[¶]Increase in urine porphyrins (especially coproporphyrin) only with hepatopathy.

the foundation for the development of animal models of this disorder using halogenated polyaromatic hydrocarbons.^{12,13} Strand and coworkers described the enzyme deficiency in AIP for the first time in 1970,¹⁴ and Bonkovsky and coworkers first reported treatment of a porphyria patient with hemin in 1971.¹⁵ In the past several decades, the enzymes of the heme biosynthetic pathway have been defined in terms of their amino acid composition, genomic and complementary DNA (cDNA) sequences, and crystal structures. Erythroid-specific and housekeeping transcripts have been described for at least four enzymes in the pathway, and progress made in understanding the regulation of heme synthesis in specific tissues, especially the marrow and liver. Multiple mutations have been described in each of the human porphyrias, and some specific treatments introduced.

ETIOLOGY AND PATHOGENESIS

HEME

Heme (iron protoporphyrin IX; Fig. 58-2) is essential for all cells and functions as the prosthetic group of numerous hemoproteins such as hemoglobin, myoglobin, respiratory cytochromes, cytochromes P450 (CYPs), catalase, peroxidase, tryptophan pyrrolase, and nitric oxide synthase. Approximately 85 percent of heme is synthesized in the marrow to meet the requirement for hemoglobin formation; the remainder is synthesized largely in the liver.¹⁶ Most heme synthesized in the liver is required for CYPs, which are located primarily in the endoplasmic reticulum where they turn over rapidly and oxidize a variety of chemicals, including drugs, environmental carcinogens, endogenous steroids, vitamins, fatty acids, and prostaglandins.¹⁷

The term *heme* may refer more specifically to ferrous protoporphyrin IX, and is readily oxidized *in vitro* to hemin, that is, ferric protoporphyrin IX. Hemin has one residual positive charge and is usually isolated as a halide, most commonly as the chloride. In alkaline solution the halide is replaced by a hydroxyl ion to form hematin (Fig. 58-3). Heme can form further hexacoordinated complexes with nitrogenous bases to form a *hemochrome* or *hemochromogen*; for example, pyridine

Figure 58-2. Structure of heme. The pyrrole rings are labeled A through D, according to the nomenclature of Hans Fischer.

Figure 58-3. Forms of iron protoporphyrin IX. The porphyrin macrocycle is represented only by its pyrrole nitrogen atoms.

hemochromogen is useful for identification and quantification of heme and hemoproteins. In medicine, hemin is also a generic term for heme preparations used as intravenous therapies for acute porphyrias, such as lyophilized hematin and heme arginate.

The ferrous iron atom (Fe^{2+}) in heme has six electron pairs, of which four are bound to the pyrrolic nitrogens of the porphyrin macrocycle, leaving two unoccupied electron pairs, one above and the other below the plane of the porphyrin ring. In hemoglobin, one of these pairs is coordinated with a histidine residue of the globin chain. The other coordination site in deoxyhemoglobin is protected from oxidation by the nonpolar environment of surrounding amino acid residues, and is available to bind molecular oxygen for transport from the lung to other tissues. To reversibly bind oxygen, the iron in hemoglobin must be in the ferrous state. Methemoglobin (oxidized hemoglobin) that is generated in erythrocytes is continuously reduced to ferrous hemoglobin by the reduced form of nicotinamide adenine dinucleotide–cytochrome b_5 reductase–cytochrome b_5 system (Chap. 50).

Heme Biosynthesis

Figure 58-4 shows the enzymatic steps involved in heme biosynthesis in eukaryotic cells. The first and last three enzymes are mitochondrial and the intermediate four are cytosolic. Erythroid heme synthesis occurs in marrow erythroblasts and reticulocytes, which contain mitochondria. Circulating erythrocytes lack mitochondria and no longer synthesize heme. They contain residual cytosolic enzymes of the heme biosynthetic pathway, zinc protoporphyrin and a small amount of metal-free protoporphyrin. These enzyme activities and protoporphyrin decline during the life span of erythrocytes in the circulation.

δ -Aminolevulinic Synthase (Succinyl Coenzyme A: Glycine C-Succinyl Transferase; Enzyme Commission (EC) 2.3.1.37) The first enzyme in the heme biosynthetic pathway catalyzes the condensation of glycine and succinyl coenzyme A (CoA) to form ALA (see Fig. 58-4, step 1), and requires pyridoxal 5'-phosphate as a cofactor. δ -Aminolevulinic acid synthase (ALAS) in mammalian cells is localized to the mitochondrial matrix.¹⁸ The enzyme is synthesized as a precursor protein in the cytosol and transported into mitochondria. Two separate ALAS genes encode housekeeping (tissue nonspecific) and erythroid-specific forms of the enzyme (ALAS1 and ALAS2, respectively).¹⁹ The gene locus for human ALAS1 is at 3p.21, and for ALAS2 it is at Xp11.2.¹⁹ The human ALAS2 gene encodes a precursor of 587 amino acids, with an Mr of 64,600 Da. Nucleotide sequences for the ALAS2 and the ALAS1 isoforms are approximately 60 percent similar. No homology is observed between the aminoterminal regions, whereas high homology (approximately 73 percent) is seen after residue 197 of the housekeeping form.²¹ The two human ALAS genes appear to have evolved by duplication of a common ancestral gene that encoded a primitive catalytic

Figure 58-4. The heme biosynthetic pathway. The subcellular distribution of the eight enzymes and their substrates and intermediates are shown; enzymes within the light blue shading are located in the mitochondrion, and the others in the cytosol. The substrate positions that are changed are shown in blue, bold lines. ALA, δ -aminolevulinic acid; Copro'gen, coproporphyrinogen; HMB, hydroxymethylbilane; PBG, porphobilinogen; Proto'gen, protoporphyrinogen; Uro'gen, uroporphyrinogen. a, $-\text{CH}_2\text{COOH}$; p, $-\text{CH}_2-\text{CH}_2-\text{COOH}$; m, $-\text{CH}_3$; v, $-\text{CH}=\text{CH}_2$; carbon groups shown in red, carbon atom derived from the α -carbon of glycine; *, location of the α -carbon atom from glycine in the pyrrole ring that undergoes reversion. *Step 1*, ALA synthase (ALAS); *step 2*, ALA dehydratase (ALAD); *step 3*, PBG deaminase (PBGD); *step 4*, uro'gen III cosynthase (UROS); *step 5*, uro'gen decarboxylase (UROD); *step 6*, copro'gen oxidase (CPO); *step 7*, proto'gen oxidase (PPO); *step 8*, ferrochelatase (FECH).

site. Subsequently the DNA sequences were modified to encode gene-specific regulatory regions, functioning mostly at the amino termini.²²

The promoter in the human ALAS2 gene contains several putative erythroid-specific *cis*-acting elements including both a GATA-1 and an NF-E2 binding site.^{22,23} Both GATA-1 and NF-E2 are erythroid transcription factors that also bind other DNA sites, such as the promoters of the human β -globin, porphobilinogen deaminase (PBGD), and uroporphyrinogen synthase (UROS) genes.²⁴ Thus, expression of ALAS2 is under the regulatory influence of erythroid transcription factors such as GATA-1 and is coordinated with expression of other genes involved in hemoglobin synthesis. Additionally, ALAS2 mRNA

contains an iron-responsive element in its 5'-untranslated region,²³ similar to mRNAs encoding ferritin and the transferrin receptor (Chap. 42).²⁵ Gel retardation analysis shows that the iron-responsive element in ALAS2 mRNA is functional and suggests that translation of the erythroid-specific mRNA is directly linked to the availability of iron, or heme, in erythroid cells.²⁶

In the liver, synthesis of ALAS1 is induced by a variety of chemicals, including drugs and steroids that increase the demand for hepatic CYPs. Upstream enhancer elements in the ALAS1 gene and certain hepatic CYP genes respond to inducing chemicals and interact with the pregnane X receptor (PXR).²⁷ Hemin represses synthesis of ALAS1

in liver,²⁸ accounting for the beneficial effects of intravenous treatment of the acute porphyrias with heme. At higher concentrations, heme induces heme oxygenase, resulting in its enhanced catabolism.²⁹ Thus, hepatic heme availability is balanced between the rate of synthesis controlled primarily by ALAS1 and the rate of degradation controlled by heme oxygenase, both of which are regulated by heme at different intracellular concentrations. ALAS1 is also upregulated by the peroxisomal proliferator-activated cofactor 1 α (PGC-1 α),³⁰ a coactivator of nuclear receptors and transcription factors. Transcriptional regulation of ALAS1 by PGC-1 α is mediated by interaction of NRF-1 (nuclear regulatory factor 1) and FOXO-1 (a forkhead family member) with the ALAS1 promoter.³¹ When glucose levels are low, transcription of PGC-1 α is upregulated,³² in turn increasing ALAS1, which might precipitate an attack of acute porphyria in an individual with the appropriate inherited enzyme deficiency. Thus, upregulation of PGC-1 α provides an explanation for the induction of acute attacks of porphyria with fasting, as well as the therapeutic value of glucose loading.

Regulation of heme synthesis in erythroid cells is distinct from the liver. ALAS2 expression in erythroid cells is increased during erythroid differentiation when heme synthesis is increased.^{33,34} Experimentally, ALAS2 is often upregulated by heme, whereas in liver ALAS1 is downregulated by heme. The β subunit of human ATP-specific succinyl CoA synthetase (SCS- β A) associates with human ALAS2 but not with ALAS1, and thereby contributes to heme synthesis in the marrow.³⁵

More than 20 ALAS2 mutations are associated with X-linked sideroblastic anemia (Chap. 59); many are in exon 9, which contains the binding site for pyridoxal 5'-phosphate (K391), and these cases are typically responsive to high doses of pyridoxine. At least one mutant enzyme (D190V) in a patient with pyridoxine-refractory X-linked sideroblastic anemia,³⁶ failed to associate with SCS- β A, whereas other ALAS2 mutants did not have this property. The mature D190V mutant protein, but not its precursor protein, underwent abnormal processing; indicating that appropriate association of SCS- β A and ALAS2 is necessary for functioning of ALAS2 in mitochondria.³⁶ Gain-of-function mutations of ALAS2 have been identified in patients with XLP.³⁷

δ -Aminolevulinic Dehydratase (Porphobilinogen Synthase; δ -Aminolevulinic Hydrolase; EC 4.2.1.24) ALA dehydratase (ALAD) is a cytosolic enzyme that catalyzes the condensation of two molecules of ALA to form the monopyrrole PBG, with removal of two molecules of water (see Fig. 58–4, step 2). The enzyme functions as a homo-octamer, and requires intact sulfhydryl groups and zinc for activity. ALAD activity is inhibited by sulfhydryl reagents³⁸ and by lead, which displaces zinc.³⁹ In lead poisoning (Chap. 52), erythrocyte ALAD activity is markedly inhibited, urinary ALA and coproporphyrin excretion increased, erythrocyte zinc protoporphyrin elevated, and neurologic symptoms resemble those seen in acute porphyrias.⁴⁰ 4,6-Dioxoheptanoic acid (succinylacetone) is a substrate analogue and potent inhibitor of ALAD,^{41,42} and is a byproduct of the enzyme deficiency in hereditary tyrosinemia type I. This substance is found in urine and blood of patients with this disease, who may also have increased ALA and symptoms resembling acute porphyrias.⁴³

Human ALAD mRNA has an open-reading frame of 990 bp, encoding a protein with an Mr of 36,274.⁴⁴ Sequences known to be essential for enzymatic activity, are those for the active site lysine residues and for the cysteine- and histidine-rich zinc binding sites. The gene for human ALAD is localized to chromosome 9p34.⁴⁵

Studies using [¹⁴C]-ALA have shown that of the two ALA molecules used as substrate, the ALA molecule contributing the propionic acid side is initially bound to the enzyme.³⁸ The tertiary structure of the yeast ALAD has been solved to 2.3-Å resolution, revealing that each subunit adopts a triosephosphate isomerase barrel fold with a 39-residue

N-terminal arm. Pairs of monomers then wrap their arms around each other to form compact dimers, and these dimers associate to form a 422 symmetric octamer.⁴⁶ All eight active sites are on the surface of the octamer and possess two lysine residues (210 and 263). The Lys263 residue forms a Schiff base link to the substrate. The two lysine side chains are close to two zinc binding sites. One binding site is formed by three cysteine residues; the other involves Cys234 and His142.

Although there are no tissue-specific ALAD isozymes, the ALAD mRNA has two splice variants, a housekeeping (1A) and an erythroid-specific (1B) form.⁴⁵ In both humans and mice, the promoter region upstream of exon 1B contains GATA-1 sites, providing for significant tissue-specific control of these transcripts.⁴⁷

The human enzyme is polymorphic with two common alleles that occur in three combinations (1–1, 1–2, and 2–2).⁴⁴ The allele 2 sequence differs from allele 1 only by a G→C transversion of nucleotide 177 in the coding region, resulting in replacement of lysine by asparagine, a more electronegative amino acid.⁴⁸ ALAD exists primarily as a homo-octamer. Mutations associated with ALAD porphyria favor formation of the less active hexamer.^{49,50}

Porphobilinogen Deaminase (Hydroxymethylbilane Synthase; Porphobilinogen Ammonia-Lyase [Polymerizing], EC 4.3.1.8) The fourth enzyme in the heme biosynthetic pathway catalyzes the deamination and condensation of four molecules of PBG to yield the linear tetrapyrrole hydroxymethylbilane (HMB; see Fig. 58–4, step 3).⁵¹ PBG deaminase was previously known as *uroporphyrinogen I synthase*, and the enzyme activity is commonly measured in the laboratory after converting HMB to uroporphyrin I.

This enzyme has a unique cofactor, which is a dipyrromethane that binds the pyrrole intermediates at the catalytic site until six pyrroles (including the dipyrrole cofactor) are assembled in a linear fashion, after which the tetrapyrrole HMB is released.⁵² The apo-deaminase generates the dipyrrole cofactor to form the holo-deaminase, and this occurs more readily from HMB than from PBG.⁵³ High concentrations of PBG may inhibit formation of the holo-deaminase.

The gene encoding human PBG deaminase maps to chromosome 11q23→11qter,⁵⁴ and consists of 15 exons spread over 10 kb of DNA.⁵⁵ Distinct erythroid-specific and housekeeping isoforms are produced through alternative splicing of two distinct primary mRNA transcripts arising from two promoters.⁵⁶ The housekeeping promoter is upstream of exon 1 and is active in all tissues, while the erythroid-specific promoter, which is upstream of exon 2, is active only in erythroid cells. The human housekeeping and erythroid-specific enzymes isoforms contain 361 and 344 amino acid residues, respectively.⁵⁷ Of the additional 17 residues at the N-terminal end of the housekeeping form, 11 are encoded by exon 1, and 6 by a short segment of exon 3 that immediately precedes a methionine codon that initiates translation of the erythroid isoform. Erythroid-specific *trans*-acting factors, such as GATA-1 and NF-E2, recognize sequences in the erythroid promoter.⁵⁸ A 1320-bp stretch of perfect identity is present between the erythroid and the nonerythroid PBG deaminase, but with a mismatch in the first exon at their 5' extremities. An additional inframe AUG codon present 51 bp upstream from the initiating codon of the erythroid cDNA accounts for the additional 17 amino acid residues at the N-terminus of the housekeeping isoform. Accordingly, a splice site mutation at the last position of exon 1, or a base transition in intron 1, in certain patients with AIP results in decreased PBG deaminase expression in nonerythroid tissues including the liver, but not in erythroid cells, because transcription of the gene in erythroid cells starts downstream of the site of the genetic lesion.⁵⁹

Uroporphyrinogen III Synthase (Uroporphyrinogen III Cosynthase; EC 4.2.1.75) UROS, a cytosolic enzyme, catalyzes the formation of uroporphyrinogen III from HMB. The process involves an intramolecular

rearrangement that affects only ring D of the porphyrin macrocycle (see Fig. 58–4, *step 4*).⁵¹ In the absence of this enzyme, HMB spontaneously forms the ring structure uroporphyrinogen I, which, like the III isomer, is a substrate for uroporphyrinogen decarboxylase (UROD). However, because coproporphyrinogen I is not a substrate for coproporphyrinogen oxidase (CPO) the type I porphyrinogen isomers are not further metabolized, and only the type III isomers are precursors of heme.

The UROS cDNA has an open-reading frame of 798 bp, and the predicted protein product consists of 263 amino acid residues, with an Mr of 28,607 Da.²⁰ The amino acid compositions of the hepatic and the purified erythrocyte enzyme are essentially identical, and no tissue-specific isoforms have been described.

The interspecies homology for the UROS proteins is below 10 percent, depending on the number and divergence of the species being compared. However, the crystal structures of uroporphyrinogen III synthase from human and *Thermus thermophilus* have been solved and are very similar.^{60,61} The structure supports a mechanism that includes the formation of a spirolactam intermediate by positioning the A and D rings such that the noncatalytic closure, to form uroporphyrinogen I, is not possible.⁶¹

Uroporphyrinogen Decarboxylase (EC 4.1.1.37) UROD is a cytosolic enzyme that catalyzes the sequential removal of the four carboxylic groups of the carboxymethyl side chains in uroporphyrinogen to yield coproporphyrinogen (see Fig. 58–4, *step 5*). The four successive decarboxylation reactions yield 7-, 6-, 5-, and 4-carboxylated porphyrinogens. Increased amounts of these intermediates can be identified as the corresponding oxidized porphyrins in liver, plasma, urine and stool in human PCT and in laboratory animal models in which hepatic UROD is inhibited. An inhibitor of UROD activity, a partially oxidized substrate molecule,⁶² is produced in liver of experimental animals in response to halogenated polycyclic aromatic hydrocarbons such as hexachlorobenzene, dioxin, and polychlorinated biphenyls, as well as other compounds able to activate the Ah receptor.⁶³ This porphomethene compound is believed to explain UROD inhibition in human PCT.⁶² Human UROD is a 42-kDa polypeptide encoded by a single gene containing 10 exons spread over 3 kb and functions as a homodimer.⁶⁴ The gene has been mapped to chromosome 1p34.⁶⁵

Although the UROD gene contains two initiation sites, both sites are used with the same frequencies in all tissues, and the gene is transcribed into a single mRNA.⁶⁶ Recombinant human UROD purified to homogeneity has been crystallized, and its crystal structure was determined at 1.60-Å resolution.⁶⁷ The purified protein is a dimer with a dissociation constant of 0.1 μ M.⁶⁷ The 40.8-kDa polypeptide forms a single domain with a distorted (β/α)₈-barrel fold, and a distinctive deep cleft for the enzyme's active site is formed by loops at the C-terminal ends of the barrel strands. The protein forms a homodimer with one active-site cleft per monomer located adjacent to its neighbor in the dimer. The structure creates a single extended cleft that is large enough to accommodate two substrate molecules in close proximity. Although both uroporphyrinogen I and III are metabolized by UROD, only the coproporphyrinogen III isomer is further metabolized to heme.⁶⁸

Coproporphyrinogen Oxidase (EC 4.1.1.37) CPO is located on the outer surface of the inner mitochondrial membrane in mammalian cells.⁶⁹ The enzyme catalyzes the removal of the carboxyl group and two hydrogens from the propionic groups of pyrrole rings A and B, forming vinyl groups at these positions (see Fig. 58–4, *step 6*). The enzyme is isomer specific for coproporphyrinogen III, yielding protoporphyrinogen IX (see Fig. 58–4, *step 6*). The gene for human CPO has been assigned to chromosome 3q12, spans approximately 14 kb, and consists of seven exons and six introns.⁷⁰ cDNA cloning for this enzyme was first reported in mouse erythroleukemia cells.⁷¹ The predicted mouse protein comprises

354 amino acid residues (Mr = 40,647 Da), with a putative leader sequence of 31 amino acid residues. The result is a mature protein consisting of 323 amino acid residues (Mr = 37,225 Da).⁷¹ Potential regulatory elements exist in the GC-rich promoter region of the gene, such as six Sp1, four GATA-1, one CACCC site, and the CPO gene promoter regulatory element (CPRE).⁷² CPRE binds specifically to a CPRE-binding protein, which has a leucine-zipper-like structure and serves as a DNA sequence-specific transcription factor that regulates gene expression.⁷² Tissue-specific expression of CPO is significant. For example, binding proteins to the Spl-like element, CPRE and GATA-1, cooperatively function in CPO gene expression in erythroid cells. The CPRE-binding protein by itself plays a principal role in basal expression of CPO in nonerythroid cells.⁷³ CPO mRNA increases during erythroid cell differentiation.⁷⁴

Newly synthesized human CPO contains a 110-amino-acid N-terminal signal peptide,⁷⁴ which is removed during transport into the intermembrane space of mitochondria, yielding a mature protein of 354 amino acid residues (Mr = 36,842 Da). A five-base insertional mutation in the middle of this presequence has been described in one patient with HCP.⁷⁵

Protoporphyrinogen Oxidase (EC 1.3.3.4) The penultimate step in heme biosynthesis is the oxidation of protoporphyrinogen IX to protoporphyrin IX, with removal of six hydrogen atoms. This reaction is mediated by the mitochondrial enzyme protoporphyrinogen oxidase (PPO; see Fig. 58–4, *step 7*). Human PPO cDNA has been cloned.⁷⁶ The gene is present as a single copy per haploid genome, at chromosome 1q22.⁷⁷ PPO consists of 477 amino acids with an Mr of 50,800 Da. The deduced protein exhibits a high degree of homology over its entire length to the amino acid sequence of PPO encoded by the *HEMY* gene of *Bacillus subtilis*. PPO has been crystallized and the structure shows that the enzyme is a homodimer.⁷⁸ Sequences required for import into the mitochondria have been identified.⁷⁹ Expression of PPO is upregulated, approximately fourfold, in the developing erythron from two GATA-1 binding sites located in exon 1.⁸⁰

Ferrochelatase (Protoheme-Ferrolase; EC 4.99.1.1) The final step of heme biosynthesis is the insertion of iron into protoporphyrin IX. This reaction is catalyzed by the mitochondrial enzyme ferrochelatase (FECH; see Fig. 58–4, *step 8*). The enzyme uses protoporphyrin IX, rather than its reduced form, as substrate, but requires the reduced ferrous form of iron.⁸¹ The gene encoding human FECH has been assigned to chromosome 18q.⁸² Two FECH mRNA species, approximately 2.5 kb and approximately 1.6 kb in size, are derived from the utilization of two alternative polyadenylation sites in the mRNA. The human FECH gene contains a total of 11 exons and has a minimum size of approximately 45 kb. A major site of transcription initiation is at an adenine, 89 bp upstream from the translation-initiating ATG. The promoter region contains a potential binding site for several transcription factors, Sp1, NF-E2, and GATA-1, but not a typical TATA or CAAT sequence. The transcripts are identical in all tissues examined.

The crystal structure of *B. subtilis* FECH has been determined at 1.9-Å resolution.⁸³ Subsequently the structure of human FECH was solved and the location of the substrate binding site determined. The enzyme functions as a homodimer and associates with the inside of the inner mitochondrial membrane.⁸³ The mechanism of catalysis has not been identified nor has a function been assigned to the ²Fe-²S cluster that is present in human FECH. Lead inhibits FECH, and a structure of the protein-lead complex has been solved indicating a critical role for the pi helix in catalysis.⁸⁴ FECH seems to have a structurally conserved core region that is common to the enzyme from bacteria, plants, and mammals.

Control of Heme Synthesis in the Liver and Erythroid Cells

Tissue-specific aspects of heme synthesis have been studied mostly in erythroid cells and hepatocytes, as the marrow and liver have the

greatest requirements for heme. The rate of heme synthesis in the liver is largely regulated by ALAS1 activity. The synthesis of ALAS1, in turn, is under feedback control by heme, which regulates ALAS1 at the levels of transcription, translation, and transfer into mitochondria. Many chemicals, hormones, and drugs increase the synthesis of hepatic CYPs, which increases the demand for heme and lead to induction of ALAS1. In addition, the ALAS1 gene contains upstream enhancer elements that are responsive to inducing chemicals and interact with the PXR. Therefore, ALAS1 and CYPs are subject to direct induction by xenobiotics and certain steroids.²⁷ Chemical exposures that induce hepatic heme oxygenase and accelerate the destruction of hepatic heme, or inhibit heme formation, can also induce hepatic ALAS1.

ALAS2 is not inducible in erythroid cells by drugs that induce ALAS1 in hepatocytes.⁸⁵ The synthesis of ALAS2 is uninfluenced, or often upregulated, by hemin, at both the transcriptional and the translational levels. Hemin treatment of marrow cultures increases erythroid colony-forming units,⁸⁶ whereas hemin treatment of hepatocytes inhibits synthesis of ALAS1 and CYPs. An additional distinct difference in these ALAS isoforms is that SCS- β A associates with ALAS2 but not with ALAS1, suggesting a tissue-specific difference in mitochondrial transport of these isoforms.

ERYTHROPOIETIC PORPHYRIAS

There are two major erythropoietic porphyrias in humans. CEP is caused by mutations of the *UROS* gene. It is one of the least-common porphyrias, but is well known as a result of its long history and the severe photomutilation of exposed areas such as the face and fingers that is a dramatic feature in many cases (Fig. 58–5). EPP, which is caused by *FECH* mutations, is the third most common porphyria, and the most common in children, but was not well described until 1965. XLP is much less common, has the same phenotype as EPP, but normal *FECH* activity. In 2008, the discovery of gain-of-function mutations in the last exon of *ALAS2* provided an explanation for the increased level of erythrocyte protoporphyrin seen in this type of protoporphyria.³⁷ Characteristics in most patients with erythropoietic porphyrias that are distinct from the hepatic porphyrias include childhood onset, stable symptoms and levels of porphyrins over time, and severity largely determined by genotype rather than factors that affect the heme pathway, primarily in the liver. Substantial increases in erythrocyte zinc protoporphyrin in ADP and homozygous forms of other hepatic porphyrias, such as HEP (the homozygous form of familial PCT), AIP, HCP, and VP, suggest that an erythropoietic component may be important in these conditions.⁸⁷

CONGENITAL ERYTHROPOIETIC PORPHYRIA

Definition and History

CEP is caused by a deficiency of UROS (see Fig. 58–4, *step 4*), is an autosomal recessive condition, and is also known as Günther disease. It results in accumulation and excretion of isomer I porphyrins, especially uroporphyrin I and coproporphyrin I (see Table 58–1 and Fig. 58–1). Characteristic manifestations of CEP include chronic, severe photosensitivity and hemolytic anemia evident in early childhood. Atypical presentations include milder disease that resembles PCT, and onset during adult life often in association with a myeloproliferative disorder.⁸⁸ Early case descriptions of CEP appeared in 1874 and 1898,³ and approximately 130 cases were reported up to 1997.⁸⁹ However, some of these patients may have had HEP, which has very similar clinical features. Perhaps the most well-known patient was Mathias Petry, who survived until age 34, and beginning in 1915, worked with the porphyrin chemist Hans Fisher, providing samples for early studies of porphyrin chemistry.⁹⁰

Figure 58–5. A 23-year-old Scottish fisherman with congenital erythropoietic porphyria and scarring and mutilation of the face, ears, and digits as a consequence of repeated sun exposure. He was described in 1898 as having red urine containing excess porphyrins and “hydroa aestivale,” because the symptoms, which began at age 3 years, worsened in early summer. A 26-year-old brother was similarly affected. (Reproduced with permission from Anderson TM: *Hydroa aestivale* in two brothers, complicated with the presence of haematoporphyrin in the urine. *Br J Dermatol* 10:1, 1898.)

Pathophysiology

The uroporphyrinogen III synthase defects in CEP are remarkably heterogeneous at the molecular level, with at least 46 different mutations of the *UROS* gene, and one *GATA-1* mutation reported as of this writing.⁸⁷ The *UROS* mutations include deletions, insertions, rearrangements, splicing abnormalities, and both missense and nonsense mutations.

The missense mutations are well distributed throughout the gene. Of the 12 single-base substitutions, four (T228M, G225S, A66V, A104V) were hotspot mutations, occurring at CpG dinucleotides.⁹¹ The identification of a mutation that altered the penultimate nucleotide in exon 4, resulting in an E81D mutation, also produced exon skipping on approximately 85 percent of the transcripts from that allele. With the exception of V82F, all CEP missense mutations occurred in amino acid residues that are conserved in both the mouse and the human enzyme.

Genotype–phenotype correlation in CEP was studied by prokaryotic expression of mutant *UROS* cDNAs. Mean activities of the mutant enzymes expressed in *Escherichia coli* ranged from 0 to 36 percent of the activity expressed by the normal cDNA. The majority of the mutant cDNAs expressed polypeptides with no enzymatic activity. However, V82F, E81D, A66V, A104V, and V99A showed 36, 30, 15, 8, and 6 percent enzyme activity, respectively, compared with the normal control. A66V and V82F were thermodynamically unstable mutants.⁹¹ Homolelism for C73R, the most common mutation, found in five patients, was associated clinically with the most severe phenotypes, such as hydrops fetalis and transfusion dependency from birth.

Pathogenesis of the Clinical Findings

Porphyrins in their oxidized state are reddish, fluorescent, and photosensitizing, whereas porphyrin precursors and the reduced porphyrinogens are colorless and nonfluorescent. Most marrow normoblasts in CEP display marked fluorescence as a result of porphyrin accumulation (located principally in the nuclei, probably because of fixation artifact).⁹² Anemia and the excess production and excretion of porphyrins is largely accounted for by ineffective erythropoiesis in the marrow. Porphyrin concentrations are also increased in circulating erythrocytes, and intravascular hemolysis may result from exposure to light in the dermal capillaries, causing erythrocyte damage and lysis or uptake by the spleen. Splenomegaly is very common in CEP and is presumed to be secondary to the hemolytic process. The excess porphyrins that are produced by the marrow or released by hemolysis are transported in plasma to the skin, leading to photosensitivity.

Clinical Features

Severe cutaneous photosensitivity is noted soon after birth in most cases. The disease may be recognized even earlier as a cause of hydrops fetalis. Phototherapy for hyperbilirubinemia may cause severe cutaneous burns and scarring in newborns with unrecognized CEP. Brown staining of the teeth by porphyrins (erythrodontia) is evident when the teeth erupt. Blistering and scarring resemble those found in PCT, but are usually much more severe, reflecting the much higher plasma porphyrin levels observed in CEP. Some cases are relatively mild, and can closely mimic PCT. Late-onset cases are often associated with myeloproliferative disorders, with expansion of a clone of erythroid cells bearing a somatic mutation and displaying UROS deficiency.⁸⁸

Subepidermal bullous lesions are characteristic, and progress to crusted erosions that heal with scarring and areas of hyper- and hypopigmentation. Also common is hypertrichosis, which is sometimes severe, and alopecia. Loss of facial features and digits are common and result from recurrent blisters, infection, and scarring. Fingers may be shortened and tapered as a consequence of scarring and contraction of the skin during childhood growth. Erythrodontia, with brown staining and red fluorescence of the teeth under long-wave ultraviolet light is characteristic, and results from deposition of porphyrins in the developing deciduous and permanent teeth *in utero*. Porphyrins are also deposited in bone. The skeleton is also affected by expansion of the marrow, leading to pathologic fractures, vertebral compression, short stature, and osteolytic and sclerotic lesions. Vitamin D deficiency resulting from avoiding sunlight might also contribute.

Anemia may be severe and lead to transfusion dependence in the more severe cases. Uncorrected anemia can increase erythropoiesis, which, in turn, is a stimulus to porphyrin production by the abnormal erythropoietic cells in the marrow. Erythrocytes exhibit polychromasia, poikilocytosis, anisocytosis, and basophilic stippling, and reticulocytes and nucleated red blood cells are increased.⁹³

Diagnosis

CEP may be suspected even before birth if a sibling is known to have CEP. However, the family history is often negative. CEP should be suspected as a cause of hydrops fetalis, as the disease can be diagnosed and treated *in utero*. Aspirated amniotic fluid is dark brown in color and contains large amounts of porphyrins. The diagnosis of CEP is often made after birth when pink to dark-brown staining of the diapers, with red fluorescence under long-wave ultraviolet light, is noted. Cutaneous vesicles and bullae on sun-exposed areas may be severe, with scarring.

Urinary porphyrin excretion is markedly increased, and often in the range of 50 to 100 mg/day (normal: up to ~0.3 mg/day). Uroporphyrin I and coproporphyrin I account for most of the increase, although the III isomers and hepta-, hexa-, pentacarboxylate porphyrins are

also increased. Fecal porphyrins are increased, and are predominantly coproporphyrin I. Plasma total porphyrins are markedly increased as well, with a pattern of individual porphyrins similar to that in urine. Markedly increased erythrocyte porphyrins are predominantly uroporphyrin I and coproporphyrin I, although protoporphyrin IX may predominate especially in milder cases.

CEP must be distinguished by biochemical testing from other causes of blistering skin lesions. HEP can present with photosensitivity in early childhood. Mild cases of CEP may be misdiagnosed as PCT.

The diagnosis should be confirmed in all cases by DNA studies, which can identify causative mutations in almost all cases. This is especially important for genetic counseling and for prenatal diagnosis in subsequent pregnancies. Demonstration of a GATA-1 mutation in one case, illustrates that on occasion a genetic defect outside the heme biosynthetic pathway can cause CEP.⁹³

Therapy

Patients should be advised that to avoid severe scarring and loss of facial features and digits it is essential to avoid sunlight, trauma to the skin, and infections. Topical sunscreens that block long-wave ultraviolet light (ultraviolet A light) and oral treatment with β -carotene are somewhat helpful,⁹⁴ but are marginally beneficial in most cases. Erythrocyte transfusions are essential in patients with severe anemia.⁹⁵ Transfusions to maintain the hematocrit above 35 percent, with an iron chelator to avoid iron overload, has been beneficial in some cases.⁹⁶ Hydroxyurea to reduce erythropoiesis and porphyrin production may also be considered.⁹⁷ Splenectomy has provided short-term benefit. Oral charcoal reportedly was quite effective in one patient,⁹⁸ and ascorbic acid and α -tocopherol improved anemia in another.⁸⁹ Unaffected infants born to mothers with CEP may have erythrodontia as a result of exposure to maternal porphyrins before birth.⁹⁹

Hematopoietic stem cell transplantation is the treatment of choice when a suitable donor is available, especially for young patients.¹⁰⁰ When transplantation is successful, there is marked clinical improvement and reduction in porphyrin levels, even if these are not completely normalized. Gene therapy is being explored using retroviral and lentiviral vectors and hematopoietic stem cells from patients with CEP.^{101,102}

ERYTHROPOIETIC PROTOPORPHYRIA

Definition and History

EPP is caused by a partial deficiency of FECH (see Fig. 58-4, *step 8*) activity, which results in the accumulation of the substrate protoporphyrin in the marrow. XLP has the same phenotype but is much less common, and is a result of ALAS2 gain-of-function mutations (ALAS; see Fig. 58-1).³⁷ EPP and XLP are characterized by onset of nonblistering cutaneous photosensitivity in early childhood. EPP is the most common porphyria in children and the third most common in adults. Reported prevalence varies between 5 and 15 cases per 1 million individuals.¹⁰³⁻¹⁰⁵ Protoporphyrinic hepatopathy is a potentially fatal complication estimated to occur in less than 5 percent of patients.

Pathophysiology

In most families, EPP is best described as an autosomal recessive disease, in which a severe *FECH* mutation is inherited from one parent and a low-expression (hypomorphic) *FECH* allele from the other. More than 75 different severe mutations, including nonsense, missense, and splice-site mutations, and deletions, insertions, and rearrangements have been described. Splicing mutations are most common. Recombinant human FECH, when engineered to have individual exon skipping for exons 3 through 11, lacks significant enzyme activity when expressed in *E. coli* and almost all such variants lacked the [²Fe-²S] cluster.¹⁰⁶

EPP was usually described in the past as an autosomal dominant disorder, with variable penetrance. However, it was noted that EPP patients have only 30 percent or less of normal FECH activity, rather than 50 percent, which would be expected in an autosomal dominant condition. It was then shown that, in addition to a severe FECH mutation, a low-expression (hypomorphic) intronic polymorphism (a -23C→T transition) is found in the other FECH allele of patients with EPP, which is inherited from the other parent.^{107–109} This transition favors the use of a cryptic acceptor splice site 63 bases upstream of the normal splice site. The aberrantly spliced mRNA contains a premature stop codon and is degraded by a nonsense-mediated decay mechanism.¹⁰⁹ The result is a lower steady-state level of wild-type FECH mRNA. Coinheritance of the hypomorphic allele in *trans* to a loss-of-function mutant allele was found in 98 percent of French cases with EPP,¹¹⁰ and with a similar frequency in South African patients.¹⁰⁵ The frequency of the IVS3–48C hypomorphic allele is common in the white population, and by itself has no phenotype. Its frequency varies widely in different populations and relates to the observed differences in the prevalence of EPP.^{103–105}

Other underlying genetic mechanisms must be considered in newly identified EPP families. In a few families, a severe FECH mutation, at least one of which must produce some FECH enzyme, is inherited from each parent and the hypomorphic allele is not present. Interestingly, EPP in such families is sometimes associated with seasonal palmar keratoderma, unusual neurologic symptoms, less-than-expected increases in erythrocyte protoporphyrin and absence of liver dysfunction.¹¹¹

XLP was first perceived as a variant form of EPP in which FECH mutations were absent. After family studies suggested sex-linked inheritance, gain-of-function mutations of ALAS2 (the only heme pathway enzyme found on the X chromosome) were discovered.³⁷ This is the only porphyria caused by mutations of ALAS, the first enzyme in the pathway.

EPP can develop late in life in patients with clonal hematologic disorders and expansion of a clone of hematopoietic cells with mutations of a FECH allele.^{112,113} For example, a patient with a myeloproliferative disorder later developed severe EPP because of clonal expansion of a cell of erythropoietic lineage with a FECH deletion and the IVS3–48C/T polymorphism, and died of EPP-induced liver disease.¹¹⁴

Pathogenesis of the Clinical Findings

Marrow reticulocytes are thought to be the primary source of the excess protoporphyrin in EPP.^{115,116} Most of the excess erythrocyte protoporphyrin in circulating erythrocytes is found in younger cells as metal-free protoporphyrin (i.e., not complexed with zinc), in contrast to other conditions associated with increased erythrocyte protoporphyrin content. Metal-free protoporphyrin declines much more rapidly with red cell age than it does zinc protoporphyrin.^{115,116} Metal-free protoporphyrin, but not zinc protoporphyrin, is released from erythrocytes following solar irradiation, which may explain why lead intoxication and iron deficiency, which are associated with elevated erythrocyte zinc protoporphyrin levels, are not associated with photosensitivity.¹¹⁷ Excess metal-free protoporphyrin enters plasma from reticulocytes, as well as from circulating erythrocytes, and is taken up by hepatocytes, excreted in bile and feces, and may undergo enterohepatic recirculation. Hepatocytes may also provide a limited additional source of excess protoporphyrin in this disease.

Light-excited protoporphyrin in EPP generates free radicals and singlet oxygen,¹¹⁸ which in EPP can lead to peroxidation of lipids¹¹⁹ and crosslinking of membrane proteins. Skin irradiation in EPP patients leads to complement activation and polymorphonuclear chemotaxis, which contributes to the development of skin pathology.¹²⁰ Skin histopathology is not specific but may include thickened capillary walls in the papillary dermis surrounded by amorphous hyaline-like deposits,

immunoglobulin, complement, and periodic acid-Schiff–positive mucopolysaccharides.¹²¹ Basement membrane abnormalities are less marked than in other forms of porphyria.¹²²

Protoporphyrin hepatopathy is a feared complication that develops in less than 5 percent of patients, and is attributed to the cholestatic effects of excess protoporphyrin presented to the liver. This complication may begin with chronic abnormalities in liver function tests and then progress rapidly as a vicious cycle of increasing protoporphyrin levels in plasma and erythrocytes and worsening liver function and photosensitivity. Hepatopathy is sometimes precipitated by another cause of liver dysfunction such as viral or alcoholic hepatitis. Protoporphyrin is cholestatic, and can form crystalline structures in hepatocytes and impair mitochondrial function, leading to decreased hepatic bile formation and flow.^{123,124} Accumulated protoporphyrin may appear as brown pigment in hepatocytes, Kupffer cells, and biliary canaliculi, and these deposits are doubly refractive with a Maltese cross appearance under polarizing microscopy.¹²⁵ DNA microarray studies in explanted livers of patients with hepatopathy revealed significant changes in expression of several genes involved in wound-healing, organic anion transport, and oxidative stress.¹²⁶

Clinical Features

Photosensitivity is present from early childhood in almost all cases. Parents may observe that an affected infant cries and develops skin swelling and erythema when exposed to sunlight. Although EPP is the most common porphyria in children, there is often considerable delay in diagnosis.

Cutaneous photosensitivity in EPP is acute and nonblistering, which is distinctly different from the more chronic, blistering skin manifestations of the other cutaneous porphyrias. Table 58–3 tabulates symptoms in a series of 32 patients with EPP. Skin symptoms are usually worse during spring and summer and affect light-exposed areas, especially of the face and hands. Characteristically, stinging or burning pain develops within 1 hour of sunlight exposure, and if exposure continues is followed by erythema and edema—described as solar urticaria, sometimes with petechiae, and less commonly purpura. Blistering and crusted lesions are uncommon. Artificial lights may contribute to photosensitivity.¹²⁷ Patients typically avoid sunlight and may display no objective cutaneous signs. Repeated light exposure can lead to chronic changes including leathery hyperkeratotic skin especially on the dorsa of the hands and finger joints, mild scarring, and separation of the nail plate (onycholysis).

TABLE 58–3. Common Clinical Features of Erythropoietic Protoporphyrinemia from a Series of 32 Cases

Symptoms and Signs	Incidence (% of Total)
Burning	97
Edema	94
Itching	88
Erythema	69
Scarring	19
Vesicles	3
Anemia	27
Cholelithiasis	12
Abnormal liver function results	4

Data from Bloomer J, Wang Y, Singhal A, et al: Molecular studies of liver disease in erythropoietic protoporphyrinemia, *J Clin Gastroenterol* 2005 Apr;39(4 Suppl 2):S167–S175.

Mild anemia with microcytosis, hypochromia, reduced iron stores, but usually normal serum iron, and serum transferrin receptor-1, is a common feature of EPP,^{115,128,129,130,131} but there is little evidence for impaired erythropoiesis or abnormal iron metabolism,^{129,130} and hemolysis is absent or very mild.^{131,153} Iron accumulation in erythroblasts and ring sideroblasts have been noted in marrow in some patients.¹³² Findings in XLP are similar. Also, iron is proposed to have a role in splicing of FECH mRNA, where decreased iron leads to an increase in incorrect splicing of the mRNA.¹³³ Binding of iron-responsive elements binding proteins (IRPs) to the 5'-iron-responsive element (IRE) in *ALAS2* mRNA, in low iron conditions, prevents translation of *ALAS2* mRNA. When iron is supplemented, the IRPs no longer have high affinity for the *ALAS2* 5'-IRE, leading to increased translation, import into the mitochondria, and enhanced production of ALA.¹³⁴

Precipitating factors that are important in the hepatic porphyrias do not appear to play an important role in EPP. Although more long-term followup studies are needed, porphyrin levels and symptoms typically do not change over time, unless liver dysfunction develops. Concurrent iron deficiency or other marrow problems might also lead to further increases in porphyrin levels and photosensitivity. Pregnancy is reported to lower erythrocyte protoporphyrin levels somewhat and increase tolerance to sunlight.¹³⁵

Neurovisceral manifestations are absent in uncomplicated EPP. Patients with severe protoporphyrin hepatopathy may develop a severe motor neuropathy similar to that seen in the acute porphyrias.¹³⁶ Autosomal recessive EPP associated with palmar keratoderma has also been associated with unexplained neurologic symptoms.¹¹¹

Gallstones containing large amounts of protoporphyrin are common, and may require cholecystectomy at an unusually early age.¹³⁷ Liver function and liver protoporphyrin content are usually normal in EPP. Protoporphyrin hepatopathy, which is the most life-threatening complication of EPP, results from the cholestatic effects of protoporphyrin presented in excess amounts to the liver. It can be the major presenting feature of EPP,¹³⁸ and may be chronic or progress rapidly to death from liver failure. Unnecessary surgery for suspected biliary obstruction can be detrimental and should be avoided.¹²⁴ Operating room lights during liver transplantation or other surgery, especially in patients with hepatopathy, can cause marked photosensitivity with extensive burns of the skin and peritoneum and photodamage of circulating erythrocytes.¹³⁹

Diagnosis

Painful, nonblistering photosensitivity suggests the diagnosis. A substantial elevation of erythrocyte protoporphyrin is expected, but is not specific, as erythrocyte zinc protoporphyrin is predominantly increased in conditions such as homozygous porphyrias (other than most cases of CEP), iron deficiency, lead poisoning, anemia of chronic disease,¹⁴⁰ hemolytic conditions,¹⁴¹ and many other erythrocyte disorders. A unique finding in EPP is increased erythrocyte protoporphyrin with a predominance of metal-free rather than zinc protoporphyrin. This occurs because FECH, which can utilize metals in addition to iron, catalyzes the formation of zinc protoporphyrin, and this activity is deficient in EPP. Because FECH is not deficient in XLP, erythrocytes contain increased amounts of both zinc and metal-free protoporphyrin, although the latter still predominates in most cases.

Consequently, the diagnosis of EPP requires demonstration of an increase in metal-free protoporphyrin in red cells. Amounts of metal-free and zinc protoporphyrin in erythrocytes can be measured by ethanol or acetone extraction or high-performance liquid chromatography. There is confusion about terminology used by different laboratories. For example, the term "free erythrocyte protoporphyrin," refers to protoporphyrin results measured with a hematofluorometer as an indicator of lead exposure, but actually refers to zinc protoporphyrin rather than

metal-free or total protoporphyrin. At this writing, we are aware of only two laboratories in the United States (Mayo Clinic Laboratories and the Porphyria Laboratory at the University of Texas Medical Branch), that reliably report the amounts of total, metal-free, and zinc protoporphyrin, as is needed for confirmation of a diagnosis of EPP. The proportions of metal-free and zinc protoporphyrin can also usually distinguish XLP (50 to approximately 85 percent metal-free protoporphyrin) from EPP (>85 percent metal-free protoporphyrin).

The plasma porphyrin concentration is almost always at least mildly increased in EPP, but often less than in other cutaneous porphyrias, and may be normal in mild cases. Plasma porphyrins in EPP are particularly subject to photodegradation during sample processing unless great care is taken to shield the sample from natural or fluorescent light.¹⁴² For these reasons, measurement of erythrocyte rather than plasma porphyrin should be relied upon for diagnosis of EPP and XLP.

Fecal porphyrins are normal or somewhat increased, and consist mostly of protoporphyrin. Urine porphyrins are normal, except after hepatopathy develops, which causes increases in urinary coproporphyrin as is typical for other forms of liver diseases.

Therapy

Avoidance of the sunlight exposure is important, and often requires changes in lifestyle and the working environment. Topical sunscreens that absorb ultraviolet A and sunblocks containing zinc oxide or titanium dioxide may be helpful. Orally administered β -carotene, which probably quenches activated oxygen radicals,^{143,144} may afford some protection after 1 to 3 months of therapy, but results are variable. A daily dose of 120 to 180 mg or higher is recommended to achieve a serum β -carotene level of 600 to 800 mcg/dL.¹²⁷ Oral cysteine may also quench excited oxygen species and increase tolerance to sunlight in EPP.¹⁴⁵ Other treatments that aim to either increase skin pigmentation or scavenge activated oxygen species have been reviewed¹⁴⁴ and include dihydroxyacetone/Lawsone, vitamin C and narrow-wave ultraviolet B phototherapy to increase melanin.¹⁴⁶ Afamelanotide, an α -melanocyte-stimulating hormone analogue that increases skin melanin, has shown benefit in clinical trials.¹⁴⁷

It is advisable to monitor liver function tests at least yearly, and avoid severe caloric restriction and drugs or hormone preparations that impair hepatic excretory function.^{148,149} Because iron deficiency might be detrimental by further limiting heme synthesis and increasing protoporphyrin accumulation, ferritin levels should be followed in EPP and XLP patients, keeping in mind that ferritin in the lower part of the normal range (especially for women) may indicate depleted iron stores. Iron supplementation has been reported to worsen photosensitivity in some cases (although increases in protoporphyrin levels were not documented) and to correct microcytosis without increasing porphyrin levels in others. Therefore, at present iron supplementation in EPP and XLP is controversial, and systematic studies are needed. Because patients avoid sunlight exposure, vitamin D supplementation is recommended.

Management of protoporphyrin liver disease is difficult. The condition may resolve spontaneously especially if another reversible cause of liver dysfunction, such as viral hepatitis or alcohol, is contributing.^{122,150} Cholestyramine,^{124,151,152} ursodeoxycholic acid,¹⁵³ vitamin E, red blood cell transfusions,¹⁵⁴ plasma exchange, and intravenous hemin may be given in combination to bridge patients until liver transplantation or there is spontaneous improvement.¹⁵⁵ Success of liver transplantation is comparable to that in other liver diseases, even though protoporphyrin hepatopathy may recur in the new liver, a result of the continued erythrocyte protoporphyrin release by the marrow.¹⁵⁶ Acute motor neuropathy has developed in some patients with protoporphyrin liver disease after transfusion¹⁵⁷ or liver transplantation,^{158,159} and is sometimes reversible.¹⁵⁸

Marrow transplantation can achieve remission in human EPP,¹⁶⁰ as well in murine models of protoporphyria.¹⁶¹ Sequential liver and marrow transplantation can correct the overproduction of protoporphyrin by the marrow and prevent recurrence of liver disease.¹⁶² Promising studies in murine models suggest a future role for gene therapy in human EPP.^{163,165}

ACUTE PORPHYRIAS

The acute porphyrias are comprised of four disorders caused by different enzyme deficiencies, and are distinctive for neurologic symptoms that usually occur as acute exacerbations during adult life. Similar symptoms occur in lead poisoning, hereditary tyrosinemia type I, and in some reported cases of porphyria with dual enzyme deficiencies.

