led to the use of agents that target the two common epigenetic silencing mechanisms: histone deacetylase inhibitors and DNA methyltransferase 1 inhibitors.

The histone deacetylase inhibitors that have been most widely used in early phase small clinical trials in SCD and in some patients with β -thalassemia are butyrate derivatives (arginine butyrate, sodium phenyl butyrate, isobutyramide). Arginine butyrate has to be administered by IV infusion; earlier studies suggested that continuous daily infusions of arginine butyrate were not very effective in leading to a sustained increase in HbF.²⁵⁸ Later, it was shown that daily continuous infusion induced tachyphylaxis and hence the failure to cause a sustained HbF response. An intermittent schedule of administration (4 days, given every 4 weeks) was efficacious in increasing HbF.³⁵⁸ Although orally administered sodium phenyl butyrate was effective in increasing HbF, the daily doses required for maintaining a HbF response required the administration of a large number of tablets and was impractical.³⁵⁹ A phase II trial studying the efficacy of oral 2,2-dimethylbutyrate sodium salt (HQB1001) did not show significant increase in HbF and was associated with a trend for increased VOE.³⁶⁰

The two DNA methyltransferase inhibitors with antiswitching activity are 5'-azacytidine and decitabine. Both of these agents are myelosuppressive when used in higher doses; however, at low doses, they are potent inhibitors of DNA methyltransferase 1 and have been shown to increase HbF synthesis in baboons and in patients with SCD.³⁶¹⁻³⁶⁸ Unlike 5'-azacytidine, which incorporates into both DNA and RNA, decitabine incorporates only in DNA and is believed to have a better genotoxicity profile. It has been effective in increasing HbF and ameliorating the disease severity in patients with SCD who have been refractory to hydroxyurea.³⁶³

Immunomodulatory agents (thalidomide and derivatives) increase HbF synthesis in erythroid colonies from SCD patients.³⁶⁹ Pomalidomide augments HbF in sickle cell mice.³⁷⁰ Data from use in sickle cell patients is awaited. The finding that the KLF-1-BCL11a axis is the major factor in the switch from β - to γ -globin has made these factors attractive targets for therapy; however, to date, no effective means of targeting these transcription factors has been developed.

Allogeneic Hematopoietic Stem Cell Transplantation

Because SCD is an inherited defect in the hematopoietic stem cell, stem cell transplantation (SCT) is an attractive option to permanently cure the disease rather than managing its sequelae piecemeal. However, the

tremendous phenotypic variability that characterizes the disorder combined with lack of an accurate predictive model to foretell which patients are likely to have a catastrophic disease course, make selecting patients for allogeneic hematopoietic stem cell transplantation (AHSCT) challenging. AHSCT should be done in patients who are likely to have a severe disease course, but should be instituted early, prior to end-organ damage. The risk-to-benefit ratio of the morbidity and mortality associated with AHSCT has to be weighed against the disease severity of a nonmalignant hematologic disorder.

AHSCT is an underused treatment modality in SCD even in eligible patients secondary to lack of donor availability and socioeconomic factors.³⁷¹ Human leukocyte antigen (HLA)-matched sibling donor transplant with myeloablative conditioning represents the most common transplant type in SCD. Cerebrovascular disease, recurrent ACS, and frequent VOEs despite adequate hydroxyurea therapy are the most common indications for SCT. Data from approximately 1200 patients worldwide show an overall survival of 95 percent; early or late allograft failure resulting in disease recurrence occurs in 10 to 15 percent of patients.^{371,372} The most common myeloablative regimen used is busulfan, cyclophosphamide, and antithymocyte globulin; the addition of antithymocyte globulin resulted in a significant reduction in allograft rejection. Transplant-related mortality ranges between 2 and 8 percent.³⁷² Acute graft-versus-host disease occurs in approximately 10 to 15 percent of patients, whereas chronic graft-versus-host disease has been reported in 12 to 20 percent of patients. Most series have used cyclosporine alone or in combination with methotrexate for graft-versus-host disease prophylaxis (Chap. 21).

Risk of increased incidence of neurologic complications following transplantation has been ameliorated with the use of prophylactic anti-convulsants, strict control of arterial hypertension, correction of hypomagnesemia, and maintenance of Hb greater than 10 g/dL and platelets greater than $50 \times 10^9/L$. Long-term toxicity still remains a concern, especially in relation to growth, reproduction, and secondary malignancies. Followup data on AHSCT in children between 1991 and 2000 show significant gonadal toxicity and infertility, especially in females.³⁷³

AHSCT in adults is problematic given toxicity of the conditioning regimen. In an attempt to address this issue, reduced-intensity conditioning has been used but has resulted in an increased rate of graft failure. A small cohort of patients who received blood stem cells from HLA-matched siblings and used low-dose total-body radiation plus alemtuzumab as the conditioning regimen followed by sirolimus for graft-versus-host disease prophylaxis had stable engraftment at 30 months of followup.³⁷⁴

Cord blood and HLA haploidentical transplantation have been used in a small number of patients with SCD, but graft failure remains a significant issue.^{371,375,376}

Transfusion

Red cell transfusions are used frequently in SCD on an acute or chronic basis. The rationale for transfusion in SCD is twofold. Besides increasing Hb concentration, thereby increasing the oxygen-carrying capacity of the blood, transfusion also decreases the percentage of circulating HbS-containing red cells. Hb level alone should not constitute an indication to transfusion as patients adapt to their level, making it important to know the patient's baseline Hb concentration. It is also important to calculate whether the reticulocyte count, a measure of marrow red cell production, is adequate or not.

Indications for red cell transfusion include symptomatic anemia, ACS, stroke, aplastic and sequestration crises, other major organ damage secondary to vasoocclusion, and occurrence of unrelenting priapism. Transfusion is also required prior to major surgery or surgery involving critical organs. The best-established indication for chronic transfusion is stroke and an abnormal TCD velocity. Patients with other chronic or recurrent events are sometimes placed on chronic transfusion as well. Inappropriate indications for transfusion include chronic steady-state anemia, uncomplicated VOE, pregnancy, minor surgeries, infection, and avascular necrosis.³⁷⁷

Simple red cell or exchange transfusion can be used.³⁷⁸ Simple transfusion is easier to perform and is generally associated with fewer complications. Exchange transfusion, however, has the advantage of not raising total Hb, and thereby blood viscosity, while decreasing percentage of circulating sickle cells because sickle cell patients transport less oxygen to their tissues beyond a hematocrit of 30 percent as a result of increased blood viscosity.^{379–381} Exchange transfusion has also the advantage of not causing iron overload.

Alloimmunization occurs in 20 to 50 percent of transfused SCD patients.^{382–384} In the United States, the majority of blood donors are of European descent, and the majority of SCD patients are of African descent (Chaps. 136 and 138). This results in blood group antigenic disparity, and antibodies to E, C, K, Jkb, S, and Fyb antigens are common. Age at first transfusion, total number of transfusions, transfusion in the context of inflammation, and influence of immunoregulatory genes may affect the rate and extent of alloimmunization.³⁸⁴ Extended antigen phenotyping (Kell, Duffy, Kidd, Lewis, Lutheran, P, and M&S) in addition to the usual ABO and D antigens (Chaps. 136 and 138) and leukodepletion of blood products are recommended.^{378,382,384,385} Delayed hemolytic transfusion reaction complicates 4 to 11 percent³⁸⁶ of transfusions in SCD and may present as a painful crises. It typically occurs a week after transfusion and is caused by alloantibodies to non-ABO antigens. It can cause the Hb to fall lower than the prior pretransfusion Hb and can be associated with a depressed reticulocyte count and autoantibodies. Alloantibody mediated hemolysis will present as a rapid decrease in the percent of HbA as opposed to HbS. A failure to demonstrate a new alloantibody posttransfusion should not exclude the diagnosis of delayed hemolytic transfusion reaction (Chaps. 136 and 138). Patients should be transfused only if symptomatic under such circumstances as further transfusion can exacerbate the problem.^{377,384}

Iron overload and its attendant complications and infection transmission are the other major complications of transfusion.

Iron Overload

Iron overload (Chap. 43) in SCD is similar to other chronically transfused populations.^{169,387,388} The multicenter study of the iron overload research group showed that transfused sickle cell patients had increased

morbidity and mortality when compared to transfused thalassemic patients and nontransfused SCD patients.³⁸⁹

Diagnosing significant iron overload accurately and early can be difficult. Serum ferritin is an easy, widely employed method, but is unreliable in SCD as it is an acute phase reactant. Its measurement can result in over- or underestimation and is poorly correlated to liver iron content.³⁹⁰ A serum ferritin value of greater than 1000 mg/mL in the steady-state has been used as an indication of iron overload. Liver iron content is the current accepted standard and a value of 7.7 mg/g dry weight is used as indication for treatment.³⁹¹ However, noninvasive methods of assessment of iron overload, like superconducting quantum interference device (SQUID) or MRI T2* (Chap. 43), are becoming standard. Transfusion of 120 mL of red blood cells/kg of body weight can also be used as a chelation trigger.³⁸²

Iron chelation (Chap. 43) was typically carried out with desferrioxamine at a dose of 25 to 40 mg/kg per day given over 8 hours subcutaneously.³⁹² Desferrioxamine can reverse cardiac iron overload. A once-daily oral iron chelator, deferasirox, is now approved and available for use in the United States. It is a tridentate ligand that binds iron with a high affinity in a 2:1 ratio. It has a half-life of 8 to 16 hours and is metabolized by glucuronidation and excreted in the feces. In an open-label phase II trial of deferasirox versus desferrioxamine in a 2:1 randomization, safety and tolerability were established. Nausea and vomiting, abdominal pain, rash, reversible increase in liver function tests, and stable increases in serum creatinine were reported. Rare cases of anaphylaxis occurring mostly in the first month of starting treatment have also been reported. Postmarketing reports suggest an increased incidence of renal failure, and caution is to be exercised in a patient population where renal insufficiency may not be readily appreciated prior to starting treatment. Postmarketing experience has also reported cases of fatal hepatotoxicity and agranulocytosis. Auditory and ophthalmic side effects occur in less than 1 percent of patients; however, annual eye and auditory examinations are recommended for deferasirox as they are for desferrioxamine. The recommended daily dose is 20 mg/kg body weight; this dose may be adjusted every 3 to 5 months in increments of 5 to 10 mg/kg if the therapeutic goal is not achieved, although the total dose should not exceed 40 mg/kg. Safety in combination with other iron chelators has not been established.³⁹³ Deferiprone is not available in the United States but has been used in other parts of the world. It is orally administered and is considered a better chelator of cardiac iron because of its ability to cross cell membranes.³⁹⁴ Although iron chelation in SCD follows the general guidelines of iron chelation in other iron overloaded populations, rigorous studies of its effects on morbidity and mortality in SCD are lacking.^{394,395}

Evolving Therapies

Given the complex pathophysiology of SCD, numerous therapies targeting different pathways have been tried to ameliorate disease manifestations. Many drugs have failed to show efficacy, especially in phase II/III trials, because of failure to choose appropriate end points or because they were too narrowly focused. Table 49–4 is a comprehensive list of trials and their outcomes. A few of the novel and promising studies are with immunomodulatory agents (thalidomide/pomalidomide), E- and P-selectin inhibitors, iNKT agonists, and Aes-103, and all are in trials as of this writing.

OTHER ABNORMAL HEMOGLOBINS

The number of Hb variants discovered to the time of writing this chapter totals 1187. The vast majority of these variants are benign, without any significant clinical or hematologic problems, but are of interest to geneticists and biochemists (<http://globin.cse.psu.edu>). Most of the

TABLE 49–4. Novel Therapies for Sickle Cell Disease

Drug	Mechanism of Action	Pathway Targeted in SCD	Trial Phase/Type	Number Enrolled	Outcomes	Ref.
GMI1070	E-selectin inhibitor	Abnormal cell adhesiveness	I	15	Decrease in coagulation, leukocyte, and endothelial cell activation	412
Aes-103	Allosteric modifier of Hb	RBC sickling, membrane stabilization under shear stress	I/IIa	18	Decrease in pain and markers of RBC sickling	
Regadenoson	iNKT A ₂ A receptor agonist	Inflammation	I	27	Safety demonstrated; iNKT cells inhibited	413,414
Omega-3 fatty acid	Reduction in oxidative injury	Abnormal cell adhesiveness	RCT	140	Decreased VOE, anemia, and blood transfusion in supplemented group	415
Arginine	Increased NO production	NO signaling	RCT	38	Decreased parenteral opioids use and pain scores	416
Magnesium sulfate	Increased cellular hydration	Cellular dehydration	RCT	106	No difference on LOS, pain scores, or analgesia use	417
Prasugrel	P2Y ₁₂ ADP receptor antagonist	Platelet activation	II	62	Pain rate and intensity decreased in intervention; platelet activation biomarkers decreased	418
Eptifibatide	Platelet $\alpha_{IIb}\beta_3$ inhibitor	Platelet activation	RCT	13	Safe but no difference in VOE resolution	419
Senicapoc	Gardos channel inhibitor	Cellular dehydration	III	144	Increased hemoglobin and hematocrit and decreased erythrocytes and reticulocytes	420
Poloxamer 188	Amphipathic copolymer	Tissue oxygenation	III	255	Safe and well tolerated and demonstrated crisis resolution in a percentage of patients (greater in children than adults)	421
TRF-1101	P-selectin inhibitor	Abnormal cell adhesiveness	II	5	Safe and increased microvascular blood flow	422

ADP, adenosine diphosphate; Hb, hemoglobin; iNKT, invariant natural killer T cell; LOS, length of stay; NO, nitric oxide; RBC, red blood cell; RCT, randomized controlled trial; SCD, sickle cell disease; VOE, vasoocclusive episode.

Hb variants are missense mutations in the globin genes (α , β , γ , or δ) resulting from single nucleotide substitutions. Other uncommon mechanisms include deletion or insertion of one or more nucleotides altering the reading frame and fusion of globin genes with deletion of intergenic DNA sequences ($\gamma\beta$ fusion in Hb_{Kenya} and $\delta\beta$ fusion in Hb_{Lepore}), mutations of the termination codon leading to the production of elongated globin chains.

Hb variants that significantly alter the structure, stability, synthesis, or function of the molecule have hematologic and/or clinical consequences. These can be classified in certain categories (Table 49–5). HbS and HbC are two examples of mutations on the surface of the Hb molecule that alter both the charge and the physical/chemical properties of the molecule with polymer formation in the case of deoxyhemoglobin S and crystallization in HbC with profound effects on the function, morphology, rheology, and life span of the red cells. Several mechanisms account for the pathogenesis of unstable Hb variants. The common mechanism involves the precipitation of the unstable Hb molecule within the red cell with attachment to the inner layer of the red cell membrane (“Heinz body” formation); red cells containing

membrane-attached Heinz bodies (see Chap. 31, Fig. 31–11) have impaired deformability and filterability leading to their premature destruction (congenital Heinz body hemolytic anemia). Mutations in certain residues alter the oxygen affinity of the Hb molecule; a stabilization of the R (relaxed, oxy) state will result in high O₂ affinity variants and erythrocytosis. Conversely, a stabilization of the T (tense, deoxy) configuration will result in a variant with low O₂ affinity with enhanced unloading of O₂ to the tissues with resultant cyanosis and anemia in certain cases (because of the suppression of the O₂ sensing pathway) (Chaps. 32 and 50). Mutations of the heme binding site, particularly those affecting the conserved proximal (F8) and distal (E7) histidine residues, lead to the oxidation of the iron atom in heme from ferrous (Fe²⁺) to ferric (Fe³⁺) state with resultant methemoglobinemia (M Hbs) and cyanosis (Chap. 50). A group of mutations alter both the structure and the synthetic rate of the globin chain leading to a “thalassemic” phenotype (Chap. 48). These include fusion Hbs (e.g., Hb_{Lepore}, where the 5′ δ -globin sequences are fused to 3′ β -globin sequences with deletion of the intergenic DNA; this puts the $\delta\beta$ -fusion gene under the transcriptional control of the inefficient δ -globin promoter with low expression

TABLE 49–5. Clinically Significant Hemoglobin Variants

I. Altered physical/chemical properties
A. HbS (deoxyhemoglobin S polymerization): sickle syndromes
B. HbC (crystallization): hemolytic anemia; microcytosis
II. Unstable hemoglobin variants:
A. Congenital Heinz body hemolytic anemia (N = 135)
III. Variants with altered oxygen affinity
A. High-affinity variants: erythrocytosis (N = 92)
B. Low-affinity variants: anemia, cyanosis
IV. M hemoglobins
A. Methemoglobinemia, cyanosis (N = 9)
V. Variants causing a thalassemic phenotype (N = 50)
A. β -Thalassemia
1. Hb _{Leopore} ($\delta\beta$) fusion (N = 3)
2. Aberrant RNA processing (HbE, Hb _{Knossos} , Hb _{Malay})
3. Hyperunstable globins (Hb _{Geneva} , Hb _{Westdale} , etc.)
B. α -Thalassemia
1. Chain termination mutants (Hb _{Constant Spring})
2. Hyperunstable variants (Hb _{Quong Sze})

Data from Bunn HF, Forget BG: *Hemoglobin: Molecular, Genetic, and Clinical Aspects*. Philadelphia, PA: WB Saunders; 1986.

of the fusion globin (hence the thalassemic phenotype), mutations that cause both a missense mutation and create an aberrant splice site (such as HbE, Hb_{Knossos}, and Hb_{Malay}), and “hyperunstable” globins where the nascent globin chains are highly unstable, undergo rapid proteolytic degradation, and result in a reduction in the affected globin.

Except for the commonly occurring variants (HbS, HbC, HbE, and HbD_{Los Angeles}), very few abnormal Hbs have been observed in the homozygous state. Variant Hbs are usually found in the heterozygous state. Although γ -chain variants are expressed in fetal life and their level gradually decreases as the γ -globin to β -globin (fetal to adult) switch progresses during the postnatal period, β - and α -chain variants are expressed throughout life. δ -Globin variants are expressed at very low levels and can be detected only after the switch to adult globin synthesis is complete. Because α -globin chains are present in all of the Hbs expressed after the embryonic stage (HbF- $\alpha_2\gamma_2$; HbA- $\alpha_2\beta_2$, and HbA₂- $\alpha_2\delta_2$), α -chain variants are associated with the production of variant HbF ($\alpha_2^x\gamma_2$) and HbA₂ ($\alpha_2^x\delta_2$) as well. In heterozygous states, β -chain variants constitute 40 to 50 percent of the Hb in red cells; it should, however, be kept in mind that certain factors affect the amount of variant β chains in carriers. These factors include the stability of the variant, the surface charge of the variant β -chain, and the presence of concomitant α - or β -thalassemia (Chap. 48). The more unstable the variant, the lower the quantity. Surface charge of the variant also plays a role in determining the quantity in red cells; this is because the formation of the $\alpha\beta$ -dimers ($\alpha_1\beta_1$ and $\alpha_2\beta_2$ contacts) is the critical first step in Hb tetramer formation, and this step is primarily driven by electrostatic interactions between α and β chains. The α -globin chains have a relatively positive surface charge, they interact more readily with relatively negatively charged β -globin variants to form $\alpha\beta$ dimers. This is reflected in the higher percentage of negatively charged β -globin variants such as HbN_{Baltimore} ($\beta 95\text{Lys}\rightarrow\text{Glu}$), which is found in approximately 50 percent in heterozygotes compared to β -globin variants with a positive surface charge, HbS ($\beta 6\text{Glu}\rightarrow\text{Val}$) or HbC ($\beta 6\text{Glu}\rightarrow\text{Lys}$) whose quantity in the

heterozygote is 40 to 45 percent. In the presence of α -thalassemia, negatively charged β -globin variants compete more favorably for the available α -chains; this phenomenon is reflected in even lower percentages of HbS and HbC in heterozygous carriers of these variants in the presence of common deletional forms of α -thalassemia (HbS of 30 to 35 percent in individuals with heterozygous α^+ -thalassemia, $-\alpha/\alpha$; and 25 to 30 percent in homozygous α^+ -thalassemia, $-\alpha/-\alpha$).^{396,397} Conversely, the amount of a β -globin variant will increase if there is a β -thalassemia allele in *trans*; the percentage of the variant will be inversely proportional to the output of the β -thalassemia allele; thus, the higher the variant the lower the output of the β^+ -thalassemia allele. In the case of a β^0 -thalassemia allele in *trans*, the variant will amount to greater than 90 percent or more of the Hb in red cells, with HbA₂ and HbF constituting the remainder. The quantity of α -globin variants is also variable, depending on the α -globin gene involved, and the presence of concomitant α - or β -thalassemia. Because there are normally four α -globin loci ($\alpha\alpha/\alpha\alpha$) and the upstream 5' α -globin gene (α_2) is expressed at a higher level, some of the variation in the level of α -globin variants depends on which α -globin gene carries the mutation; α_2 -globin mutations are usually present at 20 to 25 percent of the total Hb, whereas 3' downstream α_1 -globin variants are expressed at a lower level (15 to 20 percent). Concomitant α -thalassemia results in a higher level of expression of α -globin variants. Observations on the different levels of expression of the common α -globin variant, HbG_{Philadelphia} ($\alpha 68\text{Asn}\rightarrow\text{Lys}$), is a case in point.³⁹⁸ Although this variant is found in approximately 25 percent of Northern Italians, its percentages in Americans of African descent can be either 33 or approximately 50 percent. This is clearly related to the different genotypes found in these two distinct populations: In northern Italy and Sardinia, the genotype is $\alpha^c\alpha/\alpha\alpha$, with an expression level of approximately 30 percent, whereas in Americans of African descent, the HbG_{Philadelphia} mutation is commonly found on a hybrid $\alpha_2\alpha_1$ gene associated with the common 3.7 kb α^+ -thalassemia deletion ($-\alpha^c/\alpha\alpha$) with approximately 33 percent expression. When there is an α^+ -thalassemia deletion in *trans* ($-\alpha^c/-\alpha$ genotype), as expected, the level of HbG_{Philadelphia} will be approximately 50 percent. Coinheritance of α -chain variants with β -thalassemia results in the increase of the α -chain variant.

HEMOGLOBIN C DISEASE

Definition and History

HbC was the second Hb variant described after HbS.³⁹⁹ Homozygous HbC was described by Spaet and colleagues⁴⁰⁰ and Ranney and colleagues.⁴⁰¹ HbC trait is found in 2 percent of Americans of African descent, and approximately one in 6000 have homozygous HbC.⁴⁰² Coinheritance of HbC with HbS results in HbSC disease, which is the second most common form of SCD in the United States. There are also rare cases of HbC- β^+ -thalassemia and HbC- β^0 -thalassemia. HbC is thought to have originated in Central West Africa and in parts of West Africa, where the prevalence of HbC can reach 12.5 percent. The HbC gene was found on three distinct β -globin cluster haplotypes, termed CI, CII, and CIII; the most common is CI, accounting for 70 percent or more of HbC studied.⁴⁰³

Etiology and Pathogenesis

HbC is the result of a GAG \rightarrow AAG transition in codon 6 of the β -globin gene, which changes the amino acid residue at this position from glutamic acid to lysine (Glu \rightarrow Lys). The resultant positively charged Hb variant can easily be distinguished from HbA and HbS by electrophoresis and chromatography, including high-performance liquid chromatography. HbC does not differ from HbA in its solubility; however, purified solutions of HbC form tetragonal crystals in high-molarity phosphate buffer. The Hb in red cells from homozygous HbC individuals also

Occasional target cells. **B.** Phase-contrast microscopy of wet preparation. Note the three sickled cells with terminal fine-pointed projections as a result of tactoid formation and occasional target cells. **C.** HbSC disease. Blood film. Note the high frequency of target cells characteristic of HbC and the small dense, irregular, contracted cells reflective of their content of HbS. **D.** HbCC disease. Blood film. Characteristic combination of numerous target cells and a population of dense (hyperchromatic) microspherocytes. Of the nonspherocytic cells, virtually all are target cells. **E.** HbCC disease postsplenectomy. Blood film. Note the rod-like inclusions in two cells as a result of HbC paracrystallization. These cells are virtually all removed in patients with spleens. **F.** HbCC disease postsplenectomy. Phase-contrast microscopy of wet preparation. Note the HbC crystalline rod in a cell. **G.** HbDD disease. Blood film. Note frequent target cells admixed with population of small spherocytes, poikilocytes, and tiny red cell fragments. **H.** HbEE disease. Blood film. Hypochromia, anisocytosis, and target cells. **I.** HbE thalassemia. Blood film. Marked anisocytosis (primarily microcytes) and poikilocytosis. Hypochromia. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

form crystals when incubated with hypertonic saline; HbC crystals are also observed *in vivo*, particularly in the red cells of splenectomized HbCC patients (Fig. 49-11F). Crystal-containing HbCC red cells have impaired deformability and filterability. HbCC red cells have a propensity for potassium (K^+) loss, which is followed by water loss; unlike in sickle red cells, this K^+ leak does not appear to be mediated through either the potassium chloride cotransport or the calcium ion activated K^+ efflux (Gardos) channel; it is thought to be a volume-stimulated K^+ efflux.⁴⁰² The consequence of this K^+ loss is dehydrated, often spherocytic, red cells with increased MCHC, and decreased osmotic fragility. These changes result in impaired rheologic properties of HbCC red cells; their life span is reduced to 40 days.

Clinical Features

Mild to moderate splenomegaly is a common feature of homozygous HbC. Like many other chronic hemolytic states, cholelithiasis may be present. HbCC individuals do not suffer from vasoocclusion or episodic pain. Occasionally, abdominal pain may be present and can be a

result of splenomegaly and/or cholelithiasis. Pregnancy does not pose an increased risk to women with HbCC. Life expectancy of HbCC individuals is comparable to non-HbC Americans of African descent. In a recent single-institution study, splenomegaly and cholelithiasis occurred in approximately 2.5 percent of patients younger than 8 years of age, but it was far more common (71 percent) in individuals older than 8 years of age.⁴⁰⁴

Laboratory Features

HbCC individuals have a mild to moderate hemolytic anemia. Hb is usually in the 10 to 11 g/dL range. There is associated reticulocytosis usually in the 3 to 4 percent range. There usually is mild microcytosis (mean corpuscular volume [MCV] 70 to 75 fL) and, often, an elevated MCHC. The blood film is characteristic, showing an abundance of target cells, microspherocytes, and HbC red cell crystals, especially in splenectomized patients (see Fig. 49-11F). Indirect bilirubin may be mildly elevated. White cell and platelet counts are normal in the absence of hypersplenism.

Differential Diagnosis

Differential diagnosis is usually achieved by Hb electrophoresis. HbC moves to a cathodic position, comigrating with HbA₂, HbE, and HbO_{Arab} on alkaline pH (cellulose acetate) electrophoresis. The distinction from these Hbs can be made by electrophoresis on citrate agar in acid pH where HbE and HbA₂ comigrate with HbA; HbO_{Arab} has a HbS-like mobility, and HbC has a unique migration pattern. Alternatively, newer diagnostic methods can be used; these include isoelectric focusing, where HbC can readily be distinguished from other Hbs with similar mobility on cellulose acetate electrophoresis. In cation exchange HPLC and capillary electrophoresis, HbC has a distinct elution pattern and can be distinguished from HbE and HbO_{Arab}; these latter methods also have the advantage of separating and quantifying HbA₂ in HbC homozygotes and in HbC trait. This confers the advantage of readily differentiating between HbCC and rare cases of HbC-β⁰-thalassemia (where HbA₂ is significantly higher, ~5 percent).

Therapy

The vast majority of HbCC individuals do not require any therapeutic intervention. Cholecystectomy may be required in individuals who have symptomatic gallstones. Few patients with HbCC develop hypersplenism with a reduction in white cell and platelet counts, and occasionally worsening of anemia. In such instances, splenectomy should be considered. Another indication for splenectomy is pain associated with an enlarged spleen. It is important to apply the usual precautions in patients considered for splenectomy (appropriate vaccinations, prophylactic antibiotic use, and delaying splenectomy in young children). Folic acid supplementation, as usually done in many chronic hemolytic states, is of no proven value.

HEMOGLOBIN DISEASE

Definition and History

HbE (β₂₆Glu→Lys) was the fourth abnormal Hb described.⁴⁰⁵ It is most commonly found in Southeast Asia; in some areas (in the border between Thailand, Laos, and Cambodia, the so-called HbE triangle) the reported gene frequency may reach as high as 0.50.⁴⁰⁶ This high frequency is thought to be from a protective effect against malaria. HbE is also found in other malaria-endemic areas such as Bangladesh, India, and Madagascar. HbE now has a wide distribution as a result of the large population movements from Southeast and South Asia to Western Europe and North America, and may now be the most common Hb variant worldwide.

Etiology and Pathogenesis

The GAG→AAG mutation in codon 26 of the β-globin gene not only leads to a missense mutation (Glu→Lys) at this position, but also activates a cryptic donor splice site at the boundary of exon 1 and intron 1 by increasing the sequence similarity of this site to a consensus splice sequence. The resultant aberrant splicing through this alternate site leads to a decrease in the correctly spliced messenger RNA and hence a β⁺-thalassemic phenotype. This is reflected in the fact that heterozygotes for HbE have 25 to 30 percent of the variant; in the presence of concomitant α-thalassemia, this quantity decreases even further. The coinheritance of HbE with a host of other globin mutants (α-thalassemia, β-thalassemia, other Hb variants), which are also common in the populations where HbE is prevalent, results in a wide spectrum of hemoglobinopathies with varying degrees of severity (HbE disorders or HbE syndromes). The most significant of these is HbE-β-thalassemia syndromes. HbE has also been reported in combination with HbS (HbSE disease).

Clinical Features

Individuals with homozygous HbE are asymptomatic. Most patients do not have hepatosplenomegaly or jaundice. They are usually diagnosed

during screening programs or family studies of individuals with severe HbE disorders, or on routine evaluation of a blood film with significant microcytosis without anemia. HbE-β-thalassemia is a rather heterogeneous group of disorders varying from a mild thalassemia intermedia like phenotype to severe transfusion dependent thalassemia major (Chap. 48). Part of this heterogeneity results from the type of coinherited β-thalassemia mutation. Patients who are compound heterozygotes for HbE and one of the mild β⁺-thalassemia mutations (such as the mild promoter mutation, -28A→G) have a mild to moderate anemia, whereas patients with compound heterozygosity for HbE and one of the more severe β⁺-thalassemia mutations (such as IVS I nucleotide 5 or IVS II nucleotide 654 mutations) do have a more severe phenotype with severe anemia and transfusion dependency. There is also a large heterogeneity among patients with HbE-β⁰-thalassemia; these patients do not produce any HbA and have only HbE and varying amounts of HbF. Known factors that influence the phenotype include the ability to produce HbF and the presence of concomitant α-thalassemia. Individuals who have the propensity to synthesize significant amounts of HbF (such as those who have the Xmn I C→T mutation in the C_γ-globin promoter) are able to ameliorate the globin chain imbalance and thus have a milder phenotype. Concomitant α-thalassemia also mitigates the course of the disease by decreasing globin chain imbalance. In some cases, there may be nonglobin modifiers that impact on the phenotype. Patients with severe forms of HbE-β⁰-thalassemia have clinical features very similar to β-thalassemia major; they develop complications such as hypersplenism, iron overload, increased susceptibility to infections, thromboembolic complications, and heart failure, and have a shortened life expectancy.⁴⁰⁶ Splenectomized HbE-β-thalassemia patients have more pronounced intravascular hemolysis, markers of endothelial cell activation, and activation of coagulation with increased levels of cell free Hb, sE-selectin, sP-selectin, high-sensitivity C-reactive protein, and thrombin-antithrombin complex compared to nonsplenectomized patients.⁴⁰⁷

Laboratory Features

HbE-trait individuals have a borderline microcytosis (MCV in the lower 80s) but are not anemic. Homozygotes for HbE are usually only borderline or mildly anemic (Hb 11 to 13 g/dL), but they are microcytic (MCV ~70 fL). Blood film shows target cells, hypochromia, and microcytosis (see Fig. 49-11H). Osmotic fragility of the red cells is decreased. Hb electrophoresis shows greater than 90 percent HbE and 5 to 10 percent HbF. Certain chromatography techniques that can separate HbE from HbA₂ reveal elevated levels of HbA₂. Patients with mild forms of HbE-β⁺-thalassemia (Chap. 48) have Hb levels in the 9.0 to 9.5 g/dL range, whereas those with severe HbE-β⁺-thalassemia are more severely anemic (Hb 6.5 to 8.0 g/dL). Individuals with HbE-β⁰-thalassemia have varying degrees of anemia, depending on their ability to produce HbF; these patients have HbE in the 40 to 60 percent range, with the remainder being HbF. Patients with higher HbF values are less anemic.

Therapy

HbE homozygotes do not require any therapy. Patients with severe HbE-β⁰-thalassemia are similar to thalassemia intermedia or major; most of the latter patients should be on a chronic transfusion regimen aiming at Hb levels of approximately 10 g/dL; iron chelation should be a part of standard therapy. Splenectomy should be considered when hypersplenism develops. Patients with a thalassemia intermedia-like phenotype may require sporadic transfusions. Hydroxyurea can increase HbF levels and decrease ineffective erythropoiesis in HbE-β-thalassemia.⁴⁰⁸ AHSCT (including umbilical cord blood-derived stem cells in one patient) has also been used in HbE-β-thalassemia.

Course and Prognosis

The prognosis is dependent upon the clinical phenotype. Patients with milder phenotypes tend to do well. Severe HbE- β -thalassemia patients require chronic red cell transfusion and iron-chelation therapy; this places a great burden on the economies of countries where this disease is prevalent. AHSCT, although potentially curative, will not be available for the vast majority of these patients. Prenatal diagnosis and neonatal screening should be an important part of the strategies to decrease the disease burden and improve care. Long-term use of hydroxyurea and other novel HbF-inducing agents as modifiers of disease (histone deacetylase inhibitors and DNA methyltransferase 1 inhibitors) can be an important addition to therapy.

HEMOGLOBIN D DISEASE

HbD was the third Hb variant identified.⁴⁰⁹ The substitution in HbD is a glutamic acid to glutamine at the 121st amino acid of the β -globin chain (β 121Glu \rightarrow Gln). HbD has an S-like mobility on alkaline electrophoresis, but comigrates with HbA on acid pH. Subsequently, a number of other Hb variants with the same electrophoretic properties were discovered and named HbD (HbD_{Ibadan}, HbD_{Gainesville}, etc.). The most common HbD is HbD_{Los Angeles} (β 121Glu \rightarrow Gln), the originally discovered HbD, which is identical to HbD_{Punjab}. It is most commonly found in Punjab, India where 2 to 3 percent of the population have the HbD gene. Subsequently, it has also been found in a number of other populations including Europeans of Mediterranean region, and Americans of African descent.⁴¹⁰

HbD heterozygotes are asymptomatic, are not anemic, and have normal red cell indices. Homozygotes for HbD_{Los Angeles} are asymptomatic and are hematologically normal with normal red cell indices. Blood films may show target cells (see Fig. 49-11G). Osmotic fragility may be decreased. Compound heterozygotes for HbD_{Los Angeles} and a β^0 -thalassemia mutation have mild microcytic anemia and show minimal hemolysis. Coinheritance of HbD_{Los Angeles} with HbS results in a severe SCD phenotype not different from homozygous HbS.

HbD_{Los Angeles} should be distinguished from HbS. This can be done by a combination of routine alkaline and acid Hb electrophoretic methods. Techniques such as isoelectric focusing, HPLC, and capillary electrophoresis readily provide this distinction. Such methods allow accurate diagnosis of SCD from compound heterozygosity for HbS and HbD_{Los Angeles}.

UNSTABLE HEMOGLOBINS

Unstable Hbs form an important group of clinically significant Hb variants. Several different mechanisms lead to the generation of unstable variants, which result in a congenital hemolytic anemia with inclusion bodies in red cells (Heinz bodies), hence the term *congenital Heinz body hemolytic anemia*.

Definition and History

Cathie reported a 10-month-old child with hemolytic anemia, jaundice, and splenomegaly in 1952.⁴¹¹ Splenectomy did not result in improvement. The patient's red cells had large Heinz bodies (Chap. 31). Similar cases were reported from around the world, and the observation that these cases were characterized by the precipitation of their hemolysate upon exposure to heat, suggested a Hb abnormality as the cause. Subsequently, nearly all of similar cases were found to have a variant Hb, and Cathie's case was found to have Hb-Bristol (β 67Val \rightarrow Asp). To date, 146 unstable variants have been reported; the vast majority is sporadic cases reported only once. Few have been observed repeatedly in different populations.

Etiology and Pathogenesis

Several different mechanisms lead to the instability of the globin molecule with precipitation in the red cell leading to hemolysis. These are summarized below.

Substitutions Near the Heme Pocket Heme is inserted into a hydrophobic pocket in each globin molecule where it is in contact with a number of invariant nonpolar amino acid residues (see Fig. 49-2). Substitution of these invariant nonpolar residues will decrease the stability of heme-globin association and ultimately lead to the instability of the globin moiety. Hb_{Zurich} (β 63His \rightarrow Arg), Hb_{Kohn} (β 98Val \rightarrow Met), and Hb_{Hammersmith} (β 42Phe \rightarrow Ser) are examples of this group.

Disruption of Secondary Structure (α -Helix) The secondary structure of globin chains is 75 percent in the conformation of an α helix (see Fig. 49-1). Proline residues cannot participate in an α helical conformation. Thus, the substitution of a proline residue for any other amino acid except for the first three residues of an α helix will disrupt the secondary structure and lead to the disruption and precipitation of the mutant globin chain.

Mutations in α , β_1 Interface The first step in the assembly of the Hb tetramer is the formation of an $\alpha\beta$ dimer. This structure is stabilized by a secondary structure that exposes the charged amino acids (glutamic acid, aspartic acid, lysine, and arginine) on the surface of the molecule in contact with water and stabilizes the interior of the molecule (α , β_1 interface) with hydrophobic interactions. Substitution of a charged (polar) residue for a nonpolar amino acid involved in α , β_1 contact will disrupt and destabilize this dimer formation and lead to the precipitation of the Hb molecule.

Amino Acid Deletions Deletion of one or more amino acid residues is expected to disrupt the secondary structure of the globin chains and may lead to instability of the mutant chain. Mutant globins with deletion of one or more residues have been reported. Examples of this type include Hb_{Leiden} (β 6 or β 7Glu \rightarrow 0), Hb_{Gun Hill} (β 91-95 \rightarrow 0), and Hb_{Freiburg} (β 23Val \rightarrow 0).

Elongated Globin Chains Some variants result from either a mutation in the termination codon or a frameshift leading to the synthesis of longer than normal globin chains. These variants tend to be unstable because of the presence of a nonfunctional fragment. Examples include Hb_{Cranston} and Hb_{Tak}.

Whatever the underlying mechanism may be, unstable Hb variants precipitate within developing red cell precursors forming hemichromes (intermediate substances in Hb denaturation) and ultimately aggregates that attach to the inner layer of red cell membrane (Heinz bodies). Heinz bodies can be visualized with supravital stains, such as brilliant cresyl blue. Red cells with Heinz bodies have impaired rheologic properties (deformability and filterability) and are trapped in the splenic circulation (Chaps. 6, 34, and 56) with pitting of the membrane attached bodies. Hemolysis ultimately ensues. The degree of hemolysis is proportionate to the quantity and the instability of the variant.

Clinical Features

Patients with unstable Hb variants have varying degrees of hemolytic anemia. This can range from a compensated, asymptomatic hemolytic state to severe, life-threatening hemolysis. Generally, hemolytic anemia is mild to moderate and does not require therapeutic intervention. Typically, hemolysis is exacerbated by increased oxidant stress such as infections and the use of oxidant drugs. Patients may have jaundice and splenomegaly. As is the case with other chronic hemolytic states, gallstones may develop. Hypersplenism can be a problem in some cases. Many unstable Hb variants that are associated with mild, compensated hemolysis are diagnosed fortuitously or during population screening for hemoglobinopathies. Unstable variants are inherited in a mendelian pattern; they usually manifest in the heterozygous state. There are

instances of *de novo* mutations without evidence of the variant in parents of an affected individual. Many of the 146 known unstable variants are found in a single individual or in a limited number of instances. However, some unstable variants like Hb_{Kohn} ($\beta 98\text{Val}\rightarrow\text{Met}$) and Hb_{Zurich} ($\beta 67\text{His}\rightarrow\text{Arg}$) have been found in many populations around the world.

Laboratory Features

Patients with unstable Hb variants may have varying degrees of anemia. Generally, the anemia is mild and does not require therapeutic intervention. However, exacerbation of anemia during exposure to oxidant stress (such as infections and the use of oxidant drugs) is a common feature. Features of a hemolytic state (reticulocytosis, indirect hyperbilirubinemia, elevated LDH, decreased or undetectable haptoglobin) are present. Red cell morphology shows polychromasia, anisocytosis, poikilocytosis, and occasionally basophilic stippling. A typical feature of this disorder is the presence of Heinz bodies, best visualized with supravital staining with brilliant cresyl blue as membrane attached inclusion bodies in red cells. Hb electrophoresis reveals the presence of an additional abnormal Hb band. The quantity of the variant Hb is variable and inversely proportional to the degree of instability of the abnormal Hb (e.g., the more unstable the variant, the less the quantity). More accurate quantification can be achieved with cation exchange or reversed phase HPLC. The presence of an unstable variant in the hemolysate can be demonstrated by simple tests of stability. The most commonly used tests are heat denaturation and isopropanol precipitation. The heat denaturation test is more cumbersome and time consuming and is seldom used in practice. The isopropanol precipitation test is a simple screening test for unstable variants and involves the incubation of the hemolysate with a 17 percent solution of isopropanol; hemolysates containing unstable Hb variants will form a precipitate, whereas a normal hemolysate will remain clear.

HEMOGLOBINS WITH ALTERED OXYGEN AFFINITY

M Hbs result from mutations around the heme pocket that disrupt the hydrophobic nature of this structure with resultant oxidation of the iron in the heme moiety from ferrous (Fe^{2+}) to ferric (Fe^{3+}) state and cause methemoglobinemia (Chap. 50). Mutations in certain critical areas of the globin molecule alter the affinity of the globin for oxygen. In general, mutations that stabilize the molecule in the T state lead to low O_2 -affinity variants, which can clinically manifest as cyanosis or mild anemia. Mutations that stabilize the R state or destabilize the T state result in high O_2 -affinity variants. These variants will cause secondary polycythemia (Chap. 57). The mutations that affect the ligand binding affinity of the Hb molecule are mostly in the $\alpha_1\beta_2$ interface. Rarely, mutations in the $\alpha_1\beta_1$ interface lead to altered O_2 affinity. Another mechanism in the generation of high O_2 affinity mutants involves mutations that alter the binding of 2,3-BPG.

CHAPTER 50

METHEMOGLOBINEMIA AND OTHER DYSHEMOGLOBINEMIAS

Archana M. Agarwal and Josef T. Prchal

SUMMARY

Normal hemoglobin can be oxidized to methemoglobin. Methemoglobinemia occurs because of either increased production of oxidized hemoglobin from exposure to environmental agents or diminished reduction of oxidized hemoglobin because of underlying germline mutations. Cyanosis is virtually invariant in patients with methemoglobinemia. Hemoglobin can also bind carbon monoxide and nitric oxide, resulting in the formation of carboxyhemoglobin and nitrosohemoglobin. Sulfhemoglobinemia occurs because of increased production secondary to occupational exposure to sulphur compounds or exposure to oxidant medications. These modified hemoglobins are known as *dyshemoglobins*. Depending upon the severity and individual predisposition, presence of dyshemoglobins can result in varying degree of clinical manifestations. Prompt diagnosis is the key to effective and timely treatment.

METHEMOGLOBINEMIA

DEFINITION AND HISTORY

A bluish discoloration of the skin and mucous membrane, designated *cyanosis*, has been recognized since antiquity as a manifestation of lung or heart disease; however, in methemoglobinemia and sulfhemoglobinemia, it has a different molecular basis than in hemoglobin oxygen desaturation. Cyanosis resulting from drug administration has also been recognized since before 1890.¹ Toxic methemoglobinemia occurs when various drugs or toxic substances either oxidize hemoglobin (Hb) directly in the circulation or facilitate its oxidation by molecular oxygen.

In 1912, Sloss and Wybauw² reported a case of a patient with idiopathic methemoglobinemia. Later Hitzenger³ suggested that a hereditary form of methemoglobinemia might exist and, subsequently,

Acronyms and Abbreviations: AOP2, antioxidant protein 2; 2,3-BPG, 2,3-bisphosphoglycerate; cGMP, cyclic guanosine monophosphate; CO, carbon monoxide; COHb, carboxyhemoglobin; GSH, reduced glutathione; N_2O_3 , dinitrogen trioxide; NADH, nicotinamide adenine dinucleotide (reduced form); NADPH, reduced nicotinamide adenine dinucleotide phosphate; NO, nitric oxide; NOS, nitric oxide synthase; P_{50} , the partial pressure of oxygen at which 50 percent of the blood hemoglobin is saturated with oxygen; RBC, red blood cells; SNO-Hb, S-nitrosohemoglobin; SpCO, arterial carboxyhemoglobin concentration; SpMet, arterial methemoglobin concentration; SpO₂, arterial oxygen saturation.

numerous such cases were reported.⁴ In 1948, Hörlein and Weber⁵ described a family in which eight members over four generations had cyanosis. The absorption spectrum of methemoglobin was abnormal and they demonstrated that the defect must reside in the globin portion of the molecule. Subsequently, Singer⁶ proposed that such abnormal hemoglobins be given the designation hemoglobin M. The cause of another form of methemoglobinemia that occurs independently of drug administration and without the existence of any abnormality of the globin portion of hemoglobin was first explained by Gibson,⁷ who clearly pointed to the site of the enzyme defect, nicotinamide adenine dinucleotide (reduced form) (NADH) diaphorase, also designated as methemoglobin reductase, and now known as cytochrome b_5 reductase. More than 50 years after Gibson's insightful studies, the genetic disorder that he had predicted was verified at the DNA level.⁸

The existence of abnormal hemoglobins that cause cyanosis through quite another mechanism was first recognized in 1968 with the description of hemoglobin Kansas.⁹ Here the cyanosis resulted not from methemoglobin, as occurs in hemoglobin M, but rather from an abnormally low oxygen affinity of the mutant hemoglobin. Thus, at normal oxygen tensions, a large amount of deoxygenated hemoglobin is present in the blood of affected patients.

EPIDEMIOLOGY

Methemoglobinemia occurring as a result of cytochrome b_5 reductase deficiency is more common among Native Americans, both in Alaska and in the continental United States, and among the Evenk people of Yakutia of Russian Siberia than in other ethnic groups.^{10–12} Methemoglobinemia resulting from hemoglobin M is inherited and sporadic. The occurrence of methemoglobinemia due to toxic chemicals is acquired, transient, and is also sporadic.

ETIOLOGY AND PATHOGENESIS

Methemoglobinemia decreases the oxygen-carrying capacity of blood because the oxidized iron cannot reversibly bind oxygen. Moreover, when one or more iron atoms have been oxidized, the conformation of hemoglobin is changed so as to increase the oxygen affinity of the remaining ferrous heme groups. In this way methemoglobinemia exerts a dual effect in impairing the supply of oxygen to tissues.¹³

Toxic Methemoglobinemia

Hemoglobin is continuously oxidized *in vivo* from the ferrous to the ferric state. The rate of such oxidation is accelerated by many drugs and toxic chemicals, including sulfonamides, lidocaine and other aniline derivatives, and nitrites. A vast number of chemical substances may cause methemoglobinemia.^{14–16} Table 50–1 lists some of the agents that are responsible for clinically significant methemoglobinemia in clinical practice.

The most common offenders include benzocaine and lidocaine.^{17–19} In some cases, the patients have been unaware that they have been ingesting one of the drugs known to produce methemoglobinemia; dapson is apparently used in some “street drugs.”^{20,21} Nitrites and the nitrites contaminating water supplies or used as preservatives in foods are also common offending agents.^{22–30}

Cytochrome b_5 Reductase Deficiency

Cytochrome b_5 reductase, also known as NADH diaphorase, catalyzes a step in the major pathway for methemoglobin reduction. This enzyme reduces cytochrome b_5 , using NADH as a hydrogen donor. The reduced cytochrome b_5 reduces, in turn, methemoglobin to hemoglobin. A

TABLE 50-1. Some Drugs That Cause Methemoglobinemia

Phenazopyridine (Pyridium) ¹⁶³⁻¹⁶⁵

Methylene blue ⁸⁷
Chloramine ^{171,181}

steady-state methemoglobin level is achieved when the rate of methemoglobin formation equals the rate of methemoglobin reduction either through the cytochrome b_5 reductase or through a relatively minor auxiliary mechanism such as direct chemical reduction by ascorbate and reduced glutathione. A reduced nicotinamide adenine dinucleotide phosphate (NADPH)-linked enzyme, NADPH diaphorase, does not play a role in methemoglobin reduction except when a linking dye such as methylene blue is supplied (see “Therapy, Course, and Prognosis” below). A marked diminution in the activity of cytochrome b_5 reductase will result in the accumulation of the brown pigment in circulating erythrocytes.

A balance to methemoglobin formation is antioxidant protein 2 (AOP2), which is present in high concentrations in human and mouse red cells (Chap. 47). This member of the peroxiredoxin protein family binds to hemoglobin and prevents both spontaneous and oxidant-induced methemoglobin formation.³¹ Mutations of this gene or its acquired deficiency are theoretical candidates responsible for congenital and acquired methemoglobinemia. Cyanosis resulting from abnormal hemoglobins (both hemoglobin M and low-oxygen affinity hemoglobins) is inherited as an autosomal dominant disorder. In contrast, hereditary methemoglobinemia resulting from cytochrome b_5 reductase deficiency is inherited in an autosomal recessive fashion.

Many mutations of cytochrome b_5 reductase that cause methemoglobinemia have been identified at the nucleotide level,⁸ and the functional effect of some of these have been deduced from the structure of the enzyme.^{32,33} Although most of the mutants have been found in persons of European descent, five unique mutations were found in Chinese,³⁴ at least three in Thais,³⁵ two in Americans of African descent,³⁶ and one in an Asian Indian.³⁷ In addition, a common polymorphism (allele frequency = 0.023) has been identified in Americans of African descent; it does not appear to impair the activity of the enzyme.³⁸ Most of the patients with cytochrome b_5 reductase deficiency merely have methemoglobinemia and the enzyme deficiency is limited to the red cells, and these have been classified as having type I disease. In type II cytochrome b_5 reductase deficiency, which represents 10 to 15 percent of cases of enzyme deficient congenital methemoglobinemia, cytochrome b_5 reductase is decreased in all cells. In addition to cyanosis, severe developmental abnormalities can occur; most affected infants die

in the first year of life.^{39,40} Patients with this form of disease are afflicted, in addition to methemoglobinemia, with a progressive encephalopathy and mental retardation. The finding that fatty acid elongation is defective in the platelets and leukocytes of such patients⁴¹ provides a clue to the type of defect that could occur in the central nervous system, where fatty acid elongation plays an important role in myelination. Rare patients with deficiency of cytochrome b_5 reductase in nonerythroid cells do not suffer any neurologic disorder, and it has been suggested that they be designated as having type III disease⁴²; however, existence of such an entity has been challenged and type III disease likely does not exist.⁴³

Heterozygosity for Cytochrome b_5 Reductase Deficiency

Heterozygotes for cytochrome b_5 reductase deficiency are not usually clinically methemoglobinemic or cyanotic. However, under the stress of administration of drugs that normally induce only slight, clinically unimportant, methemoglobinemia, such persons have been reported to become severely cyanotic because of methemoglobinemia.⁴⁴ Although in this report the affected patients were Ashkenazi Jews, the prevalence of cytochrome b_5 reductase deficiency in 500 unselected Jewish subjects was found to be low.⁴⁵ In addition, predisposition to acute toxic methemoglobinemia in heterozygous subjects for cytochrome b_5 reductase deficiency seems to be quite uncommon.⁴³

Animal models of cytochrome b_5 reductase deficiency have been described in dogs, cats, and horses.^{46,47}

Infant Susceptibility

A combination of both increased hemoglobin oxidation and decreased methemoglobin reduction also may occur. Because the activity of cytochrome b_5 reductase is normally low in newborn infants,⁴⁸ they are particularly susceptible to the development of methemoglobinemia. Thus, serious degrees of methemoglobinemia have been observed in infants as a result of toxic materials, such as aniline dyes used on diapers,⁴⁹ and the ingestion of nitrate-contaminated water^{24,30} and even of beets.⁵⁰ Bacterial action in the intestinal tract may reduce nitrates to nitrites, which, in turn, cause methemoglobinemia. In rural areas, fatal methemoglobinuria in infants caused by drinking water from wells contaminated with nitrates still occurs.⁵¹

Inhaled nitric oxide (NO) is approved for treatment of infants with pulmonary hypertension because of its vasodilatory effect on pulmonary vessels. During the binding and release of NO from hemoglobin, methemoglobin is formed at a higher rate. In one study of 81 premature and 82 term infants, methemoglobin was above 5 percent in preterm infants and between 2.5 and 5 percent in 16 infants.⁵²

Methemoglobinemia occurring in acidotic infants with diarrhea is a syndrome that may have a fatal outcome.⁵³ Such infants have normal red cell cytochrome b_5 reductase activity, and the mechanism by which methemoglobinemia occurs is unknown. However, the syndrome seems most common when soy formula is being fed⁵⁴ and breastfeeding appears to protect against this.⁵¹

Cytochrome b_5 Deficiency

Rarely, the defect leading to methemoglobinemia may not be in the cytochrome b_5 reductase that transfers hydrogen to the cytochrome b_5 , but rather to a deficiency in the cytochrome b_5 itself.⁵⁵

Hemoglobin M

The molecular mechanisms by which hemoglobin binds oxygen and releases it are discussed in Chap. 49. Heme is held in a hydrophobic “heme pocket” between the E and F α -helices of each of the four globin chains. The iron atom in the heme forms four bonds with the pyrrole nitrogen atoms of the porphyrin ring and a fifth covalent bond with the imidazole nitrogen of a histidine residue in the nearby F α -helix (Fig. 50-1).⁵⁶

Figure 50-1. Diagrammatic representation of the heme group inserted into the heme pocket. *A*, Proximal histidine; *B*, distal histidine. **A.** In the deoxygenated form the larger ferrous atom lies out of the plane of the porphyrin ring. **B.** In the oxygenated form the now smaller “ferric-like” atom can slip into the plane of the porphyrin ring. As a result, the proximal histidine, and helix F into which it is incorporated, are displaced. (Reproduced with permission from Lehmann H, Huntsman RG: *Man’s Haemoglobins*. Philadelphia PA: Lippincott Williams & Wilkins; 1974.)

This histidine, residue 87 in the α chain and 92 in the β chain, is designated as the proximal histidine. On the opposite side of the porphyrin ring the iron atom lies adjacent to another histidine residue to which, however, it is not covalently bonded. This distal histidine occupies position 58 in the α chain and position 63 in the β chain. Under normal circumstances oxygen is occasionally discharged from the heme pocket as a superoxide anion, removing an electron from the iron and leaving it in the ferric state. The enzymatic machinery of the red cell efficiently reduces the iron to the divalent form, converting the methemoglobin to hemoglobin (Chap. 47).

In most of the hemoglobins M, tyrosine has been substituted for either the proximal or the distal histidine. Tyrosine can form an iron-phenolate complex that resists reduction to the divalent state by the normal metabolic systems of the erythrocyte. Four hemoglobins M are a consequence of substitution of tyrosine for histidine in the proximal and distal sites of the α and β chains. As Table 50-2 shows, these four hemoglobins M have been designated by the geographic names of their discovery, Boston, Saskatoon, Iwate, and Hyde Park.

Analogous His \rightarrow Tyr substitutions in the γ chain of fetal hemoglobin have also been documented and have been designated hemoglobin FM_{Osaka}⁵⁷ and FM_{Fort Ripley}⁵⁸.

Another hemoglobin M, HbM_{Milwaukee}^{*} is formed by substitution of glutamic acid for valine in the 67th residue of the β chain. The glutamic acid side chain points toward the heme group and its γ -carboxyl group interacts with the iron atom, stabilizing it in the ferric state.

It is rare for methemoglobinemia to occur as a result of hemoglobinopathies other than hemoglobins M, but Hb_{Chile} (β 28 Leu \rightarrow Met) is such a hemoglobin. Producing hemolysis only with drug administration, this unstable hemoglobin is characterized clinically by chronic methemoglobinemia.⁵⁹

TABLE 50-2. Properties of Hemoglobins M

Hemoglobin	Amino Acid Substitution	Oxygen Dissociation and Other Properties	Clinical Effect	Reference
HbM _{Boston}	α 58 (E7)His \rightarrow Tyr	Very low O ₂ affinity, almost nonexistent heme-heme interaction, no Bohr effect	Cyanosis resulting from formation of methemoglobin	182
HbM _{Saskatoon}	β 63 (E7)His \rightarrow Tyr	Increased O ₂ affinity, reduced heme-heme interaction, normal Bohr effect, slightly unstable	Cyanosis resulting from methemoglobin formation, mild hemolytic anemia exacerbated by ingestion of sulfonamides	182,183
HbM _{Iwate} (HbMKankakee, HbMOldenburg, HbMSendai)	α 87 (F8)His \rightarrow Tyr	Low O ₂ affinity, negligible heme-heme interaction, no Bohr effect	Cyanosis resulting from formation of methemoglobin	182,184
HbM _{Hyde Park}	β 92 (F8)His \rightarrow Tyr	Increased O ₂ affinity, reduced heme interaction, normal Bohr effect, slightly unstable	Cyanosis resulting from formation of methemoglobin, mild hemolytic anemia	79
Hb M(hyde park) (HbMilwaukee 2)				
HbM _{Akita}				
HbM _{Milwaukee}	β 67 (E11)Val \rightarrow Glu	Low O ₂ affinity, reduced heme-heme interaction, normal Bohr effect, slightly unstable	Cyanosis resulting from methemoglobin formation	185
HbFM _{Osaka}	γ 63His \rightarrow Tyr	Low O ₂ affinity, increased Bohr effect, methemoglobinemia	Cyanosis at birth	57
HbFM _{Fort Ripley}	γ 92His \rightarrow Tyr	Slightly increased O ₂ affinity	Cyanosis at birth	186

CLINICAL FEATURES

Drug Ingestion

Methemoglobinemia may be chronic or acute and acquired or congenital. Acquired severe acute methemoglobinemia, usually the consequence of drug ingestion or toxic exposure, can produce symptoms of anemia, since methemoglobin lacks the capacity to transport oxygen. Symptoms may include shortness of breath, palpitations, and vascular collapse. Chemicals that induce methemoglobinemia are often also capable of causing hemolysis, and a combination of hemolytic anemia and methemoglobinemia may occur. Chronic methemoglobinemia, whether a result of exposure to drugs or toxins or of hereditary causes, is usually asymptomatic. Cyanosis, even if present, may not be discernable in persons with very dark skin coloration.⁶⁰ In instances when the methemoglobin levels are chronically very high (>20 percent of the total pigment), mild erythrocytosis may be noted (Chap. 57).