δ-AMINOLEVULINIC ACID DEHYDRATASE PORPHYRIA

Definition and History

ADP is an autosomal recessive disorder resulting from severe deficiency of ALAD activity (see Table 58–1 and Fig. 58–1). This is the rarest of the porphyrias, with only six cases documented at the molecular level.^{50,168}

Pathophysiology

All reported cases were males.^{164,166–169} Compound heterozygosity for two distinct ALAD mutations was documented in five cases (see Fig. 58–4, *step 2*).^{167,168} Four (three in Germany and one in the United States) experienced onset of symptoms in their teens, whereas one Swedish case developed severe symptoms in infancy.¹⁶⁶ The sixth patient was a Belgian male who developed ADP at age 63 years and was found to have two inherited base transitions in one allele, and was therefore heterozygous for ALAD deficiency.^{164,169} He also developed polycythemia vera and his erythrocyte ALAD activity was less than 1 percent of normal, while lymphocyte ALAD activity was greater than 20 percent of normal. Heterozygous ALAD deficiency was apparently clinically silent in this patient until there was expansion of a clone of erythroid cells that carried the mutant ALAD allele.¹⁶⁹

Thus ADP is highly heterogeneous at the molecular level, with a total of 11 mutant alleles identified in these 6 patients.¹⁶⁸ An additional mutation was found in a healthy Swedish girl with markedly decreased ALAD activity (12% of normal), which was detected by ALAD measurement during neonatal screening for hereditary tyrosinemia.¹⁷⁰ The same mutation was found in a U.S. male patient with acute porphyria who also had a *CPO* mutation and an unusual pattern of porphyrin precursors and porphyrins reflecting dual enzyme deficiencies.¹⁷¹ Thus, heterozygous ALAD deficiency may rarely be combined with another enzyme deficiency, or may itself cause porphyria if a marrow disorder leads to clonal expansion of the mutant *ALAD* allele.

Human ALAD consists of eight identical oligomers, each with two zinc-binding sites. Lead can bind at least one of these sites and impair enzyme activity. Some mutations found in ADP may affect zinc binding, or favor assembly of a hexameric enzyme with decreased activity. Thus ADP has been described as a conformational disease.⁵⁰

ADP is classified as one of the hepatic porphyrias because it closely resembles the other acute porphyrias. However, the site of overproduction of ALA is not established, and the Swedish infant with severe, early onset disease did not benefit from liver transplantation.¹⁷² Substantial increase in erythrocyte zinc protoporphyrin also suggests an erythroid component. The excess urinary coproporphyrin III in ADP may originate from metabolism of ALA to porphyrinogens in a tissue other than the site of ALA overproduction. Indeed, ALA loading in normal

subjects was shown to cause substantial coproporphyrinuria.¹⁷³ The pathogenesis of the neurologic symptoms is poorly understood, as in other acute porphyrias.

Clinical Features

The four adolescent males had intermittent symptoms resembling other acute porphyrias, including abdominal pain, vomiting, extremity pain, and motor neuropathy, although exacerbating factors were less evident.^{168,174} Two German cases had initial acute attacks and then remained well during 20 years of followup.¹⁷⁵ The third German case¹⁷⁶ and the U.S. case¹⁶⁸ had further attacks and were maintained on prophylactic hemin infusions. The Swedish infant had more severe neurologic disease, including failure to thrive, and died after liver transplantation.¹⁷⁷ The 63-year-old man in Belgium, developed an acute motor polyneuropathy concurrently with a myeloproliferative disorder.^{88,164,178}

Diagnosis

A biochemical diagnosis of ADP includes demonstration of markedly deficient erythrocyte ALAD activity, marked elevation in urinary ALA and coproporphyrin III and erythrocyte zinc protoporphyrin, with little or no increase in urinary PBG. Erythrocyte ALAD activity is approximately half-normal in both parents. Lead poisoning is differentiated by increased blood lead and restoration of ALAD activity *in vitro* by reduced glutathione or dithiothreitol.^{167,179} Although biochemical measurements can strongly suggest ADP, the diagnosis must be confirmed by DNA studies.

Patients with hereditary tyrosinemia type I may also have ALAD inhibition and increased excretion of ALA.⁴³ Dioxoheptanoic acid (succinylacetone), a structural analogue of ALA and a potent ALAD inhibitor, accumulates as a result of an inherited deficiency of fumarylacetoacetate hydrolase in these patients. The presence of this inhibitor can be demonstrated in urine by measuring ALAD activity in normal blood after addition of a patient's urine. ALAD protein is not reduced in this disease.¹⁸⁰

Therapy

Because few cases have been documented, treatment recommendations are based on limited experience. Hemin was beneficial in the four male patients, but there was little or no response to glucose. A long-term preventive hemin regimen was effective in two of these patients. The Swedish infant did not respond to glucose or hemin, and did not improve greatly after liver transplantation.¹⁷² Whether transplantation would benefit less severe cases is unknown. Hemin produced a biochemical response but no clinical improvement in the late-onset case in Belgium, who had a peripheral neuropathy but no acute attacks.¹⁷⁸

ACUTE INTERMITTENT PORPHYRIA

Definition and History

AIP is an autosomal dominant disorder caused by a partial deficiency of PBG deaminase (see Table 58–1 and Fig. 58–1). Symptoms usually occur as acute attacks and are neurologic in origin. In most countries this is the most common acute porphyria and the second most common porphyria. Most individuals who inherit the enzyme deficiency (probably more than 90 percent) never develop symptoms, but are at some risk to develop symptoms after puberty. The first case of acute porphyria was described in 1889 by Stokvis⁵ who noted a relationship of the symptoms to the drug sulfonal, which is related to the barbiturates.

Prevalence of AIP was estimated to be 1 to 2 per 100,000 population in Europe,¹⁸¹ and 2.4 per 100,000 population in Finland.¹⁸² Up to 300 *PBGD* mutations have been described in AIP, with many found in only one or a few families.^{183,184} The disease occurs in all races, but

clusters as a result of founder effects occur in some countries. A founder mutation in northern Sweden is associated with a disease prevalence of 1 per 1500 population.¹⁸⁵ The prevalence of low PBG deaminase activity, which includes latent gene carriers of AIP, is as high as 1 per 500 in the general population of Finland.¹⁸⁶ Based on DNA studies, the minimal prevalence of the AIP-associated genes in France has been calculated to be 1 per 1675 population.¹⁸⁷

Pathophysiology

PBG deaminase is also known as HMB synthase, and formerly as uroporphyrinogen I synthase. *PBGD* mutations have been classified based in part on the presence or absence of cross-reactive immunologic material (CRIM), which indicates the presence of inactive enzyme protein. *Type I* mutations are CRIM-negative, with reduction of both enzyme activity and protein to approximately 50 percent of normal in heterozygotes. *Type II* mutations are associated with reduced *PBGD* activity only in nonerythroid tissue. These patients with “variant AIP” comprise less than 5 percent of AIP patients, and have normal erythrocyte *PBGD* activity and decreased hepatic activity because, as explained earlier in the section on hydroxymethylbilane synthase, transcription of the gene to form the erythroid-specific enzyme starts downstream of the site of the mutation. *Type III* are CRIM-positive mutations that result in decreased activity with structurally abnormal enzyme protein.¹⁸⁸

Pathogenesis of the Clinical Findings

A partial deficiency of *PBGD* rarely causes clinical expression of AIP, and most individuals who inherit this enzyme deficiency remain healthy with normal porphyrin precursor excretion throughout life. Certain drugs and hormones that exacerbate AIP can directly induce *ALAS1*²⁷ and also increase the demand for heme by inducing CYP enzymes, which turn over rapidly and use most of the heme synthesized in the liver.¹⁸⁹

When heme synthesis is stimulated, the partial enzyme deficiency in AIP apparently impairs heme synthesis sufficiently to compromise negative feedback by the regulatory heme pool, which controls synthesis of the rate-limiting enzyme *ALAS1*. This leads to marked induction of *ALAS1* and overproduction of ALA, PBG and porphyrins in the liver.

It is generally accepted, although not proven, that hepatic *PBGD* remains constant at approximately 50 percent of normal activity during exacerbations and remissions of AIP, as in erythrocytes. An early report suggested that the enzyme activity is considerably less than half-normal in liver during an acute attack,¹⁴ but additional data is lacking. It has been suggested that once the disease becomes activated, excess PBG may interfere with assembly of the dipyrromethane cofactor for this enzyme.

Clinical improvement and normalization of porphyrin precursor excretion after liver transplantation in patients with severe AIP is a clear indication that the liver plays an essential role in neuropathic processes in the acute porphyrias.¹⁹⁰ Proposed explanations for neurologic dysfunction in the acute porphyrias include the following. (1) Heme pathway intermediates or products derived from them may be neurotoxic. This hypothesis is most favored, although the evidence is not conclusive. (2) PBG deaminase deficiency in the nervous system tissues may limit heme synthesis and formation of important hemoproteins. For example, decreased activity of the hemoprotein nitric oxide synthase might decrease production of nitric oxide and cause vasospasm, which might account for some cerebral manifestations of AIP,^{191,192} and possibly compromise intestinal blood flow.¹⁹³ However, regulation of heme and hemoprotein synthesis in nervous tissue and blood vessels is difficult to study, and convincing evidence is lacking. (3) Impaired hepatic heme synthesis during an attack may lead to decreased activity of hepatic tryptophan pyrrolase, which might increase levels of

tryptophan in plasma and brain, leading to increased synthesis of the neurotransmitter 5-hydroxytryptamine.

ALA is increased in a number of disorders with similar neurologic manifestations, including all four of the acute porphyrias, lead poisoning, and hereditary tyrosinemia type I, which favors a neuropathic role for this porphyrin precursor or perhaps a derivative. ALA can enter cells readily and be converted to porphyrins, which, in turn, may have toxic potential.¹⁹⁴ ALA is also structurally similar to γ -aminobutyric acid and can interact with γ -aminobutyric acid receptors.^{195,196} However, studies of ALA loading have not shown adverse effects.

Impaired motor function with ataxia develops in mice with *PBGD* deficiency resulting from compound heterozygous or homozygous mutations induced by gene targeting.¹⁹⁷ Induction of hepatic CYPs is impaired in these animals and corrected by heme.¹⁹⁸ But motor neuropathy can develop even with normal or only slightly increased ALA in plasma and urine, suggesting a primary role for heme deficiency in porphyric neuropathy in this murine model.¹⁹⁹

Precipitating Factors Acute attacks are precipitated in some heterozygotes by various endogenous or exogenous factors that are additive. Additional unknown genetic factors are also likely to contribute. Some individuals remain susceptible to repeated attacks even after avoidance of known precipitants. Many precipitating factors cause *induction of hepatic ALAS1*, which is closely associated with induction of CYPs and leads to overproduction of ALA and other pathway intermediates.

Drugs and Other Exogenous Chemicals Most drugs that are harmful in acute porphyrias are known inducers of hepatic CYPs. These drugs increase *de novo* heme synthesis, thereby derepressing hepatic *ALAS1*, and also directly induce this rate-limiting enzyme.²⁷ [Table 58–4](#) identifies some drugs that are known to be harmful or safe. Information regarding safety of many drugs in clinical practice is uncertain or lacking. More extensive drug safety databases are available at the websites of the American Porphyria Foundation (www.porphyrifoundation.com) and the European Porphyria Initiative (www.porphyrria-europe.com). These drug classifications are often based on limited evidence and may be controversial. Ethanol and other alcohols are inducers of hepatic *ALAS1* and some CYPs.²⁰⁰ Smoking is known to increase CYPs in humans, probably from effects of polycyclic aromatic hydrocarbons, and has been associated with more frequent symptoms of acute porphyria.²⁰¹

Endocrine Factors Rarity of symptoms before puberty and more common clinical expression in women point to hormonal factors as important contributors in AIP. Although estrogens are considered harmful, it is likely that progesterone is mostly responsible for cyclic premenstrual attacks that occur in some women. Progesterone, certain metabolites of testosterone, and synthetic progestins are potent inducers of *ALAS1*. Thus administration of progestational agents should be avoided. Diabetes mellitus is not known to precipitate attacks of porphyria, and has been observed to decrease the frequency of attacks and lower porphyrin precursor levels, possibly in relation to high circulating glucose levels.²⁰²

Pregnancy Pregnancy is usually well tolerated.²⁰³ Attacks during pregnancy are sometimes a result of harmful drugs or reduced caloric intake. Metoclopramide, considered at least by some a contraindicated drug, is associated with exacerbation of the disease when used to treat hyperemesis gravidarum.^{204,205} But for reasons that are not clear, some women experience attacks during pregnancy even when harmful factors are avoided.

Nutrition Reduced intake of calories and carbohydrate can exacerbate acute porphyrias. This may occur from efforts to lose weight, bariatric surgery or from metabolic stress from an illness or surgery. Under these conditions, upregulation of *PGC-1 α* can lead to induction of *ALAS1*, increases in ALA and PBG, and symptoms of

TABLE 58-4. A Partial List of Drugs Known to Be Unsafe or Safe in the Acute Porphyrrias

Unsafe		Safe
Alcohol	Meprobamate*	Acetaminophen
Barbiturates*	(also mebutamate*, tybamate*)	Aspirin
Carbamazepine*	Methyprylon	Atropine
Carisoprodol*	Metoclopramide*	Bromides
Clonazepam (high doses)	Phenytoin*	Cimetidine
Danazol*	Primidone*	Erythropoietin*†
Diclofenac* and possibly other NSAIDs	Progesterone and synthetic progestins*	Gabapentin
Ergots	Pyrazinamide*	Glucocorticoids
Estrogens*‡	Pyrazolones (aminopyrine, antipyrine)	Insulin
Ethchlorvynol*	Rifampin*	Narcotic analgesics
Glutethimide*	Succinimides (ethosuximide, methsuximide)	Penicillin and derivatives
Griseofulvin*	Sulfonamide antibiotics*	Phenothiazines
Mephenytoin	Valproic acid*	Ranitidine*†
		Streptomycin
		Vigabatrin

NSAIDs, nonsteroidal antiinflammatory drugs.

*Porphyria is listed as a contraindication, warning, precaution, or adverse effect in U.S. labeling for these drugs.

†Although porphyria is listed as a precaution in U.S. labeling, these drugs are regarded as safe by other sources.

‡Estrogens are unsafe for porphyria cutanea tarda, but can be used with caution in the acute porphyrias.

NOTE: More complete sources, such as the websites of the American Porphyria Foundation (www.porphyrifoundation.com) and the European Porphyria Initiative (www.porphyrria-europe.com) should be consulted before using drugs not listed here, keeping in mind that classifications may not be supported by high-quality evidence.

acute porphyria, and these effects are reversed by administration of carbohydrate.^{30,206} Starvation, may also induce hepatic heme oxygenase,²⁰⁷ which may deplete hepatic heme and contribute to ALAS1 induction.

Stress Various forms of physical or psychological stress may exacerbate acute porphyrias, although the mechanisms are not well defined. Medical illnesses, fever, infections, alcoholic excess, and surgery may decrease food intake and contribute to induction of hepatic ALAS1 and heme oxygenase. Psychological stress may also lead to decreased food intake and have other metabolic effects.

Clinical Features

Symptoms are almost never seen before puberty, and most commonly develop in women in the third or fourth decade of life. Acute attacks are life-threatening but rarely fatal if promptly recognized and treated. Frequently recurring attacks and chronic symptoms can develop and be disabling. Although the most prominent symptoms are a result of effects on the nervous system, liver and kidney damage may be important in the long-term. In very rare homozygous cases, severe neurologic manifestations are seen early in childhood, and acute attacks are not prominent.^{207a,209}

Symptoms and signs are nonspecific and highly variable. Abdominal pain is the most common symptom, occurring in 85 to 95 percent

of cases.²¹⁰ It is usually severe, steady, and poorly localized, but may be cramping, and is often accompanied by nausea, vomiting, constipation, and abdominal distention because of ileus. Pain in the chest and extremities are also common. Tachycardia is the most common physical sign, occurring in up to 80 percent of acute attacks,²¹¹ and often accompanied by hypertension, sweating, tremors, and other effects of sympathetic overactivity and excess catecholamine production. There is little or no abdominal tenderness, fever, or leukocytosis because inflammation is not prominent. Bowel sounds are usually decreased, but are sometimes increased with diarrhea. The urine is often dark (because of porphobilin, a degradation product of PBG) or reddish (because of porphyrins, including uroporphyrin formed nonenzymatically from PBG). Urinary hesitancy and dysuria may occur as a consequence of bladder dysfunction. Acute mental symptoms may include insomnia, anxiety, restlessness, disorientation, paranoia, and hallucinations.

Paresis because of peripheral motor neuropathy usually occurs with prolonged, severe attacks, but is sometimes an early or even initial manifestation.^{212,213} Porphyric neuropathy is primarily motor and results from axonal degeneration, which may be followed by demyelination.²¹⁴ Muscle weakness may not be detected until it is quite advanced because it usually begins in the proximal muscles of the upper extremities. Paresis is usually symmetrical, but may be asymmetrical or focal. Course tremors, clonus and increased reflexes are sometimes prominent. Magnetic resonance imaging may demonstrate cortical densities resembling the posterior reversible encephalopathy syndrome.¹⁹² Sensory loss may develop, especially in the distal extremities. Cranial nerve involvement and cortical blindness have been described.

Motor neuropathy may progress to respiratory and bulbar paralysis and death especially if diagnosis and treatment are delayed and harmful drugs continued. Death may also result from respiratory arrest or cardiac arrhythmia.^{214,215} Most attacks treated promptly resolve within days or even hours. Advanced neuropathy from a severe attack is potentially completely reversible, with improvement continuing for up to 1 to 2 years.²¹⁶

Hyponatremia is common during severe attacks and is sometimes a result of hypothalamic involvement and the syndrome of inappropriate antidiuretic hormone secretion. However, hyponatremia may be accompanied by reductions in blood volume,²¹⁷ indicating that increased antidiuretic hormone secretion in this setting is an appropriate physiologic response.²¹⁵ Hyponatremia may sometimes result from gastrointestinal loss, poor intake, and excess renal sodium loss.^{215,218} A possible nephrotoxic effect of ALA may explain renal tubular sodium loss and impaired renal function in some patients.²¹⁸ Other electrolyte abnormalities may include hypomagnesemia and hypercalcemia.²¹⁹ Seizures may result from hyponatremia or represent a neurologic effect of acute porphyria.

Chronic mental symptoms, such as depression, are difficult to attribute to AIP. But chronic pain accompanied by depression develops in some patients after frequent exacerbations, and risk for suicide is increased. The disease also predisposes to chronic arterial hypertension and impaired renal function.^{203,220,221} The latter may progress and require renal transplantation.^{222,223}

Mild abnormalities in serum transaminases are common in AIP.²²⁴ More advanced liver disease may develop and the risk of hepatocellular carcinoma is greatly increased (60- to 70-fold) in AIP, and is not related to specific *PBGD* mutations. Serum α -fetoprotein was not increased and the uninvolved liver was not cirrhotic in most acute porphyria cases with liver cancer reported as of this writing. Increased serum thyroxin levels because of increased thyroxin-binding globulin occurs in some patients with AIP, and occasionally hyperthyroidism and porphyria occur together.²²⁵ Elevated low-density lipoprotein cholesterol is apparently less commonly observed in this disorder than in the past.²²⁶

Diagnosis

A high index of suspicion and knowing when to suspect these diseases contributes to making an *initial diagnosis* of acute porphyria. Because the disease so often remains latent, there is often no family history of porphyria. Acute porphyria should be considered in patients with unexplained abdominal pain or other characteristic symptoms when initial evaluation does not suggest another more common explanation, and ruled in or out by rapid assessment of urinary PBG, which is both sensitive and specific. A substantial increase in PBG, which can be determined rapidly by a commercial kit,²²⁷ establishes that a patient has either AIP, HCP, or VP. Consensus recommendations are that all major medical centers should retain the capacity for rapid urinary PBG testing on single-void urine specimens, as collection of 24 hour urines and reliance on outside laboratories for screening can greatly delay diagnosis and treatment. The urine specimen should be saved for later quantitative measurement of PBG, ALA, and total porphyrin levels. If PBG is substantially increased, samples of plasma, erythrocytes and feces should also be obtained prior to treatment with hemin. This approach provides for rapid initial diagnosis of AIP, HCP, and VP, subsequent biochemical differentiation of these conditions and diagnosis of ADP. In patients with renal failure, PBG can be measured in serum by a specialized laboratory. Figure 58–6 presents a diagnostic flow chart for use when acute porphyria is suspected.

PBG excretion is generally 50 to 200 mg/day (normal range: 0 to ~4 mg/day) during acute attacks of AIP. Excretion of ALA is usually about half that of PBG (expressed as mg/day). Increases in ALA and PBG can persist for prolonged periods between attacks, especially in AIP. Increases in ALA and PBG are less striking during acute attacks of HCP and VP and often decrease more rapidly.

The diagnosis of an acute attack is largely clinical, and is not based on a specific level of ALA or PBG. Levels of ALA and PBG during an

acute attack may be increased compared to baseline levels, which fluctuate considerably and can be difficult to establish between attacks. Intravenous hemin causes dramatic, rapid but often transient decreases in these levels.

Urinary porphyrins are increased in AIP, are predominantly uroporphyrin and account for reddish urine (ALA and PBG are colorless). Uroporphyrin can form nonenzymatically from PBG in urine even prior to excretion. However, there is evidence that porphyrins in this condition are predominantly type III, which may be formed enzymatically,²²⁸ perhaps from ALA transported to tissues other than the liver.¹⁹⁴ Total fecal porphyrins and plasma porphyrins are normal or slightly increased in AIP, and erythrocyte zinc protoporphyrin concentrations may be nonspecifically increased.

Erythrocyte PBGD activity is approximately half-normal in most (70 to 80 percent) patients with AIP. However, this measurement is not definitive for confirming or excluding the diagnosis. As described earlier, some PBGD mutations cause the enzyme to be deficient only in nonerythroid tissues. Moreover, the ranges of activity for normals and AIP are wide and overlapping, and the erythrocyte enzyme is highly age-dependent, such that an increase in the proportion of younger cells in the circulation can raise the activity into the normal range in AIP patients with a concurrent condition such as hemolytic anemia or hepatic disease.^{229,230} A decrease in this enzyme also does not distinguish between latent and active disease. For these reasons, and because it does not detect other acute porphyrias, erythrocyte PBGD measurement is not useful for initial diagnosis of ill patients.

Once the diagnosis of AIP is established by biochemical methods, the underlying PBGD mutation should be identified. This confirms the diagnosis and, most importantly, enables reliable and definitive identification of other gene carriers by DNA testing. Erythrocyte PBGD

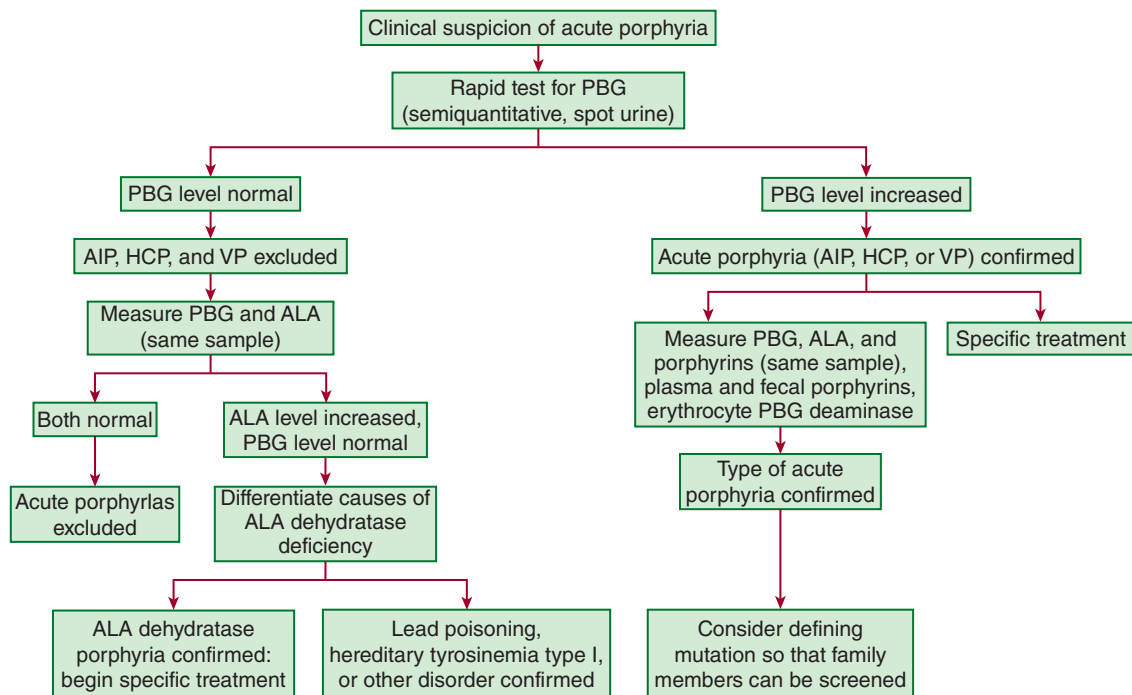

Figure 58–6. Recommended laboratory evaluation of patients with concurrent symptoms suggesting an acute porphyria, indicating how the diagnosis is established or excluded by biochemical testing and when specific therapy should be initiated. This schema is not applicable to patients who were recently treated with hemin or who have recovered from past symptoms suggestive of porphyria. Levels of δ -aminolevulinic acid (ALA) and porphobilinogen (PBG) may be less increased in hereditary coproporphyria (HCP) and variegate porphyria (VP) and decrease more quickly with recovery than in acute intermittent porphyria (AIP). Mutation detection provides confirmation and greatly facilitates detection of relatives with latent porphyria.

measurement is useful for screening of asymptomatic family members if a known case in the family has low erythrocyte enzyme activity, but is less dependable than DNA testing. PBGD deficiency can be documented in the fetus by measuring the enzyme activity or by identifying the maternal or paternal mutation in amniotic fluid cells. However, prenatal diagnosis is usually not indicated because the great majority of heterozygous carriers of PBGD mutations have a good prognosis.

Therapy

Hospitalization is usually required for treatment of attacks, although well-characterized patients with frequently recurring attacks that respond rapidly to treatment are sometimes managed as outpatients. Hospitalization facilitates treatment of severe symptoms, intravenous therapies and monitoring of respiration, electrolytes and nutritional status. Admission to intensive care is warranted if the vital capacity is impaired. Harmful drugs should be discontinued whenever possible. Pain, nausea, and vomiting are generally severe and require narcotic analgesics, chlorpromazine or another phenothiazine, or ondansetron. Low doses of short-acting benzodiazepines are probably safe for anxiety and insomnia. β -Adrenergic blocking agents may be useful to control tachycardia and hypertension, but may be hazardous in patients with hypovolemia or incipient cardiac failure.²³¹ Seizures are treated by correcting hyponatremia, if present. Almost all anticonvulsant drugs have at least some potential for exacerbating acute porphyrias. Clonazepam may be less harmful than phenytoin, barbiturates, or valproic acid.^{232,233} Bromides, gabapentin, and vigabatrin are safe.

Carbohydrate Loading Glucose and other carbohydrates repress hepatic ALAS1 and reduce porphyrin precursor excretion, but the effects are weak compared to those of hemein. Attacks with mild pain and without severe manifestations such as paresis and hyponatremia may be treated with carbohydrate loading. Oral glucose polymer solutions may be given if tolerated. Intravenous treatment with 300 to 500 g of intravenous glucose, usually administered as a 10 percent solution, is recommended. However, the dilutional effects of a large volume of free water may increase risk of hyponatremia. A more complete parenteral nutrition regimen may be needed if oral or enteral feeding is not possible.

Intravenous Hemin Hemin is much more potent in reducing levels of ALA and PBG compared to glucose. Although controlled clinical trials are lacking for all current therapies for acute attacks of porphyria, consensus recommendations are that the clinical benefits of hemein are superior to other available therapies.^{234,235,243a} Hemein is available in the United States as a lyophilized hematin preparation (Panhematin, Recordati Rare Diseases, Northfield, IL), and was the first drug approved under the Orphan Drug Act. Heme arginate (Normosang, Orphan Europe, Paris, France), which is a stable preparation of heme and arginine, is available in Europe and South Africa.^{235,236} Hemein, when infused intravenously as hematin or heme arginate, becomes bound to circulating hemopexin and albumin and is then taken up primarily by hepatocytes. It then enters and reconstitutes the regulatory heme pool and represses the synthesis of hepatic ALAS1. This results in a dramatic reduction in porphyrin precursor excretion. The standard regimen for treatment of acute attacks is 3 to 4 mg/kg daily for 4 days. Treatment may be extended if a response is not observed within this time. Hemein has been administered safely during pregnancy.^{235,236,243a}

Product labeling recommends reconstitution of hematin with sterile water. But it was subsequently discovered that degradation products of hematin begin to form immediately upon reconstitution with water, and these are responsible for phlebitis at the site of infusion, which occurs frequently and can lead to loss of venous access with repeated dosing, and a transient anticoagulant effect.^{236a} Stabilization of hematin with 25 percent human albumin can prevent these adverse effects,²³⁸ and is currently recommended.²³⁹ Uncommon side effects include fever,

aching, malaise, hemolysis, anaphylaxis, and circulatory collapse.^{240,241} Excessive dosing caused reversible acute renal tubular damage in one case.²⁴²

Controlled trials comparing initial treatment with either glucose or hemein are lacking, except for one randomized, double-blind, placebo-controlled trial of heme arginate for acute attacks of porphyria, which was underpowered (only 12 patients). Although treatment with hemein was delayed for 2 days, striking decreases in urinary PBG and trends in clinical benefit were noted.²⁴³ In contrast, a larger uncontrolled study enrolled 22 patients who had 51 acute attacks, and heme arginate was initiated within 24 hours of admission in 37 attacks (73 percent); all patients responded and hospitalization was less than 7 days in 90 percent of cases.²³⁵ Therefore, based on this and numerous other uncontrolled clinical studies, it is now recommended that most acute attacks of porphyria be treated promptly with intravenous hemein, without an initial trial of intravenous glucose.^{235,243a} Response to hemein may be delayed or incomplete when there is advanced neurologic damage. Subacute or chronic symptoms are unlikely to respond.

Liver Transplantation Liver transplantation has been highly effective in several patients who were disabled by recurrent attacks of AIP.¹⁹⁰ This may be an option for severely affected patients.

Other Therapies Cimetidine has been recommended for human acute porphyrias based on uncontrolled observations in small numbers of patients.^{244,245} This drug inhibits hepatic CYPs, and can prevent experimental forms of porphyria induced by agents such as allylisopropylacetamide that undergo activation by these enzymes.²⁴⁶ However, these mechanisms are not immediately relevant to inherited porphyrias in humans. Therefore, cimetidine cannot be recommended as an alternative to hemein.

Prevention of Acute Attacks Multiple inciting factors must be avoided especially in patients who continue to have repeated attacks. Consultation with a dietitian may be useful to identify dietary indiscretions, and to help maintain a well-balanced diet somewhat high in carbohydrate (60 to 70 percent of total calories). There is little evidence that additional dietary carbohydrate helps further in preventing attacks. Iron deficiency, if present, should be corrected. Patients who wish to lose excess weight should do so gradually and when they are clinically stable.

Gonadotropin-releasing hormone analogues can prevent repeated attacks that are confined to the luteal phase of the menstrual cycle,^{247,248} but are less effective in patients with attacks partially associated with the cycle. If treatment is effective after several months, low-dose estradiol, preferably by the transdermal route, or a bisphosphonate may be added to prevent bone loss and other side effects, or treatment changed to a low-dose oral contraceptive. Hemein administered once or twice weekly can prevent frequent, noncyclic attacks of porphyria in some patients.²⁴⁹

Long-Term Monitoring Patients with acute porphyrias are at risk for renal damage and hepatocellular carcinoma. Renal function should be monitored, hypertension controlled, and nephrotoxic drugs avoided. Current recommendations are that patients with acute porphyrias who are older than age 50 years, and especially those with continued elevations of ALA and PBG, be screened at least annually by ultrasonogram or an alternative imaging method to detect hepatocellular carcinoma at an early stage.^{243a}

HEREDITARY COPROPORPHYRIA AND VARIEGATE PORPHYRIA

Definition

These closely related hepatic porphyrias are caused by deficiencies of CPO and PPO, the sixth and seventh enzymes of the heme biosynthetic pathway. They present with neurovisceral symptoms, as in AIP, or with

blistering skin lesions identical to those seen in PCT. Cutaneous manifestations are much more common in VP than in HCP. The enzyme deficiency in each is inherited as an autosomal dominant trait with variable penetrance (see Table 58–1 and Fig. 58–1). As in AIP, most individuals who inherit the trait remain asymptomatic. Both disorders are less common and generally less severe than AIP in most countries. The incidence of HCP was estimated to be 2 per 1,000,000 population in Denmark,²⁵⁰ and the incidence of VP in Finland reported at 1.3 per 100,000 population.²⁵¹

Because of a founder effect, VP is especially common among whites of Dutch descent in South Africa, where almost all cases share the same *PPO* mutation (R59W). The incidence of VP in that country was estimated at 3 per 1000 population.²⁵² Very rare cases of homozygous HCP and VP are manifested by severe neurologic impairment early in life, but not acute attacks, and severe photosensitivity.²⁵³

Pathophysiology

Like other porphyrias, HCP and VP are heterogeneous at the molecular level. At least 43 *CPO* mutations, mostly missense mutations, have been identified in HCP,²⁵⁴ and 130 *PPO* mutations in VP (see Table 58–1). Clinical expression is variable and onset of neurologic manifestations is influenced by the same factors that are important in AIP.

CPO catalyzes the two-step decarboxylation of coproporphyrinogen III to yield protoporphyrinogen IX, with intermediate formation of harderoporphyrinogen, a tricarboxyl porphyrinogen. A single active site carries out both decarboxylations, and most of the harderoporphyrinogen formed is not released before being further decarboxylated to protoporphyrinogen IX. However, a variant form of HCP, termed *harderoporphyria*, is a result of *CPO* mutations that favor premature release of harderoporphyrinogen from the enzyme.²⁵⁵

Clinical Features

Neurovisceral manifestations are identical to those in other acute porphyrias. Although both HCP and VP are generally less severe than AIP, attacks may be life-threatening. Blistering skin lesions may be seen, and are much more common in VP than in HCP. Factors that contribute to attacks, including drugs, hormones, and dietary factors, are also the same as in AIP. Oral contraceptives may precipitate cutaneous manifestations of VP. Risk of chronic hypertension, renal disease, and hepatocellular carcinoma are increased, as in AIP.

Diagnosis

Urinary PBG is elevated during acute attacks, and usually is the basis for diagnosis of these acute porphyrias. However, increases in PBG may be less than in AIP, and more transient. Levels of coproporphyrin III are markedly increased in urine and feces, whereas in AIP fecal porphyrins are normal or only slightly increased. Fecal porphyrins in HCP are almost entirely coproporphyrin III, whereas in VP both coproporphyrin III and protoporphyrin are approximately equally increased. The fecal coproporphyrin III:I ratio is sensitive for diagnosis of HCP, even in asymptomatic stages of the disease.²⁵⁶ Plasma porphyrin concentration is commonly increased in VP, seldom increased in HCP unless there are cutaneous manifestations, and are normal or only slightly increased in AIP. A characteristic plasma porphyrin fluorescence maximum observed at neutral pH is a very specific marker for VP, and is believed to represent protoporphyrin bound covalently to plasma proteins.²⁵⁷ The fluorescence maximum is at approximately 626 nm in VP, approximately 634 nm in EPP, and approximately 620 nm in other porphyrias. This fluorometric method is more effective than examination of fecal porphyrins for detecting asymptomatic VP,²⁵⁷ and is useful for rapidly differentiating VP and PCT. Erythrocyte PBG deaminase activity is normal in HCP and VP, and usually deficient in AIP. Assays for *CPO* and

PPO are not widely available. DNA studies are most reliable for identifying asymptomatic carriers, once the mutation affecting the family is identified.

Harderoporphyria is a variant form of HCP that results from a homozygous defect of a structurally altered *CPO*, such that harderoporphyrinogen is released prematurely from the enzyme. This variant is identified by finding a predominance of harderoporphyrin in urine and feces. Neonatal hemolytic anemia is a distinctive feature of this condition.²⁵⁸ Increases in porphyrin precursors and porphyrins may be more severe in homozygous HCP and VP, with substantial increases in erythrocyte zinc protoporphyrin.

Therapy

The identification and avoidance of precipitating factors is essential. Treatment of acute attacks is the same as in AIP. Treatment of the phototoxic manifestations is not satisfactory. Although the lesions are identical to the blistering skin lesions seen in PCT, there is no response in HCP and VP to phlebotomies or low-dose chloroquine or hydroxychloroquine. Therefore, avoidance of sunlight and use of protective clothing is most important. Yearly screening for hepatocellular carcinoma by imaging is recommended after age 50 years, especially in individuals with persistent increases in porphyrin precursors or porphyrins.

PORPHYRIA CUTANEA TARDA AND HEPATOERYTHROPOIETIC PORPHYRIA

Definition

PCT is caused by a deficiency of hepatic *UROD* activity and is manifested by the development of chronic, blistering skin lesions on the dorsal aspects of the hands and other sun-exposed areas of skin in middle or late life. This iron-related disorder is the most common and readily treated form of porphyria (see Table 58–1 and Fig. 58–1). The enzyme deficiency develops specifically in the liver as a result of generation of a *UROD* inhibitor in the presence of multiple susceptibility factors. The disease has been classified as types 1 to 3, based on the presence or absence of heterozygous *UROD* mutations and other unknown inherited factors. Patients with familial (type 2) PCT are heterozygous for *UROD* mutations, which are inherited as an autosomal dominant trait with low penetrance. HEP is the homozygous (or compound heterozygous) form of familial (type 2) PCT, which usually presents in childhood and resembles CEP clinically. Rarely, hepatocellular carcinomas may secrete porphyrins and simulate PCT; however the enzyme defect was not established in such cases.²⁵⁹

PCT must be differentiated from other porphyrias that cause identical blistering skin lesions and from pseudoporphyria (also known as pseudo-PCT). The latter is a poorly understood condition that presents with lesions that closely resemble PCT, but with plasma porphyrins that are not significantly increased. Potentially photosensitizing drugs, such as nonsteroidal antiinflammatory agents, are sometimes implicated.

Pathophysiology

UROD sequentially decarboxylates uroporphyrinogen (which has eight carboxyl side chains) to yield coproporphyrinogen (with four carboxyl groups). When hepatic *UROD* is profoundly inhibited, the substrate and the intermediate and final products of the reaction accumulate as the oxidized porphyrins in the liver (mostly uroporphyrin and heptacarboxylporphyrin), and then appear in plasma and urine. Photosensitivity results from activation of porphyrins in the skin by long-wave ultraviolet light and generation of reactive oxygen species.

Hepatic *UROD* activity is inhibited to less than approximately 20 percent of normal in all patients with PCT. Types 1, 2, and 3 are not fundamentally different or clinically distinguished from each other. Patients

with type 1 or “sporadic” PCT have no *UROD* mutations and no family history of PCT. Approximately 80 percent of patients fall into this category. Type 2 or “familial” PCT comprises approximately 20 percent of cases who are heterozygous for *UROD* mutations; but because the penetrance of this trait is low there are usually no other documented cases in the family. In families with type 3, which is rare, more than one member has PCT, but there is no *UROD* mutation; these familial cases presumably share other inherited or environmental susceptibility factors.

Although hepatic *UROD* activity must be reduced to approximately 20 percent of normal for PCT to be manifest, the amount of enzyme protein, when measured immunochemically in liver, remains at its genetically determined level, which in type 2 cases is approximately 50 percent of normal.²⁶⁰ Mice heterozygous for mutant *UROD* alleles are much more sensitive to porphyrinogenic stimuli than wild-type animals.²⁶¹ In heterozygous mice that display porphyric phenotypes, hepatic *UROD* protein is half normal, but the catalytic activity of the enzyme is reduced to approximately 20 percent, suggesting the existence of an inhibitor of hepatic *UROD*.²⁶¹

Although iron does not directly inhibit *UROD*, there is considerable evidence that PCT is an iron-related disease, with hepatic siderosis seen in many cases. This explains why *HFE* (hemochromatosis gene) mutations that lead to increased intestinal iron absorption predispose to development of PCT (Chap. 42). Individuals who inherit a *UROD* mutation have approximately 50 percent of normal enzyme activity from birth, such that a *UROD* inhibitor can more readily reduce enzyme activity to less than approximately 20 percent of normal. How iron and other known or suspected susceptibility factors such as alcohol, smoking, estrogens, hepatitis C, HIV, hepatic steatosis, and other suspected factors contribute to the development of PCT is less-well understood, but these may act in part by increasing oxidative stress in hepatocytes. A deficiency of ascorbic acid,^{261a} and perhaps other antioxidants,²⁶³ may play a role in some patients. Smoking may also act by inducing hepatic CYPs, including CYP1A2, which is essential for causing uroporphyrin in rodent models,^{264,265} and may produce a *UROD* inhibitor, which has been characterized as a uroporphomethene. This substance is a product of partial oxidation of uroporphyrinogen, and is found in the liver of mice that are heterozygous for a *UROD* mutation, homozygous for an *HFE* mutation (C282Y), and develop uroporphyrin spontaneously.⁶² Other potential mechanisms for lowering of hepatic *UROD* activity in PCT, such as oxidative damage to *UROD* active site residues, are less favored but have not been excluded.²⁶⁶

At least 70 different *UROD* mutations have been identified in type 2 PCT and HEP (see Table 58–1). These reduce *UROD* activity and immunoreactivity to approximately 50 percent of normal in all tissues from birth. Most are missense mutations, with each occurring in one or a few families. Homozygosity for a null *UROD* mutation is lethal in early neonatal life. Therefore, in HEP at least one of the mutant *UROD* alleles must preserve at least some catalytic activity. Knowledge of the crystal structure of *UROD* allows mapping of specific mutations and prediction of their impact on enzyme structure and function. Expression studies in eukaryotic cells suggest that some mutations may destabilize the enzyme protein in a tissue-specific manner.²⁶⁷

Pathogenesis of the Clinical Findings

A distinctive feature of PCT is massive accumulation of porphyrins in the liver. As a result, fresh hepatic tissue shows strong red fluorescence on exposure to long-wave ultraviolet light. Microscopic, birefringent, needle-like inclusions are found in lysosomes, and paracrystalline inclusions in mitochondria. Increased stainable iron is very common. Other nonspecific hepatic findings are probably partly a result of the disease itself, although the effects of associated factors such as alcohol and hepatitis C are difficult to differentiate. Liver histopathology includes

hepatocyte necrosis, inflammation, increased iron, and increased fat. Mild abnormalities in liver function tests, especially serum transaminases and γ -glutamyltranspeptidase, are present in almost all cases, but cirrhosis is unusual. The risk of hepatocellular carcinoma is increased, especially in those with more prolonged disease, cirrhosis, or other risk factors such as hepatitis C or alcoholic liver disease.^{268–270}

Excess porphyrins are transported in plasma from the liver. Skin histopathology includes subepidermal blistering and deposition of periodic acid-Schiff–positive material around blood vessels and fine fibrillar material in the upper dermis and at the dermoepithelial junction. Immunoglobulin G, other immunoglobulins, and complement are deposited around dermal blood vessels and at the dermoepithelial junction. Splits in the lamina lucida of the basement membrane lead to formation of fluid-containing bullae.²⁷¹ These histologic changes are found in other cutaneous porphyrias, as well as pseudoporphyria, and are not diagnostic for PCT. Activation of the complement system after irradiation has been demonstrated in PCT patients both *in vivo* and *in vitro* in sera,²⁷² and is thought to result from generation of reactive oxygen species.

Susceptibility Factors PCT is a highly heterogeneous disease, with multiple susceptibility factors expected in the individual patient.²⁷³ Multiple factors are important in familial as well as sporadic PCT, because heterozygosity for a *UROD* mutation is a susceptibility factor that does not of itself reduce hepatic enzyme activity sufficiently to cause the disease. The environmental, infectious, and inherited factors discussed below, none of which is invariably present, are known or suspected to play an important role. Their prevalence may show considerable geographic variation in PCT patients as well as healthy subjects.

Alcohol PCT has long been associated with excess alcohol use. Alcohol and its metabolites may induce ALA1 and CYP2E1, generate active oxygen species that contribute to oxidative damage, cause mitochondrial injury, deplete reduced glutathione and other antioxidant defenses, increase production of endotoxin, activate Kupffer cells, decrease the iron regulatory hormone hepcidin²⁷⁴ and increase iron absorption.

Smoking and Cytochrome P450 Enzymes Smoking is less extensively studied as a risk factor but is commonly associated with alcohol use in PCT.²⁷³ Smoking may increase oxidative stress in hepatocytes, and induces CYP1A2, which is essential to the development of uroporphyrin in rodent models. CYP levels have been found to be increased in liver in human PCT, but it is not clear which CYP might be important in pathogenesis of the human disease. A study of caffeine metabolism did not find evidence for increased CYP1A2 activity *in vivo* in PCT, even when smokers and nonsmokers were analyzed separately.²⁷⁵ However, a more inducible polymorphism of CYP1A2 has been found to be more common in PCT than in normal subjects.²⁷⁶

Estrogens Estrogen use is very common in women with PCT.^{273,277,278} In the past, some men developed the disease after treatment of prostate cancer with estrogens.²⁷⁷ Female rats or males treated with estrogens are more susceptible to development of chemically induced uroporphyrin than untreated males.²⁷⁹ The mechanism is not established, although estrogens can generate reactive oxygen species in some experimental systems.²⁶⁶

Hepatitis C Reported prevalence of hepatitis C in PCT has ranged from 21 to 92 percent in various countries, and greatly exceeds the prevalence of this viral infection in healthy subjects, which shows considerable geographic variation. Hepatitis C is associated with excess fat, some iron accumulation, mitochondrial dysfunction, and oxidative stress in hepatocytes, which may contribute to the development of PCT. Dysregulation of hepcidin may contribute to iron accumulation in hepatitis C.²⁸⁰

Human Immunodeficiency Virus PCT is less commonly associated with HIV infection than with hepatitis C.²⁸¹ Occasionally PCT is the initial manifestation of this infection. The mechanism is unknown.

Iron and HFE Mutations Mild to moderate iron overload is found in most patients with PCT, and iron deficiency is protective. The importance of iron has been confirmed in animal models, such as rodents treated with hexachlorobenzene and other halogenated polyaromatic hydrocarbons.²⁶⁶ Mice with disruption of one *UROD* allele (*UROD*[+/-]) and two disrupted *HFE* alleles (*HFE*[-/-]) develop uroporphyrin without administration of exogenous chemicals.²⁶¹ Prevalence of the *C282Y* mutation of the *HFE* gene, which is the major cause of hemochromatosis in whites, is increased in both sporadic and familial PCT, and 10 to 20 percent of patients may be *C282Y* homozygotes (Chap. 43).²⁸² In southern Europe, where the *C282Y* is less prevalent, the *H63D* mutation is more commonly associated with PCT.²⁸³ Excess iron may contribute to *UROD* inhibition by providing an oxidative environment that is apparently needed for generation of a *UROD* inhibitor. Hepatic hepcidin expression is reduced in hemochromatosis, and is also reduced in PCT patients without hemochromatosis genotypes when compared to patients without PCT and comparable iron overload, suggesting that reduced expression of this peptide is important in causing hepatic siderosis in PCT.²⁷⁴

Antioxidants Substantial reductions in plasma levels of ascorbate and carotenoids have been noted in some patients with PCT.²⁶³ Ascorbate deficiency in rodents enhances susceptibility to development or uroporphyrin, and ascorbate decreases uroporphyrin accumulation except in animals treated with large amounts of iron.²⁶²

A large outbreak of PCT occurred during a period of food shortage in a population in eastern Turkey in the 1950s from consumption of seed wheat treated with the fungicide hexachlorobenzene.¹¹ Smaller outbreaks and individual cases have occurred after exposures to other chemicals such as 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD, dioxin).²⁸⁴ These chemicals were subsequently shown to cause hepatic *UROD* deficiency and biochemical features resembling PCT in laboratory animals, and many studies that followed have greatly increased our understanding of this acquired enzyme deficiency.^{266,285} But such exposures are rarely identified in PCT patients in current clinical practice.

Clinical Features

Disease onset is usually in the fourth or fifth decade of life, and is more common in men. Onset may occur earlier in familial (type 2) disease or

in cases with the *C282Y/C282Y HFE* genotype.²⁸⁶ Fluid-filled vesicles develop most commonly on the backs of the hands (Fig. 58-7A). Skin friability is increased and blisters often follow minor trauma. These also occur on the forearms, face, ears, neck, legs, and feet. The blisters often rupture, crust over, and are prone to infection before healing slowly. Milia may precede or follow vesicle formation. Facial hypertrichosis and hyperpigmentation are particularly noticed by female patients (Fig. 58-7B). Severe thickening of affected areas of skin is termed *pseudoscleroderma* and resembles systemic scleroderma.

Blistering skin lesions in VP and HCP are identical to those in PCT. Those in CEP and HEP resemble PCT but are usually much more severe and mutilating. Mild or moderate erythrocytosis is common in PCT, and is not well explained. Chronic lung disease from smoking may contribute.

Drugs that exacerbate the acute porphyrias are only occasionally reported to play a role in PCT.²⁸⁷ PCT may occur with other conditions predisposing to iron overload such as myelofibrosis^{288,289} and end-stage renal disease,²⁹⁰ and with diabetes mellitus²⁷⁰ and cutaneous and systemic lupus erythematosus. PCT associated with end-stage renal disease is usually more severe, sometimes with severe mutilation. Lack of urinary porphyrin excretion in these patients leads to much higher concentrations of porphyrins in plasma, and the excess porphyrins are poorly dialyzable.²⁹⁰ The disease occasionally develops during pregnancy, perhaps related to effects of estrogen.

The clinical manifestations of HEP usually resemble CEP, with onset of blistering skin lesions, hypertrichosis, scarring, and red urine in infancy or childhood. Sclerodermoid skin changes are sometimes prominent. Excess porphyrins originate mostly from the liver in this condition. Unusually mild cases have been described.²⁹¹

Diagnosis

A diagnosis of PCT is established by finding a substantial elevation of porphyrins in urine or plasma, with a predominance of highly carboxylated porphyrins (uroporphyrin and hepta-, hexa-, and pentacarboxylporphyrins); coproporphyrins are also increased. Levels of PBG are normal, and urinary ALA is normal or slightly increased. The pattern of porphyrins in feces is complex, and includes heptacarboxylporphyrins and isocoproporphyrins. The latter are overproduced in the presence of *UROD* deficiency because pentacarboxylporphyrinogen is a substrate

Figure 58-7. Cutaneous findings in porphyria cutanea tarda include (A) bullous lesions most commonly on the dorsal aspects of the hands and fingers, which rupture and crust over, and (B) facial hirsutism most noticeable on the upper cheeks.

for CPO, leading to formation of dehydroisocoproporphyrinogen, which is excreted in bile and undergoes oxidation by intestinal bacteria to isocoproporphyrins.²⁹²

Measurement of plasma porphyrins and determination of the fluorescence emission peak at neutral pH is especially useful for screening patients with blistering skin lesions. A substantial increase with a peak at approximately 620 nm is most commonly caused by PCT, and excludes VP and pseudoporphyria, which are the most common conditions that mimic PCT clinically.^{292a} Plasma porphyrin measurements are essential for diagnosis of PCT in patients with advanced renal disease; the reference range is higher in patients with renal failure than in normals.²⁹³

Erythrocyte porphyrins are substantially increased in CEP and HEP, but are normal or only modestly increased in PCT. Rare cases of HCP with blistering lesions are identified by a predominance of coproporphyrin III in urine and especially feces. Familial (type 2) cases are identified by half-normal erythrocyte UROD activity or preferably by DNA studies to identify a *UROD* mutation. Erythrocyte UROD activity is 5 to 30 percent of normal in HEP, and DNA studies reveal that a *UROD* mutation is inherited from each parent.