M Hemoglobins

Patients with hemoglobin M also manifest cyanosis. In the case of α -globin variants, the dusky color of the infants will be noted at birth, but the clinical manifestations of β -globin variants become apparent only after β chains have largely replaced the fetal γ chains at 6 to 9 months of age. In spite of the impaired hemoglobin function, no cardiopulmonary symptoms are observed and there is no clubbing. In the case of HbM_{Saskatoon} and HbM_{Hyde Park}, hemolytic anemia with jaundice may be present. The hemolytic state may be exacerbated by administration of sulfonamides.⁶¹

Cytochrome b5 Reductase Deficiency

Hereditary methemoglobinemia resulting from cytochrome b5 reductase deficiency may, as noted above, be associated with mental retardation, failure to thrive and early death. In one case, skeletal anomalies were documented as well.⁶²

LABORATORY FEATURES

Toxic Methemoglobinemia

In toxic methemoglobinemia, an elevated level of methemoglobin is found, but the activity of cytochrome b5 reductase is normal. Methemoglobin levels are best measured using the change of absorbance of methemoglobin at 630 nm that occurs when cyanide is added, converting the methemoglobin to cyanmethemoglobin, a principle used in the Evelyn–Malloy method.^{63,64} Errors in diagnosis are frequently made when automated instruments designed to estimate levels of reduced hemoglobin, oxygenated hemoglobin, methemoglobin, and carboxyhemoglobin (COHb) are used. Most automated instruments do not properly make this distinction.^{65,66}

The clinical incidence of methemoglobinemia can be overestimated by cooximeter measurements compared to the more specific Evelyn–Malloy method.⁶⁷ Evelyn–Malloy method involves direct spectrophotometric analysis and should be used when methemoglobinemia is suspected. This is achieved by lysing the blood in a slightly acid buffer and measuring the optical density at 630 nm before and after adding a small amount of neutralized cyanide. The absorption of methemoglobin at this wavelength disappears when it is converted to cyanmethemoglobin. Although this method was described in 1938,⁶³ it remains the most accurate technique for the estimation of methemoglobin in the blood. Details of its performance can be found in an earlier edition of this text⁶⁸ and elsewhere.⁶¹

An eight-wavelength pulse oximeter, Masimo Rad-57 (Rainbow-SET Rad-57 Pulse CO-Oximeter, Masimo Inc, Irvine, CA), has been approved by the FDA for the measurement of both COHb and

methemoglobin. The Rad-57 uses eight wavelengths of light instead of the usual two and is thereby able to measure more than two species of human hemoglobin.⁶⁹ In addition to the usual SpO₂ value, the Rad-57 displays SpCO and SpMet, which are the pulse oximeter's estimates of COHb and methemoglobin concentrations, respectively. In a study on healthy human volunteers in whom controlled levels of methemoglobin and COHb were induced, the Rad-57 measured COHb with an uncertainty of ± 2 percent within the range of 0 to 15 percent and measured methemoglobin with an uncertainty of 0.5 percent within the range of 0 to 12 percent,⁶⁹ the usefulness of this instrument has been verified also by other studies.^{70,71}

Cytochrome b5 Reductase Deficiency

In hereditary methemoglobinemia resulting from cytochrome b5 reductase deficiency, between 8 and 40 percent of the hemoglobin is in the form of methemoglobin. The blood may have a chocolate-brown color and cyanosis is present. Cytochrome b5 reductase activity is best measured using ferricyanide as a receptor, measuring the rate of oxidation of NADH.^{72,73} The residual level of enzyme activity is usually less than 20 percent of normal in patients with methemoglobinemia resulting from deficiency of this enzyme. An immunoassay has been described,⁷⁴ but such an assay would not detect mutants in which enzyme molecules with impaired catalytic activity are present. For unknown reasons, glutathione reductase activity (Chap. 47) is usually also diminished.⁷⁵

Cytochrome b5 Deficiency

Cytochrome b5 assays may be useful if cytochrome b5 reductase activity is normal, and the presence of hemoglobin M is ruled out.⁷⁶

M Hemoglobins

Optical Spectrum Figure 50-2 illustrates the spectrum of normal methemoglobin A at pH 7.0.⁷⁷ Hemoglobins M may be differentiated from methemoglobin formed from hemoglobin A by its absorption spectrum in the range of 450 to 750 nm. Because only some 20 to 35 percent of the total hemoglobin will ordinarily be the hemoglobin M, the mixed spectra of methemoglobin A and the hemoglobin M may be difficult to interpret. Therefore, it is preferable to perform these spectral studies on purified hemoglobin M isolated by electrophoretic or chromatographic means.⁵⁶

Electrophoresis All hemoglobin M samples should be converted to methemoglobin so that any difference found in electrophoresis will be the result of the amino acid substitution and not the different charge of the iron atom. Electrophoresis at pH 7.1 is most useful for separation of hemoglobins M because the imidazole groups of histidine have a net positive charge at this pH, while at higher pH levels the histidines and the substituting tyrosines are both neutral.

Other Biochemical Methods The hemoglobins M differ in their reactivity to cyanide and to azide ions.⁷⁸ This property may help to identify the subunit affected, as the iron-phenolate bonds are stronger in the α -chain variants than in the β -chain variants. However, definitive identification of the variant requires peptide or DNA analysis. Hemoglobins that cause cyanosis because of a diminished oxygen affinity may be detected by determining the oxygen dissociation curve of blood, being certain that the 2,3-bisphosphoglycerate (2,3-BPG) level is normal, or by estimating the oxygen dissociation curve of hemoglobin, which has been stripped of 2,3-BPG by extensive dialysis against an appropriate buffer. Many of the hemoglobins with decreased oxygen affinity are unstable (Chap. 49) and will precipitate in the isopropanol stability test.⁷⁸ In many laboratories, it may be easier to analyze the coding sequence of the globin chains at the DNA level than to attempt to determine the properties of the hemoglobin.⁷⁹

Figure 50-2. Absorption spectra at pH 7.0. A, Methemoglobin A; B, methemoglobin M_{Boston} ; C, methemoglobin $M_{Saskatoon}$; D, methemoglobin A fluoride complex. For purposes of comparison, all the optical densities have been made equal to 0.61 at 500 nm. (Reproduced with permission from Gerald PS, George P: *Second spectroscopically abnormal methemoglobin associated with hereditary cyanosis*. *Science* 1959 Feb 13;129(3346):393-394.)

TREATMENT AND COURSE

Toxic Methemoglobinemia

Acute toxic methemoglobinemia may represent a serious medical emergency. Because of the loss of oxygen-carrying capacity of the blood and the left shift in the oxygen dissociation curve that occurs when methemoglobin is present in high concentrations,⁸⁰ acute methemoglobinemia may be life-threatening when the level of the pigment exceeds one-third of the total circulating hemoglobin. Levels of methemoglobin exceeding 50 percent of the total pigment may be associated with vascular collapse, coma, and death,^{81,82} but recovery was documented in one patient with a level as high as 81.5 percent of the total pigment.⁸³

Methylene blue⁸⁴ is an effective treatment for patients with methemoglobinemia because NADPH formed in the hexose monophosphate pathway can rapidly reduce this dye to leukomethylene blue in a reaction catalyzed by NADPH diaphorase (Chap. 47). Leukomethylene blue, in turn, nonenzymatically reduces methemoglobin to hemoglobin.⁸⁵ An exception to the efficacy of this treatment exists in those patients who are glucose-6-phosphate dehydrogenase deficient (Chap. 47). In these subjects, methylene blue would not only fail to give the desired effect on methemoglobin levels, but might compound the patient's difficulty by inducing an acute hemolytic episode⁸⁶ or increasing the level of methemoglobin.⁸⁷

In patients with acute toxic methemoglobinemia who are symptomatic or whose methemoglobin level is rising rapidly, the intravenous administration of 1 or 2 mg methylene blue per kilogram body weight over a period of 5 minutes is the preferred treatment because of its very rapid action.⁸⁸ Use of excessive amounts of methylene blue should be avoided; the administration of repeated doses of 2 mg methylene

blue per kilogram body weight has produced acute hemolysis even in patients with normal glucose-6-phosphate dehydrogenase levels.⁸⁹

The response to treatment is so rapid, with marked lowering or normalization of methemoglobin levels within an hour or two, that no other treatment is usually needed, but the patient should be observed carefully because continued absorption of a toxic substance from the gastrointestinal tract may cause recurrence of the methemoglobinemia. In patients who are in shock, blood transfusion may be helpful. Cimetidine, used as a selective inhibitor of N-hydroxylation, may decrease the methemoglobinemia produced by dapsone in patients with dermatitis herpetiformis.⁹⁰

Hereditary Methemoglobinemia

The course of hereditary methemoglobinemia is generally benign (although not in type II cytochrome *b5* reductase deficiency), but patients with this disorder should be shielded from exposure to aniline derivatives, nitrites, and other agents that may, even in normal persons, induce methemoglobinemia.

Hereditary methemoglobinemia resulting from cytochrome *b5* reductase deficiency is readily treated by the administration of ascorbic acid, 300 to 600 mg orally daily divided into three or four doses. Although intravenously administered methylene blue is very effective in correcting this type of methemoglobinemia, it is not suitable for the long-term therapy that needs to be given if the state is to be treated at all. Riboflavin administration seems to benefit some patients⁹¹ but not others.⁹²

The iron phenolate complex that exists in the hemoglobins M prevents the reduction of ferric to ferrous iron. For this reason, the methemoglobinemia does not respond to administration of ascorbic acid or of methylene blue. No effective treatment exists for the cyanosis that is present in patients with abnormal hemoglobins with reduced oxygen affinity.

SULFHEMOGLOBIN

DEFINITION AND HISTORY

Sulfhemoglobinemia refers to the presence in the blood of hemoglobin derivatives that are defined by their characteristic absorption of light at 620 nm, even in the presence of cyanide. Sulfhemoglobin derives its name from the fact that it can be produced *in vitro* from the action of hydrogen sulfide on hemoglobin⁹³ and that the feeding of dogs with elemental sulfur has been associated with sulfhemoglobinemia.⁹⁴

ETIOLOGY AND PATHOGENESIS

Sulfhemoglobin may contain one excess sulfur atom. The sulfur atom appears to be bound to a β -pyrrole carbon atom at the periphery of the porphyrin ring.⁹⁵⁻⁹⁷ Sulfhemoglobinemia has been associated with the ingestion of various drugs, particularly sulfonamides, phenacetin, acetanilid, and phenazopyridine.^{65,98} It also occurs independently of drug use, and has been thought to be related to chronic constipation or to purging.⁹⁹ Some patients with sulfhemoglobinemia or a past history of this disorder appear to have increased levels of red blood cell reduced glutathione (GSH).¹⁰⁰ The reason for this and its relationship to sulfhemoglobinemia are not clearly understood, but it may be of significance that some of the types of drugs that are associated with sulfhemoglobinemia cause an elevation of red cell GSH levels, probably by activating the enzyme glutathione synthase¹⁰¹ or by increasing intracellular glutamate levels.¹⁰²

Evidence for the occurrence of hereditary sulfhemoglobinemia is not convincing,¹⁰³ and it is likely that the single family reported represents a hemoglobin M hemoglobinopathy.

CLINICAL FEATURES

Sulfhemoglobinemia is characterized by cyanosis. Drugs that cause sulfhemoglobinemia often have the capacity to produce accelerated red cell destruction as well. Thus, mild hemolysis is sometimes observed in patients with sulfhemoglobinemia.

LABORATORY FEATURES

Sulfhemoglobin is detected in the lysate of blood treated with ferricyanide, cyanide, and ammonia by comparing the optical density at 620 nm with that at 540 nm.^{63,64}

TREATMENT AND COURSE

Sulfhemoglobinemia is almost always a benign disorder. Unlike methemoglobin, sulfhemoglobin does not produce a left shift in the oxygen dissociation curve; instead, it decreases the affinity of hemoglobin for oxygen.⁹⁸ The disorder tends to recur in the same persons after exposure to drugs but does not generally appear to affect their overall health. Unlike methemoglobin, sulfhemoglobin cannot be converted to hemoglobin. Thus, once sulfhemoglobinemia occurs, it will persist until the erythrocytes carrying the abnormal pigment reach the end of their life span.

● LOW-OXYGEN-AFFINITY HEMOGLOBINS: A CAUSE OF CYANOSIS

ETIOLOGY AND PATHOGENESIS

In some hemoglobin variants, the deoxy conformation of the hemoglobin molecule is favored because the angle of the heme is altered from that found normally in deoxyhemoglobin. Such changes occur in Hb_{Hammersmith}, Hb_{Bucaresti}, Hb_{Torino}, and Hb_{Peterborough}. In other instances, the quaternary conformation is changed by mutations involving the $\alpha_1\beta_2$ contact (Hb_{Kansas}, Hb_{Titusville}, and Hb_{Yoshizuka}). Table 50-3 summarizes the properties of abnormal hemoglobins associated with low oxygen affinity.

CLINICAL FEATURES

In response to the improved tissue oxygen supply brought about by a right-shifted oxygen dissociation curve, the “oxygen sensor” of the body decreases the output of erythropoietin.¹⁰⁴ As a result, the steady-state level of hemoglobin is diminished; mild anemia and cyanosis are characteristics of patients with hemoglobins with a decreased oxygen affinity.

LABORATORY FEATURES

The affinity of hemoglobin with oxygen is expressed as P_{50} , which is the partial pressure of oxygen at which 50 percent of the blood hemoglobin is saturated with oxygen. The venous P_{50} can be measured directly using a coximeter, which is no longer easily available in either routine

or reference laboratories. A mathematical formula has been developed that can be used to calculate P_{50} reliably from a venous blood sample.¹⁰⁵ Calculating P_{50} using this formula requires the following venous gas parameters: partial pressure of oxygen (venous), venous pH, and venous oxygen saturation, and uses an antilog mathematical function that many clinicians find difficult to use for calculation. An electronic version (in Microsoft Excel) of this mathematical formula is available for rapid calculation of P_{50} from venous blood gases.¹⁰⁶ The P_{50} of a healthy person with normal hemoglobin is 26 ± 1.3 torr. An abnormally low P_{50} reflects an increased affinity of hemoglobin for oxygen and vice versa, and is especially useful for detecting those high affinity hemoglobin mutants associated with polycythemia (Chaps. 49 and 57).

DIFFERENTIAL DIAGNOSIS

Cyanosis resulting from methemoglobinemia or sulfhemoglobinemia should be differentiated from cyanosis resulting from cardiac or pulmonary disease, particularly when right-to-left shunting is present. In the latter instances, the arterial oxygen tension will be low, whereas in methemoglobinemia and sulfhemoglobinemia it should be normal. One should be certain, however, that the oxygen tension was measured directly and not deduced from the percent saturation of hemoglobin. Blood from a patient with cyanosis because of arterial oxygen desaturation promptly becomes bright red upon being shaken with air. In addition, these causes of cyanosis are readily differentiated by carrying out quantitative blood methemoglobin and sulfhemoglobin levels. Because of the potential lethal nature of high levels of methemoglobin and because prompt treatment may be life-saving, a high index of suspicion is important. A patient with cyanosis whose arterial blood is brown with an SpO_2 that is found to be normal on blood gas examination is likely to have methemoglobinemia. One should not rely on the readings of a standard pulse oximeter, as false readings may be obtained in the presence of methemoglobin. Rapid examination of a blood sample using an automatic analyzer, such as a coximeter, is the first step in confirming the diagnosis. Treatment should not be delayed, but, as pointed out in “Laboratory Features” above, direct spectrophotometric analysis should be carried out on the pretreatment sample as soon as possible to distinguish between methemoglobinemia and sulfhemoglobinemia.

A family history, as well as any information as to whether it is acquired or congenital, is helpful in differentiating hereditary methemoglobinemia as a result of cytochrome *b5* reductase deficiency from hemoglobin M disease. The former has a recessive mode of inheritance, the latter a dominant mode. Thus, cyanosis in successive generations suggests the presence of hemoglobin M; normal parents but possibly affected siblings implies the presence of cytochrome *b5* reductase. Consanguinity is more common in cytochrome *b5* reductase deficiency. In cytochrome *b5* reductase deficiency, incubation of the blood with small amounts of methylene blue will result in rapid reduction of the methemoglobin; in hemoglobin M disease, such reduction does not take place. The absorption spectra of methemoglobin and its derivatives

TABLE 50-3. Some Abnormal Hemoglobins Associated with Low Oxygen Affinity

Hemoglobin	Amino Acid Substitution	Oxygen Dissociation and Other Properties	Clinical Effect	Reference
Hb _{Seattle}	$\beta 70$ (E14) Ala→Asp	Decreased O ₂ affinity normal heme-heme interaction	Mild chronic anemia associated with reduced urinary erythropoietin; physiologic adaptation to more efficient oxygen release to tissues	104
Hb _{Kansas}	$\beta 102$ (G4) Asn→Thr	Very low O ₂ affinity, low heme-heme interaction, dissociates into dimers in ligand form	Cyanosis resulting from deoxyhemoglobin, mild anemia	187

are normal in cytochrome *b5* reductase deficiency; they are abnormal in hemoglobin M disease. In the case of toxic methemoglobinemia, cyanosis is generally of relatively recent origin, and a history of exposure to drug or toxin may usually be obtained; in hereditary methemoglobinemia, a history of lifelong cyanosis may usually be elicited.

OTHER DYSEMOGLOBINS

CARBON MONOXIDE AND CARBOXYHEMOGLOBIN

Carbon monoxide (CO) is a toxic, odorless, colorless, and tasteless gas. It can be unknowingly inhaled to dangerous levels with serious clinical implications when present in high concentration in the atmosphere.¹⁰⁷

Epidemiology

Acute CO intoxication is one of the most common causes of morbidity from poisoning in the United States. In the United States, CO poisoning results in approximately 50,000 emergency department visits per year,^{108,109} and approximately 500 accidental deaths as a result of CO poisoning occur annually, with the number of intentional CO-related deaths being five to 10 times higher.^{110,111} Primary sources of CO are home appliances, and the majority of exposures occur during the fall and winter months and during weather-related disasters.^{112,113} During warmer months, boating activities are another source of exposure.¹¹⁴ The death rate is highest among the elderly and can be attributed to delayed diagnosis because symptoms often resemble those of associated comorbidities.^{115,116} The exhaust produced by the typical home-use 5.5-kW generator contains as much CO as that of six idling automobiles.¹¹⁷

Chronic CO intoxication is commonly caused by cigarette smoking, which can increase the COHb level up to 15 percent. Houses with defective heating exhaust systems and vehicles that leak CO into the passenger compartment, either because of mechanical failure or driving with the rear hatch-door open, are the second most common cause of chronic CO exposure. Occupations that involve a high risk for CO intoxication include garage work with improper ventilation, toll booth attendants, tunnel workers, fire fighters, and workers exposed to paint remover, aerosol propellant, or organic solvents containing dichloromethane.¹¹⁸

Etiology and Pathogenesis

CO binds with high affinity to heme and with lesser affinities to myoglobin and cytochromes at the iron core, a site it shares with O₂.¹¹⁹

At equilibrium in physiologic conditions, CO affinity for hemoglobin is approximately 240 times greater than that of O₂. This very high equilibrium constant is the result of reaction kinetics. Contrary to popular belief, CO reacts more slowly than O₂ with the heme of hemoglobin. Once CO is bound to heme, its “off” rate is only 0.015 mol/L per second in contrast to 35 mol/L per second for O₂.¹¹⁹ This extraordinarily slow-release process produces a very high affinity constant of CO for heme and a life-threatening danger for individuals exposed to high levels of CO. Once two molecules of CO are bound to hemoglobin, the hemoglobin switches to the relaxed (R) state, which increases the affinity of hemoglobin for oxygen. As a consequence of this phenomenon, called the Darling–Roughton effect,⁸⁰ the hemoglobin O₂ affinity increases in parallel with increasing CO levels, making tissue delivery of oxygen more difficult.

In the absence of environmental CO, the blood of adults contains approximately 1 to 2 percent COHb. This represents approximately 80 percent of the total body CO, the remainder probably sequestered in myoglobin and other heme binding proteins. This CO is endogenously produced,¹²⁰ originating from the degradation of heme by the

rate-limiting heme oxygenase–cytochrome P450 complex, which produces CO and biliverdin. Caloric restriction, dehydration, infancy, and the genetic variations reported in Japanese and Native Americans generate higher endogenous levels of CO. Hemolytic anemia (Chap. 33), hematomas, and infection tend to increase CO production up to threefold. Fetuses and newborns have double the normal adult levels of COHb. Drugs such as diphenylhydantoin and phenobarbital, by inducing the cytochrome P450 complex, increase CO production. Normal adult level of COHb is less than 2 percent. Hemolysis can produce COHb levels of more than 2 percent. Levels more than 3 percent must have an exogenous origin, except for rare conditions as occur in carriers of abnormal hemoglobins such as Hb_{Zurich}. The affinity of Hb_{Zurich} for CO is approximately 65 times that of normal hemoglobin.¹²¹

Pregnant women and fetuses are particularly at risk¹²² because they already have higher levels of COHb. CO readily crosses the placenta, and the half-life of CO in the fetus is as much as five times longer than it is in the mother.¹²³ The O₂ affinity of fetal hemoglobin (HbF) is shifted to the left^{124,125} owing to its lack of 2,3-BPG binding, making the Darling–Roughton effect particularly pernicious. This is one of the reasons why cigarette smoking during pregnancy is hazardous to the fetus.

Clinical and Laboratory Features

CO poisoning is a clinical diagnosis that is confirmed by laboratory testing. Signs and symptoms consistent with CO poisoning in certain circumstances should raise the suspicion of CO intoxication. A higher index of suspicion should attend the simultaneous presentation of multiple patients from the same family or housing complex. The eight-wavelength pulse oximeter, Masimo Rad-57 (see paragraphs on “Laboratory features” of methemoglobinemia.) has been reported to be accurate in measuring COHb concentration in normal healthy volunteers,⁶⁹ as well as in emergency room patients.¹²⁶

Acute intoxication with CO rapidly affects the central and peripheral nervous systems and cardiopulmonary functions. Cerebral edema is common, as is impairment of the peripheral nervous system. CO induces increased capillary permeability in the lungs, resulting in acute pulmonary edema. Cardiac arrhythmias, generalized hypoxemia, and respiratory failure are the common causes of CO-related death. In survivors, considerable neuropsychological deficits might remain. In a prospective longitudinal study, approximately 45 percent of patients with CO poisoning had cognitive sequelae 6 weeks after poisoning.^{127,128} Acute CO intoxication in children¹²⁹ sometimes has unique symptomatology resembling gastroenteritis. Surviving children are more likely to have severe sequelae such as leukoencephalopathy and severe myocardial ischemia.¹³⁰

Chronic intoxication in adults might result in irritability, nausea, lethargy, headaches, and sometimes a flu-like condition. Higher COHb levels produce somnolence, palpitations, cardiomegaly, and hypertension, and could contribute to atherosclerosis. Chronic CO poisoning can produce erythrocytosis, the magnitude of which varies with the level of COHb. By increasing red cell production, chronic CO poisoning can mask the mild anemia of acquired or congenital hemolytic disorders.

Therapy, Course, and Prognosis

The most important step in the treatment for CO poisoning is prompt removal of patients from the source of CO, followed by administering 100 percent supplemental O₂ via a tight-fitting mask. The serum elimination half-life of CO is 5 hours when breathing room air and 30 minutes with O₂ therapy (100 percent O₂ at 3 atmospheres).¹²³

For mild to moderate cases of CO poisoning, which more often happen with chronic intoxication, removing the patient from the source of environmental CO is usually curative. If the COHb level is high, breathing 100 percent O₂ will increase the rate of CO removal.

Figure 50-3. S-nitrosohemoglobin (SNO-Hb) and hypoxic vasodilation. (Reproduced with permission from Parker C: SNO-Hb a Snow Job? *The Hematologist: ASH News and Reports*. 6:12;2009.)

In severe cases of CO poisoning, which more often occur with acute intoxication, after identification and removal of the source of CO, 100 percent O_2 should be administered, with cardiac monitoring. Endotracheal intubation should be done in any patient with impaired mental status, and other interventions should be dictated by the symptomatology.

Because of conflicting evidence, there is no absolute indication for the use of hyperbaric O_2 treatment for patients with CO poisoning. Hyperbaric O_2 might be indicated in patients who have obvious neurologic abnormalities, cardiac dysfunction, persistent symptoms despite normobaric O_2 , or metabolic acidosis.¹³¹ Hyperbaric O_2 has complications of its own, such as bronchial irritation and pulmonary edema, and should be reserved for exceptional cases of CO intoxication. Locations of hyperbaric chambers throughout the world and in the United States can be found at the Undersea and Hyperbaric Medical Society website (<http://www.uhms.org>) under "chamber directory."

Pregnant women exposed to CO are at particularly high risk. CO poisoning is especially dangerous to the fetus because CO readily crosses the placenta and the half-life of CO in the fetus is as much as five times longer than it is in the mother. For these reasons, treatment with hyperbaric O_2 should be carried out during pregnancy when the COHb levels exceed 15 percent. In a limited number of studies done on pregnant patients, hyperbaric O_2 does not seem to adversely affect the fetus.^{132,133}

NITRIC OXIDE AND NITRIC OXIDE HEMOGLOBINS

Physiology and Chemistry

NO, a soluble gas, is continuously synthesized in endothelial cells by isoforms of the NO synthase (NOS) enzyme. A functional NOS transfers electrons from NADPH to its heme center, where L-arginine is oxidized to L-citrulline and NO.¹³⁴ Vasodilation is caused by diffusion of NO into the smooth muscle cells, wherein NO binds avidly to the heme of soluble guanylyl cyclase, producing cyclic guanosine monophosphate

(cGMP), which activates cGMP-dependent protein kinases and ultimately produces smooth muscle relaxation.¹³⁴

Blood NO levels are set by the balance between the production of NO by NOS and the binding or scavenging of NO by the heme groups of erythrocyte hemoglobin. The half-life of NO in whole blood is extremely short, estimated to be 1.8 milliseconds.¹³⁵ The short half-life of NO greatly limits its diffusional distance in blood and only maintains NO as a paracrine vasoregulator.^{136,137} This does not explain how hemoglobin is capable of transducing NO bioactivity far from its location of formation.

Interaction of the red blood cells with NO is a complex phenomenon (Fig. 50-3). Two models have been proposed: (1) The first model, an S-nitrosohemoglobin (SNO-Hb)-dependent mechanism, proposes that NO binds to heme when the hemoglobin is in the T state (deoxygenated). In the oxygenated state, NO gets transferred from heme to a cysteine residue on the globin portion of hemoglobin, forming SNO-Hb.^{138,139} Nitric oxide is transported by red blood cells from the lungs to hypoxic tissues in a protected form as SNO-Hb, and is delivered in the hypoxic microvasculature at the same time as oxygen, coupling hemoglobin deoxygenation to vasodilation. (2) The second model is of deoxyhemoglobin-mediated nitrite reduction to NO.¹⁴⁰ In the blood, deoxygenated hemoglobin functions as the predominant nitrite reductase.¹⁴¹ Deoxygenated hemoglobin reacts with nitrite to form NO and methemoglobin and causes vasodilation along the physiological oxygen gradient. Although this reaction is experimentally associated with NO generation, kinetic analysis suggests that NO should not be able to escape inactivation in the erythrocyte.¹⁴² This inactivation or scavenging of NO is avoided by the formation of an intermediate species, that is, dinitrogen trioxide (N_2O_3). Products of the nitrite-hemoglobin reaction generate N_2O_3 via a novel reaction of NO and nitrite-bound methemoglobin.¹⁴³ N_2O_3 diffuses out of the red cell, later forms NO, and affects vasodilation and/or forms nitrosothiols (Fig. 50-4). According to this paradigm, nitrite, previously thought to be an inert end product of endogenous NO metabolism, is the main stable NO reservoir in blood and tissues.^{144,145} Nitrite is formed during normoxic conditions

Figure 50–4. Hemoglobin deoxygenation (purple) occurs in capillaries. Nitrite reacts with deoxyHb that is oxidized to MetHb and NO. The NO binds to hemes of deoxyHb, and also undergoes dioxygenation to form nitrate and MetHb from oxyHb. MetHb binds nitrite to form an adduct with some Fe(II)-NO₂⁻, that is, Hb-NO. This species reacts quickly with NO to form N₂O₃, which can diffuse out of the red cell forming NO and effecting vasodilation and/or forming nitrosothiols (SNOs). (Reproduced with permission from Basu S, et al: Catalytic generation of N2O3 by the concerted nitrite reductase and anhydrase activity of hemoglobin, *Nature Chemical Biology* 2007 Dec;3(12):785-794.)

and then is reduced to NO and N₂O₃ along the physiologic oxygen and pH gradient by the heme globins.¹⁴³

Cell free hemoglobin and red cell microparticles formed during hemolytic conditions and long storage of red blood cells (RBCs) lead to NO scavenging 1000 times faster than regular RBCs and to insufficient NO bioavailability.¹⁴⁶ Stored RBCs are also stored in acidic solution that also leads to a decrease in SNO-Hb levels. This has been further substantiated by the fact that renitrosylated RBCs lead to improved oxygen delivery in animal models.¹⁴⁷ This could explain the morbidity and mortality associated with stored RBCs. Moreover, underlying recipient endothelial dysfunction, for example, obesity or hypertension, can also induce increased RBC membrane damage in transfused blood, leading to increased microparticle formation and increased NO scavenging.^{148,149}

Pathophysiology and Potential Therapeutic Applications

Nitric oxide was long considered highly toxic. Exogenous administration of NO by inhalation activates cytosolic guanylate cyclase, increasing intracellular levels of cGMP, and resulting in relaxation of the smooth muscles in the pulmonary arteries.

Based on this observation, inhaled NO (iNO) has been used to manage the acute pulmonary hypertension seen in adult respiratory distress syndrome, sickle cell disease, and primary or secondary pulmonary hypertension. Even though NO lowers the pulmonary artery pressure and improves oxygenation in acute respiratory distress syndrome in both adults and children, it has not consistently resulted in an improvement in mortality.

At present, prolonged administration of iNO is not considered as first-line therapy for pulmonary artery hypertension and instead is used only for vasoreactivity testing in these patients.¹⁵⁰ iNO has beneficial effects in animal models, as well as in preliminary human trials of acute vasoocclusive crisis and chest syndrome associated with sickle cell disease.^{151–153} Some animal data suggest beneficial effects of iNO therapy in the setting of ischemia–reperfusion injury (lung, heart, and intestine).¹⁵⁴ However, iNO is also associated with multiple side effects, such as methemoglobinemia,¹⁵⁵ left-heart failure,¹⁵⁶ renal insufficiency,¹⁵⁷ and a “rebound” increase in pulmonary artery pressure upon discontinuation of iNO that may result in cardiovascular collapse.¹⁵⁸

Direct repletion of S-nitrosothiol in the lung and blood has the potential to avoid toxicities related to iNO. In a porcine model of acute lung injury, inhaled ethyl nitrite, but not iNO, efficiently repleted lung SNO-Hb, lowered pulmonary vascular resistance, improved oxygenation dose-dependently, and had a protective effect against a decline in cardiac output.¹⁵⁹

In humans, newborns with persistent pulmonary hypertension showed improved oxygenation and hemodynamics following ethyl

nitrite inhalation.¹⁶⁰ Use of cell free hemoglobin is associated with vasoconstriction and subsequent development of hypertension. Increased vascular resistance and vasoconstriction has been shown to be mediated mainly by the scavenging of NO because of the high affinity of free hemoglobin for NO.^{161,162}

CHAPTER 51

FRAGMENTATION HEMOLYTIC ANEMIA

Kelty R. Baker and Joel Moake

SUMMARY

Erythrocyte fragmentation and hemolysis occur when red cells are forced at high shear stress through partial vascular occlusions or over abnormal vascular surfaces. “Split” red cells, or schistocytes, are prominent on blood films under these conditions, and considerable quantities of lactate dehydrogenase are released into the blood from traumatized red cells. In the high-flow (high-shear) microvascular (arteriolar/capillary) or arterial circulation, partial vascular obstructions are caused by platelet aggregates in the systemic microvasculature during episodes of thrombotic thrombocytopenic purpura by platelet-fibrin thrombi in the renal microvasculature in the hemolytic uremic syndrome; and by malfunction of a cardiac prosthetic valve in valve-related hemolysis. Less-extensive red cell fragmentation, hemolysis, and schistocytosis occur under conditions of more moderate vascular occlusion or endothelial surface abnormalities, sometimes under conditions of lower shear stress. These latter entities include excessive platelet aggregation, fibrin polymer formation, and secondary fibrinolysis in the arterial or venous microcirculation (disseminated intravascular coagulation); in the placental vasculature in preeclampsia/eclampsia and the syndrome of hemolysis, elevated liver enzymes and low platelets (HELLP) in march hemoglobinuria; and in giant cavernous hemangiomas (the Kasabach-Merritt phenomenon).

● PREECLAMPSIA/ECLAMPSIA AND HELLP SYNDROME

DEFINITION AND HISTORY

A life-threatening condition of pregnancy denoted by eclampsia, hemolysis, and thrombocytopenia was first noted in the German literature by Stanke in 1922.¹ Subsequently, Pritchard and coworkers described three cases in English and suggested that an immunologic process might account for both the preeclampsia or eclampsia and the hematologic abnormalities.²

Acronyms and Abbreviations: ADAMTS13, a disintegrin and metalloproteinase with thrombospondin domain 13; ALT, alanine transaminase; aPTT, activated partial thromboplastin time; AST, aspartic acid transaminase; AT, antithrombin; DIC, disseminated intravascular coagulation; HELLP, hemolysis, elevated liver enzymes, and low platelet count; LDH, lactate dehydrogenase; MAHA, microangiopathic hemolytic anemia; NO, nitrous oxide; PGF, placental growth factor; PGI₂, prostaglandin I₂; PT, prothrombin time; PTT, partial thromboplastin time; sEng, soluble endoglin; sFlt-1, soluble form of fms-like tyrosine kinase 1; sVEGFR-1, soluble vascular endothelial growth factor receptor-1; TGF- β , transforming growth factor- β ; TTP, thrombotic thrombocytopenic purpura; VEGF, vascular endothelial growth factor; VWF, von Willebrand factor.

Although initially known as edema-proteinuria-hypertension gestosis type B,³ a catchier phrase, HELLP syndrome (H for hemolysis, EL for elevated liver function tests, and LP for low platelet counts), was later applied by Louis Weinstein in 1982.⁴

EPIDEMIOLOGY

HELLP syndrome occurs in approximately 0.5 percent of pregnancies overall,⁵ in 4 to 12 percent of those complicated by preeclampsia (hypertension + proteinuria), and in 30 to 50 percent of those complicated by eclampsia (hypertension + proteinuria + seizures); however, approximately 15 percent of patients ultimately diagnosed with HELLP syndrome present with neither hypertension nor proteinuria.⁶ Two-thirds of HELLP patients are diagnosed antepartum, usually between 27 and 37 weeks. The remaining one-third are diagnosed in the postpartum period, from a few to 48 hours following delivery (occasionally as long as 6 days).^{7,8} Risk factors for HELLP syndrome include European ancestry, multiparity, older maternal age (older than age 34 years), and a personal or familial history of the disorder.⁵ Although the presence of homozygosity for the 677 (C→T) polymorphism of the methylenetetrahydrofolate reductase gene may be a modest risk factor for the development of preeclampsia, this weak association does not exist for HELLP syndrome.⁹ Whether or not the factor V Leiden or prothrombin 20210 gene mutations are risk factors for HELLP syndrome remains controversial.^{10–12}

ETIOLOGY AND PATHOGENESIS

A developing embryo must acquire a supply of maternal blood to survive. During a normal pregnancy, the first wave of trophoblastic invasion into the decidua occurs at 10 to 12 days. This is followed by a second wave at 16 to 22 weeks, when these specialized placental epithelial cells replace the endothelium of the uterine spiral arteries and intercalate within the muscular tunica, increasing the vessels' diameters and decreasing their resistance. As a result, the spiral arteries are remodeled into unique hybrid vessels composed of fetal and maternal cells, and the vasculature is converted into a high-flow–low-resistance system resistant to vasoconstrictors circulating in the maternal blood.¹³ In a preeclamptic pregnancy, the second wave fails to penetrate adequately the spiral arteries of the uterus, perhaps as a result of reduced placental expression of syncytin and subsequent altered cell fusion processes during placentogenesis.¹⁴ The resultant poorly perfused, hypoxic placenta then releases the extracellular domain (soluble) form of fms-like tyrosine kinase 1 (sFLT-1), also known as soluble vascular endothelial growth factor receptor-1 (sVEGF receptor-1, or sVEGFR-1). sVEGFR-1 functions as an antiangiogenic protein because it binds to vascular endothelial growth factor (VEGF) and placental growth factor (PGF), and prevents their interaction with endothelial cell receptors. The result is glomerular endothelial cell and placental dysfunction.^{15–17} Direct and indirect sequelae include increased vascular tone, hypertension, proteinuria, enhanced platelet activation and aggregation, and decreased levels of the vasodilators prostaglandin I₂ (PGI₂) and nitrous oxide (NO).^{5,17} Concurrent activation of the coagulation cascade results in platelet-fibrin deposition in the capillaries, multiorgan microvascular injury, microangiopathic hemolytic anemia, elevated liver enzymes because of hepatic necrosis, and thrombocytopenia because of peripheral consumption of platelets.⁵

Another antiangiogenic molecule, a soluble form of endoglin (sEng), also increases in patient serum during early and severe preeclampsia.¹⁸ Endoglin is part of the transforming growth factor- β (TGF- β) complex, and is expressed on vascular endothelial cells and syncytiotrophoblasts. The shed extracellular domain of endoglin, sEng, is

capable of binding to and inactivating the proangiogenic growth factors, TGF- β_1 and TGF- β_3 . The presence of elevated serum levels of both sFLT-1 (sVEGFR-1) and sEng may be associated with the progression of preeclampsia to HELLP.^{17,18}

CLINICAL FEATURES

Ninety percent of patients with HELLP syndrome present with malaise and right upper quadrant or epigastric pain. Between 45 and 86 percent have nausea or vomiting, 55 to 67 percent have edema, 31 to 50 percent have headache, and a smaller percentage complain of visual changes. Fever is not typically seen. Although hypertension is found in 85 percent of affected patients, 15 percent of those with HELLP syndrome do not develop either hypertension or proteinuria.⁶

LABORATORY FEATURES

There is no consensus regarding the laboratory criteria necessary to diagnose HELLP syndrome, so clinical judgment in conjunction with judicious interpretation of a variety of laboratory tests constitute the diagnostic standard. In 54 to 86 percent of patients, the blood film has schistocytes, helmet cells, and burr cells consistent with microangiopathic hemolytic anemia. Reticulocytosis can be present. Low haptoglobin levels are both sensitive (83 percent) and specific (96 percent) for confirming the presence of hemolysis, and return to normal within 24 to 30 hours postpartum.⁶

Lactate dehydrogenase (LDH) levels are usually above normal. The ratio of LDH-5 (an isoenzyme found specifically in the liver) to total LDH is elevated in proportion to the severity of HELLP. The high LDH seen in HELLP is most likely the result, principally, of liver damage rather than hemolysis. Serum levels of aspartic acid transaminase (AST) and alanine transaminase (ALT) can be more than 100 times normal, whereas alkaline phosphatase values are typically only about twice normal and total bilirubin ranges between 1.2 and 5.0 mg/dL. Liver enzymes usually return to normal within 3 to 5 days postpartum.⁶

The degree of thrombocytopenia has been used in a classification system to predict maternal morbidity and mortality, the rapidity of postpartum recovery, the risk of disease recurrence, and perinatal outcome. This *Mississippi triple-class system* places those patients with platelet counts less than $50 \times 10^9/L$ in class 1 (approximately 13 percent incidence of bleeding); those with platelet counts between 50 and $100 \times 10^9/L$ in class 2 (approximately 8 percent incidence of bleeding); and those with a platelet count greater than $100 \times 10^9/L$ in class 3 (no increased bleeding risk). Patients with class 1 HELLP syndrome suffer the highest incidence of perinatal morbidity and mortality, and have the most protracted recovery periods postpartum.¹⁹ There is a direct correlation between the extent of thrombocytopenia and measurements of liver function,²⁰ but the same cannot be said for the severity of associated hepatic histopathologic changes.²¹ If a marrow aspiration and biopsy are performed, abundant megakaryocytes are found consistent with a consumptive thrombocytopenia causing reduction of the normal platelet life span of approximately 10 days to 3 to 5 days.¹⁹ The platelet count nadir occurs 23 to 29 hours postpartum, with subsequent normalization within 6 to 11 days.⁷

The prothrombin time (PT) and activated partial thromboplastin time (aPTT) are usually within normal limits, although one report cited a prolonged aPTT in 50 percent of patients.²² Although low fibrinogen levels are inconsistently found, other measures of increased coagulation and secondary fibrinolysis may be present. These include decreased protein C and antithrombin III (AT III) levels, and increased D-dimer and thrombin-AT III values. von Willebrand factor (VWF) antigen levels increase in proportion to the severity of the disease, reflecting the extent

of endothelial damage; however, no unusually large VWF multimers are present in plasma²³ and ADAMTS13 (a disintegrin and metalloproteinase with thrombospondin domains-13) levels are within a broad normal range (ADAMTS13 normally declines moderately during pregnancy).^{24,25} This is in contrast to the severe deficiency of ADAMTS13 in familial and autoantibody-mediated types of thrombotic thrombocytopenic purpura (TTP).²⁶ Unlike TTP, the thrombi found in organs involved in the HELLP syndrome contain increased amounts of fibrin and low levels of VWF.²³

In patients with severe liver involvement, hepatic ultrasonography shows large, irregular, well-demarcated (or “geographical”) areas of increased echogenicity.²⁷ Liver biopsy shows periportal or focal necrosis, platelet-fibrin deposits in the sinusoids, and vascular microthrombi. As the disease progresses, large areas of necrosis can coalesce and dissect into the liver capsule. This produces a subcapsular hematoma and the risk of hepatic rupture.⁵

DIFFERENTIAL DIAGNOSIS

Other complications of pregnancy that can be confused with HELLP include TTP²⁸ and the hemolytic uremic syndrome, sepsis, disseminated intravascular coagulation (DIC), connective tissue disease, antiphospholipid antibody syndrome, and acute fatty liver of pregnancy. This latter entity is also seen in the last trimester or postpartum and presents with thrombocytopenia and right upper quadrant pain, but the levels of AST and ALT only rise to 1 to 5 times normal and the PT and partial thromboplastin time (PTT) are both prolonged. Oil-red-O staining of liver biopsies demonstrates fat in the cytoplasm of centrilobular hepatocytes, and routine stains show inflammation and patchy hepatocellular necrosis as a result of the HELLP syndrome. Because it causes right upper quadrant pain and nausea, HELLP has also been misdiagnosed as viral hepatitis, biliary colic, esophageal reflux, cholecystitis, and gastric cancer. Conversely, other conditions misdiagnosed as HELLP syndrome include cardiomyopathy, dissecting aortic aneurysm, acute cocaine intoxication, essential hypertension and renal disease, and alcoholic liver disease.¹⁹

THERAPY

Supportive care of HELLP includes intravenous administration of magnesium sulfate to control hypertension and prevent eclamptic seizures, management of fluids and electrolytes, judicious transfusion of blood products, stimulation of fetal lung maturation with beclomethasone, and delivery of the fetus as soon as possible.¹⁹ Indications for delivery include a severe disease presentation, maternal DIC, fetal distress, and a gestational age greater than 32 weeks with evidence of lung maturity.⁶ Cesarean section under general anesthesia is used in 60 to 97 percent of cases, but vaginal delivery after induction can be attempted if the fetus is older than 32 weeks of age and the mother’s cervical anatomy is favorable. Postpartum curettage is helpful in lowering the mean arterial pressure and increasing the urine output and platelet count. Transfusion therapy with packed red cells, platelets, or fresh-frozen plasma is indicated in cases complicated by severe anemia or bleeding because of coagulopathy.

Although previously thought to be beneficial based upon the results of observational studies and small randomized trials, the use of dexamethasone has fallen out of favor after large randomized trials found that it didn’t reduce the duration of hospitalization, amount of blood products transfused, maternal complications, or time to normalization of laboratory abnormalities.²⁹

Plasma exchange cannot arrest or reverse HELLP syndrome when used antepartum, but may minimize hemorrhage and morbidity when

used peripartum. It can also be tried postpartum in the 5 percent of patients who fail to improve within 72 to 96 hours of delivery. These women are more likely to be younger than 20 years of age or nulliparous.⁷ Whether or not plasma exchange can effectively lower circulating levels of sVEGF and/or sEng is not known. Liver transplantation may be necessary in occasional patients with HELLP complicated by large hematomas or total hepatic necrosis. It is not yet known if replacement with some (possibly modified) form of VEGF and/or TGF- β may have future therapeutic use in preeclampsia or HELLP. A single case report describes the successful use of eculizumab to prolong by 17 days a pregnancy affected by severe HELLP, without associated maternal or fetal morbidity or mortality.³⁰

COURSE AND PROGNOSIS

Most patients stabilize within 24 to 48 hours following delivery; however, maternal death still occurs in 3 to 5 percent even with best supportive care. Mortality rates as high as 25 percent were reported prior to 1980. Events leading to maternal death include cerebral hemorrhage, cardiopulmonary arrest, DIC, adult respiratory distress syndrome, and hypoxic ischemic encephalopathy.⁵ Other complications include infection, placenta abruptio, postpartum hemorrhage, intraabdominal bleeding, and subcapsular liver hematomas with resultant rupture (a fatal event in 50 percent of those in whom it occurs).⁶ The latter patients complain of right-sided shoulder pain and are found to be in shock with ascites or pleural effusions. The hematoma is usually present in the anterior superior portion of the right lobe of the liver.⁵ If the liver remains intact when discovered, abdominal palpation, seizures, and emesis should be avoided or prevented. Emergency surgery is required for hepatic artery embolization or ligation, hepatic lobectomy, or even liver transplantation in patients with total hepatic necrosis.^{5,19}

Renal complications of HELLP include acute renal failure, hyponatremia, and nephrogenic diabetes insipidus as a result of impaired hepatic metabolism of vasopressinase and resultant “resistance to vasopressin” (antidiuretic hormone). Pulmonary complications of HELLP include pleural effusions, pulmonary edema, and adult respiratory distress syndrome. Neurologic sequelae of HELLP not mentioned above include retinal detachment, postictal cortical blindness, and hypoglycemic coma.³¹

Fetal morbidity and mortality are between 9 and 24 percent.⁶ Complications arise as a result of prematurity, placental abruption, and intrauterine asphyxia. Intrauterine growth retardation is seen in 39 percent of infants. One-third of all babies born to mothers with HELLP have thrombocytopenia, but intraventricular hemorrhage is seen in only 4 percent of thrombocytopenic infants.³²

HELLP syndrome complicates 2 to 5 percent of all pregnancies,⁵ and can recur in as many as 27 percent of those affected during subsequent pregnancies.³³ Other hypertensive disorders of pregnancy (preeclampsia or pregnancy-induced hypertension) are also relatively common in future pregnancies (27 percent of second and subsequent pregnancies).³⁴ Women who recover from preeclampsia/HELLP may also be more likely to develop subsequent hypertension and cardiovascular disorders, possibly because of some persistent abnormal balance between proangiogenic and antiangiogenic factors.¹⁷

DISSEMINATED MALIGNANCY

DEFINITION AND HISTORY

The association between widespread malignancy and hemolytic anemia associated with pathologic changes in small blood vessels was first noted by Brain and colleagues in 1962.³⁵

EPIDEMIOLOGY

Cancer-associated microangiopathic hemolytic anemia (MAHA) has been described in a wide variety of malignancies (Table 51-1). MAHA is more likely to be associated with metastatic malignant disease than with localized cancers or benign tumors.³⁶ Approximately 80 percent of the tumors are mucinous adenocarcinomas of either the stomach (55 percent), breast (13 percent), or lung (10 percent). The median age at diagnosis is 50 years, with a slight male predominance.³⁷

ETIOLOGY AND PATHOGENESIS

MAHA as a result of malignancy can be caused by either of two distinct mechanisms: (1) DIC with intravascular occlusions (often partial) of small vessels by platelet-fibrin thrombi; or (2) intravascular tumor emboli.^{35,38} In the first mechanism,¹ intravascular activation of coagulation may occur from excessive exposure of tissue factor on phagocytes, activated endothelial cells, or tumor cells. Alternatively, a protease in the mucin secreted by adenocarcinomas may directly activate factor X.³⁹ Subsequent activation of coagulation factors, thrombin generation, fibrin polymer deposition, and platelet aggregation result in the formation of intravascular platelet-fibrin thrombi, and the shearing of red cells attempting to maneuver past the partial platelet-fibrin occlusions in the high-flow microvasculature. Also, circulating carcinoma mucins may interact with leukocyte L-selectin and platelet P-selectin, causing the rapid generation of platelet-rich microthrombi.⁴⁰ In the second mechanism,² intravascular tumor emboli partially occlude small vessels, mechanically or chemically disrupt the endothelium and promote platelet adherence to exposed subendothelium, coagulation activation and fibrin polymer formation, intimal hyperplasia, and vascular hypertrophy.^{35,37,38}

LABORATORY FEATURES

Patients with cancer-associated DIC/MAHA present with moderate-to-severe anemia. The blood film reveals schistocytes (accounting for approximately 5 to 21 percent of the red cells), burr cells, microspherocytes, reticulocytes/polychromasia, and nucleated red cells.³⁸ Although the reticulocyte count can be high, it is an unreliable measure of hemolysis because extensive replacement of the marrow by metastatic tumor (Chap. 45) may prevent the reticulocytosis expected with MAHA. Other indicators of hemolysis that could be more reliable include increased levels of serum unconjugated bilirubin and LDH, the presence of plasma hemoglobin, and elevated urine urobilinogen and hemoglobinuria (as $\alpha\beta$ dimers).³⁷ Absent or low levels of haptoglobin may also be found; however, haptoglobin is an acute-phase reactant that may be increased in malignancy.³⁸ The direct antiglobulin test is negative.^{37,41}

Additional findings in MAHA include thrombocytopenia, with mean platelet counts of approximately $50 \times 10^9/L$ (range: 3 to $225 \times 10^9/L$),³⁷ caused by a shortened platelet life span without demonstrable sequestration of platelets in the liver or spleen. Some patients with malignant tumors, however, may have preexisting thrombocytosis, and so superimposed MAHA may reduce the platelet count only toward “normal” values.³⁸ A normal-to-high white cell count with immature myeloid precursors may also be seen.^{37,38,41} Leukoerythroblastosis caused by marrow invasion (Chap. 45), along with MAHA, is highly suggestive of metastatic malignancy.³⁸ Marrow aspiration and biopsy will demonstrate erythroid hyperplasia, normal-to-high numbers of megakaryocytes, and (in 55 percent of patients) cancer cells.⁴¹

Additional laboratory evidence of DIC has been reported in approximately 50 percent of patients with MAHA secondary to malignancy. Findings include reduced levels of fibrinogen (mean: 177 g/dL; range: 8 to 490 mg/dL), increased levels of D-dimers (or fibrin degradation products), and prolonged prothrombin and thrombin times.³⁷ In the early phase of DIC, aPTTs may be shortened (e.g., to <23 seconds).^{42–45} It is not known if shortened aPTT values reflect the presence of activated coagulation factors in the plasma, consumption of coagulation inhibitor proteins faster than their production by hepatic cells (e.g., protein C, protein S, AT, tissue factor pathway inhibitor), or the presence in plasma of a cysteine protease capable of directly activating factor X.³⁹ Cancer-related DIC has been reported to be associated with a deficiency of the VWF-cleaving protease, ADAMTS13.⁴⁶ Although this was disputed by some investigators,⁴⁷ ADAMTS13 levels gradually decrease in DIC patients with poor survival rates,⁴⁸ perhaps as a result of ADAMTS13 consumption onto the long VWF multimeric strings released from cytokine-stimulated endothelial cells.⁴⁹

DIFFERENTIAL DIAGNOSIS

The most common cause of anemia in malignancy is anemia of chronic disease (Chap. 37). Other diagnostic considerations include blood loss, myelophthisis as a result of disease metastatic to the marrow (Chap. 45), DIC/MAHA (Chap. 129), and autoimmune hemolytic anemia (Chap. 54). The latter is more often found with lymphoproliferative disease (Chap. 95) but is occasionally seen with carcinoma of the stomach, colon, breast, and cervix.⁵⁸ The treatment of cancer can also induce anemia by causing myelosuppression, oxidative hemolysis (doxorubicin, pentostatin), autoimmune hemolysis (cisplatin, chlorambucil, cyclophosphamide, melphalan, teniposide, methotrexate), or thrombotic microangiopathic anemia (mitomycin C, cisplatin, gemcitabine, and targeted cancer agents⁵⁰).

THERAPY

Heparin, glucocorticoids, dipyridamole, indomethacin, and ϵ -aminocaproic acid have all been tried without success for malignancy-associated DIC/MAHA. Plasma infusion and platelet transfusions, sometimes with

additional cryoprecipitate containing fibrinogen, may be useful during bleeding episodes associated with prolonged PT and aPTT, low fibrinogen levels, and thrombocytopenia. Control of the underlying metastatic malignancy, if achievable, has been beneficial.⁵¹

COURSE AND PROGNOSIS

MAHA caused by cancer is usually a preterminal event. Life expectancy following diagnosis is 2 to 150 days, with a mean of 21 days.^{37,38}

HEART VALVE HEMOLYSIS

DEFINITION AND HISTORY

Anemia arising after cardiac valve replacement was first described in 1954,⁵⁹ soon after corrective valvular surgery became possible. This anemia was subsequently shown to be caused by erythrocyte shearing and fragmentation as the red cells traversed the turbulent flow through or around the prosthetic valve.⁶⁰ Since then, prevention of irreversible red cell injury has been a goal when designing new prostheses; as a result, the incidence of significant valve-associated hemolysis has declined from 5 to 15 percent in the 1960s and 1970s^{61,62} to less than 1 percent with newer-generation prostheses.⁶³ However, compensated hemolysis can occur with any type of valve prosthesis and can be detected in almost every patient when assayed using appropriate methods.^{61,64,65} Additionally, intravascular hemolysis can be seen following mitral valve repair⁶⁶ and in unoperated patients with native valvular disease⁶¹ and hypertrophic obstructive cardiomyopathy.⁶⁷

EPIDEMIOLOGY

A variety of factors can increase the chance of valvular hemolysis: the presence of central or paravalvular regurgitation,^{62,68} placement of small valve prostheses with resultant high transvalvular pressure gradients,⁶² and regurgitation because of bioprosthetic valve failure, seen especially once the valve is more than 10 to 15 years old.⁶⁸ Patients with ball-and-cage valves,⁶⁴ bileaflet valves versus tilting disk valves,⁶⁹ mechanical valve prostheses versus xenograft tissue prostheses,⁷⁰ and double-valve as compared to single-valve replacement,⁶⁹ are more likely to experience clinically significant hemolysis. Some studies have found no difference in the degree of hemolysis when comparing aortic and mitral valve prostheses,^{65,69} whereas others have found that the aortic location is associated with slightly greater hemolysis than the mitral location.^{71–73}

ETIOLOGY AND PATHOGENESIS

Valve-related hemolysis occurs when red cells are exposed to the shearing stresses created by turbulent blood flow through and around a valve prosthesis, impaction against foreign surfaces or cardiac structures such as the wall of the atrial appendage,⁶⁸ or large pressure fluctuations between cardiac chambers. A transvalvular pressure gradient of more than 50 torr can generate shearing forces exceeding 4000 dynes/cm², more than the 3000 dynes/cm² usually needed to cause red cell fragmentation.⁷⁴ In a study looking at malfunctioning mitral valve prostheses, sophisticated computer modeling using transesophageal echocardiography demonstrated a maximal shear value of 6000 dynes/cm² when the regurgitant jet was divided by a solid structure such as a loose suture or dehiscence annuloplasty ring. A maximal shear rate of 4500 dynes/cm² was found when the regurgitant jet was suddenly decelerated by a solid structure like the left atrial appendage, or when the blood was regurgitated through a small orifice (<2 mm in diameter) such as a leaflet perforation or a paravalvular leak.⁶⁸ Lack of endothelialization of the prosthetic ring may contribute to the severity of hemolysis following valve repair or replacement, but it is unclear if this is primary or secondary to the high-velocity jet of blood preventing fibrous incorporation of the prosthetic materials.^{68,75}

Figure 51-1. Two cases of fragmentation hemolytic anemia as a result of heart valve hemolysis. The red cell shape abnormalities are varied and characteristic of fragmentation hemolysis, although they are not specific for the cause. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

Similarly, lack of endothelialization of the Teflon patch can result in clinically significant hemolysis necessitating reoperation following repair of a ventricular septal defect.⁷⁶ These sorts of surface interactions appear to be more important at lower shear-stress values (<1500 dynes/cm²) when the amount of hemolysis depends more directly on the area of the contact surface and the time of exposure.⁷⁷ Additionally, excessive wear of the cloth that covers caged-ball prostheses, such as the Starr-Edwards valve, can cause ballooning of the material into the blood jet, with resultant turbulence and hemolysis.⁷⁸ A modified Blalock-Taussig shunt also has been reported to cause hemolytic anemia.⁷⁹

CLINICAL FEATURES

Patients with valve-induced hemolysis can present with symptoms caused by anemia or congestive heart failure, pallor, icterus, and dark urine (described variously as red, brown, or black). Urine excreted during periods of physical activity may be darker than that excreted at rest.⁸⁰ Similarly, hemolysis can be exacerbated by supraventricular tachycardia or other tachyarrhythmias and regress once normal sinus rhythm is restored.⁸¹ Anecdotally, some patients with severe valve hemolysis complain of chest pain subsequently proven to be caused by esophageal spasm, and one can speculate that the culprit is NO depletion such as that reported in paroxysmal nocturnal hemoglobinuria.⁸²

LABORATORY FEATURES

Helpful laboratory studies include review of the blood film, which will reveal moderate poikilocytosis, schistocytosis, and polychromasia

(Fig. 51-1). The red cells are usually normochromic and normocytic but can occasionally be hypochromic and microcytic as a result of long-standing urinary iron loss⁶¹ and increased erythropoiesis caused by ongoing hemolysis.⁶² The reticulocyte count, urine hemosiderin, plasma hemoglobin, and serum levels of total and indirect bilirubin, and LDH can be elevated, whereas the serum haptoglobin will be depressed. Both the number of schistocytes in the blood^{61,64} and the elevation of LDH^{64,65,83,84} correlate with the severity of hemolysis. Hemoglobinuria is usually seen only in those with particularly severe hemolysis and high LDH levels. There is no correlation between the severity of hemolysis and bilirubin levels, however, and whether the reticulocyte count is helpful in assessing the severity of hemolysis is controversial.^{64,65} The aforementioned laboratory tests can be used as a means to determine the degree of hemolysis and to help guide management (Table 51-2).⁶⁴

Red cell labeling studies demonstrate that erythrocyte life span is markedly shortened to between 6 and 9 days.^{76,80} Measurement of erythrocyte creatine, a relatively simple but not yet widely available assay, can be performed in lieu of red cell labeling studies. Young erythrocytes contain much higher levels of creatine than older cells. Thus, an increase in erythrocyte creatine represents shortened red cell survival and is significantly correlated with total peak flow velocity across the valve and the severity of any associated hemolysis.⁸⁵ When performed, marrow aspiration will be remarkable for erythroid hyperplasia.^{75,80} As a result of hemosiderin deposition, magnetic resonance imaging of the kidneys will reveal reduced signal intensity of the renal cortex compared with the medulla on T1- and T2-weighted images, both with and without gadolinium enhancement.⁸⁶

TABLE 51-2. Severity of Prosthetic Valve Hemolysis

	Mild	Moderate	Severe
Hemosiderinuria	Present	Present	Marked
Hemoglobinuria	Absent	Absent	Absent
Schistocytosis	<1%	>1%	>>1%
Reticulocytosis	<5%	>5%	>>5%
Haptoglobin	Decreased	Absent	Absent
LDH	<500 U/L	>500 U/L	>>500 U/L

LDH, lactate dehydrogenase.

Data from Eyster E, Rothchild J, Mychajliw O: Chronic intravascular hemolysis after aortic valve replacement, *Circulation* 1971 Oct;44(4):657-665.