Biochemical findings in HEP resemble PCT, with predominant accumulation and excretion of highly carboxylated porphyrins and isocoproporphyrins. However, in contrast to PCT, erythrocyte zinc protoporphyrin is substantially increased. At least one genotype may be associated with predominant excretion of pentacarboxylporphyrin.²⁹¹

Therapy

Treatment is highly effective but specific in both sporadic and familial PCT, and therefore should be initiated only after the diagnosis is well established. It is sometimes reasonable to start treatment after PCT is validated with a plasma porphyrin screen and excludes VP and pseudoporphyria (see "Diagnosis" above). Patients should be questioned and tested for all known susceptibility factors, including use of alcohol, tobacco, and estrogens, hepatitis C, HIV, *HFE* mutations, and inherited *UROD* deficiency (erythrocyte UROD activity or, preferably, *UROD* mutations), because their presence influences management. Serum ferritin should be measured before starting treatment. Patients are advised to stop drinking and smoking and to discontinue estrogens. A nutritionally adequate intake of ascorbic acid and other nutrients should be assured, but this vitamin should not be administered as primary therapy.

Improvement may occur after removing one or more susceptibility factor, but without phlebotomy or low-dose hydroxychloroquine recovery is unpredictable or slow.²⁹⁴ Repeated phlebotomy is the preferred treatment at most centers. The original rationale proposed by Ippen in 1961 was to decrease the commonly associated mild or moderately increased hemoglobin, stimulate erythropoiesis, and perhaps channel excess heme pathway intermediates to hemoglobin synthesis.²⁹⁵ However, the oxidized porphyrins that accumulate in PCT cannot reenter the heme biosynthetic pathway and be converted to heme, and it is now understood that phlebotomy is effective by reducing body iron stores and liver iron content. Treatment with an iron chelator such as desferrioxamine is less efficient than phlebotomies in reducing iron, but may be tried when the latter are contraindicated.²⁹⁶

Approximately 450 mL of blood is removed, usually at 2-week intervals. In one series an average of 5.4 phlebotomies was required for remission, but many more are needed in some patients with coexisting hemochromatosis and marked increases in serum ferritin levels. Hemoglobin or hematocrit levels are followed as safety (not therapeutic) targets, to prevent symptomatic anemia. Usually, the hemoglobin should not fall below 10 to 11 g/dL, but the baseline value and the age and clinical condition of the patient are also considered. The therapeutic target is a serum ferritin near 15 ng/mL, which is close to the lower limit of normal and associated with tissue iron depletion but usually not

anemia. Additional iron depletion is not beneficial, and causes anemia. Treatment is also guided by plasma (or serum) porphyrin levels, which are more convenient to measure repeatedly than urine porphyrins, and fall more slowly than the serum ferritin. Plasma porphyrins usually decline from initial levels of 10 to 25 mcg/dL during treatment, to below the upper limit of normal (~1 mcg/dL) within weeks after phlebotomies are completed.²⁹⁷ New skin lesions are generally decreased at the end of treatment, but some may occur for a few weeks after plasma porphyrin levels become normal. Severe sclerodermatous changes and liver function abnormalities can also improve.

After a remission, continued phlebotomies are generally not needed. However, relapses may occur, especially in patients who resume use of alcohol, and are treated by another course of phlebotomies. For patients with the *C282Y/C282Y* or *C282Y/H63D HFE* genotypes, management guidelines for hemochromatosis should be followed. Continued phlebotomies as needed to maintain a serum ferritin below approximately 50 ng/mL may also be beneficial in patients who have experienced recurrences of PCT, although published experience is limited. It is also advisable to follow porphyrin levels and reinstitute phlebotomies promptly if porphyrin levels begin to rise. Liver imaging and a serum α -fetoprotein determination should be repeated as screening for hepatocellular carcinoma. After remission, transdermal estrogen can be resumed in women, if needed, with little risk for recurrence of PCT.²⁷⁵

A low-dose regimen of hydroxychloroquine or chloroquine is also effective,^{266,298–303} and most appropriate when phlebotomy is contraindicated or poorly tolerated, if iron overload is not severe. However, this treatment is preferred at some centers because it is more convenient and much less expensive. These 4-aminoquinoline antimalarials do not appear to deplete hepatic iron, and the mechanism for their effect in PCT is not fully understood. Full therapeutic doses of these drugs exacerbate photosensitivity in PCT, induce fever, malaise, and nausea, markedly increase urinary and plasma porphyrins, and increase serum transaminases, other liver function tests, and ferritin. This reaction can even unmask previously unrecognized PCT.³⁰⁴ Although these adverse effects, which are unique to PCT, are followed by complete remission,³⁰⁵ they should be avoided by a low-dose treatment regimen (hydroxychloroquine 100 mg or chloroquine 125 mg—one-half of a standard tablet—twice weekly) at least until plasma or urine porphyrins are normalized.^{298,301,302} However, some patients may respond poorly and require later treatment with larger doses, or phlebotomy.³⁰⁵ There is a small risk of retinopathy,³⁰⁶ which may be lower with hydroxychloroquine. A recent prospective study found that time to biochemical remission with low-dose hydroxychloroquine was comparable to that with phlebotomy.³⁰⁷ In a retrospective study, low-dose chloroquine was ineffective in patients homozygous for the *C282Y* mutation of the *HFE* gene,³⁰⁸ which suggests that the degree of excess hepatic iron may influence response to this treatment.

These 4-aminoquinolines are not effective in other porphyrias, and do not mobilize all types of porphyrins from liver and other tissues.³⁰⁹ Chloroquine may form complexes with a variety of porphyrins, which might promote their mobilization from liver,^{310,311} but this does not appear to explain the effects in PCT. It was suggested that mobilization of hepatic iron may be important,^{302,312,313} but serum ferritin concentrations do not change significantly during treatment. Most likely, these drugs colocalize with excess porphyrins in lysosomes and other intracellular organelles and promote their release by a process that involves transient cell damage.

PCT may improve after treatment of coexisting hepatitis C. However, for several reasons PCT should be treated first and hepatitis C later in most cases. First, PCT is usually more symptomatic and can be treated more quickly and effectively. Second, there is some evidence that treatment of hepatitis C may be more effective after iron reduction.

Third, interferon and ribavirin commonly cause anemia, which usually precludes phlebotomy for PCT. Hydroxychloroquine may be an option during treatment with interferon and ribavirin, but initial worsening of liver function tests, even with a low-dose regimen, may cause concern. It is reasonable to consider continuing low-dose hydroxychloroquine after PCT is in remission to avoid a reoccurrence of PCT during treatment of hepatitis C, but there is little experience with this approach. Reports that PCT patients are often resistant to treatment of hepatitis C,^{314,315} contrast with reports of successful treatment, and prospective studies are needed. Studies are needed with newer and more effective agents for hepatitis C as these become available.

Treatment of PCT associated with end-stage renal disease is more difficult, as phlebotomy is often contraindicated by anemia. Erythropoietin administration can correct anemia, mobilize iron, and support phlebotomy in many cases.^{290,316,317} High-flux hemodialysis may remove porphyrins from plasma and provide some benefit.³¹⁸ PCT is not a contraindication to renal transplantation, which is likely to lead to remission³¹⁹ partly because of resumption of endogenous erythropoietin production. The level of plasma porphyrins are often especially high in these patients, and should be assessed prior to surgery, because there may be some risk of skin and peritoneal burns from exposure to operating room lights.

Management of HEP emphasizes avoiding sunlight, as in CEP. Oral charcoal was helpful in a severe case associated with dyserythropoiesis.⁹⁸ Phlebotomy has shown little or no benefit. Retrovirus-mediated gene transfer can correct porphyria in cell lines from patients with this disease, which suggests that gene therapy may be applicable in the future.³²⁰

CHAPTER 59

POLYCLONAL AND HEREDITARY SIDEROBLASTIC ANEMIAS

Prem Ponka and Josef T. Prchal

SUMMARY

Sideroblastic anemias are characterized by the presence of ring sideroblasts in the marrow. These cells are erythroid precursors that have accumulated abnormal amounts of mitochondrial iron. A variety of abnormalities of porphyrin metabolism in affected erythroid cells have been documented. Hereditary sideroblastic anemias are usually X linked, as the result of mutations in the erythroid form of 5-aminolevulinic acid synthase. Inherited autosomal and mitochondrial forms are seen, occasionally. Acquired sideroblastic anemias can occur as a result of the ingestion of drugs, alcohol, or toxins such as lead or zinc, or copper deficiency. Patients with acquired sideroblastic macrocytic anemia and variable degrees of thrombocytopenia and leukopenia from copper deficiency have been recognized more frequently; the hematologic abnormalities typically resolve after copper replacement. Ring sideroblasts are also a feature of myelodysplastic neoplasms, and are discussed in Chap. 87. Some patients with sideroblastic anemia may respond to pharmacologic doses of pyridoxine. Iron loading is common in the sideroblastic anemias and can be treated by phlebotomy when the anemia is mild or with iron chelators (Chap. 43) when it is more severe.

DEFINITION AND HISTORY

Sideroblastic anemias are a heterogeneous group of disorders that have as a common feature the presence of: (1) large numbers of pathologic sideroblasts in the marrow, which characteristically display abnormal mitochondrial iron accumulation in a circumnuclear position in erythroblasts; these are referred to as ringed sideroblasts; (2) ineffective erythropoiesis; (3) increased levels of tissue iron; and (4) varying proportions of hypochromic erythrocytes in the blood. They may be acquired or hereditary (Table 59-1).^{1,2}

Acquired monoclonal sideroblastic anemia is a neoplastic disease; that is, a clonal cytopenia or oligoblastic myelogenous leukemia that can progress to acute leukemia. This subject is considered in Chap. 87,

Acronyms and Abbreviations: ABCB7, ATP-binding cassette; ALA, 5-aminolevulinic acid; ALAS2, gene encoding ALA synthase 2; CPO, coproporphyrinogen oxidase; FECH, ferrochelatase; Fe-S, iron-sulfur; GLRX5, glutaredoxin 5; MLASA, mitochondrial myopathy and sideroblastic anemia; PUS1, pseudouridine synthase 1 gene; SLC25A38, mitochondrial carrier family gene; STEAP 3, six-transmembrane epithelial antigen of prostate 3-ferric reductase; TFR, transferrin receptor; tRNA, transfer RNA; XLSA/A, X-linked sideroblastic anemia, associated with ataxia.

Myeloid Neoplasms, in which ringed sideroblasts are a common phenotypic feature. Acquired polyclonal sideroblastic anemia may also develop as a result of the administration of certain drugs, exposure to toxins, or coincident to neoplastic or inflammatory disease. Hereditary sideroblastic anemias include X-linked, autosomal, and mitochondrial entities. Occasionally, a patient with familial disease develops a myelodysplastic syndrome later,^{1,2} but with these rare exceptions, the disorders are distinct and do not coexist or evolve one from the other.

Although the perinuclear distribution of siderotic granules in the erythroblasts of patients with various types of anemia was described in 1947,^{3,4} the concept of sideroblastic anemia as a generic designation was not generally accepted until the publications of Björkman,⁵ Dacie,⁶ Heilmeyer,^{7,8} Bernard,⁹ and Mollin.¹⁰ After these descriptions of the acquired, “primary adult form of refractory sideroblastic anemia,”^{5,6} similarity to the morphologic and erythrokinetic changes in hereditary (sex-linked) hypochromic anemia was recognized. Cooley¹¹ described a patient with an anemia with ovalocytosis who was shortly thereafter shown to have inherited a hereditary sex-linked disorder¹² that we now know resulted from the mutation of erythroid-specific aminolevulinic acid (ALA) synthase, ALAS2.¹³ Autosomally inherited cases were also described,¹⁴ and prominent sideroblastic changes of the marrow were found in Pearson marrow-pancreas syndrome (Chap. 36), a disorder that is caused by mutations of mitochondrial DNA.¹⁵⁻¹⁹ Sideroblastic anemia can also be associated with a wide variety of diseases,²⁰ therapy with antituberculosis drugs,^{21,22} and lead intoxication.²³⁻²⁶ In some patients, the anemia responded to large doses of pyridoxine and was designated “pyridoxine-responsive anemia.”^{10,27-29} These “secondary” acquired disorders were then incorporated into the classification.

EPIDEMIOLOGY

All of the hereditary forms are rare, and no particular ethnic predilection is known. Drug-induced forms occur sporadically among subjects taking the drugs listed in Table 59-1.

ETIOLOGY AND PATHOGENESIS

MORPHOLOGIC ASPECTS: THE SIDEROBLASTS

Sideroblasts are erythroblasts containing aggregates of non-heme iron that appear as one or more Prussian blue–positive granules on light microscopy.³⁰ The morphology of these cells in normal and abnormal states is discussed in detail in Chap. 31. In normal marrow, virtually every erythroblast has siderosomes, iron-containing organelles that are demonstrable by transmission electron microscopy. Light microscopy of Prussian blue–stained marrow aspirates or biopsy sections is a relatively insensitive method to identify these structures. One can usually identify approximately 25 to 35 percent of erythroblasts with one to three very fine Prussian blue–stained granules in the cytoplasm of a well-prepared marrow sample. Pathologic sideroblasts may be of two types: erythroblasts with a marked increase in the number and size of siderotic granules in the cytoplasm, compared to normal erythroblasts, or ringed sideroblasts. Ringed sideroblasts are the hallmark of the sideroblastic anemias. In contrast to the normal cytoplasmic location of siderotic granules, the pathologic sideroblasts in the sideroblastic anemias have large amounts of iron deposited as dust- or plaque-like ferruginous micelles between the cristae of mitochondria (Fig. 59-1).³¹ The iron-loaded mitochondria are distorted and swollen, their cristae are indistinct, and identification of mitochondria may itself be difficult. In humans, the mitochondria of the erythroblast are distributed perinuclearly,²³ which accounts for the distinctive “ringed” sideroblast identified by Prussian blue staining

TABLE 59–1. Classification of Sideroblastic Anemias

I. Acquired
A. Primary sideroblastic anemia (myelodysplastic syndromes) (Chap. 88)
1. Subunit 1 of the mitochondrial cytochrome oxidase ^{54,55}
B. Sideroblastic anemia secondary to:
1. Isoniazid ^{21,22}
2. Pyrazinamide ^{21,22}
3. Cycloserine ¹⁴⁹
4. Chloramphenicol ¹⁴⁹
5. Ethanol ¹¹⁸
6. Lead ²⁴
7. Chronic neoplastic disease (Chap. 8)
8. Zinc-induced copper deficiency ^{124,125}
II. Hereditary
A. X chromosome linked
B. Autosomal
1. Defects in the erythroid specific mitochondrial carrier family protein SLC25A38 ⁴⁷
2. Mitochondrial myopathy and sideroblastic anemia (<i>PSU1</i> mutations) ^{57,108,109}
C. Mitochondrial
1. Pearson marrow-pancreas syndrome ^{15–19}

when mitochondrial iron overload is present (Fig. 59–1). The morphologic features that characterize pathologic sideroblasts in various disorders have been summarized.³²

PATHOGENESIS

The pathogenesis of most of the sideroblastic anemias is not well understood.^{33,34} It is not clear whether the basic mechanism by which abnormal accumulations of intramitochondrial iron occurs is the same in inherited and acquired forms of the disease. However, it seems appropriate,

given the present state of knowledge, to discuss both forms together. The pathogenesis of the disorder may be viewed from two standpoints: the underlying biochemical lesions and the mechanism(s) of the anemia itself.

Biochemical Lesions and Genetics

In the search for the biochemical lesions responsible for the development of sideroblastic anemia, attention has been focused upon an intramitochondrial defect in heme synthesis and on possible disturbances in pyridoxine metabolism.

Defects in Heme Synthesis

The role of defects in heme biosynthesis have occupied central stage since the early studies of Garby and colleagues,³⁵ who postulated that such a defect might exist; they demonstrated that the level of free erythrocyte protoporphyrin was decreased. Subsequently, a variety of abnormalities of the levels of precursors and of their rate of incorporation into heme was documented (Chap. 58).^{36–41} However, the findings have not all been consistent, as levels of free erythrocyte protoporphyrin have often been increased,^{42,43} not diminished. The role of mitochondria in the etiology of sideroblastic anemia gained further credence when mutations of the mitochondrial genome were found in patients with Pearson syndrome.^{15–19}

Hereditary Sideroblastic Anemias

Shortly after the identification of erythroid-specific ALA synthase (ALAS2, the first enzyme in heme synthesis; Fig. 59–2), it became apparent that most patients with hereditary X-linked sideroblastic anemias (XLSAs) had mutations in the *ALAS2* gene.^{44–46} However, a proportion of patients with congenital sideroblastic anemia had autosomal recessive inheritance. At least some such patients have a defect in the gene encoding the erythroid-specific mitochondrial carrier protein, SLC25A38.⁴⁷ This transporter is important for the biosynthesis of heme in eukaryotes and it was proposed that this protein may be translocating glycine into mitochondria (Fig. 59–2).⁴⁷ Hence, SLC25A38 defects would be expected to generate a phenotype identical to that seen in patients with defects in ALAS2. One can speculate that, in erythroid cells, a common control mechanism exists that regulates acquisition of the two substrates for heme synthesis (iron and glycine).

Figure 59–1. Marrow films. **A.** Normal marrow stained with Prussian blue. Note several erythroblasts without apparent siderotic (blue-stained) granules. The arrow indicates erythroblast with several very small cytoplasmic blue-stained granules. It is very difficult to see siderosomes in most erythroblasts in normal marrow because they are often below the resolution of the light microscope. **B.** Sideroblastic anemia. Note the florid increase in Prussian blue–staining granules in the erythroblasts, most with circumnuclear locations. These are classic examples of ringed sideroblast, which are by definition pathologic changes in the red cell precursors. In some cases, cytoplasmic iron granules are also increased in size and number, also a pathologic change. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

Figure 59-2. Schematic of iron uptake from transferrin and its delivery to the hemoglobin (Hgb) molecule. Extracellular diferric transferrin is bound by the membrane-bound transferrin receptor (TfR) and internalized via receptor-mediated endocytosis into an endosome. Iron is released from transferrin by a decrease in pH (~pH 5.5), reduced by STEAP 3 (six-transmembrane epithelial antigen of prostate 3-ferrous reductase), following which the metal is transported through the endosomal membrane by DMT 1. In erythroid cells, more than 90 percent of iron must enter mitochondria wherein ferrochelatase (FECH), the enzyme that inserts Fe^{2+} into protoporphyrin IX (Proto IX), resides on the inner leaflet of the inner mitochondrial membrane. The transport of coproporphyrinogen (Copro'gen) into mitochondria is not fully understood. Neither mechanisms nor the regulation of the transport of heme from mitochondria to globin polypeptides are known; however, it has been proposed that a carrier protein, heme binding protein 1 (gene: *HEBP1*), is involved in this process. CPO, coproporphyrinogen oxidase; NAD(P), nicotinamide adenine dinucleotide phosphate; NAD(P)H reduced form of nicotinamide adenine dinucleotide phosphate; PPO, protoporphyrinogen oxidase. (Reproduced with permission from Anderson GJ, McLaren G: Iron Physiology and Pathophysiology in Humans. New York, NY: Humana Press; 2012.)

Hereditary sideroblastic anemia with spinocerebellar degeneration with ataxia is a rare X-linked syndrome that appears to be distinct from the other forms of sideroblastic anemia.⁴⁸⁻⁵¹ It is caused by mutation of ATP-binding cassette (ATCB7).^{48,52,53}

Heteroplasmic point mutations in subunit 1 of the mitochondrial cytochrome oxidase have been documented in some patients with sideroblastic anemia.⁵⁴⁻⁵⁶

Rare autosomal forms of inherited sideroblastic anemia have also been reported,^{57,58} including those with a deficiency of uroporphyrinogen decarboxylase^{59,60} and ferrochelatase (FECH)^{36,41,61-63} enzymes, both necessary for the synthesis of heme (Chap. 58). The other reported defects of ferrochelatase could result from the inhibitory effect of mitochondrial iron overload on enzyme activity.⁴¹ A defect in coproporphyrinogen oxidase (CPO) could not be confirmed by direct measurement.⁶⁴

An unusual phenotype with of inherited sideroblastic anemia, developmental delay with variable neurologic defects and B-cell lymphopenia with hypogammaglobulinemia was reported of yet unknown etiology.⁶⁵

Pyridoxine Metabolism

A role for pyridoxine has been supported by the demonstration that pyridoxine deficiency in animals is a prototype of sideroblastic anemia.³¹ Sideroblastic anemia can be induced by drugs that reduce the level of pyridoxal phosphate in blood, which decreases the ALAS2 activity in normoblasts.^{22,36,40} Moreover, certain sideroblastic disorders, although not a result of pyridoxine deficiency, are nonetheless responsive to pharmacologic doses of pyridoxine.^{44,66-68} Pyridoxal phosphate is a necessary coenzyme for the initial reaction of protoporphyrin synthesis, the condensation of glycine and succinyl coenzyme A to form

ALA, a reaction mediated by ALA synthetase (Chap. 58). Furthermore, pyridoxal phosphate is a factor in the enzymatic conversion of serine to glycine (Chap. 41). This reaction generates a form of folate coenzyme necessary for the formation of thymidylate, an important step in DNA synthesis. Pyridoxal 5'-phosphate, the active form of the coenzyme, must itself be enzymatically synthesized from pyridoxine. Deficiencies in its biosynthesis have also been invoked as the possible cause of certain sideroblastic anemias,^{27,69} but direct measurements of pyridoxal kinase failed to confirm that the postulated lesion was present.⁷⁰

Other Metabolic Defects and Acquired Associations with Sideroblastic Anemia of Uncertain Significance

Increased levels of uroporphyrinogen 1 synthase are commonly encountered in patients with sideroblastic anemias.³⁹ Alcohol, a common cause of secondary sideroblastic anemia, inhibits heme synthesis at several steps.³⁸ Dramatically altered activity ratios of a wide diversity of enzymes have been described,^{71,72} for example, elevated arginase activity.

Sideroblastic anemia has been found in a patient with apparent antibody-mediated red cell aplasia.⁷³ There are alterations in red cell antigen patterns frequently with an increase of i and a loss of A_i antigens (Chap. 136).⁷⁴ Similar findings occur in certain hereditary and acquired refractory anemias with cellular marrows but without ringed sideroblasts.⁷² Such dyscrasias are also characterized by ineffective erythropoiesis and, except for the lack of ringed sideroblasts, may in some instances be virtually indistinguishable from their sideroblastic counterparts.⁷⁵

Pathogenesis of Ring Sideroblast Formation

Iron accumulation within mitochondria is an unusual pathologic phenomenon occurring only in erythroblasts of patients with sideroblastic anemias and, to a much lesser degree, in cardiomyocytes of patients with Friedreich ataxia.^{76,77} Mitochondrial iron accumulation has not been demonstrated in patients with either primary or secondary iron overload. The pathophysiology of ring sideroblast formation in patients with ALAS2 defects and those resulting from inhibitors of porphyrin biosynthesis (see Table 59-1) is likely because of the unique aspects of the regulation of iron metabolism and heme synthesis in erythroid cells (Chap. 58).⁷⁸ These differences can account for the accumulation of non-heme iron in erythroid mitochondria of sideroblastic anemia patients. In hemoglobin-synthesizing cells, iron is specifically targeted toward mitochondria that avidly take up iron even when the synthesis of protoporphyrin IX is suppressed (Chap. 58).⁷⁹⁻⁸² In contrast, non-erythroid cells store iron in excess of metabolic needs within ferritin.⁸³ Hence, erythroid-specific mechanisms and controls are involved in the transport of iron into mitochondria in erythroid cells, but the nature of these processes, including the role of mitoferrin 1 (Chap. 42); an inner mitochondrial membrane protein, which presumably provides Fe^{2+} to FECH,⁸⁴ is poorly understood. The transferrin-bound iron is used for hemoglobin synthesis^{78,82} with a high degree of efficiency and is targeted into erythroid mitochondria (Chap. 52), and because no intermediate for cytoplasmic iron transport has ever been identified in erythroid cells, the following hypothesis of intracellular iron trafficking in developing red cells has been proposed (see Fig. 59-2 from Chap. 52). This model postulates that iron released from transferrin in the endosome is passed directly from protein to protein until it reaches FECH, which incorporates Fe^{2+} into protoporphyrin IX⁸⁵ in the mitochondrion. Such a transfer bypasses the cytosol, as the movement of iron between proteins could be mediated by a direct interaction of the endosome with the mitochondrion.^{78,86} The results of supporting experiments revealed that (1) iron, delivered to mitochondria via the transferrin-transferrin receptor (TfR) pathway, is unavailable to cytoplasmic chelators^{87,88}; (2) transferrin-containing endosomes move to and contact mitochondria in erythroid cells; and (3) endosomal movement is required for iron

delivery to mitochondria (see Fig. 59-2).⁸⁷ These studies also revealed that cytoplasmic iron not bound to transferrin is inefficiently used for heme biosynthesis and that the endosome-mitochondrion interaction increases chelatable mitochondrial iron.⁸⁷

An important distinction between erythroid and nonerythroid cells is the presence of a feedback mechanism in which "uncommitted" heme inhibits iron acquisition from transferrin.⁸⁹⁻⁹² Although it is still unresolved whether heme inhibits transferrin endocytosis^{89,90} or iron release from transferrin,⁹² the lack of heme plays an important role in mitochondrial iron accumulation. Additionally, non-heme iron, which accumulates in erythroid mitochondria, cannot be released from the organelle unless it is inserted into heme.⁸² This finding suggests that mitochondria can release iron only when the metal is in a proper chemical form, in this case, inserted into protoporphyrin IX. These considerations provide framework to the pathogenesis of mitochondrial iron accumulation in erythroblasts of patients with sideroblastic anemia caused by ALAS2 defects, as well as those caused by agents inhibiting porphyrin biosynthesis (see Table 59-1).

Of considerable interest, in 2014, Fleming and his coworkers⁹³ demonstrated that mutations in an enhancer element in ALAS2 intron 1, which contains a GATA-binding site, cause a clinical phenotype similar to patients with XLSA resulting from mutations in the ALAS2 coding sequence itself.

A distinct form of XLSA, that associated with ataxia (XLSA/A), was described in several families with putative mutations mapped to chromosome region Xq13.⁵⁰ In contrast to ALAS2-linked disease, the XLSA/A syndrome is associated with elevated erythrocyte protoporphyrin IX levels. It was demonstrated that mutations of the *ABCB7* gene is responsible for XLSA/A,⁴⁸ and this was confirmed by other reports.^{52,94} The *ABCB7* protein is thought to transfer iron-sulfur (Fe-S) clusters from mitochondria to the cytosol (Chap. 42).^{76,95,96} How the disruption of Fe-S cluster export might impede heme biosynthesis is, however, not clear, but the accumulation of erythrocyte zinc-protoporphyrin IX is found in XLSA/A.^{48,50,52} Additionally, mouse erythrocytes with mutated (E433K) *ABCB7* have an increase in zinc-protoporphyrin IX-to-heme ratios.⁹⁷ Because the formation of zinc-protoporphyrin IX requires FECH, *ABCB7* mutations cannot interfere with the activity of this enzyme. Instead, the loss of function of *ABCB7* may, by a yet-to-be-defined mechanism, diminish the availability of reduced iron (the only substrate of iron for FECH) required for the assembly of heme from protoporphyrin IX. In XLSA, as in ALAS2-associated sideroblastic anemia, decreased levels of heme likely contribute to the pathogenesis of ring sideroblast formation.

Another type of hereditary hypochromic anemia was described in *shiraz* (*sir*) zebra fish mutants.⁹⁸ These mutants have a deficiency of glutaredoxin 5 (*GLRX5*) encoded by a gene (*GLRX5*) whose product is required for Fe-S cluster assembly. This study demonstrated that the loss of the Fe-S cluster in the iron-regulatory protein 1 (*IRP1*) blocked ALAS2 translation by binding to the iron-responsive element (*IRE*) located in the 5'-untranslated region of ALAS2 mRNA. Subsequently, a case of *GLRX5* deficiency in an anemic male with iron overload and a low number of ringed sideroblasts was reported.⁹⁹ As in zebra fish with *shiraz* mutants, ferritin levels were low and TfR levels were high in the patient's cells; this can be explained by increased *IRP1* binding to *IREs* in mRNAs of these two proteins. However, erythroblasts from zebra fish *shiraz* mutants were not found to contain iron-loaded mitochondria.

Primary Acquired Sideroblastic Anemia (Refractory Anemia with Ring Sideroblasts—Myelodysplastic Syndrome)

The pathophysiology of acquired idiopathic sideroblastic anemias associated with myelodysplastic syndrome is distinct from the above discussed XLSAs. In these patients there is no evidence for a decrease

in the formation of protoporphyrin IX levels; instead, the amount of protoporphyrin IX is moderately increased.⁴³ Impaired iron reduction could cause intramitochondrial iron accumulation in patients with myelodysplastic syndromes. The ferric reductase, STEAP 3 (six-transmembrane epithelial antigen of prostate 3-ferric reductase), is involved in the reduction of Fe³⁺ to Fe²⁺ in endosomes.¹⁰⁰ Based on the model of the direct interorganellar transfer of iron (see Fig. 59–2), it can be assumed that there is only one reduction step during the path of iron from endosomes to FECH. However, the efficient insertion of ferrous ions into protoporphyrin IX may still require a reducing environment in mitochondria that would be provided by an uninterrupted respiratory chain. This proposal is compatible with the fact that sideroblastic anemia accompanying Pearson marrow-pancreas syndrome¹⁰¹ is caused by deletions of mitochondrial DNA genes, products of these are involved in electron transport.¹⁰² Indeed, there are at least some myelodysplasia-associated sideroblastic anemia patients described caused by acquired mutations in cytochrome oxidase, encoded by mitochondrial DNA.^{54,55,103–105} However, a rigorous study failed to find cytochrome oxidase mutations in 10 patients with myelodysplasia-associated sideroblastic anemia.¹⁰⁶ Alternatively, there is some evidence that *ABC7* (see the above discussion on XLSA/A) could be a possible candidate gene for the formation of ringed sideroblasts in refractory anemia with ring sideroblasts.¹⁰⁷

Mitochondrial Myopathy and Sideroblastic Anemia

There are some similarities and some dissimilarities between Pearson marrow-pancreas syndrome and patients with mitochondrial myopathy and sideroblastic anemia (MLASA).^{57,108,109} In both cases, there are defects in the mitochondrial electron transport chain, likely creating an environment that retards iron access to FECH in the reduced form. Both disorders are hereditary, but Pearson syndrome is caused by large deletions of mitochondrial DNA, whereas MLASA results from a homozygous missense mutation in the genomic DNA of pseudouridine synthase 1, encoded by *PUS1* gene.¹⁰⁸ It has been proposed that deficient pseudouridylation of mitochondrial transfer RNAs (tRNAs) explains the pathogenesis of MLASA type of sideroblastic anemia.¹⁰⁸

Mitochondrial Ferritin Mitochondrial ferritin is a ferritin isoform with ferroxidase activity that is expressed only in mitochondria (Chap. 42). This protein is encoded by an intronless nuclear gene and can store iron within a shell of homopolymers.^{110–112} Although the function and regulation of expression of this protein is not fully understood, the induction of mitochondrial ferritin causes the transfer of iron from cytosolic ferritin to mitochondrial ferritin.¹¹³ The mitochondrial ferritin has a very low expression in all tissues except testis.^{110,112} Although mitochondrial ferritin is not expressed in normal erythroblasts, it is expressed in ring sideroblasts of patients with sideroblastic anemias,¹¹⁴ caused by *ALAS2* defects, as well as those associated with myelodysplastic syndromes. In both, iron is sequestered within mitochondrial ferritin.¹¹⁴ Because mitochondrial ferritin has ferroxidase activity, it likely protects mitochondria by converting the toxic ferrous iron to ferric iron that is stored. Further research is needed to explain the mechanism of mitochondrial ferritin induction in erythroblasts of patients with sideroblastic anemias, both hereditary and acquired. Whether the mitochondrial ferritin also accumulates iron in ring sideroblasts of patients with XLSA/A has not yet been studied.

Mechanism of Anemia

The dominant factor that determines anemia is ineffective erythropoiesis (intramedullary apoptosis); the rate of red cell destruction is usually near-normal or only moderately accelerated to levels for which a normally functioning marrow can compensate.¹¹⁵ The half-time of disappearance of intravenously injected tracer doses of radioactive iron is

usually is rapid (25 to 50 minutes; normal mean: 90 to 100 minutes) but in some patients may be normal. The plasma iron turnover tends to be increased (1.5 to 5.9 mg/dL of blood per day; normal: approximately 0.30 to 0.70 mg/dL per day), but incorporation of radioactive iron into heme and its delivery to the blood as newly synthesized hemoglobin are depressed (15 to 30 percent of tracer dose; normal: 70 to 90 percent). Red cell survival ranges between 40 and 120 days, indicating some cases have moderate or only very slightly shortened red cell life-span, whereas in other cases red cell survival is normal. As in other kinds of anemia characterized by ineffective erythropoiesis, the fecal stercobilin excreted per day may be greater than can be accounted for by the daily catabolism of circulating hemoglobin.

CLINICAL AND LABORATORY FEATURES

PRIMARY ACQUIRED (CLONAL) SIDEROBLASTIC ANEMIA

The primary acquired sideroblastic anemia is described in Chap. 87. Anemia is present in more than 90 percent of patients. Patients may be asymptomatic or, if anemia is more severe, have the nonspecific symptoms of anemia including pallor, weakness, loss of a sense of well-being, and exertional dyspnea. A small proportion of patients have infections related to severe granulocytopenia or hemorrhage related to severe thrombocytopenia at the time of diagnosis; however, this variant of myelodysplastic syndrome has the lowest probability of symptomatic neutropenia, thrombocytopenia, and acute leukemic transformation among all myelodysplastic syndromes (Chap. 87). Hepatomegaly or splenomegaly occurs also rarely in this type of myelodysplastic syndrome. Iron overloading regularly accompanies this disorder, usually in those who have a large requirement for transfusion, and may be the cause of death (Chap. 87).

SECONDARY ACQUIRED SIDEROBLASTIC ANEMIA

Drugs and Alcohol

The administration of certain drugs and the ingestion of alcohol may cause sideroblastic anemia (see Table 59–1). The drugs that are most commonly associated with this type of anemia are isonicotinic acid hydrazide,¹¹⁶ pyrazinamide,^{21,22,117} and cycloserine,^{21,22,117} all pyridoxine antagonists. Although plasma pyridoxal phosphate levels are often low in alcoholic patients, there is no correlation between these levels and the appearance of ringed sideroblasts in the marrow.¹¹⁸

Anemia secondary to drugs may be quite severe, even necessitating transfusion,²² but characteristically the anemia improves rapidly when the patient is given pyridoxine and/or when administration of the offending drug is discontinued. The red cells are hypochromic, and a dimorphic appearance of the erythrocytes in the blood film may be notable, that is, two populations of red cells can be distinguished; hypochromic and anisocytic, along with normochromic and normocytic. The reticulocyte count is low or normal.¹¹⁹ In rare instances, a sideroblastic anemia first observed during the course of drug administration has progressed in the face of discontinuing the putative offending drug. In such cases, the patient presumably was suffering from an unmasked underlying myelodysplastic neoplasm.

Copper Deficiency

In 1974, two patients with sideroblastic anemia, one also with neutropenia, following extensive bowel surgery and long-term parenteral nutrition were described.¹²⁰ In 2002, another patient was described who

developed progressive macrocytic anemia, thrombocytopenia, and leukopenia with ringed sideroblasts after gastroduodenal bypass (Billroth II procedure). This patient also had optic neuritis and other neurologic abnormalities.¹²¹ The hematologic abnormalities, but not neurologic defects, resolved fully with copper therapy. Since that time numerous similar cases, with and without neurologic abnormalities, have been reported.^{122,123} A similar hematologic picture can be seen with zinc-induced copper deficiency.^{124,125}

HEREDITARY SIDEROBLASTIC ANEMIA

Hereditary sideroblastic anemia is very uncommon. More instances of the X-chromosome linked varieties than of apparently autosomally inherited cases have been documented.¹²⁶ The disorder is heterogeneous. The variant with ataxia is characterized by neurologic impairment and typically mild anemia in males. The neurologic symptoms include ataxia, dysmetria, dysdiadochokinesis, dysarthria, and intention tremor that are referred to as spinocerebellar syndrome. A mild intellectual impairment may be also seen.

In some of the cases of hereditary iron-loading anemia that are cited below, the presence of the sideroblasts in the marrow or the hereditary nature of the disorder is documented, whereas in others it is presumed but not clearly documented.

Anemia is usually apparent during the first few months¹²⁷ or years^{35,37} of life; it may even occur prenatally.¹⁰³ However, there are patients in whom microcytic anemia first became evident in the eighth and ninth decade of life and were found to have a microcytic, pyridoxine response anemia apparently related to inherited mutations of the *ALAS2* gene.^{128,129}

Pallor is the most prominent physical finding; splenomegaly may be present,¹³⁰ but not universally so.^{35,127} The anemia is characteristically microcytic and hypochromic, and prominent dimorphism of the red cell population has been noted in carrier females of the sex-linked form of the anemia.^{12,127,131} This has been regarded as evidence of X-inactivation affecting the locus responsible for this disorder,^{37,127,131,132} but it is notable that marked dimorphism sometimes is seen in the red cells of affected males as well,^{12,35} and in autosomal forms of the disease.¹³³ The degree of anisocytosis and poikilocytosis is usually striking. Sometimes the anemia can be macrocytic,^{2,134} especially in mitochondrial forms of the disease. The red cells show marked heterogeneity with respect to resistance to osmotic lysis: a flattened curve indicates that cells with both increased and decreased resistance to lysis are present.^{35,135} The white cell count is usually normal or slightly decreased, unless splenectomy has been performed. Then it may be greatly elevated.¹³⁶ Splenomegaly is present in most cases.¹³⁶ In one family, a platelet function abnormality resembling a storage pool defect was noted,¹³⁷ but this could have been an independently inherited disorder.

Pearson marrow-pancreas syndrome is a refractory sideroblastic anemia with vacuolization of marrow precursors and exocrine pancreatic dysfunction (Chap. 36).^{56,138} It is often fatal in infancy or early childhood, is characterized by marrow failure with macrocytic sideroblastic anemia, which is typically transfusion dependent. Neutropenia and thrombocytopenia may also be present. However, the invariable dysfunction of the exocrine pancreas from fibrosis and acinar atrophy resulting in chronic malabsorption and diarrhea may, in some affected patients, be dominant features of morbidity and mortality of Pearson syndrome. Lactic acidosis, caused by a defect in oxidative phosphorylation and other organ dysfunction, including liver impairment, is also common. The usual causes of death are bacterial sepsis from neutropenia, metabolic crisis, and hepatic failure. Most patients die in infancy, although there is considerable phenotypic variation, presumably depending upon the number of mitochondria affected and their tissue distribution.

TREATMENT

Many patients with hereditary sideroblastic anemia have some response to treatment with pyridoxine in doses of 50 to 200 mg/day,^{12,127,131,136,139–141} but failures have also been observed.^{8,35,42} Some patients have responded to doses as low as 2.5 mg/day.¹³⁶ An additional effect may be achieved by the administration of folic acid.¹²⁷ Very rarely, patients have been reported to respond to a crude liver extract, and tryptophan may be an active principle, enhancing the effect of pyridoxine.^{142,143} Responses to pyridoxine may result in an increase in the steady-state hemoglobin level of the blood or a decrease in the transfusion requirement, but normalization of the hemoglobin level does not usually occur and the anemia relapses when pyridoxine administration is discontinued.

Iron overloading regularly accompanies this disorder and may be the cause of death (Chap. 43).⁴¹ Iron storage may be enhanced when any of the mutations of hereditary hemochromatosis are coinherited.¹⁴⁴ If the anemia is not too severe or if it can be partially corrected by the administration of pyridoxine, phlebotomy may be used to diminish the iron burden.^{145,146} Otherwise, it may be advisable to attempt to decrease the amount of body iron by iron chelation (Chap. 43).

Marrow transplantation, both ablative¹⁴⁷ and nonmyeloblastic,¹⁴⁸ has been used on rare occasions to treat patients with severe hereditary sideroblastic anemia.

CHAPTER 60

STRUCTURE AND COMPOSITION OF NEUTROPHILS, EOSINOPHILS, AND BASOPHILS

C. Wayne Smith

SUMMARY

Early in precursor development in the marrow, cells destined to be leukocytes of the granulocytic series—neutrophils, eosinophils, and basophils—synthesize proteins and store them as cytoplasmic granules. The synthesis of primary or azurophilic granules defines the conversion of the myeloblast, a virtually agranular, primitive cell that is the earliest granulocyte precursor identifiable by light microscopy, into the promyelocyte, which is rich in azurophilic granules. Synthesis and accumulation of secondary or specific granules follows. The appearance of specific granules marks the progression of the promyelocyte to neutrophilic, eosinophilic, or basophilic myelocytes. Thereafter, the cell continues maturation into an amitotic cell with a segmented nucleus, capable of chemotaxis, phagocytosis and microbial killing. The mature granulocytes also develop cytoplasmic and surface structures that permit them to attach to and penetrate the wall of venules. The mature granulocytes enter the blood from the marrow, circulate briefly, and move to the tissues to carry out their major function of host defense. Blood neutrophils exhibit the capacity for changes in phenotypic characteristics and life span depending on the stimulating milieu of cytokines and chemokines. Gene expression profiling studies indicate the neutrophil is a transcriptionally active cell, responsive to environmental stimuli, and capable of a complex series of early and late changes in gene expression.

Acronyms and Abbreviations: AML1, AML2, AML3, transcription factor for various hematologic lineages; C3a, serum complement fragment 3a; C5a, serum complement fragment 5a; CBFA1, CBFA2, core-binding factor subunit α -1 or -2; CCR, C-C chemokine receptor; C/EBP ϵ , regulating factor of gene expression; CD11b/CD18, Mac-1 or integrin α _{IIb} β ; ECP, eosinophil cationic protein; EDN, eosinophil-derived neurotoxin; Fc γ RIIIB, receptor IIB for the Fc region of IgG; GATA-1, lineage-specific transcription factor; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; GRO, growth-regulated protein; IFN, interferon; Ig, immunoglobulin; IL, interleukin; IP-10, interferon- γ -induced protein 10; JAK2, Janus-associated kinase 2; LPS, lipopolysaccharide; MBP, major basic protein; MMP-8, metalloproteinase-8, also called collagenase; MMP-9, metalloproteinase-9, also called gelatinase B; NADPH, reduced form of nicotinamide adenine dinucleotide phosphate; PAF, platelet-activating factor; PMN, polymorphonuclear neutrophil; RUNX1, RUNX2, RUNX3, runt-related transcription factor 1, 2, or 3; SNAP, soluble NSF (N-ethylmaleimide-sensitive factor) attachment protein; TGF, transforming growth factor; TNF, tumor necrosis factor; VAMP, vesicle-associated membrane protein.

In the normal adult human, the life of granulocytes is spent in three environments: marrow, blood, and tissues. Marrow is the site of differentiation of hematopoietic stem cells into granulocyte progenitors and of proliferation and terminal maturation (Fig. 60-1). Precursor cell proliferation, which consists of approximately five divisions, occurs only during the first three stages of maturation (blast, promyelocyte, and myelocyte). After the myelocyte stage, the cells are no longer capable of mitosis and enter a large marrow storage pool from which they are released into the blood where they circulate for a few hours before entering tissues.

● NEUTROPHILS

LIGHT MICROSCOPY AND ELECTRON MICROSCOPY

The Myeloblast

The myeloblast is an immature cell with a large, oval nucleus, sizable nucleoli, and few or no granules. As the earliest precursor in the evolution of the neutrophil from the colony forming unit, it is an immature cell with a large nucleus and multiple nucleoli (Fig. 60-2). The nucleolus is the site of assembly of ribosomal proteins and ribosomal RNA, and is a prominent feature of early maturing cells. The scant cytoplasm contains reaction product for peroxidase within the rough-surfaced endoplasmic reticulum and Golgi cisternae and, sometimes, in early developing azurophilic granules. The dense product of the peroxidase reaction serves as a marker of azurophilic granules in human marrow and blood cells for electron and for light microscopy.¹⁻⁴

The Promyelocyte

In the promyelocyte stage, the azurophilic or primary granules, large peroxidase-positive granules that stain metachromatically (reddish-purple) with a polychromatic stain such as Wright stain, are formed. Figure 60-3 shows that the promyelocyte produces and accumulates a large population of peroxidase-positive granules. Most of the granules are spherical and have a diameter of 500 nm, but ellipsoid, crystalline forms and small granules connected by filaments also are present.⁵ As with other secretory cells, peroxidase is present throughout the secretory apparatus of the promyelocyte, including cisternae of the rough endoplasmic reticulum, all Golgi cisternae, some vesicles, and all developing granules.²

The Neutrophilic Myelocyte

During the myelocyte stage of maturation, the specific or secondary granules, which are peroxidase negative, are formed (see Fig. 60-2). At the end of the promyelocyte stage, peroxidase abruptly disappears from rough endoplasmic reticulum and Golgi cisternae, and the production of azurophilic granules ceases. The myelocyte stage begins with production of peroxidase-negative specific granules.²

The only peroxidase-positive elements at this stage are the azurophilic granules. The specific granules are formed by the Golgi complex. The granules vary in size and shape but typically are spherical (approximately 200 nm) or rod shaped (130 × 1000 nm). Figure 60-4 shows the cell also labeled with immunogold particles to illustrate the presence of lactoferrin, a specific granule marker. Approximately three cell divisions occur at this stage of maturation. Mitoses can be observed (Fig. 60-5), and the two types of granules appear to be distributed to the daughter cells in fairly equal numbers.

Metamyelocyte, Band, and Mature Neutrophil

The metamyelocyte and band neutrophils are nonproliferating cells that precede the development of the mature neutrophil (see Fig. 60-2).

Figure 60-1. Diagrammatic representation of neutrophil (polymorphonuclear neutrophil [PMN]) and stages of maturation (see text for discussion). Of every 100 nucleated cells in marrow, 0.5 percent are myeloblasts, 5 percent are promyelocytes, 12 percent are myelocytes, 22 percent are metamyelocytes and bands, and 20 percent are maturing and mature neutrophilic cells, yielding a total of approximately 60 percent of cells representing developing neutrophils in normal human marrow. (Reproduced with permission from Lichtman's Atlas of Hematology. www.accessmedicine.com.)

The mature, segmented neutrophilic cells contain primary, peroxidase-positive granules and specific peroxidase-negative granules in a 1:2 ratio. The nucleus of the circulating neutrophil is segmented, usually into two to four interconnected lobes. The late stages of maturation consist of nondividing cells that can be distinguished by their nuclear morphology, mixed granule populations, small Golgi regions, and accumulations of glycogen particles. On average, an electron micrograph of a neutrophil displays 200 to 300 granules, and approximately one-third are peroxidase-positive (Fig. 60-6).

The violet-colored granules seen with light microscopy in mature neutrophils on Wright-stained blood films are azurophilic granules whose staining characteristics altered during maturation (Fig. 60-7). Therefore, with light microscopy, the most reliable method for identifying azurophilic granules on blood films is staining the cells for peroxidase. The size of most of the peroxidase-negative granules (approximately 200 nm) is at the limit of resolution of the light microscope. The granules cannot be distinguished individually but are responsible for the pink background color of neutrophil cytoplasm during and after the myelocyte stage.

Peroxidase-negative granules are more numerous than peroxidase-positive granules during the myelocyte stage because peroxidase granule formation ceases after the promyelocyte stage, the number of oxidase-positive granules per cell is reduced by mitoses, and peroxidase-negative granules continue to be produced by each myelocyte generation.¹

The purpose of nuclear segmentation is not known. Fluorescence *in situ* hybridization with chromosome-specific probes has shown that chromosomes are randomly distributed among the nuclear lobes.⁶ Some mature neutrophils in women have drumstick- or club-shaped nuclear appendages. These appendages contain the inactivated X chromosome. An X-chromosome-specific nucleic acid probe has confirmed the position of the X chromosomes in the drumstick structure of leukocyte nuclei by *in situ* hybridization.⁷

● NEUTROPHIL GRANULES

The diversity of neutrophil granules appears to be linked to the timing of biosynthesis during myelopoiesis. The hypothesis is that the different subsets of granules are the result of differences in the biosynthetic windows of the various granule proteins during maturation⁷ and not the result of specific sorting between individual granule subsets (Chap. 66). The control of biosynthesis is exerted by transcription factors that control the expression of the genes for the various granule proteins. Several transcription factors identified as important in the timing of granule protein synthesis, including the lineage-specific transcription factor GATA-1, the lineage-specific transcription factor PU.1, transcription factor for various hematologic lineages, AML1 (also known as runt-related transcription factor 1 [RUNX1] or core-binding factor subunit alpha-2 [CBFA2]), AML2 (also known as RUNX3), and AML3 (also known as RUNX2 or CBFA1), and regulating factor of gene expression C/EBPε.⁷⁻⁹ The importance of C/EBPε has been emphasized by the recognition of mutations in this protein in patients with the rare syndrome called “specific granule deficiency,”¹⁰⁻¹² a condition that leads to increased susceptibility to bacterial infections. In neutrophils from these patients, total cellular content and release of the secondary and tertiary granule markers (e.g., lactoferrin, B₁₂ binding protein, and lysozyme) are diminished, although levels of primary granule constituents (e.g., myeloperoxidase, β-glucuronidase) generally are normal.