DIFFERENTIAL DIAGNOSIS

Factors that can promote valve-associated hemolysis or worsen the resultant anemia include iron deficiency (Chap. 43), because anemia increases cardiac output and shear stress and iron-poor red cells are more fragile than normal; folate deficiency (Chap. 41) arising from increased erythropoiesis; anemia of chronic disease because of endocarditis; anticoagulant-induced gastrointestinal hemorrhage (Chaps. 37, 133, and 134); and increased cardiac output as a consequence of strenuous physical exertion.⁸²

THERAPY

Appropriate therapy for hemolytic anemia arising from valvular dysfunction consists of iron and folate replacement (if deficient) and surgical repair or replacement of the malfunctioning prosthesis (if indicated).⁸⁷ Poor surgical candidates with perivalvular leaks may benefit from percutaneous closure with an Amplatzer occluder device.⁸⁸ Adjunctive measures to be tried include β -blockade to slow the velocity of the circulation,⁸⁹ erythropoietin therapy to stimulate erythropoiesis further,⁹⁰ and pentoxifylline therapy to increase the deformability of red cells.⁹¹

Although some authors have not found the use of pentoxifylline to be beneficial,⁹² several case reports have described amelioration of valve-related hemolysis and resultant decreased need for red cell transfusion in patients receiving pentoxifylline.^{93–95} A prospective study of 40 individuals with double (mitral and aortic) valve replacements randomized patients to receive either no treatment or pentoxifylline 400 mg orally three times daily for 120 days. The group who received pentoxifylline had significantly higher hemoglobin and haptoglobin levels, and significantly lower LDH, total and indirect bilirubin, and corrected reticulocyte levels, after 4 months of treatment. Of the nine patients with severe hemolysis (LDH >1500 U/L), six individuals had amelioration or complete resolution of their disease, while three patients' hemolysis persisted unchecked, suggesting that pentoxifylline therapy is beneficial in more than 60 percent of those with valve-related hemolysis.⁹⁶

Between 15 and 30 percent of patients will develop black pigment gallstones following valve surgery, the majority occurring within 6 months of the procedure. Whether this is a result of acute hemolysis associated with use of the heart–lung machine⁹⁷ or chronic hemolysis because of the valve replacement itself^{98,99} is uncertain; however, therapy with ursodeoxycholic acid 600 mg daily beginning 1 week before surgery significantly decreases the incidence of gallstone formation from approximately 29 percent in those who were left untreated to approximately 8 percent ($P < 0.01$).¹⁰⁰

COURSE AND PROGNOSIS

Evidence of hemolysis can be seen within days⁶⁰ or weeks^{64,76,80} following valve surgery. If reoperation is required, reported mortality rates range between 0 and 6 percent,^{75,101} and hemolytic anemia can occasionally recur.^{60,101}

OTHER CAUSES OF NONIMMUNE HEMOLYSIS

MARCH HEMOGLOBINURIA

In 1881, Fleischer described a German soldier in whom hemoglobinuria was brought on by marching.¹⁰² Although usually reported in young males, no doubt explained by their more frequent participation in severe and prolonged exertion, it can also be seen in women.^{103,104} The presenting complaint is passage of dark urine immediately following

physical exertion in the upright position, occasionally accompanied by nausea, abdominal cramps, aching in the back or legs, a “stitch in the side,” or a burning feeling in the soles of the feet. Physical examination is usually unrevealing, although hepatosplenomegaly and transient jaundice have been rarely reported.¹⁰⁵

Davidson proved definitively in 1969 that march hemoglobinuria is caused by red cell trauma within the vessels of the soles of the feet, and its severity is influenced by the hardness of the running surface, the distance run, the heaviness of the athlete's stride, and the protective adequacy of his footwear.¹⁰⁵ In addition, he showed that the condition could be prevented by using padded insoles, a finding later substantiated by other authors.^{106,107} Hemoglobinuria has also been seen following other types of trauma in activities as diverse as repetitive slapping of the forehead,¹⁰⁸ karate exercises,¹⁰⁹ basketball followed by congo drum playing,¹¹⁰ and kendo (a Japanese martial art where heavily padded combatants strike each other repeatedly with bamboo swords).¹⁰³

Because the estimated quantity of blood hemolyzed in an average paroxysm is only 6 to 40 mL, anemia is uncommon and if present is usually mild¹⁰⁵; however repeated episodes can cause iron deficiency, which may lead to or accentuate anemia (Chap. 43). Morphologic evidence of red cell damage is not seen, although one patient was found to have poikilocytes and occasional “four-leaf clover” cells after exercise.¹¹¹ Renal damage is also not commonly seen, but cases of acute tubular necrosis and resultant acute renal insufficiency have been described.^{112–115}

KASABACH-MERRITT PHENOMENON

First described in 1940,¹¹⁶ the Kasabach-Merritt phenomenon is a syndrome that usually develops in early childhood, and is characterized by thrombocytopenia, MAHA, consumptive coagulopathy, and hypofibrinogenemia caused by an enlarging kaposiform hemangioendothelioma or tufted angioma.¹¹⁷ Kaposiform hemangioendotheliomas are highly aggressive, vascular tumors that occur equally in males and females, and show little tendency to resolve spontaneously. They can be locally invasive but have never been reported to metastasize.¹¹⁸ Complications can include hemothorax or pericardial effusion.^{118,119} It is postulated that endothelial cell abnormalities and vascular stasis lead to activation of platelets and the coagulation cascade within the tumor's vessels, with subsequent depletion of both platelets and clotting factors. Microangiopathic hemolytic anemia results from mechanical trauma sustained by the erythrocytes traversing the tumor's abnormal, partially thrombosed vascular channels.¹²⁰

Although numerous therapies are used, the mortality rate of Kasabach-Merritt phenomenon can be as high as 30 percent.¹²¹ Even though surgical resection is always followed by normalization of hematologic parameters, many lesions are too large to be resected without severe disfigurement. Other treatments include glucocorticoids, interferon- α , antifibrinolytic agents, and the antiplatelet agents ticlopidine and aspirin, low-molecular-weight heparin, embolization, radiation, laser therapy, and chemotherapy using vincristine, cyclophosphamide, actinomycin D, or methotrexate.^{117,118,120,122,123}

MISCELLANEOUS

Microangiopathic hemolytic anemia has also been seen in malignant systemic hypertension, pulmonary hypertension, giant cavernous hemangiomas of the liver,¹²⁴ and various vasculitides, including Wegener granulomatosis^{125,126} and giant cell arteritis.¹²⁷ Osmotically induced hemolysis has occurred when distilled water is used as an irrigant during transurethral resection of the prostate.¹²⁸

CHAPTER 52

ERYTHROCYTE DISORDERS AS A RESULT OF CHEMICAL AND PHYSICAL AGENTS

Paul C. Herrmann

SUMMARY

Erythrocyte disorders from physical or chemical agents occur via such processes as red cell volume expansion within hypotonic solutions, erythrocyte membrane damage from biotoxins, damage to the spectrin skeleton from insults such as heat, and eryptosis associated with oxidizing agents such as oxygen, arsine gas, and chlorates. Erythrocyte damage also can be induced by other agents that lack well defined mechanisms of action (see Table 52–1). These processes include erythrocyte damage caused by lead, copper, and radiation, as well as neocytolysis, a phenomenon once thought unique to microgravity, but subsequently observed in individuals demonstrating altitude induced polycythemia upon transition to normoxic conditions.

MECHANISTICALLY DESCRIBED ERYTHROCYTE DAMAGE

Chemical and physical agents causing erythrocyte disorders within the context of enzyme deficiency, unstable hemoglobins, cell fragmentation or immune dysfunction are discussed in Chaps. 46 to 51 and 54. The present chapter deals with drugs, toxins, and other physical agents that can cause red cell disorders, which are not discussed elsewhere within this text.

ERYTHROCYTE VOLUME EXPANSION AND HYPOTONIC LYSIS

When large amounts of distilled water gain access to the systemic circulation, either by intravenous injection or when used as an irrigating solution during surgery, hemolysis will occur.¹ Severe hemolysis may also result from water inhalation in near-drowning.² Occasionally self-induced hypotonic lysis secondary to water intoxication from polydipsia in the setting of psychiatric illness or hazing rituals occurs.³ In all cases, hemolysis follows expansion of the erythrocyte volume, transition to a spherical shape and ultimately cell rupture.⁴

DAMAGE TO THE RED BLOOD CELL MEMBRANE

Bee^{5,6} and wasp^{7–9} stings, as well as contact with caterpillar bristle from *Lonomia obliqua*,¹⁰ are associated with severe hemolysis. In addition,

Abbreviations and Acronyms: AsH₃, arsenic hydride (arsine gas); EDTA, ethylenediaminetetraacetic acid; G6PD, glucose-6-phosphate dehydrogenase; NADPH, reduced nicotinamide adenine dinucleotide phosphate.

spider and scorpion bites occasionally are followed by hemolytic anemia and hemoglobinuria.^{11–16} The spiders usually responsible are *Loxosceles laeta* and *Loxosceles reclusae*. In such cases, sphingomyelinase D is one of the causative toxins. The venom preferentially hydrolyzes band 3 of the red cell membrane protein.¹⁷ Band 3 has dual functions of ion exchange and anchoring of the cell membrane to the underlying cellular skeleton.¹⁸ It appears disruption of the structural role is responsible for cell lysis.

One of the most intriguing mechanisms of membrane damage is that induced by a class of pore-forming cytotoxins, usually from *Bacillus cereus*.¹⁹ Toxins using similar mechanisms of hemolysis are found in marine organisms including jelly fish (*Chironex fleckeri*),²⁰ sea cucumbers (*Cucumaria echinata*),²¹ and sea anemones (*Stichodactyla helianthus*).²² X-ray crystallography reveals these toxins to be composed of proteins that associate to span the erythrocyte membrane forming an ion permeable pore.²¹ Aged cells appear preferentially damaged.

Additional discussion of hemolysis associated with microorganism-produced toxins, including *Clostridium*-induced spherocytosis and massive hemolysis, is found in Chap. 53.

DAMAGE TO SKELETAL OR STRUCTURAL PROTEINS

Gross hemoglobinemia was observed in 11 of 40 patients with second- and third-degree burns involving 15 to 65 percent of body surface area.²³ Within the first 24 hours following a burn, hemolytic anemia results from the direct effect of heat on circulating erythrocytes. Blood heated to temperatures above 49°C demonstrates morphologically similar damage (Fig. 52–1A), consistent with increased osmotic and mechanical fragility.^{24,25}

In addition to acute damage, heat decreases erythrocyte resilience. A normal erythrocyte in liquid behaves physically as a drop of fluid because the flexible membrane allows the surface of the cell to rotate around the intracellular contents.²⁶ These fluid-like properties couple collisional energy between the erythrocyte membrane and the viscous hemoglobin solution within the cell, allowing dissipation of collisional energy through the entire cell and ultimately protecting the cell membrane. When heated, the spectrin comprising the erythrocyte skeleton melts, and upon cooling becomes rigid. This rigidity prevents collisional energy dissipation, making such cells particularly susceptible to membrane damage.²⁷ The ensuing damage to the erythrocyte membrane structure results in splenic sequestration and cell removal.²⁸

OXIDANT DAMAGE

Although oxygen is a powerful oxidizing agent, quantum mechanical properties of the oxygen molecule prevent spontaneous oxidation of biologic membranes.²⁹ When bound to hemoglobin, oxygen has significantly different quantum mechanical properties and occasionally, an exceptionally reactive superoxide molecule escapes.³⁰ It is estimated that 2 to 3 percent of total hemoglobin would be oxidized daily in the absence of enzyme systems to protect against escaped superoxide.^{31,32} Although the hemolysis that occurs when these systems are overwhelmed is dealt with in Chap. 47, a few additional examples are briefly described below. Hemolysis following oxidation is thought to occur via eryptosis (Chap. 33). In addition to oxidative stress, osmotic shock and certain toxic ions, including gold and aluminum, may act through eryptosis.^{33,34}

Oxygen Gas and Ozone

Hemolytic anemia can occur when ambient oxygen (O₂) concentration is increased markedly.³⁵ Hyperbaric oxygenation has been associated with acute hemolysis.³⁶ Ozone (O₃), which has been widely used in

Figure 52-1. **A.** Blood film prepared at admission from a patient who had suffered severe burn injury involving a large percentage of the body surface. Note the presence of normal erythrocytes (apparently from vessels not exposed to heat damage) along with populations of normocytic and microcytic spherocytes. In addition, there are numerous red cell fragments, some smaller than platelets. **B.** Blood film prepared from a patient exposed to arsenic hydride. Note the very pale red cells resulting from partial hemoglobin loss secondary to membrane damage. An extreme example, represented by the virtual ghost thinly rimmed with scant residual hemoglobin, can be found in the upper left-hand corner. **C.** Wilson disease. In this image from a patient with Wilson disease, there are numerous visible sequelae of oxidative damage caused by excess copper. The striking microspherocytosis indicates damage to the membrane. Damage to hemoglobin is demonstrated by the Heinz bodies projecting from red cells (asterisks show two examples). The horizontal arrow points to one of several spherocytes. The vertical arrow points to a macrocyte (reticulocyte). An occasional cell shows damage to both membrane and hemoglobin. The presence of echinocytes (oblique arrows show two examples) suggests that the liver is also affected. (A & B, reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com. C, used with permission of Barbara J. Bain, Imperial College, London, UK.)

some countries for a variety of therapeutic purposes, had no apparent effect *in vivo* on red cell enzymes and intermediates at the 30 mcg/mL concentration commonly infused, but did produce some *in vitro* hemolysis at that concentration.³⁷

Arsenic Hydride

Arsenic exposure is a major cause of anemia in regions with high environmental concentration. Examples include Bangladesh's tainted water supply, and areas of China where arsenic laden coal is used.³⁸ Arsine gas (arsenic hydride, AsH_3) is the most erythrotoxic form of arsenic and inhalation of arsine gas is a well-recognized cause of hemolytic anemia (see Fig. 52-1B).³⁹⁻⁴¹ Arsine is formed during many industrial processes, including the reaction of hydrogen with available arsenic compounds in metallurgical processes. The arsenic is usually a contaminant, so contact with arsenic compounds may not be apparent from the patient's history. The mechanism of erythrocyte damage occurs via oxidation of sulfhydryl groups in the erythrocyte membrane and associated cytoskeleton,^{42,43} and decreased levels of reduced glutathione in erythrocytes exposed to AsH_3 are observed.⁴⁴

Chlorates and Chloramines

Sodium and potassium chlorate are oxidative drugs that produce methemoglobinemia, Heinz bodies, and hemolytic anemia.⁴⁵ Although it has been presumed that the mechanism of hemolysis is similar to that resulting from other oxidative drugs, enigmatically, no cases have been observed in patients deficient in glucose-6-phosphate dehydrogenase (G6PD). Hemolytic anemia with Heinz body formation has also occurred in patients undergoing dialysis when the water contained a substantial amount of chloramines. Oxidative damage to the red cells of these patients was demonstrated by the presence of Heinz bodies, a positive ascorbate-cyanide test, and methemoglobinemia.^{46,47}

Formaldehyde

Leaching of formaldehyde from plastic used in water filters employed for hemodialysis is also a cause of hemolytic anemia. The low level of formaldehyde in the contaminated water does not result in a fixative effect, but instead induces metabolic changes within the red cells.⁴⁸

CHEMICAL AND PHYSICAL AGENTS NOT DEFINITELY DESCRIBED MECHANISTICALLY

A variety of chemical and physical agents cause erythrocyte disorders through unknown or not well-characterized mechanisms. There are isolated reports of hemolytic anemia occurring after the administration of a variety of chemical substances, some of which are listed in Table 52-1. What follows is a collection of miscellaneous erythrocyte damaging agents and processes for which the mechanisms are still largely undefined or disputed.

NEOCYTOLYSIS

Astronauts experience significant anemia after space flight even in the presence of normal or elevated ambient oxygen concentration.³⁵ The

TABLE 52-1. Drugs and Chemicals That Have Been Reported to Cause Hemolytic Anemia Secondary to Erythrocyte Damage

Chemicals	Drugs
Aniline ⁸⁶	Amyl nitrite ⁹⁴
Apiol ⁸⁷	Mephesisin ⁹⁵
Dichlorprop (herbicide) ⁸⁸	Methylene blue ⁹⁶
Formaldehyde ⁴⁸	Omeprazole ⁹⁷
Hydroxylamines ⁸⁹	Pentachlorophenol ⁹⁸
Lysol ⁹⁰	Phenazopyridine (Pyridium) ⁹⁹
Mineral spirits ⁹¹	Salicylazosulfapyridine (Azulfidine) ¹⁰⁰
Nitrobenzene ⁹²	Tacrolimus ¹⁰¹
Resorcin ⁹³	

mechanism of this anemia remains elusive with intriguing observations of altered erythropoietin levels and radiolabeling studies of astronaut erythrocytes suggesting selective hemolysis of young erythrocytes less than 12 days old.⁴⁹ In addition to space flight, neocytolysis has been invoked to explain the anemia resulting when high-altitude dwellers relocate to sea level.⁵⁰

LEAD

Lead poisoning (plumbism) has been recognized since antiquity. The ingestion of beverages containing lead leached from highly soluble lead based glazes or earthenware containers has been blamed for the decline and fall of the Roman aristocracy and is still an occasional cause of lead intoxication.⁵¹ The distillation of alcohol in leaded flasks is another rare cause of plumbism, although the practice was prohibited in 1723 by the Massachusetts Bay Colony after it was noticed that consumption of rum so distilled resulted in abdominal pain known as the “dry gripes.”⁵¹ Among the earliest published descriptions of lead poisoning is a letter written in 1786 by Benjamin Franklin.⁵²

Lead intoxication in children generally results from ingestion of flaking lead paint or chewing lead-painted articles. Lead poisoning tends to be more severe in iron-deficient children, as a relatively close relationship exists between blood lead levels and hematocrit.⁵³ In adults, lead poisoning primarily occurs as the result of inhalation of lead compounds from industrial processes such as battery manufacture,^{54,55} or ingestion of food having leached lead from pottery or dishes.^{56,57} Lead poisoning from restoring tapestries and producing ceramics also has been noted.^{58,59}

Generally, the erythrocyte disorder associated with lead intoxication *in vivo* is thought to be a result of interference with normal production of erythrocytes. There is direct evidence that lead inhibits red blood cell (RBC) 5' nucleotidase and results in basophilic stippling and hemolysis indistinguishable from the morphologic changes observed with inherited deficiency of this enzyme. The other lead-poisoning-associated morphologic changes are observed when chronic lead exposure is associated with sideroblastic anemia, but are not observed in acute lead poisoning.^{60,61} In addition, modest shortening of red cell life span is a relatively constant feature of lead intoxication.^{62,63} The literature describes a number of tantalizing observations and proposed mechanisms. For instance, *in vitro* treatment of red cells with lead produces membrane damage and inhibition of activity of the hexose monophosphate shunt.⁶⁴ Lead interferes with the erythrocyte cation pump,^{65,66} possibly by inhibiting membrane adenosine triphosphatase.^{67,68} Free radical and Fenton type chemistry around the iron atoms of hemoglobin have also been described.⁶⁹

Microscopic examination of the blood provides the key diagnostic clue to lead poisoning. Complete observations of the acute hematologic changes, including erythrocyte distortion, occurring after the intravenous injection of lead in an attempt to treat malignant disease were first published in 1928.⁷⁰ Lead induces normocytic and slightly hypochromic erythrocytes, with the hypochromia possibly resulting from coexisting iron deficiency.⁷¹ Basophilic stippling of the erythrocytes may be fine or coarse, and the number of granules seen in each cell may be quite variable. Blood collected in heparin may most reliably demonstrate basophilic stippling, as storage of red blood cells in ethylenediaminetetraacetic acid (EDTA) is associated with the disappearance of stippling.⁷² Young polychromatophilic cells are most likely to be stippled. Electron microscopic studies have demonstrated that the basophilic granules represent abnormally aggregated ribosomes.⁷³ Ringed sideroblasts are frequently found in the marrow (Chaps. 32 and 59). Iron-laden mitochondria are present, but do not appear to contribute to the basophilic stippling that is observed on light microscopy.⁷³

COPPER

Erythrocyte damage has resulted from ingestion of copper sulfate in suicide attempts and from copper accumulation when hemodialysis fluid is contaminated by copper pipes.^{74,75} Hemolysis in Wilson disease has been attributed to the elevated plasma copper levels characteristic of that disorder.⁷⁶⁻⁷⁸ Spherocytic anemia with a hematocrit below 25 percent may be the presenting symptom (see Fig. 52-1C).⁷⁹ The pathogenesis may be related to oxidation of intracellular glutathione, hemoglobin, and the reduced nicotinamide adenine dinucleotide phosphate (NADPH), along with inhibition of G6PD by copper.⁸⁰ However, the amount of copper required to inhibit G6PD is large. Copper in much lower concentrations inhibits pyruvate kinase, hexokinase, phosphogluconate dehydrogenase, phosphofructokinase, and phosphoglycerate kinase, suggesting a global metabolic insult.^{81,82} Plasma exchange successfully prevents hemolytic anemia in Wilson disease.⁸³

RADIATION

Although decreased red cell survival is part of the complex series of events occurring after administration of large doses of total body radiation, erythrocytes appear to be very resistant to the direct effects of radiation.^{84,85} Shortened red cell survival after radiation is likely related to red cell loss through internal bleeding and various secondary events such as infection.

CHAPTER 53

HEMOLYTIC ANEMIA RESULTING FROM INFECTIONS WITH MICROORGANISMS

Marshall A. Lichtman

SUMMARY

Hemolytic anemia is a prominent part of the clinical presentation of patients infected with organisms such as the *Plasmodium* sp., *Babesia*, and *Bartonella*, which directly invade the erythrocyte. Malaria is the most common cause of hemolytic anemia on a worldwide basis, and much has been learned about how the parasite enters the erythrocyte and the mechanism of anemia. Falciparum malaria, in particular, can cause severe and sometimes fatal hemolysis (blackwater fever). Other organisms cause hemolytic anemia by producing a hemolysin (e.g., *Clostridium perfringens*), by stimulating an immune response (e.g., *Mycoplasma pneumoniae*), by enhancing macrophage recognition and hemophagocytosis, or by as yet unknown mechanisms. The many different infections that have been associated with hemolytic anemia are tabulated and references to the original studies provided.

Shortening of erythrocyte life span occurs commonly in the course of inflammatory and infectious diseases. This effect may occur particularly in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency (Chap. 47), splenomegaly (Chap. 56), and in the microvascular fragmentation syndrome (Chaps. 51 and 132). In some infections, however, rapid destruction of erythrocytes represents a prominent part of the overall clinical picture (Table 53-1).¹⁻⁴⁹ This chapter deals only with the latter states.

Several distinct mechanisms may lead to hemolysis during infections.⁴⁹ These include direct invasion of or injury to the erythrocytes by the infecting organism, as in malaria, babesiosis, and bartonellosis; elaboration of hemolytic toxins, as by *Clostridium perfringens*; and development of antibodies, either autoantibodies against red cell antigens or deposition of microbial antigens or immune complexes on erythrocytes, which result in hemolytic anemia.⁵⁰

Acronyms and Abbreviations: CR1, complement receptor 1; EBA, erythrocyte-binding antigen; G6PD, glucose-6-phosphate dehydrogenase; ICAM, intercellular adhesion molecule; PfEMP, *Plasmodium falciparum* erythrocyte membrane protein; RSP-2, ring surface protein 2; VCAM, vascular cell adhesion molecule.

MALARIA

EPIDEMIOLOGY

Known since antiquity, malaria is the world's most common cause of hemolytic anemia.³⁶ Human malaria is caused by one of five species of a protozoan, *Plasmodium*. In 2012, an estimated 207 million episodes of malaria occurred worldwide, resulting in approximately 627,000 deaths, mainly children in sub-Saharan Africa.⁵¹ Severe malaria anemia is most commonly seen in young children and pregnant women.⁵²

Malaria transmission depends on geography, rainfall patterns, and the breeding sites of the *Anopheles* mosquito, the specific vector. Some regions have conditions that make malaria common throughout the year, so-called endemic areas, whereas in other places there are seasonal peaks, usually the rainy season when mosquito breeding is enhanced. Persons in Africa, Asia, the Middle East, and parts of Europe may be at risk. Travelers to such places are at high risk because of lack of immunity and because when they return home, the diagnosis might not be considered promptly. Malaria may also be transmitted by blood transfusion or organ donation from an infected donor.

LIFE CYCLE

Sporozoites enter the circulation while the female *Anopheles* mosquito takes a blood meal. They invade and multiply in hepatocytes. The latter cells rupture when engorged and release merozoites that invade the red cell. In the red cell, the merozoites also cycle through these stages: trophozoites (ring-forms), which then can convert to schizonts. Mature schizonts burst the red cells and release merozoites that invade other red cells. The bursting and release coincides with the abrupt rises in temperature and related signs and symptoms seen in malaria. A small fraction of merozoites in red cells convert to male and female gametocytes that are ingested when the mosquito bites. In the mosquito, they fuse and form an oocyst that divides asexually into numerous sporozoites. The sporozoites migrate to the mosquito's salivary glands from where they reenter a victim's blood upon the next bite, initiating a malarial infection. *Plasmodium vivax* and *Plasmodium ovale* can persist in the liver in a dormant stage (hypnozoites) and produce relapses months or years later.

ALTERATIONS IN THE INFECTED RED CELL

After the host is bitten by an infected female *Anopheles* mosquito, the sporozoites invade the liver and possibly other internal organs in the asymptomatic tissue stage of malaria. Merozoites, emerging at first from the tissues and later from previously parasitized red cells, use specialized invasion proteins such as the erythrocyte binding-like (EBA) and reticulocyte homology (RH) protein families, which bind to receptors on the erythrocyte surface, including glycophorins A/B/C, CR1 (CD35), and basigin (CD147).⁵³⁻⁵⁵ A complex series of events eventuates in invasion of the interior of the red cell by the parasite.^{35,53} Having entered the erythrocyte, the parasite grows intracellularly, nourished by the cell's contents, and modifies the host cell by exporting hundreds of proteins into the cytoplasm, some of which are inserted into the red cell membrane.⁵⁶

Erythrocytes infected with *Plasmodium falciparum* develop surface knobs⁵⁷ that contain receptors, especially the *P. falciparum* erythrocyte membrane protein-1 (PfEMP-1), for endothelial proteins. All parasites bind to CD36 antigen (platelet glycoprotein IV) and thrombospondin found on endothelial surfaces, whereas some bind to the intercellular adhesion molecule-1 (ICAM-1), and a few bind to the vascular cell adhesion molecule (VCAM)⁵⁸⁻⁶² and mediate the

<i>Yersinia enterocolitica</i> ⁴⁸

adherence of parasitized cells to endothelium. Activated endothelium secretes strands of ultralarge von Willebrand factor, which bind platelets, allowing PfEMP-1 to interact with platelet CD36 and this provides an additional means of cytoadherence.⁶³ Rosetting of parasitized cells with unparasitized cells also occurs through a mechanism mediated by

complement receptor-1 (CR1) on uninfected erythrocytes.⁶⁴ One of the membrane proteins of *P. falciparum* binds specifically to the spectrin on the inner surface of the red cell membrane.⁶⁵ The anemia of falciparum malaria is characteristically normocytic-normochromic anemia with a paucity of reticulocytes (see “Pathogenesis of the Anemia” below). If microcytosis is present, the concomitant presence of α - or β -thalassemia or iron deficiency should be considered.⁶⁶ A large number of genetic polymorphisms that interfere with invasion of erythrocytes by parasites and their proliferation have developed in areas where malaria has been a leading cause of death for many generations.^{64,67–69} These include G6PD deficiency, Southeast Asian ovalocytosis, CR1 deficiency, the thalassemias, sickle cell anemia (Chaps. 46 to 48), and other hemoglobinopathies.

PLASMODIUM SPECIES AND SEVERITY OF ANEMIA

There are five plasmodial species that cause human malaria: *P. falciparum*, *P. vivax*, *Plasmodium malariae*, *P. ovale* and *Plasmodium knowlesi*. The first two cause the most cases worldwide and are principally associated with hemolytic anemia. *P. vivax* invades only young red cells, whereas *P. falciparum* attacks both young and old cells. Thus, anemia tends to be more severe in the latter form of malaria and is the most deadly type.³⁵

PATHOGENESIS OF THE ANEMIA

Hemolytic Mechanisms

Destruction of parasitized red cells appears to occur largely in the spleen, and splenomegaly typically is present in chronic malarial infection. The “pitting” of parasites from infected erythrocytes may also occur in the spleen.⁷⁰ The degree of parasitemia, in part, determines the destruction of infected erythrocytes. Low rates of red cell parasitemia may have little effect on the development of anemia, whereas high rates, for example, 10 percent, may have very significant effects.⁷¹ The degree to which anemia develops often seems to be disproportionate to the number of cells infected with the parasite. It is estimated that 10 times the number of uninfected red cells are removed for each infected red cell, dramatically magnifying the hemolytic rate. Osmotic fragility is increased in nonparasitized cells, as well as in cells containing plasmodia.⁷² The erythrocyte cation permeability is altered in monkeys with malaria.⁷³ Hemin accumulation facilitates hemolytic cell loss via a process of programmed cell death, referred to as eryptosis. This suicidal death pathway is mediated by increased cell calcium, increased annexin-V binding, and ceramide formation.⁷⁴ Oxidative damage to red cell lipids occurs^{75,76} and there is an abnormality in the phosphorylation of membranes of parasitized red cells.⁷⁷ *P. falciparum*-infected red cells have a highly irregular surface produced by the intracellular growth of the plasmodium, but nonparasitized cells often have similar surface defects.⁷⁸ Activation of hepatosplenic macrophages enhance red cell clearance supported by red cell surface changes in both parasitized and unparasitized cells that foster recognition and erythrophagocytosis by macrophages. Both marked loss of red cell deformability and deposition of immunoglobulin G and complement (C3d), sometimes resulting in a positive direct antiglobulin reaction, may enhance red cell removal by macrophages.^{79,80} Parasite products are part of the immune complexes on the red cell surface. The *P. falciparum* ring surface protein 2 (RSP-2) mediates adhesion of infected red cells to endothelial cells and is deposited on uninfected cells, undoubtedly providing a mechanism for removal of these cells by mediating complement-dependent phagocytosis.⁶⁶ Splenomegaly further enhances red cell removal from the circulation.

Decrease in Erythropoiesis

P. falciparum also decreases the erythropoietin response, resulting in less erythropoiesis than expected for the degree of anemia, reticulocytopenia, and coincidentally striking dyserythropoiesis with stippling, cytoplasmic vacuolization, nuclear fragmentation and multinuclearity.⁶⁶ The inhibition of the erythroid response (anemia of chronic disease) is secondary to release of the cytokines interferon- γ and tumor necrosis factor- α , and the interleukin-10-to-tumor-necrosis-factor ratio, which when low correlates with severe malarial anemia in children (Chap. 37).⁶⁶

BLACKWATER FEVER

The fever associated with malaria, accompanied by rigors, headache, abdominal pain, nausea and vomiting, and extreme fatigue, is characteristically cyclic, varying in frequency according to the malaria type. Although classic periodicity is often absent, febrile paroxysms of *P. vivax* malaria tend to occur every 48 hours; those of *P. malariae* infection occur every 72 hours; and those of *P. falciparum* malaria, daily. In the latter cases, the periodicity is the result the synchronization of schizogony with schizont rupture occurring at regular intervals. It is schizont rupture that accounts for the fever and associated symptoms. Falciparum malaria is occasionally associated with particularly severe

hemolysis, hemoglobinemia, hemoglobinuria, and the passage of dark, almost black, urine. This disorder, also called *blackwater fever*, is no longer common. At one time it was seen frequently among Europeans in Africa and in India, usually after quinine was given to treat malaria. The event seems to be related to the intermittent use of antimalarials.⁸¹

DIAGNOSTIC METHODS

Diagnosis of malaria depends upon demonstration of the parasites on the blood film, or the presence of antigenic parasite proteins using rapid detection tests (RDTs).⁸² Alternative techniques involve polymerase chain reaction (PCR) to demonstrate the appropriate DNA sequences in the blood^{83,84} or the use of automated hematology analyzers to identify parasites as part of a routine complete blood count (CBC) investigation.⁸⁵ The morphologic differentiation of *P. falciparum* from other forms of malaria, principally *P. vivax*, is clinically important as *P. falciparum* infection may constitute a clinical emergency. If more than 5 percent of the red cells infected contain parasites, the infection is almost certainly with *P. falciparum*. In an infection with this organism, rings are practically the only form of parasite evident on the blood film. The finding of two or more rings within the same red cells is regarded as pathognomonic of *P. falciparum* (Fig. 53–1A and B). In nonimmune

A

B

C

D

Figure 53–1. **A.** Blood film from a patient with malaria caused by *Plasmodium falciparum*. Several red cells contain ring forms. Note red cell with double ring form in center of the field, characteristic of *P. falciparum* infection. Note the ring form with double dots at the left edge of figure, suggestive of *P. falciparum* infection. Note also high rate of parasitemia (~10 percent of red cells in this field) characteristic of *P. falciparum* infection. **B.** Blood film from a patient with malaria caused by *Plasmodium vivax*. Note mature schizont. **C.** Blood film from a patient with *Babesia microti* infection. The heavy parasitemia is characteristic of babesiosis (approximately two-thirds of red cells infected). **D.** Blood film from a patient with *Clostridium perfringens* septicemia. Few red cells evident as a result of intense erythrolysis. Neutrophil with two bacilli (*C. perfringens*). (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

patients, examination of the blood film for malarial parasites should be made for at least 3 days after onset of symptoms because parasitemia may not reach detectable levels for several days.

TREATMENT

Early treatment is important. The spread of antimalarial therapy has resulted in major problems with drug resistance. Eradication of blood forms can be achieved with individual agents or combinations of antimalarials. Artemisinins are the most effective agents for *P. falciparum*. Numerous studies are in progress to determine the best single agent or combination of agents to be used in the treatment of malaria in different regions.⁸⁶ Many such drugs are capable of producing severe hemolysis in patients with G6PD deficiency, which is relevant in areas with endemic malaria (Chap. 47).⁸⁷

PREVENTION

An initial test of a *P. falciparum* sporozoite vaccine, administered intravenously in five doses, has shown efficacy in a small number of experimental subjects. The immunologic responses were closely correlated with vaccine dose. Although a very important step forward, the practical limitations of five intravenous doses will have to be circumvented for extensive application to susceptible populations.⁸⁸ Another vaccine, RTS,S, is the first candidate to be tested in phase 3 clinical trials, but the preliminary results have been disappointing. Protection against clinical malaria in infants ranged between 30 and 50 percent and the effect waned after several months.^{88a}

COURSE AND PROGNOSIS

When acute, unusually severe hemolysis occurs in the course of falciparum malaria (blackwater fever), the physician should be certain that a hemolytic drug is not being administered to a G6PD-deficient individual. Transfusions may be needed with severe hemolysis, and if renal failure occurs, extracorporeal dialysis may be required. With early institution of therapy the prognosis in malaria is excellent. However, when treatment is delayed or the strain is resistant to the administered agent, *P. falciparum* malaria may follow a rapid, fatal course.

● BARTONELLOSIS (OROYA FEVER)

EPIDEMIOLOGY

In 1885, Daniel A. Carrión, a medical student, inoculated himself with blood obtained from a verrucous node of the skin of a patient with verruca peruviana. He developed a fatal hemolytic anemia with the characteristics of Oroya fever, a disease that had first been observed some years earlier among workers in a railroad construction project near the city of Oroya in the Peruvian Andes. This fatal self-experiment established the identity of the verrucosa form and the hemolytic phase of human bartonellosis, an infection that now bears the name Carrión disease.^{5,5a} Human bartonellosis is transmitted by the sandfly.

PATHOGENESIS

After a sandfly bite, the red blood cells become infected with *Bartonella bacilliformis*. It is believed that the organism does not grow within the red cell, but rather adheres to its exterior surface: When infected red cells are washed with citrated plasma, free organisms are found but the red cells are not hemolyzed. In hanging-drop cultures, masses of organisms are clearly seen outside the erythrocytes, while the cells themselves are intact.⁸⁹ The osmotic fragility of the red cells is normal.⁵ They are rapidly removed from the circulation, apparently both by liver

and spleen. Normal red cells transfused into patients with bartonellosis meet a similar fate.⁴ A 130-kDa *Bartonella* protein that causes erythrocytes to acquire trenches, indentations, and invaginations has been purified from culture broths and has been called *deformin*.⁹⁰ In addition, two *B. bacilliformis* genes, designated *ialA* and *ialB*, predicted to encode polypeptides of 170 amino acids (20.1 kDa) and of 186 amino acids (19.9 kDa), respectively, greatly enhance the ability of *Escherichia coli* to invade erythrocytes.⁹¹

CLINICAL FINDINGS

As demonstrated by Carrión's experiment, bartonellosis has two clinical stages. The acute hemolytic anemia, *Oroya fever*, represents the early, invasive stage of a chronic granulomatous disorder, the late stage of which is designated *verruca peruviana*. Most patients manifest no clinical symptoms during the Oroya fever phase, but when anemia does occur, its onset is dramatic. Red counts as low as 750,000/ μ L (0.750×10^{12} /L) have been documented.⁹² In addition to symptoms of anemia, patients manifest thirst, anorexia, sweating, and generalized lymphadenopathy. Spleen and liver enlargement are unusual. Large numbers of nucleated red cells appear in the blood film, and reticulocytosis is often striking. The white cell count is variable. Diagnosis is established by demonstrating the presence of the organism *B. bacilliformis* on the erythrocytes. Giemsa-stained blood films reveal red-violet rods varying in length from 1 to 3 μ m and in width from 0.25 to 0.2 μ m. Although molecular methods for diagnosis of *Bartonella* species are available,⁹³ in a person with the clinical picture, the examination of the blood film can be accomplished and therapy initiated, rapidly.

TREATMENT AND COURSE

Oroya fever responds well to treatment with penicillin, streptomycin, chloramphenicol, and the tetracyclines. The mortality rate among untreated patients is very high, but those who do survive undergo a sudden transitional period in which the *Bartonellae* change from an elongated to a coccoid form, the number of parasitized cells decreases, and the red cell count increases. Lymphocytosis and improved neutrophil count are observed with disappearance of the fever and abatement of other symptoms. The second stage of *Bartonella* infection, verruca peruviana, is a nonhematologic disorder characterized by an eruption over the face and extremities developing into bleeding warty tumors.

Other species of *Bartonella* cause human febrile infections such as "cat-scratch fever," or "trench fever," or can infect individuals with acquired immunodeficiency disease, but these disorders are not ordinarily associated with severe hemolytic anemia.⁹⁴⁻⁹⁶

● BABESIOSIS

EPIDEMIOLOGY

Babesiae are intraerythrocytic protozoas known as piroplasms. They are transmitted by ticks that may infect many species of wild and domestic animals. Humans occasionally become infected with *Babesia microti* (North America) or *Babesia divergens* (Europe), species that normally parasitize rodents, and, deer, elk, and cattle, respectively.⁹⁷ Other *Babesia*-like piroplasms, such as *Babesia WA1*, first isolated from a patient in the state of Washington, and *Babesia MO1*, isolated in Missouri, may also produce human disease.⁹⁸ Once thought to be rare, babesiosis is being recognized with increasing frequency.^{99,100} The disease is usually tickborne in humans, but has also been transmitted by transfusion.¹⁰¹⁻¹⁰⁶ Cases of babesiosis, mostly caused by *B. microti* but also by *Babesia WA1* species, have been transmitted by transfusion of blood from asymptomatic infected blood donors. The risk of transfusion-transmitted

babesiosis is higher than generally appreciated and represents a threat to the blood supply in endemic areas. Presumably because of the distribution of the vector in the United States, the disease is most common in the northeastern coastal and Great Lakes regions where it became known as “Nantucket fever,” but has also been encountered in the Midwest.¹⁰⁷ Infections with *B. divergens* usually occur in splenectomized patients, but this is not the case with *B. microti* infections.³

CLINICAL FINDINGS

The symptoms are prompted by reproduction of the organisms in the red cell and subsequent cell lysis. The clinical expression is broad, reflecting the degree of parasitemia. The incubation period ranges from 1 week to 3 months but usually is about 3 weeks. The disease generally has a gradual onset with malaise, anorexia, and fatigue, followed by fever (sometimes as high as 40°C), chills, sweats, and muscle and joint pains. The onset, occasionally, may be fulminant. Hepatic and splenic enlargement may be evident.¹⁰⁸

A moderate degree of hemolytic anemia is usually present; on occasion it has been sufficiently severe to cause hypotension,¹⁰⁹ and transfusion has occasionally been required.⁹⁷ The hemolysis may last a few days, but in asplenic, elderly, or otherwise immunocompromised patients, it can go on for months. Elevation in serum transaminases, lactic dehydrogenase, unconjugated bilirubin, and alkaline phosphatase correlates with the severity of the parasitemia. Thrombocytopenia and leukopenia may occur, which may be the result of inflammatory cytokine release.¹⁰⁸

DIAGNOSIS

The history may indicate exposure to a tick-infested area, recent blood transfusion, or asplenia. Parasites can be seen in the red cells in Giemsa-stained thin blood films. They appear as darkly stained ring forms with light blue cytoplasm. Merozoites may also be visible. Infrequently, the classical Maltese cross tetrad can be found. This intraerythrocytic structure consists of four daughter cells of *Babesia* connected by cytoplasmic bridges, resembling a Maltese cross. The parasitemia can be very high, affecting more than 75 percent of red cells (see Fig. 53-1C).¹⁰⁸ Immunofluorescent tests for antibodies to *Babesia* are available and PCR-based diagnostic tests are the test of choice for confirmation of an active infection in an individual bearing antibodies to *Babesia* and for following the response to therapy.¹⁰⁸

The onset of fever and hemolytic anemia after transfusion should lead to the consideration of babesiosis.

TREATMENT AND COURSE

Most mild *B. microti* infections respond without treatment. The infection has responded to drug therapy with clindamycin and quinine,¹¹⁰ but failure to respond to antibiotics has also been encountered.¹⁰² The two-drug combination can increase rate of clearance of parasites, but they have consequential side effects. A combination of atovaquone and azithromycin has also been proposed as treatment.^{98,111} Whole-blood or red cell exchange can result in marked improvement in recalcitrant cases.^{108,111}

COINFECTION

In endemic areas two or more parasites may coinfect an individual by a tick bite. *B. microti* and *Borrelia burgdorferi* (Lyme disease) may both enter the human circulation as a result of the *Ixodes* tick bite, as can several other parasites (e.g., human granulocytic ehrlichiosis). Initial signs and symptoms may be similar. Successful early treatment for Lyme

disease may leave a residual *B. microti* infection because antibiotic therapy for the former will not eradicate the latter.¹⁰⁸

● CLOSTRIDIUM PERFRINGENS SEPTICEMIA

EPIDEMIOLOGY

C. perfringens (formerly *Clostridium welchii*) sepsis is most likely to occur in patients who have undergone septic abortion. It has also been observed following acute cholecystitis,¹¹² as a result of an intrahepatic abscess,⁹ and, rarely, after amniocentesis (amnionitis).¹¹³

PATHOGENESIS

C. perfringens are Gram-positive, encapsulated, spore-forming, anaerobic bacilli. The organism causes gas gangrene in soft tissues. The α toxin of *C. perfringens* is a lecithinase C that reacts with lipoprotein complexes at cell surfaces, liberating potent hemolytic substances, lys-olecithins. This toxin is the agent that causes intravascular hemolysis and its subsequent effects. It has also been suggested that erythrocyte membrane proteolysis plays an important role in hemolysis.¹¹⁴

CLINICAL FEATURES

Severe, often fatal hemolysis occurs in patients with *C. perfringens* septicemia. Striking hemoglobinemia and hemoglobinuria occur. The serum may become a brilliant red, and the urine is a dark-brown mahogany color. The lysis of red cells (decreasing packed red cell volume) and the high plasma hemoglobin can produce a marked dissociation between the blood hemoglobin and hematocrit level. For example, hematocrits approaching zero with blood hemoglobins as high as 8 g/dL can occur. Dehemoglobinized red cells (“ghosts”) may be evident on the blood film (see Fig. 53-1D). Microspherocytes are prominent (Chap. 46), and both leukocytosis with a left shift and thrombocytopenia are often present. Acute renal and hepatic failure usually develops, and the prognosis is grave; more than half of the patients die, even with appropriate treatment (Chap. 129).^{8,115}

THERAPY AND COURSE

Therapy consists of antibiotic therapy, fluid support, red cell transfusion, and where appropriate surgical debridement.¹¹⁶ The infection is often of abrupt onset and overwhelming, and the profundity of the hemolysis and secondary organ damage (e.g., renal) results in a high mortality rate.

● OTHER INFECTIONS

A variety of other infections occasionally have been associated with hemolytic anemia. The mechanisms involved vary. Some organisms, among them such common pathogens as *Haemophilus influenzae*, *E. coli*, and *Salmonella* species, can produce red cell agglutination *in vitro*, but it is not known whether this phenomenon is important in initiating *in vivo* hemolysis.¹¹⁷ Bacteria may also produce destruction of red cells indirectly when bacterial polysaccharides are adsorbed onto erythrocytes. Action of an antibody directed against the antigen-coated cells results in their agglutination¹¹⁸ or in complement-mediated lysis.²³ The unmasking of T-type antigens by bacteria renders the cell polyagglutinable. This may be a rare cause of hemolysis occurring in the course of bacterial infections.^{119,120}

Many different types of microorganisms may play a role in precipitating autoimmune hemolytic disease (Chap. 54). In one study of

234 patients,¹⁰ 55 were found to have an antecedent bacterial infection, 18 of these exhibiting an “unequivocal etiologic relationship” of infection to anemia. However, the principal evidence for such a relationship was a temporal one. A number of viral agents, including measles, cytomegalovirus, varicella, herpes simplex, influenzas A and B, Epstein-Barr, human immunodeficiency virus^{24–26} (Chap. 82), and coxsackievirus have also been associated with immune hemolytic disease.^{10,121} Various mechanisms have been postulated, including absorption of immune complexes and complement, cross-reacting antigen, and a true autoimmune state with possible loss of tolerance secondary to the infectious organism.¹⁰ Histopathologic and sometimes virologic evidence of infection with cytomegalovirus has been reported in a high percentage of children with lymphadenopathy and hemolytic anemia.¹²² A positive antiglobulin reaction was demonstrated in some of these patients, and it has been suggested that some cases of “idiopathic autoimmune hemolytic anemia” are in reality caused by cytomegalovirus infection.¹²²

The high cold agglutinin titer that sometimes develops in the course of *Mycoplasma pneumoniae* pneumonia (Chap. 54) may occasionally result in hemolytic anemia^{1,33} or compensated hemolysis, although most patients with high cold agglutinin titers do not become anemic. The red cells of a number of patients with kala azar were found to be agglutinated with anticomplement and anti- γ -globulin serum.³⁰ Both splenic and hepatic sequestration of red cells appears to occur in this disease.¹³

Microangiopathic hemolytic anemia is discussed in detail in Chaps. 51 and 129. This disorder may be triggered by a variety of infections, some of which are caused by well-characterized organisms such as Shiga toxin-producing *Escherichia coli*, *Shigella dysenteriae* type 1,¹²³ *Campylobacter*,¹²⁴ and *Aspergillus*.¹

CHAPTER 54

HEMOLYTIC ANEMIA RESULTING FROM IMMUNE INJURY

Charles H. Packman

SUMMARY

Autoimmune hemolytic anemia (AHA) is characterized by shortened red blood cell (RBC) survival and the presence of autoantibodies directed against autologous RBCs. Demonstration of antibody and/or complement on RBC membranes, usually by a positive direct antiglobulin test (DAT, also referred to as the Coombs test) is essential for diagnosis. Most patients with AHA (80 percent) exhibit warm-reactive antibodies of the immunoglobulin (Ig) G isotype on their red cells. Most of the remainder of patients exhibit cold-reactive autoantibodies. Two types of cold-reactive autoantibodies to RBCs are recognized: cold agglutinins and cold hemolysins. Cold agglutinins are generally of IgM isotype, whereas cold hemolysins usually are of IgG isotype. The DAT may detect IgG, proteolytic fragments of complement (mainly C3), or both on the RBCs of patients with warm-antibody AHA. In cold-antibody AHA, only complement is detected because the antibody dissociates from the RBCs during washing of the cells. About half of patients with AHA have no underlying associated disease; these cases are termed primary or idiopathic. Secondary cases are associated with underlying autoimmune, malignant, or infectious diseases or with ingestion of certain drugs.

Although most patients do not require transfusion of RBCs, transfusion should not be withheld from those with symptomatic anemia. In warm-antibody AHA, rituximab and glucocorticoids are effective in slowing the rate of hemolysis. Splenectomy is indicated for patients who are refractory to medical therapy or who require an unacceptably high maintenance dose or prolonged administration of glucocorticoids. Intravenous immunoglobulin may provide short-term control of hemolysis. Immunosuppressive drugs and danazol have been used successfully in refractory cases. In cold agglutinin- and cold hemolysin-mediated hemolysis, keeping the patient warm and treating underlying lymphoproliferative disorders usually are effective. Rituximab has been effective in about half of cases of cold AHA. Drug-induced immune hemolytic anemia usually is ameliorated by discontinuation of the offending drug.

Acronyms and Abbreviations: AHA, autoimmune hemolytic anemia; CLL, chronic lymphocytic leukemia; DAF, decay-accelerating factor; DAT, direct antiglobulin test; HLA, human leukocyte antigen; HRF, homologous restriction factor; HS, hereditary spherocytosis; IAT, indirect antiglobulin test; Ig, immunoglobulin; IGHV, immunoglobulin heavy chain variable region; PNH, paroxysmal nocturnal hemoglobinuria; RBC, red blood cell; SLE, systemic lupus erythematosus.

DEFINITION AND HISTORY

The two main features of immune red blood cell (RBC) injury are (1) shortened RBC survival *in vivo* and (2) evidence of host antibodies reactive with autologous RBCs, most frequently demonstrated by a positive direct antiglobulin test (DAT), also known as the Coombs test. Most cases in adults are mediated by warm-reactive autoantibodies. A smaller proportion of patients exhibit cold-reactive autoantibodies or drug-related antibodies.

By the early 20th century, reticulocytes, spherocytes, and osmotic fragility of RBCs had been described. Clinicians could diagnose hemolytic anemia, but the distinction between congenital and acquired forms was imprecise. Some clinicians even doubted the existence of acquired hemolytic anemia.¹ The sera of some patients with hemolytic anemia directly agglutinated saline suspensions of normal or autologous human RBCs. These serum factors, later shown to be specific antibodies (largely of the immunoglobulin [Ig] M class), were termed *direct* or *saline agglutinins*. In a smaller proportion of cases, the patients' sera could mediate lysis of the test RBCs in the presence of fresh serum as a complement source. The heat-stable factors (antibodies) necessary for *in vitro* complement-mediated lysis were called *hemolysins*. However, in the majority of cases of hemolytic anemia, neither direct agglutinins nor hemolysins could be demonstrated. In 1945, Coombs and colleagues² reported that RBCs coated with nonagglutinating Rh antibodies (now known to be of the IgG isotype) could be agglutinated by rabbit anti-serum to human γ -globulin. That is, the rabbit antiglobulin serum crosslinked IgG antibody-coated RBCs to produce visible agglutination. Addition of rabbit antiglobulin serum to a suspension of washed RBCs isolated from patients with suspected acquired hemolytic anemia produced agglutination in many cases, including those patients lacking saline agglutinins or hemolysins. RBCs from patients with congenital hemolytic anemia did not agglutinate.^{3,4} This procedure now is termed the *direct antiglobulin (Coombs) test*. Subsequent studies established that positive direct antiglobulin reactions in autoimmune hemolytic anemia (AHA) are attributable to coating of the RBCs with immunoglobulins (mainly IgG) and/or complement proteins. When the RBCs are coated chiefly with complement proteins, a positive DAT depends upon the presence of anticomplement (principally anti-C3) in the antiglobulin reagent. In warm-antibody AHA, the autoantibodies, chiefly of IgG isotype, bind optimally to RBCs at 37°C. Warm antibodies may or may not activate complement binding to RBCs.

Cryopathic hemolytic syndromes are caused by autoantibodies that bind RBCs optimally at temperatures less than 37°C and usually less than 31°C. Two major types of "cold antibody" may produce AHA. Cold agglutinins, which directly agglutinate RBCs, mediate cold agglutinin disease. The Donath-Landsteiner autoantibody, which is not an agglutinin but a potent hemolysin, mediates paroxysmal cold hemoglobinuria. In both cryopathic syndromes, the complement system plays a major role in RBC injury (Chap. 19); as such, much greater potential exists for direct intravascular hemolysis than in warm-antibody-mediated AHA.

Cold agglutinins were first described by Landsteiner⁵ in 1903. However, recognition of the connection among cold agglutinins, hemolytic anemia, and Raynaud-like peripheral vascular phenomena evolved slowly. In 1918, Clough and Richter⁶ detected cold agglutinins in a patient with pneumonia. In 1925 and 1926, Iwai and MeiSai^{7,8} reported two patients with cold agglutinins and Raynaud phenomenon and showed that flow of blood through capillary tubes *in vitro* or in superficial capillaries *in vivo* was impeded at low temperatures. During the late 1940s and early 1950s, the observations of many investigators gradually established the pathogenic importance of cold agglutinins in RBC injury. Schubothe⁹ introduced the term *cold agglutinin disease* in

1953 and clearly distinguished the disorder from other acquired hemolytic syndromes.

In current usage, cold agglutinin disease pertains to patients with chronic AHA in which the autoantibody directly agglutinates human RBCs at temperatures below body temperature, maximally at 0 to 5°C. Fixation of complement to a patient's RBCs by cold agglutinins *in vivo* occurs at higher temperatures but generally less than 37°C. Cold agglutinins typically are IgM, although occasionally they may be immunoglobulins of other isotypes. The cold agglutinins in chronic cold agglutinin disease generally are monoclonal. Most cold agglutinins have specificity for oligosaccharide antigens (I or i) of the RBC (see "Origin of Cold Agglutinins" below).

Donath and Landsteiner first described the cold hemolysin that bears their name in 1904. The Donath-Landsteiner antibody is responsible for complement-mediated hemolysis in paroxysmal cold hemoglobinuria, a rare form of AHA in adults. The disorder is characterized by recurrent episodes of massive hemolysis following cold exposure.^{10,11} A related form of hemolytic anemia occurs much more commonly in children (or young adults) as an acute, self-limited hemolytic process following several types of viral syndromes.¹⁰⁻¹⁶ The disease was recognized during the latter half of the 19th century, when the disease was more common because of its association with congenital or tertiary syphilis. With the advent of effective therapy for syphilis, this cause of paroxysmal cold hemoglobinuria has almost disappeared. Now, recurrent paroxysmal cold hemoglobinuria occurs very rarely in a chronic idiopathic form.^{10,11} An increasing proportion of Donath-Landsteiner autoantibody-mediated hemolytic anemias occurs as a single post-viral episode in children, without recurrent attacks (paroxysms). The prognosis for such cases is excellent. Thus, rather than paroxysmal cold hemoglobinuria, a proposed term for this latter entity is *Donath-Landsteiner hemolytic anemia*.^{13,14}

The first example of drug-related immune blood cell destruction was Ackroyd's description of sedormid purpura in 1949.¹⁷ In 1953, Snapper and coworkers¹⁸ described a case of immune hemolysis and pancytopenia in a patient treated with mephenytoin (Mesantoin). Hemolysis ceased upon withdrawal of the drug. In 1956, Harris¹⁹ reported what are now classic studies of a patient who developed immune hemolytic anemia during a second course of stibophen administered for treatment of schistosomiasis. Since then, many drugs have been implicated in the production of positive DATs and accelerated RBC destruction.

CLASSIFICATION

Warm-Reactive versus Cold-Reactive Red Cell Antibody

AHA can be classified in two complementary ways (Table 54-1). The majority of cases (80 to 90 percent in adults) are mediated by warm-reactive autoantibodies^{10,11,20} or antibodies displaying optimal reactivity with human RBCs at 37°C. A smaller proportion of cases is attributable to cold-reactive autoantibodies exhibiting greater affinity for RBCs at temperatures less than 37°C. The distinction is important, not only because of differences in the pathophysiology of RBC injury but also in the therapeutic approaches required. An even smaller proportion of patients with AHA exhibit both cold-reactive and warm-reactive autoantibodies,^{21,22} which apparently recognize different antigens on the RBC membrane.²³ RBC destruction is generally more severe in mixed cases.

Absence or Presence of an Associated Disease

Classification of AHA based on the presence or absence of underlying diseases also is useful (see Table 54-1). When no recognizable underlying disease is present, the AHA is termed *primary* or *idiopathic*. When AHA appears to be a manifestation or complication of an underlying

TABLE 54-1. Classification of Hemolytic Anemia as a Result of Immune Injury

- I. Warm-Autoantibody Type: Autoantibody Maximally Active at Body Temperature (37°C)
 - A. Primary or idiopathic warm autoimmune hemolytic anemia (AHA)
 - B. Secondary warm AHA
 1. Associated with lymphoproliferative disorders (e.g., Hodgkin lymphoma)
 2. Associated with the rheumatic disorders, particularly systemic lupus erythematosus (SLE)
 3. Associated with certain nonlymphoid neoplasms (e.g., ovarian tumors)
 4. Associated with certain chronic inflammatory diseases (e.g., ulcerative colitis)
 5. Associated with ingestion of certain drugs (e.g., *α*-methyl dopa)
- II. Cold-Autoantibody Type: Autoantibody Optimally Active at Temperatures <37°C
 - A. Mediated by cold agglutinins
 1. Idiopathic (primary) chronic cold agglutinin disease (usually associated with clonal B-lymphocyte proliferation)
 2. Secondary cold agglutinin hemolytic anemia
 - a. Postinfectious (e.g., *Mycoplasma pneumoniae* or infectious mononucleosis)
 - b. Associated with malignant B-cell lymphoproliferative disorder
 - B. Mediated by cold hemolysins
 1. Idiopathic (primary) paroxysmal cold hemoglobinuria (very rare)
 2. Secondary
 - a. Donath-Landsteiner hemolytic anemia, usually associated with an acute viral syndrome in children (relatively common)
 - b. Congenital or tertiary syphilis in adults (very rare)
- III. Mixed Cold and Warm Autoantibodies
 - A. Primary or idiopathic mixed AHA
 - B. Secondary mixed AHA
 1. Associated with the rheumatic disorders, particularly SLE
- IV. Drug-Immune Hemolytic Anemia
 - A. Hapten or drug adsorption mechanism
 - B. Ternary (immune) complex mechanism
 - C. True autoantibody mechanism

disorder, the term *secondary AHA* is applied. Lymphocytic malignancies, particularly chronic lymphocytic leukemia (CLL) and lymphomas, account for approximately half of all secondary AHA cases and for the majority of AHA cases mediated by cold agglutinins.²⁴ Systemic lupus erythematosus (SLE) and other autoimmune diseases account for a lesser but considerable proportion of secondary AHA cases. A large proportion of patients with mixed cold and warm autoantibodies have SLE.^{21,22} Infectious mononucleosis and *Mycoplasma pneumoniae* occasionally are associated with cryopathic AHA. Despite the frequent occurrence of immune thrombocytopenia and positive DATs in patients infected with HIV, AHA is relatively rare in these patients.²⁵⁻²⁷ Table 54-1 lists other associated diseases that are less-commonly reported. The etiologic and

pathogenic significance of these associations is poorly understood, but most of the associated diseases involve components of the immune system, either by neoplasia or by aberrant immunopathologic responses.

Drug-Mediated Cases

Certain drugs also mediate immune injury to RBCs, and three general mechanisms are recognized (see Table 54–1 and Fig. 54–1). This classification is based on the effector mechanism of RBC injury, because the induction mechanism for formation of drug-related RBC antibodies is unknown. Two of the mechanisms, hapten-drug adsorption and ternary complex formation, involve drug-dependent antibodies. In the third mechanism, the drugs in question appear to induce formation of true autoantibodies capable of reacting with human RBCs in the absence of the inciting drug. These types of drug-mediated immune injury to RBCs often are referred to collectively as *drug-immune hemolytic anemia* to distinguish them from *de novo* AHA. Distinguishing among the mechanisms is not always possible, and some cases involve a combination of mechanisms. In addition, drug-related non-immunologic protein adsorption by RBCs may result in a positive DAT without actual RBC injury. This phenomenon should be distinguished from the three forms of drug-immune RBC injury. Table 54–2 lists drugs documented to cause either immune injury or a positive DAT.