The granular constituents are released from the membrane-enclosed granules into phagosomes or transported to the cell surface by a process of exocytosis following stimulation of the neutrophil.¹³ The signal cascade following stimulation of specific receptors on the cytoplasmic membrane results in elevated intracellular Ca²⁺, lipid remodeling, and protein kinase activation, which culminate in fusion of granules with phagosomes or the cell surface membrane. The process is rapid, highly efficient, and involves families of docking proteins related to those found in neurons (e.g., vesicle-associated membrane protein [VAMP]-2, syntaxin-4, soluble NSF (N-ethylmaleimide-sensitive factor)-attachment protein [SNAP]-23).¹⁴

The granule subsets appear to have a significant differential sensitivity to undergo exocytosis, ranging from secretory vesicles to tertiary,

Figure 60-2. Marrow films. **A.** Myeloblast is the smaller cell to the lower right. It is the first recognizable precursor in the granulocytic series. Relatively high nuclear-to-cytoplasmic ratio. Note nucleoli and agranular cytoplasm. Promyelocyte in upper left. This cell is the largest granulocyte precursor in the marrow. It often has overt nucleoli, usually more cytoplasm, and azurophilic (primary) granules scattered throughout the cytoplasm and overlying the nucleus. **B.** Two very early neutrophilic myelocytes. They are very similar to the promyelocyte in appearance with nucleoli and scattered azurophilic granules throughout the cytoplasm. The distinguishing feature is the burst of tan coloring at the site of the Golgi zone, indicating the initial synthesis of neutrophilic granules. **C.** Large cell to the left is an early neutrophilic myelocyte with more neutrophilic granules evident spreading from the Golgi zone at the hilus of the nucleus. It still has some features of the promyelocyte. The cell beneath the asterisk is a late neutrophilic myelocyte. The cell has decreased in size, the nuclear chromatin has condensed. Nucleoli are not evident and the cytoplasm is nearly filled with neutrophilic granules. Below the neutrophilic myelocyte is a neutrophilic metamyelocyte, characterized by its reniform nucleus and cytoplasm filled with neutrophilic granules. The cell above the large early myelocyte on the left is a band neutrophil. The nucleus has reached the shape of a sausage and is about equal in diameter through its length. **D.** A band neutrophil (*left*) and a segmented neutrophil (*right*). Neutrophilic granules, because of their small size, are not resolvable by the light microscope and are inferred by the characteristic tan staining quality of the cytoplasm. (Reproduced with permission from Lichtman's Atlas of Hematology. www.accessmedicine.com.)

secondary, and primary granules, with primary granules being most resistant. The significance of this differential release is incompletely understood, but some aspects are apparent in the functions of the constituents within the granules and granular membranes. For example, secretory vesicles and tertiary granules contain receptors, such as CD11b/CD18 (adhesion molecule, Mac-1), formyl peptide receptor (chemotactic receptor), FcγRIIIB (Fc receptor), and gelatinase (metalloproteinase [MMP]-9), which potentially enhance extracellular interactions of the neutrophil. Primary granules contain microbicidal proteins and acid hydrolases, and the acidic environment of the phagolysosome creates an optimal pH for these enzymes.

BIOACTIVE FACTORS IN GRANULES

Neutrophil granules are particularly rich in factors with antimicrobial activity. Some (e.g., myeloperoxidase) function in conjunction with

the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, whereas others (e.g., defensins) exhibit activity independent of the oxidative burst. Table 60-1 lists the principal contents of the four granule types in neutrophils: primary (azurophilic), secondary (specific), tertiary, and secretory vesicles.¹⁵⁻⁵⁶

EOSINOPHILS

LIGHT MICROSCOPY OF EOSINOPHILS IN MARROW AND BLOOD FILMS

The earliest morphologically identifiable form of an eosinophilic leukocyte is as a late myeloblast or early promyelocyte (see Fig. 60-1). This cell is approximately 15 μm in diameter and has a large nucleus with nucleoli and a few blue or azurophilic granules in intensely basophilic

Figure 60-3. Electron micrograph of a neutrophilic promyelocyte from normal human marrow reacted for peroxidase. This cell is the largest of the neutrophilic series. It has a sizable, slightly indented nucleus with a nucleolus, a prominent Golgi region (G), centriole (ce), and cytoplasm packed with dense peroxidase-positive (p+) azurophilic granules of varying shapes and sizes. Peroxidase reaction product is visible in less concentrated form within all compartments of the secretory apparatus—endoplasmic reticulum (er), perinuclear cisterna (pn), and Golgi cisternae (G), and there are peroxidase negative granules (p-). No reaction product is apparent in the cytoplasmic matrix or mitochondria. (×8000).

cytoplasm. The later eosinophilic promyelocyte and myelocyte contain mostly acidophilic granules. A lineage-committed eosinophil progenitor has recently been identified that expresses high levels of interleukin (IL)-5 receptor α and is negative for myeloperoxidase.⁵⁷ The fully mature eosinophilic leukocyte has a bilobed nucleus (see Fig. 60-7), and its cytoplasm is filled with large eosinophilic granules whose rims stain for peroxidase and Sudan black. Multilobed nuclei, comparable to those of neutrophils, are rare. Eosinophils are susceptible to mechanical damage during preparation of blood films.

ELECTRON MICROSCOPY AND CYTOCHEMISTRY

Eosinophils of the promyelocyte and myelocyte stages stain positively for peroxidase in all cisternae of the rough-surfaced endoplasmic reticulum, including transitional elements and the perinuclear cisterna;

Figure 60-4. Portion of cytoplasm stained for peroxidase to mark the azurophil granules and then immunolabeled with gold particles to detect lactoferrin. The peroxidase-positive (p+) azurophil granules contain dense reaction product, whereas the lighter specific granules are peroxidase negative. Many of the peroxidase-negative granules (arrows) have gold label within their matrix (×70,000).

clusters of smooth vesicles at the periphery of the Golgi complex; all cisternae of the Golgi complex; and all immature- and mature-specific granules.^{4,58} Mature granules are completely filled with peroxidase except in areas occupied by centrally located crystals.

In the later stages of development, after granule formation has ceased, the eosinophils contain few of the organelles associated with the synthesis and packaging of secretory proteins. The endoplasmic reticulum is sparse or virtually nonexistent. The Golgi complex is small and inconspicuous. The cytoplasm of the mature eosinophil (Fig. 60-8) primarily contains granules and glycogen. Most of the granules are specific granules with crystals, which usually are centrally located. After the myelocyte stage, peroxidase can no longer be detected in the endoplasmic reticulum or Golgi elements of the eosinophil by any of the enzyme procedures; however, peroxidase can be found in the matrix of granules.^{1,58}

GRANULES

Contents

As with neutrophils, eosinophils contain distinct granular organelles: primary granules, crystalloid granules, small granules and secretory vesicles.⁵⁹ The crystalloid granules (see Fig. 60-8)

Figure 60-5. Myelocyte from rabbit marrow in the late stage of mitosis. This myelocyte is in telophase. Note that the granules are relatively equally distributed to the daughter cells ($\times 15,000$).

Figure 60-6. Mature neutrophil from normal human marrow reacted for peroxidase. The cytoplasm is filled with granules of the two basic types: (1) the smaller, pale, peroxidase-negative granules (p-) and (2) the large, dense, peroxidase-positive granules (p+). The nucleus is condensed and lobulated (n¹-n⁴), the Golgi region (G) is small and without any forming granules, the endoplasmic reticulum is scant, and mitochondria (m) are few ($\times 21,000$).

are the largest, 0.5 to 0.8 μm in diameter, and contain much of the granular protein. The proteins packaged in these granules are highly basic proteins, with the crystalline core being mostly major basic protein (MBP).^{60,61} The granule matrix contains eosinophil peroxidase, eosinophil cationic protein (ECP), and eosinophil-derived neurotoxin (EDN). The primary granules contain Charcot-Leyden crystals. Charcot-Leyden crystals are bipyramidal crystals observed in fluids in association with eosinophilic inflammatory reactions. They possess lysophospholipase activity and compose

7 to 10 percent of total eosinophil protein.^{62,63} The ultrastructural localization of this protein is in a large, crystal-free granule and supports the presence of a distinct primary granule population in mature eosinophils.^{4,63,64} MBP consists of two homologues and is an abundant granular protein, 5 to 10 μg per cell. Mature eosinophils can no longer express this protein so all MBP is stored during development.⁶⁵ Eosinophil peroxidase is an abundant heme-containing protein (approximately 15 μg per cell) that catalyzes the peroxidation of halides together with hydrogen peroxide forming

ATPase, adenosine triphosphatase; BPI, bactericidal/permeability-increasing protein; hCAP, human cationic peptide; HNP, human neutrophil peptide; MMP-9, metalloproteinase-9; NGAL, neutrophil gelatinase-associated lipocalin; TNF, tumor necrosis factor; uPAR, urokinase plasminogen activator receptor; VAMP, vesicle-associated membrane protein.

Data regarding antimicrobial factors from Refs. 15 to 41. Data regarding enzymes from Refs. 42 to 56.

Figure 60-8. Human mature eosinophil incubated for peroxidase. Reaction product is present only in granules (g). The rough endoplasmic reticulum (er), including the perinuclear cisterna (pn) and the Golgi cisternae (Gc), does not contain reaction product. Most of the granules (arrow) contain the distinctive crystalline bar ($\times 8000$).

Figure 60-9. Mature basophil from human blood reacted for peroxidase. Note the unusually large nucleus (N) and scattered glycogen particles (gl). Human basophil granules contain peroxidase, as illustrated by their density (as a result of the presence of reaction product) in this type of preparation. They usually are spherical, difficult to fix, and may be speckled in appearance (arrow) ($\times 17,000$).

bactericidal hypohalous acids.^{66,67} ECP is a bactericidal protein exists in two isoforms (ECP-1 and ECP-2) with activity toward helminthic parasites. EDN shares high sequence homology with ECP and is abundant, approximately 10 pg per cell. Other granule-stored proteins include several enzymes of potential importance in inflammation, including acid phosphatase, collagenase (MMP-8), matrix metalloproteases, histaminase, catalase, and phospholipase D.⁶⁸⁻⁷⁰ Chapter 62 discusses the functional aspects of these granular proteins. In addition, mature eosinophils retain the ability to synthesize a diverse array of proteins including cytokines and chemokines,^{71,72} adhesion molecules,⁷³⁻⁷⁶ receptors for cytokines, complement components, lipid mediators, and immunoglobulins.⁷⁷⁻⁸²

BASOPHILS AND MAST CELLS

Basophils (see Fig. 60-7) and mast cells were considered to be derived from distinct lineages, but recent data indicates a common basophil-mast cell progenitor exists from which mast cells exit the marrow as immature precursors and terminally differentiate in tissues; basophils mature in the marrow before entering the circulation.⁸³⁻⁸⁶ This common progenitor is derived from the granulocyte-monocyte progenitor. The granules of the two cell types stain metachromatically but are distinct when examined by electron microscopy (Figs. 60-9 and 60-10). Identification of basophils in tissue at the light microscopic level is difficult without the use of cell specific antibodies.⁸⁷ Basophils and mast cells express the FcεR1 receptor. The cells can phagocytose sensitized red cells but are less active phagocytes than the other granulocytes. They lack significant amounts of antibacterial or lysosomal enzymes. Basophils are found in small numbers in blood (0.5 percent) and can be seen in tissues in which inflammation resulting from hypersensitivity to

Figure 60-10. Portion of a mast cell from human marrow. Note the granules are filled with scroll-like (s) and crystal (c) images and are distinct from human basophil granules (see Fig. 60-9) in fine structural morphology ($\times 50,000$).

proteins, contact allergy, or skin allograft rejection is present. They have been shown to be rich sources of IL-4 and IL-13.^{83,84,88}

Mast cells are normal residents of connective tissue throughout the body. Mast cell granules contain various substances, including several preformed biologically active substances such as histamine, which causes increased vascular permeability; eosinophil chemotactic factor of anaphylaxis; and heparin, which has antithrombin activity.⁸⁹⁻⁹² This accounts for the metachromatic staining quality of the granules. The generation of anaphylatoxin (C3a, C5a) or the interaction of allergen with immunoglobulin (Ig) E receptors of plasma membrane can stimulate extracellular release of these granule contents and of several newly formed substances, such as slow-reacting substance of anaphylaxis, a leukotriene that causes contraction of human bronchioles and increased vascular permeability, and platelet-activating factor (PAF), which causes platelet aggregation and the subsequent release of serotonin. This phenomenon is called IgE-mediated mast cell degranulation.⁹⁰ Mast cells also have been implicated in various diseases that are accompanied by neovascularization (Chap. 63).

● METABOLISM OF NEUTROPHILS

CARBOHYDRATE METABOLISM

Glycolysis

Glycolytic (Embden-Meyerhof) Pathway The main energy-producing pathway in the neutrophil is glycolysis, resulting in the conversion of glucose to lactate.⁹³⁻⁹⁵ When intact or homogenized leukocytes are incubated with glucose uniformly labeled with ¹⁴C, approximately 80 percent of the radioactivity is recovered in lactic acid. Glycolysis is inhibited by cortisol.^{96,97} In some cases, the conditions under which the neutrophils are disrupted have a significant effect on the activities measured.⁹⁸ Hexokinase is the rate-limiting enzyme of glycolysis in normal neutrophils.⁹⁴ The rate of glycolysis is not altered during phagocytosis,⁹⁵ but ATP levels, normally 1.9 nmol/10⁶ cells, fall to 0.8 nmol/10⁶ cells. Both the glycogen stores of neutrophils and the glucose of the plasma can serve as the source of glucose. Galactose, mannose, and fructose can also be metabolized by leukocytes.⁹⁹ Table 60-2 shows the glycolytic and other principal enzymes of the neutrophil.

Hexose Monophosphate Shunt Pathway

Neutrophils also metabolize glucose by way of the hexose monophosphate shunt,¹⁰⁰⁻¹⁰² thus accounting for some of the oxygen consumption of the cells. In resting cells, the amount of glucose metabolized via this route amounts to only 2 to 3 percent of the total glucose consumed by the cell.¹⁰¹⁻¹⁰³ The operation of the hexose monophosphate shunt, however, is of special importance to the neutrophil, because this pathway provides the NADPH needed for generation of microbicidal oxidants.

Glycogen Metabolism

Neutrophils contain a large quantity of glycogen arising mostly from glucose. Little net synthesis from substrates occurs at the triose phosphate level. Glycogen turnover increases when these cells are deprived of glucose, especially if they are engaged in phagocytosis, but resynthesis occurs when adequate glucose is added.^{95,104,105} During phagocytosis by glucose-starved cells, glycogen phosphorylase activity rises, but phosphorylase kinase and glycogen synthase levels remain unchanged.¹⁰⁵ Glycogen first appears in myelocytes and increases with cell maturation.¹⁰⁶

PROTEIN SYNTHESIS BY MATURE NEUTROPHILS

Mature neutrophils have been classically viewed as terminally differentiated cells without the ability to synthesize proteins. This view has changed as a result of numerous investigations *in vitro* and *in vivo* showing that neutrophils can synthesize numerous proteins (e.g., cytokines, chemokines, growth factors, interferons) potentially important to the inflammatory process and the regulation of immune reactions. Table 60-3 lists some of the proteins expressed by mature neutrophils. The database for these observations has been extensively reviewed,^{107,108} and some potentially important concepts are discussed here. As is evident from this list, the diversity is impressive, but the extent of production of each protein by individual neutrophils is limited when compared to mononuclear cells. However, because neutrophils make up the majority of infiltrating cells early in an acute inflammatory process, often emigrating in massive numbers, their aggregate synthetic ability may be significant to the course of the inflammatory or healing response. *In vitro*, an array of stimuli have been used to induce protein expression, including lipopolysaccharide (LPS), cytokines, chemotactic factors, adhesive ligands, opsonized particles, and modulatory cytokines such as IL-10 and IL-4.

The signaling pathways leading to new protein synthesis are subjects of extensive studies and are briefly described here. Granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and IL-10 have the ability to activate signal transducer and activator of transcription (STAT) proteins in neutrophils. Both STAT-1 and STAT-3 and the upstream kinase Janus-associated kinase 2 (JAK2) are rapidly tyrosine phosphorylated.^{109,110} Neutrophils express nuclear factor κ B-1 (NF κ B1)/p50, p65/RelA, and c-Rel. Tumor necrosis factor- α (TNF- α), IL-1 β , and IL-15 lead to the rapid loss of I κ B α and the concomitant nuclear accumulation of NF κ B/Rel proteins. This pathway is not activated by G-CSF, GM-CSF, IL-8, or IL-10. PU.1 is expressed in mature neutrophils and constitutively binds DNA, and the AP-1 transcription factor is evident. Several of the inflammatory mediators produced by mature neutrophils are AP-1 driven (e.g., TNF, IL-1, IL-8, intercellular adhesion molecule [ICAM]).⁶⁸ Production of the CXC chemokine IL-8 by neutrophils has been extensively studied, and a wide range of stimuli can induce its expression.¹¹¹ Cytokines such as TNF- α , IL-15, IL-1 β , and GM-CSF; chemotactic factors such as C5a, PAF, and leukotriene B₄ (LTB₄); particles such as monosodium urate crystals; microbial products such as LPS and zymosan; interaction with antibody and complement opsonized bacteria and yeasts; and interactions with extracellular matrix molecules such as laminin and fibronectin, all have been shown to induce synthesis of IL-8 by neutrophils. In most studies, release of significant amounts of protein from the neutrophils and synthesis of mRNA have been demonstrated. Immunocytochemistry and *in situ* hybridization studies have provided evidence of IL-8 production in neutrophils infiltrating inflammatory sites.

Some of the stimuli that induce expression of IL-8 also stimulate production by mature neutrophils of other proinflammatory agents, such as growth-regulated protein (GRO)- α , TNF- α , IL-1 β , oncostatin M, and C-C chemokines. In addition, neutrophils may produce anti-inflammatory agents such as IL-1RA and transforming growth factor (TGF)- β , and of interest is the observation that cytokines such as IL-10 may have some selectivity with regard to induction of anti-inflammatory factors in neutrophils. Thus, considerable evidence exists for protein synthesis capability in neutrophils, but because this field of study is relatively new, much work remains to define the importance of the various proteins to inflammation, immune reactions and healing, the selectivity of the conditions, and disease states linked to the synthetic activities of neutrophils. In keeping with its critical role in the inflammatory

VLA-4 (CD49d/CD29)	$\alpha_4\beta_1$ -Integrin	VCAM-1, fibronectin
VLA-5 (CD49e/CD29)	$\alpha_5\beta_1$ -Integrin	Fibronectin
VLA-6 (CD49f/CD29)	$\alpha_6\beta_1$ -Integrin	Laminin
VLA-9	$\alpha_9\beta_1$ -Integrin	VCAM-1, tenascin
$\alpha\beta_3$ (CD51/CD61)	β_3 -Integrin	Vitronectin

GPIIb_a, glycoprotein Iba; ICAM, intercellular adhesion molecule; LFA, leukocyte function-associated antigen; PSGL, P-selectin glycoprotein ligand; sLe^x, sialyl Lewis X; VCAM-1, vascular cell adhesion molecule-1; VLA, very-late antigen.

process, the neutrophil's movement from blood to tissues requires surface adhesion molecules (Table 60-4), chemotactic receptors (Table 60-5), and the requirement to phagocytize microorganisms through opsonin receptors (Table 60-6).

PHENOTYPIC CHANGES

Phenotypic changes occur in neutrophils under specific conditions.^{112,113} Degranulation results in marked changes in surface expression of an array of proteins arriving at the surface from the storage pools of granules (e.g., CD11b/CD18, CD66, some β_1 -integrins). These phenomena can be seen in degrees in circulating neutrophils. Exposure of neutrophils to activating factors results in surface and functional changes as a result of new synthesis (e.g., Fc region of IgG [Fc γ R]I following elevations in interferon [IFN]- γ) or shedding (e.g., loss of L-selectin), also seen in circulating neutrophils. Cytokines (e.g., IL-15, IL-1, TNF) induce *de novo* synthesis of proteins (as noted in Table 60-1) to various degrees in blood neutrophils. Substantial changes occur once the neutrophil leaves the vasculature, increasing its expression of β_1 -integrins, C-C chemokine receptors (CCRs), and protein synthesis.

Evidence indicates that in response to specific combinations of cytokines (e.g., GM-CSF, TNF- α , IFN- γ), neutrophils can acquire phenotypic and functional characteristics of immature dendritic antigen-presenting cells.¹¹² Thus, any consideration of the "composition" of neutrophils requires a detailed understanding of the stage of development and the environment to which the neutrophil is exposed *in vivo*. The neutrophil is a remarkably versatile cell.

TABLE 60-5. Chemotactic Receptors on Human Neutrophils

Receptor	Ligands
Formyl peptide receptor (FPR) (high affinity)	f-met-leu-phe (fMLP), other f-met peptides of bacterial origin
Formyl peptide receptor-like 1 (FPRL-1) (low affinity)	f-met peptides, LXA ₄ , SAA, HIV envelope domains
C5aR (high affinity)	C5a complement fragment
CXCR1 (high affinity)	IL-8 (CXCL8)
CXCR2 (high affinity)	GRO- α (CXCL1), GRO- β (CXCL2), ENA-78 (CXCL5)
CXCR4 in marrow (high affinity)	SDF-1 α (CXCL12)
CCR2 (induced; high affinity)	MCP-1 (CCL2)
CCR6 (induced; high affinity)	LARC (CCL20), β -defensin
Platelet-activating factor R (low and high affinity)	Platelet-activating factor
BLT1 (high affinity)	LTB ₄
BLT2 (low affinity)	LTB ₄ , other eicosanoids

CCR, C-C chemokine receptor; CXCR, chemokine-related receptor; GRO, growth-regulated protein; IL, interleukin; LTB₄, leukotriene B₄; MCP, monocyte chemoattractant protein; SDF, stromal cell-derived factor.

TABLE 60-6. Opsonic Receptors on Neutrophils

Receptor	Characteristics	Ligand
Fc γ RI (CD64)	72 kDa, transmembrane, induced by IFN- γ	IgG ₁ , high affinity
Fc γ RIIA (CD32)	40 kDa, transmembrane, constitutive, A isoform associates with CR3	IgG ₃ > IgG ₁ , low affinity, binds polymeric IgG
Fc γ RIIIB (CD16)	50 kDa, GPI-linked, constitutive, associates with CR3	IgG ₁ , low affinity, binds polymeric IgG
Fc α R (CD89)	60 kDa, transmembrane, constitutive	IgA, polymeric (e.g., sIgA)
CR1 (CD35)	160–250 kDa, transmembrane, constitutive	C3b, C4b
CR3 (CD11b/CD18)	165/90 kDa, transmembrane, heterodimer, storage pool in granules	iC3b
CR4 (CD11c/CD18)	145/90 kDa transmembrane, heterodimer	iC3b

CR, complement receptor; Fc γ R, Fc region of IgG; GPI, glycosyl phosphatidylinositol; IFN, interferon; Ig, immunoglobulin; sIgA, secretory immunoglobulin A.

Gene expression profiling has provided rich insights into the capacity of the mature neutrophil to change in response to environmental stimuli. Following exposure to 10 ng/mL *Escherichia coli* LPS, 307 genes are activated or repressed.¹¹⁴ These changes include transcription factors, cytokines, chemokines, interleukins, surface antigens, toll-like receptors, and members of immune mediator gene families. Major changes in gene expression occur following LPS,¹¹⁵ migration in wounds,¹¹⁶ activation by phagocytosis,¹¹⁷ or during the processes of apoptosis.¹¹⁸ These findings indicate that the neutrophil is a transcriptionally active cell responsive to environmental stimuli and capable of a complex series of both early and late changes in gene expression.

OTHER BIOCHEMICAL FEATURES OF NEUTROPHILS.

The neutrophil is particularly rich in glycogen. The concentration of this complex polysaccharide has been reported to average 7.36 mg/10⁹ cells.^{119–121} The rate of glucose metabolism by neutrophils is affected by insulin in diabetics but not in normal subjects.^{122,123} Inflammatory activation of normal neutrophils stimulates glucose uptake. The plasma membrane and the membranes of the intracellular organelles are rich in lipids. Five percent of the wet weight of neutrophils is lipid, which is distributed among various classes, as shown in Table 60–7.^{124,125} The rare polyphosphoinositides are of special interest as sources of inositol 1,4,5-trisphosphate (a calcium-releasing mediator) and diacylglycerol (which activates protein kinase C).^{126,127} The main glycolipid of neutrophils is lactosylceramide.¹²⁸

The reduced glutathione content of neutrophils is 9.8 nmol/10⁷ cells.¹²⁹ The protein content of the neutrophil is 74.2 ± 3.1 (mean ± 1 SE [standard error]) mg/10⁹ cells. These proteins include those of the structural matrix of the neutrophil; proteins required for its locomotion, chemotactic properties, and adhesiveness; and the many granule proteins with bactericidal, hydrolytic, and inflammatory functions. Table 60–8 summarizes the unbound amino acid concentration in neutrophils.

Table 60–9 summarizes the levels of nucleotides in the neutrophils.^{130,131} Neutrophils contain all the forms of RNA needed for protein synthesis.^{132,133} The DNA content of neutrophils is identical to that of all other haploid cells, at 0.7 pg DNA phosphorus per cell.¹³⁴

TABLE 60–7. Lipid Composition of Neutrophils

Lipid	Content (%)
Phospholipid	35
Phosphatidylcholine	12
Phosphatidylethanolamine	12
Sphingomyelin	6.5
Phosphatidylserine	1.5
Phosphatidylinositol	1.5
Phosphatidic acid	1.5
Triglyceride	20
Glycolipid	16
Cholesterol	10

Data from DiScipio RG, Schraufstatter I U: The role of the complement anaphylatoxins in the recruitment of eosinophils. *Int Immunopharmacol* 7:1909, 2007 and Sullivan BM, Locksley RM: Basophils: a nonredundant contributor to host immunity. *Immunity* 30:12, 2009.

TABLE 60–8. Unbound Amino Acid Concentrations in Leukocytes (Lymphocytes Included)

Amino Acid	μmol/kg Water*
Alanine	2881 ± 256
Arginine	<290
Ergothioneine	<300
Ethanolamine	<250
Glutamic acid	2745 ± 251
Glutamine	2650 ± 251
Histidine	762 ± 70
Leucine plus isoleucine	1999 ± 195
Lysine	2111 ± 216
Methionine	391 ± 54
O-phosphoethanolamine	2651 ± 389
Ornithine	1767 ± 113
Phenylalanine	647 ± 105
Proline	862 ± 79
Serine plus glycine	13,021 ± 1480
Taurine	28,683 ± 2726
Threonine	2345 ± 174
Tryptophan	222 ± 31
Tyrosine	480 ± 97
Valine	1335 ± 132

*Mean ± 1 SD.

The average folic acid content of the leukocytes of normal subjects is 0.1 mcg/mL of packed leukocytes. Approximately 20 percent of the folic acid is free and the remainder conjugated. The cocarboxylate content of neutrophils is 340 mcg/10¹¹ cells,¹³⁵ pyridoxal phosphate 0.24 to 0.38 ng/10⁶ cells,¹³⁶ thiamine 67.5 ± 4.1 mcg/100 mL,¹³⁷ ascorbic acid 16.5 ± 5.1 mg/100 mL,¹³⁷ and folate 92 ng/mL.¹³⁸

TABLE 60–9. Nucleotides in Leukocytes (Lymphocytes Included)

Nucleotide	nmol/10 ⁹ Cells (Mean ± SE)
NAD (nicotinamide adenine dinucleotide)	32 ± 2.0
NADH (reduced form of nicotinamide adenine dinucleotide)	25 ± 2.3
NADP (nicotinamide adenine dinucleotide phosphate)	8 ± 1.5
NADPH (reduced form of nicotinamide adenine dinucleotide phosphate)	24 ± 39
ATP	8800
ADP (adenosine diphosphate)	1600
AMP (adenosine monophosphate)	6100

CHAPTER 61

PRODUCTION, DISTRIBUTION, AND FATE OF NEUTROPHILS

C. Wayne Smith

SUMMARY

Blood neutrophil levels are maintained in a normal steady state by hematopoiesis in the marrow, the distribution of neutrophils between the marginated pool in the microvasculature and the freely circulating pool in the blood, and the rate of egress from blood to tissues. Marrow production of neutrophils is regulated by three principal glycoprotein hormones, or cytokines: interleukin-3, granulocyte-monocyte colony-stimulating factor, and granulocyte colony-stimulating factor (G-CSF), but only the genetic elimination of G-CSF has a measurable effect on blood neutrophil levels. The latter two cytokines are available as recombinant pharmaceutical products that can be administered therapeutically to ameliorate certain causes of neutropenia. Neutrophil interaction with endothelium is mediated by selectins, glycoproteins with sugar-binding sites that support shear-dependent rolling on endothelium, and by integrins on the neutrophil binding to ligands on the endothelial cells, permitting firm attachment to endothelium and emigration into tissues. Neutrophils have a short life span in blood, with a disappearance half-time of approximately 7 hours. The process can be accelerated when inflammation is present and highlights the need for a sustained rate of production to maintain a normal blood neutrophil count. The pathogenesis of neutropenia is more complex to analyze kinetically than anemia or thrombocytopenia because at least four compartments are involved: marrow storage pool, circulating pool, marginated pool, and tissue pool. The latter is particularly difficult to assay. Measurements can be further complicated in the nonsteady state, when dramatic increases in turnover rates and distribution among the four principal pools are in disequilibrium, as occurs during acute inflammatory states.

Acronyms and Abbreviations: β_2 -Integrin, a member of family of receptors that mediate attachment between a cell and the tissues surrounding it; C5a, chemotactic fragment of complement component C5; CD, one of the cluster of differentiation antigens; CSF, colony-stimulating factor; DF³²P, diisopropyl fluorophosphate; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-monocyte colony-stimulating factor; IL, interleukin; L-selectin (and other selectins), a member of selectin family of proteins, which are leukocyte cell-adhesion molecules; Mr, relative molecular mass; NTR, neutrophil turnover rate; $T_{1/2}$, half-time; TBNP, total blood neutrophil pool; TNF- α , tumor necrosis factor- α .

DEFINITION AND HISTORY

Neutrophils are produced in the marrow, where they arise from progenitor and precursor cells by a process of cellular proliferation and maturation. They differentiate from the pluripotential stem cell^{1,2} through a series of progressively more committed progenitor or colony-forming units, including the granulocyte-monocyte colony-forming unit and the granulocyte colony-forming unit, which give rise to neutrophils.^{3,4} The early progenitor cells cannot be recognized under the microscope but can be identified retrospectively by the type of colony formed in culture of marrow cells (Chap. 18). The earliest morphologically recognizable neutrophil precursor is the myeloblast. From there, the formal sequence of precursor development is myeloblast \rightarrow promyelocyte \rightarrow myelocyte \rightarrow metamyelocyte \rightarrow band neutrophil \rightarrow segmented neutrophil (Chap. 60). The term *granulocyte* often is loosely used to refer to neutrophils but strictly speaking includes eosinophils and basophils. Eosinophilic (Chap. 62) and basophilic granulocytes (Chap. 63) develop from progenitors in a manner analogous to the neutrophils, although commitment to neutrophilic, eosinophilic, or basophilic development probably is established at an early progenitor stage, and are dependent on the cytokines interleukin (IL)-5 and stem cell factor, respectively.

The normal human neutrophil production rate is 0.85 to 1.6×10^9 cells/kg per day. Mature neutrophils are stored in the marrow before they are released into the blood. In the absence of an inflammatory focus, they leave the circulation randomly, with a half-disappearance time of approximately 7 hours. The cells then enter the tissues and probably function for 1 or 2 days before their death or loss into the gastrointestinal tract through mucosal surfaces.

The marrow has an impressive capacity to produce neutrophils, yet it is carefully regulated both at steady state and in times of heightened demand. This chapter outlines current concepts of neutrophil production, distribution, and survival. For detailed data and methods, the reader is referred to original articles and reviews on neutropoiesis and neutrophil kinetics.⁵⁻¹⁷

REGULATION OF NEUTROPHILIC GRANULOPOIESIS

Although the primary cellular manifestation of commitment is the expression of receptors for lineage-specific hematopoietic growth factors, the “decision” for a stem cell to self-renew is, at least partially, a stochastic event.^{1,18} On the other hand, stromal elements, collectively referred to as the *hematopoietic microenvironment*, release short-range signals that regulate the process of commitment from multipotential stem cell pools. Although many details of hematopoietic stem cell regulation (Chap. 18) remain to be elucidated, much is known regarding the interaction of hematopoietic cytokines with their receptors and actions on the committed granulocyte progenitor cells and their mature progeny.¹⁹⁻²⁴

HUMORAL REGULATORS

The humoral regulators involved in granulopoiesis have been defined by *in vitro* culture systems.^{20,21} Originally identified by their ability to stimulate colony formation from marrow progenitor cells, the hemopoietic cytokines were initially termed *colony-stimulating factors* (CSFs) based on this assay system.²⁵ With regard to neutrophil production, at least four human CSFs have been defined. Granulocyte-monocyte colony-stimulating factor (GM-CSF) is a

22,000 relative molecular mass (Mr) glycoprotein that stimulates the production of neutrophils, monocytes, and eosinophils. Granulocyte colony-stimulating factor (G-CSF) has a Mr of 20,000 and stimulates exclusively the production of neutrophils. IL-3, or multi-CSF, also has a Mr of 20,000 and acts relatively early in hematopoiesis, affecting pluripotential stem cells. Finally, stem cell factor (also known as *c-kit* ligand or steel factor), with a Mr of 28,000, acts in combination with IL-3 and/or GM-CSF to stimulate the proliferation of the early hematopoietic progenitor cells, basophils and mast cells.

In addition to their effects on neutrophil precursors, G-CSF and GM-CSF act directly on the neutrophil, enhancing its function. These cytokines regulate the production, survival, and functional activity of neutrophils.^{21,22,26,27} In a murine model of severe bacterial infection, endothelial cells translate pathogen signals into G-CSF-driven marrow neutrophil production.²⁸ The mature neutrophil lacks IL-3 receptors and thus is not affected by IL-3. In fact, the genetic elimination of IL-3 obliterates delayed type hypersensitivity. However, IL-3 receptors are present on mature eosinophils and monocytes. IL-3 is produced by activated T lymphocytes and thus is expected to have a physiologic role in circumstances of cell-mediated immunity. GM-CSF also is produced by activated lymphocytes. However, like G-CSF, it also is elaborated by mononuclear phagocytes and endothelial and mesenchymal cells when these cell types are stimulated by certain cytokines, including IL-1 and tumor necrosis factor, or bacterial products, such as endotoxin.²⁹⁻³¹ Stem cell factor is secreted by a variety of cells, including marrow stromal cells,^{32,33} and affects the development of several kinds of tissues.^{32,34}

The activities of exogenously administered biosynthetic (recombinant) human G-CSF and GM-CSF in humans are well documented.^{22,27,35-37} G-CSF administration rapidly induces neutrophilia, whereas GM-CSF causes an increase in neutrophils, eosinophils, and monocytes. GM-CSF cannot be detected easily in normal plasma; thus, its role as a day-to-day, long-range modulator of neutrophil production is uncertain. Mice in which the GM-CSF gene is “knocked out” have generally normal hematopoiesis, but show macrophage abnormalities, pulmonary alveolar proteinosis, and decreased resistance to microbial challenge.³⁸⁻⁴¹ However, G-CSF appears to be a critical regulator of neutrophil development, as giving an animal an antibody to G-CSF leads to profound neutropenia.⁴² The G-CSF knockout mouse shows severe neutropenia.⁴³ Neutropenia that results from a production disturbance, such as exposure to cytotoxic drugs, is associated with high circulating serum concentrations of G-CSF.⁴⁴

NEUTROPHIL KINETICS

Methods used to study granulocyte kinetics can be categorized as follows: (1) neutrophil depletion or destruction to determine the size and rate of mobilization of reserves and the level of compensatory neutrophil production; (2) use of radioactive tracers to study neutrophil distribution, production rates, and survival times; (3) mitotic indices of marrow granulocytic cells to assess proliferative activity and cell cycle times; and (4) induced inflammatory lesions to study cell movement into the tissues. Of these categories, the most popular has been the use of radioactive tracers.

Neutrophil production and neutrophil kinetics usually are analyzed by describing neutrophil movement through a number of interconnected compartments. These compartments can be arranged into three major groups: the marrow, the blood, and the tissue (Fig. 61-1). The complexities of analyzing these compartments are covered in several recent reviews.⁴⁵⁻⁴⁸

The Marrow

Marrow neutrophils can be divided into the mitotic, or proliferative, compartment and the maturation storage compartment. Myeloblasts, promyelocytes, and myelocytes are capable of replication and constitute the mitotic compartment. Earlier progenitor cells are few in number, not morphologically identifiable, and usually neglected in kinetic studies. Metamyelocytes, bands, and mature neutrophils, none of which replicate, constitute the maturation storage compartment.

The average number of cell divisions from the myeloblast to the myelocyte stage in the proliferative compartment has been estimated between four and five.⁴⁹ Data obtained using radioactive diisopropyl fluorophosphate (DF³²P) suggest the existence of three divisions at the myelocyte stage, but the number of cell divisions at each step may not be constant. The major increase in neutrophil number probably occurs at the myelocyte level, because the myelocyte pool is at least four times the size of the promyelocyte pool. Because of the difficulties in measuring human intramarrow neutrophil kinetics, a precise model of the dynamics of the mitotic compartment is not available.

Table 61-1 lists the estimated sizes of the marrow neutrophil compartments and the transit times and cell-cycle stages of the cells in the various compartments. Precise studies have measured a postmitotic pool of $(5.59 \pm 0.9) \times 10^9$ cells/kg and a mitotic pool (promyelocytes and myelocytes) of $(2.11 \pm 0.36) \times 10^9$ cells/kg. These studies led to a

Figure 61-1. Scheme of maturation of neutrophil precursor cells. The myeloblast is the first recognizable precursor of neutrophils. Myeloblasts undergo division and maturation into promyelocytes and thereafter into neutrophilic myelocytes after which stage mitotic capability is lost. The major compartments of precursor proliferation and distribution are indicated across the top of the figure: marrow, blood, and tissues. The marrow precursor compartment is made up of the proliferating compartment (myeloblasts through myelocytes) and the maturation and storage compartment (metamyelocytes to mature polymorphonuclear neutrophils [PMN]). Under normal conditions, cells do not return from the tissue compartment to the blood or marrow.

TABLE 61-1. Marrow Neutrophil Kinetics

	Fraction in Mitosis (Mitotic Index)	Fraction in DNA Synthesis (S Phase)	Transit Time Range (h)	Total Cells ($\times 10^9/\text{kg}$)
Mitotic compartment				
Myeloblast	0.025	0.85	23	0.14
Promyelocyte	0.015	0.65	26–78	0.51
Myelocyte	0.011	0.33	17–126	1.95
Maturation storage compartment				
Metamyelocyte			8–108	2.7
Band			12–96	3.6
Polymorphonuclear neutrophil			0–120	2.5

calculated normal marrow neutrophil production of 0.85×10^9 cells/kg per day. Radioautographic studies with [^3H]thymidine support the concept of an orderly progression from metamyelocytes to mature neutrophils within the maturation storage compartment. These studies also suggest a “first in, first out” pattern for cells leaving this compartment and entering the blood. Several labeling techniques indicate the myelocyte-to-blood transit time is 5 to 7 days.^{12,50} Previous studies with DF³²P reported a range from 8 to 14 days.^{9,49} During infections, however, the myelocyte-to-blood transit time may be as short as 48 hours.⁵¹

Whether the production of neutrophils in the mitotic compartment exactly equals the neutrophil turnover rate (NTR) is not known with certainty. Studies in dogs suggest some immature neutrophils die in the marrow (“ineffective granulopoiesis”).⁵² Ineffective granulopoiesis has not been shown in normal humans,^{14,53} although ineffective granulopoiesis occurs in some pathologic states, including the myelodysplastic syndromes,⁵⁴ myelofibrosis, and some of the idiopathic neutropenic disorders. At present, however, no convenient means of quantitating ineffective granulopoiesis is available.

On completion of maturation, the neutrophils are stored in the marrow and are referred to as the *mature neutrophil reserve*. The reserve contains many more cells than are normally circulating in the blood. Table 61-2 lists comparative data on the characteristics of the maturation storage compartment. Under stress, maturation time may be shortened, divisions may be skipped, and release into the blood may occur prematurely.

The Blood

Neutrophils leave the marrow storage compartment and enter the blood without significant reentry into the marrow. The total blood neutrophil pool (TBNP) consists of all the neutrophils in the vascular spaces. Some of these neutrophils are free in the circulation (the circulating pool), while others roll along the endothelium of small vessels or

are temporarily sequestered in the alveolar capillaries of the lung (the marginated pool).^{55,56} Cells in the two pools are freely exchangeable. When neutrophils labeled with DF³²P are injected into normal subjects, approximately half can be accounted for in the circulating pool; the remainder enters the marginated pool.⁵⁻⁷ Neutrophils shift from the marginated to the circulating pool with exercise, epinephrine injection, or stress, but eventually the neutrophils leave the blood and enter the tissues. Once the neutrophils enter the tissues, they do not normally return to the blood. The flow of cells is unidirectional.

DF³²P-labeled neutrophils disappear from the circulation with a half-time ($T_{1/2}$) of 6.7 hours.^{7,57,58} These data are supported by the finding that more than half of Pelger-Huët cells infused into a normal individual disappeared after 6 to 8 hours.⁵⁹ Data obtained with ⁵¹Cr-labeled neutrophils give substantially longer half-times.⁶⁰ The exponential disappearance of cells from the blood suggests the cells leave in a random manner. Thus, neutrophils newly released from the marrow are as likely to leave the blood as are neutrophils that have been circulating for several hours. Neutrophils also are eliminated by programmed cell death and disposed of by the macrophage system.^{51,61-64}

Direct observations of blood vessels have revealed some degree of leukocyte rolling along the endothelium (first observed many years ago by Atherton and Born⁶⁰). Although the observation has been clearly confirmed by numerous laboratories in different species of animals, the extent to which this phenomenon contributes to the marginated pool of neutrophils is uncertain.

A more compelling concept of the marginated pool is derived from investigations of the vascular bed of the lung. A distinctive characteristic of this tissue is the complex interconnecting network of short capillary segments where the path from arteriole to venule crosses several alveolar walls (often more than eight) and often contains more than 50 capillary segments.⁶⁵⁻⁶⁹ Compared to blood in the large vessels of most vascular beds, the blood in this complex network

TABLE 61-2. Comparative Data on Marrow Maturation Storage Compartment

Size (Cells $\times 10^9$ kg)	Transit Time (Days)	Measurement Technique	Reference

5.6	6.6	⁵⁹ Fe and neutrophil/erythroid ratio	14

DF³²P, diisopropyl fluorophosphate.

contains approximately 50-fold more neutrophils and even more lymphocytes and monocytes.⁷⁰ Videomicroscopic study of these vessels in animal models has revealed the transit of neutrophils through this network required a median time of 26 seconds and mean time of 6.1 seconds.^{71,72} In contrast, the transit times of red blood cells ranges from 1.4 to 4.2 seconds. The increased transit time results primarily from the time neutrophils are stopped within this vascular network. The longer time required for the neutrophils to pass through this bed apparently accounts for their increased concentration.

Recruitment of neutrophils into the lungs through the alveolar capillary network contrasts with the recruitment of neutrophils through postcapillary venules at sites of inflammation in a number of important ways. The tethering mechanisms required to capture neutrophils from flowing blood in larger vessels apparently are not necessary in the alveolar capillary bed. The diameters of spherical neutrophils (6 to 8 μm) are larger than the diameters of many capillary segments (2 to 15 μm). Approximately 50 percent of the capillary segments would require neutrophils to change their shape in order to pass through.⁷²⁻⁷⁵ Given the large number of capillary segments through which a neutrophil must pass (often more than 50), most neutrophils must change shape during transit from arteriole to venule. Morphometric analysis of neutrophils in the alveolar capillary beds has revealed significant deviation from spherical shape.^{72,73} Computational models of the capillary bed describing flow, hematocrit, pressure gradients, and the effects of deformation on the capillary transit times of neutrophils support the concept that the structure of the capillary bed and the deformation of neutrophils are critical under normal conditions. Thus, the enormous lung vascular bed contains a substantial number of neutrophils that can be mobilized into the systemic circulation with stimuli such as epinephrine or exercise.

During inflammation, much of the sequestration and infiltration occur through vessels so narrow that physical tapping is sufficient to stop the flowing neutrophil.^{68,72,76,77} Binding of mediators such as chemotactic factors (e.g., C5a, the chemotactic fragment of complement component C5) to neutrophil receptors induces a transient resistance of the cells to deformation.⁷⁸⁻⁸³ Because neutrophils must deform to pass through the capillary bed, leukocyte activation by inflammatory mediators could affect further concentration of neutrophils at the alveolar walls.^{65,76} The role of mechanical factors in the initial sequestration of neutrophils in the alveolar capillaries is supported by evidence that neither L-selectin nor β_2 -integrins are required.^{76,84,85} In contrast, both selectins and β_2 -integrins are required for localization of neutrophils in postcapillary venules at sites of inflammation.

The events following the initial sequestration of neutrophils within alveolar capillary beds are influenced by adhesion molecules. For example, simple systemic activation of neutrophils by intravenous injection of chemotactic factors (e.g., IL-8 or C5a) results in rapid (<1 minute) neutropenia with massive sequestration of neutrophils within alveolar capillaries. This event is not dependent on L-selectin or β_2 -integrins, but the retention times within this capillary bed are influenced by these adhesion molecules.^{76,85} Adhesion likely is an interaction of leukocyte adhesion molecules and endothelial adhesion molecules. Blockade of the adhesive mechanism (e.g., using blocking monoclonal antibodies) results in release of neutrophils from the lungs.^{76,84,86-88} Mediator-induced decreases in deformability are temporally correlated with upregulation of β_2 -integrins (e.g., both occurring within approximately 1 minute of exposure to IL-8). This allows both physical trapping and sticking to the vascular wall within the alveolar capillary bed. A similar phenomenon occurs in the liver where sequestration is the result of physical trapping and liver injury is heavily dependent on adhesion of leukocytes through the β_2 -integrins.⁸⁹

Assuming a random loss of neutrophils from the blood, NTR can be calculated from $T_{1/2}$ and TBNP: $\text{NTR} = 0.693 \times \text{TBNP}/T_{1/2}$. In the

TABLE 61-3. Definitions and Calculations Relating to Blood Neutrophil Kinetics

Circulating neutrophil pool (CNP) = Blood neutrophil concentration \times blood volume
Total blood neutrophil pool (TBNP) = All neutrophils in the circulation
Marginal neutrophil pool (MNP) = TBNP – CNP
Blood clearance half-time ($T_{1/2}$) = Disappearance time of half the labeled neutrophils from circulation
Neutrophil turnover rate (NTR) = $\frac{0.693 \times \text{TBNP}}{T_{1/2}}$

steady state, NTR measures the rate of effective neutrophil production. Table 61-3 lists the definitions and calculations related to blood neutrophil kinetics. Table 61-4 lists data for normal human blood neutrophil kinetics. The high production rate of neutrophils under normal conditions is remarkable, especially given that the rate may increase several fold in response to inflammatory stimuli.

Glucocorticoids increase TBNP by increasing influx from the marrow and decreasing efflux from the circulation. Five hours after a pharmacologic dose of glucocorticoid, the neutrophil count increases by approximately 4000/ μL because of release from the marrow, demargination, and prolongation of $T_{1/2}$ to approximately 10 hours.⁹⁰⁻⁹² Consistent with the increase in $T_{1/2}$, prednisone reduces the accumulation of neutrophils at induced sites of skin inflammation.⁷⁵ With alternate-day, single-dose prednisone, neutrophil counts and kinetics are normal 24 hours after administration and during the day off.⁹³ Endotoxin causes a prompt neutropenia as a result of cell margination and sequestration, followed in 2 to 4 hours by a rebound neutrophilia as a result of cell release from the marrow. The size of the neutrophilic response correlates with the functional marrow reserves.⁹⁴⁻⁹⁷ After epinephrine administration, a peak leukocytosis occurs in 5 to 10 minutes and rarely lasts more than 20 minutes. This finding reflects a shift of cells from the margined to the circulating pool.

MIGRATION OF NEUTROPHILS INTO TISSUES

The migration of neutrophils from blood into tissue at sites of inflammation involves a series of sequential adhesive steps proceeding from tethering (rolling adhesion) on endothelium under shear conditions in

TABLE 61-4. Data for Human Blood Neutrophil Kinetics

Pool	Mean Pool Size $\times 10^7$ kg	95% Limits
TBNP	70	14–160
CNP	31	11–46
MNP	39	0–85
	Mean Value	95% Limits
Blood clearance $T_{1/2}$	6.7 h	4–10 h
NTR	63×10^7 kg/day	$50\text{--}340 \times 10^7$ kg/day

CNP, circulating neutrophil pool; MNP, marginal neutrophil pool; NTR, neutrophil turnover rate; $T_{1/2}$, half-time; TBNP, total blood neutrophil pool.

postcapillary venules.⁹⁸ This model has been investigated in a variety of vascular beds⁹⁹ and *in vitro* with monolayers of endothelial cells in parallel plate flow chambers.⁹⁸ The tethering event in this model depends on adhesion molecules in the selectin family, E-selectin and P-selectin on the endothelium, L-selectin on the neutrophil, and ligands for the selectins expressed on both cell types. These adhesion molecules are necessary to efficiently initiate the cascade of adhesive steps ultimately leading to firm attachment of the neutrophils to endothelium. The cascade appears to be necessary for neutrophils to move from blood to tissues because the unstimulated neutrophil is not adhesive to endothelium.^{98,100} The integrins necessary for firm adhesion and cell locomotion require stimulation to promote sufficient increases in avidity or affinity to support these functions (Chap. 19).

LIFE SPAN OF NEUTROPHILS

After emigrating into tissue, the life span of neutrophils can be significantly prolonged (24 to 48 hours).¹⁰¹ Programmed cell death (apoptosis) accounts for significant removal of tissue neutrophils through phagocytosis by macrophages. The constitutive rate of apoptosis of neutrophils is altered by inflammatory cytokines and chemokines. For example, tumor necrosis factor- α (TNF- α) accelerates the rate, but endotoxin, G-CSF, GM-CSF, IL-15, and IL-3 inhibit the rate of apoptosis. The balance of these effects at specific inflammatory sites is poorly understood, but the functional life of neutrophils in tissue appears to be controlled by the rate of apoptosis. Apoptotic neutrophils lose the ability to release granular enzymes in response to external stimuli (see below), and marked changes in cell surface proteins occur (e.g., CD16, CD43, CD62L are greatly reduced). Although the loss of responsiveness may contribute to resolution of the inflammatory process, evidence indicates macrophages also are altered by the phagocytosis of apoptotic neutrophils. In contrast to the macrophage response to phagocytosis of microbes, where secretion of proinflammatory cytokines (e.g., IL-1 β) and chemokines (e.g., IL-8) is stimulated, phagocytosis of apoptotic neutrophils fails to provoke secretion of proinflammatory factors; instead, phagocytosis stimulates release of factors that may suppress inflammatory responses (e.g., transforming growth factor- β and prostaglandin E₂). Macrophage recognition of apoptotic neutrophils is partially understood to involve the vitronectin receptor $\alpha_v\beta_3$ and the thrombospondin receptor CD36 on the macrophage surface. In addition, phosphatidylserine residues on the neutrophil are involved.⁹⁸

Neutrophils are capable of phenotypic changes depending on the tissue and cytokine/chemokine milieu at the time of their migration into tissue (Chap. 60). Because our understanding of neutrophil physiology is relatively new, knowing the extent of this phenomenon on neutrophil life span in tissues is not possible at present.

EVALUATION OF ADEQUACY OF NEUTROPHIL RESERVES

WHITE CELL COUNT AND MARROW CELLULARITY

White cell and absolute neutrophil counts are the most widely used guides to the status of neutrophil production. They are useful in evaluating the effects of cytotoxic chemotherapy, although they do not provide quantitative information on the rate of neutrophil production or destruction, the status of marrow reserves, or the presence of abnormalities in cell distribution.

Gauging neutrophil production by the appearance of marrow films, clot sections, or biopsies suffers from the limitations of sampling

error and relatively poor correlation with kinetics, as measured by other techniques.⁶⁸ For example, the morphologic findings in the marrow of a “maturation arrest,” with little neutrophil development beyond the promyelocyte or myelocyte stage, does not distinguish between a defect in precursor cell maturation and rapid mobilization of postmitotic cells from the marrow. Similarly, distinguishing by purely morphologic means neutropenic conditions resulting from ineffective neutrophil production from conditions caused by peripheral destruction of neutrophils often is difficult. However, despite these limitations, when the absolute neutrophil count and marrow cellularity are used together, they provide a useful guide in most clinical settings. If the absolute neutrophil count is less than $1.0 \times 10^9/L$ and multiple marrow aspirations and/or biopsies are hypocellular, the patient almost invariably has impaired production of marrow neutrophils. Very low neutrophil counts predispose to infections by bacteria and certain fungi (e.g., *Candida* and *Aspergillus*). Such infections become especially troublesome as the neutrophil count falls below $0.5 \times 10^9/L$ (Chap. 65). Unfortunately, the converse is not true. The finding of cellular marrow and neutrophil count $>1.0 \times 10^9/L$ does not mean production is normal. Nevertheless, when marrow cellularity and absolute neutrophil count are considered together, they provide the most clinically useful assessment of neutrophil production.

FUNCTIONAL EVALUATION

Several agents that increase neutrophil numbers in circulation, including glucocorticoids, endotoxin, and etiocholanolone, have been used to evaluate neutrophil reserves in a clinical setting. These agents have been supplanted by recombinant human G-CSF, a remarkably nontoxic cytokine that, when given in therapeutic doses (5 to 8 mcg/kg), increases the blood neutrophil count by stimulating neutrophil production and accelerating neutrophil release from the marrow storage compartment (Chap. 65). The increase in neutrophil production results from a threefold increase in the number of cell divisions in the mitotic compartment and shortening of the maturation time from myelocyte to neutrophil from 4 to 5 days to less than 1 day.^{102,103} Thus, as a byproduct of its therapeutic action, G-CSF administration directly tests an individual's capacity to produce neutrophils. This effect of G-CSF makes obsolete most of the older methods for evaluating neutrophil compartments.

G-CSF does not test the distribution of neutrophils between the marginated and circulating pools. On the rare occasions when such information is desirable, epinephrine stimulation can be used to assess the distribution. For this purpose, epinephrine 0.1 mg infused intravenously over 5 minutes has been used, and blood for white counts is obtained before and 1, 3, and 5 minutes after completion of the epinephrine infusion. Normally the neutrophils increase by approximately 50 percent after epinephrine infusion.¹⁰⁴

CHAPTER 62

EOSINOPHILS AND RELATED DISORDERS

Andrew J. Wardlaw

SUMMARY

Eosinophils continue to be studied intensively, in large part, as a result of their potential role in the pathogenesis of asthma. The concept of the eosinophil as a cell that has protective effects against helminthic parasite infection, but can cause tissue damage when inappropriately activated, remains intact, although the evidence for both these roles is circumstantial. Eosinophil production and function are profoundly influenced by interleukin (IL)-5; and, thus, eosinophilia is associated with diseases characterized by T-helper (Th)2-mediated immune responses, including infections by helminthic parasites and extrinsic asthma. However, eosinophilia also occurs in diseases not obviously associated with Th2 dominance, such as intrinsic asthma, hypereosinophilic syndromes (HESs), and inflammatory bowel disease. Thus, IL-5 and other eosinophil mediators can be generated in various types of inflammatory response.

The eosinophil, like other leukocytes, can generate proinflammatory mediators. Eosinophil-specific granule proteins are toxic for a range of mammalian cells and parasitic larvae. Eosinophils, like mast cells, produce sulfidopeptide

Acronyms and Abbreviations: AAV, ANCA-associated vasculitides; AHR, airway hyperresponsiveness; ANCA, antineutrophil cytoplasmic antibodies; BAL, bronchoalveolar lavage; BSA, bovine serum albumin; CCL, chemokine (C-C motif) ligand; CCR, chemokine receptor; CEL, chronic eosinophilic leukemia; CLC, Charcot-Leyden crystal; CLM-1, CMRF35-like molecule-1; CMPD, chronic myeloproliferative disease; ECP, eosinophil cationic protein; EDN, eosinophil-derived neurotoxin; EGPA, eosinophilic granulomatosis with polyangiitis; EM, electron microscopic; EMR, mucin-like hormone receptor; FEV₁, forced expiratory volume in 1 second; FISH, fluorescence *in situ* hybridization; GM-CSF, granulocyte-monocyte colony-stimulating growth factor; GPA, granulomatosis with polyangiitis; HES, hypereosinophilic syndrome; HLA, human leukocyte antigen; ICAM, intercellular adhesion molecule; iHES, idiopathic hypereosinophilic syndrome; IL, interleukin; ILC, innate lymphoid cell; LAMP, lysosome-associated membrane protein; LIMP, lysosome integral membrane protein; LT, leukotriene; mAb, monoclonal antibody; MBP, major basic protein; MPA, microscopic polyangiitis; NADPH, nicotinamide adenine dinucleotide phosphate oxidase; NO, nitric oxide; ORMDL3, orosomucoid-like 3; PAF, platelet-activating factor; PIN1, peptidylprolyl isomerase; PSGL, P-selectin glycoprotein ligand; Siglec, sialic acid-recognizing animal lectin; SNARE, soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor complex; TGF, transforming growth factor; Th, T-helper; TRAIL, tumor necrosis factor-related apoptosis-inducing ligand; T_{REG}, T-regulatory cell; TSLP, thymic stromal lymphopoietin; TXB₂, thromboxane B₂; VCAM, vascular cell adhesion molecule; VIP, vasoactive intestinal peptide; VLA, very-late antigen; WHO, World Health Organization.

leukotrienes, as well as other lipid mediators, such as platelet-activating factor (PAF). Cytokine production by eosinophils broadens their potential functions, for example in wound healing through their generation of transforming growth factor (TGF)- α . Synthesis of TGF- β may explain the propensity of eosinophils to be associated with fibrotic reactions such as endomyocardial fibrosis, characteristic of HES, and fibrosing alveolitis.

Considerable effort has gone into trying to unravel the molecular basis of eosinophil tissue recruitment. The selective accumulation of eosinophils is the result of a concerted and integrated series of events involving their production in the marrow and egress therefrom, adhesion to endothelium, selective chemotaxis, and prolonged survival in tissues. These events are controlled, either directly or indirectly, by production of IL-4, IL-5, and IL-13.

The discovery that a proportion of patients with HES have either a clonal myeloid neoplasm resulting from an acquired mutation that generates a constitutively active, novel tyrosine kinase (FIP1L1-PDGFR α [F/P]) or a T-cell lymphoproliferative disease causing a reactive eosinophilia has offered the prospect of new and more effective treatments for these conditions, as well as giving new insights into the control of eosinophil production. There has long been a debate about the extent to which eosinophils cause tissue damage, are innocent bystanders, or even help to ameliorate the condition. This is now being resolved with data showing that specific reduction in eosinophils using anti-IL-5 monoclonal antibody is beneficial in eosinophilic airway disease and HES.

● BIOLOGY OF EOSINOPHILS

EOSINOPHIL MORPHOLOGY AND RECEPTOR PHENOTYPE

Eosinophils are spherical, end-stage, nondividing leukocytes, approximately 8 μm in diameter derived from the marrow.¹ *In vitro* granulocyte-monocyte colony-stimulating factor (GM-CSF), interleukin (IL)-3 and IL-5 stimulate colony growth; additionally, IL-5 is a critical eosinopoietic factor *in vivo* involved in late differentiation.² The electron microscopic (EM) morphology of the mature eosinophil has been well described (Fig. 62-1).^{3,4} The relatively specific features which distinguish the eosinophil from other leukocytes are the bilobed nucleus, the specific granules with an electron dense core, the paucity of mitochondria (approximately 20 per cell) and endoplasmic reticulum, and the dense network of cytoplasmic tubulovesicular structures or secretory vesicles that contain albumin and cytochrome *b*₅₅₈ and are therefore thought to be involved in superoxide production. Eosinophils also contain lipid bodies, which are the major site of eicosanoid synthesis, primary granules, and small granules.⁵ Small granules are particularly prominent in tissue eosinophils and contain arylsulphatase B, acid phosphatase, and catalase. They may be derived from specific granules and act as a lysosomal compartment since specific granules express lysosome-associated membrane proteins (LAMP) 1 and 2, as well as lysosome integral membrane protein (LIMP, CD63) 1.⁶ Eosinophils also contain multilaminar bodies that contain transforming growth factor (TGF)- α . Eosinophil precursors derived from cord blood can be first identified morphologically when specific core containing granules appear, although expression of Charcot Leyden crystal (CLC) protein and the basic granules proteins can be detected by immunohistochemistry or mRNA expression at the promyelocyte stage where they are found in the endoplasmic reticulum, Golgi apparatus and large round coreless granules, most of which develop

Figure 62-1. Transmission electron micrograph ($\times 10,000$) of an eosinophil showing the characteristic specific granules with their electron dense core and various mediators, receptors and granule proteins produced by eosinophils. into specific granules. Electron microscopy can distinguish activated from resting blood eosinophils by the increased number of lipid bodies, primary and small granules, secretory vesicles, and endoplasmic reticulum. Cytoplasmic crystals of CLC protein may also be present. Eosinophils are relatively inefficient phagocytes, although they can ingest opsonized zymosan, which gets taken up into phagolysosomes formed in part by fusion with specific granules. The eosinophil also degranulates onto large opsonized surfaces such as a Sephadex bead or parasitic larvae in a process called *frustrated phagocytosis*.

The ultrastructure of *in vitro* activated and tissue-infiltrating eosinophils has suggested three potential mechanisms of degranulation: necrosis or cytolytic degranulation, exocytosis or “classical degranulation,” and piecemeal degranulation.⁷ Cytolytic degranulation is associated with loss of eosinophil plasma membrane integrity and results in the release of clusters of free membrane-bound granules (termed *Cfegs*). This is commonly observed in eosinophilic inflammation and is particularly marked in severe disease, such as fatal attacks of asthma in which large quantities of basic proteins can be detected in the tissue by immunohistochemistry often with relatively few intact eosinophils.⁸ Exocytosis or classical degranulation occurs in mast cells and basophils after crosslinking of immunoglobulin (Ig) E receptors. It describes a process by which granules migrate to the plasma membrane and fuse with it leading to the extrusion of membrane free granule contents. This phenomenon has been described for eosinophils in the gut, but not the airway mucosa. Piecemeal degranulation has been described in cord blood derived eosinophils⁹ and refers to the appearance of empty or partially empty granules together with small vesicles in the cytoplasm which transport the granule proteins to the cell surface where they are released.¹⁰ These appearances are common in tissue eosinophils in asthma and other allergic diseases.

Many studies have used a mouse model involving ovalbumin challenge to generate a lung eosinophilia and increased airway hyperresponsiveness (AHR). A striking feature of this model is that lung eosinophils do not have the appearance of having undergone degranulation by either cytolysis or piecemeal degranulation.¹¹ Immunostaining of the mouse lung in this model locates all the basic proteins within intact eosinophils and bronchoalveolar lavage (BAL) contains no free major basic protein (MBP).¹² This is quite unlike human disease in which the

cell free basic proteins can be readily detected in both tissue and BAL. Consistent with this observation, mice in which the gene for eosinophil peroxidase or MBP has been deleted had the same phenotype as wild-type mice.¹³ However some degranulation may be seen in the airway lumen.¹⁴ Mice were genetically modified using two approaches to completely delete eosinophils, one by inserting an eosinophil toxic gene into the lineage (PHIL) and one by deleting a high-affinity binding site in the GATA-1 promoter.^{15,16} The GATA mice still developed AHR and mucus secretion but not airway remodeling, which is consistent with evidence for their role in asthma. In contrast, the PHIL mouse did not develop AHR and mucus hypersecretion after airway challenge. Two other strains of mice, iPHIL and eoCRE, have been developed. iPHIL can induce eosinophil cell death at any point in the life of the mouse using diphtheria toxin and eoCRE can be used to selectively induce gene expression in eosinophils. These flexible “knock-in” strains of mice have revealed unexpected complexity in the role of the eosinophil in the allergic immune response.¹⁷ Apoptotic eosinophils are small cells with a shrunken nucleus and condensed chromatin but an intact plasma membrane. They are readily identifiable in aged cell populations *in vitro* and in cells from the airway lumen such as sputum, but are more difficult to identify in tissue. This has led some investigators to argue that the majority of airway eosinophils, at least in asthma and rhinitis, are removed through luminal entry rather than by undergoing apoptosis in tissue.⁷

Like all leukocytes, eosinophils express a large number of membrane receptors which allow them to interact with the extracellular environment (Tables 62-1 and 62-2). These include receptors required for locomotion, activation, growth and mediator release. Most of the receptors are shared to some extent with other leukocytes but some have a degree of specificity in terms of level of expression and function. An important feature of tissue eosinophils is that they express a different pattern of receptors, compared to blood eosinophils, consistent with a more activated phenotype. This includes induction of expression of CD69, intercellular adhesion molecule (ICAM)-1 and Fc γ R1 and increased expression of human leukocyte antigen (HLA)-DR and Mac-1. Changes in expression can be induced *in vitro* by culture with cytokines such as IL-5, but also occur to some extent as the result of transmigration through endothelium.¹⁸ A major difference between eosinophils and neutrophils that has been exploited to purify eosinophils

by immunomagnetic selectin is the expression of CD16 by neutrophils but not eosinophils. Another important difference is the expression of VLA-4 by eosinophils, but not to any great extent in neutrophils. Sialic acid-recognizing animal lectin (Siglec) 8 has been identified as a receptor expressed only by eosinophils, mast cells, and basophils.¹⁹⁻²¹ Siglecs are of the immunoglobulin superfamily. Eosinophils, as well as monocytes and a subset of dendritic cells, also express Siglec 10.²² In contrast, neutrophils express Siglec 9.²³ Siglec 8 is important in triggering eosinophil apoptosis.^{24,25} Epidermal growth factor-like module containing mucin-like hormone receptor 1 (EMR1) is expressed exclusively on eosinophils and has the potential to be a therapeutic target for eosinophilic disorders.²⁶ Eosinophils express both CD48 and its ligand CD244 (2B4), both members of the IgG superfamily. Crosslinking of CD48 causes eosinophil degranulation.²⁷ Eosinophils also express a number of inhibitory receptors including CMRF35-like molecule-1 (CLM-1) that negatively regulate eotaxin-induced eosinophil responses.²⁸

EOSINOPHIL PRODUCTION

Eosinophils are nondividing, end-stage cells that, like other leukocytes, differentiate from the hematopoietic stem cell in the marrow. They share a progenitor with basophils before further differentiation separates the lineages. GATA-1 is a particularly important transcription factor for eosinophil development with deletion of the high-affinity binding site in GATA-1 resulting in specific loss of the eosinophil lineage.²⁹ The F/P receptor mutation which is responsible for a myeloproliferative form of hypereosinophilic syndrome (HES)/chronic eosinophilic leukemia (CEL) works through cEBPα and GATA-2, as well as GATA-1, showing that these transcription factors are also important in eosinophil development.³⁰ Eosinophilopoiesis requires the combined expression of MBP and eosinophil peroxidase.³¹

Eosinophils migrate into the blood, where they circulate with a half-life of about 18 hours before entering the tissues. Eosinophils are primarily tissue-dwelling cells, and it has been estimated that there are approximately 100 tissue eosinophils for each eosinophil in the blood, although relatively few studies have been performed on eosinophil kinetics and even fewer have compared eosinophil turnover in health and disease. However, studies demonstrate that eosinophils can be tracked *in vivo* using radiolabeling and that the kinetics of migration through the lung, spleen, and marrow are distinct from that of neutrophils.^{32,33} Normal human adult marrow contains approximately 3 percent eosinophils of which one-third are mature and two-thirds are precursors.

Eosinophilia is often T-cell dependent. Characterization of T-cell-derived supernatants led to the characterization of IL-5 and awareness of the pivotal role that this cytokine plays in eosinophil development.³⁴ IL-3 and GM-CSF are also important in eosinophil development. The three cytokines bind to receptors that share a common β chain but have distinct α chains. IL-5 seems to be a rate-limiting step for eosinophil production in that administration of IL-5 either exogenously or through transgenic manipulation in mice results in a marked eosinophilia³⁵ and anti-IL-5 in humans dramatically diminishes the blood eosinophil count in asthma.³⁶ Increased eosinophilopoiesis as a result of increased IL-5 synthesis appears to be a feature of a number of diseases, including parasitic and allergic diseases. For example, pulmonary eosinophilia caused by *Necator americanus* infection in mice is IL-5-dependent³⁷ and both the eosinophilia and host defense to filariasis and *Trichinella spiralis* is markedly impaired in IL-5-deficient mice.³⁸ In asthma, IL-5 mRNA can be detected in increased amounts in the airways in asthma.³⁹ However, IL-5 gene-deleted mice have a baseline eosinophilia and can develop pulmonary eosinophilia after infection with paramyxovirus, demonstrating that other late differentiation factors such as chemokine (C-C motif) ligand (CCL)-3 may be involved.^{40,41} It is therefore an accepted paradigm that a blood and tissue eosinophilia in IgE-mediated diseases, such as atopic asthma and helminthic parasite infections, are a result of antigen-dependent activation of T-helper (Th)-2 cells leading to IL-5 production and increased eosinophilopoiesis and tissue recruitment of eosinophils. The control of development of Th2 and Th1 cells is beyond the scope of this chapter, but may relate to the cytokine milieu at the time of sensitization, genetically regulated transcriptional control of IL-4, or the route of sensitization and the way in which the antigen is presented (Chap. 76).^{42,43} The HLA haplotype of individuals responsive to certain allergens has also been investigated. A degree of restriction has been observed, particularly to simple allergens, with, for example, the phenotype DR2.2 being overrepresented in individuals atopic to the ragweed allergen Amb a V. However, with the majority of allergens, no clear pattern has emerged. Although HLA haplotypes may influence responses to individual allergens, it is unlikely to provide a universal explanation for Th2-type responsiveness.

Many eosinophilic diseases, including many cases of pulmonary eosinophilia, are not associated with atopy and IgE production and therefore do not entirely fit with the Th2-driven eosinophilic paradigm. Intrinsic asthma is generally assumed to be associated with IL-5-producing T cells; however, the evidence for this is limited. One model for non-IgE-associated eosinophilic disease is those cases of eosinophilic esophagitis caused by a defined food allergen in which there is no specific IgE.⁴⁴ In some of these cases, the patients are patch-test-positive to the food allergen concerned, which raises the possibility of a Th2 type of type IV cell-mediated immunity, but this is still unexplored.

There is increasing interest in the role of T regulatory cells (T_{REG}) in controlling inappropriate immune responses including those associated with Th2 cell activation.⁴⁵ T_{REG} were first identified as mediating some aspects of immune tolerance and were then found to play an important role in suppressing immune-mediated inflammatory bowel disease in mice. Three types of T_{REG} cells have been identified: $CD4^+/CD25^+$ cells which require direct contact to mediate their immunosuppressive effects, T_{REG} cells producing TGF- β and T_{REG} cells producing IL-10.^{46–48} A current idea is that the increase in allergic disease that is also paralleled by an increase in autoimmune disease is not caused by a Th1 to Th2 switch, but by a failure to develop T_{REG} responses, which leads to enhancement of both Th1 and Th2 immunity.^{49–51} IL-10 producing T_{REG} is of particular interest in the context of pulmonary eosinophilia because of evidence that immunotherapy works by inducing expansion of an antigen specific IL-10 producing T_{REG} cells.⁵² In addition, regulatory T cells were able to suppress ovalbumin-induced pulmonary eosinophilia in mice.⁵³

EOSINOPHIL HETEROGENEITY

Blood eosinophils from normal individuals are relatively dense cells that can be separated from other leukocytes by density-gradient centrifuge. For many years these differences were the basis for the standard method of purifying eosinophils. This method has now been largely superseded by negative immunomagnetic selection based on the expression of the low affinity (Fc γ RIII, CD16) IgG receptor by neutrophils but not eosinophils. This latter technique has the advantage of improved purity and cell yields as well as enabling purification of eosinophils from individuals with low eosinophil counts. A proportion of eosinophils from individuals with elevated eosinophil counts are less dense than eosinophils from normal subjects. So-called hypodense eosinophils appear to be vacuolated and contain smaller granules, although in equal numbers to normal-density eosinophils. The mechanism for this heterogeneity is unclear; although a correlation with eosinophil activation has been a favored hypothesis, the evidence to support this hypothesis is contradictory.⁵⁴

EOSINOPHIL TRAFFICKING AND TISSUE ACCUMULATION

Eosinophils are not normally found in tissues other than the gut and the appearance of increased numbers of these cells can be a notable feature of the pathology of a number of diseases. The normal pattern of gut homing of eosinophils is likely to be mediated by CCL-11 (eotaxin 1), which is constitutively expressed in the gut, and the integrin $\alpha_4\beta_7$, binding to mucosal addressin cell adhesion molecule (MAdCAM)-1, which is selectively expressed in the intestine.⁵⁵ Type 2 innate lymphoid cells are central to this process, constitutively producing IL-5, which generates an eosinophilia, and IL-13, which stimulates production of eotaxin. Activation of innate lymphoid cell (ILC)-2 was modulated by nutrient intake and circadian rhythms, which may explain the circadian cycling of blood eosinophils.⁵⁶ Although an eosinophilia can accompany a

general inflammatory response, as for example in idiopathic pulmonary fibrosis where increased numbers of eosinophils and neutrophils can be seen in the BAL fluid, it often occurs without a marked increase in other leukocytes raising the question of the mechanism behind the specific tissue accumulation of these picturesque leukocytes. Selective eosinophil accumulation occurs as a result of the coordinated effect of a number of adhesion, chemotactic and growth/survival orientated signals at each stage in the life cycle of the cell. Generally speaking, these events are controlled by mediators associated with Th2 cells, in particular the cytokines IL-4, IL-5, IL-13, and possibly IL-9.^{57,58} Another group of epithelial derived cytokines—IL-25, IL-33, and thymic stromal lymphopoietin (TSLP)—play a key role in the development of eosinophilic inflammation through the activation of a newly described class of innate immune cells called ILC2.⁵⁹

As well as being crucial for differentiation, IL-5 is also important in promoting emigration from the marrow. In particular, it acts as a priming factor for specific chemoattractants such as eotaxin.⁶⁰ The observation that eotaxin decreased adhesion to vascular cell adhesion molecule (VCAM)-1 while increasing adhesion to the CD18 ligand bovine serum albumin (BSA) may be a mechanism for promoting egress from the marrow.⁶¹ Localized inflammatory responses can cause systemic effects after allergen challenge in mice in which IL-5-producing cells (both T cells and non-T cells), increase in the marrow.⁶²

Accumulation of leukocytes in tissue is a highly regulated process with the aim of being able to respond effectively to noxious insults without causing an inappropriate inflammatory response. An obligate step in the migration of all leukocytes from the systemic circulation into tissue is their capture by endothelium as they flow at high shear rates through the postcapillary endothelium. A key receptor mediating eosinophil capture is P-selectin, whose low-level surface expression is selectively induced on endothelium by IL-4 and IL-13. Eosinophils express higher levels of P-selectin glycoprotein ligand (PSGL)-1 (the primary receptor for P-selectin) than other leukocytes and this results in increased avidity for P-selectin compared to neutrophils, especially at the low levels of expression induced by Th2 cytokines.⁶³ Increased expression of PSGL-1 leading to enhanced recruitment has also been reported in allergic disease.⁶⁴ IL-4 and IL-13 can also induce low levels of VCAM-1 expression which can bind eosinophils through very-late antigen (VLA)-4 and also capture flowing cells albeit at lower shear stresses. VLA-4/VCAM-1 and PSGL-1/P-selectin cooperate as a major endothelial control point for selective eosinophil migration.⁶⁵ Once captured, eosinophils roll along the surface of the blood vessel until they are activated, which allows the CD18 integrins binding to ICAM-1 and ICAM-2 to nonselectively promote transmigration. VLA-4/VCAM-1 can also exert selective pressure at this stage.⁶⁶ In mice, this process is dependent on the intracellular RAC-binding protein SWAP-70.⁶⁷ The activation step mediated by chemoattractants expressed on the endothelial surface is another potential point of eosinophil selection, as shown by the effect of exogenously added chemoattractants such as eotaxin, but the identity of the endogenous chemoattractant involved and the extent to which it is selectively expressed in eosinophilic inflammation remains to be conclusively resolved. Orosomucoid-like 3 (ORMDL3), a molecule that has been identified by genetic epidemiology to be associated with asthma, is expressed by eosinophils and gene deletion in a mouse model resulted in reduced adhesion and recruitment into the lung.⁶⁸

Once the eosinophil has transmigrated through the endothelium it has to migrate through the basement membrane and into the tissue. Chemokines as well as other eosinophil chemoattractants are likely to be central to this process (Table 62–3). Many eosinophil-active chemokines bind to the chemokine receptor (CCR)-3 and deletion of this gene severely impairs eosinophil migration into the lung in the mouse asthma model. The three specific eosinophil chemokines, eotaxins 1 to 3, appear

TABLE 62-3. Eosinophil Chemokine Receptors and Their Ligands

Receptor	Chemokine

*Only expressed on eosinophils from some donors.

[†]Only active on *in vivo*-activated or cytokine-primed eosinophils (may be indirect effect via neutrophils).

to play overlapping roles in eosinophil migration into the lung in mice.⁶⁹ However, a potent CCR3 antagonist had no effect on eosinophil migration into the airways in human asthma, questioning the physiologic relevance of the mouse data in human disease.⁷⁰

Apoptosis is the universal mechanism by which cells undergo cell senescence in a manner that allows them to be efficiently removed by macrophages without inducing an inflammatory response. Morphologic observations have indicated that eosinophil apoptosis is an unusual event in tissue and that most eosinophils either die by cytolysis or migrate into the lumen where they do become apoptotic.⁷ A slow rate of apoptosis in tissues is consistent with the survival signals delivered to eosinophils by the extracellular matrix as part of normal homeostasis as well as increased production of eosinophil growth factors during Th2-mediated inflammation.^{71,72} The importance of prolonged survival of eosinophils in tissue as a mechanism for selective accumulation has been emphasized by studies using anti-IL-5, which effectively inhibits blood and sputum eosinophil numbers but has a much-less-marked effect on tissue eosinophils.⁷³ Unlike neutrophils, where they prolong survival, glucocorticoids directly enhance the rate of eosinophil apoptosis, an effect inhibited by IL-5.⁷⁴ Tumor necrosis factor-related apoptosis-inducing ligand (TRAIL), another family of survival modulating mediators related to tumor necrosis factor (TNF)- α , prolongs eosinophil survival, both *in vitro* and *ex vivo*, after allergen challenge.⁷⁵

The biochemical mechanism by which growth factors mediate eosinophil survival is dependent on both new protein synthesis and phosphorylation events. The survival effects of IL-5 are dependent on activation of the Ras-Raf-MEC pathway and the Jak-2 Stat 1 and Stat 5 pathways, and involve LYN kinase, which binds to the IL-5R α chain.⁷⁶ The roles of p38 and phosphatidylinositol (PI) 3 kinase are less clear, and wortmannin, which blocks PI3 kinase, had no effect on eosinophil apoptosis, although it did inhibit IL-5 enhancement of adhesion to fibrinogen. Eosinophils express significant amounts of the proapoptotic BAX and the antiapoptotic BCL-xl, but very little Bad or BCL-2. As in other cell types, both spontaneous and FAS-induced eosinophil apoptosis is associated with the migration of BAX into the mitochondria. This event led to loss of mitochondrial membrane potential, cytochrome c release, and activation of downstream caspases. These events are all inhibited by IL-5, demonstrating that IL-5 works by blocking BAX translocation.^{77,78} Inhibition of BAX activation prevents eosinophil apoptosis even in the absence of cytokine. Treatment of eosinophils with dexamethasone also leads to loss of mitochondrial permeability.⁷⁹ GM-CSF-activated ERK1/2, which phosphorylates BAX at Thr167, facilitates interaction with peptidylprolyl isomerase (PIN1). If interaction with PIN1 is prevented, BAX is activated and translocated to the mitochondria, resulting in apoptosis. It appears, therefore, that the eosinophil growth factors exert their antiapoptotic effects through fostering the PIN1-BAX interaction.⁸⁰ IL-5-mediated eosinophil survival is

also regulated by the balance between the signaling through two paired immunoglobulin-like receptors, PIR-A and PIR-B, with PIR-B counteracting the proapoptotic effect of PIR-A.⁸¹

Another potential mechanism involved in eosinophil tissue accumulation is *in situ* differentiation from eosinophil precursors. Eosinophil precursors can be identified in an IL-5R α ⁺CD34⁺ population in blood, increased after allergen challenge and in atopic disease. These cells have also been found in asthmatic airways.⁸²

Of equal importance as endothelial interactions to the kinetics of eosinophil migration are the factors controlling the fate of the eosinophil once it enters the tissue. There are three possible outcomes. The eosinophil can remain in the tissue interacting with matrix proteins, other leukocytes, or structural cells such as, in the bronchial mucosa, the epithelium, airway smooth muscle, mucus glands, and nerves; alternatively, the cell can migrate into the lumen of the gut or airway where it is likely to undergo apoptosis and be removed; or it can return to the circulation via the lymphatics. The length of time that eosinophils remain in tissue before migrating into the lumen is unclear as there are virtually no studies of the kinetics of eosinophil migration *in vivo* in humans. An anti-IL-5 completely inhibited migration into the lumen, which suggests that transepithelial migration is IL-5-dependent. However, it only inhibited tissue numbers by at best 50 percent, emphasizing that different compartments are controlled by different mechanisms.⁷³ In the mouse model of asthma, eosinophil migration into the lumen does not occur in the MMP-2 gene-deleted mouse, and the lack of migration causes the mouse to asphyxiate.⁸³ As with senescent neutrophils, when tissue eosinophils become senescent they start to alter their receptor phenotype in a way that inhibits tissue retention and promotes migration into the lumen.⁸⁴ The factors controlling the retention and survival of eosinophils in tissue are likely to involve the integration of chemoattractant, adhesive, and survival signals delivered by interactions with matrix proteins and structural cells. Studies modeling eosinophil migration in a tissue context using collagen gels have shown a different pattern to standard Boyden chamber assays with a much greater, albeit random, migratory response to growth factors than to chemoattractants.⁸⁵ This observation suggests that migration into the lumen requires both a growth factor and a chemotactic stimulus.

ANIMAL MODELS OF EOSINOPHILIC DISEASE

Animal models, particularly the mouse model of ovalbumin challenge, which results in a selective and marked pulmonary eosinophilia, have been used extensively to analyze the molecular basis of eosinophil trafficking and the pathologic consequences of this movement.⁸⁶ The majority of studies have focused on the role of eosinophilic inflammation in asthma.⁸⁷ The combination of transgenic, gene-deletion, and antibody-based manipulations in the mouse make this a powerful tool for analyzing the biology of eosinophil migration, although the relevance of the findings to human disease should be treated with caution. Generally speaking, these studies support the concept of eosinophil migration as being caused by a series of interlinked and obligate steps with IL-5 necessary for providing a pool of circulating eosinophils, priming eosinophils for chemotactic responsiveness, and prolonging eosinophil survival. IL-4 and IL-13 control adhesion-related events in the endothelium and enhance the release of eosinophil chemoattractants, particularly CCR3-binding chemokines from mesenchymal cells within the airway.⁵⁸ However, there are a number of other studies that look at other aspects of the immune response and as a result challenge this neat concept, in particular showing potential roles for innate immunity as well as other inflammatory mediators.⁸⁸⁻⁹⁰ Our understanding of the role of eosinophils in health and disease, using mouse models of disease, has been summarized.¹⁷

EOSINOPHIL FUNCTIONS

The eosinophil exerts its effects largely through its mediators (see Fig. 62–1). These chemicals are either newly generated, as is the case with leukotrienes and other lipid mediators, or stored preformed in various compartments within the cytoplasm and released when the eosinophil receives a degranulating stimulus. The eosinophil is relatively biosynthetically inactive and, although new protein synthesis does occur, the majority of its protein mediators are stored. Although the eosinophil can phagocytose particles its interactions with larval forms of helminthic parasites have formed the model by which eosinophil function has been described. In this situation, the eosinophil adheres tightly to the organism and releases its granule contents in local, high concentrations onto the surface in a process described as frustrated phagocytosis. The paradigm of eosinophil effector function in host defense was developed from the observation that the basic granule proteins, in particular, were highly toxic for larval parasites. This observation was extended to include a proinflammatory role in which they were also shown to be toxic for bronchial epithelium and, therefore, associated with the epithelial desquamation which is a well-established feature of severe asthma. Eosinophils are not thought to play a major role in bacterial host defense and, indeed, bacterial sepsis causes an eosinopenia; however, eosinophils can release mitochondrial DNA which has antibacterial properties.⁹¹ Eosinophils can also release a plethora of cytokines and chemokines although many of these are generated in low amounts compared to other cells and the extent to which they are important in eosinophil function is not clear.⁹²

Role in Immunoregulation

Most research into the role of eosinophils has focused on host defense against helminthic parasites and as effector cells in asthma. However, since 2010 there has been groundbreaking research emphasizing a potential homeostatic role for eosinophils in a number of areas, including antigen presentation, tissue repair, adipogenesis and glucose homeostasis, and B-cell development.⁹³ There has been evidence for many years that eosinophils can present antigen to T cells, although the physiologic relevance of this function in the context of an intact dendritic cell antigen-presenting capacity remains uncertain.⁹⁴ Type 2 immunity is necessary for the regeneration of skeletal muscle after injury. Muscle damage resulted in the rapid recruitment of eosinophils, which secretes IL-4 and activates muscle resident stem cells.⁹⁵ Similarly, eosinophil-derived IL-4 was necessary for liver regeneration.⁹⁶ A role in adipose tissue and glucose homeostasis was first suggested in 2011 when it was demonstrated that eosinophils, through the production of IL-4, were necessary for the maintenance of adipose tissue associated alternatively activated macrophages, which, in turn, were necessary to control glucose metabolism and body fat.⁹⁷ This same pathway in concert with ILC2 cells is involved in the development of cold-induced, beige fat, which provides a defense against cold and obesity.^{98,99} Long-lived plasma cells, which survive in specialized niches in the marrow, do so as a result of growth factors (APRIL and IL-6) supplied by colocalized eosinophils.¹⁰⁰ Eosinophils are also important in gut immune homeostasis, with eosinophil deficiency resulting in a reduction in IgA⁺ plasma cells and secreted IgA, as well as defects in the intestinal mucous shield, alteration in the gut microbiota, and the formation of CD103⁺ Tr and dendritic cells.¹⁰¹ B-cell development was also shown to be regulated by eosinophils in mice and humans.¹⁰² These studies were almost exclusively undertaken in mice, but they are potentially clinically relevant as a number of biologic therapies targeted at the Th2 pathway, including specific antieosinophil therapies, are in the late stages of clinical development for asthma and other eosinophilic diseases. So far, these drugs appear relatively free of serious adverse effects, so it is possible that the relatively modest effects of these drugs on the tissue eosinophilia means that the homeostatic role of eosinophils will not be perturbed.

Mediator Release

Eosinophils can release a number of lipid mediators and are one of the relatively few sources of sulphidopeptide leukotrienes, although per cell they release approximately 10-fold less than mast cells and basophils.¹⁰³ This is in contrast to neutrophils that produce large amounts of leukotriene (LT)B₄, but little, if any, LTC₄. LTC₄ generation by human eosinophils also occurs after stimulation with opsonized zymosan and beads coated with IgG. Eosinophils can also generate substantial quantities of 15-HETE (hydroxyeicosatetraenoic acid) via 15-lipoxygenase. Eosinophils also generate platelet-activating factor (PAF) after stimulation with either calcium ionophore or IgG-coated beads. Eosinophils can also generate mediators of the cyclooxygenase pathway, including prostaglandins E₁ and E₂, thromboxane B₂ (TXB₂), and prostaglandin D₂.¹⁰⁴ The principal sites of eicosanoid formation in eosinophils are the lipid bodies, which contain large amounts of arachidonic acid and enzymes required for eicosanoid synthesis, including 5-lipoxygenase, LTC₄ synthase, and cyclooxygenase.¹⁰⁵ Eosinophils release significant amounts of TGF-β and TGF-α and this has stimulated interest in a potential role in causing airway remodeling. There is evidence that TGF-β released by eosinophils can promote the generation of fibrocytes and anti-IL-5 reduced the amount of tenascin in the reticular subepithelial membrane.^{106,107} Thickening of this membrane is closely associated with eosinophilic airway inflammation, although not with AHR or airflow obstruction.¹⁰⁸ Vasoactive intestinal peptide (VIP) has been detected in eosinophils in granulomas from mice infected with schistosomes and the eosinophil contains a number of granule-stored enzymes, whose roles in eosinophil function are not clear. These enzymes include acid phosphatase, collagenase, arylsulfatase B, histaminase, phospholipase D, catalase, nonspecific esterases, vitamin B₁₂-binding proteins, and glycosaminoglycans. Eosinophils can undergo a respiratory burst with release of superoxide ion and H₂O₂ in response to stimulation, with both particulate stimuli, such as opsonized zymosan, and soluble mediators, such as leukotriene and phorbolmyristate acetate. Eosinophils are twice as chemoluminescent as neutrophils.

Eosinophil Granule Proteins

A specific and important feature of eosinophils is the large amounts of basic proteins they contain within their specific granules. These are MBP, eosinophil cationic protein (ECP), eosinophil peroxidase, and eosinophil derived neurotoxin (EDN).¹⁰⁹ MBP has a molecular mass of 13.8 kDa and an isoelectric point (pI) of 10.9. Its 17 arginine residues account for its alkalinity. It is initially synthesized as an acidic proprotein that is stored in the eosinophil granule. MBP becomes toxic only after it is released and processed into its final form. Purified MBP is cytotoxic for the schistosomula of *Schistosoma mansoni*, and adherence of eosinophils to IgG-coated schistosomula results in the secretion of MBP onto the tegument of the larvae, resulting in loss of viability.¹¹⁰ MBP at concentrations as low as 10 mg/mL is toxic for both guinea pig and human respiratory epithelial cells, as well as for rat and human pneumocytes. The mechanism of action of MBP on epithelial cells is mediated through inhibition of adenosine triphosphatase (ATPase) activity. MBP and eosinophil peroxidase are strong agonists for platelet activation as well as activation of mast cells, basophils, and neutrophils.¹¹¹ The mechanisms of action of MBP is likely to be related to its hydrophobicity and strong negative charge. Basophils also contain MBP but only approximately 2 percent that of eosinophils.

Eosinophil peroxidase is a heme-containing protein that is synthesized as a single protein and then cleaved into 14- and 58-kDa subunits. The molecule shares a 68 percent identity in amino acid sequence with human neutrophil myeloperoxidase as well as other peroxidase enzymes. The protein is toxic for parasites, respiratory epithelium, and pneumocytes, either alone, or (more potently) when combined with H₂O₂ and halide, the preferred ion *in vivo* being bromide.

ECP is an arginine-rich protein. The complementary DNA (cDNA) encodes for a 27-amino-acid leader sequence and a 133-amino-acid mature polypeptide with a molecular mass of 15.6 kDa. ECP has 66 percent amino-acid-sequence homology with EDN and 31 percent homology with human pancreatic ribonuclease, but it has low ribonuclease activity compared to EDN. ECP is toxic for helminthic parasites, isolated myocardial cells, and guinea pig tracheal epithelium. ECP also inhibits lymphocyte proliferation *in vitro*. Both ECP and EDN produce neurotoxicity (the Gordon phenomenon) when injected into the cerebrospinal fluid of experimental animals. ECP may damage cells by a colloid osmotic process, as it can induce non-ion-selective pores in both cellular and synthetic membranes.

EDN, also called EPX, is a 16-kDa, glycosylated protein possessing marked ribonuclease activity. The cDNA predicts a 134-amino-acid, mature polypeptide that is identical to human urinary ribonuclease. Like ECP, it is a member of a ribonuclease multigene family. EDN expression is not restricted to eosinophils, as it is found in mononuclear cells and possibly neutrophils. It is also probably secreted by the liver. It does not appear to be toxic to parasites or mammalian cells, and its only known effect, other than its ribonuclease activity, is neurotoxicity.

A major constituent of eosinophil is CLC protein, which is a lysophospholipase. It constitutes up to 10 percent of eosinophil protein and is also found in large quantities in basophils. It was thought to possess lysophospholipase activity, but this is not the case. It is a member of the galectin family (galectin 10).¹¹² Its function is unknown.

EOSINOPHIL SECRETION AND ACTIVATION

A striking feature of eosinophil-rich inflammatory reactions is the high concentration of granule proteins, often in the presence of relatively small numbers of intact eosinophils. Sometimes free granules can be seen independent of eosinophils.¹¹³ This may occur as part of a cytolytic nonapoptotic process involving nicotinamide adenine dinucleotide phosphate oxidase (NADPH) and the formation of extracellular DNA traps.^{114,115} Mediator secretion can be triggered physiologically by engagement of immunoglobulin Fc receptors, especially after eosinophil activation has been primed with soluble mediators such as PAF, IL-5, and GM-CSF. Priming by GM-CSF involves phosphorylation of L-plastin and PKC β II.¹¹⁶ The eosinophil expresses receptors for IgG, IgA, and IgD. The eosinophil also binds IgE, and eosinophils can undertake a number of IgE-dependent functions, including killing of schistosomes opsonized with specific IgE. The receptor involved is unclear as the accumulated evidence now suggests that eosinophils do not express either the low-affinity (Fc ϵ RII) or high-affinity (Fc ϵ RI) IgE receptor to any degree although they do express high intracellular levels of the α chain of Fc ϵ RI.¹¹⁷

Three receptors for IgG have been described: the high-affinity receptor Fc γ RI (CD64), and two low-affinity receptors Fc γ RII (CDw32) and Fc γ RIII (CD16). CD16 is expressed both as a transmembrane form and a form with a phosphatidylinositol anchor, transcribed from two distinct genes. Only Fc γ RII is constitutively expressed by eosinophils to any significant degree. A number of eosinophil functions are mediated via this receptor, including schistosomula killing, phagocytosis, secretion of granule proteins, and generation of newly formed, membrane-derived lipid mediators such as PAF and LTC $_4$. After stimulation for 2 days *in vitro* with interferon (IFN)- γ , eosinophils express CD16 and CD64 as well as CD32. Perhaps the most potent stimulus for eosinophil degranulation is crosslinking of IgA receptors, especially when the cells have been primed with growth factors. Consistent with the preference of eosinophils to secrete their mediators onto a large surface, Fc-mediated degranulation is enhanced if the eosinophils are adherent to a protein-coated surface via integrin $\alpha_M\beta_2$.¹¹⁸ Eosinophils are particularly

effective in generating reactive oxygen species with about 1.7-fold greater generation than neutrophils after stimulation with PMA (phorbol myristate acetate), possibly as a result of a 10-fold greater expression of the voltage-gated channel Hv1.¹¹⁹

The killing of schistosomula opsonized with nonimmune serum is presumed to be mediated via the complement receptors, CR1 and CR3. Incubation of eosinophils with serum-coated beads results in the release of 15 percent of ECP. Similarly, opsonized zymosan interacts with eosinophils, causing generation of hydrogen peroxide and the phagocytosis of the zymosan. Soluble mediators, such as PAF, LTB $_4$, and 5-oxoeicosatetraenoate, can elicit the direct secretion of both granule proteins and lipid mediators, although only with highly activated eosinophils or when used in conjunction with cytochalasin B, which inhibits microtubule assembly. Eosinophils release their granule components by exocytosis, with individual granules fusing with the plasma membrane. This process involves a guanosine triphosphate (GTP)-binding protein and is modulated by the intracellular calcium concentration. In common with other secretory cells degranulation is controlled by soluble N-ethylmaleimide-sensitive factor attachment protein (SNAP) receptor complex (SNARE) proteins that guide the granules to the cell surface. Vesicular SNAREs expressed on granules bind to target SNAREs expressed on the plasma membrane. The SNARE proteins VAMP 2 and VAMP 7 are important in eosinophil secretion from granules and their function in eosinophils is regulated by cyclin-dependent kinase 5.¹²⁰

EOSINOPHILS IN DISEASE

MEASUREMENT OF EOSINOPHILS IN THE BLOOD

Eosinophils can be enumerated in the blood either by “wet counts” in modified Neubauer chambers, differential counts on dried films, or by automated cell counting by flow cytometry. Automated counting that uses detection of eosinophil peroxidase is the most accurate method, followed by counting in a cell chamber. Counting on films is least accurate because of the tendency for eosinophils to congregate at the margins of the slide. Common wet stains for eosinophils include eosin in acetone, phloxine, and Kimura stain, which was originally developed to stain basophils.¹²¹ Many stains, including May-Grunewald-Giemsa, Romanowsky, chromotrope 2R, and Biebrich scarlet, will identify eosinophils in blood films, cytospin preparations, or tissues.

The eosinophil count should preferentially be evaluated in absolute numbers rather than as a percentage of white cells, as the latter will depend on the total white cell count. The normal eosinophil count is generally taken as less than $0.4 \times 10^9/L$, although healthy medical students in the United States had a range of 0.015 to $0.65 \times 10^9/L$.¹²² Eosinophil counts are higher in neonates (Chap. 7). Clinical trials of anti-Th2 therapies are using a lower cut off in the region of $0.3 \times 10^9/L$ to identify patients with eosinophilic asthma suggesting that the “normal” eosinophil count in people without allergic disease is below this level. The eosinophil count varies with age, time of day, exercise status, and environmental stimuli, particularly allergen exposure. Blood eosinophil counts undergo diurnal variation, being lowest in the morning and highest at night. This effect results in a greater than 40 percent variation and may be related to the reciprocal diurnal variation in cortisol levels, which are highest in the morning. The factors that control blood eosinophil counts in health are imperfectly understood. Concentrations of eosinophil growth factors are likely to be important, but other factors may be involved, including an element of genetic control.¹²³ Normal counts vary by up to 40-fold, and, in populations where eosinophilia is common, such as endemically parasitized areas, there are marked variations in the blood eosinophil level, independent of

the degree of infection. This variation is comparable to variations in IgE levels. There are no differences between ethnic groups in eosinophil counts.

The eosinophil count in hospitalized patients is less than $0.01 \times 10^9/L$ in only 0.1 percent of patients, and in virtually all patients the eosinopenia can be ascribed to glucocorticoids or to disease activity. Acute infection, or treatment with glucocorticoids or adrenaline, decreases eosinophil counts. In contrast, β -blockers inhibit adrenaline-induced eosinopenia and can cause a rise in the eosinophil count.

There have been several isolated case reports of patients with absent eosinophils in the blood and marrow.¹²⁴ A rare disorder, eosinophil peroxidase deficiency, may be brought to light by automatic counting that uses detection of eosinophil peroxidase to count eosinophils. Eosinophil peroxidase deficiency does not have any adverse clinical consequences.

CAUSES OF AN EOSINOPHILIA

An eosinophilia accompanies a discrete number of diseases and a high eosinophil count is always a clinically notable observation that requires explanation, although this is not always forthcoming.¹²⁵ The causes of eosinophilia can be classified according to the degree and frequency of occurrence (Table 62–4). Division of eosinophil counts is arbitrary, but a mild eosinophilia could be regarded as less than $1.0 \times 10^9/L$, a moderate elevation as 1.0 to $5.0 \times 10^9/L$, and a high count as greater than $5.0 \times 10^9/L$. The most common cause of an eosinophilia worldwide is infection with helminthic parasites, which can often result in a very high eosinophil count. The most common cause of an eosinophilia in industrialized countries is the atopic allergic diseases, seasonal and perennial rhinitis, atopic dermatitis, and asthma. Allergic disease generally results in only a mild increase in eosinophil counts. A moderate or high eosinophil count in asthma, especially outside a severe exacerbation, raises the possibility of a complication such as eosinophilic granulomatosis with polyangiitis (EGPA, formerly Churg-Strauss syndrome), allergic fungal airway disease, or eosinophilic pneumonia.¹²⁶ Drug allergy is not always straightforward to diagnose as a cause of an eosinophilia and less-common causes include Addison disease (although the eosinophilia is not usually marked).

THE ROLE OF EOSINOPHILS

For years eosinophils were thought to ameliorate inflammatory responses, a view that is possibly coming back into vogue as noted above (see “Role in Immunoregulation” above); then through the 1980s and 1990s they were believed to cause tissue damage in some situations. The subsequent use of anti-IL-5 and tyrosine kinase inhibitors to inhibit eosinophil production has suggested a complex interaction between eosinophilic inflammation and target organ damage.¹²⁷ Eosinophils, in part through release of cytokines such as TGF- α , may also have a homeostatic role in certain circumstances, such as wound healing and mammary gland development.^{128,129} Eosinophils can certainly cause severe tissue damage under certain circumstances. Chronically high eosinophil counts from many causes, including drug reactions, parasitic infections, eosinophilic leukemia, and HES, are associated with endomyocardial fibrosis. The observation in the mid-1970s that eosinophils could kill parasite targets led to the hypothesis that the principal role of eosinophils was to counter parasitic infection, although this remains a controversial area.¹³⁰ Eosinophils in a mouse model had a protective effects against fungal growth in the lungs and eosinophils have also been demonstrated in mice to protect against lethal respiratory virus infection.^{131,132} Eosinophils are therefore associated with a number of different types of pathologic and reparative processes ranging from the permanent tissue damage seen in HES, the partly reversible tissue

damage seen in asthma and pulmonary eosinophilia, and tissue repair characteristic of wound healing. The factors that determine which role the eosinophil adopts are unclear.