EPIDEMIOLOGY

The annual incidence of warm-antibody AHA is 1 per 75,000 to 80,000 population.¹¹ Estimates of the frequency of primary (idiopathic) AHA vary from 20 to 80 percent of all types of AHA, depending on the referral patterns of the reporting center.^{11,20,118} In general, AHA is considered

secondary (1) when AHA and the underlying disease occur together with greater frequency than can be accounted for by chance alone; (2) when the AHA reverses simultaneously with correction of the associated disease; or (3) when AHA and the associated disease are related by evidence of immunologic aberration.¹¹ Using these criteria, the frequency of primary warm-antibody AHA probably is closer to 50 percent of all cases. Careful followup of patients with primary AHA is essential, because hemolytic anemia may be the presenting finding in a patient who subsequently develops overt evidence of an underlying disorder. For example, in one series, 18 of 107 patients with AHA developed a malignant lymphoproliferative disorder at a median of 26.5 months after diagnosis of the AHA.¹¹⁹

Warm-antibody AHA has been diagnosed in people of all ages, from infants to the elderly. The majority of patients are older than 40 years of age, with peak incidence around the seventh decade. This age distribution probably reflects, in part, the increased frequency of lymphoproliferative malignancies in the elderly, resulting in an age-related increase in the frequency of secondary AHA. Although multiple cases are occasionally observed in families,^{120–122} most cases of primary AHA arise sporadically. Development of AHA does not have an apparent association with any particular human leukocyte antigen (HLA) haplotype or other genetic factor.

Cold agglutinin disease is less common than warm-antibody AHA, with a prevalence of approximately 14 per 1 million population,²⁴ accounting for only 10 to 20 percent of all cases of AHA.^{10,11,123} Women are affected more commonly than men.^{10,11} No genetic or racial factors are known to contribute to the pathogenesis of this disease.

Secondary cold agglutinin disease is seen most commonly in adolescents or young adults as a self-limited process associated with

Figure 54–1. Effector mechanisms by which drugs mediate a positive direct antiglobulin test. Relationships of drug, antibody-combining site, and red blood cell membrane protein are shown. Panels **A**, **B**, and **C** show only a single immunoglobulin Fab region (bearing one combining site). **A.** Drug adsorption/hapten mechanism. The drug (▼) binds avidly to an unknown red blood cell membrane protein *in vivo*. Antidrug antibody (usually immunoglobulin [Ig] G) binds to the protein-bound drug. The membrane protein is not known to be part of the epitope recognized by the antidrug antibody. The direct antiglobulin test (with anti-IgG) detects IgG antidrug antibody on the patient's circulating (drug-coated) red blood cells. The indirect antiglobulin test detects antibody in the patient's serum only when the test red blood cells have been previously coated with the drug by incubation *in vitro*. **B.** Ternary complex mechanism. Drug binds loosely or in undetectable amounts to red blood cell membrane. However, in the presence of appropriate antidrug antibody, a stable trimolecular (ternary) complex is formed by drug, red blood cell membrane protein, and antibody. In general, the antibody-combining site (*Fab*) recognizes both drug and membrane protein components but binds only weakly to either drug or protein unless both are present in the reaction mixture. In this mechanism, the direct antiglobulin test typically detects only red blood cell-bound complement components (e.g., C3 fragments) that are bound covalently and in large number to the patient's red blood cells *in vivo*. The antibody itself escapes detection, possibly because of its low concentration but also because washing of the red cells (in the antiglobulin test procedure) apparently dissociates antibody and drug from the cells, leaving only the covalently bound C3 fragments. The indirect antiglobulin test also detects complement proteins on the test red blood cells when both antibody (patient serum) and a complement source (fresh patient serum or fresh normal serum) are present in the reaction mixture together with the drug. **C.** Autoantibody induction. Some drug-induced antibodies can bind avidly to red blood cell membrane proteins (usually Rh proteins) in the absence of the inducing drug and are indistinguishable from the autoantibodies of patients with autoimmune hemolytic anemia. The direct antiglobulin test detects the IgG antibody on the patient's red blood cells. The indirect antiglobulin test usually detects antibody in the serum of patients with active hemolysis. **D.** Drug-induced nonimmunologic protein adsorption. Certain drugs cause plasma proteins to attach nonspecifically to the red blood cell membrane. The direct antiglobulin test detects nonspecifically bound IgG and complement components. If special antiglobulin reagents are used, other plasma proteins, such as transferrin (TF), albumin (Alb), and fibrinogen (Fibr), also may be detected. In contrast to the other mechanisms of drug-induced red blood cell injury, this mechanism does not shorten red blood cell survival *in vivo*.

TABLE 54-2. Association between Drugs and Positive Direct Antiglobulin Tests

Drug	Reference	Drug	Reference
HAPTEN OR DRUG ADSORPTION MECHANISM			
Penicillins	28-34	Tolbutamide	44, 45
Cephalosporins	35-39	Cianidanol	46
Tetracycline	40, 41	Hydrocortisone	47
6-Mercaptopurine	42	Oxaliplatin	48
Carbromal	43	Cimetidine	49
TERNARY COMPLEX MECHANISM			
Stibophen	19	Cephalosporins	37-39, 64
Quinine	50	Diethylstilbestrol	65
Quinidine	51, 52	Amphotericin B	66
Chlorpropamide	53, 54	Doxepin	67
Metformin	55	Diclofenac	68, 69
Rifampicin	56	Etodolac	70
Antazoline	57	Hydrocortisone	47
Thiopental	58	Oxaliplatin	48
Tolmetin	59	Pemetrexed	71
Probenecid	60	Cimetidine	49
Nomifensine	61-63	lomeprol	72
AUTOANTIBODY MECHANISM			
Cephalosporins	39	Latamoxef	84
Tolmetin	59	Glafenine	84
Nomifensine	61	Procainamide	85
α -Methyldopa	73-76	Diclofenac	69, 86
L-dopa	78-81	Pentostatin	87
Mefenamic acid	82, 83	Fludarabine	88, 89
Teniposide	84	Cladribine	90
Oxaliplatin	48	Efalizumab	91
Cianidanol	46	Lenalidomide	92
NONIMMUNOLOGIC PROTEIN ADSORPTION			
Cephalosporins	93, 94		
Oxaliplatin	48		
Carboplatin	48		
Cisplatin	48, 95		
UNCERTAIN MECHANISM OF IMMUNE INJURY			
Mesantoin	18	Erythromycin	106
Phenacetin	50	5-fluorouracil	107
Insecticides	96	Nalidixic Acid	108
Chlorpromazine	97	Sulindac	109
Melphalan	98	Omeprazole	110
Isoniazid	99	Temafloxacin	111
<i>p</i> -Aminosalicylic acid	100	Carboplatin	112
Acetaminophen	101	Efavirenz	113
Thiazides	102	Etoricoxib	114
Streptomycin	103	Levofloxacin	115
Ibuprofen	104	<i>Pueraria</i> (Chinese herb)	116
Triamterene	105	Cabergoline	117

The drugs listed above are those which, in the author's opinion, have been documented to cause a positive direct antiglobulin test, with or without immune injury. Other drugs, omitted from this list, have been alleged to cause immune injury but laboratory confirmation is lacking. New drugs will be added to this list in the future. When an association between a drug and hemolysis is suspected, it is important to evaluate for an immune etiology and to document the mechanism, by referral to a reference laboratory if necessary.

M. pneumoniae infections or infectious mononucleosis and, rarely, in children with chickenpox. The term also has been used to describe a chronic disorder occurring in older patients with known malignant lymphoproliferative diseases. On the other hand, idiopathic (primary) chronic cold agglutinin disease has its peak incidence after age 50 years. This disorder, with its characteristic monoclonal IgM cold agglutinins, may be considered a special form of monoclonal gammopathy (Chap. 106). Nearly all of these patients exhibit clonal B lymphocyte proliferation.²⁴ As with other “essential” or idiopathic monoclonal gammopathies, some patients in this group gradually develop features of a B-cell lymphoproliferative disorder resembling Waldenström macroglobulinemia, CLL, or a B-cell lymphoma. Thus, the distinction between primary and secondary types of chronic cold agglutinin disease is not absolute.

Although the majority of patients with mycoplasma pneumonia have significant cold agglutinin titers, they only infrequently develop clinical hemolytic anemia.^{124–126} However, subclinical RBC injury may occur. In *M. pneumoniae* infections, weakly positive direct antiglobulin reactions and/or mild reticulocytosis are often noted in the absence of anemia in a substantial number of cases.¹²⁴ Cold agglutinins occur in more than 60 percent of patients with infectious mononucleosis, but again, hemolytic anemia is rare.^{127–129}

Medical centers that receive many referrals report that paroxysmal cold hemoglobinuria constitutes 2 to 5 percent of all cases of AHA.^{10,11} Among children, however, Donath-Landsteiner hemolytic anemia accounted for 32.4 percent of 68 immune hemolytic syndromes diagnosed over a 4-year period.¹⁵ Commonly, the diagnosis is missed because of lack of physician awareness or failure to perform the proper serologic studies (see “Serologic Features” below).^{12,15} Thus, the true incidence may be higher. Although familial occurrence has been reported, no racial or genetic risk factors are known.¹⁰ As noted, most childhood cases follow either specific viral infections or upper respiratory infections of undefined etiology.^{10–15}

Older series report that drug-induced immune hemolytic anemia accounts for 12 to 18 percent of immune hemolytic anemias.¹¹ The disorder is much less common now that α -methyl-dopa and megaunit doses of penicillin rarely are used. The current incidence of drug-induced immune hemolytic anemia is estimated at 1 per 1 million population, approximately 88 percent of which result from the second- and third-generation cephalosporins, cefotetan, and ceftriaxone.^{89,130} Fludarabine has replaced α -methyl-dopa as the most common cause of drug-induced autoantibodies.⁸⁹

ETIOLOGY AND PATHOGENESIS

ETIOLOGY

Warm-Antibody Autoimmune Hemolytic Anemia

The etiology of AHA is unknown. In warm-antibody AHA, the autoantibodies that mediate RBC destruction are predominantly (but not exclusively) IgG globulins possessing relatively high binding affinity for human RBCs at 37°C. As a result, the major share of plasma autoantibody is bound to the patient’s circulating RBCs. Eluates prepared from the patient’s washed, autoantibody-coated RBCs constitute an important source of purified autoantibody for investigation of specificity, immunoglobulin structure, or other properties. In addition, sera from patients with warm AHA often are used in blood banks for crossmatching and for general screening of antibody specificity. The quantity of such autoantibody in serum may be low and in some cases may not reflect the full spectrum of anti-RBC specificity revealed in concurrently prepared RBC eluates.¹²⁴

In patients with primary AHA, erythrocyte autoantibodies are the only recognizable immunologic aberration. Furthermore, the

autoantibodies of any one patient often are specific for only a single RBC membrane protein (see “Serologic Features” below). The narrow spectrum of autoreactivity suggests the mechanism underlying AHA development in such patients is not secondary to a generalized defect in immune regulation. Rather, these patients may develop warm-antibody AHA through an aberrant immune response to a self-antigen or to an immunogen that mimics a self-antigen.

In patients with secondary AHA, the disease may be associated with a fundamental disturbance in the immune system, for example, when in the setting of lymphoma, CLL, SLE, primary agammaglobulinemia (common variable immunodeficiency), or hyper-IgM immunodeficiency syndrome. In these settings, warm-antibody AHA most likely arises through an underlying defect in immune regulation, although the contribution of an aberrant immune response to self-antigen cannot be excluded. AHA seems especially frequent in patients with low-grade lymphoma or CLL treated with fludarabine^{88,89} or 2-chlorodeoxyadenosine (cladribine).⁹⁰ The T-lymphocytopenia induced by these drugs may exacerbate the preexisting tendency of patients to form autoantibodies.

A long-recognized but poorly understood phenomenon, the development of AHA or a positive DAT following RBC transfusion, has received renewed interest lately.^{132,133} Although generally transient, the positive DAT may persist for up to 300 days in some transfusion recipients, long after any transfused RBCs have disappeared.^{134,135} It is not clear whether this represents true autoimmunity or some other mechanism, for example, microchimerism resulting from temporary engraftment of passenger memory lymphocytes from the RBC donor.¹³²

A still unexplained observation is that certain drugs, such as α -methyl-dopa, can induce warm-reacting IgG anti-RBC autoantibodies in otherwise normal persons. The autoantibodies induced by α -methyl-dopa have Rh-related serologic and immunochemical¹³⁶ specificity similar to that of autoantibodies arising in many patients with “spontaneous” AHA. A critical difference is that the drug-associated autoantibodies subside when the drug is discontinued, suggesting that (1) the latent potential to form this type of anti-RBC autoantibody is present in many immunologically normal individuals, and (2) the steps required to generate such autoantibodies do not necessarily create a sustained autoimmune state. On the other hand, maintenance of chronic idiopathic AHA may be either secondary to a continuing (but unknown) stimulus or induced by a short stimulus to which the patient continues to respond.

Normal subjects sometimes have a positive DAT when they volunteer to donate blood.^{137,138} The positive DAT in these normal donors often results from warm-reacting IgG autoantibodies, similar in serologic specificity¹³¹ and in IgG subclass¹³⁷ to the autoantibodies occurring in AHA. Although many of these donors remain DAT-positive without developing overt hemolytic anemia, a few have been documented to develop AHA.^{137,138} The prevalence of positive DATs in normal blood donors is approximately 1 in 10,000 donors.^{137,139} Because blood donation *per se* likely does not contribute to an increased risk of developing autoantibodies, the 1 in 10,000 proportion likely is the approximate frequency of positive DATs in the entire population. A proportion of patients who present with clinically overt primary AHA may come from a subset of asymptomatic individuals who are DAT-positive, but this notion is not established.

Several concepts have been developed to explain immunologic tolerance to self-antigens.^{140–143} Relevant to warm-antibody AHA, membrane-bound antigens expressed in a multivalent array at high concentration may induce tolerance by effecting clonal deletion of autoreactive B cells.¹⁴⁴ Both the Rh-related and the non-Rh types of RBC antigens targeted by AHA autoantibodies (see “Serologic Features” below) are expressed normally by human fetal erythrocytes, as early as

10 to 12 weeks of life.¹⁴⁵ However, because new B cells develop daily in the marrow throughout life and because B cells may somatically mutate their Ig receptors, self-tolerance in the B cell compartment is never assured. Analogy to observations in NZB (New Zealand black) mice^{146,147} suggests the peritoneal cavity is a privileged compartment that shelters autoreactive B cells from host RBCs, allowing them to escape deletion, later to produce anti-RBC autoantibodies with appropriate T-cell help. The strong predominance of IgG antibodies in AHA suggests B-cell isotype switching, which is consistent with the idea of an antigen-driven process. Moreover, because T-cell help is necessary for inducing B-cell isotype switching, the pathway(s) to autoantibody induction in AHA also may involve an abnormal or unique mode of antigen presentation to T cells.¹⁴⁸

Origin of Cold Agglutinins

A high proportion of monoclonal IgM cold agglutinins with either anti-I or anti-i specificity have heavy-chain variable regions encoded by IGHV4-34 (immunoglobulin heavy chain variable region), formerly designated IGHV4.21.^{143,149-151} IGHV4-34 encodes a distinct idiotype identified by the rat monoclonal antibody 9G4. This idiotype is expressed both by the cold agglutinins themselves and on the surface immunoglobulin of B cells synthesizing cold agglutinins or related immunoglobulins possessing IGHV4-34 sequences.¹⁵² Using the 9G4 monoclonal antibody as a probe, this idiotype was found not only in a very high proportion of circulating B cells and marrow lymphoplasmacytoid cells of patients with lymphoma-associated chronic cold agglutinin disease, but also in a smaller proportion of B cells in the blood and lymphoid tissues of normal adult donors and in the spleens of 15-week human fetuses.¹⁵² These data suggest B cells expressing the IGHV4-34 gene (or a closely related sequence) are present throughout ontogeny. Therefore, chronic cold agglutinin disease may represent a marked, unregulated expansion of a subset (clone) of such B cells.

Light-chain V-region gene use in anti-I cold agglutinins is highly selective. A strong bias toward use of the κ III variable region subgroup (V κ -III) is observed.¹⁵⁰⁻¹⁵³ Light-chain selection among anti-i cold agglutinins, however, is much more variable and includes the λ type.¹⁵⁰⁻¹⁵⁴

Observations that pathologic cold agglutinins are synthesized with distinct and highly selected V-region sequences must be viewed against the background of two other subsequent observations. First, IGHV4-34 or related IGHV genes also may encode the heavy-chain variable regions of other types of antibodies, such as rheumatoid factor autoantibodies and alloantibodies to a variety of blood group antigens, including polypeptide determinants such as Rh.¹⁵⁵ Second, normal human antibodies to an exogenous carbohydrate antigen, *Haemophilus influenzae* type b capsular polysaccharide, also are encoded by a restricted set of IGHV genes¹⁵⁶ and Ig light-chain V genes.¹⁵⁷ Thus, regulation of Ig gene use for production of anti-I or anti-i cold agglutinins may not differ fundamentally from normal antibody formation to other carbohydrate antigens.

In the setting of B-cell lymphoma or Waldenström macroglobulinemia, cold agglutinins may be produced by the malignant clone itself. Two patients with lymphoma and monoclonal cold agglutinin were identified as having a karyotypically abnormal B-cell clone that produced a cold agglutinin identical to that found in their sera.^{158,159} Trisomy 3 has been the most frequently observed karyotypic abnormality in patients with non-Hodgkin lymphoma and cold agglutinins.^{158,160}

Normal human sera generally have naturally occurring polyclonal cold agglutinins in low titer (usually 1/64 or less).¹⁰ Otherwise healthy persons may develop elevated titers of cold agglutinins specific for I/i antigens during certain infections (e.g., *M. pneumoniae*, Epstein-Barr virus, cytomegalovirus). In contrast to other forms of cold agglutinin disease, hyperproduction of these postinfectious cold agglutinins is transient. Some evidence indicates postinfectious cold agglutinins may

be less clonally restricted than those occurring in chronic cold agglutinin disease,¹⁶¹ but this finding is not universal.¹⁶² Whether IGHV4-34 also encodes most heavy-chain variable regions of all naturally occurring or postinfectious cold agglutinins remains to be determined.

The increased production of cold agglutinins in response to infection with *M. pneumoniae* may be secondary to the fact that the oligosaccharide antigens of the I/i type serve as specific *Mycoplasma* receptors.¹⁶³ This process may lead to altered antigen presentation involving a complex between a self-antigen (I/i) and a non-self-antigen (*Mycoplasma*). Alternatively, the anti-i cold agglutinins may arise as a consequence of polyclonal B cell activation, as occurs in infectious mononucleosis (Chap. 82).

The mechanism(s) whereby dissimilar infectious agents (e.g., spirochetes and several types of virus) induce the immune system to produce Donath-Landsteiner antibodies with specificity for the human P blood group antigen (see "Serologic Features" below) is not known.

PATHOGENESIS

Pathogenic Effects of Warm Antibodies

Warm autoantibodies to RBCs in AHA are pathogenic. In contrast to autologous RBCs, labeled RBCs lacking the antigen targeted by the autoantibodies may survive normally in patients with warm-antibody AHA.^{10,164,165} Furthermore, transplacental passage of IgG anti-RBC autoantibodies from a mother with AHA to the fetus can induce intrauterine or neonatal hemolytic anemia.¹⁶⁶ Finally, despite notable exceptions and differences related to IgG subclass of the autoantibody, in general, an inverse relationship between the quantity of RBC-bound IgG antibody and RBC survival is noted in serial studies performed on animals and patients.¹⁶⁷⁻¹⁷²

In warm-antibody AHA, the patient's RBCs typically are coated with IgG autoantibodies with or without complement proteins. Autoantibody-coated RBCs are trapped by macrophages in the Billroth cords of the spleen and, to a lesser extent, by Kupffer cells in the liver (Chap. 68).^{164,167,168,170-174} The process leads to generation of spherocytes and fragmentation and ingestion of antibody-coated RBCs.^{175,176} The macrophage has surface receptors for the Fc region of IgG, with preference for the IgG₁ and IgG₃ subclasses^{177,178} and surface receptors for opsonic fragments of C3 (C3b and C3bi) and C4b.¹⁷⁹⁻¹⁸¹ When present together on the RBC surface, IgG and C3b/C3bi appear to act cooperatively as opsonins to enhance trapping and phagocytosis.^{170,171,180-184} Although RBC sequestration in warm-antibody AHA occurs primarily in the spleen,^{164,171-173} very large quantities of RBC-bound IgG^{167,168,174} or the concurrent presence of C3b on the RBCs^{167,170,171} may favor trapping in the liver.

Interaction of a trapped RBC with splenic macrophages may result in phagocytosis of the entire cell. More commonly, a type of partial phagocytosis results in spherocyte formation. As RBCs adhere to macrophages via the Fc receptors, portions of RBC membrane are internalized by the macrophage. Because membrane is lost in excess of contents, the noningested portion of the RBC assumes a spherical shape, the shape with the lowest ratio of surface area to volume.^{175,176,185} Spherical RBCs are more rigid and less deformable than normal RBCs. As such, spherical RBCs are fragmented further and eventually destroyed in future passages through the spleen. Spherocytosis is a consistent and diagnostically important hallmark of AHA,¹⁸⁶ and the degree of spherocytosis correlates well with the severity of hemolysis.¹⁰

Direct complement-mediated hemolysis with hemoglobinuria is unusual in warm-antibody AHA, even though many warm autoantibodies fix complement. The failure of C3b-coated RBCs to be hemolyzed by the terminal complement cascade (C5-C9) has been attributed, at least in part, to the ability of complement regulatory proteins (factors

I and H) in plasma and C3b receptors on the RBC surface to alter the hemolytic function of cell-bound C3b and C4b.¹⁸⁷ Glycosylphosphatidylinositol-linked erythrocyte membrane proteins, such as decay-accelerating factor (DAF; CD55) and homologous restriction factor (HRF; CD59), may limit the action of autologous complement on auto-antibody-coated RBCs.^{188–190} DAF inhibits the formation and function of cell-bound C3-converting enzyme,¹⁸⁸ thus, indirectly limiting formation of C5-converting enzyme. HRF, on the other hand, impedes C9 binding and formation of the C5b–9 membrane attack complex.¹⁸⁹

Cytotoxic activities of macrophages and lymphocytes also may play a role in the destruction of RBCs in warm-antibody AHA. Monocytes can lyse IgG-coated RBCs *in vitro* independently of phagocytosis.^{191,192} Cell-bound complement is neither necessary nor sufficient for such cytotoxicity, but bound C3b/C3d can potentiate the effects of IgG.¹⁹² In one study, cytotoxicity, but not phagocytosis, was inhibited by hydrocortisone *in vitro*.¹⁹¹ Lymphocytes also can lyse IgG antibody-coated RBCs *in vitro*.^{193–195} The relative contribution of antibody-dependent monocyte- and lymphocyte-mediated cytotoxicity to RBC destruction in patients with warm-antibody AHA is not known.

Pathogenic Effects of Cold Agglutinins and Hemolysins

Most cold agglutinins are unable to agglutinate RBCs at temperatures higher than 30°C. The highest temperature at which these antibodies cause detectable agglutination is termed the *thermal amplitude*. The value varies considerably among patients. Generally, patients with cold agglutinins with higher thermal amplitudes have a greater risk for cold agglutinin disease.⁹ For example, active hemolytic anemia has been observed in patients with cold agglutinins of modest titer (e.g., 1:256) and high thermal amplitudes.¹⁹⁶

The pathogenicity of a cold agglutinin depends upon its ability to bind host RBCs and to activate complement.^{10,182,197,198} This process is called *complement fixation*. Although *in vitro* agglutination of the RBCs may be maximal at 0 to 5°C, complement fixation by these antibodies may occur optimally at 20 to 25°C and may be significant at even higher physiologic temperatures.^{10,196,197} Agglutination is not required for the process. The great preponderance of cold agglutinin molecules are IgM pentamers, but small numbers of IgM hexamers with cold agglutinin activity are found in patients with cold agglutinin disease. Hexamers fix complement and lyse RBCs more efficiently than do pentamers, suggesting that hexameric IgM plays a role in the pathogenesis of hemolysis in these patients.¹⁹⁹

Cold agglutinins may bind to RBCs in superficial vessels of the extremities, where the temperature generally ranges between 28 and 31°C, depending upon ambient temperature.²⁰⁰ Cold agglutinins of high thermal amplitude may cause RBCs to aggregate at this temperature, thereby impeding RBC flow and producing acrocyanosis. In addition, the RBC-bound cold agglutinin may activate complement via the classic pathway. Once activated complement proteins are deposited onto the RBC surface, the cold agglutinin need not remain bound to the RBCs for hemolysis to occur. Instead, the cold agglutinin may dissociate from the RBCs at the higher temperatures in the body core and again be capable of binding other RBCs at the lower temperatures in the superficial vessels. As a result, patients with cold agglutinins of high thermal amplitude tend toward a sustained hemolytic process and acrocyanosis.²⁰¹ In contrast, patients with antibodies of lower thermal amplitude require significant chilling to initiate complement-mediated injury of RBCs. This sequence may result in a burst of hemolysis with hemoglobinuria.²⁰¹ Combinations of these clinical patterns also occur. Cold agglutinins of the IgA isotype, an isotype that does not fix complement, may cause acrocyanosis but not hemolysis.²⁰² Thus, the relative degree of hemolysis or impeded RBC flow is influenced significantly by the properties and quantity of the cold agglutinins in a given patient.

Complement fixation by cold agglutinins may affect RBC injury by two major mechanisms: (1) direct lysis and (2) opsonization for hepatic and splenic macrophages. Both mechanisms probably operate to varying degrees in any patient. Direct lysis requires propagation of the full C1 to C9 sequence on the RBC membrane. If this process occurs to a significant degree, the patient may experience intravascular hemolysis leading to hemoglobinemia and hemoglobinuria. Intravascular hemolysis of this severity is relatively rare because phosphatidylinositol-linked RBC membrane proteins (DAF and HRF) protect against injury by autologous complement components. Thus, the complement sequence on many RBCs is completed only through the early steps, leaving opsonic fragments of C3 (C3b/C3bi) and C4 (C4b) on the cell surface. The fragments provide only a weak stimulus for phagocytosis by monocytes *in vitro*.^{184,203} However, activated macrophages may ingest C3b-coated particles avidly.²⁰⁴ Accordingly, RBCs heavily coated with C3b (and/or C3bi) may be removed from the circulation by macrophages either in the liver or, to a lesser extent, the spleen.^{171,197,205,206} The trapped RBCs may be ingested entirely or released back into the circulation as spherocytes after losing plasma membrane.

In vivo studies of the fate of ⁵¹Cr-labeled C3b-coated RBCs^{170,197,205,206} indicate many of the erythrocytes trapped in the liver or spleen gradually may reenter the circulation. The released cells generally are coated with the opsonically inactive C3 fragment C3dg. Conversion of cell-bound C3b or C3bi to C3dg results from the action of the naturally occurring complement inhibitor factor I in concert with factor H or CR1 receptors.¹⁸¹ The surviving C3dg-coated RBCs circulate with a near-normal life span^{170,197,205,206} and are resistant to further uptake of cold agglutinins or complement.^{197,205,207} However, C3dg-coated RBCs also may react *in vitro* with anticomplement (anti-C3) serum in the DAT. In fact, most of the antiglobulin-positive RBCs of patients with cold agglutinin disease are coated with C3dg.

In paroxysmal cold hemoglobinuria, the mechanism of hemolysis probably parallels *in vitro* events (see “Serologic Features” below). During severe chilling, blood flowing through skin capillaries is exposed to low temperatures. The Donath-Landsteiner antibody and early acting complement components presumably bind to RBCs at the lowered temperatures. Upon return of the cells to 37°C in the central circulation, the cells are lysed by propagation of the terminal complement sequence through C9. The Donath-Landsteiner antibody itself dissociates from the RBCs at 37°C. Erythrocyte membrane proteins that restrict C5b–9 assembly (e.g., HRFs) may be less effective in controlling Donath-Landsteiner antibody-initiated complement activation than that initiated by cold agglutinins.

Pathogenesis of Drug-Mediated Immune Injury

Table 54–3 summarizes the three mechanisms of drug-mediated immune injury to RBCs. Drugs also may mediate protein adsorption to RBCs by nonimmune mechanisms, but RBC injury does not occur.

Hapten or Drug Adsorption Mechanism This mechanism applies to drugs that can bind firmly to proteins, including RBC membrane proteins. The classic setting is very-high-dose penicillin therapy,^{28–34} which is encountered less commonly today than in previous decades.

Most individuals who receive penicillin develop IgM antibodies directed against the benzylpenicilloyl determinant of penicillin, but this antibody plays no role in penicillin-related immune injury to RBCs. The antibody responsible for hemolytic anemia is of the IgG class, occurs less frequently than the IgM antibody, and may be directed against the benzylpenicilloyl,³¹ or, more commonly, nonbenzylpenicilloyl determinants.^{28–30,32} Other manifestations of penicillin sensitivity usually are not present.

All patients receiving high doses of penicillin develop substantial coating of RBCs with penicillin. The penicillin coating itself is not

TABLE 54-3. Major Mechanisms of Drug-Related Hemolytic Anemia and Positive Direct Antiglobulin Tests

	Hapten/Drug Adsorption	Ternary Complex Formation	Autoantibody Binding	Nonimmunologic Protein Adsorption
Prototype drug	Penicillin	Quinidine	α -Methyldopa	Cephalothin
Role of drug	Binds to red cell membrane	Forms ternary complex with antibody and red cell membrane component	Induces formation of antibody to native red cell antigen	Possibly alters red cell membrane
Drug affinity to cell	Strong	Weak	None demonstrated to intact red cell but binding to membranes reported	Strong
Antibody to drug	Present	Present	Absent	Absent
Antibody class predominating	Immunoglobulin (Ig) G	IgM or IgG	IgG	None
Proteins detected by direct antiglobulin test	IgG, rarely complement	Complement	IgG, rarely complement	Multiple plasma proteins
Dose of drug associated with positive antiglobulin test	High	Low	High	High
Presence of drug required for indirect antiglobulin test	Yes (coating test red cells)	Yes (added to test medium)	No	Yes (added to test medium)
Mechanism of red cell destruction	Splenic sequestration of IgG-coated red cells	Direct lysis by complement plus splenic–hepatic clearance of C3b-coated red cells	Splenic sequestration	None

injurious. If the penicillin dose is very high (10 to 30×10^6 units per day, or less in the setting of renal failure) and promotes cell coating, and if the patient has an IgG antipenicillin antibody, the antibody binds to the RBC-bound penicillin molecules and the DAT with anti-IgG becomes positive (see Fig. 54-1A).^{29,31,32,51,208} Antibodies eluted from patients' RBCs or present in their sera react in the indirect antiglobulin test (IAT) only against penicillin-coated RBCs. This step is critical in distinguishing these drug-dependent antibodies from true autoantibodies.

Not all patients receiving high-dose penicillin develop a positive DAT reaction or hemolytic anemia because only a small proportion of such individuals produce the requisite antibody. Destruction of RBCs coated with penicillin and IgG antipenicillin antibody occurs mainly through sequestration by splenic macrophages.^{30,209} In some patients with penicillin-induced immune hemolytic anemia, blood monocytes and presumably splenic macrophages may lyse the IgG-coated RBCs without phagocytosis.²¹⁰ Hemolytic anemia resulting from penicillin typically occurs only after the patient has received the drug for 7 to 10 days and ceases a few days to 2 weeks after the patient discontinues taking the drug.

Low-molecular-weight substances, such as drugs, generally are not immunogenic in their own right. Induction of antidrug antibody is thought to require firm chemical coupling of the drug (as a hapten) to a protein carrier. In the case of penicillin, the carrier protein involved in antibody induction need not be the same as the erythrocyte membrane protein to which penicillin is coupled in the effector phase, that is, when the IgG antipenicillin antibodies bind to penicillin-coated RBCs. In contrast to evidence on the ternary complex mechanism, no evidence indicates the drug-dependent antibodies responsible for RBC injury in this hapten/drug adsorption mechanism also recognize native erythrocyte membrane structures.

Cephalosporins have antigenic cross-reactivity with penicillin^{211,213} and bind firmly to RBC membranes, as do semisynthetic penicillins.^{33,34} Hemolytic anemia similar to that seen with penicillin has been ascribed to cephalosporins³⁵⁻³⁹ and some semisynthetic penicillins.^{33,34}

Tetracycline^{40,41} and tolbutamide^{44,45} also may cause hemolysis by this mechanism. Carbromal causes positive IgG antiglobulin reactions by a similar mechanism,⁴³ but hemolytic anemia has not been described.

Ternary Complex Mechanism: Drug–Antibody–Target Cell Interaction Many drugs can induce immune injury not only of RBCs but also of platelets or granulocytes by a process that differs in several ways from the mechanism of hapten/drug adsorption (see Table 54-3). First, drugs in this group (see Table 54-2) exhibit only weak direct binding to blood cell membranes. Second, a relatively small dose of drug is capable of triggering destruction of blood cells. Third, cellular injury appears to be mediated chiefly by complement activation at the cell surface. The cytopathic process induced by such drugs previously has been termed the *innocent bystander* or *immune complex mechanism*. The terminology reflected the prevailing notion that, *in vivo*, drug–antibody complexes formed first (immune complexes) and then became secondarily bound to target blood cells as “innocent bystanders,” either nonspecifically or possibly via membrane receptors (e.g., Fc γ receptors on platelets or C3b receptors on red cells), with the potential for subsequent activation of complement by bound complexes.

The “immune complex” and “innocent bystander” terminology now seems less appropriate because of models developed from research on analogous drug-dependent platelet injury²¹⁴⁻²¹⁶ (Chap. 117) and a series of relevant serologic observations on drug-mediated immune hemolytic anemia. These studies suggest blood cell injury is mediated by a cooperative interaction among three reactants to generate a ternary complex (see Fig. 54-1B) involving (1) the drug (or drug metabolite in some cases), (2) a drug-binding membrane site on the target cell, and (3) antibody. For example, several patients possessed drug-dependent antibodies that exhibited specificity for RBCs bearing defined alloantigens such as those of the Rh, Kell, or Kidd blood groups. That is, even in the presence of drug, the antibodies were selectively nonreactive with human RBCs lacking the alloantigen in question.^{58,84,217-219} In each case, high-affinity drug binding to cell membrane could not be demonstrated. The drug-dependent antibody is thought to bind, through its

Fab domain, to a compound neoantigen consisting of loosely bound drug and a blood group antigen intrinsic to the red cell membrane. Elegant studies on quinidine- or quinine-induced immune thrombocytopenia have demonstrated the IgG antibodies implicated in this disorder bind through their Fab domains, not by their Fc domains to platelet Fc γ receptors.^{220,221}

The data elucidate how one patient with quinidine sensitivity may have selective destruction of platelets and another may have selective destruction of RBCs. This process occurs because the pathogenic antibody recognizes the drug only in combination with a particular membrane structure of the RBC (e.g., a known alloantigen) or of the platelet (e.g., α domain of the glycoprotein Ib complex). Therefore, at least in these cases, the target cell does not appear to be purely an innocent bystander. Binding of the drug itself to the target cell membrane is weak until the attachment of the antibody to *both* drug and cell membrane is stabilized. Yet the binding of the antibody is drug dependent. Such a three-reactant interdependent “troika” is unique to this mechanism of immune cytopenia.

The foregoing discussion depicting drugs as creating a “self + non-self” neoantigen on the target cell applies to the effector phase as opposed to the induction phase of the process. However, the same drug-binding membrane protein appears to be involved in forming the immunogen that induces the antibody, as evidenced by drug-dependent antibodies exhibiting selective reactivity with defined red cell alloantigens (carrier specificity).^{58,84,217–219} How this process is accomplished in the absence of evidence for strong, covalent binding of the drugs in this group to a host membrane protein remains to be elucidated.

RBC destruction by this mechanism may occur intravascularly after completion of the whole complement sequence, resulting in hemoglobinemia and hemoglobinuria. Some destruction of intact C3b-coated RBCs may be mediated by splenic and liver sequestration via the C3b/C3bi receptors on macrophages. The DAT is positive usually only with anticomplement reagents, but exceptions occur. Sometimes, however, the drug-dependent antibody itself can be detected on the RBCs if the offending drug (or its metabolites) is included in all steps of the antiglobulin test, including washing.²²²

Autoantibody Mechanism A variety of drugs induce the formation of autoantibodies reactive with autologous (or homologous) RBCs in the absence of the instigating drug (see Tables 54–2 and 54–3). The most studied drug in this category has been α -methyl dopa, an antihypertensive agent that no longer is commonly used.^{73–76} Levodopa and several unrelated drugs also have been implicated.^{39,46,59,61,68,77–86} Patients with CLL treated with pentostatin,⁸⁷ fludarabine,⁸⁸ or cladribine⁹⁰ are particularly predisposed to autoimmune hemolysis, which usually is severe and sometimes fatal.

Positive DAT reactions (with anti-IgG reagents) in patients taking α -methyl dopa vary in frequency from 8 to 36 percent. Patients taking higher doses of the drug develop positive reactions with greater frequency.^{73,75,76} A lag period of 3 to 6 months exists between the start of therapy and development of a positive antiglobulin test. The delay is not shortened when the drug is administered to patients who previously had positive antiglobulin tests while taking α -methyl dopa.⁷⁵

In contrast to the frequent observation of positive antiglobulin reactions, less than 1 percent of patients taking α -methyl dopa exhibit hemolytic anemia.⁷⁴ Development of hemolytic anemia does not depend on drug dose. The hemolysis usually is mild to moderate and occurs chiefly by splenic sequestration of IgG-coated RBCs. α -Methyl dopa has been proposed to suppress splenic macrophage function in some patients, and normal survival of antibody-coated RBCs in such patients may be related, in part, to this effect of the drug.²²³

The DAT reaction usually is positive only for IgG.¹¹ Occasionally, weak anticomplement reactions also are encountered.¹¹ Patients with

immune hemolytic anemia resulting from α -methyl dopa therapy typically exhibit strongly positive DAT reactions and serum antibody, evidenced by the IAT reaction.¹¹ Antibodies in the serum or eluted from RBC membranes react optimally at 37°C with unaltered autologous or homologous RBCs in the absence of drug (see Fig. 54–1C).^{74,76,224} Frequently the autoantibodies are reactive with determinants of the Rh complex,^{74,76,224} and at least some appear to target the same 34-kDa Rh-related polypeptide targeted by the autoantibodies in many cases of “spontaneously arising” AHA.¹³⁶ Thus, distinguishing these drug-induced antibodies from similar warm-reacting autoantibodies in idiopathic AHA currently is not possible.

The mechanism by which a drug induces formation of an autoantibody is unknown. Radiolabeled α -methyl dopa does not react directly with the membranes of intact human RBCs.^{76,225} However, both α -methyl dopa and levodopa reportedly bind to isolated RBC membranes. Binding of the drug to membranes of intact RBCs is inhibited by RBC superoxide dismutase and probably by hemoglobin.^{225,226} Although not formally demonstrated, these drugs probably bind to membrane antigens of cells that are relatively hemoglobin free, for example, cells at the early proerythroblast stage or RBC stroma. In any case, the resulting altered membrane antigens then may induce autoantibodies. The concept that a drug-membrane compound neoantigen could lead to production of an autoantibody is supported by studies of patients receiving drugs unrelated to α -methyl dopa. Patients simultaneously developed a drug-dependent antibody and an autoantibody, both of which showed specificity for the same RBC alloantigen.⁸⁴ Another hypothesis is that α -methyl dopa interacts with human T lymphocytes, resulting in loss of suppressor cell function.²²⁷ Subsequent studies, however, have failed to demonstrate any evidence for such a mechanism.²²⁸

Patients with CLL treated with the purine analogues fludarabine^{88,229,230} or cladribine⁹⁰ may develop AHA. Risk factors for hemolysis include previous therapy with a purine analogue, high β_2 -microglobulin, a positive DAT prior to therapy, and hypogammaglobulinemia. Purine analogues are potent suppressors of T lymphocytes. These drugs may accelerate the preexisting T-cell immune suppression that normally occurs during progression of CLL, exacerbating the underlying tendency to autoimmunity in CLL. However, the degree of depletion of T-cell subsets is similar in patients who develop hemolysis and in patients who do not.

Nonimmunologic Protein Adsorption Less than 5 percent of patients receiving cephalosporin antibiotics develop positive antiglobulin reactions¹¹ as a result of nonspecific adsorption of plasma proteins to their RBC membranes.^{93,94,231} This process may occur within 1 to 2 days after the drug is instituted. Multiple plasma proteins, including immunoglobulins, complement, albumin, fibrinogen, and others, may be detected on RBC membranes in such cases.^{231,232} Hemolytic anemia resulting from this mechanism has not been reported. The clinical importance of this phenomenon is its potential to complicate cross-match procedures unless the drug history is considered. Cephalosporin antibiotics also may induce RBC injury by the hapten mechanism, by the ternary complex mechanism, and by the autoantibody mechanism. The latter reactions are more serious but apparently occur less frequently than nonimmunologic protein adsorption.

CLINICAL FEATURES

WARM-ANTIBODY AUTOIMMUNE HEMOLYTIC ANEMIA

Presenting complaints of warm-antibody AHA usually are referable to the anemia itself, although occasionally jaundice is the immediate cause for the patient to seek medical advice. Symptom onset usually is slow

and insidious over several months, but occasionally a patient has sudden onset of symptoms of severe anemia and jaundice over a period of a few days. In secondary AHA, the symptoms and signs of the underlying disease may overshadow the hemolytic anemia and associated features.

In idiopathic AHA with only mild anemia, results of physical examination may be normal. Even patients with relatively severe hemolytic anemia may have only modest splenomegaly. However, in very severe cases, particularly those of acute onset, patients may present with fever, pallor, jaundice, hepatosplenomegaly, hyperpnea, tachycardia, angina, or heart failure.

Clinical warm-antibody AHA may be aggravated or first become apparent during pregnancy.^{166,233,234} Most cases are mild, however, and the prognosis for the fetus is generally good, provided the mother is treated early.²³³

COLD-ANTIBODY AUTOIMMUNE HEMOLYTIC ANEMIA

Most patients with cold agglutinin hemolytic anemia have chronic hemolytic anemia with or without jaundice. In other patients, the principal feature is episodic, acute hemolysis with hemoglobinuria induced by chilling (see discussion of thermal amplitude in “Pathogenic Effects of Cold Agglutinins and Hemolysins” above). Combinations of these clinical features may occur. Acrocyanosis and other cold-mediated vasoocclusive phenomena affecting the fingers, toes, nose, and ears are associated with sludging of RBCs in the cutaneous microvasculature. Skin ulceration and necrosis are distinctly unusual. Hemolysis occurring in *M. pneumoniae* infections is acute in onset, typically appearing as the patient is recovering from pneumonia and coincident with peak titers of cold agglutinins. The hemolysis is self-limited, lasting 1 to 3 weeks.¹¹ Hemolytic anemia in infectious mononucleosis develops either at the onset of symptoms or within the first 3 weeks of illness.¹²⁸

Other physical findings are variable, depending upon the presence of an underlying disease. Splenomegaly, a characteristic finding in lymphoproliferative diseases or infectious mononucleosis, may be observed in idiopathic cold agglutinin disease.

In paroxysmal cold hemoglobinuria, constitutional symptoms are prominent during a paroxysm. A few minutes to several hours after cold exposure, the patient develops aching pains in the back or legs, abdominal cramps, and perhaps headaches. Chills and fever usually follow. The first urine passed after onset of symptoms typically contains hemoglobin. The constitutional symptoms and hemoglobinuria generally last a few hours. Raynaud phenomenon and cold urticaria sometimes occur during an attack; jaundice may follow.

DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

A careful history of drug exposure should be obtained from all patients with hemolytic anemia and/or a positive DAT. As in idiopathic AHA, the clinical picture in drug-induced immune hemolytic anemia is quite variable. The severity of symptoms largely depends upon the rate of hemolysis. In general, patients with hapten/drug adsorption (e.g., penicillin) and autoimmune (e.g., α -methyl dopa) types of drug-induced hemolytic anemia exhibit mild to moderate hemolysis, with insidious onset of symptoms developing over a period of days to weeks. In contrast, the ternary complex mechanism (e.g., cephalosporins or quinine) often causes sudden, severe hemolysis with hemoglobinuria. In the latter setting, hemolysis can occur after only one dose of the drug in a patient previously exposed to the drug. Acute renal failure may accompany severe hemolysis by the ternary complex mechanism.^{39,56,58,62,63,86} Several reports indicate that second- and third-generation cephalosporins may cause severe, even fatal, hemolysis by the ternary complex mechanism.^{37–39,64}

LABORATORY FEATURES

GENERAL FEATURES

By definition, patients with AHA present with anemia, the severity of which ranges from life-threatening to very mild. Patients with warm-antibody AHA may present with hematocrit levels less than 10 percent or may have compensated hemolytic anemia and a near-normal hematocrit. For the latter patients, the predominant laboratory features are an increased reticulocyte count and a positive DAT. Occasionally, the patient has leukopenia and neutropenia.^{10,235} Platelet counts typically are normal. Rarely, severe immune thrombocytopenia is associated with warm-antibody AHA. This constellation is termed *Evans syndrome*.²³⁶ In this syndrome, the RBC and platelet antibodies are apparently distinct.²³⁷

Patients with classic chronic cold agglutinin disease exhibit mild to moderate, fairly stable anemia, with hematocrit levels only occasionally as low as 15 to 20 percent. In contrast, patients with paroxysmal cold hemoglobinuria have hematocrit levels that decrease rapidly during a paroxysm. During a paroxysm, leukopenia is noted early, followed by leukocytosis. Complement titers frequently are depressed because of consumption of complement proteins during hemolysis.

In drug-induced immune hemolytic anemia of the hapten/drug adsorption and true autoantibody types, the hematologic findings are similar to those described for spontaneously occurring warm-antibody AHA. Most patients exhibit anemia and reticulocytosis. Leukopenia and thrombocytopenia may be noted in cases of ternary complex-mediated hemolysis.

Evaluation of the blood film can reveal several features related to all types of AHA (Fig. 54–2). Polychromasia indicates a reticulocytosis, reflecting an increased rate of reticulocyte egress from the marrow. Spherocytes are seen in patients with moderate to severe hemolytic anemia. If hereditary spherocytosis can be excluded, this finding suggests an immune hemolytic process. RBC fragments, nucleated RBCs, and occasionally erythrophagocytosis by monocytes may be seen in severe cases (Fig. 54–2). Most patients have mild leukocytosis and neutrophilia. Additionally, patients with cold-antibody AHA may exhibit RBC autoagglutination in the blood film and in chilled anticoagulated blood (Fig. 54–3).

The reticulocyte count usually is elevated. Nevertheless, early in the course of the disease, more than one-third of all patients may have transient reticulocytopenia despite a normal or hyperplastic erythroid marrow.^{238–241} The mechanism is unknown, but autoantibodies reactive against antigens on reticulocytes are speculated to lead to their selective destruction.²³⁹ One unusual patient with warm-antibody AHA, reticulocytopenia, and marrow erythroid aplasia had a serum autoantibody that inhibited erythroid colony formation *in vitro*.²⁴² The aplastic crisis remitted after the serum IgG level was lowered by immunoadsorption. Reticulocytopenia also may be seen in patients with marrow function compromised by an underlying disease, parvovirus infection, toxic chemicals, or nutritional deficiency. Marrow examination usually reveals erythroid hyperplasia and may provide evidence of an underlying lymphoproliferative disorder.

Hyperbilirubinemia (chiefly unconjugated) is highly suggestive of hemolytic anemia, although its absence does not exclude the diagnosis. Total bilirubin is only modestly increased (up to 5 mg/dL) and, with rare exceptions, the conjugated (direct) fraction constitutes less than 15 percent of the total. Urinary urobilinogen is increased regularly, but bile is not detected in the urine unless serum conjugated bilirubin is increased. Usually, serum haptoglobin levels are low, and lactate dehydrogenase levels are elevated. Hemoglobinuria is encountered in rare patients with warm-antibody AHA and hyperacute hemolysis, more commonly in patients with cold agglutinin disease, and characteristically in patients

Figure 54-2. **A.** Blood film. Autoimmune hemolytic anemia. Moderately severe. Note high frequency of microspherocytes (small hyperchromatic RBCs) and the high frequency of macrocytes (putative reticulocytes). **B.** Blood film. Autoimmune hemolytic anemia. Severe. Note the low density of red cells on the film (profound anemia), high frequency of microspherocytes (hyperchromatic), and the large red cells (putative reticulocytes). Note the two nucleated RBCs and the Howell-Jolly body (nuclear remnant) in the macrocyte. Nucleated RBCs and Howell-Jolly bodies may be seen in autoimmune hemolytic anemia with severe hemolysis or after splenectomy. **C.** Blood film. Autoimmune hemolytic anemia. Severe. Monocyte engulfing two red cells (erythrophagocytosis). Note frequent microspherocytes and scant red cell density. **D.** Reticulocyte preparation. Autoimmune hemolytic anemia. Note high frequency of reticulocytes, the large cells with precipitated ribosomes. Remaining cells are microspherocytes. with paroxysmal cold hemoglobinuria and with drug-induced immune hemolytic anemia mediated by the ternary complex mechanism.

Direct Antiglobulin Test Pattern

Diagnosis of AHA or drug-induced immune hemolytic anemia requires demonstration of immunoglobulin and/or complement bound to the patient's RBCs. As a screening procedure, use of a "broad-spectrum"

antiglobulin (Coombs) reagent—that is, one that contains antibodies directed against human immunoglobulin and complement components (principally C3)—is customary. If agglutination is noted with a broad-spectrum reagent, antisera reacting selectively with IgG (the "gamma" Coombs) or with C3 (the "nongamma" Coombs) are used to define the specific pattern of RBC sensitization. Monospecific antisera to IgM or IgA also have been used in selected cases.

Figure 54-3. Blood films. **A.** Cold-reactive (IgM) antibody. Red cell agglutination at room temperature. **B.** Same blood examined at 37°C. Note marked reduction in agglutination. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

TABLE 54–4. Major Reaction Patterns of the Direct Antiglobulin Test and Associated Types of Immune Injury

Reaction Pattern	Type of Immune Injury
Immunoglobulin (Ig) G alone	Warm-antibody autoimmune hemolytic anemia Drug-immune hemolytic anemia: hapten drug adsorption type or autoantibody type
Complement alone	Warm-antibody autoimmune hemolytic anemia with subthreshold IgG deposition Cold-agglutinin disease Paroxysmal cold hemoglobinuria Drug-immune hemolytic anemia: ternary complex type
IgG plus complement	Warm-antibody autoimmune hemolytic anemia Drug-immune hemolytic anemia: autoantibody type (rare)

Three possible *major* patterns of direct antiglobulin reaction in AHA and drug-induced immune hemolytic anemia exist: (1) RBCs coated with only IgG, (2) RBCs coated with IgG and complement components, and (3) RBCs coated with complement components without detectable immunoglobulin.^{10,123,243,244} In patterns 2 and 3, the complement components most readily detected are C3 fragments (mainly C3dg). Each pattern is associated with accelerated RBC destruction. Positive antiglobulin reactions with anti-IgA or anti-IgM are encountered less commonly, often in association with bound IgG and/or complement.^{245–251} Table 54–4 summarizes the diagnostic significance of each of these major patterns (see “Serologic Features” below).

SEROLOGIC FEATURES

Warm-Antibody Autoimmune Hemolytic Anemia

Free versus Bound Autoantibody The autoantibody molecules in patients with warm-antibody AHA exist in a reversible, dynamic equilibrium between RBCs and plasma.^{252,253} In addition to the major portion of autoantibody bound to the patient’s RBCs (detected by the DAT), “free” autoantibody may be detected in the plasma or serum of these patients by the IAT. In the IAT, the patient’s serum or plasma is incubated with normal donor erythrocytes at the appropriate temperature (in this case, 37°C). The cells are washed, suspended in saline solution, and then tested for agglutination by antiglobulin serum. The presence of unbound autoantibody in plasma depends upon the total amount of antibody being produced and the binding affinity of the antibody for RBC antigens. In general, patients whose RBCs are heavily coated with IgG more likely exhibit plasma autoantibody. Protease-modified RBCs are more sensitive than native RBCs in detecting plasma autoantibody, but such data must be interpreted with caution, because alloantibodies, naturally occurring antibodies to cryptic antigens, and other serum components may interact with enzyme-modified RBCs. Patients with a positive IAT as a result of a warm-reactive autoantibody should also have a positive DAT. A patient with a serum anti-RBC antibody (positive IAT) and a negative DAT probably does not have an autoimmune process but rather an alloantibody stimulated by prior transfusion or pregnancy.

Quantity, Affinity, and Isotype of Red Blood Cell-Bound Autoantibody

Direct Antiglobulin Test–Negative Autoimmune Hemolytic Anemia

Figure 54–4 relates the intensity of the direct antiglobulin reaction, using specific anti-IgG serum, to the number of IgG molecules bound per RBC. The latter was determined by a sensitive antibody-consumption method.²⁵⁴ A trace-positive antiglobulin reaction (read macroscopically) detects 300 to 400 molecules of IgG per cell.^{254,255} In another laboratory, a trace-positive antiglobulin reaction with anti-C3 was obtained with 60 to 115 molecules C3 per cell.¹⁸²

Sometimes patients with warm-antibody AHA and many of its hallmarks, for example, anemia, reticulocytosis, spherocytes, elevated lactate dehydrogenase (LDH), low or absent haptoglobin, present with a negative DAT. There are three principal causes for the negative DAT: IgG or complement sensitization below the threshold of detection of commercial antiglobulin (Coombs) reagents; low affinity IgG sensitization with loss of cell-bound antibody during the cell washing steps before the direct antiglobulin reaction; sensitization with IgA or IgM antibodies which many commercial DAT reagents cannot detect because they contain only anti-IgG anti-C3.

More sensitive methods for quantifying RBC-bound IgG allow identification of AHA patients having all the usual features of warm-antibody AHA but a negative DAT with antiimmunoglobulin and anticomplement reagents.^{254–256} In these cases, specialized methods (e.g., anti-IgG consumption assays, automated enhanced agglutination techniques, enzyme-linked immunoassays, radioimmunoassays, flow cytometry) detect very small quantities of cell-bound IgG. In such cases, studies with highly concentrated RBC eluates confirm these IgG molecules are warm-reacting anti-RBC autoantibodies.²⁵⁴ Patients generally have relatively mild hemolysis and often respond favorably to glucocorticoid therapy. By these specialized methods, subthreshold IgG also may be detected in a significant number of patients exhibiting the “complement alone” pattern of direct antiglobulin reaction in the absence of

Figure 54–4. Comparison of direct antiglobulin reactions (with anti-immunoglobulin [Ig]G serum) with molecules of red blood cell-bound IgG determined by a quantitative antibody consumption assay (method described by Gilliland and colleagues²⁴⁷). The two assays were conducted concurrently on the same blood specimen. The antiglobulin reactions were performed manually and read macroscopically.

drug sensitivity or cold agglutinins. Studies with concentrated RBC eluates suggest subthreshold quantities of bound IgG antibodies are capable of fixing much larger quantities of C3 to the cell membrane.²⁵⁴ In cases of low-affinity IgG sensitization, detection of IgG bound to RBCs may be accomplished by cold washing (0 to 4°C) or by use of low ionic strength saline in the wash steps prior to the DAT reaction. Cell Bound IgA and IgM may be detected by means of antisera to IgA and IgM. DAT-negative AHA has been reviewed extensively elsewhere.^{257–259}

Nature of the Autoantibodies and Red Blood Cell Target Antigens In any series of warm-antibody AHA patients, the correlation between the strength of the antiglobulin reaction (IgG molecules per RBC) and the rate of RBC destruction is variable. The IgG subclass of warm autoantibodies influences the degree to which these antibodies shorten RBC survival. IgG₁ is the most commonly encountered subclass, either alone or in combination with other IgG subclasses.^{245,260} IgG₁ and IgG₃ autoantibodies appear to be more effective in decreasing RBC life span than do those of the IgG₂ or IgG₄ subclass.^{245,261}

The difference may result from the greater affinity of macrophage Fc receptors for IgG₁ and IgG₃^{177,178} and the higher complement-fixing activity of IgG₁ or IgG₃ antibodies relative to the activity of IgG₂ or IgG₄ antibodies.¹⁸⁷

Autoantibodies eluted from patients' RBCs or present in their plasma typically bind to all the common types of human RBCs represented in test panels used by blood banks and thus might appear to be nonspecific. However, the antibodies of any one patient typically recognize one or more antigenic determinants (epitopes) that are common to almost all human RBCs, that is, "public" antigens. These antibodies have been useful for evaluating RBC membrane structures and for identifying rare RBC phenotypes, namely, RBCs that lack a common blood group antigen(s). Nearly half of all AHA patients have autoantibodies specific for epitopes on Rh proteins.^{10,11,131,262,264} The autoantibodies of such patients commonly do not react with human Rh_{null} RBCs, which lack expression of the Rh complex. Occasionally, the anti-Rh autoantibodies have anti-e, anti-E, or anti-c (or, more rarely, anti-D) specificity. Patients who have autoantibodies with selective specificity (e.g., anti-e) nearly always have other autoantibodies reactive with all human RBCs, except Rh_{null}. Autoantibodies with such specificity are designated collectively as Rh related.^{136,264}

The remaining patients with warm-antibody AHA have IgG autoantibodies that are fully reactive with Rh_{null} RBCs.^{10,11,131,262–264} The exact specificity of the autoantibodies for many of these patients is undefined. However, in other instances, autoantibody specificity for serologically defined blood group antigens outside the Rh system has been identified (using RBCs of appropriate antigen-deficient phenotype) including anti-Wr^b,¹³¹ anti-En^a,²⁶⁵ anti-LW,²⁶⁶ anti-U,²⁶⁷ anti-Ge,^{250,268} anti-Sc1,²⁶⁹ or antibodies to Kell blood group antigens.²⁷⁰ For ease of reference, the entire group of autoantibodies is designated non-Rh related.^{136,264}

Immunochemical studies indicate the autoantibodies from almost any AHA patient react with individual membrane proteins. The major target of Rh-related autoantibodies is a 32- to 34-kDa nonglycosylated polypeptide lacking on Rh_{null} RBCs.^{136,271} This polypeptide is similar, if not identical, to the polypeptide expressing the Rh(e) alloantigen. Many α -methyl dopa-induced autoantibodies also react with this polypeptide.¹³⁶ Autoantibodies with non-Rh serologic specificity react with the band 3 anion transporter^{136,272} or with both band 3 and glycophorin A.¹³⁶ The latter autoantibodies may react with an epitope formed through the interaction of these two proteins on the RBC membrane.²⁷³ It is interesting to note that anti-RBC autoantibodies in NZB mice exhibit anti-band 3 specificity.²⁷⁴ Furthermore, naturally occurring anti-band 3 IgG autoantibodies are found in almost all humans.^{275,276} These autoantibodies may play a role in the clearance of senescent RBCs by reacting with neoantigens formed on these cells by proteolytic alteration²⁷⁵ or

aggregation²⁷⁶ of band 3 proteins. Such neoantigens are not found on younger RBCs. An important but unanswered question concerns the possible relationship between naturally occurring and pathologic anti-band 3 autoantibodies.