EOSINOPHILS AND ASTHMA

The relationship between airway inflammation and asthma is complex. In particular, there is no close relationship between the severity of eosinophilic airway inflammation and either the severity of symptoms, AHR, or abnormalities in forced expiratory volume in 1 second (FEV_1).¹³³ The potential dissociation between an airway smooth muscle dysfunctional phenotype, which leads to many of the symptoms and physiologic abnormalities in asthma, and an eosinophilic inflammation-predominant phenotype more closely associated with severe exacerbations was demonstrated in an examination of asthma heterogeneity using cluster analysis techniques.¹³⁴ This dissociation was further illustrated by clinical trials of mepolizumab, an anti-IL-5 monoclonal antibody (mAb), which markedly reduced eosinophils in the blood and sputum but had no effect, either on AHR or lung function in patients with mild asthma, or on the late response to allergen challenge.³⁶ The interpretation of this study and others using the anti-IL-5 antibody was complicated by the observation that anti-IL-5 only partially decreases the tissue eosinophilia.⁷³ A dissociation between AHR and eosinophilia has also been seen in animal models of allergen challenge. For example, anti-VLA-4 mAb was able to block ovalbumin-induced AHR, but not airway eosinophilia when given by aerosol to mice.¹³⁵ Strikingly, in a condition called *eosinophilic bronchitis* in which patients have an eosinophilic airway inflammation but no evidence of asthma (no AHR or variable airflow obstruction), the asthma phenotype correlated with the number of mast cells in the airway smooth muscle and the tissue eosinophilia did not differ between the asthmatic and eosinophilic bronchitis groups.¹⁰⁸ Large numbers of eosinophils and mononuclear cells are found in and around the bronchi of patients who have died of asthma, and their bronchial tissue contains large amounts of MBP.⁸ The pathology of asthma deaths is at the extreme end of the pathology of asthma exacerbations. There is increasing evidence that an airway eosinophilia is closely associated with the risk of having severe exacerbations. There is now definitive evidence from two studies using mepolizumab that eosinophils are directly causal in the pathogenesis of severe exacerbations of asthma. Asthmatics with documented eosinophil airway inflammation were treated for up to a year with the drug with the primary outcome of a reduction in severe exacerbations in one study and dose of corticosteroids in another. Both demonstrated that mepolizumab was an effective form of treatment with response correlating with the effect on reducing eosinophils.^{136,137} These observations were confirmed in phase II and III clinical trials and mepolizumab is now going through the licensing procedure for the treatment of asthma.^{138,139} Of note, a dose of mepolizumab that was suboptimal for suppressing the airway eosinophilia was as effective in preventing exacerbations as a higher dose that did suppress sputum eosinophils. Both doses effectively suppressed the blood eosinophilia, suggesting this is a better biomarker of response. The exact mechanism by which mepolizumab prevents exacerbations of asthma is therefore not entirely clear, especially as it does not obviously suppress eosinophil activation in the airway lumen.¹⁴⁰

EOSINOPHILS AND THE SKIN

A large number of skin conditions are associated with infiltration of the skin by eosinophils.¹⁴¹ The normal skin contains few eosinophils, so their presence is usually associated with pathology. The commonest causes of eosinophilic infiltration of the skin is atopic dermatitis where, as with asthma, the relationship to pathogenesis remains contentious.¹⁴²

TABLE 62-4. Causes of an Eosinophilia

Disease	Frequency of Cause of Eosinophilia	Usual Degree of Eosinophilia	Comment
INFECTIONS			
Parasitic disease	Common worldwide	Moderate to high	
Bacterial	Rare		Almost invariably causes an eosinopenia
Mycobacterial	Rare		Secondary to drug therapy
Invasive fungal	Unusual		Apart from allergic responses which are common and coccidiomycosis, in which as many as 88% of patients have an eosinophilia
Rickettsial infections	Rare		
Yeast	Rare		Cryptococcus reported as causing cerebrospinal fluid eosinophilia
Viral infections	Rare		Occasional case reports of an eosinophilia in a variety of viral infections, including herpes and HIV infection
ALLERGIC DISEASES			
Allergic rhinitis	Common	Mild	
Atopic dermatitis	Common especially children	Mild to moderate	
Urticaria/angioedema	Common	Mild	Eosinophils seen in skin even with normal count
Fungal allergy	Common	Mild to high	Immunoglobulin (Ig) E sensitization to thermotolerant colonizing yeast (e.g., <i>Candida albicans</i>) and molds, e.g., <i>Aspergillus fumigatus</i> is a common cause of an eosinophilia
Asthma	Common	Mild	Syndrome of intrinsic asthma, nasal polyps, and aspirin intolerance associated with higher-than-usual eosinophil counts
DRUG REACTIONS			
Many drugs	Uncommon	Mild to high	Antibiotics, nonsteroidal antiinflammatory drug, and antipsychotics commonest groups; count should return to normal on stopping drug
NEOPLASMS			
Acute eosinophil leukemia	Rare	High	
Chronic eosinophilic leukemia	Rare	high	See text on hypereosinophilic syndrome
Myeloid leukemia	Uncommon	Moderate to high	Raised eosinophil counts can be seen in chronic myeloid leukemia
Lymphomas	Uncommon	Moderate	Often intense tissue eosinophilia with moderate blood eosinophil count; Hodgkin disease commonest type
Histiocytosis X	Rare	Mild	Intense tissue eosinophilia in eosinophilic granuloma but blood eosinophilia unusual
Solid tumors	Uncommon	Mild to high	Many different tumors reported
MUSCULOSKELETAL			
Rheumatoid arthritis	Rare	Mild to high	Occasional case reports. More usually secondary to therapy
Eosinophilic fasciitis	Rare	Moderate	
GASTROINTESTINAL			
Eosinophilic gastroenteritis	Rare	Mild to moderate	Characterized by irritable bowel syndrome–like symptoms; mucosal biopsies often normal
Eosinophilic esophagitis	Increasingly recognized	mild	Marked tissue eosinophilia with mild or absent blood eosinophilia
Celiac disease	Uncommon	Normal	Tissue eosinophilia
Inflammatory bowel disease			Eosinophils seen in biopsies in both Crohn and ulcerative colitis, but blood eosinophilia unusual
Allergic gastroenteritis	Rare	Mild to high	Young children

(continued)

TABLE 62-4. Causes of an Eosinophilia (Continued)

Disease	Frequency of Cause of Eosinophilia	Usual Degree of Eosinophilia	Comment
RESPIRATORY TRACT (FOR ASTHMA SEE ALLERGIC DISEASES)			
Eosinophilic granulomatosis with polyangiitis	Rare	Moderate to high	Syndrome of eosinophilic vasculitis and asthma
Chronic eosinophilic pneumonia	Uncommon	Mild to high	Syndrome of eosinophilia and chest x-ray shadowing
Bronchiectasis/cardiac failure	Common	Mild	Often associated with asthma or allergic fungal airway disease
SKIN DISEASES (FOR ATOPIC DERMATITIS SEE ALLERGIC DISEASES)			
Bullous pemphigoid	Uncommon	Moderate	
Eosinophilic cellulitis	Uncommon	Moderate to high	High eosinophil count distinguishes from bacterial cause
Skin lymphoma (Sézary syndrome: mycosis fungoides)	Uncommon	Moderate	
MISCELLANEOUS CAUSES			
Interleukin (IL)-2 therapy	Rare	Moderate to high	For renal cell carcinoma.
Hyper-eosinophilic syndrome	Rare	Moderate to high	
Endomyocardial fibrosis	Rare	High	Secondary to any cause of a high eosinophil count
Hyper-IgE syndrome	Rare	Moderate to high	Possibly caused by fungal allergy
Eosinophilia/myalgia and toxic oil syndrome	Rare	High	Two related conditions, one caused by poisoning with contaminated cooking oil in Spain and the other by a batch of tryptophan
Graft-vs.-host disease	Uncommon	Mild to moderate	
DOCK8 (dedicator of cytokinesis 8) deficiency	Rare	Mild	May be caused by fungal allergy
Olmsted syndrome	Rare		
Kimura disease	Rare		
Angiolymphoid hyperplasia	Uncommon		
Addison disease			

The skin is one of the most commonly effected organs in HES with pruritus being the commonest symptom, although ulceration also occurs.¹⁴³

EOSINOPHILS AND THE GASTROINTESTINAL TRACT

Eosinophils are present in the normal gastrointestinal tract as a result of constitutive expression of eotaxin and MAdCAM1 (mucosal addressin cell adhesion molecule-1) the receptor for $\alpha_4\beta_7$, which is expressed by eosinophils.⁵⁵ A number of diseases are associated with a gastrointestinal eosinophilia, including eosinophilic esophagitis, eosinophilic gastroenteritis, and inflammatory bowel disease, although this latter condition does not result in a blood eosinophilia.¹⁴⁴ Eosinophilic esophagitis is an increasingly recognized condition in both children and adults. It is associated with food allergy often in the absence of specific IgE. It is another condition characterized by a marked tissue eosinophilia without a marked blood eosinophil count.¹⁴⁵

EOSINOPHILS AND PARASITIC DISEASE

The role of eosinophils in parasitic disease is complex and still incompletely understood.¹³⁰ Table 62-5 and reference 146 summarize the most common helminthic causes of an eosinophilia. Eosinophils have

been shown *in vitro* to be able to kill a number of opsonized parasites, including newborn larvae of *Trichinella spiralis*, larvae of *Nippostrongylus brasiliensis*, a gut parasite in the rat, and larvae of *Fasciola hepatica*, as well as schistosomulae of *Schistosoma mansoni*. *In vivo*, parasite larvae become opsonized with both specific IgG and IgE antibodies and components of the complement cascade such as C3bi, which can promote adhesion and activation of eosinophils. Dead larvae of *Schistosoma haematobium* and other parasites have been detected in the skin surrounded by eosinophils and eosinophil granule products. Adult worms, both *in vitro* and *in vivo*, appear resistant to eosinophil-mediated damage. Despite the circumstantial evidence of eosinophils being involved in host defense against parasites, there remains doubt about their role. A number of experiments have been carried out in animal models of helminthic infection using IL-5 gene deletion, IL-5 transgenics, and anti-IL-5 antibodies to ablate the tissue eosinophilia. These studies have suggested that eosinophils may have a protective role in *Strongyloides* and *Filariasis* but not in *Schistosoma*, *Nippostrongylus*, and *Trichuris* infections. For example, treatment of mice infected with *N. brasiliensis* or *S. mansoni* with neutralizing anti-IL-5 mAbs abolished the eosinophilia without modulating the disease process.¹⁴⁶ In contrast, using diffusion chambers eosinophils were conclusively shown to be involved in killing the larvae of *Strongyloides stercoralis*.¹⁴⁷ In *Trichinella spiralis* infections, eosinophils prolonged larval survival during the primary

TABLE 62–5. Helminthic Causes of an Eosinophilia

Parasite	Comment
NEMATODES	
<i>Ascariasis</i>	Higher eosinophil counts in children. Larvae migrate from intestine to lungs where they cause Loeffler syndrome, a form of pulmonary eosinophilia.
<i>Toxocara canis</i>	Infective eggs are present in feces of puppies and pregnant bitches. Larvae in hosts such as chicken. Eosinophilia seen mainly in children younger than 9 years of age. Can migrate to eye and cause blindness. Serologic evidence suggests infection not uncommon in industrialized countries.
<i>Filariasis</i>	Common. Invariably result in marked eosinophilia, especially Loa Loa infection. Filariasis causes tropical pulmonary eosinophilia as a result of migration of adult worms to the lung, elephantiasis because of the involvement of lymphatics (<i>Wuchereria bancrofti</i> and <i>Brugia malayi</i>), and river blindness (<i>Onchocerca volvulus</i>). Treatment can result in systemic reaction called <i>Mazzotti reaction</i> , possibly a result of massive eosinophil degranulation.
<i>Ancylostomiasis</i>	Hookworm infection. <i>Ancylostoma duodenale</i> and <i>Necator americanus</i> . One of the main causes of eosinophilia in patients returning from tropical countries. Counts in region of $2.0 \times 10^9/L$.
<i>Strongyloidiasis</i>	Subclinical infection can persist for longer than 20 years. Stool examinations often negative. Cause of eosinophilia in ex-servicemen who spent time in tropics. If strongyloides infection is not considered and these patients are given steroids for suspected hypereosinophilic syndrome or as trial of therapy, they can develop disseminated disease.
<i>Trichinosis</i>	Caused by ingestion of encysted muscle larvae of <i>Trichinella spiralis</i> . Most prominent eosinophilia seen during early stages of infection when larvae migrating into striated muscle via the blood. Fatal cases reported of which only 20% were noted to have an eosinophilia.
Others	Other nematodes that can cause eosinophilia include <i>Trichuris trichiura</i> , <i>Capillaria</i> , and <i>Gnathostomiasis</i> . The thread worm <i>Enterobius vermicularis</i> occasionally causes an eosinophilia when they invade tissues.
TREMATODES	
Schistosomiasis (Bilharzia)	Infection with one of the <i>Schistosoma</i> (blood flukes)— <i>Schistosoma mansoni</i> , <i>Schistosoma haematobium</i> , and <i>Schistosoma japonicum</i> —is perhaps the commonest cause of a moderate to high eosinophilia worldwide, with 200 million people being infected. Infection is nearly always associated with an eosinophilia.
<i>Fascioliasis</i>	Adult worms of <i>Fasciola hepatica</i> reside in the bile ducts, where they are associated with abnormal liver function tests and an eosinophilia.
CESTODES	
<i>Echinococcus</i>	Eosinophilia occurs in 25–50% of patients with hydatid disease.

infection by producing IL-10 which led to a reduction in nitric oxide (NO) synthase expression and protected the intracellular larvae from NO-mediated killing.¹⁴⁸ In contrast, eosinophils were protective for host with a secondary infection.¹⁴⁹ The mechanism of eosinophilia in parasitic disease is thought to be similar to allergic disease, with a Th2-type response mediated by both adaptive Th2 cells and innate lymphoid type 2 cells to helminthic antigens resulting in increased production of eosinophil growth factors, in particular IL-5.¹⁵⁰ Recruitment of eosinophils to the site of parasite infection may involve nematode induced production of LTB₄ by eosinophils.¹⁵¹

HYPEREOSINOPHILIC SYNDROMES

Idiopathic Hypereosinophilic Syndrome

Definition and History Idiopathic hypereosinophilic syndrome (iHES) is a rare and potentially fatal disorder first described as a distinct entity by Hardy and Anderson in 1968.¹⁵² It is defined as a persistent eosinophilia of greater than 1.5×10^9 cells/L for more than 6 months with no other explanation after comprehensive investigation and evidence of end-organ damage.¹⁵³ Patient series have consistently shown that the major target organs for tissue damage are the skin, heart, and nervous system.¹⁵⁴ The definition and

classification of HES is unsatisfactory as conditions such as EGPA, eosinophilic pneumonia, eosinophilic gastroenteritis, and other more organ-specific conditions are arbitrarily excluded. Attempts have been made to create a more comprehensive and less arbitrary system although this requires more data on specific etiologies.^{155,156} The World Health Organization (WHO) takes the view that all myeloproliferative variants of HES are malignant conditions. It previously classified them under chronic myeloproliferative diseases (CMPDs) with CEL/HES as a subcategory. In WHO's 2008 revision they have called CMPD myeloproliferative neoplasms. Where there is no defined genotypic abnormality the condition has been termed CEL-NOS (not otherwise specified), and where there is a defined mutation such as F/P they fall into a new category of their own.¹⁵⁷

Epidemiology HES is a rare disorder with an estimated prevalence (although there are limited data on this), in the region of one in 50,000. It occurs sporadically and there appears to be no geographic or environmental influences. For unknown reasons the myeloproliferative form has a strong male bias.

Differential Diagnosis The commonest causes are allergic disease and in particular allergy to thermotolerant colonizing fungi such as *Aspergillus fumigatus* and *Candida albicans*, chronic infection with helminthic parasites (see Table 62–5), severe asthma, chronic eosinophilic

pneumonia, drug allergy, malignancy, EGPA, and eosinophilic gastroenteritis (which could be regarded as part of the HES spectrum).

Etiology and Pathogenesis New insights into both the pathophysiology and management of HES have been offered by the use of anti-IL-5 and the tyrosine kinase inhibitor imatinib mesylate to treat the disease. HES appears to be a heterogeneous condition with some patients having evidence of abnormal T-cell clones, some of which overproduce IL-5 and some cases being because of somatic mutations leading to constitutively active tyrosine kinases. This finding has led to the proposal that there are two broad variants of HES: myeloid and lymphoid.¹⁵⁸ The myeloid variant has features in common with myeloproliferative neoplasms, including raised serum vitamin B₁₂ and serum tryptase, elevated neutrophil alkaline phosphatase score, clonal chromosomal abnormalities, anemia and thrombocytopenia, splenomegaly, and circulating blast cells. The cardiac and neurologic involvement that is a poor prognostic factor in HES is found mainly, but far from exclusively, in this group. A small proportion of these patients go on to develop acute eosinophilic or myeloid leukemia (see Chaps. 88 and 89). Demonstration of eosinophil clonality has been difficult but there is compelling evidence that these patients have chromosomal abnormalities leading to constitutive activation of growth factor associated tyrosine kinases. In particular, an interstitial deletion on 4q12 resulting in the encoding of a fusion protein consisting of the products of the F/P oncogene, which has constitutive tyrosine kinase activity, was found in eight of 15 patients with iHES, all of whom responded to treatment with the tyrosine kinase inhibitor imatinib.¹⁵⁹ This mutation caused the Ba/F3 cell line to become IL-3-independent and was found in the EOL-1 cell line derived from a patient with eosinophilic leukemia.¹⁶⁰ The presence of this mutation and the response to treatment with imatinib has been confirmed by other groups and is now recognized as the most common clonal abnormality in CEL/myeloid HES.¹⁶¹ Imatinib has also been effective in other patients with iHES without this particular mutation.^{159,162} A number of other rare mutated tyrosine kinases also cause the condition, including the JAK2 V617F point mutation usually associated with polycythemia vera,¹⁶³ other partners for *PDGFRα*, the *PDGFRβ* gene, and rearrangements in the *FGFR1* gene at 8p11 in which most patients progress to an aggressive leukemia or lymphoma.^{164,165} Karyotyping can identify these mutations, except the F/P mutation. The F/P mutation can be identified by fluorescence *in situ* hybridization (FISH) studies (Chap. 89). A number of other tyrosine kinase inhibitors with activity against CEL are in clinical development.¹⁶⁶ Serum tryptase appears to be a good, though not perfect, marker of this variant of iHES, suggesting that mast cells are also affected by the mutation.¹⁶⁷ It is, however, clinically distinct from systemic mastocytosis.¹⁶⁷ The lymphoid variant of HES clinically generally follows a more benign course than m-HES (myeloproliferative HES) and there is less sex bias.¹⁶⁸ Patients tend to respond well to glucocorticoids and do not develop the cardiac fibrosis and other severe complications of the disease. The lymphoid variant of HES variant is presumed to be a result of the overproduction of eosinophil-related growth factors by aberrant T cells. The eosinophils are, therefore, normal, unlike the m-HES variant. A number of different patterns of T cell abnormality have been found in association with HES the most common being a CD3⁺ CD4⁺ CD5⁺ subset of T cells¹⁶⁹⁻¹⁷² (reviewed in Ref. 173). In many cases, these clones secrete increased amounts of eosinophil-related cytokines such as IL-5, IL-4, and IL-13. Clonality of the phenotypically aberrant T cells has been demonstrated in many cases and some progress to frank malignancy.

Clinical Features HES has a heterogeneous presentation with the marked and persistent blood eosinophilia being the obvious hallmark.^{158,173,174} It is a chronic disease that usually presents in the third or fourth decade but can present at any age, including (rarely) in childhood.

It varies from being relatively asymptomatic to an aggressive disease leading to death within a few years if left untreated. The more severe complications are generally found in the myeloproliferative variant of the disease. HES can present with nonspecific symptoms such as general malaise, weight loss, aches and pains, and sweating attacks, or with one of the organ-specific features. Cardiac complications are common in the myeloproliferative variant of the disease, in particular endomyocardial fibrosis, which leads to a restrictive cardiomyopathy and left ventricular failure. Mitral incompetence can occur. Thromboembolic complications of large and small vessels are common in more severe disease some of which originate from endomyocardial clot. Many of the central neurologic features are embolic in origin. Respiratory symptoms, including cough that is (usually) productive of only small amounts of sputum and breathlessness, are common. Although airflow obstruction occurs there is a limited response to bronchodilators and AHR is often absent. Wheezing is not a prominent symptom. Pulmonary shadowing including alveolar infiltration and nodules may be present. Skin symptoms are common, particularly pruritus, which is sometimes associated with erythematous papules and urticaria. A variant of HES is Gleich syndrome in which patients have recurring episodes of angioedema. Eosinophilic cellulitis may also be a feature.¹⁷⁵ As well as embolic events, HES can be associated with confusion, loss of memory, and ataxia. Peripheral nervous system symptoms can include mononeuritis multiplex, sensorimotor neuropathy, multifocal neuropathy, and radiculopathy. The differential diagnosis with EGPA can be difficult and may be semantic.¹⁷⁶ Patients can develop mucosal ulcerations but as with the renal system, severe complications are not usually prominent.

Laboratory Features Investigations to exclude a reactive cause for the eosinophilia need to be undertaken (see “Differential Diagnosis” below), if the neoplastic nature of the eosinophilia is not evident. Examination of stools for parasites in patients with chronic eosinophilia is an insensitive investigation and serology is only available for common helminths such as *Strongyloides*, schistosomiasis, and filariasis. Empirical treatment with broad-spectrum antihelminths can sometimes be justified if there is high clinical suspicion with exposure and a high total IgE. Occult fungal allergy is another common cause of hypereosinophilia and specific IgE for thermotolerant fungi which can colonize the host, such as *A. fumigatus*, *C. albicans*, *Penicillium chrysogenum*, and *Malassezia* species, should be routinely undertaken. A scheme for stepwise investigation of patients with iHES has been suggested.¹⁷³ These are mainly aimed at determining if there is evidence of clonality, or an abnormal T-cell clone. They include a complete blood count with examination of a blood film. Serum immunoglobulins, serum vitamin B₁₂ and tryptase, examination of a marrow aspirate and biopsy, lymphocyte phenotyping and, if available, analysis of cytokine production, T-cell receptor gene rearrangement, karyotyping and analysis of the presence of the F/P fusion protein by reverse transcription polymerase chain reaction or FISH analysis. A chest radiograph, spirometry, biochemical profile, troponin, cortisol, echocardiogram and abdominal ultrasound should also be considered as well as neurologic investigations such as electromyography studies, if prior studies have not uncovered the explanation for the HES. Depending on the major site of organ damage, more detailed organ-specific investigations, such as cardiac magnetic resonance imaging, chest computerized tomography, full lung function tests, and gastrointestinal endoscopy, may be required.

Differential Diagnosis Table 62-4 lists the reactive causes of a marked eosinophilia, which causes should be excluded with appropriate investigations. Once these causes have been excluded the differential diagnosis includes familial eosinophilia, which is a rare condition that has been mapped to a region of chromosome 5q31-q33,¹⁷⁷ CEL, eosinophilia secondary to malignancy, EGPA, and

chronic eosinophilic pneumonia. Some patients also appear to have a raised eosinophil count without any evidence of organ damage, a so-called benign eosinophilia.

Treatment The rarity of HES means that there are few clinical trials and most agents are used on the basis of anecdotal experience, the opinion of the HES community or experience with related diseases.¹⁵⁴ However, the use of imatinib mesylate for some patients with the myeloproliferative variant and the potential use of anti-IL-5 for T cell-driven disease offers new promise to patients with HES.¹⁷⁸ The mainstay of treatment has been glucocorticoids, which in many cases, particularly those caused by something other than myeloproliferative disease, are effective at controlling both the eosinophil count and the target organ damage, albeit at the risk of long-term side effects. In patients with a myeloproliferative neoplasm, the eosinophil count is not completely controlled with glucocorticoids, although these drugs can still limit organ damage. In patients where glucocorticoids are not sufficiently effective, hydroxyurea is a useful second-line agent. Other cytotoxic drugs, such as vincristine and cyclophosphamide, are less commonly used than in the past. Interferon- α has also been used with some success. As discussed above, imatinib mesylate has resulted in remission in patients with the F/P mutation, usually at doses well below those used in chronic myeloid leukemia and some patients remain in remission when the treatment is stopped.¹⁷⁹ In the absence of the F/P mutation in patients with myeloproliferative features, a trial of imatinib is indicated as occasionally F/P-negative patients have responded^{180,181} and this form of CEL carries a poor prognosis.¹⁸² Response to imatinib at a dose of 400 mg a day should be rapid (within several weeks) and result in a return of the eosinophil count to within the normal range if the cause of the eosinophilia is an imatinib-responsive tyrosine kinase mutation. Resistance to imatinib treatment has emerged in some cases as it does when used for chronic myeloid leukemia.¹⁸³ In one patient who developed resistance an alternative PDGFR α inhibitor was effective.¹⁸⁴ Treatment with imatinib has caused acute left ventricular failure in some cases and cardiac troponin has been suggested to be useful in monitoring response.¹⁸⁵ Another novel approach to treatment has been the use of anti-IL-5 mAb. This approach has resulted in a dramatic response in some patients, even in the absence of raised serum IL-5 concentrations.^{186,187} In a double-blind, placebo-controlled trial of F/P-negative HES, patients requiring 20 mg or more of prednisolone, mepolizumab, a humanized mAb that binds IL-5, allowed a reduction below 10 mg of oral prednisone in 84 percent of patients, compared to 43 percent given a placebo, without any increase in the activity of the HES.

Course and Prognosis The outlook for patients with HES was poor with a series in 1973 reporting a 3-year survival of only 12 percent with cardiac failure accounting for much of the morbidity.¹⁵³ In a later report, the outlook had improved with a survival of 80 percent at 5 years.¹⁸⁸

Toxic Oil Syndrome

In 1981, more than 20,000 cases of a syndrome manifested by fever, cough, dyspnea, leukocytosis, neutrophilia, and an eosinophil count greater than $0.75 \times 10^9/L$ were reported in Spain.¹⁸⁹ Occasionally, the eosinophil count rose above normal only after the onset of the pulmonary symptoms. Eosinophil degranulation was seen in the effected tissues. Pulmonary infiltrates were evident on x-rays of the chest. Pleural effusion was common, and hypoxemia was frequent. There were 1500 deaths in the cohort. Approximately half of the patients went on to a chronic course that mimicked the eosinophilia-myalgia syndrome, with myalgias, eosinophilia, peripheral neuritis, scleroderma-like skin lesions, hair loss, and a sicca syndrome. Most patients improved from the acute or chronic symptoms and signs, but some residual nerve, muscle, or skin damage persisted. Endothelial

cell proliferation, mononuclear cell infiltrates around blood vessels (vasculitis), and perineural inflammatory infiltrates were identified histopathologically. Glucocorticoid therapy may have decreased the pulmonary symptomatology. The disease was thought to be a response to an unlabeled food oil, aniline-denatured rapeseed oil, marketed as pure olive oil.

Reactive Hypereosinophilia and Neoplasms

Eosinophilia is associated with a 2.4-fold increase of developing a hematologic malignancy over 4 years of observation compared with subjects with a normal eosinophil count.¹⁹⁰ Exaggerated tissue and blood eosinophilia has been reported in association with a variety of lymphoid and solid tumors particularly lymphoma of various types including Hodgkin and non-Hodgkin lymphoma, cutaneous T-cell lymphoma, and marginal zone lymphoma.¹⁹¹ In these cases, the eosinophilia is thought to be the result of an increase in IL-5 and other cytokines or chemokines elaborated by the tumor cells. Unlike other types of reactive eosinophilia, the blood eosinophil count may not be suppressed by glucocorticoids. The eosinophilia may precede the clinical diagnosis of the tumor but usually occurs concomitantly. There is evidence that eosinophils slow the rate of progression of solid tumors, presumably by being cytotoxic to tumor cells with the extent peritumoral eosinophils predicting recurrence of colon cancer although other studies have raised the possibility of a tumor promoting role.^{192,193}

Eosinophilic Granulomatosis with Polyangiitis

Clinical Features EGPA, formerly Churg-Strauss syndrome, is a rare disorder of unknown etiology characterized by eosinophilic asthma, chronic rhinosinusitis, and small vessel vasculitis. It is one of the three antineutrophil cytoplasmic antibodies (ANCA)-associated vasculitides (AAV), alongside microscopic polyangiitis (MPA) and granulomatosis with polyangiitis (GPA, formerly Wegener disease). Patients with EGPA are ANCA positive in approximately 40 percent of cases and generally this is of the perinuclear-ANCA antimyeloperoxidase type compared to GPA which is generally proteinase-3 positive.¹⁹⁴ ANCA titers do not appear to correlate well with disease activity. Patients who are ANCA-positive have a different profile of disease compared to those who are ANCA-negative in that vasculitic features are more prominent and renal disease more common, but there is less cardiac disease, although there is considerable overlap.^{195,196} The vasculitic process leads to a multisystem presentation commonly affecting the respiratory system, heart, skin, and peripheral nerves, although it can cause damage to any organ.¹⁹⁷ A marked blood eosinophilia is a prominent feature as are lethargy, general malaise, and weight loss. Mononeuritis multiplex is a particularly characteristic feature that sometimes leads to rapid onset of a peripheral neuropathy, which can be permanent, causing considerable morbidity. Cardiac disease with valvular damage or endomyocarditis is one of the most serious complications. The epidemiology of EGPA is not precise, but the point prevalence of new cases is approximately 1:1,000,000 with an accumulated prevalence of approximately 1:50,000, with precise numbers depending on the diagnostic criteria used. The condition generally presents in middle age and is very rare in children. The adult onset in people with preexisting asthma has led to speculation that EGPA is the result of an inflammatory stimulus on the background of a respiratory eosinophilia leading to systemic eosinophilic activation.¹⁷⁶ Consistent with this, case-control studies suggest a link with various environmental exposures, including farming, silica, and solvents, but no single trigger has been identified.¹⁹⁸ There is no obvious gender, geographic, ethnic or socio-economic predilection. There are case reports of family clusters, but in most cases there is no evidence of an inherited cause. The syndrome is heterogeneous in its

presentation depending on the main organ affected and the description of the disease in case series is influenced by the medical discipline of the reporting team. In the past, EGPA carried a poor prognosis with a 10 percent 1-year survival, but currently 5-year survival is greater than 90 percent. In most cases, patients go into remission with high-dose oral glucocorticoids, although guidelines recommend the use of other immunosuppressants, such as cyclophosphamide or azathioprine, to induce remission where there is evidence of life-threatening organ involvement.^{199,200} Once remission is achieved the patient often requires lifelong oral glucocorticoids to maintain remission. Relapse is not uncommon and this, together with the adverse effects of medication, result in significant morbidity.

There are no universally accepted criteria for the diagnosis of EGPA. The widely used American College of Rheumatology criteria were for classification purposes rather than to aid diagnosis. They were based on comparing 20 patients with EGPA against 787 control patients with other forms of vasculitis.²⁰¹ Six criteria were specified (1) asthma (2) eosinophilia of greater than 10% (3) mononeuropathy (4) fleeting pulmonary shadows (5) paranasal sinus abnormality (6) a biopsy containing a blood vessel with extravascular eosinophils. Because there was no comparison with asthma or other eosinophilic disorders, the criteria lack specificity. The differential diagnosis of EGPA includes, on the one hand, other vasculitic conditions, and on the other hand, severe adult-onset eosinophilic asthma and HES. The diagnostic hallmark is evidence of an eosinophilic vasculitis with granuloma on biopsy, but in many cases it is not possible to obtain tissue and the diagnosis is based on clinical assessment.

Putative Biomarkers Other than the blood eosinophil count and ANCA, which is used as a subgrouping biomarker for disease with more vasculitic features, there are no biomarkers that are helpful in the diagnosis or management of this condition. All patients with suspected EGPA should undergo detailed investigations to exclude other causes of a hypereosinophilia ($>1.5 \times 10^9/L$), to determine the type of vasculitis present, and to assess the extent of organ damage.¹²⁵ A subset of patients with aggressive hypereosinophilic disease have either mastocytosis in which there is a genetic defect in the KIT mast cell growth factor receptor or CEL. Both these possibilities need to be excluded with genetic testing. To identify novel biomarkers, a retrospective audit of patients who had been investigated at a tertiary center for an unexplained eosinophilia were studied. Twenty-nine patients with EGPA, 20 patients with HES and asthma, 16 patients with HES without asthma, and eight normal subjects were compared. An extensive range of cytokine and chemokine biomarkers were assayed. CCL-17 and soluble IL-2 receptor were raised but tracked with eosinophilia (demonstrating the importance of the eosinophilia control groups), but not with disease category.²⁰² However, these patients were all ANCA-negative and findings in ANCA-positive EGPA may differ.

Eosinophilic Fasciitis

This rare syndrome may occur at any age in either sex and is characterized by stiffness, pain, and swelling of the arms, forearms, thighs, legs, hands, and feet in descending order of frequency. Malaise, fever, weakness, and weight loss also occur.²⁰³ Eosinophilia greater than $1 \times 10^9/L$ is present in most patients, but may be intermittent. A biopsy, usually required for the diagnosis, shows inflammation, edema, thickening, and fibrosis of the involved fascia. Synovial tissue may show similar changes. Aplastic anemia, isolated cytopenias, pernicious anemia, and acute myelogenous leukemia have been associated with eosinophilic fasciitis and in the late 1980s a series of cases was described in association with ingestion of a particular batch of L-tryptophan.²⁰⁴ Glucocorticoids are the first-line of treatment but other immunosuppressant therapy, such as methotrexate, may be required.²⁰⁵

Eosinophiluria and Eosinophilorrachia

The urinary excretion of eosinophils is seen in several inflammatory disorders of the kidney but most often in urinary tract infection or acute interstitial nephritis.²⁰⁶ Hansel stain is superior to Wright stain in identifying eosinophils in a stained urinary sediment. Cerebrospinal fluid eosinophilia may occur with infection, shunts, and allergic reactions involving the meninges.²⁰⁷

CHAPTER 63

BASOPHILS, MAST CELLS, AND RELATED DISORDERS

Stephen J. Galli, Dean D. Metcalfe,
Daniel A. Arber, and Ann M. Dvorak*

SUMMARY

Basophils and mast cells share biochemical and functional characteristics, but they are not identical. In humans, basophils are the least frequent of the three granulocytes, typically accounting for less than 0.5 percent of blood leukocytes. Basophils circulate as mature cells and can be recruited into tissues, particularly at sites of immunologic or inflammatory responses, but they ordinarily do not reside in tissues. By contrast, mast cells typically are derived from blood precursors that lack many of the characteristic features of the mature cells and complete their maturation in the tissues. The mature mast cells can reside in tissues for long periods of time. Mast cells are particularly abundant near blood vessels and nerves and in connective tissues beneath surfaces that are exposed to the external environment, such as the skin, gastrointestinal and urogenital tracts, and respiratory system. Tissue mast cell numbers can increase at sites of parasite infection or in association with certain chronic allergic diseases or other forms of pathology, by recruitment and local maturation of blood precursors and by proliferation of resident mast cells.

Mast cells and basophils express the high-affinity receptor for immunoglobulin (Ig) E (FcεRI) on their surface. Both cell types can be triggered to release potent mediators in response to activation via FcεRI, for example, when their cell-bound IgE recognizes bivalent or multivalent allergens. Accordingly, mast cells and basophils have long been regarded as important effector cells in asthma, hay fever, and other allergic disorders. The cells' cytoplasmic granule-associated preformed mediators, including histamine and certain proteases, their lipid mediators (such as prostaglandin D₂ and leukotriene C₄), which are generated upon activation of the cells, and their cytokines, growth factors, and chemokines contribute to many of the characteristic signs and symptoms of these diseases. However, several lines of evidence indicate mast cells and basophils also contribute to protective host responses associated with

IgE production, especially those directed against parasites. In mice, mast cells can enhance innate and acquired (IgE-dependent) defense against animal venoms and also can contribute to host defense in innate immune responses to certain bacterial infections. Mast cells and basophils also may express positive and negative immunoregulatory functions through cytokine production and other mechanisms.

Although a variety of systemic disorders are associated with changes in the numbers of blood basophils and many pathologic processes can be associated with changes in the numbers of tissue mast cells, patients with primary deficiencies in basophils appear to be exceedingly rare (if they exist at all). Patients with a primary deficiency of tissue mast cells have not been reported. By contrast, neoplastic processes can affect both of the lineages. Increased numbers of basophils may be present in association with myeloproliferative neoplasms and several forms of myeloid leukemia. Increased numbers of basophils, sometimes to levels of 20 to 90 percent of blood leukocytes, occur in virtually all patients with chronic myelogenous leukemia. The basophils associated with both chronic myelogenous and acute myeloid leukemias are themselves part of the neoplastic clone. The management of patients with "basophilic leukemia" can be complicated by shock as a result of massive release of histamine and other mediators in association with acute cytotoxicity.

Disorders of mast cell hyperplasia/neoplasia include solitary mastocytomas, the pathogenesis of which is uncertain, the spectrum of disorders encompassed in the term *mastocytosis*, in which significantly increased numbers of mast cells occur in the skin and/or other organs, and mast cell leukemia. The most common form of mastocytosis, indolent systemic mastocytosis, typically presents with urticaria pigmentosa involving the skin, although other organs may be involved. Patients with indolent systemic mastocytosis have the best prognosis and can expect a normal life span. The prognosis of systemic mastocytosis with associated clonal, hematologic non-mast-cell-lineage disease depends on the course of the associated disease. Patients with aggressive systemic mastocytosis have a guarded prognosis because of complications arising from rapid increases in tissue mast cell numbers. Patients with mast cell leukemia, who often present with large numbers of immature mast cells in the blood at the time of diagnosis, have a fulminant and rapidly fatal course. Most adult patients with mastocytosis have gain-of-function mutations affecting *KIT*, which encodes the receptor for the major mast cell growth factor stem cell factor (also known as *kit ligand* and *mast cell growth factor*). Some pediatric patients with mastocytosis reportedly have the same Asp816Val gain-of-function *KIT* mutation observed in most adult patients. Some pediatric patients have a dominant inactivating *KIT* mutation, whereas others lack *KIT* mutations entirely.

Acronyms and Abbreviations: AML, acute myeloid leukemia; ASM, aggressive systemic mastocytosis; CML, chronic myelogenous leukemia; CPA3, carboxypeptidase A3; DEXA, dual-energy x-ray absorptiometry; ET-1, endothelin-1; FcεRI, high-affinity receptor for IgE; gp120, glycoprotein 120; H&E, hematoxylin and eosin; HLA, human leukocyte antigen; IFN-α, interferon α; Ig, immunoglobulin; IL, interleukin; ISM, indolent systemic mastocytosis; MCAS, mast cell activation syndrome; MCL, mast cell leukemia; MCP, mast cell-committed progenitor; MCS, mast

cell sarcoma; MMAS, monoclonal mast cell activation syndrome; mMCP, mouse mast cell protease; PUVA, psoralen ultraviolet A; qPCR, quantitative polymerase chain reaction; SCF, stem cell factor; SCT, stem cell transplantation; SM-AHNMD, systemic mastocytosis with associated clonal hematologic non-mast-cell-lineage disease; Th, T-helper; TLR, toll-like receptor; TNF-α, tumor necrosis factor α; UP, urticaria pigmentosa; VEGF, vascular endothelial growth factor; VIP, vasoactive intestinal polypeptide.

DISTINGUISHING FEATURES OF BASOPHILS AND MAST CELLS

BASOPHILS

Despite certain similarities in biochemistry and function, mammalian basophils and mast cells are not identical (Fig. 63-1).¹⁻⁵ The distinction was appreciated by Paul Ehrlich, who described the histochemical staining characteristics of these cells in the late 19th century. Much evidence indicates that basophils share a common precursor with other granulocytes and monocytes.¹⁻⁵ Basophils have a short life span^{5,6} and retain granulocytic features even after emigrating into tissues (Fig. 63-1C).⁷

The basophil is the least-common granulocyte in human blood, with a prevalence of approximately 0.5 to 0.6 percent of total leukocytes and approximately 0.3 percent of nucleated marrow cells.^{8,9} The basophil's prominent metachromatic cytoplasmic granules allow unmistakable identification in Wright-Giemsa-stained films of blood (see Fig. 63-1B) or marrow, but accurate enumeration requires absolute counting methods.^{9,10} Differential counts of blood films yield valid results only if the percentage of basophils is substantially elevated or many thousands of leukocytes are counted.

Interleukin (IL)-3 promotes the production and survival of human basophils *in vitro*^{3,11} and induces basophilia *in vivo*.¹² Findings in IL-3 $-/-$ mice indicate IL-3 is not necessary for the development of normal numbers of marrow or blood basophils, but is important for the marrow and blood basophilia associated with certain T-helper (Th) 2 cell-associated immunologic responses.^{13,14} Basophils also express receptors for several other cytokines (Table 63-1).^{5,15} IL-3 and many of these other cytokines, including IL-33, can modulate basophil function, for example, by inducing mediator release directly and/or by augmenting the cells' ability to release mediators in response to immunoglobulin (Ig) E-dependent challenge.^{3,5,12}

MAST CELLS

Mast cells normally reside in the connective tissue, particularly beneath epithelial surfaces and around blood vessels, and, in some species, in serous cavities.^{1,4,16,17} Mast cells are derived from hematopoietic

precursors.¹⁶⁻²¹ Except for a numerically minor population of mast cells residing in the marrow (see Fig. 63-1A),⁸ this lineage completes its program of maturation in other tissues.¹⁶⁻²¹ Unlike basophils, mast cells can be long-lived. At least some mast cells can proliferate in the tissues during a variety of inflammatory or reparative processes.^{1,16,17} Studies in mice, rats, nonhuman primates, and humans indicate many aspects of mast cell development are critically regulated by stem cell factor (SCF), the ligand for the KIT receptor tyrosine kinase.^{17,22-24} SCF is produced in membrane-associated and soluble forms, both of which are biologically active (Chap. 18).^{17,24} Beside promoting the migration, survival, proliferation, and maturation of cells in the mast cell lineage, SCF can directly promote mast cell mediator release^{23,25-27} and, at even lower concentrations, can augment mast cell mediator release in response to stimulation by IgE and antigen.^{25,26} Abnormalities affecting *KIT* are involved in the pathogenesis of certain types of mastocytosis (see "Disorders Affecting Mast Cells" below). Alterations in the production of SCF by fibroblasts and other cells may contribute to the changes in mast cell numbers that occur during many chronic inflammatory conditions and other pathologic responses.^{17,22,28}

MAST CELL AND BASOPHIL HETEROGENEITY

Variation in the morphologic, biochemical, and/or functional characteristics of mast cells from different anatomic locations or from the same organ or site has been reported in several mammalian species, including humans.^{16,17,21,29,30} This phenomenon, often referred to as *mast cell heterogeneity*, raises the possibility that mast cells of different phenotype express different functions in health or disease and may exhibit different sensitivities to pharmacologic manipulation. At least four mechanisms may account for phenotypic variation in mast cell populations: (1) factors promoting branching within the mast cell lineage; (2) factors influencing differentiation and maturation (within a single pathway or, if they occur, within multiple pathways); (3) factors modulating mast cell function; and (4) factors influencing local concentrations of exogenous substances not derived from mast cells but taken up and stored in mast cell granules. Of these four mechanisms, experimental evidence has been obtained for all but the first.^{21,30} Basophils can exhibit

Figure 63-1. **A.** Mast cell (M) in a Wright-Giemsa-stained marrow aspirate. **B.** A basophil (B) and lymphocyte (L) in a Wright-Giemsa-stained film prepared from the buffy coat of blood from a normal donor. **C.** Transmission electron micrograph illustrating a mast cell (M) and basophil (B) in the ileal submucosa of a patient with Crohn disease. The mast cell is a larger, mononuclear cell with a more complex plasma membrane surface and cytoplasmic granules that are smaller and more numerous than those of the basophil. In this section plane, the basophil exhibits two nuclear lobes. Several basophil cytoplasmic granules contain whorls of membranes (arrows). Osmium collidine uranyl *en bloc* processing. (C, reproduced with permission from Dvorak AM, Monahan RA, Osage JE, et al: Crohn's disease: Transmission electron microscopic studies. II. Immunologic inflammatory response. Alterations of mast cells, basophils, eosinophils, and the microvasculature. Hum Pathol 11(6):606-619, 1980.)

TABLE 63–1. Natural History, Major Mediators, and Surface Membrane Structures of Human Mast Cells and Basophils

Characteristics	Basophils	Mast Cells
NATURAL HISTORY		
Origin of precursor cells	Marrow	Marrow
Site of maturation	Marrow	Connective tissue (a few in marrow)
Mature cells in circulation	Yes (usually <1% of blood leukocytes)	No
Mature cells recruited into tissues from circulation	Yes (during immunologic, inflammatory responses)	No
Mature cells normally residing in connective tissues	No (not detectable by microscopy)	Yes
Proliferative ability of morphologically mature cells	None reported	Yes (limited; under certain circumstances)
Life span	Days (like other granulocytes)	Weeks to months (according to studies in rodents)
Major growth factor	IL-3	SCF
MEDIATORS		
Major mediators stored preformed in cytoplasmic granules	Histamine, chondroitin sulfates, tryptase,* chymase,* carboxypeptidase A,* neutral protease with bradykinin-generating activity, β -glucuronidase, elastase, cathepsin G-like enzyme, major basic protein, Charcot-Leyden crystal protein	Histamine, heparin,* chondroitin sulfates,* chymase,* tryptase,* cathepsin G,* carboxypeptidases, major basic protein, acid hydrolases, peroxidase, phospholipases
Major lipid mediators produced on appropriate activation	Leukotriene C ₄	Leukotriene B ₄ , prostaglandin D ₂ , leukotriene C ₄ , platelet-activating factor
Cytokines released on appropriate activation	IL-4, IL-6, IL-13, GM-CSF, VEGF-A, leptin	TNF, TGF- β , IFN- α , VEGF-A-D, IL-6, IL-11, IL-13, IL-16, IL-18, GM-CSF, NGF, PDGF (mouse and human mast cells can secrete many more; see text)
Chemokines	IL-8 (CXCL-8), MIP-1 α (CCL3), Eotaxin (CCL-11), MIP-5 (CCL15)	IL-8 (CXCL-8), I-309 (CCL-1), MCP-1 (CCL2), MIP-1 α (CCL3), MIP-1 β (CCL-4), MCP-3 (CCL-7), RANTES (CCL-5), Eotaxin (CCL-11)
SURFACE STRUCTURES		
Ig receptors	Fc ϵ RI, Fc γ RIIA, Fc γ RIIB	Fc ϵ RI, Fc γ RI (after IFN γ exposure), Fc γ RIIA
Cytokine or growth factor receptors for:	IL-1, IL-2 (CD25), IL-3, IL-4, IL-5, IL-6, IL-8, and IL-33; chemokines (CCR1, -2, -3, -5; CXCR1, -2, -4); and interferons; SCF (basophils express variable numbers of the SCF receptor, Kit)	SCF (ligand for Kit), IFN- γ , IL-4, IL-5, IL-6, IL-9, and IL-33; chemokines (CCR1, -3, -4, -5, -7; CXCR1, -2, -3, -4, -6); thrombopoietin receptor (CD110), GM-CSF, NGF
TLRs	TLR-2, -4 (but lack CD14)	TLR-1, -2, -3, -4, -5, -6, -7, -9

IFN, interferon; Ig, immunoglobulin; IL, interleukin; GM-CSF, granulocyte-macrophage colony-stimulating factor; MCP, monocyte chemotactic protein; MIP, macrophage inflammatory protein; NGF, nerve growth factor; PDGF, platelet-derived growth factor; RANTES, regulated on activation, normal T-cell expressed, presumed secreted; SCF, stem cell factor; TNF, tumor necrosis factor; TGF, transforming growth factor; TLR, toll-like receptor; VEGF, vascular endothelial growth factor.

*Basophil and mast cell content of these (and perhaps other) mediators vary, for example, in different subjects and tissues; and/or in association with certain inflammatory diseases.¹⁵

NOTE: Expression of these and other surface structures, including chemokine receptors, and production of individual cytokines and chemokines, can vary in different *in vitro* or *in vivo* derived basophil or mast cell populations.

Data Modified from Galli SJ, Dvorak AM, Dvorak HF: Basophils and mast cells: morphologic insights into their biology, secretory patterns, and function. *Prog Allergy* 34:1–141, 1984 and Valent P: Immunophenotypic characterization of human basophils and mast cells. *Chem Immunol* 61:34–48, 1995.

some variation in phenotypic characteristics also, such as immunoreactivity for tryptase, chymase, and carboxypeptidase A,¹⁵ or levels of expression of surface structures, including human leukocyte antigen (HLA)-DR, CD32 (Fc γ RII), and receptors for cytokines.^{5,31} Such variation in basophil mediator content and/or cell surface phenotype may reflect individual differences among different subjects and/or the effects of disease processes¹⁵ or the consequences of immunotherapy.³¹

RELATIONSHIP BETWEEN BASOPHILS AND MAST CELLS

Mature basophils and mast cells differ in morphology, natural history, tissue distribution, mediator production, cell-surface phenotype, growth factor requirements, and responses to drugs (see Fig. 63–1 and Table 63–1).^{1–5} Nevertheless, certain similarities of the two cells, taken

together with evidence indicating that tissue mast cells are derived from circulating marrow-derived precursors,^{16,18} had suggested to some investigators that basophils might be circulating precursors of mast cells. However, the following evidence strongly favors the view that mature basophils represent terminally differentiated granulocytes and not circulating mast cell precursors: (1) no evidence has been presented, in any species, indicating that mature circulating basophils are capable of either mitosis or differentiation into mast cells; (2) rare reports of patients with hereditary or acquired abnormalities affecting basophil numbers or morphology indicate that eosinophils also may be affected in these disorders but not mast cells^{32–34}; (3) morphologically identifiable human tissue mast cells can exhibit mitotic activity,³⁵ indicating that mast cells can replicate independently of a stage resembling that of basophils, and (4) in mice, evidence indicates that a mast cell–committed progenitor (MCP) present in the marrow is developmentally distinct during hematopoiesis from a Sca-1^{lo} granulocyte-macrophage progenitor.^{19,20} Evidence for a committed bipotential precursor of mast cells and basophils during hematopoiesis in the mouse has been reported by some studies^{36,37} but not others.^{19,20,38}

MORPHOLOGY OF BASOPHILS AND MAST CELLS

Routine histologic methods are poorly suited for demonstrating basophils and mast cells. Optimal visualization is achieved in appropriately prepared 1 μm sections or by electron microscopy.^{1,2} By ultrastructure, human basophils are 5 to 7 μm in spherical diameter, exhibit a segmented or unsegmented nucleus with marked condensation of nuclear chromatin, and contain round or oval cytoplasmic granules surrounded by a membrane and containing a substructure of dense particles, less-dense matrix, and, in some granules, membrane whorls and Charcot-Leyden crystals (see Fig. 63–1C).^{1,2} A minor population of small, uniform granules is characteristically located near the nucleus.³⁹ The cytoplasm of mature human basophils also contains glycogen particles, mitochondria, free ribosomes, and small membrane-bound vesicles. Lipid bodies are rarely present. Other organelles are inconspicuous.