Cold-Antibody Hemolytic Anemia

Cold agglutinins are distinguished by their ability to directly agglutinate saline-suspended human RBCs at low temperature, maximally at 0 to 5°C. The reaction is reversible by warming. In chronic cold agglutinin disease, serum titers are commonly 1:1000 or higher and may reach 1:512,000 or more.¹¹ Cold agglutinins are characteristically IgM. IgA or IgG cold agglutinins have been reported,^{11,202,277} sometimes in combination with IgM.²⁷⁸ In mixed warm- and cold-antibody AHA, warm-reactive IgG autoantibodies are found in association with IgM cold agglutinins.²¹

The DAT result is positive with anticomplement reagents. The antibody itself, however, is not detected by the DAT because the cold agglutinins readily dissociate from the RBCs both *in vivo* and during the washing steps of the standard antiglobulin procedure. In contrast, C4b and C3b are covalently bound to target RBCs via thioester linkages. In one unusual case, a low-titer IgG cold agglutinin could be detected by washing the patient's RBCs in ice-cold saline solution and performing the DAT at 4°C.²⁷⁷

The majority of cold agglutinins are reactive with oligosaccharide antigens of the I/i system, which are precursors of the ABH and Lewis blood group substances.^{279–281} The I/i determinants are bound to erythrocyte membrane glycoprotein (band 3 anion transporter) or to glycolipids.^{280,281} Anti-I and anti-i reportedly bind solubilized RBC glycoproteins at 37°C, suggesting the temperature dependence of cold agglutination of intact RBCs may be a function of temperature-induced conformational effects on the cell surface.^{282,283}

I antigens are expressed strongly on adult RBCs but weakly on neonatal (cord) RBCs. The converse is true of i antigens, indicating I/i antigen expression is developmentally regulated.²⁸⁰ The differences between adult and cord blood RBCs allow evaluation of the serologic specificity of cold agglutinins.^{10,11,202} I/i antigens, or structurally related analogues, occur in human saliva, milk, amniotic fluid, and hydatid cyst fluid,²⁰² and are expressed on human lymphocytes, neutrophils, and monocytes.²⁸⁴

Anti-I is the predominant specificity of cold agglutinins in idiopathic cold agglutinin disease, in patients with *M. pneumoniae*, and in some cases of lymphoma. Cold agglutinins with anti-i specificity are found in patients with infectious mononucleosis and in some patients with lymphoma. A small percentage of cold agglutinin-containing sera react equally well with adult and neonatal RBCs. These antibodies recognize antigens outside the I/i system, including Pr antigens, consisting of carbohydrate epitopes of glycophorins that are inactivated by protease treatment²⁰² and, less commonly, the M or P blood group antigens.^{285,286} Most cold agglutinins associated with chickenpox exhibit anti-Pr specificity. A single case with anti-I specificity has been observed.²⁸⁷ Hemolysis resulting from a cold agglutinin with anti-Pr specificity occurred following an allogeneic marrow transplant.²⁸⁸

In hemolytic anemia associated with infectious mononucleosis, the patient's serum may contain IgM anti-i cold agglutinins or cold-reactive nonagglutinating IgG anti-i with IgM cold-reactive anti-IgG antibodies ("rheumatoid factors") that may crosslink the IgG-coated RBCs to produce agglutination.²⁸⁹

In paroxysmal cold hemoglobinuria, the direct antiglobulin reaction usually is positive during and briefly following an acute attack because of the coating of surviving RBCs with complement, primarily C3dg fragments. The Donath-Landsteiner antibody is responsible for complement deposition on the cells; it is a nonagglutinating IgG that

binds RBCs only in the cold. It readily dissociates from the RBCs at room temperature. In adults subject to recurring episodes in association with cold exposure, the DAT result remains negative between attacks. The antibody is detected by the biphasic Donath-Landsteiner test, in which the patient's fresh serum is incubated with RBCs initially at 4°C and the mixture is then warmed to 37°C.¹¹ Intense hemolysis occurs. Addition of fresh guinea pig serum or ABO-compatible human serum may be necessary to serve as a source of fresh complement if the patient's serum has been stored or is complement depleted. Antibody titers rarely exceed 1:16. The Donath-Landsteiner antibody typically has specificity for the P blood group antigen, a glycosphingolipid structure.²⁸¹ The P antigen also occurs on lymphocytes and skin fibroblasts.¹⁶ The finding of P antigen on skin fibroblasts might be related in some way to the occurrence of cold urticaria in paroxysmal cold hemoglobinuria, a phenomenon that may be transferred passively by serum to normal skin.¹⁰ Antibody specificities for RBC antigens other than the P blood group have been noted.²⁹⁰

Drug-Induced Immune Hemolytic Anemia

In the hapten/drug adsorption mechanism of immune injury associated with cephalosporins or penicillin, the patient's drug-coated RBCs bind drug-specific IgG antibody and exhibit positive DAT reactions with anti-IgG. Rarely, both anti-IgG and anti-C3d antisera produce positive DAT reactions. Such cases could have superficial resemblance to warm-antibody AHA. The key serologic difference is that, in this form of drug-induced immune hemolytic anemia, the antibodies in the patient's serum or eluted from the patient's RBCs react *only* with drug-coated RBCs. In contrast, the IgG antibodies in warm-type AHA react with unmodified human RBCs and may show preference for certain known blood groups (e.g., within the Rh complex). Such serologic distinction and the history of exposure to high blood levels of penicillin or a cephalosporin should be instructive.

In hemolysis mediated by the ternary complex mechanism, the DAT is positive with anticomplement serum. Immunoglobulins are only rarely detectable on the patient's RBCs. This pattern is similar to that encountered in AHA mediated by cold agglutinins. Moreover, the brisk type of hemolysis in the ternary complex mechanism also is seen in certain cases of cold-antibody AHA. In the drug-induced cases, however, the cold agglutinin titer and the Donath-Landsteiner test result are normal, and demonstration of serum antibody acting on human RBCs depends upon the presence of the drug in the test system. Thus, the IAT reaction with anticomplement serum may be positive only if the incubation mixture permits interaction of (1) normal RBCs; (2) anti-drug antibody from the patient's serum; (3) the relevant drug, either still in the patient's serum or added *in vitro* in appropriate concentration; and (4) a source of complement, that is, fresh normal serum or the patient's own serum if freshly obtained. A negative result does not necessarily absolve the suspected drug because the critical determinant may be a metabolite of the drug in question. In some cases, use of urine or serum (of the patient or a volunteer taking the drug) as a source of drug metabolite has permitted successful demonstration of a drug-dependent mechanism.^{61,218,222,291}

In patients with true autoantibodies as a result of α -methyl dopa, the DAT reaction is strongly positive for IgG, but complement only rarely is detected on the patient's RBCs. Autoantibody to RBCs is regularly present in the serum of patients and mediates a positive IAT reaction with unmodified human RBCs, often showing specificity related to the Rh complex. No presently available specific serologic test can separate idiopathic warm-reacting IgG autoantibodies with Rh-related specificities from those induced by α -methyl dopa administration. The evidence must be circumstantial, with the helpful knowledge that discontinuation of α -methyl dopa, without any form of immunosuppressive therapy,

consistently permits a slow recovery from anemia and a gradual disappearance of anti-RBC antibodies.

Drugs now not known to cause immune RBC injury will be implicated in the future. In any patient with a clinical picture compatible with drug-related immune hemolysis, a reasonable approach is stopping any drug that is suspect while serologic studies are being performed. The patient should be monitored for improvement in hematocrit level, decrease in reticulocytosis, and gradual disappearance of the positive DAT. Repeat challenge with the suspected drug may confirm the diagnosis, but this measure is seldom necessary in patient management and may be unsafe. Therefore, rechallenge to exclude a drug-induced immune hemolytic anemia should be undertaken only for compelling reasons, such as the need to use the specific drug for the patient's illness.

DIFFERENTIAL DIAGNOSIS

Several nonautoimmune diseases may result in spherocytic anemia, such as hereditary spherocytosis (HS), Zieve syndrome, clostridial sepsis, and the hemolytic anemia preceding Wilson disease. Among the hereditary hemolytic anemias, HS can resemble acquired AHA most closely because the spherocytic anemia associated with HS may be detected first in adulthood (Chap. 46). In addition, splenomegaly may be prominent in both HS and AHA. Family studies of patients with HS, however, usually can identify other affected individuals. Most important, in hereditary hemolytic anemia the DAT is negative.

In hemolytic anemia accompanied by a positive DAT, serologic characterization of the autoantibody may distinguish warm-antibody AHA from cold-reacting autoantibody syndromes. Diagnosis of a drug-induced immune hemolytic anemia depends upon a history of appropriate drug intake supported by compatible serologic findings. In patients who recently received a transfusion, a positive DAT reaction may reflect the binding of a newly formed alloantibody to donor RBCs in the patient's circulation (delayed transfusion reaction; Chap. 138). This finding could lead to a false impression of an autoimmune process.

The venom of the brown recluse spider (*Loxosceles reclusa*) may cause severe life-threatening hemolysis.^{292,293} The DAT may be positive for IgG and or complement^{292,293} and spherocytes and RBC fragments are present on the blood film.²⁹³ The diagnosis should be considered when there is history or evidence by physical examination of a spider bite. The role of IgG and complement in hemolysis is unclear, but the terminal complement inhibitor, eculizumab, inhibits lysis *in vitro*. To date, the clinical use of eculizumab in this population has not been reported.

Recent recipients of allogeneic blood stem cell or solid-organ transplantations may develop autoimmune hemolysis.²⁹⁴ In the former, antibodies are produced by the stem cell graft against RBCs also produced by the stem cell graft; that is, both antibodies and RBCs are of donor origin. In the case of solid-organ transplantations, the recipient's own lymphocytes make antibody against recipient RBCs. In both situations, the autoimmunity is thought to arise from immunosuppressive therapy causing delayed reconstitution or dysfunction of T-cell immunity, leading to development of antibodies autologous to the offended immune system.

Recipients of transplantations may also develop an *alloimmune* hemolytic anemia that mimics warm-antibody AHA. The problem is seen in kidney, liver, or hematopoietic stem cell transplantations and usually occurs when an organ from a blood group O donor is transplanted into a blood group A or B recipient. B lymphocytes present in the donated organ or stem cell product form alloantibodies against recipient RBCs.^{295–299} Patients of blood group O who receive a stem cell

transplant from a donor of blood group A or B may develop a transiently positive DAT and hemolysis of RBCs made by the marrow graft because of temporary persistence of previously synthesized host anti-A or anti-B.³⁰⁰ Furthermore, some group O stem cell transplantation recipients exhibit mixed hematopoietic chimerism with persistence of host B lymphocytes that can make alloantibodies directed against RBCs made by the stem cell graft.³⁰⁰ In these settings, the findings of hemolysis and a positive DAT as a result of anti-A and anti-B probably are diagnostic of an alloimmune process, because *auto*antibodies directed against the major blood group antigens A and B are extremely rare.

Other acquired types of hemolytic anemia are less easily confused with either warm- or cold-antibody AHA because spherocytes are not prominent on the blood film and the DAT is negative. Patients with paroxysmal nocturnal hemoglobinuria (PNH) may complain of dark urine (hemoglobinuria). This finding is unusual in patients with warm-antibody AHA but can occur in patients with the cold-antibody syndromes. Decreased levels of CD55 and CD59 on blood cells, detected by flow analysis, are characteristic of PNH but not AHA (Chap. 40). Microangiopathic hemolytic disorders, such as thrombotic thrombocytopenic purpura and hemolytic uremic syndrome, can be distinguished from AHA by examining the blood film. In the microangiopathic hemolytic diseases, the blood film displays marked RBC fragmentation and minimal spherocytosis. In addition, microangiopathic hemolytic anemias more frequently are associated with thrombocytopenia than is either warm- or cold-antibody AHA.

The clinical and laboratory features of chronic cold agglutinin disease are sufficiently distinctive so that the diagnostic possibilities are limited. In general, a high-titer cold agglutinin (>1:512) and a positive DAT with anticomplement serum (but not with anti-IgG) are consistent with cold agglutinin disease. In many instances of drug-induced immune hemolytic anemia, the DAT result also is positive only for complement. The drug history and a low (or absent) cold agglutinin titer, however, help to distinguish drug-induced immune hemolytic anemia from cold agglutinin disease. If the patient has an elevated cold agglutinin level and a positive DAT result with both anti-IgG and anti-C3, then the patient may have a mixed-type AHA. Warm-antibody AHA, hereditary hemolytic disorders, and PNH should be excluded in cases exhibiting primarily a chronic hemolytic anemia. The pattern of antiglobulin reaction, family history, the result of analysis of CD55/CD59 on blood cells provide additional help in difficult cases. When the hemolysis is episodic, paroxysmal cold hemoglobinuria, march hemoglobinuria, and PNH also should be considered. When cold-induced peripheral vasoocclusive symptoms are predominant, the differential diagnosis should include cryoglobulinemia and Raynaud phenomenon, with or without an associated rheumatic disease. Infectious mononucleosis, *M. pneumoniae* infection, and lymphoma can be considered in appropriate clinical settings.

Paroxysmal cold hemoglobinuria must be distinguished from the subset of cases of chronic cold agglutinin disease manifesting episodic hemolysis and hemoglobinuria. This distinction is made primarily in the laboratory. In general, patients with paroxysmal cold hemoglobinuria lack high titers of cold agglutinins. Furthermore, the Donath-Landsteiner antibody is a potent *in vitro* hemolysin, in contrast to most cold agglutinins, which are weak hemolysins. Warm-antibody AHA, march hemoglobinuria, myoglobinuria, and PNH can be distinguished through the history and appropriate laboratory studies.

Immune hemolysis caused by drugs should be distinguished from (1) the warm- or cold-antibody types of idiopathic AHA, (2) congenital hemolytic anemias such as HS, and (3) drug-mediated hemolysis resulting from disorders of red cell metabolism, such as glucose-6-phosphate dehydrogenase deficiency. Patients with drug-induced

immune hemolytic anemia have a positive DAT that distinguishes this group from patients with inherited RBC defects.

● THERAPY

GENERAL

Transfusion

The clinical consequences of AHA or drug-induced immune hemolytic anemia are related to the severity of the anemia and acuity of its onset. Many patients develop anemia over a period sufficient to allow for cardiovascular compensation and hence do not require RBC transfusions. However, RBC transfusions may be necessary and should not be withheld from a patient with an underlying disease complicating the anemia, such as symptomatic coronary artery disease, or a patient who rapidly develops severe anemia with signs and/or symptoms of circulatory failure, as in paroxysmal cold hemoglobinuria or ternary complex drug-induced immune hemolysis.

Transfusion of RBCs in immune hemolytic anemia presents two difficulties: (1) crossmatching and (2) the short half-life of the transfused RBCs (Chap. 138). Finding truly serocompatible donor blood is nearly always impossible except in rare cases when the autoantibody is specific for a defined blood group antigen (see “Serologic Features” above).

It is most important to identify the patient’s ABO type so as to avoid a hemolytic transfusion reaction mediated by anti-A or anti-B. This part of the matching process allows for selection of either ABO-identical or -compatible blood for transfusion. With respect to compatibility, the more difficult technical issue relates to the detection of RBC alloantibodies which may be masked by the presence of the autoantibody.

Clinicians often speak of “least incompatible” blood for transfusion, but this term has lately fallen into disrepute because it lacks a precise definition.^{301,302} In fact all units will be serologically incompatible but units that are incompatible because of the presence of autoantibody are less dangerous to transfuse than those units that are incompatible because of an alloantibody.

Before transfusing an incompatible unit, the patient’s serum must be tested carefully for an alloantibody that could cause a severe hemolytic transfusion reaction against donor RBCs, especially in patients with a history of pregnancy, abortion or prior transfusion.^{264,303–305} Patients who have been neither pregnant nor transfused with blood products are unlikely to harbor an alloantibody. Early consultation between the clinician and the blood bank physician is essential. An understanding of the basic aspects of blood compatibility testing, coupled with the knowledge of a patient’s pregnancy and transfusion history allow for informed discussion and confident transfusion of mismatched blood if the situation demands.

Once selected, the packed RBCs should be administered slowly and in the case of cold hemolysis syndromes should be brought at least to room temperature. During the transfusion, the patient should be monitored for signs of a hemolytic transfusion reaction (Chap. 138). The transfused cells may be destroyed as fast as or perhaps even faster than the patient’s own cells. However, the increased oxygen-carrying capacity provided by the transfused cells may be sufficient to maintain the patient during the acute interval required for other modes of therapy to become effective.

For patients with AHA who require chronic transfusion support, use of prophylactic antigen-matched donor RBCs for transfusion has been proposed as a means of preventing alloimmunization.³⁰⁶ This process is feasible only in institutions with access to a good selection of phenotyped RBC units and a reference laboratory.³⁰⁷

THERAPY OF WARM-ANTIBODY AUTOIMMUNE HEMOLYTIC ANEMIA

Glucocorticoids

Therapy with glucocorticoids has reduced the mortality associated with severe idiopathic warm-antibody AHA. Glucocorticoids were first used for this disorder more than 60 years ago.³⁰⁸ Glucocorticoids can cause dramatic cessation or marked slowing of hemolysis in about two-thirds of patients.^{10,11,123,309,310} Approximately 20 percent of treated patients with warm-antibody AHA achieve complete remission. Approximately 10 percent show minimal or no response to glucocorticoids. The best responses are seen in idiopathic cases or in those related to SLE.

Most patients should be treated with oral prednisone at an initial daily dose of 1 to 1.5 mg/kg (e.g., 50 to 100 mg). Critically ill patients with rapid hemolysis may receive intravenous methylprednisolone 100 to 200 mg in divided doses over the first 24 hours. High doses of prednisone may be required for 10 to 14 days. When the hematocrit stabilizes or begins to increase, the prednisone dose can be decreased in rapid-step dose reductions to approximately 30 mg/day. With continued improvement, the prednisone dose can be further decreased at a rate of 5 mg/day every week, to a dose of 15 to 20 mg/day. These doses should be administered for 2 to 3 months after the acute hemolytic episode has subsided, after which the patient can be weaned from the drug over 1 to 2 months or treatment switched to an alternate-day therapy schedule (e.g., 20 to 40 mg every other day). Alternate-day therapy reduces glucocorticoid side effects but should be attempted only after the patient has achieved stable remission on daily prednisone in the range of 15 to 20 mg/day. Therapy should not be stopped until the DAT becomes negative. Although many patients achieve full remission of their first hemolytic episode, relapses may occur after the glucocorticoids are discontinued. Consequently, patients should be followed for at least several years after treatment. A relapse may require repeat glucocorticoid therapy, splenectomy, or immunosuppression.

Occasionally, patients who present with only a positive DAT, minimal hemolysis, and stable hematocrit require no treatment. However, these patients should be observed for clinical deterioration because the rate of RBC destruction may increase spontaneously.

Glucocorticoids may influence hemolysis in warm-antibody AHA by several mechanisms. Earlier investigators noted that hematologic improvement was often, but not always, accompanied by reduction in the strength of the DAT.¹⁰ The subsequent observation of a decrease in cell-bound and/or free serum autoantibody during stable glucocorticoid-induced remission suggested improved RBC survival following treatment with glucocorticoids resulted from a decrease in synthesis of anti-RBC autoantibodies.^{169,252} However, this finding cannot explain why glucocorticoid-treated patients often improve within 24 to 72 hours, a time much shorter than the half-life of anti-RBC autoantibody. Rather, glucocorticoids may suppress RBC sequestration by splenic macrophages.^{171,172,183,311} A quantitative decrease in one of the three known classes of Fcγ receptors^{170,171} has been observed in the blood monocytes of AHA patients during glucocorticoid therapy.³¹²

Splenectomy

Nearly one-third of patients with warm-antibody AHA require prednisone chronically in doses greater than 15 mg/day to maintain an acceptable hemoglobin concentration. These patients are candidates for laparoscopic splenectomy.

Splenectomy removes the primary site of RBC trapping. Investigations in human¹⁶⁹ and animal¹⁷¹ subjects confirm that maintenance of a given rate of RBC destruction requires 6 to 10 times more RBC-bound IgG in splenectomized subjects than in nonsplenectomized subjects.

Continuation of hemolysis after splenectomy is partly related to persisting high levels of autoantibody, favoring RBC destruction in the liver by hepatic Kupffer cells.^{169,171,174}

Several investigators noted the amount of RBC-bound autoantibody decreased in AHA patients following splenectomy.^{10,309,313} However, a significant proportion of patients show no change in cell-bound autoantibody following splenectomy. The processes determining the rate of autoantibody production are poorly understood. The beneficial effect of splenectomy may be related to several factors interacting in complex fashion.³¹⁴

A patient's clinical data constitute the best selection criteria for splenectomy. Attempts to select potential responders by ⁵¹Cr RBC sequestration studies have been disappointing.^{10,309,315} In most cases, a reasonable approach is to continue glucocorticoids for 1 to 2 months while waiting for a maximal response. However, if no response is noted within 3 weeks, the patient's condition deteriorates, or the anemia is very severe, splenectomy should be performed sooner.

Results of splenectomy are variable. Approximately two-thirds of AHA patients have a partial or complete remission following splenectomy.^{309,314} However, the relapse rate is disappointingly high. Many patients require further glucocorticoid therapy to maintain acceptable hemoglobin levels, although often at a lower dose than required prior to splenectomy.^{10,123,309} Alternate-day therapy is preferable to daily therapy in these cases if adequate control of the anemia can be achieved.

The immediate mortality and morbidity from splenectomy depend upon the presence of underlying disease and the preoperative clinical status but generally are quite low.³¹⁶ Following splenectomy, children, more than adults, have an increased risk for developing sepsis as a result of encapsulated organisms.³¹⁷ Vaccination against *H. influenzae* type b and pneumococcal and meningococcal organisms is recommended at least 2 weeks prior to surgery (Chap. 56).³¹⁸

Rituximab

Rituximab is a monoclonal antibody directed against the CD20 antigen expressed on B lymphocytes and is used for treatment of B-cell lymphoma. Its use for treatment of AHA is based on the antibody's ability to eliminate B lymphocytes, including, presumably, those making autoantibodies to RBCs. However, the mechanism of action is more complex than that, as the effect of rituximab can occur very early, before the autoantibodies can recede. In fact, sometimes in responding patients, autoantibody levels are not significantly affected.^{319,320} Opsonized B lymphocytes may decoy effector monocytes and macrophages from autoantibody complexes and normalize autoreactive T lymphocyte responses.³¹⁹

Rituximab was used initially in refractory AHA either unresponsive to or relapsed after oral glucocorticoid therapy. In a prospective series,³²¹ 13 of 15 children with warm-antibody AHA responded to rituximab 375 mg/m² weekly for 2 to 4 weeks, intravenously. Other case series support the use of similar doses of rituximab in adults, with response rates ranging from 40 to 100 percent.^{320,322} Another prospective study in adults exhibited a 100 percent response using rituximab 100 mg/m² weekly for 4 weeks along with a short course of oral glucocorticoid as first- or second-line therapy.³²³ Sustained responses were observed at 3 years in more than two-thirds of the cases.³²⁴

A phase 3 randomized controlled trial compared glucocorticoid monotherapy versus glucocorticoid and rituximab 375 mg/m² as first-line therapy in patients with warm-antibody AHA.³²⁵ The complete and partial response rates were similar (approximately 50 percent) in the two groups at 3 and 6 months. At 12 and 36 months after randomization the relapse-free survival was superior for the combination of glucocorticoids and rituximab.

Other Immunosuppressive Drugs

Cytotoxic drugs such as cyclophosphamide, 6-mercaptopurine, azathioprine, and 6-thioguanine have been given to patients with AHA to suppress synthesis of autoantibody. Direct evidence of such an effect is lacking. Although immunosuppressive therapy is not universally accepted, beneficial responses to immunosuppressive drugs have been observed in some patients who did not respond to glucocorticoids.^{11,326} Importantly, the majority of patients with warm-antibody AHA respond to glucocorticoids and/or splenectomy and usually are not candidates for immunosuppressive therapy. At present, immunosuppressive therapy should be reserved primarily for patients who do not respond to glucocorticoids, rituximab, or splenectomy, or for patients who are poor surgical risks.³²⁶

The most successful approach used high-dose cyclophosphamide 50 mg/kg ideal body weight per day for 4 consecutive days, intravenously, with granulocyte colony-stimulating factor support.³²⁷ Of nine patients, eight of whom had warm autoantibodies, all became transfusion independent. All patients had prolonged severe cytopenias and required hospitalization for a median of 21 days. Cyclophosphamide may cause severe hemorrhagic cystitis and sodium 2-mercaptoethanesulfonate (mesna) 10 mg/kg was given at 3, 6, and 8 hours following each cyclophosphamide dose, to minimize the effect of cyclophosphamide on the bladder.

For patients who may not tolerate prolonged cytopenias, the drugs of choice are cyclophosphamide 60 mg/m² or azathioprine 80 mg/m² given daily. If the patient tolerates the drug, continue treatment for up to 6 months while waiting for a response. When response occurs, the patient can be weaned slowly from the drug. If no response is observed, the alternative drug can be tried. Because cyclophosphamide and azathioprine suppress hematopoiesis, blood counts, including reticulocyte count, must be monitored with extra care during therapy. Treatment with either agent increases the risk of subsequent neoplasia.

Patients with refractory AHA have been treated effectively with the purine analogue 2-chlorodeoxyadenosine (cladribine)³²⁸ and with mycophenolate mofetil.^{329,330} Alemtuzumab was successfully used to treat 5 patients with refractory AHA associated with CLL.³³¹

Other Therapies

For patients with chronic compensated hemolysis, treatment with folate at 1 mg/day, orally, is recommended to satisfy the increased demands for the vitamin because of increased red cell production. Plasma exchange or plasmapheresis has been used in patients with warm-antibody AHA. Improvement has been reported in a few cases, but use of the method is controversial.^{332,333} A patient with life-threatening warm IgG-mediated AHA refractory to glucocorticoids and splenectomy exhibited rapid clinical improvement following manual whole blood exchange.³³⁴ A patient with severe warm IgM-mediated AHA was successfully treated with C1-esterase inhibitor (C1-inh) resulting in attenuation of complement deposition on RBCs and hemolysis, along with improved recovery of transfused RBCs.³³⁵ Another patient with refractory warm IgM-mediated AHA responded to rituximab and eculizumab.³³⁶ Thymectomy has been reported useful in a few children who were refractory to glucocorticoids and splenectomy.³³⁶ Selective injury to splenic macrophages by administration of vinblastine-loaded, IgG-sensitized platelets reportedly was successful in a few patients.³³⁷ Several anecdotal reports and a case series indicate short-term successful treatment of patients with AHA using high-dose intravenous γ -globulin.³³⁸⁻³⁴¹ Uncontrolled studies indicate danazol, a nonvirilizing androgen, may be useful in patients with AHA.^{342,343} Danazol may eliminate the need for splenectomy when combined with prednisone and may allow for a shorter duration of prednisone therapy.³⁴³ Some patients with ulcerative colitis and AHA unresponsive to glucocorticoids and splenectomy may

respond to colectomy.³⁴⁴ In patients with AHA associated with an ovarian dermoid cyst, cyst removal produces remission of the hemolysis.³⁴⁵

THERAPY OF COLD-ANTIBODY HEMOLYTIC ANEMIA

Keeping the patient warm, particularly the patient's extremities, is moderately effective in providing symptomatic relief. This action may be the only measure required in patients with mild chronic hemolysis. In symptomatic patients, rituximab is effective and well tolerated. In two prospective trials, approximately half the patients responded to rituximab 375 mg/m² weekly for 4 weeks.^{346,347} Patients who relapsed responded to a second course of rituximab at about the same rate. In a prospective trial of rituximab and fludarabine, the response rate was 76 percent, including complete responses in 21 percent with a median response duration of 66 months.³⁴⁸ In another small study, 60 percent of patients responded to low dose rituximab, 100 mg/m², a rate comparable to that seen with rituximab 375 mg/m².³²³ Chlorambucil or cyclophosphamide may be helpful for patients with symptomatic chronic cold agglutinin disease.^{9-11,349,350} In patients with lymphoma, treatment of the underlying disorder usually results in control of the cold agglutinin disease. Single patients with refractory cold agglutinin disease have exhibited responses to eculizumab^{351,352} and bortezomib.³⁵³ Results of splenectomy^{10,11,354} or use of glucocorticoids^{10,11} generally have been disappointing, although exceptions have been reported,^{10,196,277,278} particularly in atypical cases. Experimental¹⁷¹ and clinical¹⁹⁶ bases exist for considering very high doses of glucocorticoids in seriously ill patients. RBC transfusions generally are reserved for patients with severe anemia of rapid onset who are in danger of cardiorespiratory complications. Washed RBCs often are used to avoid replenishing depleted complement components and reactivating the hemolytic process. In critically ill patients, plasma exchange (with replacement by albumin-containing saline solution) may provide transient amelioration of hemolysis.³⁵⁵⁻³⁵⁷

In patients with cold agglutinin disease secondary to infection, spontaneous resolution of the hemolysis is expected in all patients after resolution of the infection. RBC transfusion may be required as a temporizing measure and in severe cases, plasma exchange may be beneficial. There is little evidence to support the use of glucocorticoids or antiviral therapy.

Most contemporary cases of paroxysmal cold hemoglobinuria are self-limited. Acute attacks in both chronic and transient forms of paroxysmal cold hemoglobinuria may be prevented by avoiding cold exposure. Glucocorticoid therapy and splenectomy have not been useful. When paroxysmal cold hemoglobinuria is associated with syphilis, effective treatment of the infection may result in complete remission. Antihistaminic and adrenergic agents may relieve symptoms of cold urticaria.

THERAPY OF DRUG-INDUCED IMMUNE HEMOLYTIC ANEMIA

Discontinuation of the offending drug often is the only treatment needed. This measure is essential and may be lifesaving in patients with severe hemolysis mediated by the ternary complex mechanism.

In the past, high-dose penicillin was not necessarily discontinued because of a positive DAT alone. A change in therapy was considered mainly in the presence of overt hemolytic anemia. For example, lowering the penicillin dose and coadministering other antibiotics sometimes allowed continuation of the drug, particularly if hemolysis was not severe. For other drugs causing only mild hemolysis by the hapten-drug adsorption mechanism, in the unlikely event that no alternatives are available, a similar approach may be effective.

In patients taking α -methyl dopa in the absence of hemolysis, a positive DAT has not necessarily been an indication for stopping the drug. However, given all the choices available, it is prudent to consider alternative antihypertensive therapy. Because less information on the natural history of autoantibodies induced by drugs other than α -methyl dopa is available, discontinuation of the offending drug is advisable unless no suitable alternative exists.

Glucocorticoids are generally unnecessary, and their efficacy is questionable. However, prednisone is effective in patients with CLL and autoimmune hemolysis caused by purine analogues,^{88,89} as are cyclosporine, rituximab, and intravenous immunoglobulin.²³⁰ For treatment of CLL, combination of cyclophosphamide with fludarabine, with or without rituximab, seems to reduce the frequency of fludarabine-induced AHA.^{229,230} Transfusions should be given in the unusual circumstance of severe, life-threatening anemia. Problems with crossmatching, similar to those encountered in warm-antibody AHA, may occur in patients with a strongly positive IAT, for example, in α -methyl dopa–related cases. Patients with hemolytic anemia resulting from the hapten/drug adsorption mechanism should have a compatible crossmatch because the serum antibody reacts only with drug-coated cells. However, if therapy with the offending drug is still in progress, transfused cells may be destroyed at an increased rate as they become coated with drug *in vivo*. Patients with ternary complex–mediated hemolysis will also hemolyze transfused RBCs until the offending drug clears from the plasma.

Several cases of transfusion-associated graft-versus-host disease as a result of purine analogues have been reported in CLL patients transfused for hemolysis.^{90,358,359} Such patients, who have an immunodeficiency state secondary to CLL, impairing their ability to eliminate the transfused lymphocytes, should receive irradiated blood products.

COURSE AND PROGNOSIS

Patients with idiopathic warm-antibody AHA have unpredictable clinical courses characterized by relapses and remissions. No particular feature of the illness has been a consistent predictor of outcome. Despite a rather high initial rate of response to glucocorticoids and splenectomy, the overall mortality rate was significant (up to 46 percent) in several older series, but much lower in more recent studies.^{10,11,309,360,361} The actuarial survival at 10 years reportedly is 73 percent.³⁶⁰

Pulmonary emboli, infection, and cardiovascular collapse are causes of death. Thromboembolic episodes in the form of deep vein thrombosis or splenic infarcts are relatively common during active phases of the disease.^{309,361} In one series, 8 of 30 patients with AHA developed venous thromboembolism; 19 of the patients had antiphospholipid antibodies, including six of the eight patients with thromboembolism.³⁶² In another retrospective analysis of 36 exacerbations of severe AHA in 28 patients, only six of whom were tested and found negative for antiphospholipid antibodies, venous thromboembolism occurred in 5 of 15 exacerbations without anticoagulation and in 1 of 21 with anticoagulation.³⁶³ The contribution of antiphospholipid antibodies to morbidity and mortality in AHA is not clear from these data. However, it seems prudent to consider prophylactic anticoagulation for patients with AHA and antiphospholipid antibodies or other risk factors for venous thromboembolism.

The prognosis in secondary warm-antibody AHA largely depends upon the course of the underlying disease.

In children, warm-antibody AHA frequently follows an acute infection or immunization.^{313,364,365} Most of these patients exhibit a self-limited course and respond rapidly to glucocorticoids. Those who recover from the initial hemolytic episode have a good prognosis and are unlikely to relapse, although exceptions are known. Children with chronic AHA tend to be older.^{364,365} The overall mortality rate is lower

than in adults, ranging from 4 to 30 percent,^{313,364–369} with higher mortality rates in those with chronic AHA^{313,368,369} and associated autoimmune thrombocytopenia (Evans syndrome).^{369,370} Evans syndrome was noted in 37 percent of children with AHA in one large study, a much higher frequency than observed in adults.³⁶⁹

Patients with idiopathic cold agglutinin disease often have a relatively benign course and survive for many years.^{9–11} Occasionally, death results from infection or severe anemia or, not uncommonly, from an underlying lymphoproliferative process.

The postinfectious forms of cold agglutinin disease typically are self-limited. Recovery generally occurs in a few weeks. A few cases with massive hemoglobinuria have been complicated by acute renal failure, requiring temporary hemodialysis.

Postinfectious forms of paroxysmal cold hemoglobinuria terminate spontaneously within a few days to weeks after onset,^{12–15} although the Donath-Landsteiner antibody may persist in low titer for several years.¹⁰ Most patients with chronic idiopathic paroxysmal cold hemoglobinuria survive for many years despite occasional paroxysms of hemolysis.

Immune hemolysis in response to drugs usually is mild, and the prognosis is good. Occasional episodes of exceptionally severe hemolysis with renal failure or death have been reported, usually because of drugs operating through the ternary complex mechanism or purine analogues in patients with CLL.^{39,56,58,62–65,67,86,108,109} In hemolysis resulting from ternary complex or hapten/drug adsorption mechanisms, the DAT becomes negative shortly after the drug is discontinued, that is, soon after the drug clears from the circulation. In addition, the hemolysis associated with α -methyl dopa–induced autoantibodies ceases promptly after drug cessation. However, a positive DAT of gradually diminishing intensity may remain for weeks or months.

CHAPTER 55

ALLOIMMUNE HEMOLYTIC DISEASE OF THE FETUS AND NEWBORN

Ross M. Fasano, Jeanne E. Hendrickson, and Naomi L. C. Luban

SUMMARY

Alloimmune hemolytic disease of the fetus and newborn is caused by the action of transplacentally transmitted maternal immunoglobulin (Ig) G antibodies on paternally inherited antigens present on fetal red cells but absent on the maternal red cells. Maternal IgG antibodies bind to fetal red cells, causing hemolysis or suppression of erythropoiesis. As a consequence, anemia, extramedullary hematopoiesis, and neonatal hyperbilirubinemia may result, with severe cases resulting in fetal loss or neonatal death or disability. Collaboration among maternal–fetal medicine specialists, hematologists, transfusion medicine physicians, radiologists, and neonatologists has substantially reduced perinatal mortality and morbidity resulting from hemolytic disease of the fetus and newborn. Antenatal diagnostic methods identify at risk fetuses, and assess disease severity in affected fetuses. After birth, phototherapy and exchange transfusions prevent serum bilirubin from rising to levels that could produce bilirubin encephalopathy and resultant brain damage (kernicterus), remove maternal antibody, and replace circulating fetal red blood cells with those negative for the implicated antigen(s). Rhlg has successfully prevented alloimmune hemolytic disease resulting from rhesus D sensitization in many at risk infants, but no prophylactic therapy exists as of this writing to prevent alloimmune hemolytic disease resulting from other red cell antibodies. Advances in immunohematology and molecular biology may offer new avenues for prevention and treatment in the future.

Alloimmune hemolytic disease of the fetus and newborn (HDFN) is a disorder in which the life span of fetal and/or neonatal red cells is shortened as a result of binding of transplacentally transferred maternal immunoglobulin (Ig) G antibodies on fetal red blood cell (RBC) antigens foreign to the mother, inherited by the fetus from the father.

Acronyms and Abbreviations: AAP, American Academy of Pediatrics; anti-D, antibody against D antigen; ccf-DNA, circulating cell-free fetal DNA; DAT, direct antiglobulin test; ΔOD_{450} , change in optical density at 450 nm; FFP, fresh-frozen plasma; FMH, fetomaternal hemorrhage; HDFN, hemolytic disease of the fetus and newborn; HDN, hemolytic disease of the newborn; IAT, indirect antiglobulin test; Ig, immunoglobulin; IUT, intrauterine transfusion; IVIG, intravenous immunoglobulin G; QT-PCR, quantitative polymerase chain reaction; RBC, red blood cell; Rh, rhesus; rHuEPO, recombinant human erythropoietin; Rhlg, Rho(D) immunoglobulin; SGA, small for gestational age; TBV, total blood volume; TSB, total serum bilirubin; WB, whole blood.

The resulting hemolysis or suppression of erythropoiesis may cause fetal and/or neonatal anemia and significant neonatal jaundice. There are three main classes of alloimmune HDFN, based on the antigen(s) involved: Rh (rhesus), minor red cell antigens (i.e., Kell, Duffy, Kidd antigens) and ABO.

Prior to the development of medical interventions in the 1950s, almost half of all newborn infants with Rh HDFN died or were severely handicapped. Although the clinical condition was described in newborn infants as early as the 1600s, it was only in the 1930s and 1940s that the pathophysiology of Rh HDFN was uncovered. In 1932, Diamond and colleagues¹ recognized that the clinical syndromes of stillbirth with unusual erythroblastic activity in the extramedullary sites and blood, fetal hydrops, anemia in the newborn, and “icterus gravis neonatorum” were closely related and likely had the same pathophysiology in the hematopoietic system. In 1938, Ruth Darrow, a pathologist who lost a baby to kernicterus, postulated that hemolysis of fetal RBCs was a result of maternal antibody produced in response to fetal hemoglobin.² The discovery of the Rh factor by Landsteiner and Weiner led to elucidation of Rh HDFN by Levine and colleagues who established that erythroblastosis fetalis was caused by immunization of an Rh-negative mother by the red cells from an Rh-positive fetus.³ Antibodies produced by the sensitized mother crossed the placenta in the next pregnancy and coated the fetal Rh-positive cells, leading to hemolysis, anemia, hydrops, and severe neonatal jaundice.

Neonatal mortality from Rh HDFN decreased considerably with the development of exchange transfusion techniques for correction of severe anemia and hyperbilirubinemia.⁴ However, severely affected fetuses continued to die *in utero* before 34 weeks’ gestation. In 1961, Liley demonstrated the prognostic value of amniotic fluid spectrophotometry in identifying fetuses at risk and then showed that intrauterine transfusions (IUTs) could prevent fetal deaths.⁵ The most dramatic reduction in the incidence of Rh HDFN was achieved in the 1960s and 1970s with the development of postpartum and antepartum anti-D prophylaxis to prevent maternal Rh sensitization.⁶

Despite these advances, Rh HDFN has not disappeared, and cases of hemolytic disease of the newborn resulting from red cell antibodies directed toward antigens other than the Rh blood group system are being increasingly recognized.^{7–11} Furthermore, maternal Rh isoimmunization and Rh hemolytic disease still occur, particularly in developing countries where anti-RhD prophylaxis is not widely available or in infants born outside of medical facilities.¹²

● EPIDEMIOLOGY

The epidemiology of HDFN varies in different ethnic and racial groups; the frequency of specific blood group alleles in a given population determines the probability of blood group incompatibility and maternal alloimmunization. Antigen-negative women may have naturally occurring antibodies to certain red cell antigens (anti-A or anti-B) or may develop antibodies as a result of exposure to foreign red cell antigens through blood transfusion or by silent fetomaternal hemorrhage during pregnancy or at delivery. More than 50 different RBC antigens are associated with maternal alloimmunization^{7–11,13} and with HDFN of varying severity; however, the vast majority of clinically significant maternal alloantibodies are within the Rh (D, CE), Kell, Duffy, MNS, and Kidd systems (Table 55–1).

Antenatal screening programs detect antibodies to clinically significant Rh or other minor RBC antigens in 0.01 to 0.4 percent of pregnant women,^{7–11,13} although these numbers vary by country. Approximately 15 percent of Americans of European descent are RhD-negative, compared to 7 percent of Americans of African descent and Hispanics,

TABLE 55-1. Blood Group Systems Associated with Hemolytic Disease of the Fetus and Newborn

Blood Group System	Antigens

5 percent of Asian Indians, and 0.3 percent of Chinese people.¹⁴⁻¹⁶ Despite the success of Rh prophylaxis, anti-D antibodies still constitute a large proportion of clinically significant antibodies detected in Europe and the United States. When RhD is excluded, non-D Rh antibodies (c, C, e, E, etc.) and antibodies belonging to the Kell, Duffy, Kidd, and MNS systems, are most frequently involved^{7,13}; Table 55-2 shows representative estimate of antibodies other than anti-D in women referred to a major national Maternal Alloimmunization Program at Wexner Medical Center at the Ohio State University.

TABLE 55-2. Incidence of Maternal Non-D Alloantibodies Associated with Hemolytic Disease of the Fetus and Newborn at a Major U.S. Referral Center*

Alloantibody	1970-1988	1989-2006
	N (%)	N (%)
Anti-c	49 (16.6)	89 (10.4)
Anti-C	3 (1.0)	30 (3.5)
Anti-e	8 (2.7)	8 (0.9)
Anti-E	77 (26.1)	198 (23.1)
Anti-Kell†	87 (29.5)	167 (19.5)

CLINICAL FEATURES OF HEMOLYTIC DISEASE OF THE FETUS AND NEWBORN

OVERVIEW

Anemia, jaundice, and hepatosplenomegaly are the hallmarks of hemolytic disease of the newborn (HDN). The clinical spectrum of affected infants is highly variable. In Rh HDN, half of the infants have mild disease and do not require intervention. One-fourth of affected infants are born at term with moderate anemia and develop severe jaundice. In the days prior to intrauterine intervention, hydrops developed *in utero* in the remaining one-fourth of infants; half became hydropic prior to 34 weeks' gestation. Hydrops recurs in 90 percent of affected pregnancies, often at an earlier gestation. In Kell HDN, the clinical spectrum of hemolytic disease is less predictable, ranging from mild anemia to frank hydrops; jaundice may be less severe than that seen in Rh HDFN, given the erythroid suppression that anti-Kell alloantibodies may induce. Jaundice is the predominant feature of ABO HDN, but anemia and mild hepatosplenomegaly may also be seen. Severe fetal anemia and hydrops are unusual in ABO hemolytic disease.¹⁷

HEMOLYTIC ANEMIA

Infants with mild HDN may have cord blood hemoglobin concentrations only slightly lower than the age-related normal range. Hemoglobin values usually continue to fall after birth in all affected infants. Hemolysis continues until all incompatible red cells and/or circulating maternal alloantibody are eliminated from the circulation. Physical examination in infants having moderate to severe anemia reveals pallor, tachypnea, and tachycardia. In cases of severe HDFN, fetal anemia secondary to hemolysis results in compensatory extramedullary hematopoiesis in the liver, spleen, kidneys, and adrenal glands, and an outpouring of immature nucleated RBCs in the fetal circulation due to increased fetal plasma erythropoietin levels.¹⁸ The marked increase in erythropoiesis may be accompanied by down-modulation of platelet and neutrophil production.¹⁹

After birth, the quantity of maternal antibodies in the neonatal circulation decreases over the next 12 weeks, with a half-life of approximately 25 days. Infants with moderate to severe hemolytic disease may develop significant anemia beyond the immediate neonatal period lasting up to 8 to 12 weeks of life. Delayed anemia is related to continuing hemolysis because of persistence of maternal antibodies and a hyporegenerative component with decreased red cell production from low serum concentrations of erythropoietin.²⁰⁻²²

NEONATAL JAUNDICE

Most infants with HDN are not jaundiced at birth because the placenta effectively transports most of the lipid-soluble unconjugated fetal bilirubin. Bilirubin concentrations in amniotic fluid reflect bilirubin concentrations in fetal blood and are influenced by fetal blood and amniotic fluid albumin concentrations.²³ The mechanism of entry of bilirubin into the amniotic fluid compartment has been debated, but of the five possible pathways (excretion through the fetal kidneys, meconium, skin, fetal lung secretions, and transmembranous), transmembranous appears to be most likely.²⁴

At birth, the newborn infant's immature liver is incapable of handling the large bilirubin load that results from the ongoing destruction of antibody-coated neonatal red cells, and jaundice usually develops during the first day of life, often in the first few hours of life in severely affected infants. The jaundice progresses in a cephalopedal direction with rising bilirubin levels. In patients with mild disease, the serum

indirect bilirubin peaks by the fourth or fifth day and then declines slowly. Premature infants may have higher levels of serum bilirubin for a longer duration because of lower hepatic glucuronyl transferase activity. Conjugated hyperbilirubinemia at birth is sometimes noted in infants who received multiple IUTs. Babies who received IUTs may still have anemia at birth and may still develop significant hyperbilirubinemia in the neonatal period.²⁵ As discussed later in the section “Postnatal Management”, these infants may require intermittent transfusion therapy until 2 to 3 months of age due to persistent anemia.

KERNICTERUS

An important complication of elevated serum levels of indirect bilirubin in the neonate is the development of bilirubin encephalopathy.²⁶ This disorder, also termed *kernicterus*, is caused by bilirubin pigment deposition in the basal ganglia and brainstem nuclei, leading to neuronal necrosis. Acute bilirubin encephalopathy is initially marked by lethargy, poor feeding, and hypotonia. With increasing severity, the infant develops a high-pitched cry, fever, hypertonia progressing to frank opisthotonos, and irregular respiration. The infants then develop any or all of the classic sequelae of kernicterus: choreoathetoid cerebral palsy, gaze abnormalities, especially in upward gaze, sensorineural hearing loss, and cognitive deficits. The clinical presentation of bilirubin encephalopathy in preterm infants may be less distinctive. Abnormal or absent brainstem auditory evoked potentials and magnetic resonance imaging scans demonstrating the characteristic bilateral lesions of the globus pallidus help confirm the clinical diagnosis of kernicterus.

Infants with HDFN are at higher risk for kernicterus than are other infants with the same bilirubin level from other causes.²⁷ Heme pigments produced during active hemolysis are hypothesized to inhibit bilirubin–albumin binding. Alternatively, many conditions that potentially compromise the blood–brain barrier, such as prematurity, acidosis, hypoxemia, hypothermia, and hypoglycemia, are present in severely affected infants, making them more vulnerable to bilirubin encephalopathy.

OTHER CLINICAL FEATURES

Extensive extramedullary hemopoiesis in the liver and spleen may cause portal and umbilical venous hypertension, leading to ascites, pleural effusions, and consequent pulmonary hypoplasia.²⁸ Trophoblastic hypertrophy and placental edema cause impaired placental function. Hypoproteinemia as a result of liver dysfunction leads to generalized edema. “Hydrops fetalis,” a state of anasarca, is the end result of a combination of anemia, hypoproteinemia, cardiac failure, elevated venous pressures, increased capillary permeability, and impaired lymphatic clearance. Hepatosplenomegaly is usually present. Cholestatic liver disease, previously believed to be associated with iron overload caused by IUTs, has been shown to occur in 13 percent of neonates with HDFN independent of previous IUT treatment and type of alloimmunization.²⁹ Hydropic babies may also have respiratory distress as a result of pulmonary hypoplasia, pleural and/or pericardial effusions, or surfactant deficiency.

Although the pathophysiology is not entirely clear, purpura associated with thrombocytopenia is sometimes seen in infants with HDFN. Thrombocytopenia at birth has been occurs in 26 percent of neonates with HDFN, independent of other comorbidities, such as lower gestational age at birth, being small for gestational age (SGA), and previous IUTs.³⁰ Severe fetal thrombocytopenia (platelet count $<50 \times 10^9/L$) has been reported in 3 percent of all fetal blood samplings and in 23 percent of severely RhD alloimmunized hydropic fetuses in one center when fetal platelet counts were measured prior to IUT.³¹ In addition, neutropenia is a common feature of HDN and may be prolonged up to a year

of life, regardless of severity of HDFN, treatment received, or antibody specificity.³²

OBSTETRIC HISTORY

The course and outcome of prior pregnancies are critically important in the initial evaluation of an alloimmunized pregnancy. A history of early fetal deaths or hydrops is ominous. In Rh alloimmunization, the severity of HDFN typically remains the same or worsens in subsequent affected pregnancies. Hydrops recurs in 90 percent of affected pregnancies, often at an earlier gestation in subsequent pregnancies. Alloimmunized women who report previous neonatal deaths, neonatal exchange transfusions, or IUTs should receive very close fetal surveillance.³³ Jaundice as a result of hemolysis often recurs to the same degree of severity in subsequent affected siblings. The history of prior blood transfusions may be obtained in women sensitized to antigens other than RhD, especially if Kell alloimmunization is detected. Establishment of paternity for each pregnancy is particularly relevant in both Rh and Kell alloimmunization, because the fetus is at risk only if the father is positive for the antigen in question. Unlike Rh and other minor alloantibody HDFN, ABO HDN may affect the first-born ABO-incompatible infant. Although rare, severe ABO HDN may recur in subsequent ABO-incompatible pregnancies.³⁴

DIFFERENTIAL DIAGNOSIS

Hydrops fetalis may be secondary to α -thalassemia (Chap. 49) cardiac anomalies or arrhythmias, fetal genetic or metabolic disorders, intrauterine infections such as syphilis or toxoplasmosis, or any of a multitude of causes that lead to severe derangements in fetal homeostasis. These disorders are classified as nonimmune hydrops and are differentiated from the etiologies discussed in this chapter by the absence of any clinically significant red cell alloantibodies in the mother’s blood. Parvovirus B19 infection of the mother at any time during gestation can cause nonimmune hydrops, profound fetal anemia, and death.

Neonatal anemia caused by intrinsic red cell defects such as hereditary spherocytosis (Chap. 46), red cell enzyme deficiencies (Chap. 47), and hemoglobinopathies, notably α -thalassemia (Chap. 48) can give a similar clinical picture to HDN. The absence of maternal red cell alloantibodies, a negative direct antiglobulin test (DAT) result, and detection of the specific defect determining the disorder clarify the diagnosis. Disorders of bilirubin metabolism can lead to unconjugated hyperbilirubinemia; however, they are not associated with anemia. Hepatitis or obstructive biliary diseases present with direct hyperbilirubinemia, most often after the first week of life.

● PATHOPHYSIOLOGY

There are three main classes of alloimmune HDFN, based on the antigen(s) involved: (1) Rh, (2) minor red cell antigens (i.e., Kell, Duffy, Kidd antigens), and (3) ABO. Factors affecting the risk to the fetus or neonate not only include the class of antigens involved, but also the titer (i.e., 4 vs. 32) and class/subclass (i.e., IgM vs. IgG₄ vs. IgG₁) of the antibody, the level of antigen expression on fetal RBCs, and the antibody’s ability to suppress erythropoiesis (i.e., anti-K).^{35,36} Rh HDFN is discussed first because it is archetypal of this condition; however, ABO incompatibility is much more common than Rh HDFN. The distinguishing features of the three classes of HDFN are highlighted below.

RHD HEMOLYTIC DISEASE

The standard nomenclature for designation of one’s blood type is ABO and Rh-positive or Rh-negative based on the presence or absence of the

RhD antigen. However, the Rh blood system consists of numerous other antigens, the most common clinically significant include C, c, E, and e, which are encoded on the paired *RHCE* gene. RhD-positive individuals may have one or two copies of *RHD* gene (heterozygous or homozygous RhD-positive, respectively). More than 150 alleles have been defined for *RHD* and more are likely to be revealed as population studies expand.³⁷ In whites, RhD-negative individuals are homozygous for deletion of the *RHD* gene, which encompasses the whole of *RHD* and part of each of the flanking Rh boxes. The resultant RhD-negative phenotype is characterized by the absence of the whole RhD protein from the red cell membrane; however the *RHCE*-encoded antigens are present. Only 18 percent of RhD-negative Americans of African Descent are homozygous for *RHD* deletion. The majority (66 percent) of RhD-negative Americans of African descent have an inactive *RHD* gene (*RHψ*), while 15 percent have a hybrid *RHD-CE-D* gene, neither of which produces epitopes of RhD antigen.

A number of *RHD* alleles responsible for RhD protein variants with altered RhD antigen expression have been classified according to their phenotype and molecular variation as partial D, weak D, and DEL. Amino acid substitutions located in extracellular domains result in different forms of partial D phenotype. Women with partial D phenotypes may develop antibodies against D epitopes absent on their cell membranes but present on the fetal RBCs. Amino acid substitutions located in the transmembrane or intracellular segments of the RhD protein result in a weak D phenotype. The expressed RhD antigen is reduced quantitatively but not qualitatively, so carriers are usually not susceptible to anti-D immunization. However, some types of weak D (weak D type 15, weak D type 4.2 or DAR, and weak D type 7) may produce anti-D. DEL is a very weakly expressed D antigen found in 30 percent of RhD-“negative” blood donors in East Asia. Anti-D antibody molecules recognize the epitopes on the external loops of RhD protein (Chap. 136).³⁷⁻³⁹

There currently are no requirements in the United States for blood banks to test for variant RhD on RhD-negative pregnant mothers. However, monoclonal RhD typing sera most commonly used for RhD typing do not detect weak D or partial D phenotypes, which results in reporting patients with variant RhD phenotypes as RhD-negative. Therefore, pregnant women with variant RhD phenotypes are usually treated with anti-D immunoglobulin prophylaxis.

RhD-negative pregnant women who appear to have both anti-D and anti-C, especially if at a similar strengths of reactivity serologically, require special consideration. In this instance, if the pregnant woman is lacking both RhD and RhC antigens, she is also lacking the RhG antigen, a combination antigen in the Rh Blood Group System found on RBCs containing either RhD or RhC antigens. In these situations, the laboratory must determine whether the antibodies are truly anti-D/anti-C rather than an anti-G because a patient who develops anti-C and/or anti-G antibodies but no anti-D should receive anti-D immunoglobulin prophylaxis.⁴⁰

Fetomaternal Hemorrhage and Anti-D Alloimmunization

Asymptomatic transplacental passage of fetal red cells occurs in 75 percent of pregnant women at some time during pregnancy or during labor and delivery.⁴¹ The incidence of fetomaternal transfusion increases with advancing gestation—from 3 percent (first trimester) to 12 percent (second trimester) to 45 percent (third trimester) and to 64 percent at delivery. The average volume of fetal blood in the maternal circulation after delivery is approximately 0.1 mL in most women and less than 1 mL in 96 percent of women.⁴² Intrapartum fetomaternal hemorrhage of more than 30 mL may occur in up to 1 percent of deliveries.⁴³ Massive fetomaternal hemorrhage may present with decreased fetal movement and sinusoidal heart rhythm (undulating wave form alternating with a

flat or smooth baseline fetal heart rate); however, it also may be clinically silent, with no clinical signs differentiating such deliveries from those with minimal fetomaternal hemorrhage.^{43,44} Fetomaternal transfusion can also result from obstetric procedures such as chorionic villus sampling, amniocentesis, funipuncture, therapeutic abortion, external cephalic version, cesarean section, and manual removal of the placenta, and from pathologic conditions such as abdominal trauma, spontaneous abortion, or ectopic pregnancy.^{42,45-47}

The presence of RhD-positive red cells in an RhD-negative mother initially provokes a weak and slow primary immune response, which develops over 4 weeks and consists of transient elevation of IgM antibodies. Subsequently, approximately 5 to 15 weeks after exposure to the RhD-positive red cells, anti-D IgG antibodies capable of crossing the placenta are produced. The RhD antigen is the most immunogenic of the Rh antigens and, indeed, of all red cell antigens (after ABO).⁴⁸ The RhD protein is processed by antigen-processing cells in the spleen and lymphoid tissue of D-negative individuals into multiple short allogeneic linear peptides, which stimulate helper T cells, which then activate B cells to produce IgM and later IgG antibodies. Memory T and B cells that are generated following the initial immune response are long lived, and exposure to the antigen, even years later, results in an accelerated antibody response as a result of rapid proliferation of antigen-specific clones. Repeated exposure to RhD-positive fetal RBCs, as in a second RhD-positive pregnancy in a sensitized RhD-negative woman, produces a brisk secondary immune response marked by rapid production of large amounts of anti-D IgG antibody by maternal memory B lymphocytes.

In the absence of Rho(D) immunoglobulin (RhIg) prophylaxis, sensitization occurs in 7 to 16 percent of RhD-negative women at risk, within 6 months after delivery of the first RhD-positive ABO-compatible fetus. The relatively low rate of 16 percent of primary alloimmunization in Rh-negative women at risk may be a result of the low volume of fetomaternal hemorrhage (FMH) in most women. In fact, as little as 0.03 mL of RhD-positive RBCs has been shown to be sufficient to immunize some RhD-negative individuals.⁴⁹

The potential for immunization of the mother is not only determined by the extent of FMH and the presence of fetomaternal blood group incompatibility, but also by other factors, such as the frequency of fetomaternal transfusion and whether the mother and fetus are ABO compatible. As an example, repetitive exposure to minuscule amounts of RhD-positive red cells in RhD-negative women who abuse intravenous drugs and share needles with RhD-positive partners has been reported to lead to severe Rh sensitization.⁵⁰ Fetomaternal ABO incompatibility offers some protection against primary Rh immunization because incompatible fetal red cells are destroyed rapidly by maternal anti-A and anti-B antibodies, reducing maternal exposure to RhD antigenic sites. Primary Rh immunization occurs in 2 to 4 percent of women at risk after delivery of an ABO-incompatible fetus.⁵¹ ABO incompatibility confers no protection against the secondary immune response once sensitization has occurred.⁵²

Binding of transplacentally transferred maternal anti-D IgG antibodies to D-antigen sites on the fetal red cell membrane is followed by adherence of the coated red cells to the Fcγ receptors of macrophages with rosette formation, leading to extravascular noncomplement-mediated phagocytosis and lysis, predominantly in the spleen.⁵¹ Although Rh antigens are found on fetal RBCs as early as week 6 of gestation,³⁹ active transport of IgG across the placenta is slow until 20 to 24 weeks of gestation. The severity of fetal anemia is influenced primarily by the anti-D IgG concentration, but is also by other factors including: the IgG subclass, the rate of transplacental transfer of maternal IgG, the functional maturity of the fetal mononuclear phagocyte system, and the presence of maternal human leukocyte antigen (HLA) antibodies and or maternal-fetal ABO incompatibility.⁵³ Although IgG anti-D consists mainly

of IgG₁ and IgG₃ subclasses, the relative contribution of each of these subclasses to the severity of HDFN remains controversial.^{51,54,55}

HEMOLYTIC DISEASE CAUSED BY OTHER RED CELL ANTIBODIES

Although antibodies against RhD tend to be the most clinically significant in terms of fetal outcomes, there are many other RBC antigens capable of inducing alloantibodies after exposure through transfusion or pregnancy. Any alloantibody capable of inducing hemolysis or suppressing erythropoiesis may be clinically significant to developing fetuses. However, the mere presence of antibodies on screening tests may not be clinically significant, because of the unique characteristics of some antibodies. For example, antibodies to Lewis antigens (Le^a, Le^b) are IgM and do not cross the placenta. Alternatively, Lutheran (Lu^a, Lu^b) and Chido antigens are poorly expressed on fetal and neonatal red cells and therefore are not susceptible to destruction by maternal antibodies.

Case reports may be biased toward more-severe cases, and there is considerable variability in the clinical spectrum of disease produced by different alloantibodies. With the widespread use of RhIg, anti-Kell has bypassed anti-D as the leading cause of HDFN in some centers.⁸ Table 55–1 lists some of the antibodies more commonly associated with HDFN.^{13,56} Of note, many cases severe enough to require IUT involve antibodies to RhD, with or without antibodies to other alloantigens being present. Figure 55–1 shows data from 178 pregnancies requiring IUT at Wexner Medical Center, Ohio State University.

Kell

The Kell blood group system consists of at least 28 discrete antigens, of which eight are associated with HDFN. The *KEL* gene is located on chromosome 7q34, and Kell antigens are located on the red cell membrane glycoprotein CD238. Kell is unique in that it spans the RBC membrane once; it has a short N-terminal domain of 47 amino acids in the cytosol and a large C-terminal domain (665 amino acids) outside the membrane. The most common of the K antigens, Kell (also known as KEL1), is expressed by erythroid progenitor cells and mature erythroid cells by 9 percent of people of European ancestry and 1 to 2 percent of people of African ancestry; most KEL1-positive individuals are heterozygous.⁵⁷ Alloimmunization to KEL1 can occur through transfusion or through pregnancy.^{58,59}

Given the relatively low prevalence of the KEL1 antigen, the likelihood of KEL1 incompatibility between mother and child is less than that of RhD. However, any KEL1-positive fetus being carried by a woman alloimmunized to the KEL1 antigen is at risk of anemia. Between 2.5 and 10 percent of alloimmunized pregnancies result in an affected infant, with fetal hydrops and severe anemia being common presentations of

Kell HDFN.^{59–61} In contrast to the hemolysis observed in RhD HDFN, the severe fetal anemia observed because of maternal anti-Kell alloantibodies is largely a result of suppression of erythropoiesis and not to hemolysis. Clinical observations of inappropriately low levels of circulating reticulocytes and normoblasts for the degree of anemia have long been noted in affected fetuses, and suppression of erythropoiesis has been established by *in vitro* studies showing that growth of Kell-positive erythroid progenitor cells is inhibited by monoclonal IgG and IgM anti-Kell antibodies.⁶² Furthermore, anti-Kell antibodies are associated with suppression of megakaryocyte and granulocyte colony-forming units with resultant fetal and neonatal thrombocytopenia and pancytopenia.^{63,64} As discussed in further detail later in this section “MATERNAL IMMUNOHEMATOLOGIC TESTING”, titers of maternal anti-Kell do not necessarily correlate with the severity of fetal anemia and thus all maternal anti-Kell alloantibodies must be considered to be potentially clinically significant to antigen positive fetuses.

Other Minor Antigens (Non-D, Non-Kell)

Many other minor RBC antigens besides D and Kell are immunogenic in transfusion and pregnancy settings, with some of these alloantibodies having the capacity of being detrimental to developing fetuses. The incidence and prevalence of other minor antigens contributing to HDFN depends in part on the geographical area evaluated, as genetics and local transfusion practices impact alloimmunization. Any IgG that can cross the placenta is, in theory, capable of binding to cognate antigen on fetal RBCs. Antigen copy number, as well as other characteristics of the antigens/antibodies (potentially including IgG subtype), may impact the clinical significance of the alloantibodies.

ABO HEMOLYTIC DISEASE

ABO HDN occurs almost exclusively in infants with blood group A or B who are born to group O mothers, given that group O mothers have naturally occurring antibodies against the A and B antigens that are of the IgG class and are thus capable of crossing the placenta. The fetal reticuloendothelial system may completely remove RBCs bound with IgG, or it may remove portions of the RBCs, resulting in microspherocytes visible on blood film. (Table 55–3 compares ABO and RhD HDN.) Infants with ABO HDN generally have less-severe disease than those with Rh incompatibility. Hydrops fetalis caused by ABO alloimmune HDN is extremely rare. Although infants affected by ABO incompatibility may require phototherapy to treat their jaundice, less than 0.1 percent require exchange transfusion.^{17,65} Unlike Rh disease, ABO HDN may affect the firstborn ABO-incompatible infant because anti-A and anti-B IgG antibodies are normally present in group O adults. Antenatal testing of anti-A and anti-B levels in group O mothers has little value in predicting ABO HDN, though the number of fully developed A or B antigens on fetal RBCs may impact disease severity. A recurrence rate of 88 percent has been reported in siblings having the same blood type as the affected index baby, with two-thirds of the affected siblings requiring therapy.³⁴ A higher incidence and greater severity of jaundice as a result of ABO incompatibility is reported in southeast Asians, Hispanics, Arabs, and South African and Americans of African descent than in whites.^{17,66,67} This may be partly a result of the extent of development of A or B antigen sites on fetal RBCs, as well as of the prevalence of Gilbert syndrome in different patient populations.⁶⁸

ANTENATAL MONITORING

The evaluation and management of HDFN require close collaboration between obstetricians, maternal fetal medicine specialists, radiologists, hematologists, transfusion medicine specialists, and neonatologists.

RBC Alloantibodies in 178 Pregnancies Requiring Intrauterine Transfusions (from the Ohio State Alloimmunization Committee, 1965–2007)

TABLE 55-3. Comparison of Rh and ABO Hemolytic Disease of the Newborn

	Rh	ABO
Blood groups		
Mother	Negative	O
Infant	Positive	A or B
Type of antibody	IgG ₁ and/or IgG ₃	IgG ₂
Clinical aspects		
Occurrence in firstborn	5%	40–50%
Predictable severity in subsequent pregnancies	Usually	No
Stillbirth and/or hydrops	Frequent	Rare
Severe anemia	Frequent	Rare
Degree of jaundice	+++	+ to ++
Hepatosplenomegaly	+++	+
Laboratory findings		
Maternal antibodies	Always present	Usually present
Direct antiglobulin test (infant)	+	+ or –
Microspherocytes	–	+
Treatment		
Antenatal measures	Yes	No
Exchange transfusion frequency	Approx. 2/3	Occasional
Donor blood type	Rh-negative, group specific when possible	Group O only
Incidence of late anemia	Common	Rare

Ig, immunoglobulin.

Figure 55-2 is an algorithm for the clinical management of an alloimmunized pregnancy.

DETERMINATION OF PATERNAL ZYGOSITY AND FETAL BLOOD TYPE

When a clinically significant alloantibody is identified, or if there is a history of a previous fetus or neonate affected by HDFN, the next step is to determine if the fetus is at risk because the fetus carries the corresponding antigen. If the father is homozygous for the corresponding antigen, the fetus is at definite risk for HDFN. The child of an antigen-negative mother and a heterozygous antigen-positive father has a 50 percent chance of being antigen-positive and thus being affected by maternal alloimmunization. When the father is heterozygous or paternal zygosity is unknown, determination of fetal blood type early in pregnancy allows early institution of monitoring and therapy in antigen-positive fetuses that are at risk and forestalling invasive and potentially risky procedures in antigen negative fetuses.

Paternal zygosity is determined using serology for all common blood group antigens implicated in HDFN except for D. Alternatively, RBC genotyping can be used when typing for antigen systems where serologic reagents are rare or nonexistent. The probable *RHD* zygosity in RhD-positive persons may be inferred, but not definitively, from

serologic phenotyping studies, based on gene frequencies in certain populations and the fact that the *C/c* and *E/e* antigens are closely linked to the *RHD* locus.^{14,56} Elucidation of the genetic structure of the prevalent *RHD* locus and haplotypes responsible for RhD-negative phenotypes has led to the development of more direct and robust methods of determination of *RHD* zygosity molecularly. *RHD* zygosity testing by quantitative fluorescence polymerase chain reaction (QF-PCR) is commercially available and uses *RHD* (exons 5 and 7) to *RHCE* (exon 7) amplification ratios to determine *RHD* copy number. Although suitable for use in both white and ethnic African individuals, this molecular technique has a false-positive rate of 1 percent as a result of rare *RHD* alleles that are not expressed, and a false-negative rate of 1 percent as a result of rare partial D alleles (i.e., DBT type 1, type 2) which lack *RHD* exons 5 and 7 but still express RhD epitopes.^{69,70}

If paternal heterozygosity is suspected or confirmed, determination of fetal blood type is helpful in planning further management. There are several sources of fetal tissue for fetal blood group genotyping. These include blood obtained by cordocentesis, chorionic villus sampling, and cervical tissue obtained by transvaginal lavage; each has risks to the fetus and issues related to quality of sample. Cordocentesis, amniocentesis, and chorionic villus sampling for fetal genetic typing carry a risk of FMH with increased risk of augmenting maternal sensitization and of fetal loss.^{45,46} The advent of noninvasive methods of prenatal diagnosis using fetal DNA extracted from maternal plasma as early as the first trimester of pregnancy has obviated those concerns and has dramatically improved the ability to perform molecular testing on fetal tissue.⁷¹

Circulating cell-free fetal DNA (ccff-DNA) in maternal plasma can be identified as early as 5 weeks of gestation and is derived from apoptotic syncytiotrophoblasts. Fetal DNA used for typing is extracted and then evaluated by real-time quantitative polymerase chain reaction (QT-PCR). Most protocols amplify three exons or more, which include *RHD* exons 4 to 7 and 10, and detect target Psi (ψ) pseudogene sequences in exon 4 to avoid false-positives when the fetus has *RHD* ψ .^{72,73} Confirmation of detection of nonmaternal markers is required and can be accomplished by testing for the presence of the Y chromosome in male fetuses and/or housekeeping genes such as hemoglobin β -chain, β -actin, albumin, or chemokine receptor 5. A recent meta-analysis reviewed 37 publications describing 44 protocols reporting noninvasive *RHD* genotyping using fetal DNA obtained from more than 3000 maternal blood samples; an accuracy rate of 94.8 percent was reported.⁷² Very high accuracy rates (>96 percent) have been reported for noninvasive fetal *RHCE* genotyping from maternal blood as well.⁷⁴ *RHD* ccff-DNA testing is commercially available, and is being increasingly used in the United States, United Kingdom, and Europe.⁷⁵ Although used more often in non-U.S. countries than in the United States at the present time, ccff-DNA testing may also be used to predict whether infants of alloimmunized women carry the cognate minor RBC antigen and are thus at risk for HDFN.

MATERNAL IMMUNOHEMATOLOGIC TESTING

The dual aims of maternal antenatal testing are to identify women who enter pregnancy already alloimmunized, and to identify those who are at high risk of becoming alloimmunized during pregnancy. The practice guidelines and recommendations for pregnancy-associated immunohematologic and molecular testing were established in the United States by the American Association of Blood Banks.⁵⁷

Every obstetrical patient should have samples obtained between 10 and 16 weeks' gestation and tested for ABO and RhD type; D typing discrepancies must always be investigated and resolved. These maternal samples should also be screened for the presence of red cell alloantibodies. A second sample should be obtained at 28 weeks' gestation to

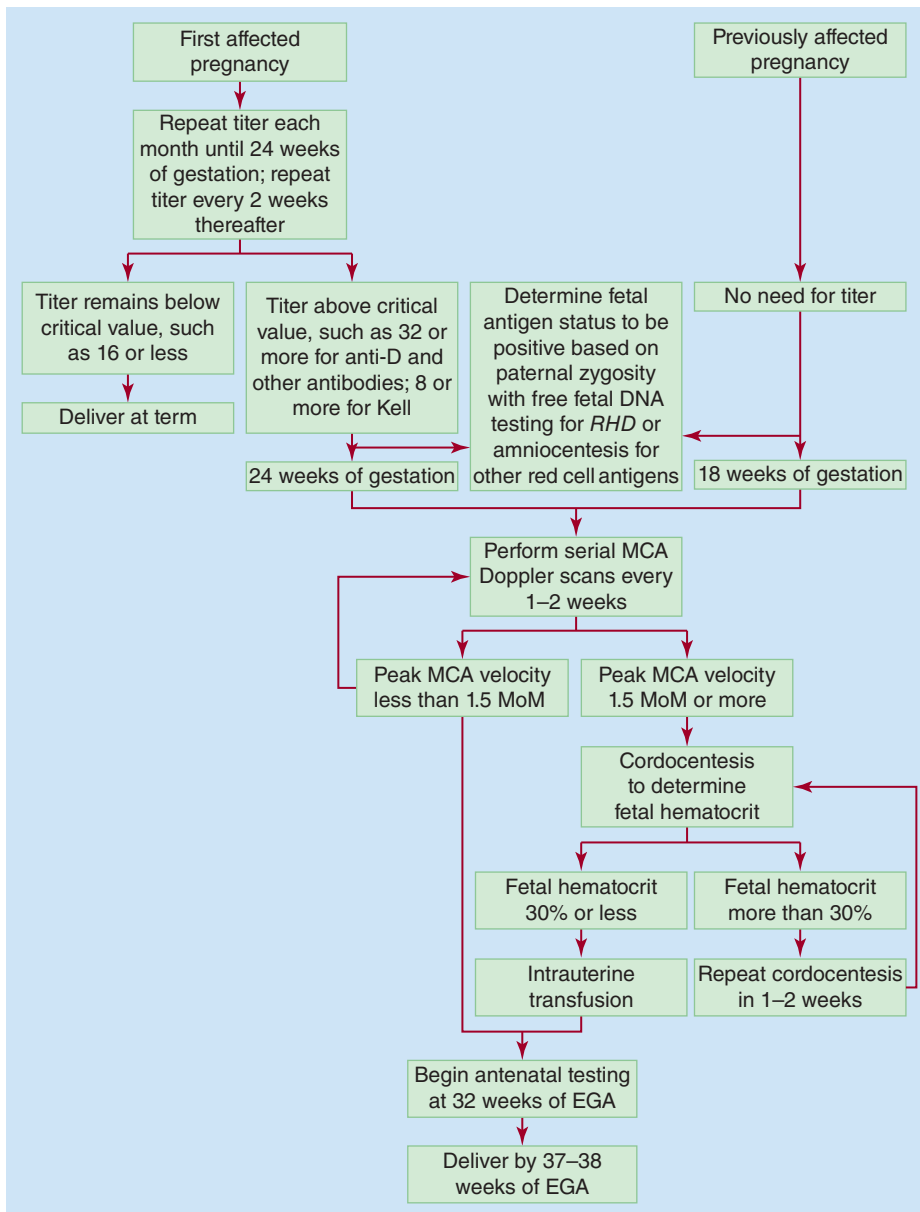

Figure 55–2. Algorithm for the clinical management of an alloimmunized pregnancy. EGA, estimated gestational age; MCA, middle cerebral artery; MoM, multiples of median. (Modified with permission from Moise KJ Jr: *Management of rhesus alloimmunization in pregnancy*. *Obstet Gynecol* 2008 Jul;112(1):164-176.)

confirm the maternal blood type, and to further evaluate the pregnant mother for other red cell alloantibodies that may have been evanescent or nonexistent earlier in pregnancy. If an unexpected antibody is identified anytime during pregnancy, the specificity, titer, and likelihood of leading to HDFN must be determined. The indirect antiglobulin test (IAT), using reagent red cells expressing C, c, D, E, e, K, k, Fy^a, Fy^b, Jk^a, Jk^b, S, s, M, N, and Le^a, is typically used for maternal antibody screening. Blood samples from women with anti-D alloantibodies should be tested monthly until 28 weeks' gestation and every 2 weeks thereafter.⁷⁶ Antibody titers are reported as the reciprocal of the highest dilution step at which agglutination is observed. A difference of two dilutions is considered a significant change. Testing should ideally be performed in parallel with previously frozen samples to minimize the possibility that changes in the titer result from differences in technique or reagent red cell selection.⁵⁷ A critical titer is defined as the titer associated with significant risk of fetal anemia or hydrops, and is the threshold at which the fetus will need monitoring. Once the critical titer is reached and a decision is made to monitor the fetus by ultrasonography or amniocentesis,

further antibody titration plays no role in assessment of fetal status. The critical titer varies from 8 to 32 in different laboratories in the United States.⁷⁶ In the United Kingdom and Europe, the level of anti-D is compared to an international standard and reported in IU/mL. Anti-D levels of 4 IU/mL or greater prompt referral to a specialist fetomaternal unit for further monitoring; at levels of 4 to 15 IU/mL, there is a potential risk of moderate HDFN; levels greater than 15 IU/mL imply a risk of severe HDN.⁷⁷ In the Netherlands, anti-Kell titers as low as 2 prompt referral to a perinatal center,⁵⁹ and the critical titer is defined as 16 or greater.⁷ When RhIg has been administered during pregnancy, a positive low anti-D antibody titer may be detected (generally 2 to 4). Specific laboratory techniques may be used, if required, to distinguish between passive RhIg and active alloimmunization to D.

The significance of titer levels for antibodies other than D has not been fully defined. Maternal anti-Kell titers, in particular, correlate poorly with fetal outcome.⁶² In a review of 156 anti-Kell-positive pregnancies over 37 years, McKenna and colleagues found that all severely affected fetuses had a titer of at least 32.⁶⁰ Bowman and

colleagues also noted that a titer of 32 or greater was present in 16 of 17 severely affected pregnancies, but 1 patient with a titer of 1:8 had a grossly hydropic fetus at 23 weeks' gestation.⁶¹ Some authors recommend further testing of the fetus if a critical titer of 8 is attained and paternal red cell typing is Kell-positive.⁷⁶ In a case series of women with anti-c isoimmunization, a titer of 32 or greater was invariably associated with severe fetal or neonatal disease.⁷⁸

The imperfect predictive value of serologic tests has led to the development of functional cellular assays that measure the ability of maternal antibodies to cause red cell destruction, thus providing better noninvasive differentiation of pregnancies at increased risk of fetal anemia. In these assays, RBCs sensitized with maternal antibodies are incubated with effector cells carrying Fcγ receptors, such as lymphocytes or monocytes, to measure cellular interaction, such as binding, phagocytosis, or cytotoxic lysis.⁷⁹ Some authors have reported on the superiority of the monocyte monolayer assay, the chemiluminescence test, and the antibody-dependent cell-mediated cytotoxicity assay, compared to serologic tests, in predicting severity of HDFN. However, these tests are complex, difficult to standardize, and are not widely used in the United States.

FETAL BLOOD SAMPLING

Fetal blood sampling (also called *percutaneous umbilical blood sampling* or *cordocentesis*) allows direct measurement of blood indices to specifically evaluate the degree of severity of fetal hemolytic disease as early as 17 to 18 weeks' gestation.⁸⁰ Indications for fetal blood sampling in alloimmunized pregnancies include fetal blood typing, confirmation of severe fetal anemia suspected based on elevated peak middle cerebral artery Doppler velocities, or ultrasonographic evidence of early or frank hydrops. Historically, fetal blood samples were obtained when amniocentesis results returned with ΔOD_{450} (change in optical density at 450 nm) measurements in Liley zone 3 or in the "intrauterine death zone" in the Queenan graph.^{76,81,82} The procedure is performed under local anesthesia. A 20- to 22-gauge spinal needle is inserted into the umbilical vein at the level of cord insertion into the placenta under ultrasonographic guidance. Specimens of fetal blood are obtained for direct measurement of complete blood count, reticulocyte count, red cell antigen phenotyping, DAT, bilirubin, blood gases, and lactate to assess acid-base status. Blood should be available for immediate IUT when the procedure is being performed for suspected severe fetal anemia. Complications of fetal blood sampling include fetal loss, with procedure-related rates ranging from 0 to 4.9 percent, umbilical cord bleeding, chorioamnionitis, and significant risk of FMH with anamnestic maternal sensitization or the formation of additional alloantibodies.^{83,84}

AMNIOTIC FLUID SPECTROPHOTOMETRY

Amniotic fluid spectrophotometry has been used for the last half century using bilirubin as an indicator to measure fetal hemolysis. Although briefly reviewed here for historical perspective, this method has now largely been replaced by noninvasive fetal monitoring techniques.^{76,85,86} Elevations of ΔOD_{450} by spectrophotometry reflect the concentration of amniotic fluid bilirubin, which is derived from the fetus.⁸¹ The original Liley chart, from 27 weeks to term, defined three zones: readings in zone 3, the upper zone, indicate severe fetal disease with hydrops or impending fetal death; readings in zone 1, the lowest zone, indicate mild or no hemolytic disease with a 10 percent risk of needing a postnatal exchange transfusion; and readings in zone 2 indicate moderate disease. The Liley chart was later modified by Queenan to include data from 14 to 40 weeks gestation and had 4 zones, with the lowest zone representing unaffected fetuses and the highest zone associated with increased risk of intrauterine death.⁸¹

ULTRASONOGRAPHY

Ultrasonography is noninvasive, can be performed serially, and can be combined with other diagnostic studies to assess the fetal condition, estimate the need for further aggressive management, and obtain a biophysical profile of the fetus to determine fetal well-being. As hydrops develops in the anemic fetus, a consistent pattern may be noted on ultrasonography. Polyhydramnios appears first, followed by placental enlargement, hepatomegaly, pericardial effusion, ascites, scalp edema, and pleural effusions in succession. Nevertheless, in the absence of overt hydrops, ultrasonographic parameters, such as intrahepatic and extrahepatic vein diameters, abdominal and head circumference, head-to-abdominal-circumference ratio, intraperitoneal volume, splenic size, and liver length have not been reliable in distinguishing mild from severe fetal anemia.⁸²

In addition to traditional ultrasonography, measurement of fetal cerebral blood flow has become an extremely valuable technique in assessing fetal anemia. Decreased viscosity of the blood and increased cardiovascular output in the anemic fetus lead to a hyperdynamic circulation; hypoxia further increases blood flow velocity. Values greater than 1.5 multiples of the median for gestational age highly correlate with moderate or severe fetal anemia (Fig. 55-3).⁸⁶ Doppler measurement of peak velocity of systolic blood flow in the middle cerebral artery is more sensitive and accurate for detecting severe fetal anemia than measurement of amniotic fluid ΔOD_{450} .⁸⁵ Measurements may be initiated as early as 18 weeks of gestation and repeated at 1- to 2-week intervals until 35 weeks' gestation. After 38 weeks, a higher false-positive rate in the detection of fetal anemia necessitates amniocentesis for ΔOD_{450} and fetal lung maturity testing if elevated levels are noted.⁷⁶

THERAPY

ANTENATAL MANAGEMENT

Intrauterine Transfusion

Prior to the institution of IUTs, many severely affected fetuses died *in utero* or soon after birth. IUT corrects fetal anemia and reduce the risk of congestive heart failure and hydrops fetalis. Fetal bilirubin is cleared very efficiently by the placenta and the mother, so bilirubin removal is not necessary until after birth. Percutaneous intraperitoneal fetal transfusion, pioneered by Liley in the 1960s,⁵ has been largely replaced by ultrasound-guided direct intravascular transfusion into the umbilical vein.^{80,87} The intravascular technique circumvents the problem of erratic and often poor absorption of RBCs from the peritoneal cavity in such fetuses. However, intraperitoneal transfusions may be necessary when intravascular access is difficult, as in early pregnancy when the umbilical vessels are narrow or later when increased fetal size prevents access to the umbilical cord.^{88,89} The first fetal blood sampling with transfusion ideally is performed before hydrops develops. Transfusions are given at fetal hematocrit levels of 25 to 30 percent or less, or if the fetal hemoglobin is 4 to 6 standard deviations below the mean for gestational age. Generally, the hematocrit drops by 1 to 2 percent per day in the transfused hydropic fetus. The fall in hematocrit is rapid in fetuses with severe hemolytic disease, often necessitating a second transfusion within 7 to 14 days. The interval between subsequent transfusions varies, but may be 21 to 28 days. The nonhydropic fetus can tolerate rapid RBC infusions of 5 to 7 mL/min because of the capacitance of the placenta. The hydropic fetus requires slower transfusion rates and can tolerate only smaller, more frequent transfusions. Very low pretransfusion fetal hematocrit levels, rapid large increases in posttransfusion hematocrit level, and increases in umbilical venous pressure during IUTs are associated with fetal death after transfusion.^{90,91}

A

B

Figure 55–3. Peak velocity of systolic blood flow in the middle cerebral artery can be measured by ultrasound (**A**) and compared to multiples of the median (MoMs) for the prediction of fetal anemia (**B**). (*A*, reproduced with permission from Dukler D, Oepkes D, Seaward G, et al., Noninvasive tests to predict fetal anemia: a study comparing Doppler and ultrasound parameters. *Am J Obstet Gynecol* 2003 May;188(5):1310–1314. *B*, reproduced with permission from Moise KJ Jr, Management of rhesus alloimmunization in pregnancy, *Obstet Gynecol* 2002 Sep;100(3):600–11.)

RBCs for IUT are typically crossmatch compatible with the mother's plasma and negative for any identified antibody; they should also be irradiated and leukoreduced.^{92,93} Many centers do not use RBCs heterozygous for sickle hemoglobin to prevent sickling in the fetus at low oxygen tension although direct evidence of its benefit is lacking, and 5 to 7 days old to maximize circulatory half-life. Obtaining RBCs from a rare donor registry may be required in cases of unusual or combination antibodies. In this circumstance, frozen, deglycerolized RBCs may be the only available product. Some centers use maternal RBCs for IUTs, supporting serial maternal donations with iron and folate therapy.⁹⁴ RBC transfusion is calculated to increase the fetal hematocrit to between 40 and 45 percent. The RBCs are often washed free of additive solutions, and packed to a hematocrit of 70 to 85 percent in a volume calculation based on estimated fetal placental blood volume, fetal hematocrit, and hematocrit of donor RBCs. Various normograms and formulas for the calculation of donor blood volume have been published.^{95,96} If the hematocrit of the donor unit is approximately 75 percent, multiplying the estimated fetal weight in grams (estimated by ultrasonography) by a factor of 0.02 provides a fairly accurate estimate of the volume of RBCs to be transfused to achieve a fetal hematocrit increment of 10 percent.⁹⁷

Van Kamp and colleagues estimated procedure-related complication rates of 2.9 percent in the absence of hydrops and 3.9 percent in the presence of hydrops in a cohort study of 254 fetuses treated with 740 IUTs in a single center.⁹⁸ The most common problem was transient fetal heart rate abnormalities, which occurred in 8 percent of procedures. The procedure-related pregnancy loss rate was calculated to be 1.6 percent per procedure. Fetal distress during or after the procedure may result in emergency cesarean section. Cord accidents such as hemorrhage from the puncture site or rupture of the cord are rare. Additional alloantibodies may develop in already alloimmunized women undergoing IUT; in one study, 25 percent (53 of 212) of “responder” women treated with IUT formed new alloantibodies, 53 percent of which were directed against non-Rh and -K antigens.⁹⁹

Delivery

The decision regarding the appropriate time to deliver the baby is based on gestational age, fetal weight and lung maturity, fetal response to the IUTs, ease of performing the transfusions, and antenatal ultrasonography and Doppler studies for fetal anemia. Transfusions usually are provided up to 35 weeks so as to prolong gestation safely until the risks of preterm birth and its attendant complications are minimized, with delivery once adequate lung maturity has occurred.⁷⁶

Other Therapies

In women with severe alloimmunization and with fetal losses or hydrops very early in pregnancy, a variety of methods have been used to suppress the antibody response and prolong survival of the fetus until IUT becomes technically feasible. Use of intravenous immunoglobulin (IVIG), serial plasmapheresis, or plasmapheresis combined with IVIG have been successful in some cases.^{89,100,101} IVIG may cause nonspecific Fc blockade of the fetal reticuloendothelial system.

POSTNATAL MANAGEMENT

Neonatal Monitoring

A sample of cord blood should be collected from all newborns at the time of delivery. However, specific testing of cord blood samples is performed only if the mother is Rh-negative, if the maternal serum contains red cell alloantibodies of potential clinical significance, or if the neonate develops signs of hemolytic disease. Tests should include ABO and Rh typing and a DAT. Many birth hospitals routinely test cord blood for the infant's blood type and DAT if the mother is O Rh-positive in order to predict which infants are at increased risk of hyperbilirubinemia. In severe Rh alloimmunization, high titers of maternal antibody may block Rh-antigenic sites on the neonatal red cells, leading to false-negative Rh typing. Antepartum RhIg given to the mother may cause a weakly positive DAT result in the infant at birth. Contamination of the cord blood sample with Wharton jelly during collection can also result in a false-positive DAT result. Although the DAT usually is positive in all forms of alloimmune HDFN, the test cannot predict reliably the degree of clinical severity.^{102,103} This is especially true for cases resulting from ABO sensitization. When fetomaternal ABO incompatibility is present, the presence of maternally derived IgG anti-A or anti-B in the infant's serum may be demonstrated by the IAT to support the diagnosis of ABO hemolytic disease. On the other hand, it is important to bear in mind that hemolysis in ABO-incompatible, DAT-negative infants may result from hematologic causes other than alloimmunization or from red cell membrane defects (Chap. 46).¹⁰⁴ Elution of maternal antibody from the infant's red cells, followed by tests to determine the specificity of the antibody in the eluate, may be useful, particularly when several antibodies are present in the maternal serum or when the maternal antibody screen is negative.⁵⁷ Infants who received IUTs may have mild or moderate anemia with little reticulocytosis. Because most of their circulating red cells are transfused antigen-negative cells, the DAT may be negative, but the IAT will be strongly positive.

Figure 55-4. Alloimmune hemolytic disease of the newborn. Blood films. **A.** Infant with ABO blood group alloimmune hemolytic anemia. Note the high prevalence of spherocytes and the large polychromatophilic cells, indicative of reticulocytosis. **B.** Infant with Rh blood group alloimmune hemolytic anemia. Note spherocytes, reticulocytes, and the nucleated red cells. The intense erythroblastosis is characteristic of Rh blood group alloimmune hemolytic anemia and is less prominent in ABO blood group alloimmune hemolytic anemia. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

Cord blood hemoglobin and indirect bilirubin determinations are useful in determining disease severity. Most infants with cord hemoglobin levels within the age-adjusted normal range do not require exchange transfusion. Usually, a cord hemoglobin level less than 11 g/dL in a term newborn and/or a cord-indirect bilirubin level greater than 4.5 to 5 mg/dL indicate severe hemolysis and often warrant early exchange transfusion. Early exchange transfusion also may be indicated if the rate of rise of bilirubin, measured every 4 to 6 hours, exceeds 0.5 mg/dL per hour. The reticulocyte count usually is greater than 6 percent and may approach 30 to 40 percent in severe Rh disease. The blood film in Rh disease is characterized by increased nucleated RBCs, polychromasia, and anisocytosis. Alternatively, the blood film in ABO HDN is marked by microspherocytes (Fig. 55-4). Severely affected infants may also have thrombocytopenia. Low reticulocyte counts disproportionate to the low hematocrit may be noted in Kell-mediated HDN. Severely affected infants may have hypoglycemia, secondary to hyperinsulinemia. Arterial blood gas analysis may reveal metabolic acidosis and/or respiratory decompensation, and hypoalbuminemia is often present.

Immediate Postnatal Management

Results of antenatal monitoring and obstetric interventions during pregnancy and the history of the outcome of previous pregnancies allow the neonatal team to anticipate the needs of the infant born with hemolytic disease. In infants with severe hemolytic disease without the benefit of IUTs, severe anemia and hydrops are the immediate life-threatening concerns and often are accompanied by perinatal asphyxia, surfactant deficiency, hypoglycemia, acidosis, and thrombocytopenia. Exchange transfusions and phototherapy are the mainstays of treatment.

Resuscitation and stabilization of hydropic infants is challenging. Endotracheal intubation and positive-pressure ventilation with oxygen is usually necessary. Drainage of pleural effusions and ascites may be required to facilitate gas exchange. Metabolic acidosis and hypoglycemia require correction. A partial exchange transfusion may initially be performed using packed red cells to improve hemoglobin levels and oxygenation. A double-volume exchange transfusion is considered only after the initial stabilization.

In a study of 191 infants born alive after IUTs between 1988 and 1999, the hematocrit at birth ranged from 13 to 51 percent.¹⁰⁵ Endotracheal ventilation was required more often in babies who had been

severely hydropic *in utero*, but the requirements for exchange transfusion or simple transfusion did not differ between babies who had been hydropic *in utero* and those without evidence of hydrops. Although some centers report no difference in the frequency of exchange transfusions in babies who have had IUTs compared with babies who have not had IUTs,^{105,106} other centers report that infants who received multiple IUTs are usually born closer to term and often require less phototherapy and fewer exchange transfusions in the neonatal period.^{25,107} Nonetheless, many infants with severe HDFN require additional RBC transfusions for severe and prolonged hyporegenerative anemia secondary to suppression of fetal erythropoiesis.^{21,22,106} Approximately three-quarters of term and near-term infants who had received IUT for Rh HDFN required transfusion within 6 months of age, compared with 26 percent of infants with Rh HDFN who had not received an IUT.¹⁰⁶ Thus, careful monitoring of the baby and the baby's lab values are necessary not only during the initial hospital course but also after hospital discharge.

Exchange Transfusion

Exchange transfusion corrects anemia, removes bilirubin and free maternal antibody in the plasma, and replaces the infant's blood with antigen-negative RBCs that should have normal *in vivo* survival. Neonatal exchange transfusions can be performed by a continuous technique (simultaneous withdrawal and replacement) or discontinuous technique (alternating withdrawal and replacement). Regardless of the technique, the kinetics of exchange are very similar. A double-blood-volume exchange replaces approximately 85 percent of the infant's blood volume with antigen-negative RBCs; however, the amount of bilirubin or maternal alloantibody removed by exchange transfusion is significantly less (25 to 45 percent) reflecting the equilibrating tissue-bound plasma pool. Infusion of albumin prior to the exchange transfusion may help bilirubin binding, thus increasing the amount of bilirubin removed. Equilibration of extravascular and intravascular bilirubin, and continued breakdown of red cells by persisting maternal antibodies, result in a rebound of bilirubin following initial exchange transfusion, sometimes requiring repeated exchange transfusions in severe hemolytic disease.

The ideal volume for an exchange transfusion is twice the infant's blood volume. There is little benefit achieved by exceeding two blood volumes because the efficiency of exchange transfusion declines exponentially as the procedure continues. The volume needed for

double-volume exchange depends on the total blood volume (TBV) recognizing differences in term and preterm infants:

- Double-blood-volume exchange volume (term) = 85 mL/kg \times 2, or 170 mL/kg
- Double-blood-volume exchange volume (preterm) = 100 mL/kg \times 2, or 200 mL/kg

To perform the exchange transfusion, aliquots of the reconstituted whole blood product are administered while equal amounts of the infant's blood are withdrawn. Careful attention not to exceed 2 mL/kg per minute (continuous) or 5 mL/kg at a time over 3 to 10 minutes (discontinuous technique) is required to prevent rapid fluctuations in arterial and intracranial pressure.¹⁰⁸

The indications for "early" exchange transfusions performed within the first 12 hours of life have remained essentially unchanged over the last 45 years, with minor modifications. Cord hemoglobin levels equal to or less than 11 g/dL, cord bilirubin levels equal to or greater than 5.5 mg/dL, and rapidly rising total serum bilirubin (TSB) equal to or greater than 0.5 mg/dL per hour despite phototherapy are commonly used criteria for early exchange transfusions. Early exchange transfusion has the advantage of replacing sensitized RBCs with normal RBCs, thereby removing not only bilirubin but also the source of future bilirubin. Because bilirubin is distributed in the extracellular fluids, efficiency is enhanced by removing sensitized cells early in the process. Newborns that have been treated with serial IUTs until term often do not require exchange transfusions; however, late anemia is common because of IUT-induced erythropoietic suppression, which may last for many weeks after delivery.¹⁰⁹

"Late" exchange transfusions are performed when serum bilirubin levels threaten to exceed approximately 20 to 22 mg/dL in term infants. The American Academy of Pediatrics (AAP) Subcommittee on Hyperbilirubinemia provided revised guidelines for exchange transfusion in infants 35 or more weeks' gestation.¹¹⁰ In view of the fact that bilirubin levels rise steadily from birth and peak at approximately 72 to 96 hours of age, exchange transfusion should be considered if serum bilirubin levels reach 15 mg/dL in an infant of 35 weeks' gestation or 17 mg/dL in an infant of 38 weeks' gestation despite intensive phototherapy. Immediate exchange transfusion is recommended in infants showing signs of acute bilirubin encephalopathy, even if bilirubin levels are falling.¹¹⁰ Conjugated or direct bilirubin values are not subtracted from total bilirubin levels when considering levels for exchange transfusions. Exchange transfusions are performed at lower bilirubin levels in premature infants, particularly those with hypoxemia, acidosis, and hypothermia, but little data are available to guide intervention in these infants. In infants with birth weights of at least 1500 g, exchange transfusions usually are performed at TSB of 13 to 16 mg/dL but may be considered even at levels as low as 8 to 9 mg/dL in sick babies of 24 weeks' gestation.¹¹¹ The bilirubin-to-albumin ratio (mg/dL:g/dL), considered to be a surrogate measure of free bilirubin, may provide additional data in determining the need for exchange transfusion in both term and preterm neonates.¹¹²

Blood components chosen for the exchange transfusion should be ABO and Rh compatible (Rh-negative in Rh HDN), negative for offending antibody(ies), and crossmatch compatible with maternal serum. In the case of ABO HDN, O RBCs should be chosen for exchange out of concern that the more developed A or B antigens on any transfused adult donor RBCs may more avidly bind maternal anti-A or anti-B and may result in hemolysis. Either reconstituted whole blood (WB) (e.g., RBCs plus fresh-frozen plasma [FFP]) or stored WB if available can be used for neonatal exchange transfusions. The RBCs are reconstituted with AB or compatible plasma to a final hematocrit of 50 to 60 percent. Fresh (<7 days) RBCs should be used. When fresh RBC units are

unavailable, some centers wash the RBCs and transfuse as soon as possible after washing to avoid hyperkalemia. Additionally, the RBC units should be leukoreduced, gamma irradiated, and sickle-negative.¹¹³

Potential complications of exchange transfusion include hypocalcemia, hyperglycemia, hypoglycemia, thrombocytopenia, dilutional coagulopathy, neutropenia, disseminated intravascular coagulation, umbilical venous and/or arterial thrombosis, necrotizing enterocolitis, and infection. Thrombocytopenia and hypocalcemia are reported to be the most common complications (incidence ranging from 29 to 47 percent).^{114,115} Thrombocytopenia results from a dilutional effect of replacing platelet rich neonatal WB with platelet-deficient reconstituted WB. Infants who may be thrombocytopenic from severe HDFN or other comorbidities should be monitored closely after an exchange transfusion as they may require platelet transfusion. Hypocalcemia occurs as a result of the citrate load infused, which an immature neonatal liver has difficulties metabolizing. In anticipation of hypocalcemia, ionized calcium levels should be monitored throughout the exchange transfusion procedure, and intravenous calcium replacement may be needed in sick preterm infants. Furthermore, attempts should be made to correct conditions that may potentiate the symptoms of hypocalcemia such as alkalosis, hypothermia, hypomagnesemia, and hyperkalemia.¹¹⁶

In a retrospective review of exchange transfusions performed in two neonatal intensive care units between 1981 and 1995, the risk of death or permanent serious sequelae was reported to be as high as 12 percent in sick infants, compared with less than 1 percent in healthy infants. Adverse outcomes were more frequent in exchanges done on preterm infants younger than 32 weeks, infants with other significant comorbidities, and when umbilical catheters were used rather than other means of central venous access.¹¹⁷ Another center reported no increase in the number of complications and no exchange transfusion-related deaths over a 21-year period, even though there was a decline in the frequency of exchange transfusions performed over the years.¹¹⁵ Careful clinical judgment is required to balance the potential risk of adverse events from exchange transfusion with the risk of bilirubin encephalopathy in neonates who are premature, sick, or both.

Phototherapy

Phototherapy is the mainstay of treatment for unconjugated hyperbilirubinemia; the objective of treatment is preventing bilirubin neurotoxicity. Exposure of bilirubin to light results in structural and configurational isomerization of bilirubin to less toxic and less lipophilic products that are excreted efficiently without hepatic conjugation. The effectiveness of phototherapy is influenced by the wavelength and irradiance of light, the surface area of exposed skin, and the duration of exposure. Intensive phototherapy involves the use of high levels of irradiance ($\geq 30 \mu\text{W}/\text{cm}^2$) in the 430- to 490-nm band, delivered to as much of the infant's surface area as possible. Intensive phototherapy effectively reduces bilirubin levels and decreases the need for exchange transfusions for hyperbilirubinemia in ABO and Rh HDN.^{118,119} Early and intensive phototherapy should be initiated in infants with moderate or severe hemolysis or in infants with rapidly rising bilirubin levels ($>0.5 \text{ mg/dL}$ per hour). In full-term infants (at least 38 weeks' gestation) with HDFN, intensive phototherapy should be initiated if TSB levels are 5 mg/dL or greater at birth, 10 mg/dL at 24 hours after birth, or approximately 13 to 15 mg/dL at 48 to 72 hours after birth.¹¹⁰ Phototherapy is recommended at lower levels for preterm or sick infants. Therapy often is initiated at TSB less than 5 mg/dL in preterm infants with HDFN so as to avoid potentially risky exchange transfusions.^{110,111}

Other Therapies

A number of small studies have reported on the successful administration of high-dose IVIG as an adjuvant treatment to standard therapy

for HDN as way to prevent the need for exchange transfusions.¹⁰⁹ The decreased bilirubin levels in infants treated with IVIG is attributed to reduction in hemolysis secondary to blockade of mononuclear phagocyte Fc receptors. A Cochrane meta-analysis of the three largest studies demonstrated that IVIG administration (0.5 to 1.0 g/kg) may prevent exchange transfusion for many term infants with HDN, which contributed to an AAP published recommendation that IVIG be considered in Rh HDN when TSB continues to rise despite aggressive phototherapy or when the TSB is within 2 to 3 mg/dL of the exchange level.¹¹⁰ However, a prospective randomized control trial showed that prophylactic IVIG (0.75 g/kg) did not decrease the duration of phototherapy, maximum bilirubin levels, need for RBC transfusion or for exchange transfusion in Rh HDN.¹²⁰ Although, the majority of the infants included in this study were treated with IUT, IVIG was not effective at reducing the need for exchange transfusion in either the group treated with IUTs or those who were not. Thus, there is no universal approach to the use of IVIG in patients with HDN; it seems justified as a temporizing measure to exchange transfusion in neonates with severe HDN unmodified by IUT or neonates with HDN where a previous sibling had suffered from severe disease requiring exchange transfusion.¹⁰⁹

Recombinant human erythropoietin (rHuEPO) given subcutaneously at a dose of 200 to 400 U/kg given three times weekly for 2 weeks is sometimes administered to infants in an effort to reduce or prevent transfusion for late-onset anemia from HDN. Some studies show its use to decrease the need for postnatal transfusions in infants with late hyporegenerative anemia of Rh HDN and in neonates with Kell HDN.^{21,121,122} In one study of 103 patients with Rh HDN, administration of 200 U/kg of rHuEPO, three times per week for 6 weeks, reduced the number of RBC transfusions to a mean of 1.5, and 55 percent of patients did not require any transfusions.¹²¹ rHuEPO is more effective in decreasing future transfusion needs in neonates that never received IUTs suggesting that IUTs may decrease the neonatal response to rHuEPO.¹²³ Despite encouraging reports in relatively small numbers of neonates, it remains unclear whether rHuEPO, or the longer-acting analogue darbepoetin, offer a distinct clinical benefit in regard to decreasing donor exposures or improvement of morbidity and/or mortality in this population. rHuEPO has been shown to lessen neurologic sequelae in term infants with hypoxic ischemic encephalopathy, therefore it may have a role as a potential treatment for perinatal brain injury in the future.¹²⁴

● OUTCOME

Perinatal survival rates greater than 90 percent have been achieved with IUT in nonhydropic fetuses with severe HDFN.^{98,105} The overall survival rate for hydropic fetuses is lower (78 to 89 percent) despite IUTs.^{105,107} An 11-year study (from 1988 to 1999) which examined 80 fetuses with immune-mediated hydrops reported a survival rate for fetuses with mild hydrops of 98 percent, and an intrauterine reversal of hydrops in 88 percent of the fetuses. The outcome in severe fetal hydrops was poor, with reversal of hydrops in 39 percent of cases, and a survival rate of 26 percent for fetuses with persistent hydrops.¹⁰⁵ This study underscores the importance of early diagnosis and treatment of fetal anemia, before hydrops develops. Implementation of a nationwide first trimester screening program for red cell antibodies in the Netherlands in 1998 was associated with increased referrals for suspected fetal anemia, more timely referrals and an increase in perinatal survival in Kell HDFN from 61 to 100 percent.⁵⁹

The neurodevelopmental outcome for infants saved by IUTs has generally been good, with almost 90 percent of survivors being free of disability, even when they have been profoundly anemic *in utero*.^{25,107} The LOTUS study evaluated 291 children at a median age of 8.2 years (range: 2 to 17 years) to determine the incidence and risk factors for

neurodevelopmental impairment in children with HDFN treated with IUT. The overall incidence of neurodevelopmental impairment was 4.8 percent with severe developmental delay seen in 3.1 percent of children. Cerebral palsy was detected in 2.1 percent and bilateral deafness in 1 percent of the children. Severe hydrops was identified as a strong predictor for neurodevelopmental impairment.¹²⁵

It is estimated that kernicterus, secondary to bilirubin encephalopathy, is associated with at least 10 percent mortality and 70 percent long-term morbidity.¹²⁶ Although the preponderance of kernicterus cases occur in infants with bilirubin levels higher than 20 mg/dL, it has been shown that when treated promptly with phototherapy or exchange transfusion, peak bilirubin levels in the range of 25.0 and 29.9 mg/dL were not associated with adverse neurodevelopmental outcomes in term or near-term infants.^{126,127} However, there was an adverse association with IQ among infants with a positive DAT and a TSB level equal to or greater than 25 mg/dL, supporting the AAP recommendations to initiate treatment at lower bilirubin levels for jaundiced infants if they have a positive DAT.^{27,110,127}

● PREVENTION

Transfusion of blood phenotypically matched for D and for Kell antigens has been advocated for all premenopausal women to prevent primary RBC alloimmunization.^{7,13} RhIg prophylaxis is very effective when administered to women exposed to RhD-positive RBCs either from pregnancy or from transfusion; however, once alloimmunization has occurred, RhIg is not effective for preventing or reducing the severity of HDFN. Unlike RhD, there are no commercially available immune globulin products for prevention of alloimmunization to minor RBC antigens (including non-D Rh antigens). If a nonpregnant woman is found to have a RBC alloantibody, counseling should be provided regarding the potential effects of the antibody on future pregnancies. Interventions which can be applied but are seldom offered to prevent HDFN in high risk maternal-paternal pairs include: artificial insemination with sperm from an antigen-negative donor; pre-implantation genetic diagnosis selecting for antigen-negative embryos; and surrogate pregnancy.¹²⁸

Rh IMMUNOGLOBULIN

Use of RhIg is the standard of care for the prevention of maternal D immunization. Postpartum administration of RhIg to all nonsensitized Rh-negative women who deliver an Rh-positive infant decreases the incidence of Rh isoimmunization from 12 percent to approximately 2 percent. Further reduction in the incidence of Rh-isoimmunization (to 0.1 percent) has been achieved by antepartum RhIg prophylaxis at 28 weeks' gestation. This is the current standard recommendation in the United States.¹²⁹ In the United Kingdom, routine antenatal anti-D prophylaxis can be given as two doses of anti-D immunoglobulin of 500 IU (one at 28 weeks' and one at 34 weeks' gestation), as two doses of anti-D immunoglobulin of 1000 to 1650 IU (one at 28 weeks' and one at 34 weeks' gestation), or as a single dose of 1500 IU at 28 weeks' gestation.¹³⁰ Although the efficacy of RhIg is clear, its mechanism of action is not. Some of the proposed mechanisms are accelerated clearance and destruction of D-positive red cells from the circulation, antibody-mediated immune suppression, and the production of immunomodulatory cytokines.⁵¹

RhIg is prepared from plasma pools of screened, sensitized human donors; the plasma is tested using polymerase chain reaction (PCR) and serologic methods for all known transfusion transmitted organisms. Several steps are taken to further inactivate potential infectious organisms, including solvent-detergent treatment, ion exchange chromatography, and nanofiltration. There are at least four formulations of RhIg,

including two preparations that may be administered intravenously.¹³¹ A 300 mcg (1500 IU) dose of RhIg affords protection against a fetomaternal transfusion of 15 mL of Rh-positive RBCs or 30 mL of Rh-positive WB. However, FMH in excess of 30 mL may occur in women without predisposing risk factors.^{42,43} The blood of all Rh-negative nonimmunized women should be tested for FMH approximately 1 hour after delivery of an Rh-positive baby.^{57,129} During the antenatal period, testing is indicated after 20 weeks' gestation if clinical circumstances suggest the possibility of excessive transplacental hemorrhage (e.g., abdominal trauma or abruptio placentae). Screening for FMH can be performed by the rosette test, which detects as little as 2.5 mL of WB. If the rosette test result is positive, the number of fetal red cells in the maternal circulation is quantified more accurately by the Kleihauer-Betke test, which is based on the resistance of fetal hemoglobin to acid elution, unlike adult hemoglobin (Fig. 55-5).¹³² False-positive results can be obtained in maternal conditions associated with increased fetal hemoglobin, such as hereditary persistence of fetal hemoglobin, sickle cell disease, or sickle cell trait. Flow cytometric methods are used in some laboratories for both screening and quantification of fetal red cells.

RhIg should be administered as soon as possible, within 72 hours of delivery of an Rh-positive baby. RhIg is thought to be ineffective once alloimmunization to RhD antigen has occurred. RhIg is also indicated following pregnancy termination, miscarriage, amniocentesis, chorionic villus sampling, or other manipulation during pregnancy. A smaller 50-mcg dose is adequate if pregnancy is terminated at less than 12 weeks' gestation.¹²⁹ If therapeutic or spontaneous abortion occurs after the first trimester, the standard 300-mcg dose is recommended.¹²⁹ If a woman was exposed to more than 30 mL of D-positive blood, the dose of RhIg should be calculated to cover the volume of D-positive cells to prevent immunization (20 mcg of RhIg for 1 mL of D+ RBCs or 2 mL of WB).^{57,131,133} Despite the efficacy of RhIg, RhD alloimmunization occurs despite recommended prophylaxis in 0.1 percent of pregnancies, but many cases of preventable Rh alloimmunization continue to occur because of failure to seek medical care or because of failure to implement immunoprophylaxis protocols.

Figure 55-5. Kleihauer-Betke test. Maternal red blood cells appear as pale "ghost cells," whereas fetal red blood cells containing hemoglobin F are resistant to acid denaturation. Crenated red cells (arrows) are an artifact of the drying in preparation of the slide. (Reproduced from Lazarchick J, *American Society of Hematology Image bank* 2011-2370.)

CONCLUSIONS

HDFN is a clinically significant problem that may potentially affect any pregnancy. Although a number of strategies are in place to prevent RhD HDFN, few options exist to prevent the development of non-D HDFN. Researchers continue to investigate strategies to prevent primary maternal RBC alloimmunization to RhD and to non-D antigens, as well as strategies to mitigate the dangers of existing maternal RBC alloantibodies. Over the past decade, the ability to identify pregnancies/fetuses "at risk" because of maternal RBC alloimmunization has significantly improved. In particular, the use of noninvasive investigations, such as evaluation of fetal RBC antigen zygosity by circulating cell free fetal DNA testing and the evaluation of fetal anemia by middle cerebral artery Doppler ultrasonography, have advanced the care of fetuses at risk for HDFN. Through the continued combined efforts of maternal-fetal medicine specialists, hematologists, transfusion medicine physicians, radiologists, neonatologists, and researchers, in combination with advancements in basic science research involving alloimmunization, the care for infants at risk for HDFN, and their mothers, will likely continue to improve in the years to come.

CHAPTER 56

HYPERSPLENISM AND HYPOSPLENISM

Jaime Caro and Srikanth Nagalla

SUMMARY

The spleen culls aged and abnormal cells from the blood; removes intraerythrocytic inclusions through a process called *pitting*; sequesters approximately one-third of the normal intravascular platelet pool; removes bacteria, foreign particles, and tumor cells from the blood; and by virtue of the T and B lymphocytes and macrophages in the white pulp, plays a role in immune surveillance and antibody formation. Splenomegaly can occur as a result of vascular engorgement or cellular infiltration, and it is frequently associated with a combination of neutropenia, thrombocytopenia, and anemia. Hypersplenism is defined as one or more blood cytopenias in the setting of splenomegaly. Hypersplenism can occur with moderate or minimal splenic enlargement as a result of exaggerated removal of physically abnormal (e.g., as in hereditary spherocytosis) or antibody-coated blood cells (e.g., as in autoimmune hemolytic anemia). The presence of splenomegaly in a patient with blood cytopenias is useful to narrow the cause of the cytopenias, although the cause of the blood cytopenias may not be solely or principally as a result of hypersplenism (e.g., as in hairy cell leukemia). Thrombocytopenia in the setting of cirrhosis and splenomegaly is the result of pooling in the enlarged spleen and a relative decrease in thrombopoietin. The role of the spleen in the anemia and neutropenia associated with cirrhosis with splenomegaly is poorly understood, but a relative reduction in erythropoietin levels and decreased marrow myeloid progenitor cells have been proposed. Splenectomy has been used in cases of severe thrombocytopenia requiring chronic platelet transfusions or leading to bleeding. Thrombopoietin receptor agonists are another option in the management of thrombocytopenia, and nonpeptide thrombopoietin receptor agonists have been shown to increase platelet counts in patients with thrombocytopenia associated with hepatitis C virus–related cirrhosis and splenomegaly. Splenectomy may be justified in the case of massive splenomegaly, infarction, or disabling symptoms of pain and compression of neighboring structures. In some circumstances, benefit can be achieved by partial destruction of splenic tissue by embolization using intraarterial infusion of gel microparticles. Hyposplenism can result from agenesis, atrophy, surgical removal of the spleen, or reduction of splenic function by disease. In the latter case, disturbance in splenic circulation disrupts the specific architecture required for the spleen's culling, phagocytic, and pitting functions. Hyposplenism may be suspected by alterations in red cell morphology, such as target cells or acanthocytes; red cell inclusions, specifically Howell-Jolly and Pappenheimer bodies (siderotic granules highlighted with polychrome stains); pitted red cells; or an elevated

platelet count. The presence of pitted red cells identified by interference-contrast microscopy is perhaps the most specific blood finding of hyposplenism, followed by Howell-Jolly bodies. The most devastating consequence of hyposplenism is sudden overwhelming sepsis by encapsulated bacteria. Immunizations and prophylactic antibiotics can decrease the risk of sepsis. A high awareness and prompt antibiotic treatment of febrile episodes are warranted.

● HYPERSPLENISM

HISTORY

The spleen has intrigued physicians and philosophers since ancient times¹ and has been assigned mysterious powers, but its association with destruction of blood cells was not elucidated until the turn of the 20th century. The exaggerated and unfounded worry about somatic complaints often reflected by the sense of pain in the spleen (left hypochondrium) led to the term *hypochondriac*. In 1899, Chauffard proposed that increased splenic activity causes hemolysis.² This proposal provided the impetus for therapeutic splenectomy, which was performed first in 1910 by Sutherland and Burghard³ in a patient with splenic anemia (hereditary spherocytosis) and subsequently by Kaznelson⁴ in a patient with essential thrombocytopenia (immune thrombocytopenic purpura) in 1916.

DEFINITION

Hypersplenism is defined as blood cytopenias in the setting of splenomegaly. This is usually accompanied by hyperplasia of the affected cell precursors in the marrow. There can be a disproportional decrease in the blood platelets, white cells, and red cells, with thrombocytopenia and leukopenia being disproportionate to the anemia as a result of hypersplenism. Splenomegaly can occur as a result of elevated splenic venous pressures and vascular congestion, histiophagocytic hyperplasia, other cellular infiltration, or because of the inability of physically abnormal red cells, such as sickle cells in infants and children (prior to infarction atrophy), or antibody-coated cells, such as in autoimmune hemolytic anemia, to navigate the circulation or avoid engulfment by the mononuclear phagocyte population of the normal spleen.⁵ The blood cytopenias are not generally corrected by relief of portal hypertension.^{6,7}

ONTOGENY

The embryonic spleen appears in the first trimester of gestation as a multiply lobulated condensation of highly vascular mesenchymal cell aggregates interposed in the arterial circulation in the dorsal mesogastrium. The full scope of the molecular basis of splenic organogenesis is not known. The *HOX11* and *WT1* genes are essential for its formation, and defects in their expression result in hyposplenia or asplenia.^{8–10}

The lymphoid compartment, the white pulp, begins its development early in the second trimester of gestation, when mature T cells, principally CD4+ lymphocytes, form a continuous layer along the length of the vessels (periarteriolar sheaths). CD8+ cells reside in splenic cords and a specialized subset of $\gamma\delta$ T cells home to the pulp (Chap. 6). Immunoglobulin (Ig) D+ and IgG+ B lymphocytes form localized deposits, the primary lymph follicles. Secondary follicles arise later in life, after exposure to immunologic stimuli, and have a distinctive structure that includes a germinal center, a mantle zone, and a marginal zone containing IgM+ and IgG+ B lymphocytes.^{11,12}

Acronyms and Abbreviations: G-CSF, granulocyte colony-stimulating factor; Ig, immunoglobulin; TPO-RA, thrombopoietin-receptor agonist.

STRUCTURE AND FUNCTIONAL ORGANIZATION

The normal adult spleen weighs 135 ± 30 g and has a blood flow that is approximately 5 percent of the cardiac output. In addition to serving as a filter, the spleen plays a role in innate and adaptive immunity and protection against microbes. The spleen is composed of white pulp, a marginal zone, and red pulp. The spleen's principal structure is organized around an arborizing array of arterioles that branch and narrow until they terminate in either (1) the stroma of cords, forming the open circulation, or (2) the sinusoids, forming the closed circulation of the spleen (Chap. 6). The cordal elements include histiocytes, antigen-presenting cells, pericytes, fibroblasts, and other cells necessary to maintain the discontinuous basal lamina that separates cords from sinusoid lumen.¹³ Lymphatic tissue is inconspicuous and found in T-cell-rich zones in the periarteriolar lymphoid sheaths.

The arterial vascular tree, which is lined by conventional CD31+ and CD34+ endothelial cells, branches into arterioles that terminate abruptly in caps of cordal macrophages. Blood cells must pass clusters of macrophages to enter the sinusoids.¹³ The sinusoids, the origin of the venous circulation, are lined by specialized cells having combined phagocytic and endothelial activities and a distinctive CD31+, CD34-, CD68+, CD8+ phenotype. A principal function of the spleen is to serve as a filter, removing aged or defective red cells and foreign particles by macrophages. This function is facilitated by diverting part of the splenic blood supply into the red pulp, where the blood slowly percolates through the nonendothelialized mesh studded with macrophages. Abnormal or senescent red cells and pathogens undergo phagocytosis by the macrophages. The blood then reenters the circulation through narrow slits, measuring 1 to 3 μm , in the endothelium of the venous sinuses. The bulk of the blood is rapidly channeled through vessels that link the arterioles with the venous sinuses. This blood is not filtered or modified.¹⁴

Approximately one-third of platelets are normally sequestered in the spleen.¹⁵ In many animals, such as dogs and horses, the red pulp is a reservoir for red cells, and splenic contraction provides the red cell volume with a functionally important boost.¹⁶ In humans, however, the splenic capsule is poorly contractile, and the spleen does not store red cells to any significant degree.¹⁷ Although margination of neutrophils occurs in the spleen, it is unclear to what degree it occurs in that site.¹⁸ Granulocyte colony-stimulating factor (G-CSF) administered to cirrhotic patients caused a rise in the blood neutrophil count; thereafter, indium scans of the spleen were performed, which did not show significant uptake by white cells.¹⁹

The slow transit of blood through the red pulp permits macrophages to recognize and destroy antibody- or complement-coated red cells and microorganisms, and to ingest poorly deformable red cells or particles retained mechanically by the narrow exit slits in the venous sinuses. The white pulp plays a major role in adaptive immunity. The spleen is involved in the phagocytosis of encapsulated bacteria including *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*.