In tissue sections, mast cells typically appear as either round or elongated cells, usually with a nonsegmented nucleus with moderate condensation of nuclear chromatin, and contain prominent cytoplasmic granules. Mast cell granules are smaller, more numerous, and generally more variable in appearance than in basophils and contain scroll-like structures, particles, and crystals, alone or in combination (see Fig. 63–1C).^{1,2} In contrast to the irregularly spaced blunt surface projections of basophils, mast cells are covered by uniformly distributed thin surface processes. Mast cells also differ from basophils in having many more cytoplasmic filaments and lacking cytoplasmic glycogen deposits. Human mast cells can contain numerous cytoplasmic lipid bodies.

BIOCHEMISTRY AND ROLE IN IMMUNOGLOBULIN E-ASSOCIATED IMMUNE RESPONSES

Mediators

The cytoplasmic granules of basophils and mast cells contain proteoglycans, consisting of sulfated glycosaminoglycans covalently linked to a protein core.⁴⁰ These substances can be stained metachromatically with basic dyes (see Fig. 63–1A and B). In humans and murine species, individual mast cell populations can contain variable mixtures of heparin and chondroitin sulfate proteoglycans.^{29,40} Although the sulfated glycosaminoglycans of normal human blood basophils have not yet been characterized, two studies of the proteoglycans synthesized by blood leukocytes (containing 10 to 75 percent basophils) of five patients with myeloid leukemia indicate that such cells may produce solely

chondroitin sulfates⁴¹ or a mixture of chondroitin sulfates (50 to 84 percent) and heparin (8 to 43 percent).⁴² Although the biologic functions of basophil and mast cell proteoglycans are not fully understood, in mice, heparin is required for normal packaging of certain neutral proteases in mast cell cytoplasmic granules.^{40,43} Both human mast cells and basophils synthesize and store histamine.^{1,4} Basophils represent the source of most (if not all) of the histamine present in normal human blood.⁴⁴ Although macrophages,⁴⁵ neutrophils,⁴⁶ and platelets,⁴⁷ as well as basophils,⁴⁴ can produce histamine, mast cells represent the source of virtually all the histamine stored in normal tissues in mice, with the notable exceptions of the glandular stomach and parts of the central nervous system.⁴⁸

In addition to proteoglycans and histamine, basophils and mast cells generate many other products that can influence the course of inflammatory processes (see Table 63–1).^{1,3–5,49–51} These substances are either preformed and granule associated (e.g., histamine, neutral proteases, proteoglycans) or produced during activation of the cell (e.g., prostaglandin D₂, leukotrienes and other metabolites of arachidonic acid, and platelet-activating factor). Appropriately stimulated mouse or human mast cells can release the cytokine tumor necrosis factor α (TNF- α),^{52,53} and many other cytokines, chemokines, and growth factors with effects on inflammation, immunity, hematopoiesis, tissue remodeling, and many other biologic processes.^{1,3–5,49–51} By contrast, the spectrum of basophil-derived cytokines appears to be more limited but includes IL-4 and IL-13, vascular endothelial growth factor (VEGF)-A,⁵⁴ certain chemokines, and, at least in mice, IL-6, TNF- α , and thymic stromal lymphopoietin (TSLP).^{4,5,55–57}

ROLE IN ACUTE REACTIONS

Basophils and mast cells have specific, high-affinity plasma membrane receptors for the Fc region of IgE (Fc ϵ RI).^{58,59} When IgE antibodies bound to Fc ϵ RI on the basophil or mast cell surface are bridged by specific divalent or multivalent antigens, anaphylactic degranulation is triggered.^{57,58} The critical signal in this event is the aggregation of Fc ϵ RI on the plasma membrane.^{57,58} Anaphylactic degranulation involves the fusion of plasma membranes with the membranes delimiting individual cytoplasmic granules or with groups of granules whose membranes have undergone fusion, leading to rapid noncytolytic release of granule contents, such as histamine and other preformed mediators.^{1,2} The complex sequence of biochemical events associated with anaphylactic degranulation, the signaling mechanisms that positively and negatively regulate this response, and the rationale for the pharmacologic manipulation of these processes have been reviewed.^{57,58}

The sudden, massive release of mediators from basophils and mast cells provokes many of the clinical manifestations of acute immediate hypersensitivity reactions in disorders such as certain forms of bronchial asthma (including fatal asthma, in which basophils can be prominent⁶⁰); urticaria; allergic rhinitis; and anaphylaxis to foods, drugs, insect stings, and other antigens.^{1,5,49,50,55–57} Both mast cells and basophils can bind IgG antibodies (as well as IgE), and the binding of IgG or IgG immune complexes can contribute to the activation of these cells (in certain mouse models of anaphylaxis) or, in other circumstances, to the downregulation of their activation (e.g., via Fc γ RIIB).^{5,55–57,61–64} Other diverse stimuli, including certain complement fragments (anaphylatoxins), neutrophil lysosomal proteins, a variety of basic peptides and peptide hormones, components of insect or reptile venoms, radiocontrast solutions, cold, calcium ionophores, and certain drugs such as narcotics and muscle relaxants, also may initiate rapid release of mediators from basophils and/or mast cells, independently of IgE.^{1,4,5,48,49,54–56} The clinical reactions provoked by these agents can closely mimic those of immediate hypersensitivity. Basophils activated via Fc ϵ RI or other mechanisms can exhibit increased surface levels of

CD63, CD69, and CD203c, and the clinical value of using such findings to monitor basophil activation *in vivo* (e.g., in the setting of allergic disorders or antigen-specific immunotherapy) is under investigation.⁶⁵

ROLE IN LATE-PHASE REACTIONS

Mast cells and basophils also can contribute to late-phase reactions. Late-phase reactions occur when antigen challenge is followed, hours after initial IgE-dependent mast cell activation, by recurrence of signs (e.g., cutaneous edema) and symptoms (e.g., bronchoconstriction).^{49,50} Much of the morbidity associated with chronic allergic conditions, including allergic asthma, is widely believed to reflect the actions of leukocytes that are recruited to sites of late-phase reactions.^{49,50} Studies in mast cell-deficient and mast cell knockin mice (genetically mast cell-deficient mice that have been selectively repaired of their mast cell deficiency) indicate mast cells are responsible for virtually all of the vascular permeability changes and leukocyte infiltration associated with IgE-dependent cutaneous late-phase reactions^{66,67} and that TNF- α can, importantly, contribute to these responses.⁶⁶ The extent to which mast cells (or TNF- α) contribute to late-phase reactions in humans, in which such reactions may have components that are either IgE or T-cell dependent (and in which it has been suggested that certain IgE-dependent mechanisms may not involve mast cells⁶³), is not yet clear.^{68,69} However, the lymphocytes, basophils, eosinophils, and other leukocytes that are recruited to these reactions likely produce cytokines and other mediators that regulate further development and, ultimately, resolution of these reactions.^{4,5,49,50}

ROLE IN CHRONIC CHANGES ASSOCIATED WITH ALLERGIC DISORDERS

Studies in mice (see “Genetic Approaches for Analyzing Basophil and Mast Cell Function” below) indicate that mast cells can contribute importantly to many of the features of asthma, as observed in certain mouse models of chronic allergic inflammation involving the lungs. The features include the development of airway hyperreactivity to immunologically nonspecific agonists of bronchoconstriction such as methacholine; infiltration of the airways and lung interstitium with inflammatory cells, including eosinophils, neutrophils, and T cells; increased deposition of collagen in the lungs and hyperplasia and/or hypertrophy of airway smooth muscle; and induction of increased numbers of mucus-producing goblet cells in the large airways.^{50,70,71} Thus, such mouse models indicate mast cells and their products can promote the development of much of the pathology and pathophysiological changes observed in longstanding asthma in humans.^{50,70,71} Studies in mice indicate that basophils also can enhance the development of IgE-dependent chronic inflammation of the skin, even in the absence of mast cells or T cells.^{56,67}

IMMUNOGLOBULIN E-DEPENDENT UPREGULATION OF Fc ϵ RI EXPRESSION AND Fc ϵ RI-DEPENDENT FUNCTION

As plasma levels of IgE increase (as often occurs in subjects with allergic diseases or parasite infections), levels of Fc ϵ RI expression on the surface of basophils and mast cells also increase.^{72,73} Compared with cells with low “baseline” levels of Fc ϵ RI expression, such cells can bind more IgE, release mediators in response to lower concentrations of allergens, and produce significantly larger amounts of preformed and lipid mediators and cytokines.⁷⁴ Thus, basophils and mast cells in subjects with high levels of IgE may have significantly

enhanced ability to express IgE-dependent and/or immunoregulatory functions.^{49,74} Exposure of mouse mast cells to certain monoclonal IgE antibodies, in the absence of exposure to the antigen for which the IgE is known to have specificity, can enhance the survival of the cells and, in some cases, induce the cells to release all three classes of mediators (preformed, lipid, cytokines).⁷⁴ Exposure to IgE in the absence of known antigen also can induce enhanced survival and cytokine and chemokine release in *in vitro* derived human mast cells.⁷⁵ Although the mechanisms responsible for these intriguing findings are not fully understood, some types of IgE antibodies appear to induce aggregation of Fc ϵ RI in the absence of known antigen.^{74,76} The clinical implications of these findings, if any, remain to be defined.

ROLES IN T-CELL-DEPENDENT RESPONSES NOT INVOLVING IMMUNOGLOBULIN E

Mast cell activation and/or infiltration of affected tissues with circulating basophils can occur during a variety of T-cell-dependent immunologic responses in both humans and experimental animals.^{1,5,49,55–57,63,64,77–79} However, despite years of study, the importance of the contributions of mast cells or basophils in such settings is not fully understood. In part this may reflect differences in the types of mast cell-deficient mice used to investigate such responses and/or the strain background of such mice, and in part this may reflect differences in the details of the experimental models used to probe the roles of mast cells and basophils in these settings (see “Genetic Approaches for Analyzing Basophil and Mast Cell Function” below). In some of the models of T-cell-dependent responses tested, authors have concluded that mast cell can either enhance or suppress features of the responses, and in some settings evidence has been reported that mast cells can enhance the features of relatively weak responses and suppress features of strong responses.^{63,64} It also has been proposed that mast cells and basophils might have immunomodulatory effects on the development or magnitude of certain acquired immune responses (e.g., positive effects via mast cell-dependent enhancement of dendritic cell migration or activation or negative effects *via* the production of IL-10 by mast cells).^{5,55–57,63,64,78–80} However, some of the findings in this area are considered controversial.^{5,63,64,79}

BIOLOGIC FUNCTIONS OF BASOPHILS AND MAST CELLS

Roles in Host Defense

Parasites Basophils and mast cells may have critical roles in the expression of host resistance to certain parasites. Whether basophils, mast cells, or both represent major effector cell types in these responses appears to vary according to factors such as species of parasite, species of host, and site of infection. Thus, in the guinea pig, basophils appear to be required for expression of immune resistance to infestation of the skin by larval ixodid *Amblyomma americanum* ticks,^{77,81} whereas expression of IgE-dependent immune resistance to the cutaneous infestation of larval *Haemaphysalis longicornis* ticks in mice is dependent on mast cells and basophils, and IgE.^{57,82} Such findings support the notion that basophils and mast cells express similar or complementary functions as effector cells in host defense against parasites and other agents.

Bacterial Infections Studies in mast cell-deficient and “mast cell knockin mice” (see “Genetic Approaches for Analyzing Basophil and Mast Cell Function” below) or in mice that lack TNF- α or certain mast cell-associated proteases indicate that mast cells can contribute to “innate” host defense against some experimental bacterial infections.^{63,64,83} Depending on the model system tested, the beneficial role of the mast

cell in such models of “innate immunity” in mice may partly reflect complement-dependent, toll-like receptor (TLR) 4-dependent, endothelin-1-dependent, or neurotensin-dependent activation of mast cells, inducing the release of mast cell–derived mediators, which, in turn, can contribute to enhanced local recruitment or activation of neutrophils and enhanced clearance of bacteria, or which may reduce harmful levels of TNF- α .^{63,64,83} Studies in mice indicate mast cells can phagocytose bacteria,⁸³ and mouse and human mast cells can produce antimicrobial peptides (cathelicidin LL-37 in humans).⁸⁴ However, mast cells also may contribute to survival during bacterial infection in mice by additional mechanisms, such as protease-dependent degradation of endothelin-1,^{85,86} neurotensin,⁸⁷ and perhaps other endogenous peptides that are produced during infections and which contribute to the pathology associated with the disorders.⁶³ On the other hand, some mast cell functions that may be expressed during bacterial infections in mice, such as the ability of mast cells to degrade IL-6 via dipeptidyl peptidase 1⁸⁸ or to produce IL-10 that suppresses host acquired immunity,⁸⁹ may have detrimental consequences. Thus, mast cells may have complex roles in innate immune responses, with some actions promoting host defense and survival and others enhancing the pathology associated with the response.

Viral Infections

Mast cell progenitors^{90–92} and basophils⁹³ can become infected with “M tropic” strains of HIV. Although mature mast cells appear to be resistant to such infection, mast cells that matured from infected progenitors while harboring latent infection exhibited enhanced viral replication upon stimulation with ligands for TLR2, TLR4, or TLR9,^{91,92} or via an IgE-dependent mechanism.⁹² At least one HIV-derived protein, glycoprotein 120 (gp120), can induce mast cell or basophil mediator release (histamine and, in basophils, IL-4 and IL-13) by binding to and crosslinking cell-surface-bound IgE.⁹³ Many patients infected with HIV develop high levels of IgE and can exhibit exacerbation of the symptoms and signs of their allergic disorders.⁹³ However, the clinical significance of such findings in HIV-infected patients remains to be determined. Many potential secreted products of mast cells or basophils may have effects that enhance (or suppress) host responses to a variety of viruses or contribute to the pathology associated with the infections.⁹⁴ However, the extent to which mast cells contribute to host defense or pathology during viral infections is not clear.

Venoms The venoms of many animals contain substances that can activate mast cells via innate mechanisms and/or can induce specific IgE responses to venom components.^{95,96} Many humans have IgE antibodies against components of honeybee or wasp venom, but only a small fraction of such “venom-sensitized” individuals have a history of anaphylaxis or other serious clinical response to such venoms.⁹⁷ Work in mast cell–deficient, mast cell knockin, and mast cell protease-deficient mice indicates that mast cells can enhance the resistance of mice to diverse animal venoms and/or their toxic components, including the venoms of three poisonous snakes,⁹⁶ the honey bee,^{96,98} the Gila monster,⁹⁹ and two species of scorpions,⁹⁹ as well as to sarafotoxin 6b, a major toxin in Israeli mole viper snake venom⁸⁶ and helodermin, a toxin in Gila monster venom.⁹⁹

Notably, carboxypeptidase A3 (CPA3) or mouse mast cell protease (mMCP-4, the functional counterpart in the mouse to human chymase) appeared to account for much or all of the protective effects against various venoms that were attributable to mast cells.^{86,98,99} CPA3 and mMCP-4 can degrade both endogenous biologically active peptides (endothelin-1 [ET-1]^{86,96} and vasoactive intestinal polypeptide [VIP],⁹⁹ respectively) and similar peptides present in animal venoms (sarafotoxin 6b and helodermin, respectively), which are thought to act in mammals via the same receptors that bind the similar endogenous

peptides. Work in mice deficient in mast cells, IgE, or components of the Fc ϵ RI suggests that mast cells also can contribute to the IgE antibody- and Fc ϵ RI-dependent enhanced resistance to challenge with potentially lethal amounts of honeybee venom that is observed in animals after an initial exposure to a sublethal amount of that venom.⁹⁸ Indeed, it has been hypothesized that the ability to participate in innate and acquired immune defenses against components of venoms and other toxins are important functions of mast cells and, in the case of acquired immunity, of IgE antibodies.^{95,96,100}

GENETIC APPROACHES FOR ANALYZING BASOPHIL AND MAST CELL FUNCTION

Factors capable of inducing basophil infiltration, mast cell proliferation, and/or basophil or mast cell activation are generated during a wide variety of immunologic or pathologic processes, including immune responses to parasites.^{1,5,30,49–51,55–57,77} As a result, speculation is considerable that basophils and mast cells express critical roles in diverse biologic responses. On the other hand, the precise functions of basophils and mast cells in most of the biologic responses in which the cells have been implicated are obscure. Studies of basophil function in guinea pigs⁸¹ and mice^{55–57} have employed antibodies to deplete basophils, and such approaches also have been used to deplete mast cells in mice¹⁰¹; however, the antibodies used may also influence other cell types.^{5,55–57,63,64,79} Various mutant or transgenic mice that exhibit constitutive or inducible depletion of some or all mast cell populations, as well as mast cell–deficient mice that have been selectively engrafted with wild-type or genetically altered mast cells (so-called mast cell knockin mice), have been used in efforts to define and quantify the contributions of mast cells to many different biologic responses.^{63,64,79} Transgenic mice also are now available that exhibit constitutive or inducible depletion of basophils, or that lack certain mast cell–associated products either globally or in selected cell populations.^{5,55–57,63,64,79} As has been extensively reviewed,^{5,54–56,74–76} the availability of such models has the potential to advance substantially our understanding of the roles of mast cells and basophils in health and disease in mice, including ascertaining the importance of strain background on some of the findings. In evaluating the results of such studies, one should keep in mind that such genetic models can have various advantages and disadvantages, and that even very strong evidence that mast cells or basophils have particular roles in mice does not prove that the cells have identical functions in humans.

No humans devoid of mast cells have been reported. In addition, the clinical findings in the rare patients who express a deficiency of basophils are not easy to interpret. One patient with a profound basopenia experienced persistent and severe infestation with scabies,³² a finding that might be viewed as consistent with the role of basophils in resisting ectoparasites in humans. However, that patient also had eosinopenia, IgA deficiency, and multiple other clinical problems.³² A second basophil-deficient patient had a history of recurrent bacterial and viral infections.³⁴ However, this patient also had a deficiency of eosinophils, hypogammaglobulinemia, abnormal suppressor T-cell function *in vitro*, and a thymoma.³⁴

● BLOOD BASOPHIL COUNT

The normal blood basophil count is difficult to define precisely, but several studies place the normal range between approximately 14 to 20 and 80 to 90/ μ L (approximately 0.014 to 0.020 and 0.080 to 0.090 $\times 10^9$ /L).^{8–10,102} The blood basophil count reportedly varies by age,¹⁰³ gender (in one study¹⁰³ but not in another⁹), and season.¹⁰⁴

BASOPHILOPENIA

Because numbers of blood basophils can be very low even in apparently normal individuals,^{8–10,102} determining whether examples of *basophilopenia* reflect pathologic processes as opposed to normal variation can be difficult. Nevertheless, reduced numbers of circulating basophils have been reported in several disorders (Table 63–2). Basophilopenia has been recorded in association with urticaria and anaphylaxis,^{105,106} but the extent to which the latter finding represents a loss of metachromatic staining of circulating degranulated cells rather than a true decrease in the number of cells is undetermined. Basophilopenia occurs in conditions that also are associated with eosinophilopenia. These conditions often are associated with increased secretion of adrenal glucocorticoids.^{102,107,108} Basophil counts may diminish, sometimes markedly, during leukocytosis accompanying infection, inflammatory states, immunologic reactions, neoplasia, or hemorrhage.¹⁰⁷ Basophil counts also are diminished in thyrotoxicosis or after pharmacologic administration of thyroid hormones. Conversely, basophil counts may be increased in myxedema or after ablation of thyroid function.¹⁰⁷ A rapid

and significant drop in blood basophil levels of up to 50 percent has been documented at ovulation.¹⁰⁸ A few patients with an apparent total lack of basophils have been reported.^{32,34}

A morphologic abnormality expressed in the majority of eosinophils and basophils but not in other leukocytes or mast cells has been described as an autosomal dominant condition affecting four members of a family.³³ Cytoplasmic inclusions and crystals in basophils resembling the May-Hegglin anomaly have occurred in healthy individuals.

BASOPHILIA

Table 63–2 lists conditions associated with increased numbers of blood basophils (*basophilia*).

Inflammatory and Immunologic Responses

An increased number of basophils is commonly associated with chronic, IgE-associated hypersensitivity disorders. These disorders often are accompanied by increased levels of IgE. Although serum IgE levels and basophil numbers are not directly related,¹⁰⁹ increased IgE levels are associated with increased expression of FcεRI on the surfaces of both basophils and mast cells.^{72,73,110} Moreover, basophils can be recruited into tissues at sites of IgE-associated and other immunologic responses.^{1,4,5,55–57,77} Basophil levels may be elevated in ulcerative colitis¹¹¹ and juvenile rheumatoid arthritis,¹¹² whereas many inflammatory conditions that cause a leukocytosis are associated with basophilopenia. Basophilia can occur in subjects exposed to ionizing radiation.¹¹³

Clonal Myeloid Diseases

Myeloproliferative Neoplasms The concentration of blood basophils is slightly increased in many patients with polycythemia vera (Chap. 84), primary myelofibrosis (Chap. 86), and essential thrombocythemia (Chap. 85). A slight increase in the absolute basophil count may be a useful early sign of a myeloproliferative neoplasm. An increased absolute basophil count occurs in virtually all patients with chronic myelogenous leukemia (CML).^{114–116} In some patients, basophils can represent 20 to 90 percent of blood leukocytes (Chap. 89). Exaggerated basophilia of this type is a poor prognostic sign and may herald transformation to the accelerated phase of CML.¹¹⁷ The basophil in myeloproliferative neoplasms is derived from the malignant clone and in CML can contain the Philadelphia (Ph) chromosome.¹¹⁸ The basophils in CML exhibit a variety of ultrastructural and biochemical abnormalities.^{119,120} In some cases, the abnormalities obscure the typical distinctions between basophils and mast cells.^{121–124} Release of basophil-associated histamine can lead to episodes of flushing, pruritus, and hypotension in occasional patients with basophilic CML.^{125,126} Severe peptic ulcer of the stomach and duodenum can occur in association with hypersecretion of gastric acid and pepsin.^{127,128} Ph chromosome–positive acute basophilic leukemia may be a presenting manifestation of CML.¹²⁹

Basophilic Leukemias The basis for designating some cases as basophilic leukemias as opposed to examples of other more typical myelogenous leukemias with an associated pronounced basophilia is not always clear. Accordingly, we refer to these conditions herein as *leukemias associated with basophilia*. Table 63–3 lists the leukemias associated with basophilia. In addition to extreme basophilia in the chronic phase CML or as a manifestation of the accelerated phase of CML, acute basophilic leukemia can rarely occur *de novo*.^{130–136} Thus, acute basophilic leukemia is included in the World Health Organization classification of acute myeloid leukemias (AMLs),¹³⁷ but the entity is poorly defined.^{135,136,138} Some cases are recognized only by electron microscopy, a procedure not used routinely in the diagnosis or classification of leukemias. One report suggests that the detection

TABLE 63–2. Conditions Associated with Alterations in Numbers of Blood Basophils

I. Decreased Numbers (Basopenia)
A. Hereditary absence of basophils (very rare)
B. Elevated levels of glucocorticoids
C. Hyperthyroidism or treatment with thyroid hormones
D. Ovulation
E. Hypersensitivity reactions

of a CD123-positive, CD203c-positive, and CD117-negative blast cell immunophenotype may be useful in making a diagnosis of acute basophilic leukemia.¹³⁹ The best defined entity of acute basophilic leukemia appears to occur in male infants and is associated with t(X;6)(p11.2;q23.3), resulting in the fusion of *MYB* and *GATA1*.^{140,141}

Other types of AML that have an associated increase in basophils are more prevalent than acute basophilic leukemia. Such acute leukemias most commonly have t(9;22), t(6;9), t(3;6), or 12p abnormalities.^{142–145} The t(9;22) AMLs have features similar to blast crisis of CML, but studies show that *de novo* cases are associated with deletion of antigen receptor genes.¹⁴⁶ The t(6;9) AML often is associated with erythroid hyperplasia and dysplasia, a high frequency of *FLT3* mutations, and poor prognosis.^{147–149}

AML with inv(16) or t(16;16) are characteristically associated with cells having large basophilic granules, but the cells containing these granules are generally thought to represent abnormal eosinophils rather than basophils.¹⁵⁰

Although the clinical and pathologic features of acute basophilic leukemia are largely similar to those of AML, affected patients occasionally exhibit symptoms that result from release of mediators (especially histamine) from degranulating or dying basophils.^{125,126,132,151} Remission induction therapy is similar to the therapy used for other types of AML, but management can be complicated by shock resulting from massive release of histamine and other mediators associated with acute cytotoxicity.

Chapter 88 provides further details on the acute leukemias associated with basophilia.

DISORDERS AFFECTING MAST CELLS

NORMAL MAST CELL LEVELS

Mast cells cannot be identified in the blood of healthy individuals using standard techniques. However, mast cells can be observed in the blood of monkeys that have been treated chronically with large amounts of the *KIT* ligand *SCF*²² and in the blood of some patients with systemic mastocytosis.¹⁵² Increases in tissue mast cells can occur by a combination of enhanced progenitor influx and proliferation of resident mast cells in tissues.^{16,153} Human mast cells have been classified according to their content of neutral proteases as MC_T , because the granules contain tryptase but not detectable chymase, and MC_{TC} , whose secretory granules contain both enzymes.²⁹ The former mast cell type ordinarily predominates in lung and gastrointestinal mucosal tissues, and the latter type in dermis and submucosal tissues.^{154–156} Mast cells that express chymase but little or no tryptase (MC_C) also have been described.¹⁵⁷

SECONDARY CHANGES IN MAST CELL NUMBERS

Although long-term treatment with glucocorticoids (particularly topical treatment of the skin) can result in diminished mast cell numbers,¹⁵⁸ no clinical disorder whose primary feature is a reduction in levels of

tissue mast cells has been reported. Studies of small numbers of patients indicate that certain mast cell populations, namely, the MC_T mast cells in the gastrointestinal mucosa, can be strikingly reduced in numbers in subjects with genetically determined or acquired (HIV-induced) immunodeficiency.¹⁵⁹ Human mast cell precursors can be infected *in vitro* with so-called M tropic strains of HIV^{90,91,93}; and *in vivo* may comprise a long-lived inducible reservoir of persistent HIV.⁹² Whether mast cell infection with HIV contributes to the reduction in gastrointestinal mast cells observed in some subjects with HIV infection remains to be determined.

A number of disorders are associated with small to up to several fold increases in mast cell numbers in or near the tissues affected by the disorder (Table 63–4). Tissues at sites of recurrent allergic reactions often exhibit increases in mast cell numbers, to levels as high as approximately fourfold normal.^{154,160} Small increases in mast cell numbers have been observed at sites of pathology in rheumatoid arthritis, psoriatic arthritis, scleroderma, and systemic lupus erythematosus.^{154,160–162} Mast cells are reported to be increased in osteoporosis,¹⁶³ but the extent to which this increase reflects decreases in other cell types and/or a decrease in bone matrix is unclear. Numbers of marrow mast cells can be increased in patients with chronic liver or renal diseases.¹⁶⁴ Increases in mast cells also have been documented in infectious diseases, particularly at sites

of infection with parasites such as *Strongyloides*, in which a greater than fourfold increase in mast cell numbers can occur.¹⁶⁵ In such settings, mast cell numbers return toward normal upon resolution of the infection. Finally, mast cell numbers can be increased several-fold in lymph nodes draining areas of tumor growth^{164,166} and in subjects with stem cell diseases and lymphoproliferative diseases, including lymphoma in the marrow and in association with CML.^{164,167–169}

DISORDERS OF MAST CELLS: HYPERPLASIA AND NEOPLASIA

DEFINITION AND HISTORY

A group of systemic disorders associated with significant increases in mast cell numbers in the skin and internal organs have been brought together under the term *mastocytosis*. The first report of a primary mast cell disorder is attributed to Unna¹⁷⁰ who, in 1887, reported that the skin lesions of urticaria pigmentosa (UP)^{171,172} contained numerous mast cells. Ellis¹⁷³ recognized the systemic nature of the disorder in 1949. In addition to the systemic disorders classified as mastocytosis, localized cutaneous aggregates of mast cells, ranging from *mast cell nevi* and *mastocytomas* in infants and children to multiple nodules in older children, may occur.^{174,175}

The clinical pattern of disease in mastocytosis and its prognosis can vary substantially among patients (see “Course and Prognosis” below). A consensus classification for mastocytosis has been developed to address the issue and to provide guidelines regarding prognosis and treatment (Table 63–5).¹⁷⁶ Patients with indolent disease, who compose the great majority of subjects with mastocytosis, can expect a normal life span. Patients with systemic mastocytosis with associated clonal, hematologic non-mast-cell-lineage disease (SM-AHNMD) have a prognosis determined by the associated hematologic disorder. Patients with aggressive systemic mastocytosis (ASM) generally have a 3- to 5-year survival. Mast cell leukemia (MCL) is often rapidly fatal.

ETIOLOGY AND PATHOGENESIS

Activating mutations in *KIT*, which encodes the SCF receptor, a member of the type III receptor tyrosine kinase family, have been documented in patients with mastocytosis. Several lines of evidence indicate such mutations can be involved in the pathogenesis of the disease. The most common of these mutations (Asp816Val), which results in

ligand-independent activation of the *KIT* receptor, was first identified in a long-term cell line derived from a patient with MCL.¹⁷⁷ It then was detected in mononuclear cells in the blood of patients with mastocytosis who had an associated hematologic disorder,¹⁷⁸ as a somatic mutation in lesional tissue obtained from one patient with an aggressive form of mastocytosis and from a second patient with an indolent form of UP,¹⁷⁹ and in the skin, but not the marrow and blood, of an 11-month-old child with mastocytosis.¹⁸⁰

Together these findings suggest the mutation occurs initially in a mast cell progenitor and that, as the clone expands, it becomes detectable in the marrow, blood, and skin lesions. The Asp816Val mutation, or similar 816 activating mutations that result in the substitution of phenylalanine or tyrosine for aspartate, now are believed to occur in more than 90 percent of adult patients with mastocytosis.¹⁸¹ Mutations at codon 816 have been identified in a subset of pediatric patients, whereas other pediatric patients exhibit *KIT* mutations elsewhere, including within the extracellular domain. These other mutations also cause constitutive activation in *KIT* to a varying degree.¹⁸¹

The extent to which the presence of various *KIT* mutations, and the anatomical distribution of the affected cells, can be used to predict prognosis or disease severity in patients with mastocytosis remains under investigation. Moreover, additional “gain-of-function” mutations of *KIT* in human subjects with mastocytosis have been reported. For example, a novel form of mastocytosis with a *KIT* mutation in the transmembrane domain (Phe522Cys) has been described.¹⁸² In a second example, a *PRKG2-PDGFRB* fusion was identified in a patient presenting with increased numbers of mast cells and peripheral basophilia.¹⁸³ The latter case falls within the World Health Organization category of myeloid neoplasms with *PDGFRB* rearrangements, rather than being categorized as a subvariant of mastocytosis. Gain-of-function mutations of *KIT* also have been reported in gastrointestinal stromal tumors.¹⁸⁴ Additional genetic lesions have been reported in aggressive mastocytosis and in patients with SM-AHNMD, including mutations in *JAK2*, *TET2*, *NRAS*, and *KRAS*.¹⁸⁵

CLINICAL FEATURES

The organs most frequently involved in systemic mastocytosis are the skin, lymph nodes, liver, spleen, marrow, and gastrointestinal tract.

The Skin

The usual presenting lesion of mastocytosis in the skin is UP/maculopapular cutaneous mastocytosis. UP lesions appear as small yellowish-tan to reddish-brown macules or slightly raised papules (Fig. 63–2), which can exhibit the Darier sign, that is, urticaria after mild friction of the skin.¹⁷⁴ The palms, soles, face, and scalp generally remain free of lesions. In many cases, UP develops before age 2 years and subsides by puberty. Adults with UP usually have extracutaneous involvement by mastocytosis. However, some patients, particularly those with SM-AHNMD, ASM, or MCL, lack cutaneous lesions. In such cases, other organs must be biopsied to make the diagnosis. Diffuse cutaneous mastocytosis is an unusual manifestation of mastocytosis.^{175,186} The skin appears yellowish-brown and is thickened. Young children with cutaneous disease may have bullous eruptions with hemorrhage.¹⁷⁵ Some adults develop prominent vascularity in association with the skin lesions, a condition that has been termed *telangiectasia macularis eruptiva perstans*.¹⁷⁵

Lymph Nodes

In one series, peripheral lymphadenopathy occurred in 26 percent and central lymphadenopathy in 19 percent of patients at diagnosis.¹⁸⁷ Lymphadenopathy is most prominent in patients with SM-AHNMD or ASM. Mast cell infiltrates are observed in the node's

Figure 63-2. Urticaria pigmentosa in an adult man with indolent systemic mastocytosis. Multiple pigmented macules are present. If local pressure is applied to the skin, individual lesions show urtication and become raised, pruritic, and erythematous.

paracortex, follicles, medullary cords, and sinuses. Additional findings include infiltrates of eosinophils, blood vessel proliferation in association with mast cells in the paracortical areas, and extramedullary hematopoiesis. In hematoxylin-and-eosin (H&E)-stained sections, mast cell infiltrates in the lymph nodes may resemble T-cell lymphomas in their pericortical distribution, the clear cytoplasm that is sometimes exhibited by the mast cells, and the associated vascular proliferation and eosinophilia.¹⁸⁷ Alternatively, when mast cells replace lymphoid follicles, the pattern may resemble follicular hyperplasia or follicular lymphoma.¹⁸⁷ Fibrosis may be observed in lymph nodes involved by mast cell infiltrates.

Liver

Patients frequently exhibit infiltration of the liver with mast cells. Many of these individuals have some associated liver pathology, but severe liver disease is uncommon. When severe liver disease does occur, it typically affects patients with SM-AHNMD or ASM. In one series of 41 patients, 61 percent had some liver disease.¹⁸⁸ Elevated serum levels of alkaline phosphatase, aminotransaminases, 5'-nucleotidase, or γ -glutamyl transpeptidase was detected in approximately half of the patients. Hepatomegaly, prominent infiltration of the liver with mast cells, and hepatic fibrosis are positively correlated with elevated levels of alkaline phosphatase and were observed more frequently in patients with aggressive disease; some of these patients also had ascites or portal hypertension. Portal fibrosis was observed in 68 percent and was positively correlated with hepatic inflammation and mast cell infiltrates. Venopathy and associated venoocclusive disease was observed in four patients, all of whom had an associated hematologic disorder.

Spleen

Splenic involvement at diagnosis has been reported in approximately half of patients with systemic disease.^{187,189} Mast cells most commonly occurred in a paratrabeular distribution, followed by perifollicular, follicular, and diffuse infiltrates. Trabecular and capsular fibrosis and eosinophilic infiltration also were observed, and extramedullary hematopoiesis was present in most cases. On H&E stained sections, the infiltrates of mast cells produced lesions that may resemble those of T-cell lymphoma, follicular hyperplasia, follicular lymphoma, myeloproliferative neoplasms, hairy cell leukemia, or a granulomatous process. Splenomegaly has also been reported in the absence of infiltration of the spleen by mast cells.¹⁹⁰ Increased splenic weights greater than 700 g generally occurred in patients within unfavorable categories of mastocytosis.

Marrow

The majority of adults with systemic mast cell disease have focal mast cell lesions in the marrow,^{189,191-194} typically appearing as foci of spindle-shaped mast cells in a fibrotic background (Fig. 63-3), sometimes with associated eosinophils and T and B lymphocytes. These focal mast cell lesions are the major criterion in the diagnosis of systemic mastocytosis (Table 63-6).¹⁷⁶ Reticulin staining may be increased, and Masson trichome staining may reveal collagen deposition. In specimens extensively involved by mast cell lesions, the bony trabeculae may be moderately to markedly thickened. Aggressive variants of mastocytosis, such as MCL, should be considered if the percentage of mast cells in the marrow aspirate film exceeds 20 percent of all nucleated cells. In the typical leukemic variant of MCL, mast cells account for 10 percent or more of blood leukocytes.¹⁷⁶ This type of MCL should be distinguished from an aleukemic variant of MCL where circulating mast cells account for less than 10 percent of white blood cells.¹⁹⁵

In H&E-stained sections, the mast cells typically exhibit a spindle-shaped or oval nucleus (see Fig. 63-3A and B), and fine eosinophilic granules are apparent in the cytoplasm at high-power magnification (see Fig. 63-3B). Mast cells with bilobed nuclei may be seen in these lesions and is a finding associated with a poor prognosis.¹⁸⁹ Mast cells stain positively for chloracetate esterase and aminocaproate esterase, and for mast cell tryptase by immunohistochemistry (see Fig. 63-3D). The latter is the procedure of choice for visualizing mast cells. Mast cells exhibit immunoreactivity for a variety of paraffin section markers.¹⁹⁶ The more specific mast cell markers in paraffin sections are CD117 (KIT) (see Fig. 63-3C) and mast cell tryptase (see Fig. 63-3D). Strong CD117 membrane staining is equally sensitive for mast cells as tryptase but is less specific.

Films of marrow aspirates or clot sections alone cannot be used to diagnose mast cell disease in the marrow. Although increased numbers of mast cells may be present in marrow aspirate films of patients with systemic mast cell diseases, similar findings have been reported in patients without mast cell disorders or in patients with a reactive increase in marrow mast cells. However, mast cells in reactive lesions usually are not spindle shaped, nor do they typically exhibit evidence of degranulation. On marrow films, a normal mast cell has a round or oval shape, a round and centrally located, nonlobated nucleus, and a fully granulated cytoplasm. Mast cells from patients with mastocytosis may exhibit phenotypic aberrations, such as a spindle shape, cytoplasmic projections, and hypogranulation. A multilobular and/or eccentrically located nucleus may be observed.¹⁷⁶ If at least 25 percent of all mast cells on aspirate smears have aberrant morphology, the findings are considered to support the diagnosis of systemic mastocytosis (minor criterion).¹⁷⁶ An aberrant mast cell phenotype also may be detected on flow cytometric analysis of the marrow aspirate. In patients with mastocytosis, mast cells may express CD2, CD25 (minor criterion), and CD33.¹⁹⁷

Figure 63-3. Marrow sections. Marrow biopsy from an adult with indolent systemic mastocytosis showing characteristic focal aggregates of mast cells, some of which are spindle-shaped, with admixed eosinophils and numerous small lymphocytes; different areas of the specimen were stained by hematoxylin and eosin (H&E) (**A, B**; $\times 40$ and $\times 200$, respectively) or with an antibody to human CD117 (**C**; $\times 200$) or tryptase (**D**; $\times 200$). Areas that contain many mast cells are depicted with *arrows* in **A**.

TABLE 63-6. Diagnostic Criteria for Systemic Mastocytosis

Major Criterion

Multifocal, dense infiltrates of mast cells (≥ 15 mast cells in an aggregate) detected in sections of marrow and/or other extracutaneous organ(s)

Minor Criteria

- In biopsy sections of marrow or other extracutaneous organs, $>25\%$ of the mast cells in the infiltrate are spindle shaped or have atypical morphology, or, of all mast cells in marrow aspirate smears, $>25\%$ are immature or atypical mast cells
- Detection of a point mutation in *KIT* at codon 816 in marrow, blood, or other extracutaneous organ
- Mast cells in marrow, blood, or other extracutaneous organs that coexpress CD117 with CD2 and/or CD25
- Serum total tryptase persistently >20 ng/mL (if there is an associated myeloid disorder, this criterion is not valid)

The diagnosis of systemic mastocytosis can be made if one major and one minor criterion are present or if three minor criteria are met.

Marrow involvement is much less common in children. In a study of 17 children with cutaneous or disseminated mast cell disease, small focal mast cell lesions were observed in marrow biopsies in 10 individuals, and increased mast cells in marrow aspirate films were noted in 5.¹⁹³ The focal lesions found in children usually are small and perivascular.

Progression of marrow involvement in systemic mast cell disease is variable. Some adults with indolent disease appear to have stable, or even decreasing, marrow involvement over time.¹⁸⁹ In contrast, a progressive increase in focal mast cell lesions is more commonly observed in patients with more aggressive patterns of disease.

CLINICAL PRESENTATION

Even though individuals may differ in the specific pathogenesis of their disease, all patients within a given category of mastocytosis (see Table 63-5) tend to exhibit similar clinical features. Manifestations of the disease largely reflect the local and systemic consequences of mediator release from tissue mast cells. Effects caused by disruption of normal structures by local collections of mast cells also may be seen.

At presentation, patients with mastocytosis may complain of vague and nonspecific constitutional symptoms, such as fatigue, weakness, flushing, and musculoskeletal pain. Some patients experience fever and/or weight loss.^{152,186} A subset of patients may present with recurrent episodes of unexplained anaphylaxis.¹⁹⁸ However, most patients with mastocytosis and a hematologic disorder are diagnosed based on marrow biopsy findings, during the investigation of their hematologic disease.^{187,189} Patients with aggressive disease often present with unexplained lymphadenopathy and splenomegaly and/or hepatomegaly.

Gastrointestinal disease and associated symptoms are commonly associated with systemic mastocytosis, either at presentation or as the disease progresses.^{174,199} Findings include nausea, vomiting, abdominal pain, and diarrhea. Peptic ulcer disease, which is thought to reflect, at least in part, the promotion of gastric acid secretion by elevated histamine levels, occurs in up to 50 percent of patients with systemic disease.¹⁹⁹ With progressive disease, patients may develop mild malabsorption.¹⁹⁹

If systemic involvement is advanced at the time of diagnosis, patients may exhibit lymphadenopathy, hepatomegaly, and splenomegaly during the initial evaluation.¹⁵² Because osteoporosis may accompany systemic disease, pathologic fractures may occur.

LABORATORY FEATURES

When systemic mastocytosis is suspected in patients based on a combination of: reports of symptoms consistent with mediator release, identification of classical skin lesions showing a 10-fold or greater increase in mast cell numbers, an elevation in serum tryptase of greater than 20 ng/mL²⁰⁰ and documentation of organomegaly, an appropriate next step is to perform a marrow biopsy and aspirate.^{152,176,201} Additional studies, including a gastrointestinal evaluation involving radiographic studies of the upper gastrointestinal tract and small intestines, computed tomographic scan of the abdomen, and endoscopy, also may be justified.

Plasma and/or urinary histamine levels may be increased in systemic mastocytosis.¹⁸⁶ However, the isolated findings of increased levels of histamine or histamine metabolites may reflect a number of other situations, including anaphylaxis. Furthermore, the accuracy of laboratory measurement of histamine depends on the assay used. Urine histamine levels may be falsely elevated as a result of bacterial contamination, pharmacologic agents and their metabolites excreted in the urine, or diets rich in histamine or histamine precursors. Similarly, serum tryptase may be elevated after anaphylaxis. Thus, no single laboratory test showing an elevation in a mast cell mediator is diagnostic of mastocytosis. Rather, the demonstration of such mediators in blood or urine should prompt the clinician to investigate further for the presence of mastocytosis.

There are patients who have symptoms of mediator release but no mastocytosis in the skin or organomegaly. Some of these patients may have experienced venom-induced anaphylaxis. These patients may also exhibit elevations in tryptase but below the 20 ng/mL which is used as a minor diagnostic criterion. In such situations, reports have suggested the detection of the D816V mutation in blood using a highly sensitive allele-specific quantitative polymerase chain reaction (qPCR) may be useful as a diagnostic parameter.²⁰¹ At the time of writing of this chapter, this test is not widely available and it is being used largely in referral centers.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of systemic mastocytosis includes allergic diseases; hereditary or acquired angioneurotic edema; idiopathic flushing, urticaria, and anaphylaxis; carcinoid tumor; and idiopathic capillary leak

syndrome. When episodic hypertension is a major finding, pheochromocytoma should be considered. Significant unexplained gastroduodenal ulcer disease requires that Zollinger-Ellison gastrinoma syndrome be ruled out. *Helicobacter pylori* infection should be considered in all patients with ulcer disease, including patients with mastocytosis.

Some diseases have hematologic findings that overlap with those of systemic mastocytosis. These disorders include tryptase-positive AML, CML with accumulation of tryptase-positive cells, primary myelofibrosis with mast cell accumulation, and acute or chronic basophilic leukemia.

A somatic mutation in *KIT* at codon 816 (most commonly Asp816Val) is associated especially with adult-onset systemic mastocytosis. Demonstration of a codon 816 gain-of-function mutation, where the most sensitive approach is to look for its presence in sorted marrow-derived mast cells, is a minor criterion in the diagnosis of mastocytosis (see Table 63–6).

THERAPY

Mastocytosis currently has no cure.²⁰² In addition, no evidence indicates that symptomatic therapy significantly alters the course of the underlying disease.

Avoiding Triggers

Management of mastocytosis includes instructing the patient on the avoidance of factors that may trigger symptoms (presumably by direct or indirect activation of mast cell mediator production). Such factors can include temperature extremes, physical exertion, or, in some unusual cases, ingestion of ethanol, nonsteroidal antiinflammatory drugs, or opiate analgesics.¹⁷⁴

Epinephrine and H₁ or H₂ Antihistamines

Anaphylaxis may follow insect stings, even in the absence of evidence of allergic sensitivity.¹⁹⁸ Epinephrine-filled syringes and instructions on their use can be given to patients considered at risk for such a reaction. Patients with mast cell disease and a history of anaphylaxis should be advised to carry epinephrine-filled syringes, instructed on their use, and taught to self-medicate, if necessary. These patients also may benefit from the concurrent use of H₁ and H₂ antihistamines prophylactically. Patients may experience severe reactions to iodinated contrast materials. Thus, consideration should be given to premedicating mastocytosis patients with H₁ and H₂ antihistamines and prednisone. Nonsedative H₁ antihistamines decrease skin irritability and pruritus.^{186,202} Pruritus may be relieved by approaches that maintain skin hydration. H₂ antihistamines, including ranitidine and famotidine, are used to treat the gastritis and peptic ulcer disease associated with mastocytosis.^{186,202–204} H₂ antihistamines may be titrated based on symptom control or to a particular level of gastric secretion. Proton pump inhibitors are useful for management of gastric hypersecretion.^{199,204}

OTHER DRUG THERAPY

Disodium Cromoglycate; Ketotifen

Oral administration of disodium cromoglycate may be useful for treatment of gastrointestinal cramping and diarrhea.^{186,202,205} The agent has been beneficial in cutaneous mast cell disease in children and infants.¹⁸⁶ Other symptoms, including headache, have improved with administration of cromolyn sodium. Ketotifen reportedly has been effective in relieving pruritus and wheal formation in cutaneous mastocytosis.²⁰⁶ By contrast, one pediatric study found ketotifen was no more effective than hydroxyzine.²⁰⁷

Bisphosphonates

Osteoporosis in patients with mastocytosis may be unrecognized and thus undertreated, especially in patients with milder forms of disease. It is thus important to utilize dual-energy x-ray absorptiometry (DEXA) scanning in the evaluation of those with mastocytosis. Recommended approaches for the treatment of osteoporosis include calcium supplementation, consideration of estrogen replacement in postmenopausal women, and use of bisphosphonates.²⁰⁴

Nonsteroidal Antiinflammatory Agents

Nonsteroidal antiinflammatory agents have been useful in some patients whose primary manifestations are recurrent episodes of flushing, syncope, or both.^{202,204} It should be noted that these agents may exacerbate ulcer disease. Patients with a history of aspirin sensitivity should not be placed on this therapy unless they first undergo desensitization.

Glucocorticoids; Methoxypsoralen

Cutaneous lesions have been treated with either glucocorticoids²⁰⁸ or 8-methoxypsoralen plus ultraviolet A (PUVA),²⁰⁹ largely to reduce pruritus or for cosmetic improvement. No evidence indicates such approaches alter the progression of systemic disease. Relapses 3 to 6 months after cessation of PUVA therapy are common. Patients may experience a decrease in the intensity of lesions after exposure to natural sunlight. Repeated or extensive application of glucocorticoids may result in cutaneous atrophy or adrenocortical suppression.²⁰⁸

Systemic glucocorticoids are used to decrease significant malabsorption and ascites²¹⁰ in patients with advanced disease. In adults, oral prednisone (40 to 60 mg/day) usually results in decreased symptoms over a 2- to 3-week period. After initial improvement, steroids usually can be tapered to an alternate-day regimen. However, with time, the ascites frequently recurs. Such patients reportedly can benefit from a portacaval shunt.

Interferon- α Cladribine

Patients with more advanced categories of systemic mastocytosis may be candidates for approaches directed at reducing the mast cell burden. None of these approaches has resulted in cure of the disease. For severe disease, some limited success has been reported for interferon α (IFN- α) and it is often considered to be a first-line drug of choice along with cladribine.^{204,211,212} It is presumed to act by restricting the proliferation of hematopoietic progenitor cells. Studies with IFN- α , often in combination with glucocorticoids, have reported variable success, with unchanged or modest reductions in marrow infiltration with mast cells, and in tryptase levels. Many patients do report symptomatic benefits. Resolutions of ascites and increased bone remineralization also have been reported. Use of IFN- α is often limited by side effects such as fever, fatigue, and cytopenias. Its use is not routinely recommended for patients with indolent systemic disease, unless there is concomitant severe osteoporosis.

Cladribine (2-chlorodeoxyadenosine), a nucleoside analogue, does not require cells in active cell cycle to exert its cytotoxic activity and may be beneficial in slowly progressing neoplastic processes. The drug has myelosuppressive and immunosuppressive properties and thus cannot be recommended for patients with indolent disease.²⁰⁴

Hematopoietic Stem Cell Transplantation

Allogeneic stem cell transplantation (SCT) has been employed as a treatment option for patients with advanced categories of mastocytosis associated with poor survival. SCT has been used to treat a hematologic disorder associated with mastocytosis in relatively few cases.^{213–216} Although these studies reported favorable responses of the associated hematologic disorders, complete remission of the mast cell disease was

reported in only one study, which used non-T-cell-depleted blood SCT in a patient with an associated myeloproliferative neoplasm.²¹⁵ The value of allogeneic SCT in mastocytosis may result from the immunotherapeutic effects of the donor marrow rather than the myeloablative conditioning regimen.²¹³ One study using nonmyeloablative blood SCT for treatment of advanced systemic mastocytosis in three patients with advanced mastocytosis reported no effect on mastocytosis progression despite the induction of a graft-versus-mast-cell response.²¹⁶ Perhaps performing targeted therapy directed at the mast cell compartment before transplantation would improve outcome.