PATHOPHYSIOLOGY

Filtration and elimination of defective cells occur notably in hereditary abnormalities of the red cell membranes, such as spherocytosis, elliptocytosis, or stomatocytosis, or with antibody-coated red cells, neutrophils, or platelets. In these circumstances, cytopenias of varying severity may ensue. The spleen not only removes antibody-coated cells, but also produces antibodies, especially antiplatelet antibodies.²⁰ Thus, the benefits of splenectomy in immune thrombocytopenic purpura is a result of both the decreased production of antiplatelet antibodies

as well as decreased clearance by macrophages of antibody-coated platelets through the Fc recognition function of its large macrophage population.

Splenomegaly increases the proportion of blood channeled through the red pulp.^{13,21} Spleen enlargement may result from expansion of the red pulp compartment with increased blood flow; extramedullary hematopoiesis, notable in primary myelofibrosis; hyperplasia or neoplasia involving the white pulp, such as in infectious mononucleosis or lymphoma; or histiophagocytic hyperplasia.

The increased size of the filtering bed is more pronounced when the splenomegaly is caused by congestion as in portal hypertension than when it is caused by cellular infiltration as in leukemias, extramedullary hematopoiesis, or amyloidosis. Even in space-occupying disorders such as Gaucher disease and primary myelofibrosis, splenomegaly may be associated with hypersplenic sequestration of normal cells.

Splenomegaly increases the vascular surface area and thereby the margined neutrophil pool.^{18,19} Platelets are especially likely to be sequestered in an enlarged spleen. However, sequestered white cells and platelets survive in the spleen and may be available when increased demand requires neutrophils or platelets, although their release may be slow.²²

Some patients with anemia and splenomegaly have a relative erythropoietin deficiency.²³ In one study of cirrhotic patients, 30 percent had a blunted erythropoietin response to anemia.²⁴ Dilution of red cells in an expanded plasma volume is another commonly cited cause of a decreased blood hemoglobin concentration,²⁵ although some studies do not demonstrate hemodilution.²⁶ Iron deficiency associated with chronic blood loss, folic acid and vitamin B₁₂ deficiency, and increased red cell destruction are frequently investigated, although rarely found in patients with liver disease.²⁷ Red cells are destroyed prematurely in the red pulp in the setting of splenomegaly, but only rarely does this explain the anemia.²⁸

Varying amounts of erythrophagocytosis are present, reflecting the normal culling of senescent red cells. Erythrophagocytosis increases as a result of hemolytic anemia and viral infections, and in alloimmunized transfusion recipients. Macrophages within the sinusoids contain red cell fragments. When the process is pronounced, the littoral cells become cuboidal and stand out on the basement membrane ("hobnails"). Sickle cell disease and red cell membrane disorders such as hereditary spherocytosis lead to sequestration of the poorly deformed red cells in the cords but little extrasinusoidal erythrophagocytosis is seen, in contrast to immune hemolytic anemia where macrophage erythrophagocytosis is prominent.¹³

The increased blood flow from an enlarged spleen expands the splenic and portal veins. A significant increase in portal venous pressure may occur when hepatic vessel compliance is decreased, as in cirrhosis or myelofibrosis. This process initiates a vicious cycle in which portal hypertension contributes to splenomegaly, organ enlargement leads to increased arterial blood flow, which, in turn, increases portal pressure.

Table 56-1 lists causes of splenomegaly, and Table 56-2 lists causes of massive splenic enlargement.

CLINICAL FEATURES

Slight to moderate enlargement of the spleen usually does not produce local symptoms. Even massive splenomegaly can be well tolerated if it develops gradually. However, not infrequently, the patient complains of a sagging feeling or other types of abdominal discomfort, early satiety from gastric encroachment, and trouble sleeping on one side. Pleuritic pain in the left upper quadrant or referred to the left shoulder may accompany splenic infarcts, which may be recurrent.

In children with sickle cell anemia or patients with malaria, the spleen may become acutely enlarged and painful as a result of a sudden increase in red cell pooling and sequestration. These sequestration crises are characterized by sudden aggravation of the anemia. Splenic

--	---	--

rupture is uncommon but can occur spontaneously with most causes of splenic enlargement or after blunt trauma. Rupture related to the splenic enlargement in infectious mononucleosis is a classic example.

The volume of an enlarged spleen is difficult to assess by palpation and percussion. Children and thin patients with low diaphragms may have a palpable spleen tip without splenomegaly.²⁹ Generally, a palpable spleen signifies splenomegaly and is measured by the number of centimeters the spleen extends below the left costal margin. Splenic size is most accurately measured with abdominal ultrasound (Fig. 56-1) or

computed tomographic scans (Fig. 56-2). Magnetic resonance imaging is used primarily to identify cysts, abscesses, and infarcts.³⁰

SPLENOPTOSIS

A wandering spleen (spleno-ptosis) is an uncommon phenomenon in which the spleen hangs by a long pedicle of mesentery. The condition may present in three ways: (1) an asymptomatic mass in the pelvis, (2) intermittent abdominal pain with or without gastrointestinal symptoms, or, less often, (3) an acute abdomen resulting from torsion.

TABLE 56–2. Causes of Massive Splenomegaly

1. Myeloproliferative disorders
 - a. Primary myelofibrosis
 - b. Chronic myeloid leukemia
2. Lymphomas

4. Extramedullary hematopoiesis
 - a. Thalassemia major
5. Infiltrative
 - a. Gaucher disease

The diagnosis of splenoptosis may be made coincidentally on an imaging study.³¹ The condition may be accompanied by signs of hypersplenism, hyposplenism, and often, when developing slowly, is initially mistaken for a pelvic or lower abdominal tumor.

LABORATORY FEATURES

The characteristic features of hypersplenism are splenomegaly, blood cytopenias, and absence of other causes of cytopenias (e.g., anemia caused by bleeding). The blood cell morphology usually is normal, although a few spherocytes may result from metabolic conditioning of red cells during repeated slow transits through the expanded red pulp. Tests, such as epinephrine mobilization, were used in the past to try to distinguish sequestration from ineffective cellular production, but results are difficult to interpret as epinephrine also releases platelets and neutrophils from marginal pools.³²

Thrombocytopenia is a common finding in patients with hepatic cirrhosis, portal hypertension, and splenomegaly. In a retrospective study, 64 percent of patients with nonalcoholic cirrhosis had thrombocytopenia.³³ Other studies have found that approximately one-third of patients with cirrhosis develop severe thrombocytopenia or neutropenia.^{34,35} Decompensated liver disease and history of alcohol consumption are independent risk factors for hypersplenism,³⁶ but why some

patients develop marked blood cytopenias is not clear, although folate deficiency is a factor in some instances. The presence of thrombocytopenia or leukopenia in patients with chronic liver disease is associated with increased mortality.³⁷

Ultrasound-guided fine-needle biopsy of the spleen can be useful in circumstances in which the spleen holds the tissue required for diagnosis, such as splenic lymphoma. However, fine-needle aspiration is rarely a definitive diagnostic tool but can indicate monoclonality of splenic lymphocytes, which is helpful and forces further diagnostic evaluation. Aspiration cytology and core biopsy can be obtained with relative safety in experienced hands using image-guided fine needles.³⁸

The response to transfusion of blood products, especially platelets, may be significantly impaired in patients with massive splenomegaly.³⁹

THERAPY, COURSE, AND PROGNOSIS

Total Splenectomy

Splenectomy is indicated as an emergency procedure after abdominal trauma and partial rupture of the spleen. It also may be indicated when splenic size or infarcts causes sustained left upper abdominal pain or discomfort. Splenectomy has been used for the treatment of functionally significant blood cytopenias.³⁹ In such circumstances, case reports have described dramatic restoration of blood counts to normal levels within days to weeks after splenectomy; however, the only controlled trial evaluating relief of cytopenias showed no improvement.⁶ Orthotopic liver transplant corrects the cytopenias in the majority of patients with cirrhosis.⁴⁰

Hereditary spherocytosis, immune thrombocytopenic purpura, and immune hemolytic anemia are the most common indications for splenectomy. Splenectomy exerts its effect in autoimmune cytopenias by improving cell survival and also by decreasing autoantibody production. In thalassemia major, an improvement in the anemia is well described after splenectomy. In such cases, splenectomy may improve the response to transfusion. Some children with sickle cell anemia may benefit from splenectomy if repeated sequestration crises with abdominal pain occur before autosplenectomy renders the spleen atrophic.⁴¹

Splenectomy in patients with a massive spleen size (>1500 g), especially in primary myelofibrosis, is accompanied by higher morbidity and mortality than is removal of the spleen for immune blood cytopenia.⁴² Possible postoperative complications include extensive adhesions with collateral blood vessels, hepatic or portal vein thrombosis, injury to the tail of the pancreas, operative site infections, and subdiaphragmatic abscesses.

Laparoscopic splenectomy performed by experienced surgeons for suitable hematologic conditions can result in less abdominal trauma

Figure 56–1. A three-way composite of abdominal computerized tomography. **A.** Normal spleen size. **B.** Enlarged spleen. **C.** Massively enlarged spleen at the level of mid-kidney. Normally the spleen would either not be visualized or only a small lower pole would be evident at the level of the mid-kidney. (White arrow in each of the three images marks edge of splenic silhouette.) (Used with permission of Deborah Rubens, MD, The University of Rochester Medical Center.)

Figure 56-2. A two-way composite of ultrasonography examination for spleen size. **A.** Image of echo indicating normal spleen size with cranial to caudal longitudinal dimension of 10.3 cm. **B.** Image of echo indicating enlarged spleen with cranial to caudal longitudinal dimension of 16.2 cm. (White arrow in each image marks edge of splenic silhouette.) The normal spleen is usually less than 13 cm in length but the examiner has to consider other dimensions in assessing spleen size (volume). (Used with permission of Deborah Rubens, MD, The University of Rochester Medical Center.)

and pain, shorter hospital stays, and smaller abdominal scars.⁴³ An advantage of open splenectomy in hematologic conditions such as the treatment of immune thrombocytopenic purpura is the increased ease of searching assiduously for accessory spleens.

Partial Splenectomy

Partial splenectomy has been explored because it may minimize the risks of immediate postsplenectomy thrombocytosis and overwhelming sepsis that may result from a complete absence of splenic function.⁴⁴ However, the degree of thrombocytosis after splenectomy wanes to some degree with time postsplenectomy. Reduction of the splenic volume has been performed with ligation of some of the splenic arteries or the intraarterial infusion of Gelfoam particles causing embolization.⁴⁵⁻⁴⁸ These procedures induce large splenic infarcts and reduce the functional splenic mass. Arterial embolization can be performed percutaneously or intravascularly, but the patients must be observed closely for a number of days to weeks to detect signs of intraabdominal rupture of the splenic infarcts. The long-term results of embolization have been encouraging.⁴⁶⁻⁴⁸ Treatment with partial arterial embolization for recurrent thrombocytopenia in children temporarily improved the platelet count in approximately 70 percent of patients.⁴⁹

Splenic Radiation

Splenic radiation for treatment of an enlarged spleen is used sparingly. The procedure may be associated with severe cytopenias and especially thrombocytopenia (abscopal effect). It can be used in patients with an absolute contraindication to splenectomy who might benefit symptomatically from reduction of a massively enlarged spleen.⁵⁰

Liver Transplantation

Thrombopoietin synthesis and secretion are impaired in liver failure and this is corrected after liver transplantation.^{51,52} However, thrombocytopenia may not be corrected after liver transplant if the splenomegaly persists.

Thrombopoietin Receptor Agonists

After thrombopoietin was cloned^{53,54} several thrombopoietin mimetic drugs have been developed and tested. A phase II study reported that

the oral thrombopoietin-receptor agonist (TPO-RA) eltrombopag increases platelet counts in patients with thrombocytopenia as a result of hepatitis C virus–related cirrhosis.⁵⁵ A phase III study done in cirrhotic patients who received eltrombopag for 2 weeks prior to elective procedures had to be terminated prematurely because of the increased incidence of portal vein thrombosis in the treatment group compared to the placebo group. Although 72 percent of the eltrombopag patients avoided platelet transfusions compared to 19 percent of the placebo group patients, there was no significant difference in the incidence of major bleeding.⁵⁶ A small study using the TPO-RA romiplostim administered subcutaneously in cirrhotic patients demonstrated the usefulness of the drug in reducing platelet transfusions in preparation for an elective surgical procedure.⁵⁷

Erythropoietin and Granulocyte Colony-Stimulating Factor

There are minimal data to support the use of erythropoietic or myeloid growth factors in patients with splenomegaly and blood cytopenias. Patients with cirrhosis who have inappropriately low serum erythropoietin levels may benefit from treatment with exogenous erythropoietin; however, it may increase spleen size. Two reports documented the use of erythropoietin before and after liver transplantation to amplify marrow erythropoiesis in patients who refused blood transfusions for religious reasons.^{58,59} These reports demonstrated that liver transplantation in the setting of advanced cirrhosis can be successfully undertaken without the use of blood products.

A rise in the neutrophil count after G-CSF administration was described in patients with cirrhosis and leukopenia. The mean absolute neutrophil count increased from $1300 \pm 200/\mu\text{L}$ to $4100 \pm 200/\mu\text{L}$ following subcutaneous administration of G-CSF for 7 days.¹⁹ However, the clinical benefit of such treatment is not clear.

● HYPOSPLENISM

DEFINITION

Hyposplenism is the designation for decreased splenic function resulting from diseases that impair function or from the absence of splenic tissue because of agenesis, atrophy (e.g., autoinfarction of sickle cell

TABLE 56-3. Conditions Associated with Hyposplenism

MISCELLANEOUS
Surgical splenectomy
Splenic irradiation
Sickle hemoglobinopathies
Congenital agenesis
Thrombosis of splenic artery or vein
Normal infants
GASTROINTESTINAL AND HEPATIC DISEASES
Celiac disease
Dermatitis herpetiformis
Inflammatory bowel disease
Cirrhosis
AUTOIMMUNE DISORDERS
Systemic lupus erythematosus
Rheumatoid arthritis
Vasculitis
Glomerulonephritis
Hashimoto thyroiditis
Sarcoidosis
HEMATOLOGIC AND NEOPLASTIC DISORDERS
Graft versus host disease
Essential thrombocytosis
Chronic lymphocytic leukemia
Non-Hodgkin lymphoma
Hodgkin lymphoma
Amyloidosis
Advanced breast cancer
Hemangiosarcoma
SEPSIS/INFECTIOUS DISEASES
Malaria
Disseminated meningococemia

disease), or splenectomy. Splenic hypofunction may be associated with a normal spleen size. In some cases, engorgement of ingested materials impairs the macrophage-dependent functions of the spleen. Impaired filtering function may cause a mild thrombocytosis. Functional or anatomical asplenia, especially after surgical removal in infants and children, increases the risk of an overwhelming bacterial infection. Table 56-3 lists conditions associated with hyposplenism.

CLINICAL FEATURES

The normal neonate and the elderly adult may have findings suggestive of impaired splenic function.⁶⁰ These include the presence of Howell-Jolly bodies and erythrocyte pits (see “Laboratory Features” below). However, the clinical significance of functional hyposplenism is uncertain.⁶¹⁻⁶³

Sickle cell anemia and surgical splenectomy are the most common causes of hyposplenism. In sickle cell anemia, hyposplenism may

be functional in young children with enlarged spleens and disordered circulation and may be the result of atrophy after repeated infarcts have destroyed splenic tissue in older children and adults. Although the presence of an enlarged spleen usually suggests hypersplenism, spleen size is not a reliable index of splenic function. Complete splenic replacement by cysts, neoplastic tissue, or amyloid is an example of hyposplenic splenomegaly.⁶⁴ Acute sequestration crises in children with sickle hemoglobinopathies, and occasionally in patients with malaria, may clog the red cell pulp with cellular debris and lead to hyposplenism.^{65,66}

Congenital asplenia may be found in infants with situs inversus and other developmental abnormalities.³⁸ Autoimmune disorders, such as glomerulonephritis,⁶⁷ systemic lupus erythematosus,^{68,69} and rheumatoid arthritis,⁷⁰ are occasionally associated with laboratory evidence and clinical manifestations (overwhelming sepsis with encapsulated bacteria) of functional hyposplenism. Hyposplenism also occurs in chronic graft-versus-host disease,^{71,72} sarcoidosis,⁷³ alcoholic liver cirrhosis,^{74,75} hepatic amyloidosis,^{76,77} celiac disease,^{78,79} and inflammatory bowel disease.^{80,81} The mechanisms for these associations are unknown.

Splenic replacement by neoplastic cells, as in lymphomas and leukemias, usually does not cause hyper- or hyposplenism. Splenic irradiation⁸² and vascular obstruction⁸³ may also lead to functional hyposplenism.

Overwhelming Sepsis

Absence of a functional spleen may lead to life-threatening infections by removal of an efficient filtering bed in which opsonized organisms are engulfed and destroyed by splenic macrophages. The responsible organism is typically an encapsulated bacteria, such as *S. pneumoniae*, *N. meningitidis*, or *H. influenzae*. Unrestrained *in vivo* proliferation of such microorganisms may cause fatal septicemia.⁸⁴⁻⁸⁶ The risk is greatest among infants whose general immunologic system has not matured enough to counteract bacterial infections, although the risk is present regardless of the patient's age. For this reason, splenectomy in children should be deferred until 5 years of age, if possible. The risk of sepsis varies depending on the reason for the splenectomy. In a child with an underlying immune disorder, such as Wiskott-Aldrich syndrome, the risk is very high. The infectious risk is higher in children with thalassemia than in those with hereditary spherocytosis and lowest in those with splenectomy for splenic trauma. The risk is reduced by the use of pneumococcal and *H. influenzae* vaccines prior to splenectomy and prophylactic penicillin therapy.⁸⁷

Because the spleen is a major component of the mononuclear phagocyte system and has substantial lymphatic tissue in the white pulp, hyposplenism or splenectomy can also reduce antibody synthesis that may be beneficial in the management of autoimmune disorders.

LABORATORY FEATURES

The reduction or absence of normal splenic function is accompanied by a slight to moderate increase in white cell and platelet counts. Howell-Jolly bodies, target cells, Pappenheimer (siderotic) bodies, and occasional acanthocytes often are present in the blood film, but the finding of pitted erythrocytes in wet preparations is the most specific of all the blood findings.⁸⁸ Target cells reflecting an increased red cell surface⁸⁹ are almost always present in the asplenic state, but only 1 in 100 to 1 in 1000 red cells is affected. A sensitive indication of hyposplenism is the appearance of pits or pocks on the cell surface.⁹⁰ These pits consist of submembranous vacuoles and can be seen only in wet preparations of red cells using direct interference-contrast microscopy. Intracellular vesiculation containing hemoglobin is a normal occurrence during aging of the red cell in the circulation. This process is intensified in the last half of the erythrocyte life span and leads to a decreased mean cell

Figure 56-3. Blood film of splenectomized patient showing three red cells with Howell-Jolly bodies (nuclear remnants). Note also the cluster of acanthocytes and scattered spherocanthocytes and the target cell. These changes are also indicative of postsplenectomy red cell changes. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

hemoglobin level as the vesicles are removed (pitted) by the spleen. In asplenic individuals the vesicles are more numerous and enlarge, forming vacuoles that are evident by interference-phase microscopy.⁸⁸ This finding is the most specific evidence of hyposplenism, followed by the presence of DNA inclusions in circulating red cells (Howell-Jolly bodies; Fig. 56-3).

Oxidative drugs may produce Heinz bodies even in normal individuals, but the spleen effectively removes these red cell inclusions, as well as Pappenheimer bodies. Heinz bodies may be observed in supravital stained blood films after splenectomy. Nucleated red cells rarely are seen on blood films after splenectomy, except in patients with hemolytic disorders in whom the number of nucleated red cells may increase dramatically. The reticulocyte count remains within normal values, and the life span of red cells is unchanged as other organs take up the function of removing senescent erythrocytes.

Technetium-99m sulfur-colloid particles are used for spleen scanning, a reliable measure of the capacity of the spleen to clear particulate matter from the bloodstream.⁹¹

THERAPY, COURSE, AND PROGNOSIS

Vaccination against *H. influenzae*, *N. meningitidis*, and *S. pneumoniae* is recommended in previously unvaccinated individuals prior to splenectomy.⁹² Prophylactic immunization has significantly reduced, but not eliminated, the risk of overwhelming infection.^{87,93-95} Oral penicillin or a macrolide antibiotic as prophylaxis for asplenic patients is recommended based on publicized guidelines despite problems with compliance and resistance.^{96,97} Physicians should advise all asplenic patients that any febrile episode (>38°C) should be considered an emergency requiring immediate medical attention. A febrile asplenic patient must have blood and urine cultures drawn, followed by antibiotic treatment. Patients should be given written information about asplenia and carry a card or medical alert bracelet to alert health professionals of the risk of overwhelming infection.^{96,97} Dental work, especially tooth extraction, should be preceded by broad-spectrum antibiotics, such as amoxicillin, if the patient is not taking prophylactic antibiotics. Patients should be educated about risks of travel, including risk of malaria infection or animal bites, which could be deadly unless promptly treated.^{96,97}

CHAPTER 57

PRIMARY AND SECONDARY ERYTHROCYTOSES

Josef T. Prchal

SUMMARY

Increased blood red cell mass can be termed either *polycythemia* or *erythrocytosis*; no clear consensus for either term has been achieved. Primary polycythemia is caused by acquired or inherited mutations causing functional changes within hematopoietic stem cells or erythroid progenitors leading to an accumulation of red cells. The most common primary polycythemia, polycythemia rubra vera, which is a clonal disorder, is discussed in Chap. 84; other primary polycythemia, such as those inherited from mutations in the erythropoietin receptor or congenital disorders of hypoxia sensing, are discussed herein. In contrast, secondary polycythemia is a result of either an appropriate or inappropriate increase in the red cell mass, most often as a result of augmented levels of erythropoietin; these polycythemia can also be either acquired or hereditary. Although the clinical presentations of primary and secondary polycythemia may be similar, distinguishing amongst them is important for accurate diagnoses and proper management.

For example, those secondary polycythemic states that represent an appropriate physiologic compensation to tissue hypoxia, should not be treated by phlebotomies. An occasional patient may experience hyperviscosity symptoms and may benefit from isovolemic reduction of hematocrit. Inappropriate polycythemia is caused by erythropoietin-secreting tumors, self-administration of erythropoiesis-stimulating agents, including androgens, inherited disorders of hypoxia sensing, or, rarely, some endocrine disorders (described in Chap. 38). Correction of hypoxia, discontinuation of erythropoiesis-stimulating agents or resection of erythropoietin-secreting tumors will typically correct the associated polycythemia.

DEFINITION AND HISTORY

The term *polycythemia*, denoting an increased amount of blood cells, has traditionally been applied to those conditions in which the mass of erythrocytes is increased. *Erythrocytosis* is an alternative term that has also been applied to circumstances in which the increased red cell

mass is the singular finding, distinguishing it from polycythemia vera in which, classically, there is an increase in red cells, granulocytes, and platelets. Although this usage has much to recommend it, no consensus about terminology has been reached and the term *polycythemia* is used interchangeably with erythrocytosis by many physicians. In some instances, time-honored terms such as post-renal transplant erythrocytosis or Chuvash polycythemia will be used. A classification of the polycythemia is presented in Chap. 34 in Table 34-2.

PRIMARY POLYCYTHEMIAS

Polycythemia vera (Chap. 84) and *primary familial and congenital polycythemia* (PFCP) are primary polycythemic disorders, which have erythroid progenitors that are hypersensitive to erythropoietin.¹⁻³ These are caused by somatic (polycythemia vera) or germline (PFCP) mutations wherein erythroid progenitors are intrinsically hyperproliferative by mechanisms other than the presence of increased levels of erythropoietin and have, as shown by *in vitro* assays, an augmented response to erythropoietin. Some congenital polycythemia, as best described in Chuvash polycythemia, have erythroid progenitors that are hypersensitive to erythropoietin, but also may have normal or even increased erythropoietin levels despite the increased red cell volume.^{4,5} Thus, some of these rare inherited polycythemia share features of both primary and secondary polycythemia.⁶

SECONDARY POLYCYTHEMIAS/ ERYTHROCYTOSES

The term *secondary polycythemia*, more appropriately *secondary erythrocytosis*, which refers to those conditions in which only erythrocytes are increased in number and volume, describes a group of disorders characterized by an increased red cell mass brought about by enhanced stimulation of red cell production by circulating physiologic mediators, most commonly erythropoietin. Secondary polycythemia may be subdivided into *appropriate polycythemia*, that is, responding normally to tissue hypoxia such as in pulmonary disease, Eisenmenger complex, high-altitude polycythemia and hemoglobins with increased affinity for oxygen (Chaps. 49 and 50), and *inappropriate polycythemia* in which erythropoiesis is being stimulated by the aberrant production of erythropoietin, as in erythropoietin-secreting tumors, by high levels of insulin growth factor 1, by cobalt toxicity, by self-administration of erythropoietin, androgens, or adrenocorticotropic hormone, or by other stimulators of erythropoiesis (as in post-renal transplant erythrocytosis).⁷

In his important monograph on barometric pressure published in 1878, Paul Bert showed that physiologic impairment observed at high altitude was caused by a reduction in the oxygen content of the air.⁸ A few years earlier, his friend and mentor, Dennis Jourdanet, had observed an increase in the number of red corpuscles in blood of the highlanders in Mexico,⁹ and Bert recognized that such an increase would tend to ameliorate the effect of atmospheric hypoxia. However, neither Bert nor Jourdanet suspected a cause-and-effect relationship. It was not until 1890, when Viault¹⁰ observed a prompt increase in the number of his own red corpuscles after having traveled from Lima, Peru, at sea level, to Morococha, at 4570 m (15,000 ft) above sea level, that altitude erythrocytosis was accepted as a compensatory adaptation to hypoxia.¹¹ At about the same time, it was observed that many patients with cyanosis were also polycythemic. Both *cardiacos negros*,¹² with severe pulmonary failure and arterial oxygen desaturation, and children with *morbus caeruleus*, or right-to-left shunt through a congenital cardiac malformation, were found to have increased red cell counts.¹³ Mechanical or neurogenic hypoventilation as a cause of cyanosis and polycythemia was

Acronyms and Abbreviations: BFU-E, burst-forming unit–erythroid; 2,3-BPG, 2,3-bisphosphoglycerate; COPD, chronic obstructive pulmonary disease; *EGLN1*, a gene encoding for PHD2; *EPAS1*, a gene encoding for HIF-2 α ; EPOR, erythropoietin receptor (protein); HCP, hematopoietic cell phosphatase; HIF, hypoxia-inducible factor; HUMARA, human androgen-receptor gene; JAK, Janus-type tyrosine kinase; OSA, obstructive sleep apnea; PAI-1, plasminogen activator inhibitor; PFCP, primary familial and congenital polycythemia; PHD2, proline hydroxylase 2; STAT, signal transducer and activator of transcription; VEGF, vascular endothelial growth factor; VHL, von Hippel-Lindau syndrome.

first popularized in 1956 with the classic description of the pickwickian syndrome by Burwell and colleagues.¹⁴ Polycythemia associated with carboxyhemoglobinemia resulting in hypoxemia as a result of smoking and with tissue hypoxia because of inherited abnormal hemoglobins with high-affinity oxygen binding to hemoglobin was recognized subsequently (Chaps. 49 and 50).¹⁵ Erythrocytosis associated with abnormal hemoglobins with an increased affinity for oxygen also represents an appropriate response to hypoxia first noted by Charache and colleagues¹⁵ in 1966 when they described hemoglobin Chesapeake.

Relative erythrocytosis is the term used to depict enhanced red cell count or blood hemoglobin values resulting from reduced plasma volume, not increased red cell mass. The disorder is, therefore, not a true polycythemia and is designated *apparent*, *spurious*, or *relative polycythemia*. The cause of the reduced plasma volume and hence relative erythrocytosis is often known, that is, diuretic use, dehydration from excessive sweating, etc. However, there are some patients with mild erythrocytosis in which neither the cause nor the clinical significance is clear. In 1905, Gaisbock reported that a number of hypertensive patients had plethora and an elevated red cell count but no splenomegaly, a condition he termed *polycythemia hypertonica*, sometimes called *Gaisbock syndrome*.¹⁶ In 1952, direct measurement of blood volume in patients with polycythemia led Lawrence and Berlin to identify a subgroup of patients with a normal red cell volume but reduced plasma volume. Although some members of this group were hypertensive, the authors were more impressed by their tense and anxious behavior and coined the term *stress polycythemia*.¹⁷

● EPIDEMIOLOGY

PRIMARY POLYCYTHEMIAS

Primary Familial and Congenital Polycythemia

This autosomal dominant disorder (designated PFCP) is uncommon but more prevalent than is generally appreciated, as many affected subjects are initially misdiagnosed as having polycythemia vera. Its prevalence is similar to congenital polycythemias because of high oxygen-affinity hemoglobin mutants, and far more common than 2,3-bisphosphoglycerate (2,3-BPG) deficiency.¹⁸

SECONDARY POLYCYTHEMIAS

Pulmonary Disease with Hypoxia

In one study of 2524 patients with severe chronic obstructive pulmonary disease (COPD), 8.4 percent had a hematocrit higher than 55 percent. In this study, hematocrit was an independent predictor of longer survival, decreased hospital admission rate, and decreased cumulative duration of hospitalization.¹⁹ In another, smaller study of 309 subjects with COPD and chronic respiratory failure, 67 percent had normal hemoglobin levels, 20 percent had anemia, and 18 percent had polycythemia.²⁰

Obstructive Sleep Apnea

Although the evidence is largely anecdotal,²¹ secondary polycythemia is a widely recognized complication of longstanding obstructive sleep apnea (OSA), being found in 5 to 10 percent of those with nocturnal apnea and hypopnea.²² The published studies remain controversial; in a study of 263 patients (189 men and 74 women), patients with severe sleep apnea had significantly higher hematocrit values than did patients with mild to moderate sleep apnea or nonapneic controls ($p < 0.01$).²³ In contrast, in other studies, there were no significant differences in hemoglobin levels or hematocrit between subjects with and without

OSA.^{24,25} The total number of hours of hypoxia per day may dictate whether the stimulus to erythropoietin production is sufficient to cause erythrocytosis.

Polycythemia Associated with Smoking

Smoking clearly increases hematocrit in COPD compared to controls of comparable pulmonary function. In a study of 2524 patients with severe COPD, 10.2 percent of patients reported as current smokers had significantly higher hematocrit values than did ex-smokers or nonsmokers of comparable pulmonary impairment of both genders, with $p < 0.02$.²⁰

Even young male smokers without pulmonary impairment have higher hematocrits. In one study, 1169 subjects (age range: 18.6 to 22.8 years; mean: 19.4 years) were recruited and 25 percent were smokers. Predictably, carboxyhemoglobin was much higher in smokers than in nonsmokers ($r = 0.958$, $p < 0.001$) and both hemoglobin and hematocrits were also markedly higher in smokers (hemoglobin ($p = 0.001$), hematocrit ($p = 0.004$)).²⁶

High Oxygen Affinity and Hemoglobins

These disorders are reviewed in detail in Chaps. 49 and 50. High oxygen-affinity hemoglobins deliver less oxygen to tissues, which is appropriately compensated by increased erythropoiesis and a higher steady-state hemoglobin concentration. While considered rare, high oxygen affinity has been found, according to one report, in approximately 20 percent of 70 unrelated subjects with otherwise idiopathic polycythemia.²⁷

Polycythemia of Eisenmenger Complex

Eisenmenger syndrome, characterized by elevated pulmonary vascular resistance and right-to-left shunting of blood, is usually accompanied by polycythemia.²⁸ Most patients with the syndrome survive for 20 to 30 years.

Polycythemia of Endocrine Disorders and from Iatrogenic or Self-Administration of Androgens

Erythrocytosis has been reported in Cushing syndrome,²⁹ primary aldosteronism,³⁰ and Bartter syndrome (Chap. 38).³¹

In a prospective trial of testosterone use in older men, erythrocytosis (defined as a hematocrit greater than 50 or 52 percent) was three times more likely to occur in the testosterone-treated group compared to placebo.³² (Refer to Chap. 38 for more details.)

Inappropriate Tissue Elaboration of Erythropoietin

The prevalence of various types of secondary polycythemia is a function of underlying causes, such as geographical location of the patient or presence of a causative neoplasm. Approximately 1 to 3 percent of all patients with pheochromocytoma or paraganglioma have erythrocytosis.³³ Rare patients with congenital erythrocytosis will develop pheochromocytoma or paraganglioma.³⁴ Uterine leiomyomas in premenopausal women are very common, estimated at 20 to 40 percent, and the occurrence of erythrocytosis ranges from 0.02 to 0.5 percent of cases.³⁵ Isolated instances of polycythemia have been attributed to myxoma of the atrium,³⁶ hamartoma of the liver,³⁷ and focal hyperplasia of the liver.³⁸ Erythrocytosis and inappropriate secretion of erythropoietin may be found in approximately 15 percent of patients with cerebellar hemangioma.^{39,40}

Self-Administration of Erythropoietin

Athletes have attempted for decades to manipulate their blood to gain a competitive advantage either by blood transfusions or erythropoietin. This evolving, but continuous, problem has been the subject of a review.⁴¹

Polycythemia of High Altitude

Elevation of red cell mass as a response to high altitude hypoxia represents an appropriate adjustment to reduced blood oxygen content and delivery. The exponentially decreasing atmospheric oxygen pressure with altitude stimulates the body to accommodate by an increase in respiratory rate and volume. Such adaptation is possible only in the short-term, because the body may not always be able to adequately enhance respiration. Polycythemia is considered to be a universal, uniform adaptation response to hypoxia that arises in normal individuals, but when it is exaggerated, in some cases it results in chronic mountain sickness with associated symptoms of fatigue, headache, and pulmonary hypertension.⁴²

Altitude above sea level should be used as an independent variable for the definition of polycythemia⁴³ and Centers for Disease Control data lists the appropriate adjustment values.⁴⁴

Post-Renal Transplant Erythrocytosis

This syndrome, defined as a persistent elevation of hematocrit at greater than 51 percent, is a relatively common condition found in approximately 5 to 10 percent of renal allograft recipients.^{45,46} Post-renal transplant erythrocytosis usually develops within 8 to 24 months after transplantation, despite persistently good function of the allograft, and resolves spontaneously within 2 years in approximately 25 percent of patients.⁴⁷ Factors that increase the likelihood of its development are lack of erythropoietin therapy prior to transplantation, a history of smoking, diabetes mellitus, renal artery stenosis, low serum ferritin levels, and normal or higher pretransplant erythropoietin levels. Post-renal transplant erythrocytosis is also more frequent in patients who are not undergoing graft rejection.

Chuvash Polycythemia

A Russian hematologist, Lydia A. Polyakova, described polycythemia in the Chuvash population (an ethnic isolate in the mid-Volga River region of Russia of Turkish descent) in the early 1960s,⁴⁸ and by 1974, 103 cases from 81 families had been described.⁴⁸ Since then, more cases have come to light; hundreds of children and adults suffer from this condition, indicating that Chuvash polycythemia is the only known

endemic congenital polycythemia in the world.⁴⁹ Outside of Chuvashia, Chuvash polycythemia has also been found sporadically in diverse ethnic and racial groups,^{50,51} and recently a high prevalence of this disorder has also been reported on the Italian island of Ischia.⁵²

ETIOLOGY AND PATHOGENESIS

PRIMARY POLYCYTHEMIAS

Primary Familial and Congenital Polycythemia

In contrast to polycythemia vera, PFCP is caused by germline rather than acquired somatic mutations. It is congenital and manifests autosomal dominant inheritance³ and, not infrequently, sporadic occurrence from *de novo* germline mutations. Like polycythemia vera (Chap. 84), it is primary in that the defect changes intrinsic responses of erythroid progenitors, and erythropoietin levels are low.

To date, 12 mutations of the erythropoietin receptor (EPOR) associated with PFCP have been described (Table 57-1). Nine of the 12 result in truncation of the EPOR cytoplasmic carboxyl terminal, and are the only mutations convincingly linked with PFCP. Such truncations lead to a loss in the negative regulatory domain of the EPOR (Chaps. 32 and 34). Three missense EPOR mutations have also been described, but these have not been linked to PFCP or any other disease phenotype (Table 57-1).

Erythropoietin-mediated activation of erythropoiesis involves several steps (also see Chap. 32). First, erythropoietin activates its receptor by inducing conformational changes of its dimers (Chap. 17). These changes lead to initiation of an erythroid-specific cascade of events. The first signal is initiated by conformation change-induced activation of Janus-type tyrosine kinase 2 (JAK2) and its phosphorylation and activation of a transcription factor, signal transducer and activator of transcription 5 (STAT5), which regulates erythroid-specific genes. This "on" signal is negated by dephosphorylation of EPOR by hematopoietic cell phosphatase (HCP), also known as SHP1, that is, the "off" signal. EPOR truncations lead to a loss of the negative regulatory domain of the EPOR, a binding site for HCP, explaining the gain-of-function properties of these EPOR mutations (Fig. 57-1).

TABLE 57-1. Summary of Erythropoietin Receptor Gene Mutations

Type of Mutation	Mutation	Structural Defect	Association with PFCP	Ref.
Deletion (7bp)	Del5985-5991	Frameshift > ter truncation	Yes	163, 192

Ter, termination codon.

Data from Kralovics R, Indrak K, Stopka T, et al. Two new EPO receptor mutations: truncated EPO receptors are most frequently associated with primary familial and congenital polycythemia. *Blood* 1997 Sep 1;90(5):2057-2061.

Figure 57-1. *Left panel:* Erythropoietin binding to a normal erythropoietin receptor (EPOR) results in interaction of a protein kinase (JAK) with the receptor. The interaction leads to phosphorylation of the receptor and initiates a cascade of signaling that ultimately results in erythroid progenitor proliferation and differentiation. This process is self-regulatory. Activated signal transduction molecules, hematopoietic cell phosphatase (HCP) binds to the C-terminal of the EPOR, which is a negative regulatory domain. This interaction dephosphorylates the receptor and turns off the signaling resulting in cessation of erythroid progenitor proliferation. *Right panel:* Patients with mutated gain-of-function *EPOR* gene lack the C-terminal portion of the receptor that contains the negative regulatory domain. Erythropoietin binds and the signal transduction pathway is activated by change of configuration of erythropoietin receptor dimer, but because there is no structure for HCP to bind on the activated EPOR dimer, the receptor is left in the activated position resulting in unbridled erythroid proliferation and an elevated red cell mass. PO4, phosphate; STAT, signal transducer and activator of transcription.

SECONDARY POLYCYTHEMIAS

The morbidity of primary polycythemia, such as polycythemia vera (Chap. 84), is largely the result of increased activated neutrophils and, perhaps, attendant pathologic platelet–endothelial interactions, whereas in secondary polycythemia it is presumably related to an increase in blood viscosity and, in part, to the resulting increased cardiac work.⁵³ In most instances, the etiology of morbidity or mortality, such as associated with congenital disorders of hypoxia sensing, is largely unknown.⁵⁴ The effect of blood viscosity on oxygen delivery is often oversimplified and the emphasis on the hematocrit alone may lead to ill-advised therapeutic interventions. In the normovolemic state, viscosity increases in a log-linear fashion as hematocrit increases, and the effect is particularly pronounced when the hematocrit rises above 50 percent. The prediction is that oxygen delivery *decreases* as hematocrit rises significantly above 50, as the greatly increased viscosity reduces blood flow, overshadowing the increased oxygen-carrying capacity of blood with a higher concentration of hemoglobin. However, polycythemia is not a normovolemic state, but is accompanied by an increase in blood volume, which, in turn, enlarges the vascular bed and decreases peripheral resistance (Chap. 34). Thus, hypervolemia can increase oxygen transport, and the optimum for oxygen transport occurs at higher hematocrit values than in normovolemic states. Consequently, despite the attendant increase in viscosity, an increase in hematocrit may generally be of benefit in appropriate secondary polycythemia. However, at some point, the high viscosity causes an increase in the work of the heart and a reduction in blood flow to most tissues and may be responsible for cerebral and cardiovascular impairment.

APPROPRIATE POLYCYTHEMIAS

High Altitude Polycythemia

Adaptive adjustments of humans living at high altitude involve a series of steps that reduce the steepness of the oxygen gradient between the atmosphere and mitochondria (Fig. 57-2).⁵⁵ The initial oxygen gradient between atmospheric and alveolar air can be reduced by an increase in respiratory rate and volume. Because dead space and water

vapor pressure are constant and acclimatized individuals do not ventilate excessively, the normal sea level gradient of about 60 torr is only reduced to approximately 40 torr at 4540 m (14,900 ft) above sea level.⁵⁵ Further reduction can be achieved, and at the top of Mount Everest, extreme hyperventilation reduces the gradient to less than 10 torr. A shift in the oxygen dissociation curve to the right, which represents decreased affinity of hemoglobin for oxygen, may be of benefit for short-term high-altitude acclimatization,⁵⁶ but its usefulness for chronic acclimatization has probably been exaggerated.⁵⁷ In the unacclimatized subject exposed acutely to high altitude, hyperventilation alkalosis leads initially to a shift of the oxygen dissociation curve to the left, representing an increased affinity of hemoglobin for oxygen, further worsening already present tissue hypoxia. The alkalosis and the hypoxia will, in turn, promote red cell synthesis of 2,3-BPG and cause the oxygen dissociation curve to shift back to a normal or even right-shifted position

Figure 57-2. The oxygen gradient from atmospheric air to the tissues in individuals living at sea level (Lima, Peru) and in Morococha, Peru, at 4540 m (14,900 ft) above sea level.

(Chap. 49). In chronic acclimatization, blood pH is slightly increased, and when this is taken into account, the dissociation curve is shifted approximately to normal.⁵⁸ It is unlikely that a shift to the right would be to the advantage of high-altitude dwellers, except as a partial compensation for respiratory alkalosis.⁵⁹ In addition, a right-shifted curve also has a decrease in oxygen loading in the alveolar capillary, minimizing any net gain in off-loading. There is a relationship between higher altitude and hemoglobin concentration response, best studied among Andean highlanders and Europeans in the United States; hemoglobin concentration is almost 10 percent higher in those Andean highlanders living at 5500 m than in those living at 4355 m. Furthermore, native Andean high-altitude dwellers have a gradual increase in their hemoglobin levels with age⁶⁰ and body weight.⁶¹ Although it has been postulated that high hemoglobin–oxygen affinity in the setting of extremely low ambient oxygen may be one such adaptive change,⁶² increased hemoglobin–oxygen affinity or increased fetal hemoglobin are not adaptive phenotypes of Tibetan or Andean highlanders.⁶³

In a subset of Andean high-altitude native dwellers, namely Quechua and Aymara Indians, polycythemia becomes excessive and often results in chronic mountain sickness with its associated constitutional symptoms and pulmonary hypertension.^{42,60} This excessive erythrocytosis, called Monge disease or chronic mountain sickness,^{42,64} is also described in Han Chinese living in Tibet⁶⁵ and occurs in whites living at high altitudes.⁶⁶

The polycythemia encountered in high-altitude dwellers is often considered to be a universal, uniform adaptation process to hypoxia that would arise in all normal individuals. In reality, there is marked variability in erythropoietin level and subsequent polycythemic response to chronic hypoxia,^{60,67} suggesting that some of these factors may be genetically determined; the same degree of hypoxia induces substantial differences in erythropoietin production in response to high altitude.^{62,68,69} Three distinct adaptations to high altitude appear to have evolved. Andean highlanders have higher oxygen saturation than Tibetans at the same altitudes.⁶² Tibetan mean resting ventilation and hypoxic ventilatory response are higher than Andean Aymaras, whereas the mean Tibetan hemoglobin concentration is below the Andean mean. High levels of nitric oxide (NO) in the exhaled breath of Tibetans may represent increased physiologic NO. This effect may improve oxygen delivery by inducing vasodilation and increasing blood flow to tissues, thus making the compensatory increase in red cell volume unnecessary.⁷⁰ Another distinct successful pattern of human adaptation in high-altitude dwellers that contrasts with both the Andean “classic” (arterial hypoxemia with polycythemia) and Tibetan (arterial hypoxemia with normal venous hemoglobin concentration) patterns evolved in Ethiopia. While Ethiopian high-altitude dwellers have hemoglobin concentrations that fall in the normal range (15.9 and 15.0 g/dL for males and females, respectively), they have a surprisingly, as-yet-unexplained high (average of 95.3 percent) oxygen saturation of hemoglobin despite their hypoxic environment (reviewed in Ref. 62). Their cerebral circulation is increased but is insensitive to hypoxia, unlike Peruvian high-altitude dwellers.⁷¹ Thus, Ethiopian highlanders maintain venous hemoglobin concentrations and arterial oxygen saturation within the ranges of sea level populations, despite the decrease in ambient oxygen tension at high altitude.⁷² Tibetans and Ethiopians have lived as mountain dwellers much longer than the Quechua or Aymara Indians,⁷³ suggesting that extreme elevation of red cell mass is a maladaptation that Tibetans avoided by evolving a more efficient, or less detrimental, compensatory mechanism than that which causes Monge disease.

With rapid advances in genomics (Chap. 11), progress has been made in identification of the molecular basis of high-altitude adaptation; most of these advances have been in our understanding of Tibetan adaptation. Several studies reported evidence for positive natural

selection in genomic regions in Tibetans; not surprisingly, most are haplotypes comprising genes that are components of hypoxia sensing that are mediated by hypoxia-inducible factors (HIFs) (described in Chap. 32). Two of these selected regions include genes that have undergone the strongest genetic selection, and are thus likely the most beneficial for Tibetan adaptation. These two regions encompass the *EPAS1* gene, encoding the α subunit of HIF-2, and the *EGLN1* gene, encoding proline hydroxylase 2 (PHD2). PHD2 is the principal negative regulator of both HIF-1 and HIF-2. Both of these haplotypes were shown to be associated with differences in hemoglobin concentration at high altitude by several independent studies.^{74–76} Intriguingly, the *EPAS1* haplotype was previously identified as having the strongest Tibetan positive selection and was found to have an unusual haplotype structure that originated by introgression of DNA from Denisovan or Denisovan-related hominins.⁷⁷ Denisovans, a sister group to the Neanderthals, branched off from the human lineage perhaps 600,000 years ago,⁷⁸ and available evidence suggests that Denisovan and Neanderthal hominins contributed to the modern *homo sapiens* admixture before their extinction, likely by interbreeding,⁷⁹ and that these hominin species provided genetic variations that helped humans adapt to new environments, such as extreme hypoxia associated with high altitude.⁷⁷ The first Tibetan adaptation gene mutation identified, which changes the encoded PHD2 protein within the selected haplotype, is a missense variant of the *EGLN1* gene, c.12C>G,⁸⁰ that is in near complete linkage disequilibrium with a previously reported missense variant, *EGLN1*:c.380G>C.⁸⁰ Both *EGLN1*:c.[12C>G; 380G>C] (PHD2^{D4E,C127S}) are in *cis*; that is, the constituting PHD2^{D4E,C127S} locus. Analysis of Tibetans and related populations suggests that 12C>G started on the 380G>C variant that is not Tibetan specific,^{80,81} that PHD2^{D4E,C127S} originated from a single individual approximately 8000 years ago,⁸¹ and that now greater than 80 percent of Tibetans carry this PHD2 variant.⁸¹ Functional assessment of homozygous PHD2^{D4E,C127S} recombinant proteins showed that the variant protein has increased hydroxylase activity under hypoxic conditions. Furthermore, native homozygous PHD2^{D4E,C127S} erythroid progenitors have blunted erythropoietic responses to hypoxia by both erythropoietin-specific and erythropoietin-independent mechanisms.⁸¹ Although this is the first identified variant that contributes to the molecular and cellular basis of Tibetan adaptation to high altitude, there are other evolutionarily selected genomic regions, and elucidation of their functional impact is, at the time of this writing, unknown.

Understanding the etiology of polycythemia of high altitude is made more complex by a study of inhabitants of the Peruvian mining community of Cerro de Pasco (altitude 4280 m) with excessive erythrocytosis (mean hematocrit: 76 percent; range: 66 to 91 percent). About half of those individuals with a hematocrit greater than 75 percent had toxic serum cobalt levels,⁸² suggesting that other erythropoiesis promoting factors such as cobalt⁸³ can augment hypoxia induction of erythropoietin, causing extreme polycythemia (Chap. 32). Most high-altitude dwellers do not have measurable levels or a history of exposure to cobalt or other heavy metals.⁸⁴

Erythrocytosis of Pulmonary Disease

Degrees of arterial hypoxia comparable to those observed in individuals at high altitudes are observed in patients with right-to-left shunting resulting from cardiac or intrapulmonary shunts or to ventilation defects, as in COPD.

Many patients with COPD with severe cyanosis are not polycythemic. This has been attributed to infections and inflammation often present in the lungs, resulting in anemia of chronic inflammation, and to an increase in plasma volume. Why some patients with lung disease and congenital heart disease develop polycythemia, while others do not, is not entirely clear.

Erythrocytosis of Eisenmenger Syndrome

Patients with right-to-left shunting (Eisenmenger syndrome) develop a degree of erythrocytosis comparable to that observed with similar degrees of desaturation at high altitudes.⁸⁵ The hematologic changes associated with this syndrome include hyperviscosity caused by erythrocytosis. Erythrocytosis is present in most patients, but excessive phlebotomy may cause microcytosis and some have attributed this effect to the exacerbation of the symptoms of hyperviscosity.⁸⁸ In view of recent understanding of physiology of HIF regulation, it may not be the microcytosis, per se, that is detrimental, but the induced iron deficiency that inhibits PHD2 and increases HIF, which then directly causes pulmonary vasoconstriction and enhanced pulmonary vascular pressure (Chaps. 32 and 34).

Obstructive Sleep Apnea-Induced Syndrome

In the colorfully named pickwickian syndrome,⁸⁶ polycythemia is characterized by its association with extreme obesity and somnolence. Today, the more widely studied OSA may not always be associated with obesity⁸⁷ but can, if severe, cause arterial hypoxemia, hypercapnia, somnolence, and secondary polycythemia.⁸⁸

Smoker's Polycythemia

Heavy smoking will result in the formation of carboxyhemoglobin, which does not transport oxygen (Chap. 50), and causes an increase in oxygen affinity of the remaining normal hemoglobin. Carboxyhemoglobin increases in relationship to the number of cigarettes or cigars smoked each day (Table 57-2). This leads to tissue hypoxia, erythropoietin production, and stimulation of red cell production.⁸⁹ Smoking may also cause a reduction in plasma volume.⁹⁰ Either augmentation of red cell mass or shrinkage of plasma volume could easily explain the rise in the hematocrit.

Polycythemia Secondary to High-Affinity Hemoglobins

Hemoglobins with certain amino acid substitutions manifest an increased affinity for oxygen, producing tissue hypoxia and compensatory erythrocytosis (Chap. 49). Mutations affecting amino acids of the $\alpha_1\beta_2$ -globin chain interface affect normal rotation within molecules and impair the rate of deoxygenation. Changes in the carboxyl terminal and penultimate amino acids also impair intramolecular motion and tend to keep molecules in a high-affinity state. Alterations in the amino acids lining the central cavity of hemoglobin destabilize the binding of 2,3-BPG in this cavity and lead to increased oxygen affinity (Chaps. 47 and 49). Finally, some heme pocket mutations interfere with deoxygenation. Most hemoglobins with a mutation involving amino acids in the

heme pocket are unstable and are associated with hemolytic anemia and cyanosis. Inheritance of these disorders is autosomal dominant. High-affinity hemoglobins result from mutations in any of three globin genes; those from α -globin gene mutations are congenital and life-long. β -Globin gene mutations are not apparent at birth but manifest after fetal to adult hemoglobin switching at approximately 6 months of life, while γ -globin gene mutations cause transient increase of hemoglobin concentration at birth lasting only about 6 months.

Polycythemia Secondary to Red Cell Enzyme Deficiencies

Deficiencies of red cell enzymes in early steps of glycolysis sometimes cause a marked decrease in the levels of 2,3-BPG (Chap. 47). Occasionally, mild polycythemia occurs in patients with methemoglobinemia as a result of cytochrome b_5 reductase (methemoglobin reductase) deficiency (Chap. 50).

The same pathophysiology as that seen in high-affinity hemoglobins is also exhibited in mutations of the *2,3-BPG mutase* gene, resulting in low 2,3-BPG. Because these mutations are very rare, with only a single family comprehensively studied,⁹¹ it is not clear if the mode of inheritance is recessive or dominant.

This condition, as well as other high-affinity hemoglobins, can only be conclusively confirmed by direct measurement of a hemoglobin dissociation curve, conveniently expressed as the partial pressure of oxygen required to saturate 50 percent of hemoglobin ($p50_{O_2}$); when equipment for this is not available, $p50$ can be estimated from pH, pO_2 and hemoglobin oxygen saturation of venous blood.^{92,93}

Chemically Induced Tissue Hypoxia

A number of chemicals have been suspected of causing histotoxic anoxia and secondary polycythemia, but the only chemical with a predictable capacity to cause erythrocytosis is cobalt.⁸³ Cobalt administration increases erythropoietin production by increasing HIFs (see Chap. 32).⁹⁴

INAPPROPRIATE POLYCYTHEMIAS

Congenital Disorders of Hypoxia Sensing

Chuvash Polycythemia Chuvash polycythemia is the only known endemic congenital polycythemia. The condition is caused by an abnormality in the oxygen-sensing pathway and causes thrombotic and hemorrhagic vascular complications that lead to early mortality; survival beyond age 65 years is uncommon.^{48,95} Inheritance is autosomal recessive, and affected patients tend to have normal blood gases, normal calculated $p50$, normal to increased erythropoietin levels, absence

TABLE 57-2. Blood Oxygen Capacity in Smokers with Polycythemia

Subject	Hemoglobin (Hgb) (g/dL)	Carboxyhemoglobin (COHb) (g/dL)	Hgb-COHb (g/dL)	Affinity Correction (g/dL)	Adjusted Hgb (g/dL)
Healthy male nonsmokers	16 (14–18)	0.16 (0.08–0.25)	15.8 (14–18)	0	16 (14–18)
Male smokers with increased Hgb concentration	20 (17–23)	2 (1–3)	18.16–21	1.5 (0.5–2.0)	16.5 (15–19)

The male smokers include 10 consecutive subjects studied with elevated hematocrit and no evidence for polycythemia vera. The Hgb available for O_2 binding in blood is the Hgb-COHb. COHb also influences the residual hemoglobin to bind oxygen more tightly, making it less accessible to tissues. A correction for this effect has been calculated and is labeled *affinity correction*. The adjusted hemoglobin indicates the blood concentrations that would be present in the subjects in the absence of excess carbon monoxide. Thus, the blood hemoglobin in this group of smokers was increased by 3.5 g/dL on the average (from 16.5 [last column] to 20 [first column]) as a result of smoking-induced carboxyhemoglobinemia.

Data from Marshall A. Lichtman, MD.

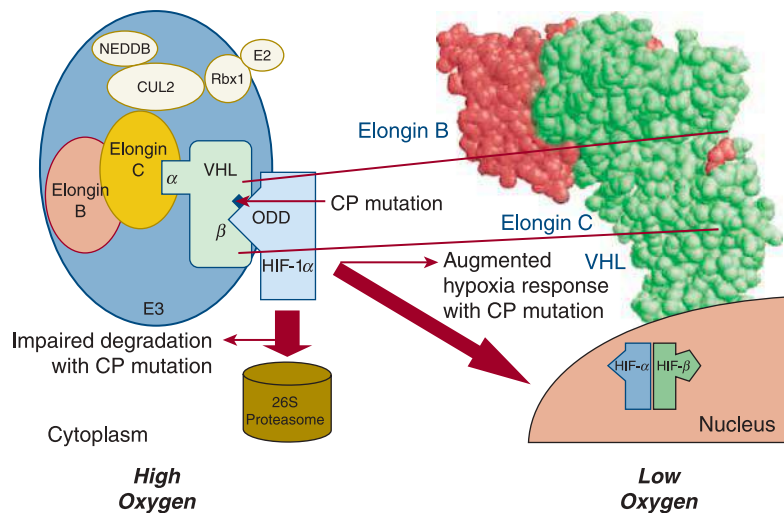

Figure 57-3. Elongins B, C, and proteins Rbx1, Cul2 E2, and NEDD 8 are interacting proteins that facilitate von Hippel-Lindau (VHL) function. Interaction of mutated VHL protein with HIF-1 α . The Chuvash VHL mutation leads to the impaired interaction with HIF-1 α , which results in impaired degradation in 26S proteasome and augmented hypoxia sensing. CP, Chuvash polycythemia.

of genetic linkage to *erythropoietin* and *EPOR* loci, and no evidence of abnormal hemoglobin.⁹⁵ In a study of five multiplex Chuvash families with Chuvash polycythemia, a homozygous mutation of the von Hippel-Lindau (*VHL*) gene (598C>T); that is, *VHL*^{R200W}, was found in all affected individuals. This mutation impairs the interaction of VHL protein (pVHL) with both HIF-1 α and HIF-2 α , thus reducing the rate of ubiquitin-mediated destruction of HIF-1 α and HIF-2 α (Chap. 32). As a result, the level of HIF-1 and HIF-2 heterodimers increases and leads to the increased expression of target genes, including the erythropoietin (*EPO*), vascular endothelial growth factor (*VEGF*), and plasminogen activator inhibitor genes (*PAI-1*), among others.^{4,5} Figure 57-3 depicts the effect of this mutation on hypoxic sensing. The role of circulating erythropoietin in the Chuvash polycythemia phenotype is indisputable. However, there must be other factors associated with the Chuvash polycythemia *VHL* mutation that contribute to the polycythemic phenotype, as the erythroid progenitors of Chuvash polycythemia patients are hypersensitive *in vitro* to extrinsic erythropoietin; the mechanism of this observation is not fully explained.^{4,5} Some, but not all, patients with other *VHL* mutations have erythropoietin hypersensitive erythroid colonies⁹⁶⁻⁹⁸; in these patients there is also increased expression of the *RUNX1* and *NFE1* genes, which can stimulate erythropoiesis.⁶

Despite increased expression of HIF-1 α , HIF-2 α , and *VEGF* in normoxia, Chuvash polycythemia patients do not display a predisposition to tumor formation. Imaging studies of 33 Chuvash polycythemia patients revealed unsuspected cerebral ischemic lesions in 45 percent, but no tumors characteristic of VHL syndrome.⁹⁹ There also, is a high prevalence of this disorder on the Italian island of Ischia.⁵² The Chuvash *VHL*^{R200W} mutation has also been described in whites in the United States and Europe, and in people of Punjabi/Bangladeshi Asian ancestry.¹⁰⁰ Some patients with congenital polycythemia have proved to be compound heterozygotes for the *VHL*^{R200W} mutation and other *VHL* mutations. Additionally, two distantly related Croatians with polycythemia are homozygous for *VHL*^{H191D}, the first example of a homozygous *VHL* germline mutation other than *VHL*^{R200W} causing polycythemia.^{51,54,101-105}

A small number of cases of congenital polycythemia that appear to have a mutation of only one *VHL* allele confound an obvious pathophysiological explanation. In a Ukrainian family, two children with polycythemia were heterozygotes for *VHL* 376G>T (D126Y), but the father with the same mutation was not polycythemic.¹⁰⁴ An English polycythemic patient was a heterozygote for *VHL* 598C>T¹⁰⁶; but the inheritance of the deletion of a *VHL* allele, or null *VHL* allele, in a *trans* position was not excluded. Subsequently, two polycythemic *VHL* heterozygous

patients were described in whom a null *VHL* allele was more rigorously excluded^{101,102}; the molecular mechanism of their polycythemic phenotype remains to be elucidated.

To address the question of whether the *VHL* 598C>T substitution occurred in a single founder or resulted from recurrent mutational events, haplotype analysis of eight highly informative single nucleotide polymorphic markers covering 340 kb spanning the *VHL* gene was performed on 101 subjects bearing the *VHL* 598C>T mutation and 447 normal unrelated individuals from Chuvash, Southeast Asian, white, Hispanic, and African American ethnic groups.⁴⁹ Polymorphism of the *VHL* locus in normal controls (having a wild *VHL* 598C allele) and subjects bearing Chuvash polycythemia *VHL* 598T were in strong linkage disequilibrium. These studies indicated that, in most individuals, the *VHL* 598C>T mutation arose in a single ancestor between 51,000 and 12,000 years ago. However, this is not the case for a Turkish polycythemic family with a *VHL* 598C>T mutation wherein the *VHL* 598C>T mutation occurred independently.¹⁰²

Chuvash polycythemia homozygotes have decreased survival because of thrombotic and hemorrhagic complications, mostly in the venous circulation,⁹⁹ and thus are under negative selection pressure. The high frequency of the mutation in some areas may be the result of random factors ("drift"), but it is also possible that propagation of the *VHL* 598C>T mutation is the result of a survival advantage for heterozygotes. Such an advantage might be related to a subtle improvement of iron metabolism, erythropoiesis, embryonic development, energy metabolism,¹⁰⁶ or some other as yet unknown effect. Indeed, heterozygotes were shown to be less likely to be anemic compared to control subjects.¹⁰⁷ Another potential protective role of a mildly augmented hypoxic response is improved protection against bacterial infections, as the hypoxia-mediated response has been reported to be essential for the bactericidal action of neutrophils.¹⁰⁸

Classic von Hippel-Lindau Syndrome VHL syndrome is an autosomal dominant genetic abnormality affecting the posttranslational control of HIF-1 α .¹⁰⁹⁻¹¹¹ The syndrome is characterized by a propensity for developing renal cell carcinomas, retinal hemangioblastomas, cerebellar and spinal hemangioblastomas, pancreatic cysts, and pheochromocytomas. The tumors result from a somatic mutation in addition to the germline mutation, that is, loss-of-heterozygosity. Polycythemia is not part of VHL syndrome but hemangioblastomas of the central nervous system, and, less commonly, pheochromocytoma and renal cancer, have been associated with polycythemia mediated by paraneoplastic erythropoietin production.¹¹¹ Other patients with VHL syndrome

Figure 57-4. von Hippel-Lindau (*VHL*) gene structure and mutation. Three exons of *VHL* genes are depicted encoding for UTR (untranslated portion of mRNA), and coding sequences (CDs). *VHL* domains β , α , β are shown. The relative number of reported *VHL* gene mutations are depicted in vertical lines. The location of the Chuvash polycythemia mutation is depicted by the diamond.

also develop acquired polycythemia.^{99,111} The *VHL* gene codes for 213 amino acids, and more than 130 germline mutations associated with classic VHL syndrome have been identified, virtually all of them 5' to the codon 200 position that is mutated in Chuvash polycythemia.¹¹² Figure 57-4 depicts the schematic effect of the Chuvash polycythemia mutation in the context of other previously found *VHL* mutations.

It is not clear why mutations of a single gene lead to these two diverse phenotypes. It has been suggested that quantitative differences in loss of activity could explain the variable phenotypes among *VHL* mutations,¹¹³ but the *VHL* gene may also have other functions, possibly as a result of interactions with other modifying factors, that can contribute to the onset of disease and that await future clarification. Another plausible explanation of polycythemia versus cancer predisposition syndrome is that almost all polycythemic subjects have germline mutations of both *VHL* alleles, whereas those with VHL cancer predisposition syndrome have only a single germline mutation and then acquire a somatic mutation that is essential for tumor genesis.

EGLN1 Gene Mutations, Proline Hydroxylase Deficiency

Another principal negative regulator of HIFs is PHD2 (encoded by the *EGLN1* gene), which targets the α subunit of HIF for degradation. The first loss-of-function mutation of PHD2 (PHD2^{P317R}) was identified in a family in which heterozygotes had mild or borderline polycythemia.¹¹⁴ Since then, 25 additional patients with unexplained polycythemia who are heterozygote carriers of different PHD2 mutations have been reported.¹¹⁵ Almost all patients with PHD2-associated polycythemia have normal erythropoietin levels. Whether the cause of polycythemia in this case is haploinsufficiency or a dominant negative effect remains to be determined.

EPAS1 (HIF-2 α) Gain-of-Function Mutations Affected patients have heterozygous missense mutations in the coding sequence of the *EPAS1* gene that encodes HIF-2 α , and typically have elevated erythropoietin levels.^{115,116} There is heterogeneity in these gain-of-function HIF-2 α mutations, but their existence supports the critical role of HIF-2 α in controlling the expression of erythropoietin. Some patients with *EPAS1* mutations, similar to Chuvash polycythemia, have erythropoietin hypersensitive colonies, thus sharing features of both primary and secondary polycythemias.⁹⁷

An explanation for the hypersensitivity of erythroid colonies bearing mutations that augment HIF stabilization remains to be discovered.

It has been proposed that mutated VHL^{R200W} protein hinders suppression of cytokine signaling SOCS1-mediated JAK2 degradation, via binding of a negative regulator of erythropoiesis, SOCS1,¹¹⁷ to the extreme 3' coding region of the *VHL* gene. Other observations are not consistent with this proposed mechanism: Another closely positioned VHL polycythemia mutation, VHL^{H191D}, is not associated with erythropoietin hypersensitivity,⁹⁶ while other, more upstream, mutations such as VHL^{P138L} are.⁸⁰ Furthermore, the hypersensitivity of erythroid colonies is also seen in some *HIF-2 α* mutations.⁸⁶ Interestingly, in some, but not all, of these families, upregulation of *NFE2*, which enhances erythropoiesis, has been found.^{6,118}

Unexplained Congenital Polycythemia with Elevated or Inappropriately Normal Levels of Erythropoietin The majority of patients with congenital polycythemia with inappropriately normal or elevated erythropoietin levels do not have *VHL* mutations, *EGLN1* or *EPAS1* mutations, hemoglobinopathies, or 2,3-BPG deficiency, and the molecular basis of polycythemia in these cases remains to be elucidated. Some such families show dominant inheritance,¹¹⁹ while in others inheritance is recessive, and in some it is sporadic. Lesions in genes linked to hypoxia independent regulation of HIF, as well as oxygen-dependent gene regulation pathways, are leading candidates for mutation screening in polycythemic patients with normal or elevated erythropoietin without *VHL*, *EGLN1* (proline hydroxylase), or *EPAS1* (HIF-2 α) mutations.

Other Inappropriate Secondary Erythrocytoses

Renal Polycythemia and Post-Renal Transplant Erythrocytosis Absolute erythrocytosis has been observed in a considerable number of patients with solitary renal cysts, polycystic renal disease, or hydronephrosis. In most of these cases, erythropoietin assays on cyst fluid, serum, or urine have disclosed the presence of erythropoietin.¹²⁰ Patients with polycystic disease have a hematocrit value slightly higher than normal and definitely higher than would have been expected of patients with uremia. In some patients on prolonged dialysis treatment, cystic transformation occurs in the native kidneys. This acquired cystic disease is occasionally associated with marked erythrocytosis.¹²¹ In patients with pheochromocytoma or paraganglioma and erythrocytosis, erythropoietin assays of serum and urine have disclosed higher-than-normal levels, and the erythrocytosis is most likely caused by excessive erythropoietin

secretion by the tumor. This assumption has been supported by the presence of erythropoietin mRNA in tumor cells.¹²² Wilms tumors¹²³ and paraganglioma¹²⁴ are also occasionally associated with an erythrocytosis. Many of these cases may have a somatic VHL gene mutation that, in combination with a germline mutation of another allele, may constitute an unrecognized VHL syndrome. A patient with congenital erythrocytosis and recurrent paraganglioma with a PHD2 mutation was described. Tumor tissue exhibited a loss of heterozygosity of PHD2 in the tumor, suggesting that PHD2 could be a tumor-suppressor gene.³⁴

Partial obstruction of the renal artery would be expected to cause renal tissue hypoxia and a physiologic stimulation of erythropoietin production. Nevertheless, it has proved quite difficult to induce erythrocytosis in laboratory animals by placing a Goldblatt clamp on the renal arteries.¹²⁵ Only a few of the many patients who have arteriosclerotic narrowing of the renal arteries have been reported to be polycythemic.¹²⁶

Post-Renal Transplantation Erythrocytosis Although the full molecular basis of post-renal transplant erythrocytosis remains unknown, angiotensin II (Chaps. 32 and 34) plays an important role in its pathogenesis.¹²⁷ Increased activity of the angiotensin II-angiotensin receptor 1 pathway makes the erythroid progenitors hypersensitive to angiotensin II.^{128,129} Furthermore, angiotensin II can modulate release of erythropoiesis stimulatory factors (Chap. 32) including erythropoietin and insulin-like growth factor (IGF)-1.^{130,131} Studies of venous effluents have determined that the native rather than the transplanted kidneys are the source of the inappropriate production of erythropoietin,¹³² and in some patients, removal of the native kidneys has led to rapid restoration of normal hematocrit values.¹³³ The condition is rarely seen in patients with nonrenal solid-organ allografts. The role of angiotensin II in augmenting erythropoiesis was confirmed by anemia in angiotensin-converting enzyme-knockout mice.¹³⁴ Prior to the late 1990s when the use of angiotensin-converting enzyme inhibitors increased as a means to reduce proteinuria, the incidence of erythrocytosis in renal transplant patients was approximately 8 to 10 percent within the first 2 years after engraftment.

Polycythemia with Connective Tissue Tumors Occasionally, there is an association of erythrocytosis with large uterine myomas.³⁵ Usually, the tumor has been huge and extirpation has routinely been followed by a hematologic “cure.” The suggestion that the tumor interferes with pulmonary ventilation has not been supported by the normal arterial blood gas findings in the few patients so studied. Another possible mechanism is that the large abdominal mass causes mechanical interference with the blood supply to the kidneys, resulting in renal hypoxia and erythropoietin production. Inappropriate erythropoietin secretion by smooth muscle cells has been demonstrated both in uterine myomas and in one case of cutaneous leiomyoma.^{35,135} Rare cases of polycythemia attributed to a myxoma of the atrium,³⁶ hamartoma of the liver,³⁷ and focal hyperplasia of the liver³⁸ have been documented.

Brain Tumors In adequately studied patients with erythrocytosis and cerebellar hemangiomas, arterial blood gas tensions have been normal. That the tumors are directly responsible for the polycythemia can be surmised from the identification of erythropoietin in cyst fluid and stromal cells and from a case in which erythropoietin mRNA was present in the tumor.¹³⁶ Although in these cases a mutation of the VHL gene was not sought, it is likely that these tumors were a manifestation of an underlying VHL syndrome as cerebellar hemangiomas are an integral feature of VHL syndrome.

Hepatoma In 1958, McFadzean and coworkers reported that almost 10 percent of patients in Hong Kong with hepatocellular carcinoma developed erythrocytosis.¹³⁷ Since then, this association has been recognized as an important clinical clue in the diagnostic consideration of patients with liver disease.¹³⁸ The cause of erythrocytosis is probably inappropriate production of erythropoietin by the neoplastic cells.¹³⁹

Normal hepatocytes, and to a lesser degree nonparenchymal liver cells, produce small amounts of erythropoietin, both constitutively and in response to hypoxia.

Congenital Polycythemia and Pheochromocytoma Pheochromocytomas have been described in association with congenital erythrocytosis.¹⁴⁰ In a growing number of reports, several individuals with congenital polycythemia have developed recurrent pheochromocytomas, paragangliomas, and sometimes somatostatinomas.¹⁴¹⁻¹⁴³ The tumors in these patients are heterozygous for gain-of-function mutations of the *EPAS1* gene (encoding HIF-2 α), and an erythropoietin transcript is present in tumor tissues (Chaps. 32 and 57). Even though these tumors may be recurrent, they bear the same heterozygous mutations of the *EPAS1* gene. However, these mutations are generally not found in nontumor tissues, so the etiology of the association of these tumors with polycythemia is not certain; it is also possible that they may be associated with postgonadal genetic mosaicism, wherein the *EPAS1* mutation predisposes to tumor development.¹⁴¹⁻¹⁴³ However, in one family the *EPAS1* mutation was inherited and also associated with the development of recurrent pheochromocytomas/paragangliomas.¹¹⁶

Endocrine Disorders Chapter 38 has additional discussion.

Aldosterone-producing adenomas,¹⁴⁴ Bartter syndrome,¹⁴⁵ and dermoid cyst of the ovary¹⁴⁶ have been described in association with erythrocytosis. Erythropoietin levels were found to be elevated in the serum and returned to normal after extirpation of the tumors. A number of pathogenetic mechanisms have been suggested (Chaps. 32 and 38), including decreased plasma volume; mechanical interference with renal blood supply; hypertensive damage to renal parenchyma; functional interaction between aldosterone, renin, and erythropoietin; and inappropriate secretion of erythropoietin by the tumors. Mild polycythemia may be present in patients with Cushing syndrome, but its pathophysiologic basis is not entirely clear (Chap. 38).

The erythropoietic effect of androgens is of considerable practical importance.¹⁴⁷ For many years, it was assumed that the higher red cell count in males was caused by androgens because the hemoglobin levels of boys and girls were identical up until the time of puberty. It was not until pharmacologic doses of testosterone were administered to women with carcinoma of the breast that the full erythropoietic potency of androgens was appreciated.¹⁴⁸ Since then, various androgen preparations have been used in the treatment of refractory anemia, occasionally causing dramatic erythropoiesis, with hemoglobin values climbing into the polycythemic range (Fig. 57-5).

The mechanism of androgen action on erythropoiesis appears to be complex, related both to their capacity to stimulate erythropoietin production¹⁴⁹ and their capacity to induce differentiation of marrow stem cells directly.¹⁴⁷ These two effects have specific structural requirements. Androgens with the 5 α -H configuration stimulate renal and extrarenal erythropoietin production, whereas androgens with the 5 β -H configuration enhance the differentiation of stem cells.¹⁴⁹ Testosterone administration is associated with an increase in erythropoietin levels and a decrease in hepcidin levels.¹⁵⁰ Although erythropoietin levels declined with continued testosterone administration, they remained inappropriately high despite improved hemoglobin levels, suggesting a new set point.¹⁵⁰

Neonatal Polycythemia Polycythemia at birth is a normal physiologic response to intrauterine hypoxia and to the high oxygen affinity of red cells containing very high proportions of hemoglobin F (Chap. 7). It may become excessive and even symptomatic, especially in infants of diabetic mothers, or if the clamping of the cord is delayed, permitting placental blood to boost the blood volume of the infant.¹⁵¹ Because it is difficult to recognize symptoms of hyperviscosity in the neonate, many pediatricians perform a partial plasma exchange transfusion if the venous hematocrit is above 65 percent at birth.¹⁵²

Figure 57-5. Erythropoietic response to testosterone derivatives in a patient with myelofibrosis. Hgb, hemoglobin; Hct, hematocrit.

One study of 25,000 neonates in Utah¹⁵³ showed that the average hematocrit at birth would be considered “polycythemic” in adults, while 2 weeks later it has fallen to “anemic” levels. This dramatic decrease of red blood cells in neonates during their first days of life likely contributes to neonatal jaundice (Chap. 33).¹⁵⁴

APPARENT (RELATIVE) POLYCYTHEMIA

(Refer to section “Secondary Polycythemia/Erythrocytoses” above.)

Some believe that apparent polycythemia is merely a mild absolute polycythemia accentuated by a compensatory reduction in plasma volume. Others suggest that it is caused by a primary reduction in plasma volume and have associated it with hypertension, obesity, and stress. When the red cell mass is documented to be normal, spurious polycythemia is also an appropriate term. Its clinical significance has also been disputed. The high hematocrit with its associated high viscosity is believed by some to be a risk factor heralding cerebral and cardiac complications, while others believe it is merely a well-tolerated anomaly. Because the designation *apparent polycythemia*¹⁵⁵ is noncommittal, it is used here.

The main clinical associations with apparent polycythemia are obesity, hypertension, and smoking. In obese patients, the finding of a normal red cell volume may be spurious because if the volume is expressed in terms of lean body weight, some of these patients would have a significant increase in red cell mass. In hypertensive patients, there is no adequate explanation for the apparent increase in red cell production or decrease in plasma volume. Sleep apnea (common in patients with congestive failure), excessive production of atrial natriuretic factor, increased adrenal activation, decreased aldosterone secretion, and hypoxic vasoconstriction are all factors that have been invoked,^{156–158} but with uncertainty. Chronic administration of diuretics to treat hypertension may be a more likely cause.¹⁵⁸

CLINICAL FEATURES

PRIMARY POLYCYTHEMIA

Primary Familial and Congenital Polycythemia

Although PFCP is uncommon, it is frequently misdiagnosed.¹⁸ Unlike patients with polycythemia vera, patients with PFCP lack splenomegaly, neutrophilia, basophilia, thrombocytosis, and a *JAK2* mutation. Unless exposed to alkylating agents or radioactive phosphorus, as many have been, these patients do not progress to acute leukemia or myelodysplastic syndrome.¹⁵⁹ Generally thought to be benign, this condition predisposes patients to severe cardiovascular problems because of chronic augmented erythropoietin signaling in all tissues bearing *EPOR*.¹⁶⁰ An increased incidence of cardiovascular disease has been observed in affected members of PFCP families.¹⁶¹ Erythrocytosis may be very severe, with hemoglobin levels that typically exceed 20 g/dL in men and 18 g/dL in women. Headaches are commonly present. Hypertension, coronary artery disease, and strokes have been reported, but do not clearly appear to be related to an elevated hematocrit as they also occur in aggressively phlebotomized patients with normal hematocrits,¹⁶² and are not a constant feature of the disorder.¹⁶³

Chuvash Polycythemia

The recessive polycythemia that is endemic in the Chuvash Autonomous Republic of the Russian Federation is characterized by elevation of the hemoglobin level to a mean of 22.6 with a standard deviation of 1.4 g/L.⁹⁵ Some patients are symptomatic, with headache, fatigue, and signs that include clubbing, hemorrhaging, and peptic ulcer. Chuvash polycythemia is also associated with thrombosis, relatively low blood pressure (also seen in heterozygotes), and varicose veins.^{4,95,99} As of yet, no significant association of thrombosis with elevated hematocrit and history of phlebotomies has been found.⁹⁹ A matched cohort study of 96 patients diagnosed in 1977 (65 spouses and 79 unaffected community members of the same age, sex, and village of birth) found that homozygosity for *VHL* 598C>T was associated with polycythemia, varicose veins, lower blood pressures, elevated serum VEGF and PAI-1 levels, and premature mortality related to cerebral vascular events and both venous and arterial thromboses.⁹⁹

Because Chuvash polycythemia is characterized by a germline mutation in the *VHL* gene, it was expected that homozygotes for this mutation may develop certain vascular tumors similar to those associated with classic VHL syndrome. However, tumors typical of classic VHL syndrome, such as spinocerebellar hemangioblastomas, renal carcinomas and pheochromocytomas/paragangliomas, were not found, indicating that increased expression of HIF-1 α and VEGF is not sufficient for tumorigenesis. Benign vertebral body hemangiomas (a distinct entity from hemangioblastoma) were found in significantly more patients with Chuvash polycythemia compared to controls (55 percent vs. 21 percent). Imaging studies of 33 Chuvash polycythemia patients revealed unsuspected cerebral ischemic lesions in 45 percent of patients.⁹⁹ Affected patients have elevated systolic pulmonary artery pressures as estimated by echocardiography compared to controls, and iron deficiency associated with phlebotomy therapy may exacerbate this finding.^{164–167}

Other Congenital Disorders of Hypoxia Sensing

Because of their only recent discovery and apparent rarity, reliable clinical information is lacking. However, these disorders, in view of their global deregulation of hypoxia sensing, are expected to also have extrerythroid manifestation(s). This author is aware of a yet unpublished large family with a gain-of-function *EPAS1* gene mutation wherein affected members appear to have early onset of strokes and cardiovascular disease, which are not prevented by control of their erythrocytosis by phlebotomies.

SECONDARY ACQUIRED POLYCYTHEMIA

High-Altitude Erythrocytosis

Tolerance to high altitudes varies greatly, but most normal individuals have no discomfort at altitudes of up to 2130 m (7000 ft). Above this level, and especially if the ascent is rapid, some manifestations of cerebral hypoxia are common. Headaches, sleeplessness, and palpitations are frequently encountered, and weakness, nausea, vomiting, and mental dullness may be present. More-severe manifestations include pulmonary and cerebral edema that may lead to death. Cheyne-Stokes respiration commonly occurs, especially during sleep. These symptoms constitute the syndrome of *acute mountain sickness*.¹⁶⁸

Ruddy cyanosis and physiologic emphysema are the two characteristic features of some humans living at high altitudes. Venous and capillary engorgement can be observed readily in the conjunctiva, mucous membranes, and skin, and may contribute to the remarkable capacity of Tibetan Sherpas to walk barefoot and sleep on ice and snow.¹⁶⁹ Asymptomatic retinal hemorrhages are seen frequently at high altitudes, but rarely at altitudes of 3000 m (9000 ft) or less.¹⁷⁰ Splenomegaly and jaundice are unusual, although the sustained erythrocytosis is associated with an increased fractional rate of red cell destruction and bilirubin generation. It has been stated that Monge disease includes low fertility,^{42,66} but this may not be universally so. It has been suggested that high-altitude native-resident Tibetans exhibit two distinct genotypes for increased oxygen affinity of hemoglobin, and that women with genotypes for high oxygen saturation have more surviving children¹⁷¹ suggesting natural selection on the locus for oxygen saturation of hemoglobin.^{72,171} However, these conclusions have been based not on measurement of the hemoglobin-oxygen dissociation curve, but on assumptions based on arterial oxygen saturation. In point of fact, when properly measured, Tibetans have normal oxygen affinity of hemoglobin when the hemoglobin-oxygen dissociation curve is rigorously determined.⁶³

Erythrocytosis Associated with Pulmonary Disease

The erythrocytosis associated with smoking is generally asymptomatic. There may be an increase in thrombotic events, but this may be from smoking rather than erythrocytosis.

When erythrocytosis is present in patients with COPD, with or without smoking, elevated hematocrit is associated with higher survival rates than anemic and normocytic subjects.^{19,20,175} Furthermore, moderate erythrocytosis has no adverse effect on vascular function in COPD¹⁷⁶ and is not associated with venous thromboembolism.¹⁷⁷

Large studies of patients with Eisenmenger syndrome²⁸ and other patients with cyanotic heart disease¹⁷⁸ caution against routine phlebotomy for asymptomatic elevation of the hematocrit; in fact, thrombotic complications were not observed in these studies. Transgenic mice with extreme polycythemia (hematocrit 85 percent) from constitutive overexpression of erythropoietin did not develop the expected thrombotic complications.¹⁷⁹ Adults with cyanotic congenital heart disease are at risk of having cerebrovascular events. This risk is increased in the presence of hypertension, atrial fibrillation, history of phlebotomy, and microcytosis, the latter condition having the strongest significance ($p < 0.005$). The authors of these findings endorsed a more conservative approach toward phlebotomy and more aggressive approach toward treating microcytosis with iron preparations in adults with cyanotic congenital heart disease.¹⁸⁰

In a prospective cohort of U.S. Veterans Health Administration outpatients with stable COPD ($n = 683$), polycythemia prevalence was low and, unlike anemia, had no association with worsened outcomes.¹⁷⁵

Renal Polycythemia and Post-Renal Transplant Erythrocytosis

Although most patients with kidney failure are anemic, a fraction (often with polycystic kidney disease) display erythrocytosis, which, like the post-renal transplant state, can be very severe. Erythrocyte counts

may be as high as 8×10^{12} cells/L and associated with hypertension and congestive failure.¹⁸¹ At higher hematocrit levels (usually >60 percent), thrombotic events may complicate the clinical course.^{46,47,182} Comorbidities that are associated with or causative of renal failure are frequently also factors predisposing to thrombosis, and the risk of erythrocytosis-associated thrombosis has not been submitted to rigorous multivariate rigorous statistical analyses. Thus, reports of increased thrombotic risks must be viewed with great caution.

Tumors

The erythrocytosis that occurs with erythropoietin-secreting tumors is generally mild,¹³⁶ and the predominating clinical manifestations are those of the tumor itself. Even moderate elevations to a hematocrit of 64 percent have been encountered without symptoms referable to the polycythemia.³⁸ Resection of the erythropoietin-secreting tumor cures the associated polycythemia.¹⁰⁵

In the syndrome of congenital polycythemia and pheochromocytoma or paraganglioma (see description in “Etiology” earlier) tumor resection does not lead to normalization of elevated hematocrit.

Neonatal Polycythemia

Of 55 infants with neonatal polycythemia, 47 (85 percent) had signs and symptoms attributed to this disorder. These included “feeding problems” (21.8 percent), plethora (20 percent), lethargy (14.5 percent), cyanosis (14.5 percent), respiratory distress (9.1 percent), jitteriness (7.3 percent), and hypotonia (7.3 percent). Other findings included hypoglycemia (40 percent) and hyperbilirubinemia (21.8 percent). In a larger group of nearly 1000 infants, six had intracranial hemorrhage.¹⁵¹

LABORATORY FEATURES

PRIMARY POLYCYTHEMIA

Primary Familial and Congenital Polycythemia

Characteristic laboratory findings of PFCP are: (1) increased red blood cell mass without increased leukocyte or platelet counts; (2) normal hemoglobin-oxygen dissociation curve; (3) invariably low serum erythropoietin levels; and (4) *in vitro* hypersensitivity of erythroid progenitors to erythropoietin.⁵ PFCP is often misdiagnosed as polycythemia vera, although with the advent of a reliable polymerase chain reaction-based test for the *JAK2*^{V617F} mutation, this should no longer ever happen. Whereas leukocytes are typically normal, platelet counts are often mildly decreased, presumably by dilution of the normal platelet mass by an often-dramatic increase of red cell and whole-blood volumes. Some patients come to attention because of concurrent medical problems that may cause leukocytosis and secondary thrombocytosis, falsely suggesting the phenotype of polycythemia vera.

Chuvash Polycythemia

Blood profiling in patients with Chuvash polycythemia indicates increased hemoglobin and hematocrit and lower white blood cell and platelet counts than in controls. Erythropoietin ranges from normal (but never close to the lower limits of normal) to elevated, at times exceeding 10 times the mean normal value. In larger studies, hemoglobin-adjusted serum erythropoietin concentrations were approximately 10-fold higher in *VHL* 598C>T homozygotes than in controls.^{4,5,99}

Affected subjects have lower CD4 counts, elevated levels of both proinflammatory and antiinflammatory cytokines, and altered plasma thiol levels, with elevated homocysteine and glutathione and low cysteine concentrations.^{164,183,184} Their serum PAI-1 and VEGF levels are also increased.^{4,95,99} Circulating transferrin receptor levels are higher in Chuvash polycythemia homozygotes as compared to their unaffected relatives and spouses.^{4,5,99} Ferritin-adjusted transferrin receptor concentrations were approximately threefold higher in *VHL*

598C>T homozygotes than in unaffected participants ($p < 0.0005$), which is consistent with upregulation by HIF-1.

Chuvash polycythemia is a relatively recently described disorder; thus, additional laboratory findings as a result of augmentation of hypoxia sensing are expected to be described.

Other Congenital Polycythemia from Augmented Hypoxia Sensing

At present, a paucity of data precludes any reliable description of other congenital polycythemia from augmented hypoxia sensing. Some affected subjects have unexpectedly low-normal erythropoietin levels.

SECONDARY ERYTHROCYTOSIS

Characteristically, only the number of erythrocytes in the blood is increased in secondary erythrocytosis. An increase in the leukocyte count and/or splenomegaly may be present as features of the underlying disease, for example, pulmonary infection in COPD with *cor pulmonale*, or as seen in Monge disease among Andean high-altitude dwellers or patients inheriting a high-affinity hemoglobin that is also unstable (Chaps. 34 and 49).

In patients with appropriate erythrocytosis, the underlying defect is usually demonstrable. Arterial hypoxia can be demonstrated in most cases. Some obese patients who, like Mr. Wardle's proverbial boy, Joe, in *The Pickwick Papers* by Charles Dickens, are always half asleep, will be very much awake when exposed to arterial puncture and ventilatory testing, and their apprehensive hyperventilation will result in the disappearance of all abnormalities in arterial oxygen tension. As soon as they return to bed, however, they will go to sleep again and display the characteristic somnolent cyanosis.

In inappropriate erythrocytosis, the laboratory findings will be those of the underlying defect.

DIFFERENTIAL DIAGNOSIS

Also refer to Chaps. 34 and 59, Table 57–3, and Fig. 57–6.

Distinguishing between polycythemia vera and other polycythemic disorders used to be challenging, but discovery of the *JAK2*^{V617F} and *JAK2* exon 12 mutations has made it, in most instances, straightforward. Some of the clinical and laboratory features that can be helpful for differential diagnosis are summarized in Chap. 34, Table 34–2, and in Fig. 57–6.

RED CELL MASS DETERMINATION

Determination of red cell mass is invaluable for differentiation of apparent (spurious) polycythemia from true polycythemic states. Unfortunately, determination of the red cell mass is expensive and, when performed by the inexperienced, often inaccurate.¹⁸⁵ It is not useful in distinguishing polycythemia vera from secondary erythrocytoses, the differentiation that is usually needed, because it is increased in both disorders. Ideally, the red cell mass and plasma volume should be measured separately. Unfortunately, the ¹³¹I-labeled albumin necessary to measure the plasma volume is often unavailable. Fortunately, in most cases, the diagnosis of polycythemia vera and other true polycythemic states can be established with confidence without measuring the red cell mass.

ERYTHROID COLONY CULTURES

In vitro assays of erythroid progenitor cells permit the study of their responsiveness to erythropoietin. This can be applied to polycythemia

vera and erythroid progenitor burst-forming unit–erythroid (BFU-E) growth without added erythropoietin,¹⁸⁶ referred to as “endogenous erythroid colonies.” Detection of endogenous erythroid colonies in cultures of marrow or blood used to be the most specific test for polycythemia vera.^{50,187,188} In one study, all patients with polycythemia vera, but none with secondary or other causes of polycythemia, had endogenous erythroid colonies.¹⁸⁹ Rare endogenous erythroid colonies may at times be observed in PFCP, Chuvash polycythemia, and in a single studied subject with the HIF-2 α mutation,¹⁹⁰ but unlike the endogenous erythroid colonies of polycythemia vera, these are abrogated by pretreatment with erythropoietin and EPOR-blocking antibodies.^{191,192}

In experienced hands, endogenous erythroid colonies is a specific and sensitive means for detecting polycythemia vera and may be useful in diagnosing patients with unusual presentations of polycythemia vera, such as Budd-Chiari syndrome^{193–196} or isolated thrombocytosis.¹⁹⁷ However, this test has not been standardized, is expensive and laborious, and technical variations make interlaboratory results difficult to compare.

ERYTHROPOIETIN LEVELS

All patients with PFCP encountered⁵⁴ have erythropoietin below normal levels or below levels of detection. Thus, a low erythropoietin level is not pathognomonic of polycythemia vera, as patients with PFCP have as low or even lower erythropoietin levels.¹⁸

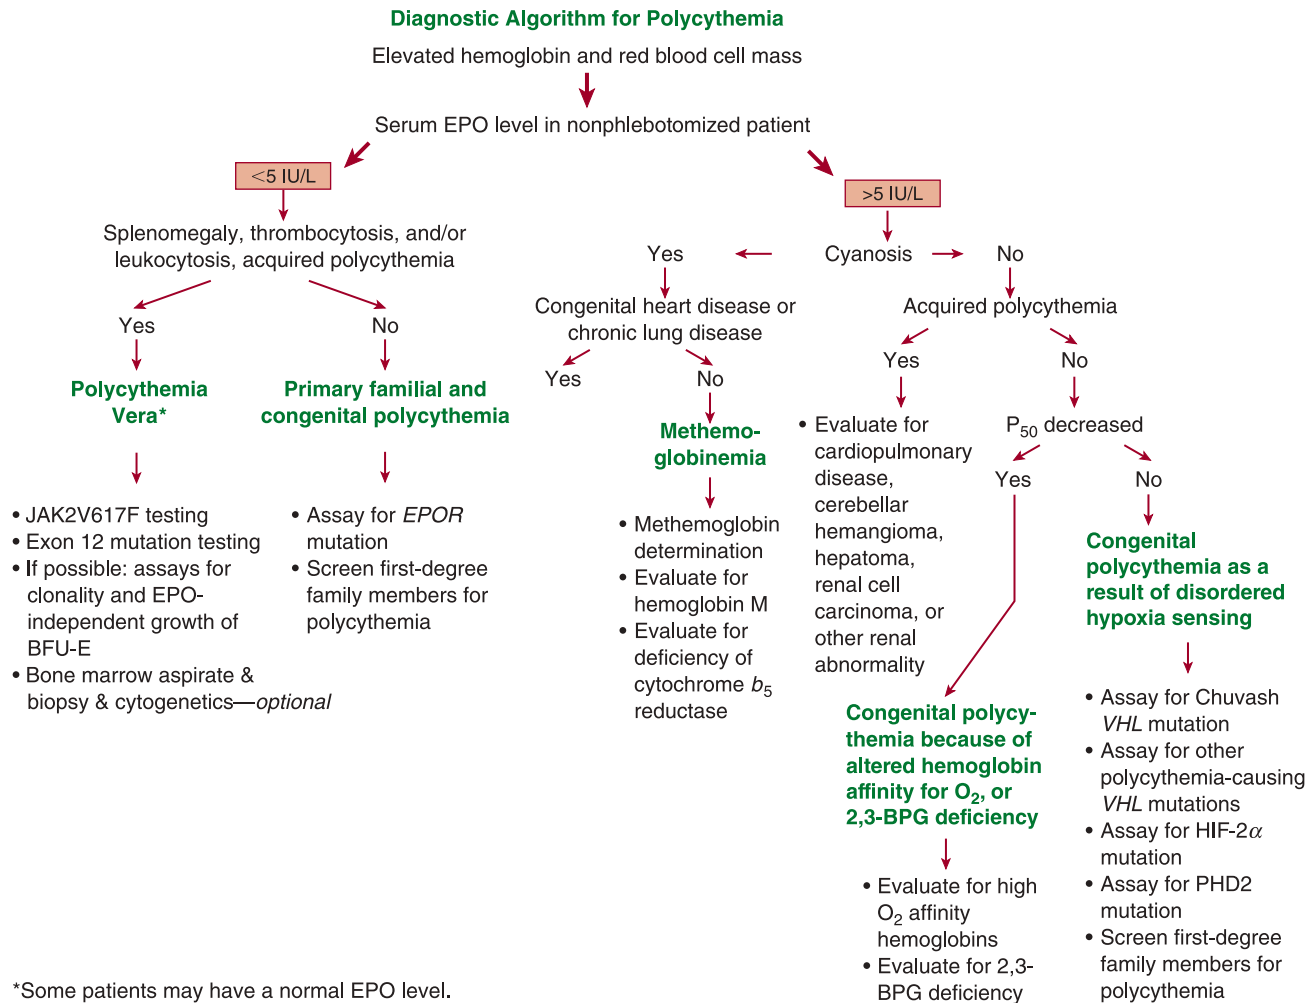

Figure 57-6. Diagnostic algorithm for polycythemia based on erythropoietin (EPO) level. 2,3-BPG, 2,3-bisphosphoglycerate; BFU-E, burst-forming unit-erythroid; *EPO*R, erythropoietin receptor gene; HIF, hypoxia-inducible factor; PHD2, proline hydroxylase 2; *VHL*, von Hippel-Lindau gene.

Because polycythemia vera is distinguished by the fact that erythroid cells proliferate even in the absence of substantial levels of erythropoietin, one would expect that at high hematocrit levels the production of erythropoietin would be inhibited and serum levels consequently reduced. Older erythropoietin assays were too insensitive to detect subnormal levels of erythropoietin, but using improved technology, several studies have documented serum erythropoietin levels below the normal reference range in patients with polycythemia vera.¹⁹⁸⁻²⁰⁰ Erythropoietin levels remain low even after phlebotomy,¹⁹⁸ which increases erythropoietin levels in normal individuals. Erythropoietin levels in Budd-Chiari syndrome may be normal or even increased.²⁰¹

Patients with secondary erythrocytosis usually have normal to elevated erythropoietin levels, although considerable overlap exists in the range of erythropoietin levels between some patients with polycythemia vera and those with secondary erythrocytosis.^{199,202}

CLONALITY IN FEMALE SUBJECTS USING ASSAYS EMPLOYING X-CHROMOSOME-BASED POLYMORPHISM ASSAYS

The principal role of the clonality assay is to differentiate polycythemia vera with an incomplete phenotype or atypical presentation from idiopathic, or as-yet undiagnosed erythrocytosis. Polycythemia vera

results from an acquired mutation in a pluripotential hematopoietic stem/progenitor cell. Clonality studies based on the phenomenon of X-chromosome inactivation²⁰³ show that red cells, granulocytes, platelets, monocytes, and B lymphocytes are all part of the clone.^{204,205} The majority of T lymphocytes and natural killer (NK) cells are polyclonal, but a small proportion of these cells are also derived from the polycythemia vera clone²⁰⁶; this is presumed to be a result of the presence of long-lived normal T cells that preceded the development of the clone. Unfortunately, interpretation of publications on the applicability of X-chromosome inactivation for differential diagnosis of polycythemia vera is hampered by the many methodologic and conceptual differences that have drawn conflicting conclusions.²⁰⁷ Some discrepancies are caused by the fact that two different approaches, which are not comparable, are used to distinguish the active from the inactive X-chromosome; one approach uses X-chromosome differential methylation,²⁰⁸ typically using the polymorphic CAG repeat in the human androgen-receptor gene (*HUMARA*),²⁰⁹ while the other approach uses more biologically sound but more technically demanding transcriptional analysis of the active X-chromosome.^{208,210} Furthermore, the wide range of skewing of the X-chromosome allelic usage that is normally present²¹¹ is often misinterpreted as clonality, and the potentially clonal myeloid cells are not compared to the polyclonal control cells of the same origin.⁵⁰ In our study of 56 PV female polycythemia vera patients, reticulocytes, platelets, and granulocytes were always

clonal, with the exception of a few patients who converted to polyclonal hematopoiesis after therapy with interferon- α .⁵⁰ While it was previously reported that clonality assays based on X-chromosome inactivation are not suitable for studies of older women using the HUMARA assay,^{212–214} that was not confirmed by studies using quantitative transcriptional analysis of active X-chromosomes.^{215,216}

OTHER POLYCYTHEMIAS

Clinical history is of the utmost importance for the differential diagnosis of polycythemic states. Differentiation of an acquired from congenital disorder, and distinction between sporadic versus familial occurrence of polycythemia, when possible, will streamline the diagnosis. Thus, an autosomal dominant disorder is likely a result of polycythemia from gain-of-function *EPOR*, *EPAS1* (HIF-2 α) or *EGLN1* (PHD2) mutations, or a high-affinity hemoglobin. Recessively inherited conditions may be from *VHL* gene mutations. Although rare patients with polycythemia vera may have a history of other affected family members (Chap. 84), polycythemia vera is always an acquired condition. Many familial polycythemias are the result of yet-to-be-discovered genetic events.

Patients with a low level of erythropoietin and autosomal dominant inheritance should have sequence analysis of the *EPOR* gene. This will define the defect in some patients with PFCP; if the polycythemia is acquired and present in multiple relatives, a diagnosis of familial clustering of polycythemia vera should be pursued.²¹⁷ Patients with secondary erythrocytosis have a genuine increase in the number of circulating erythrocytes and the red cell mass. Such patients do not typically have increased platelet or leukocyte counts or splenomegaly, which are often seen in polycythemia vera. The lack of involvement of other cell lineages in hematopoietic proliferation should arouse suspicion that the patient may have erythrocytosis other than polycythemia vera.

However, reactive thrombocytosis, leukocytosis, and splenomegaly may occasionally also be present in secondary erythrocytosis, which then renders the distinction from polycythemia vera more difficult. In patients in whom secondary erythrocytosis is caused by lung or cardiac disease, clubbing is often present. In some cases, determining the arterial oxygen saturation will clarify the diagnosis, but modest arterial oxygen desaturation may also be present in polycythemia vera.^{85,218} Imaging of the kidneys may reveal a neoplasm or cyst in some patients. Determining the hemoglobin oxygen dissociation curve (Chaps. 32, 34, 50), or estimation of p50 from venous blood⁹² will detect abnormalities related to increased oxygen affinity either because of inheritance of a high-affinity hemoglobin (Chap. 49), or because of very rare 2,3-BPG depletion, as in phosphoglyceromutase deficiency (Chap. 47). The mild erythrocytosis associated with hereditary methemoglobinemia (Chap. 50) is readily diagnosed because of coexistent cyanosis.

In patients with elevated erythropoietin, or with erythropoietin levels inappropriately normal for the degree of hemoglobin elevation, analysis of *VHL*, *EGLN1*, and *EPAS1* genes may be in order; some of these patients may have a history of autosomal recessive inheritance and have a typical history of congenital polycythemia. It may also be useful to determine the carboxyhemoglobin level of the blood if smoker's polycythemia is suspected.

SPURIOUS POLYCYTHEMIA

The erythrocytosis observed in patients with spurious polycythemia (apparent polycythemia, stress polycythemia) is the consequence of a decrease in plasma volume.¹⁵⁵ The observed erythrocytosis does not represent a true increase in the red cell mass. Usually, the increase in hematocrit is very modest. Such patients do not have an increased white blood count, thrombocytosis, splenomegaly, or *JAK2* mutation. The arterial oxygen saturation is normal. Estimation of the red cell mass and plasma volume is required to establishing a diagnosis of spurious

polycythemia, but it should be recognized that during the natural history of patients who develop primary or secondary polycythemia, their red cell mass is, at some point, within the normal range while it is rising to abnormal values. Because of the significant error rate of red cell mass measurement, it is recommended that both red cell mass and plasma volume be measured simultaneously.

THERAPY

POLYCYTHEMIAS OTHER THAN POLYCYTHEMIA VERA

Treatment of patients with post-renal transplant erythrocytosis with drugs that suppress the renal-angiotensin system has virtually eliminated the need for therapeutic phlebotomy. The maximal reduction of hemoglobin and hematocrit levels usually manifests by 6 months after starting therapy with either the angiotensin-converting enzyme inhibitor, enalapril, or the angiotensin II receptor type 1 blocker, losartan.¹²⁷ Some patients are exquisitely sensitive and may become severely anemic.

High-altitude erythrocytosis is also associated with pulmonary hypertension, proteinuria, and elevated blood pressure. A prospective randomized trial of enalapril reported decreased hemoglobin concentration, proteinuria and beneficial effects on elevated blood pressure.²¹⁹

When erythrocytosis is secondary to a renal tumor or cyst, pheochromocytoma, myoma, or brain tumor, removal of the neoplasm usually results in disappearance of the erythrocytosis, but in the syndrome of congenital polycythemia with pheochromocytoma caused by *EPAS1* mutations (see above paragraphs) erythrocytosis persist after tumor resection.

No specific therapy is currently available for polycythemic subjects with *VHL*, *EGLN1*, or *EPAS1* mutations.

Lowering the hematocrit to a normal or near-normal level by phlebotomy is the usual, but empiric, treatment of secondary erythrocytosis,^{220,221} but should always be viewed in the context of a particular subject.^{28,178} The appropriate level is that at which the patient becomes asymptomatic. Although cytotoxic agents are sometimes used for this purpose, phlebotomy is preferred, if indeed needed, because of the leukemogenic risk of the agents that are used in polycythemia vera. This author favors, in most instances, benign neglect, unless specific therapy, such as that seen in erythropoietin-secreting tumors or post-renal transplant erythrocytosis, is available. One should phlebotomize only those patients who are symptomatic from the elevated red cell mass and continue to do so cautiously only if symptoms respond promptly to phlebotomy.

COURSE AND PROGNOSIS

CHUVASH POLYCYTHEMIA

A study compared 96 patients with Chuvash polycythemia diagnosed before 1977 to 65 spouses, and 79 unrelated community members with normal hemoglobin concentration, same age, sex, and village of birth; the estimated survival to 65 years was 31 percent or less for Chuvash polycythemia patients versus 67 percent or greater for spouses and community members ($p \leq 0.002$).⁹⁹

OTHER POLYCYTHEMIAS

The clinical course of secondary erythrocytosis is largely a function of the underlying disorder. In patients with PFCP secondary to mutations of the *EPOR* gene, coronary artery disease and strokes have been reported,¹⁶² although not in all series.¹⁶³ The rarity of patients having mutations of the *EPOR*, *VHL*, *EGLN1*, and *EPAS1* genes and polycythemias from globin mutations and or red cell enzyme deficiencies precludes any meaningful prognostic evaluation.

CHAPTER 58

THE PORPHYRIAS

John D. Phillips and Karl E. Anderson

SUMMARY

Porphyrias are diseases that result from derangements of specific enzymes in the heme biosynthetic pathway that lead to overproduction and accumulation of pathway intermediates and cause neurologic symptoms, photocutaneous symptoms or both. Multiple inherited mutations have been identified in all the porphyrias. However, porphyria cutanea tarda (PCT), which is caused primarily by an acquired deficiency of the fifth enzyme in the heme biosynthetic pathway, specifically in the liver, is usually not associated with a mutation of this enzyme.

Porphyrias can be classified as either hepatic or erythropoietic, depending on the principal site of initial accumulation of excess pathway intermediates. Erythropoietic porphyrias are characterized by childhood onset and a generally stable clinical course. Hepatic porphyrias almost always develop during adult life, and are more variable because of multiple influences of drugs, hormones, and nutritional factors on the heme biosynthetic pathway in the liver.

Porphyrias are also classified as acute or cutaneous. The four acute porphyrias are associated with neurologic manifestations that usually occur as acute attacks. δ -Aminolevulinic acid dehydratase porphyria (ADP) is an autosomal recessive disorder caused by a deficiency of the second enzyme in the pathway and is the rarest type of porphyria. ADP has been classified as hepatic, but also has erythropoietic features. The three other acute porphyrias, namely acute intermittent porphyria (AIP), hereditary coproporphyrin (HCP), and variegate porphyria (VP), are autosomal dominant hepatic porphyrias, and result from deficiencies of the third, sixth, and seventh enzymes in the pathway, respectively. HCP and VP are also classified as cutaneous, because photocutaneous lesions may develop, especially in VP. AIP is the most common acute porphyria and the second most common porphyria. Disease expression is highly variable

Acronyms and Abbreviations: ADP, δ -aminolevulinic acid dehydratase deficiency porphyria; AIP, acute intermittent porphyria; ALA, δ -aminolevulinic acid; ALAD, δ -aminolevulinic acid dehydratase; ALAS, δ -aminolevulinic acid synthase; ALAS1, δ -aminolevulinic acid synthase, housekeeping form; ALAS2, δ -aminolevulinic acid synthase, erythroid-specific form; cDNA, complementary DNA to mRNA template; CEP, congenital erythropoietic porphyria; CPO, coproporphyrinogen oxidase; CPRE, coproporphyrinogen oxidase gene promoter regulatory element; CRIM, cross-reactive immunologic material; CYP, cytochrome P450; EC, enzyme commission; EPP, erythropoietic protoporphyria; FECH, ferrochelatase; HCP, hereditary coproporphyrin; HEP, hepatoerythropoietic porphyria; HFE, hemochromatosis gene; HMB, hydroxymethylbilane; IRE, iron-responsive element; IRPs, iron-responsive element binding proteins; NRF-1, nuclear regulatory factor 1; PBG, porphobilinogen; PBGD, porphobilinogen deaminase; PCT, porphyria cutanea tarda; PGC-1 α , peroxisomal proliferator-activated cofactor 1 α ; PPO, protoporphyrinogen oxidase; PXR, pregnane X receptor; SCS- β A, β subunit of ATP-specific succinyl coenzyme A synthetase; UROD, uroporphyrinogen decarboxylase; UROS, uroporphyrinogen synthase; VP, variegate porphyria; XLP, X-linked protoporphyria.

in acute porphyrias, and the great majority of individuals who inherit deficiencies of these enzymes remain latent through all or most of their lives. Attacks are produced by factors that increase hepatic heme synthesis, including certain drugs, sex steroid hormones and their metabolites and restriction of dietary calories and carbohydrate. Treatment of acute porphyrias includes glucose loading and heme infusions, which repress δ -aminolevulinic acid synthase-1, the rate-limiting enzyme of the heme biosynthetic pathway in the liver.

Cutaneous porphyrias are associated with either blistering skin lesions or, in erythropoietic protoporphyria (EPP), with acute nonblistering photosensitivity. Blistering skin manifestations are identical in PCT, HCP, and VP. Similar lesions in congenital erythropoietic porphyria (CEP) are much more severe and often associated with loss of digits and facial mutilation. CEP results from a severe deficiency of the fourth enzyme in the pathway and is inherited in an autosomal recessive fashion. Hemolytic anemia is common, and severe cases may be transfusion dependent, and may even present *in utero* with fetal hydrops. Hematopoietic stem cell transplantation in early childhood is the most effective treatment.

EPP is the third most common porphyria and the most common in children. It is usually caused by a deficiency of the final enzyme in the pathway. In most families, inheritance of EPP is best described as autosomal recessive, with a severe ferrochelatase mutation inherited from one parent and a low-expression variant allele from the other. X-linked protoporphyria (XLP) has the same phenotype as EPP, but is caused by gain-of-function mutations of δ -aminolevulinic acid synthase-2, which is expressed only in erythroblasts and reticulocytes. Protoporphyrin-containing gallstones may develop in EPP and XLP. An uncommon but potentially life-threatening complication is protoporphyric hepatopathy, which is a result of the cholestatic effects of protoporphyrin, and may require liver transplantation. Sequential marrow transplantation can prevent recurrent hepatopathy in the transplanted liver.

PCT is an iron-related hepatic porphyria that usually begins in middle or late adult life. Activity of hepatic uroporphyrinogen decarboxylase (UROD) is reduced in the presence of iron to approximately 20 percent of normal in PCT by a uroporphomethene inhibitor probably derived from uroporphyrinogen. Multiple susceptibility factors, including use of alcohol, smoking, estrogens, hepatitis C and HIV contribute. HFE (hemochromatosis gene) mutations that cause excess iron absorption are common in PCT. A minority of patients are heterozygous for UROD mutations and are said to have familial PCT. Polyhalogenated aromatic hydrocarbons cause PCT in laboratory animals and occasionally in humans. PCT responds well to treatment by repeated phlebotomy, which reduces hepatic iron, or low-dose hydroxychloroquine or chloroquine, which mobilizes accumulated hepatic porphyrins. Hepatoerythropoietic porphyria is the homozygous form of familial PCT, and is usually a severe disorder that starts in childhood and resembles CEP clinically.

DEFINITION AND HISTORY

The porphyrias are a group of metabolic diseases resulting from derangements, usually of a genetic nature, in the activity of specific enzymes in the heme biosynthetic pathway, leading to overproduction and accumulation of pathway intermediates. Symptoms of these diseases can be neurologic, photocutaneous, or both. The intermediates that accumulate include porphyrins and the porphyrin precursors δ -aminolevulinic acid (ALA) and porphobilinogen (PBG) and their derivatives. Patterns of these substances in plasma, erythrocytes, urine, and feces are characteristic for each porphyria, and are the basis for screening tests and more comprehensive biochemical characterization.

Porphyrias are classified as either *erythropoietic* or *hepatic*, depending on the principal site of accumulation of pathway intermediates. The erythropoietic porphyrias are congenital erythropoietic porphyria (CEP), which is very rare, erythropoietic protoporphyria (EPP), the third most common porphyria and the most common in children, and X-linked protoporphyria (XLP), which has the same phenotype as EPP but is less common. Hepatic porphyrias include the acute porphyrias, which cause neurologic symptoms usually in the form of acute attacks, and porphyria cutanea tarda (PCT), which is the most common of the porphyrias, and causes chronic blistering lesions on sun-exposed areas of the skin. The acute porphyrias include ALA dehydratase deficiency porphyria (ADP), acute intermittent porphyria (AIP), hereditary coproporphyria (HCP), and variegate porphyria (VP). VP, and less commonly HCP, can also cause skin manifestations identical to those in PCT.

A type of porphyria is associated with loss-of-function mutations of seven of the eight enzymes in the heme biosynthetic pathway (Table 58-1 and Fig. 58-1) PCT is primarily caused by an acquired deficiency of the fifth pathway enzyme, with heterozygous mutations of that enzyme contributing in some cases. Gain-of-function mutations of ALAS2, the erythroid form of the first pathway enzyme, cause XLP, whereas loss-of-function mutations of this enzyme cause X-linked sideroblastic anemia (Chap. 59). Table 58-2 summarizes the major clinical and laboratory features of the porphyrias.

A case of CEP reported by Schultz in 1874 was the first description of porphyria in the literature. This case was a 33-year-old man with photosensitivity since age 3 months, anemia, splenomegaly, red-wine-colored urine as a result of a pigment resembling hematoporphyrin,

and brown-colored bones at autopsy.^{1,2} In 1898, T. McCall Anderson described two brothers (ages 23 and 26 years) who most likely had CEP,³ and suffered from *hydraea aestivale*, with red urine, pruritus and blistering of sun-exposed skin, especially in summer, leading to extensive scarring and mutilation of the ears and nose (see Chap. 58, Fig. 58-5). Using available methods, their urine was also demonstrated to contain a substance related to hematoporphyrin.⁴ In 1889, Stokvis first described a case of acute porphyria in an elderly woman who developed dark-red urine and later died after taking sulphonal, a drug related to the barbiturates.⁵

Hans Günther⁶ published a monograph on porphyrins in 1911 and classified porphyrias into four groups: (1) those that have an acute onset without association with drug ingestion, (2) those that are caused by sulphonal or trional, (3) hematoporphyrin congenita, and (4) chronic hematoporphyrin. The first two groups correspond to the acute porphyrias, which may present with attacks sometimes related to ingestion of certain drugs, the second group to CEP and hepatoerythropoietic porphyria (HEP), and the fourth to PCT. In 1923, Archibald Garrod proposed the term *inborn errors of metabolism* for a number of inherited metabolic disorders, including the porphyrias.⁷

Sachs noted an Ehrlich-positive chromogen that was not urobilinogen in urine of patients with acute porphyria in 1931. In the late 1930s, Waldenström noted that excretion of this chromogen was an autosomal dominant trait in AIP families, which he identified as PBG in 1939.⁸ The classification of porphyrias as erythropoietic and hepatic was proposed in 1954 by Schmid, Schwartz, and Watson.⁹ An epidemic of hexachlorobenzene-induced PCT in eastern Turkey in 1957^{10,11} provided

TABLE 58-1. Human Porphyrias: Specific Enzymes Affected by Mutations, Modes of Inheritance, Classification, and Major Types of Clinical Features of Each of the Human Porphyrias

Porphyria*	Affected Enzyme	Known Mutations	Inheritance	Classification	Principal Clinical Features
X-linked protoporphyria	δ -Aminolevulinic acid (ALA) synthase–erythroid-specific form (ALAS2)	4 (gain of function)	X-linked recessive	Erythropoietic	Nonblistering photosensitivity
δ -Aminolevulinic acid dehydratase porphyria (ADP)	ALA dehydratase (ALAD)	10	Autosomal recessive	Hepatic†	Neurovisceral
Acute intermittent porphyria (AIP)	PBG deaminase (PBGD)	273	Autosomal dominant	Hepatic	Neurovisceral
Congenital erythropoietic porphyria (CEP)	Uroporphyrinogen III synthase (UROS)	36	Autosomal recessive	Erythropoietic	Neurovisceral
Porphyria cutanea tarda (PCT)	Uroporphyrinogen decarboxylase (UROD)	70 (includes HEP)	Autosomal dominant‡	Hepatic	Blistering photosensitivity
Hepatoerythropoietic porphyria (HEP)	UROD	–	Autosomal recessive	Hepatic†	Blistering photosensitivity
Hereditary coproporphyria (HCP)	Coproporphyrinogen oxidase (CPO)	42	Autosomal dominant	Hepatic	Neurovisceral; blistering photosensitivity (uncommon)
Variegate porphyria (VP)	Protoporphyrinogen oxidase (PPO)	130	Autosomal dominant	Hepatic	Neurovisceral; blistering photosensitivity (common)
Erythropoietic protoporphyria (EPP)	Ferrochelatase (FECH)	90	Autosomal recessive	Erythropoietic	Nonblistering photosensitivity

*Porphyrias are listed in the order of the affected enzyme in the heme biosynthetic pathway.

†These porphyrias also have erythropoietic features, including increases in erythrocyte zinc protoporphyrin.

‡UROD inhibition in PCT is mostly acquired, but an inherited deficiency of the enzyme predisposes in familial (type 2) disease.

Figure 58-1. Enzymes and intermediates in the heme biosynthetic pathway and the type of porphyria associated with a deficiency of each enzyme (indicated by Ø). Gain-of-function mutation of the erythroid form of ALA synthase is not shown. ADP, ALA dehydratase porphyria; AIP, acute intermittent porphyria; ALA, δ-aminolevulinic acid; ALAD, δ-aminolevulinic acid dehydratase; ALAS, δ-aminolevulinic acid synthase; CEP, congenital erythropoietic porphyria; CoA, coenzyme A; CPO, coproporphyrinogen oxidase; EPP, erythropoietic protoporphyria; FECH, ferrochelatase; HCP, hereditary coproporphyria; PBG, porphobilinogen; PBGD, porphobilinogen deaminase; PCT, porphyria cutanea tarda; PPO, protoporphyrinogen oxidase; SA, sideroblastic anemia; UROD, uroporphyrinogen decarboxylase; UROS, uroporphyrinogen III synthase; VP, variegate porphyria.

TABLE 58-2. Biochemical Findings Including Major Increases in Porphyrins and Porphyrin Precursors in the Human Porphyrins

Porphyria	Erythrocytes	Plasma	Urine	Stool
XLP	Metal-free and zinc protoporphyrin [§]	Protoporphyrin (~634 nm) [†]	* [¶]	Protoporphyrin*
ADP	Zinc protoporphyrin	ALA*	ALA, coproporphyrin III	*
AIP	Decreased PBGD activity (most cases)*	ALA, PBG* (~620 nm, some cases) [†]	ALA, PBG, uroporphyrin	*
CEP	Uroporphyrin I; coproporphyrin I	Uroporphyrin I, coproporphyrin I (~620 nm) [†]	Uroporphyrin I; coproporphyrin I	Coproporphyrin I
PCT and HEP	Zinc protoporphyrin (in HEP)	Uroporphyrin, heptacarboxyl porphyrin (~620 nm) [†]	Uroporphyrin, heptacarboxyl porphyrin	Heptacarboxyl porphyrin, isocoproporphyrins
HCP	*	‡(~620 nm, some cases) [†]	ALA, PBG, coproporphyrin III	Coproporphyrin III
VP	*	Protoporphyrin (~628 nm) [†]	ALA, PBG, coproporphyrin III	Coproporphyrin III, protoporphyrin
EPP	Metal-free protoporphyrin [§]	Protoporphyrin (~634 nm) [†]	* [¶]	Protoporphyrin*

ADP, δ-aminolevulinic acid dehydratase deficiency porphyria; AIP, acute intermittent porphyria; ALA, δ-aminolevulinic acid; CEP, congenital erythropoietic porphyria; EPP, erythropoietic protoporphyria; HCP, hereditary coproporphyria; HEP, hepatoerythropoietic porphyria; PBG, porphobilinogen; PCT, porphyria cutanea tarda; VP, variegate porphyria; XLP, X-linked protoporphyria.

*Porphyrin levels normal or slightly increased.

[†]Fluorescence emission peak of diluted plasma at neutral pH.