Tyrosine Kinase Inhibitors

The availability of low-molecular-weight inhibitors of tyrosine kinases suggested the mutated *KIT* tyrosine kinases in mastocytosis as a therapeutic target. Imatinib mesylate (Gleevec; Novartis, Basel, Switzerland) currently is the only such drug available. It has a specific inhibition profile that includes *ABL1*, *KIT*, and *PDGFR* (platelet-derived growth factor receptor) tyrosine kinases.^{217,218} Although the drug inhibits wild-type *KIT* and *KIT* bearing juxtamembrane-activating mutations similar to those found in gastrointestinal stromal tumors, it does not inhibit *KIT* bearing the codon 816 mutations associated with most common forms of systemic mastocytosis.^{219,220} This finding is attributed to a conformational change in *KIT* bearing the codon 816 mutation, which interferes with the association of the drug with the ATP-binding domains of the receptor. Consistent with these observations, imatinib mesylate showed a strong *in vitro* cytotoxic effect on mast cells bearing wild-type *KIT*. Mast cells bearing a codon 816 mutation isolated from marrow of patients with mastocytosis were fairly resistant to the drug.²²¹ These studies suggest imatinib mesylate is unlikely to be an effective therapy for patients who carry codon 816 mutations. However, the drug appears to be of value when there is an imatinib-sensitive mutation or in *KIT*816-unmutated patients. For example, a patient with an unusual form of systemic mastocytosis associated with a *KIT* mutation (Phe-522Cys) affecting the transmembrane region of the receptor responded to treatment with imatinib.¹⁸² Accordingly, a careful mutational analysis of a sample enriched for lesional mast cells appears to be essential in patients with mastocytosis before contemplating imatinib therapy. Other tyrosine kinase inhibitors that decrease the activity of *KIT* with codon 816 mutations including midostaurin (PKC412) and dasatinib are in clinical trials.^{222,223} Studies to date suggest that midostaurin may produce significant decreases in mast cell burden in some patients.²²²

Some patients with a variant of chronic eosinophilic leukemia (clonal hypereosinophilic syndrome) and *FIPIL1-PDGFR*A fusions exhibit elevated serum tryptase levels, increased numbers of mast cells in the marrow, some of which can appear atypical and spindle shaped, tissue fibrosis, and, like other patients who have the *FIPIL1-PDGFR*A fusion gene, are responsive to imatinib mesylate.^{224,225} Such cases are classified within the World Health Organization category of myeloid and lymphoid neoplasms with eosinophilia and abnormalities of *PDGFR*A, *PDGFR*B, or *FGFR*1.

Monoclonal Mast Cell Activation Syndrome

Monoclonal mast cell activation syndrome (MMAS) is a term adopted by a consensus conference to be applied to patients who are found to have one or two minor diagnostic criteria for mastocytosis but lack the full diagnostic criteria for systemic disease.²²⁶ Patients with such findings have been identified within groups of patients diagnosed with idiopathic anaphylaxis and patients with anaphylaxis to stinging insects. It is possible that these studies are identifying patients with a progressive clonal mast cell disorder that may one day meet the diagnostic criteria for systemic mastocytosis. For now, such patients are treated symptomatically and for anaphylaxis. Followup at yearly intervals is

recommended to determine if there is evidence of an expanding mast cell compartment.

Mast Cell Activation Syndrome

The term *mast cell activation syndrome* (MCAS) is sometimes applied as a diagnosis for patients with episodic allergic-like signs and symptoms, including flushing, urticaria, diarrhea, and wheezing, involving two or more organ systems; and where an extensive medical evaluation has failed to identify an etiology.^{227,228} The assumption is that individuals to whom this diagnosis is applied are having episodes caused by release of mediators associated with hyperreactivity of mast cells that then activate spontaneously.

Diagnostic criteria have been proposed to separate this proposed entity from other causes of such clinical findings. These criteria include response to antimediator therapy and an elevation in a marker of mast cell activation, such as serum tryptase, with an episode.²²⁷ Primary (clonal) and other clinical disorders associated with mast cell activation, as well as other conditions associated with vasoactive mediator release, must be eliminated as possible causes of the clinical findings, including allergic diseases, mast cell activation associated with chronic inflammatory or neoplastic disorders and chronic autoimmune urticaria. Once the diagnostic criteria are met, therapy is symptomatic. Patients must be followed regularly in the event that one of the diagnoses eliminated during the initial evaluation reaches the level of diagnosis.

Splenectomy

Splenectomy has been performed on patients with severe aggressive mastocytosis in an attempt to improve their limiting cytopenias.²²⁹ Based on comparisons to historical controls, splenectomy increased survival by an average of 12 months. Patients who had undergone splenectomy appeared to be better able to tolerate chemotherapy. Splenectomy is of no value in the management of indolent mast cell disease.

COURSE AND PROGNOSIS

The prognosis of adult patients with mast cell disorders is related to the disease category. The vast majority of patients who present with UP and indolent systemic mastocytosis (ISM) have a chronic protracted course that responds to symptomatic medical management. A normal life span is expected. Few of these patients progress to more severe forms of the disease; some patients may even experience a diminution in the severity of skin lesions in later years, while their marrow findings remain unchanged.²³⁰ However, elevated serum lactate dehydrogenase levels, a late age of onset, and, in patients with SM-AHNMD, presence of a significant hematologic abnormality (such as a myeloproliferative or myelodysplastic disorder or, more rarely, overt leukemia) are indicators of a poor prognosis and shortened survival.¹⁸⁹ The prognosis for patients with SM-AHNMD depends on the course of the associated hematologic disorder.

Mast Cell Leukemia

MCL is relatively rare and prognosis is poor.^{195,222} A major differential diagnosis to MCL is myelomastocytic leukemia (MML).²³¹ Patients with MCL may have fever, anorexia, weight loss, fatigue, severe abdominal cramping, nausea, vomiting, diarrhea, flushing, hypotension, pruritus, or bone pain. Peptic ulcer and gastrointestinal bleeding, hepatomegaly, splenomegaly, and lymph node enlargement are frequent findings. Anemia is a constant feature, and thrombocytopenia is nearly always present. The total leukocyte count varies from 10,000 to 150,000/ μL (10 to 150 $\times 10^9/\text{L}$), and mast cells compose 10 to 90 percent of leukocytes. Marrow biopsy shows a striking increase in mast cells, sometimes up to 90 percent of marrow cells, although the leukemic mast cells often are hypogranular or agranular.^{195,231}

Mast Cell Sarcoma

This is an exceedingly rare tumor, characterized by nodules at various cutaneous and mucosal sites.^{164,176}

CHAPTER 64

CLASSIFICATION AND CLINICAL MANIFESTATIONS OF NEUTROPHIL DISORDERS

Marshall A. Lichtman

SUMMARY

Neutrophil disorders can be grouped into deficiencies, or neutropenia, excesses, or neutrophilia, and qualitative abnormalities. Neutropenia can have the severe consequence of predisposing to infection, whereas neutrophilia usually is a manifestation of an underlying inflammatory or neoplastic disease: the neutrophilia, per se, having no specific consequences. Qualitative disorders of neutrophils may lead to infection as a result of defective cell translocation to an inflammatory site or defective microbial killing. Neutropenia may reflect an inherited disease that is evident in childhood (such as congenital [hereditary] severe neutropenia), but more often it is acquired. A common cause of neutropenia is the adverse effect of a drug. Some cases of neutropenia have no evident cause. The health consequence of neutropenia is a function of the mechanism of the neutropenia, the abruptness and severity of the decrease in the blood neutrophil count, and the duration of the decrease. Neutrophils have also been identified as mediators of vascular or tissue injury. Table 64–1 provides a comprehensive categorization of quantitative and qualitative neutrophil disorders.

CLASSIFICATION

Table 64–1 lists disorders that result from a primary deficiency in neutrophil numbers or function. Neutropenia or neutrophilia also occurs as part of a disorder that affects multiple blood cell lineages, as in infiltrative diseases of the marrow, or intrinsic disorders of multipotential marrow hematopoietic cells, or removal of several blood cell types in the circulation. These diseases are not included in this classification and are discussed in other chapters of this text. This classification and chapter considers disorders in which the neutrophil either is the only cell type affected or the dominant cell type affected.

A pathophysiologic classification of neutrophil disorders has proved elusive. Techniques for measuring mechanisms of (1) impaired production resulting from hypoplasia or exaggerated apoptosis of marrow precursors (ineffective neutropoiesis) or (2) accelerated destruction of neutrophils are more difficult and complex than the techniques used to measure decreases in red cells or platelet concentrations. The low concentration of blood neutrophils, accentuated in neutropenic states, makes radioactive-labeling techniques for studying the kinetics of autologous cells in neutropenic subjects difficult, if not impossible.

Acronyms and Abbreviations: CD, cluster of differentiation; G-CSF, granulocyte colony-stimulating factor; HLA-DR, human leukocyte antigen-D related.

The two compartments of neutrophils in the blood (cells margined along vascular beds as distinct from cells circulating and counted in the blood neutrophil count [Chap. 65]), the random disappearance of neutrophils from the circulation, the short circulation time of neutrophils, the absence of practical techniques for measuring the size of the tissue neutrophil compartment, and the disappearance of neutrophils by apoptosis or excretion from the tissue compartment also make multi-compartmental kinetic analysis difficult. Also, neutropenic disorders are uncommon, and few laboratories are able, or prepared, to undertake the studies necessary to define the mechanisms of their development in sporadic cases. Therefore, efforts to understand the pathophysiology and kinetics of neutropenia have been of more limited success than that of red cells or platelets. Hence, the classification of neutrophil disorders is partly pathophysiologic and partly descriptive (see Table 64–1). Classification, although imperfect, does provide a language for communication and a basis for rectification as knowledge of the cause and mechanism of each entity advances.

The classification is self-explanatory except in two areas. First, certain childhood (congenital or hereditary) syndromes listed under decreased neutrophilic granulopoiesis could have been listed under chronic hypoplastic neutropenia or chronic idiopathic neutropenia; however, they seem to hold a special interest. Their unique status and their pathogenesis have become further clarified as the mutations linked to each are identified. Three childhood syndromes that are associated with neutropenia are omitted because the neutropenia is part of a more global suppression of hematopoiesis: Pearson syndrome,^{1,2} Fanconi anemia,^{3,4} and dyskeratosis congenita (Chap. 35).^{5,6}

A second area requiring explanation is the chronic idiopathic neutropenias. This group includes (1) cases with normocellular marrows but an inadequate compensatory increase in granulopoiesis for the degree of neutropenia and (2) cases with hyperplastic granulopoiesis that apparently is ineffective as a result of apoptosis of marrow neutrophils and late precursors. Unlike hypoplastic neutropenia in which the granulocyte precursors are markedly reduced or absent, precursors are present in the marrow in the idiopathic neutropenias, but the extent of effective granulopoiesis probably is low. A variety of mutations have been discovered that are causal for inherited or sporadic neutropenia syndromes. For example, mutation of the serine protease neutrophil elastase 2 gene (*ELANE*) is found in 70 percent of cases of the autosomal dominant form of severe congenital neutropenia and in most cases of cyclic neutropenia.⁷ Kostmann syndrome is the autosomal recessive form of severe congenital neutropenia and is caused by mutations in the *HAX1* gene.⁸ Some cases of severe congenital neutropenia have been related to mutations in *GPI1*, *G6PC3*, and others.^{9–11} There is evidence that these mutations result in apoptotic loss of marrow neutrophil precursors as a result of downregulation of the BCL-2 family of antiapoptotic proteins, the upregulation of the proapoptotic FAS receptor, or other apoptosis-enhancing pathways, described more fully in Chap. 65. A comprehensive listing of the genetic mutations found in monogenic congenital neutropenia and the extra hematopoietic manifestations of those disorders can be found in a publication of the Service d'Hématologie Oncologie Pédiatrique Registre des neutropénies.¹²

Qualitative disorders of neutrophils affect their ability to enter the circulation, to leave the circulation, enter inflammatory exudates, or to ingest or kill microorganisms. Chapter 66 describes these abnormalities in more detail.

CLINICAL MANIFESTATIONS

The clinical manifestations of decreased concentrations or abnormal function of neutrophils principally result from infection. The combined deficit of neutrophils and monocytes characteristic of aplastic anemia,

hairy cell leukemia, and cytotoxic therapy leads to susceptibility to a broader spectrum of infectious agents. Increased concentrations of normal neutrophils per se are usually not associated with clinical manifestations; although, increased concentrations of leukemic neutrophil precursors can produce clinical manifestations of microcirculatory leukostasis (Chap. 83). Neutrophils also play a role in deleterious vascular or tissue effects, as noted in the last entries in Table 64-1 (see “Neutrophilia” below).

NEUTROPENIA

The lower limit of the normal neutrophil count is approximately $1800/\mu\text{L}$ ($1.8 \times 10^9/\text{L}$) in subjects of European descent and $1400/\mu\text{L}$ ($1.4 \times 10^9/\text{L}$) in subjects of African descent.¹⁷⁴⁻¹⁷⁷ An additional small proportion (~5 percent) of persons of African descent have neutrophil counts between $1000/\mu\text{L}$ ($1.0 \times 10^9/\text{L}$) and 1400 ($1.4 \times 10^9/\text{L}$) without evidence of associated abnormalities and this finding also may represent “ethnic neutropenia.” These findings have not been explained by exaggerated margination of neutrophils.¹⁷⁶ Neutropenia is especially striking in Yemenite Jews, another ethnic group with very low “normal” neutrophil counts,¹⁷⁸ and has been reported in West Africans, Caribbean inhabitants of African descent, Ethiopians, and some Arab groups.^{176,177} Persons of African descent do not have the increase of neutrophil count seen in Europeans who smoke or are administered glucocorticoids; however, they have an appropriate increase of neutrophils in response to infection. Americans of Mexican descent have a slightly elevated neutrophil count.¹⁷⁶ A decrement in neutrophil concentration to $1000/\mu\text{L}$ ($1.0 \times 10^9/\text{L}$) usually poses little threat in the individual with an intact immune system. If the neutrophil count drops farther, the risk of infection may increase, if the decrease reflects a decrease in flux rate into the tissues. Subjects who are chronically neutropenic, as a result of severe marrow cell production abnormalities, with counts less than 500 neutrophils/ μL ($0.5 \times 10^9/\text{L}$) may be at heightened risk for developing recurrent infections.¹⁷⁹

The relationship of frequency or type of infection to neutrophil concentration is imperfect. The cause of the neutropenia, the coincidence of monocytopenia or lymphopenia, concurrent use of alcohol or glucocorticoids, exposure to nosocomial infections, and other factors influence the likelihood of infection. A breakdown in the barrier function of the skin or circumstances such as indwelling catheters, also, increase the risk of infection in severely neutropenic subjects. Lower neutrophil counts in African (Malawian) mothers infected with HIV were associated with an increased risk of HIV in their newborns.¹⁸⁰

Infections in neutropenic subjects who are not otherwise compromised usually result from Gram-positive cocci and usually are superficial, involving skin, oropharynx, bronchi, anal canal, or vagina. However, any site can become infected and Gram-negative organisms, viruses, or opportunistic organisms can be involved.

A decrease in neutrophil count can occur abruptly or gradually (Chap. 65). One type of drug-induced neutropenia is distinguished by the rapidity of onset. Abrupt-onset neutropenia more likely is severe and leads to symptoms. If the neutrophil count approaches zero (agranulocytosis), high fever; chills; necrotizing, painful oral ulcers (agranulocytic angina), and prostration may occur, presumably as a result of sepsis.¹⁸¹ As the disease progresses, headache, stupor, and rash may develop. In the preantibiotic era, persistent agranulocytosis had a fatality rate approaching 100 percent. Even with bactericidal, broad-spectrum antibiotics, severe, sustained neutropenia or agranulocytosis is a serious illness with a high fatality rate.

Pus formation decreases in patients with severe neutropenia.¹⁸² The failure to suppurate can mislead the clinician and delay identification of the infection site because minimal physical or radiographic findings

develop. For example, lack of pneumonic consolidation is characteristic of pneumonia in granulocytopenic subjects. An exudate, swelling, heat, and regional adenopathy are much less prevalent in granulocytopenic patients. Fever is common, and local pain, tenderness, and erythema nearly always are present despite a marked reduction in neutrophils.¹⁸¹

The mechanism of neutropenia and the severity of the deficiency of cells play roles in clinical manifestations. Chronic idiopathic (benign) neutropenia is associated with apparent normal granulopoiesis in the marrow and is asymptomatic even when the neutropenia has been present for prolonged periods, sometimes in the face of neutrophil counts approaching zero for prolonged periods.⁵⁰ Presumably the delivery of neutrophils from marrow to tissues is sufficient to prevent infection despite the low blood pool size. Monocyte counts are normal, which may aid in host defenses because monocytes are effective phagocytes.

Chronic idiopathic (symptomatic) neutropenia often is associated with pyoderma and otitis media in children. The former usually is caused by *Staphylococcus aureus*, *Escherichia coli*, and *Pseudomonas* species, and the latter usually results from infection by pneumococci or *Pseudomonas aeruginosa*. Unexplained chronic gingivitis may be a manifestation of chronic neutropenia. Pneumonia, lung abscesses, stomatitis, hepatic abscesses, or infections in other sites can occur.

Chronic cyclic neutropenia is characterized by periodic oscillations in the number of neutrophils, with the nadir occurring at approximately 3-week intervals.⁴³ During a period of neutropenia, patients develop malaise; fever; buccal, labial, or lingual ulcers; and cervical adenopathy. Furuncles, carbuncles, cellulitis, infected cuts with lymphangitis, chronic gingivitis, and abscesses of the axilla or groin may occur. Although severe infections may be fatal, life-threatening complications are uncommon. The cycling involves other hematopoietic cells as well, but the neutropenia is the most consequential functionally (Chap. 65).

Some individuals have neutropenia because a larger fraction of their blood neutrophils is in the marginal rather than the circulating pool. The total blood neutrophil pool is normal, and infections do not result from this atypical distribution of neutrophils. This alteration has been called *pseudoneutropenia*.⁷⁶⁻⁷⁸

NEUTROPHILIA

An increased neutrophil count can accompany virtually any cause of inflammation, especially inflammation caused by bacterial or fungal organisms, and a variety of cancers, especially if metastatic. Certain drugs, such as glucocorticoids or hematopoietic growth factors and minocycline, can induce neutrophilia, as can ethylene glycol intoxication (see Table 64-1). Acute hemolysis or acute hemorrhage may also result in neutrophilia. A notable cause of neutrophilia is cancers that elaborate granulocyte-colony stimulating factor (G-CSF). Numerous cancers are associated with neutrophilia and, in many cases, elaboration of very high concentrations of G-CSF has been documented. In these cases, neutrophil counts exceeding $100,000/\mu\text{L}$ ($100 \times 10^9/\text{L}$) are common. Neutrophilia exceeding $50,000$ neutrophils/ μL ($50 \times 10^9/\text{L}$) has been designated a “leukemoid reaction” and reflects an underlying inflammatory (e.g., pancreatitis), infectious (e.g., pneumococcal pneumonia), or neoplastic (e.g., carcinoma of the lung) cause. A leukemoid reaction can mimic rare types of chronic myelogenous or chronic neutrophilic leukemia. The leukemoid reaction classically (1) is composed largely of mature neutrophils with a low proportion of bands and myelocytes, (2) has increased leukocyte alkaline phosphatase reaction in neutrophils, (3) has increased granulopoiesis with normal maturation and morphology of cells in the marrow, (4) has normal cytogenetics of marrow cells, (5) has polyclonal-derived cells in women in whom such studies can be conducted (using the human androgen receptor gene assay), and (6) has cytometric analysis of neutrophils indicating a cluster

of differentiation (CD) 13 and CD15 phenotype with absent expression of human leukocyte antigen-D related (HLA-DR) and CD34.

● QUALITATIVE NEUTROPHIL ABNORMALITIES

Neutrophil function depends on the ability of neutrophils to exit the marrow, adhere to vascular endothelium, move, respond to chemotactic gradients, ingest microorganisms, and kill ingested pathogens. Loss of any of these functions can predispose to infection (Chap. 66). Defects in each step of the neutrophil's participation in the inflammatory response have been identified. Defects in adhesion molecules, cytoplasmic contractile proteins, granule synthesis or contents, or intracellular enzymes may underlie a movement, ingestion, or killing defect. These defects may be inherited or acquired. Chronic granulomatous disease^{113,114} and Chédiak-Higashi disease^{145,146} are two examples of inherited defects. Among the acquired disorders are those extrinsic to the cell, as in the movement, chemotactic, or phagocytic defects of diabetes mellitus, the effects of alcohol abuse, or glucocorticoid excess. Acquired intrinsic disorders usually are manifestations of clonal hematopoietic (myeloid) disorders such as acute myelogenous leukemia (Chap. 85).

Severe defects in bacterial killing, as occur in chronic granulomatous disease, result in *S. aureus*, *Klebsiella-Aerobacter*, *E. coli*, and other catalase-positive bacterial infections. Suppurative lymphadenitis, pneumonia, dermatitis, hepatic abscesses, osteomyelitis, and stomatitis occur, and chronic granulomatous reactions in these sites give the disease its name. Fatality rates have been high. Functional disorders may be severe, as in chronic granulomatous disease. Mild functional disorders predispose to infections that occur infrequently and respond readily to antibiotics. Severe functional disorders result in suppurative lesions because neutrophil influx into inflammatory foci is not impaired, whereas agranulocytosis is associated with nonsuppurative lesions.

NEUTROPHIL-INDUCED VASCULAR OR TISSUE DAMAGE

An overabundance of neutrophils does not result in specific clinical manifestations. Neutrophils, however, can transiently occlude capillaries, as determined by supravital microscopy, and such occlusions may reduce local blood flow transiently and contribute to the development of ischemia. Impairment of reperfusion of the coronary microcirculation has been thought to be dependent, in part, on neutrophil plugging of myocardial capillaries, but these effects can occur at normal neutrophil concentrations. An elevated neutrophil count is a feature of sickle cell disease and is a prognostic variable, increasing the likelihood of vasoocclusive events. Neutrophil adhesion to the vascular wall is an intrinsic part of the vasoocclusive events and the salutary effect of hydroxyurea is related to the decrease in neutrophil concentration that accompanies its use.^{157,173} In patients with ischemic vascular disease, an increased neutrophil count is associated with an increased probability of acute thrombotic episodes and the severity of chronic atherosclerosis.¹⁸³

Neutrophil products may contribute to the pathogenesis of inflammatory skin, bowel, synovial, glomerular, and bronchial and interstitial pulmonary diseases (see Table 64-1). Diabetic retinopathy has been ascribed in part to the effects of hyperadhesive neutrophils on retinal capillaries.¹⁵⁷ Neutrophils may act as mediators of tissue injury in stroke and myocardial infarction.¹⁵⁷ Highly reactive oxygen products of neutrophils may be mutagens that increase the risk of neoplasia. This action may explain, for example, the development of carcinoma of the bowel in patients with chronic ulcerative colitis and the relationship between elevated leukocyte count and the occurrence of lung cancer, independent

of the effect of cigarette usage. The oxidants, especially hypochlorous acid and chloramines, released by the neutrophil are extremely short lived and may play a role in tissue injury by inactivating several protease inhibitors in tissue fluids, permitting proteases, especially elastase, collagenase, and gelatinase, to cause tissue injury. Thrombogenesis also has been ascribed to leukocyte products.

CHAPTER 65

NEUTROPENIA AND NEUTROPHILIA

David C. Dale and Karl Welte

SUMMARY

Neutropenia designates a blood absolute neutrophil count that is less than 2 SD below the mean of a normal population. Neutropenia can be inherited or acquired. It usually results from decreased production of neutrophil precursor cells in the marrow. Neutropenia also can result from a shift of neutrophils from the circulating into the marginated cell pools in the circulation. Less commonly, neutropenia results from accelerated destruction of neutrophils or increased egress of neutrophil from the circulation into the tissues. When neutropenia is the sole or dominant abnormality, the condition is called “selective” or “isolated” neutropenia, such as severe congenital neutropenia, chronic idiopathic neutropenia, or drug-induced neutropenia. Neutropenia can occur in other inherited or acquired marrow failure syndromes, such as severe aplastic anemia or Fanconi anemia, in which the condition is a bicytopenia or pancytopenia. In some diseases, several cell lineages are mildly affected but the reduction in neutrophil is the most severe, such as Feltz syndrome. Neutropenia may be an indicator of an underlying systemic disease, such as early vitamin B₁₂ or transcobalamin deficiency. Neutropenia, particularly severe neutropenia (neutrophil counts $<0.5 \times 10^9/L$ [$500/\mu L$]), increases susceptibility to bacterial or fungal infections and impairs the resolution of these infections. Therapy with the hormone primarily responsible for neutrophil production, granulocyte colony-stimulating factor, can increase blood neutrophil counts for most types of neutropenia, although whether its administration makes a clinically useful impact is dependent on the origin, duration and severity of the neutropenia. Clinical guidelines have been published on the rational use of the drug.

Neutrophilia is an increase in the absolute neutrophil count to a concentration greater than 2 SD above the normal population mean value. Neutrophilia contributes to the inflammatory response and to resolution of infections. Inflammatory and infectious diseases are the most frequent causes of neutrophilia. Bacterial infections usually produce neutrophilia, whereas viral infections may not produce neutrophilia or may raise the neutrophil count only slightly. Solid tumors occasionally engender striking neutrophilia. Hereditary neutrophilia can be caused by activating mutations within the *CSF3R* gene. When the neutrophil count is very high, it may be referred to as a leukemoid reaction. The rare neutrophilic variants of chronic myeloid leukemia and chronic neutrophilic leukemia may result in striking neutrophilia. Demargination of neutrophils or rapid release of neutrophils from a large marrow pool may transiently increase the blood neutrophil count. Sustained increased require increased production of these cells.

Acronyms and Abbreviations: ANA, antinuclear antibody; BTK, Bruton tyrosine kinase; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; Ig, immunoglobulin; IL, interleukin; TRAIL, tumor necrosis factor-related apoptosis-inducing ligand.

● NEUTROPENIA

Neutropenia refers to an absolute blood neutrophil count (total leukocyte count per microliter \times percent of neutrophils) that is less than 2 SD below the normal mean of the population. The terms *leukopenia*, a reduced total white blood cell count, and *granulocytopenia*, reduced numbers of blood granulocytes (neutrophils, eosinophils, and basophils), sometimes are imprecisely used as synonyms for neutropenia. *Agranulocytosis* literally means a complete absence of blood granulocytes, but this term often is used to indicate severe neutropenia, that is, counts less than $0.5 \times 10^9/L$ ($0.5 \times 10^3/\mu L$).

The concentration of neutrophils in blood is influenced by age, activity, and genetic and environmental factors (Chap. 2). For children from 1 month to 10 years old, neutropenia is defined as a blood neutrophil count less than $1.5 \times 10^9/L$. For individuals older than age 10 years, neutropenia is defined as a count less than approximately $1.8 \times 10^9/L$ (see Chap. 7 regarding levels in newborns). Healthy older persons have the same blood neutrophil counts as younger individuals (Chap. 9). Some racial and ethnic groups, such as Africans, African Americans, and Yemenite Jews, have lower mean neutrophil counts than persons of Asian or European ancestry (see Chap. 2, Table 2–2). The mean differences in neutrophils are modest and have no recognized health consequences.^{1,2}

Severe neutropenia is a predisposing factor for infections. The organisms normally are found on the skin, in the nasopharynx, and as part of the intestinal flora. The risk of infections is inversely related to the severity of the neutropenia (Chap. 24). Individuals with neutrophil counts of 1.0 to $1.8 \times 10^9/L$ are at little risk of infection. In general, neutrophil counts between 0.5 and $1.0 \times 10^9/L$ are associated with only slight risk of infection unless other contributing factors are present. Individuals with neutrophil counts less than $0.5 \times 10^9/L$ are at substantially greater risk, but the frequency of infections varies considerably, depending on the cause and duration of neutropenia. Severe acute neutropenia (i.e., developing over a few hours or days) usually is associated with greater risk of infection than severe chronic neutropenia (usually present for months or years). Neutropenia resulting from disorders of production that affect early hematopoietic precursor cells (e.g., aplastic anemia, severe congenital neutropenia) leads to greater susceptibility to infections than do conditions with adequate neutrophil precursors in the marrow and neutropenia attributed to accelerated turnover in the blood (e.g., rheumatoid arthritis, Feltz syndrome, autoimmune neutropenia). For patients made severely neutropenic by cancer chemotherapy, the risk is greater when the neutrophils are decreasing than with similar counts when neutrophils are increasing. Neutropenia accompanied by monocytopenia, lymphocytopenia, or hypogammaglobulinemia is more serious than isolated neutropenia. Other factors, such as the integrity of the skin and mucous membranes, the vascular supply to tissues, and the nutritional status of the patient, also influence the risk of infections.

PATHOPHYSIOLOGIC MECHANISMS

General Mechanisms

Neutropenia occurs because of (1) hypoplastic neutropoiesis, (2) ineffective neutropoiesis (resulting from exaggerated apoptosis of late precursors), (3) accelerated removal or utilization of circulating neutrophils, (4) shifts of cells from the circulating to the marginal blood pools, or (5) a combination of these mechanisms (Fig. 65–1). Some production disorders are caused by intrinsic abnormalities of hematopoietic progenitor cells (Chap. 83). Other disorders in cell production are caused by extrinsic factors, including changes in the marrow environment, such as tumor infiltration, fibrosis, or irradiation (Chap. 45).

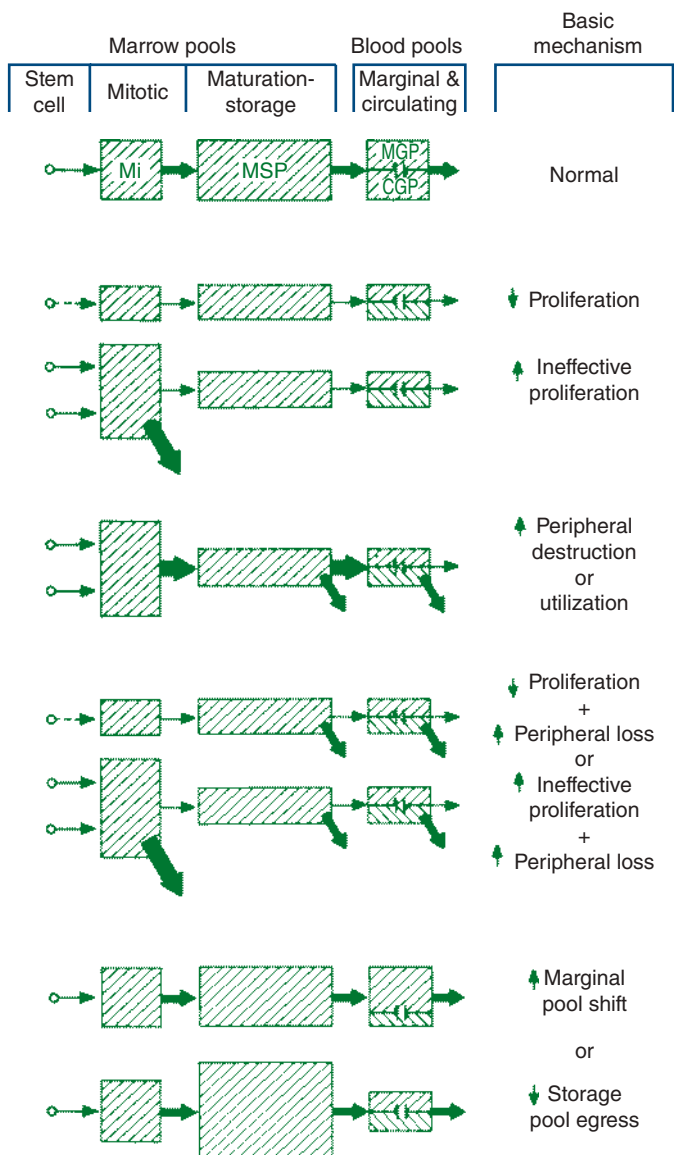

Figure 65-1. Mechanisms of neutropenia are shown schematically. The size of each pool is represented by the size of the *cross-hatched areas*. The rate of flow of cells through each compartment is represented by the size of the *arrows*. CGP, circulating granulocyte (neutrophil) pool; MGP, marginated granulocyte (neutrophil) pool; Mi, mitotic; MSP, maturation (marrow storage) pool.

Myelotoxic chemotherapeutic drugs commonly cause neutropenia because of the high proliferative activity of neutrophil precursors in the marrow and short half-life (4 to 8 hours) of neutrophils in the blood. Production of neutrophils is defined as ineffective when, under a steady state of hematopoiesis, a relative abundance of early neutrophil precursors, a paucity of late-maturing cells, and neutropenia occur. This condition has often been referred to as “maturation arrest,” but it is almost always explained by either the apoptotic loss of late precursors in the marrow as an intrinsic defect in cell maturation or rapid release of segmented neutrophils because of exaggerated tissue demands.

Accelerated neutrophil utilization occurs with autoimmune neutropenia and acute bacterial infections. When rapid neutrophil utilization and impaired production occur, acute severe neutropenia often develops. The condition is illustrated by the abrupt and sustained fall

in neutrophils when an alcoholic patient develops pneumococcal pneumonia. Alcohol suppresses the marrow, and the infection consumes the available neutrophil supply. After myelotoxic cancer chemotherapy, the abrupt fall in blood neutrophils at the onset of infections reflects a similar mechanism: high demand and limited supply. With idiosyncratic drug-induced neutropenia, the counts may fall abruptly because both blood and marrow cells are simultaneously damaged. Acute neutropenia that develops because of a shift of blood neutrophils from the circulating to the marginal blood pools, that is, increased margination (e.g., after injection of endotoxin, with exposure of blood to dialysis membranes, or after intravenous granulocyte colony-stimulating factor [G-CSF] or granulocyte-macrophage colony-stimulating factor [GM-CSF]) usually is a transient event. The marginated cells reenter the circulating pool, and the blood supply of neutrophils is rapidly restored from the large reserves of marrow neutrophils entering the blood.

Cellular and Molecular Mechanisms of Neutropenia

Our understanding of the mechanisms of neutropenia at the cellular and molecular levels is increasing rapidly because of advances in molecular genetics and cell biology. For many inherited forms of neutropenia, the genetic mutations causing these diseases are now known, and the mutant protein products have been identified. Some mutations and acquired defects shorten the survival of the precursor cells, that is, they accelerate apoptosis. This form of cell loss now is thought to be the mechanism for “maturation arrest” in several diseases. Examples of increased apoptosis causing neutropenia include vitamin B₁₂ or transcobalamin deficiency,³ clonal cytopenias (myelodysplasia),⁴ myelokathexis,⁵ congenital and cyclic neutropenia,^{6,7} and the Shwachman-Diamond syndrome.⁸ Neutrophils also can be depleted from the blood and the marrow as a result of extrinsic factors such as antineutrophil antibodies and toxic cytokines generated by other cells.^{9,10} Some disorders that cause neutropenia also perturb neutrophil function, such as glycogen storage disease type 1b,¹¹ Chédiak-Higashi syndrome,¹² and HIV infection.¹³ Susceptibility to infection in these conditions relates to the combination of defects.

CAUSES OF NEUTROPENIA

Causes of neutropenia are classified physiologically as disorders of production, distribution, or turnover. Not every condition fits neatly into this scheme, but it provides a framework for understanding these diverse disorders.

Disorders of Production

Cytotoxic drugs given for cancer chemotherapy and as immunosuppressive agents regularly cause neutropenia by decreasing cell production (Chap. 22). These drugs now are probably the most frequent cause of neutropenia in the United States. Neutropenia as a result of impaired production is a common feature of several diseases affecting hematopoietic stem cells, such as acute leukemia (Chaps. 88 and 91), the myelodysplastic syndromes (Chap. 87), and aplastic anemia (Chap. 35). The selective causes of impaired production, progressing from disorders of early precursors to disorders presumed to involve defective maturation (ineffective production), are described briefly as follows.

Congenital Neutropenias (Kostmann Syndrome and Related Disorders) In 1956, Kostmann described congenital neutropenia (agranulocytosis) as an autosomal recessive disease occurring in an extended family in northern Sweden.¹⁴ Phenotypically similar sporadic cases and families with autosomal dominant congenital neutropenia have been reported.^{15,16} In severe congenital neutropenia, symptoms and signs of otitis, gingivitis, pneumonia, enteritis, peritonitis, and bacteremia usually begin in the first months of life. At diagnosis,

Figure 65–2. Morphology of a marrow sample from a patient with congenital neutropenia showing the maturation arrest at the level of promyelocytes.

the neutrophil count usually is less than $0.2 \times 10^9/L$.¹⁷ Monocytosis, mild anemia, thrombocytosis, and splenomegaly frequently are present. Characteristically, the marrow shows early neutrophil precursors (myeloblasts, promyelocytes) but few or no myelocytes or mature neutrophils (Fig. 65–2). Marrow eosinophilia is common. *In vitro* marrow culture studies show poor growth in response to various growth factors and with reduced numbers of marrow neutrophil and monocyte progenitor cell colonies.¹⁸ Usually blood lymphocyte numbers are normal, immunoglobulin levels are normal or increased, and lymphocyte functions are intact.

The majority of patients with sporadic or autosomal dominant severe congenital neutropenia have heterozygous mutations of the gene for neutrophil elastase (also called *ELANE*). Its product is a protease found normally in the neutrophil's primary granules and lead to the induction of the unfolded protein response in the endoplasmic reticulum.^{15,19,20} A variety of mutations in exons 2 through 5 as well as in introns III and IV are the cause of this disease.^{20–23} In the original Kostmann family, and some other families with autosomal recessive disease, neutropenia is caused by mutations in the *HAX-1* gene.²⁴ *HAX-1* is a mitochondrial protein, and the mutations lead to accelerated apoptosis of myeloid cells, as well as neurologic abnormalities. In addition, mutations in *HAX-1* lead to defective G-CSF receptor signaling via *HCLS1* and *LEF-1*.²⁵ Mutations in the gene for glucose-6-phosphatase catalytic subunit 3 (*G6PC3*) also cause severe neutropenia as a result of apoptosis of neutrophil precursors, as well as congenital cardiac and urogenital abnormalities.²⁶ Additional autosomal-dominant, autosomal-recessive, X-linked, and sporadic forms have been described, with mutations in other genes, including *GFII*,²⁷ *WAS*,²⁸ *p14*,²⁹ *TAZ*,³⁰ *JAGN1*,³¹ *TCIRG1*,³² and many others, although the genetic causes in many patients with severe congenital neutropenia remain unidentified.

Mutations in the gene for the receptor for G-CSF also occur in patients with severe congenital neutropenia^{33,34}; however, most of these receptor mutations have caused truncations of the distal portion of the cytoplasmic domain of the receptor, an abnormality associated with altered sensitivity to G-CSF. G-CSF receptor mutations are part of the evolution to myelodysplasia or acute myelogenous leukemia and are not the primary cause of this neutropenia. An exception may be a patient identified with a mutation in the external domain of the G-CSF receptor who responded to treatment with G-CSF and glucocorticoids and has not developed leukemia over several years of observation.³⁵ There are

rare cases of biallelic mutations within the extracellular domain of the G-CSF receptor which lead to nonresponse to treatment with G-CSF.³⁶

G-CSF is a very effective therapy for all of the recognized subtypes of severe congenital neutropenia, increasing the neutrophil counts and reducing recurrent fevers and infections.³⁷ G-CSF acts to increase the neutrophil counts by enhancing expression of a critical transcription factor for granulopoiesis, *C/EBPβ* (CCAAT/enhancer binding protein β), and the “emergency” pathway of myelopoiesis (as during steady state *C/EBPα* is not functional).³⁸ Approximately 5 percent of patients do not respond to G-CSF. Hematopoietic transplantation is the only other therapy known to improve the clinical course for these patients.^{39,40} Untreated patients and patients treated with G-CSF are at risk for developing acute myelogenous leukemia. The risk increases with time on treatment with G-CSF, particularly in poorly responsive patients.⁴¹ A novel molecular pathway of leukemogenesis was recently identified: mutations in the hematopoietic cytokine receptor (G-CSFR) in combination with the second mutations in the downstream hematopoietic transcription factor (*RUNX1*), which could be used as a marker for identifying severe congenital neutropenia patients with a high risk of progressing to leukemia or myelodysplastic syndrome.⁴²

Congenital Immunodeficiency Diseases Neutropenia is a feature of the congenital immunodeficiency diseases and a contributing factor to their susceptibility to infections (Chap. 80). In most of these conditions, neutropenia is attributed to a production disorder based largely on histologic examination of the marrow. In X-linked agammaglobulinemia, which is attributed to defective B-cell development and a mutation in a cytoplasmic (Bruton) tyrosine kinase (*BTK*), severe neutropenia is present in approximately 25 percent of patients.⁴³ Children with common variable immunodeficiency often have neutropenia associated with thrombocytopenia and hemolytic anemia.⁴³ Neutropenia occurs in almost half of patients with the X-linked hyperimmunoglobulin-M syndrome, a disorder caused by a mutation in the gene encoding the CD40 ligand.⁴⁴ In severe combined immunodeficiency, neutropenia is not always present. The neutropenia varies over time in individual patients. Neutropenia is particularly prominent in the rare immunodeficiency state, reticular dysgenesis.⁴³ Neutropenia is a less-common feature of adenosine deaminase deficiency, the T–B+, T–B–, Wiskott–Aldrich, and Omenn syndromes.^{43,45,46} Neutropenia also occurs on an autoimmune basis in some cases of the Wiskott–Aldrich syndrome.^{34,46} Mutations in the genes for growth factor independent protein-1 (*GFI 1*) can also cause neutropenia.⁴⁷

G-CSF therapy is effective in most patients with neutropenia associated with these immunodeficiency syndromes.

Cartilage Hair Hypoplasia Syndrome This rare autosomal recessive disorder is characterized by short-limbed dwarfism, hyperextensible digits, very fine hair, neutropenia, lymphopenia, and recurrent infections.⁴³ The genetic locus is at 9p13 and affects a gene coding for an endoribonuclease. The degree of neutropenia is variable, with blood counts ranging from 0.1 to $2.0 \times 10^9/L$. An accompanying defect in T-cell proliferation results from an abnormality in the transition from the G_0 to the G_1 phase of the mitotic cycle. Patients have frequent bacterial and viral respiratory infections. Hematopoietic stem cell transplantation can correct the neutropenia and immune deficiency.^{48,49}

Shwachman-Diamond Syndrome This autosomal recessive disorder combines short stature, pancreatic exocrine deficiency, and marrow failure with neutropenia beginning early in the neonatal period.^{50–53} Thrombocytopenia and anemia may be severe (Chap. 35). The chromosomal locus of the mutation is at 7qll, and the mutation affects the *SBDS* gene.⁵⁰ The mutation causes a proliferative defect and increased apoptosis of early myeloid progenitor cells.⁵¹ A chemotactic defect also occurs in mature neutrophils.⁵² The patients are malnourished, but the neutropenia is not corrected by improving the patients' nutritional status.

Treatment with G-CSF raises blood neutrophil levels, and hematopoietic stem cell transplantation corrects the hematologic abnormalities.⁵³ Without transplantation, the risk of evolution to myelodysplastic syndrome and acute myelogenous leukemia is 20 percent or greater.⁵³

Diamond-Blackfan Syndrome Neutropenia is a rare complication of hereditary hypoplastic anemia.⁵⁴ Other features include congenital anomalies of the head and upper limbs. Two genetic loci have been identified: 19q13.2 and 8p23.^{55,56} The varying severity of neutropenia may reflect genetic heterogeneity among patients with this diagnosis (Chap. 36).

GrisCELLI Syndrome This rare autosomal recessive disorder is characterized by pigmentary dilution and variable degrees of cellular immunodeficiency. The syndrome consists of three types. Neutropenia is a feature of type 2 but not types 1 or 3. In type 2, the neutropenia is relatively mild and associated with pancytopenia. These hematologic abnormalities are attributable to a mutation located at 15q21 affecting the *RAB27a* gene.⁵⁷ The gene product is a guanosine triphosphatase (GTPase). The mutation also causes abnormal release of granule proteins and hemaphagocytosis.⁵⁸ As in the Chédiak-Higashi syndrome (Chap. 66), type 2 patients may develop an acute phase of uncontrolled lymphocyte and macrophage activation leading rapidly to death.⁵⁹ Hematopoietic stem cell transplantation can correct the hematologic features. Evolution to myelodysplasia has been reported.⁶⁰

Chédiak-Higashi Syndrome This rare autosomal recessive disorder is characterized by partial oculocutaneous albinism, giant granules in many cells (including granulocytes, monocytes, and lymphocytes), neutropenia, and recurrent infections (Chap. 66). This syndrome now is attributable to a chromosomal mutation at 1q43 affecting the *LYST* gene.⁶¹ The product of this gene regulates lysosomal trafficking. In Chédiak-Higashi syndrome, the neutropenia usually is mild, and susceptibility to infection is attributed to neutropenia and defective microbicidal activity of the phagocytes.⁶²

Myelokathexis, WHIM, and Related Syndromes Myelokathexis is a rare autosomal dominant or sporadically occurring disorder in which patients have severe neutropenia and lymphocytopenia, with total white cell counts often less than $1.0 \times 10^9/L$.⁶³ WHIM syndrome, characterized by warts, hypogammaglobulinemia, infections, and myelokathexis, now is attributable to a mutation in the gene encoding the receptor for the CXC chemokine CXCL12 (previously termed stromal cell-derived factor-1), termed CXCR-4.^{64,65} The ligand-receptor pair CXCL-12/CXCR-4 is important for regulating the trafficking of all type of blood and marrow cells, including hematopoietic stem cells, from the marrow to the blood and tissues. In these syndromes, the marrow usually shows abundant precursors and developing neutrophils. Neutrophils in the marrow and the blood show hypersegmentation with pyknotic nuclei and cytoplasmic vacuoles. These morphologic changes and some molecular studies suggest cell loss in the marrow and blood caused by accelerated apoptosis. Favorable responses to G-CSF and GM-CSF occur, as does evolution to the myelodysplastic syndrome. A myelokathexis-like variant of myelodysplastic syndrome has been reported.⁶⁶

Cohen Syndrome Cohen syndrome is another rare cause of neutropenia. Mental retardation, postnatal microcephaly, facial dysmorphism, pigmentary retinopathy, myopia, and intermittent neutropenia are characteristic features. Patients with Cohen syndrome of diverse origins have mutations in the *COH1* gene.⁶⁷ Current studies suggest that *COH1* plays a role in vesicle-mediated sorting and transport of proteins within many types of cells.

Glycogen Storage Diseases These autosomal recessive disorders are characterized by hypoglycemia, hepatosplenomegaly, seizures, and failure to thrive in infants. Only type 1b is associated with neutropenia.⁶⁸ The genetic defect in type 1b maps to chromosome 11q23 and is

attributed to a defect in an intracellular transport protein for glucose.⁶⁹ The marrow appears normal despite severely reduced blood neutrophils. The neutrophils have a reduced oxidative burst when stimulated and defective chemotaxis.^{70,71} Treatment with G-CSF is effective for correcting the neutropenia and improving the associated inflammatory bowel disease, but has been associated with evolution to acute myelogenous leukemia.⁷²

Cyclic Neutropenia Cyclic neutropenia is an autosomal dominant or sporadically occurring disease characterized by regularly recurring episodes of severe neutropenia, usually every 21 days.⁷³ Regular oscillations of other white cells, reticulocytes, and platelets are sometimes observed. Cyclic neutropenia now is attributable to mutations in the gene for neutrophil elastase (*ELANE*) at locus 19q3. Most mutations in the *ELANE* gene are in the regions of exons 4 and 5, but there are also mutations in exons 2 and 3, as well as in the introns II and IV.^{74,23} The diagnosis usually is made in the first year of life, especially in the presence of a family history of the condition.⁷⁵ The neutropenic periods last for 3 to 6 days and often are accompanied by fever, malaise, anorexia, mouth ulcers, and cervical lymphadenopathy. A few cases of acquired cyclic neutropenia in adults, some of whom have an associated clonal proliferation of large granular lymphocytes (Chap. 94), have been reported.⁷⁶

The diagnosis of cyclic neutropenia can be made only by serial differential white cell counts, at least two or three times per week for a minimum of 6 weeks. Sequencing of the gene may be helpful in confirming the diagnosis.⁷⁷ Most affected children survive to adulthood, with symptoms often milder after puberty. Fatal clostridial bacteremia has been reported in several cases, and careful observation is warranted with each neutropenic period in untreated patients. Treatment with G-CSF is very effective.⁷⁸ G-CSF does not abolish cycling, but it shortens the neutropenic periods sufficiently to prevent symptoms and infections. In contrast to severe congenital neutropenias, cyclic neutropenia patients have no risk to develop leukemias.

Other Inherited Neutropenia Neutropenia caused by genetic defects of folate, cobalamin, and transcobalamin IIA varieties of congenital disorders lead to disturbed function of methylmalonyl coenzyme A mutase and methionine synthetase, the two cobalamin-requiring enzymes. Each of these disorders causes neutropenia, anemia, and thrombocytopenia as a result of ineffective hematopoiesis (Chap. 41).⁷⁹⁻⁸¹

Several disorders, currently with only descriptive names, may be genetically determined forms of neutropenia. These cases often are called familial (benign) neutropenia and probably are autosomal dominant disorders.⁸²⁻⁸⁴ Some cases of chronic benign neutropenia of childhood (usually a negative family history) may represent new mutations, and patients with chronic idiopathic neutropenia of adulthood may be childhood cases escaping early detection. Until better information is available, these conditions probably are best referred to as “idiopathic neutropenias.”

Acquired Disorders Neutropenia in Neonates of Hypertensive Mothers Hypertensive women often have low-birth-weight infants with low neutrophil counts, attributed to decreased production.⁸⁴ The neutropenia often is severe with a high risk of infection, particularly during the first few weeks of life. The neutropenia usually resolves within a few weeks. G-CSF elevates the neutrophil count in this form of neonatal neutropenia, but the clinical benefit of treatment remains to be determined.⁸⁵

Neutropenia Resulting from Nutritional Deficiencies Neutropenia is an early and consistent feature of megaloblastic anemias resulting from vitamin B₁₂ or folate deficiency. When present it usually is accompanied by macrocytic anemia and mild thrombocytopenia (Chap. 41). Copper deficiency can cause neutropenia in patients on total

parenteral nutrition, with a history of gastrectomy, and in malnourished children^{86–88} and the bicytopenia or tricytopenias with a marrow showing dysplastic precursors can masquerade as myelodysplastic syndrome.

Neutropenia Resulting from Immune Suppression of Production Pure white cell aplasia is a rare acquired disorder causing severe selective neutropenia. The marrow is devoid or nearly devoid of neutrophils and their precursors.⁸⁹ Ibuprofen, chlorpropamide, excessive zinc, and various infectious and inflammatory diseases are considered possible causes of this syndrome. Differential diagnosis includes aplastic anemia, myelodysplasia, hairy cell leukemia, and neutropenia associated with the large granular lymphocyte syndrome. Immunosuppressive therapy with antithymocyte globulin, glucocorticoids, and cyclosporine has been used in individual cases.

Chronic Idiopathic Neutropenia in Adults This is a distinct syndrome predominantly affecting young adult women ages 18 to 35 years; the female-to-male ratio is approximately 8:1.⁹⁰ The medical history (lack of episodes of fever, gingivitis, mouth sores, or other infections) and previous blood counts suggest the condition is acquired in most cases. Erythrocyte, reticulocyte, and platelet counts usually are normal. Mild leukopenia and lymphocytopenia may be present, and the spleen is normal or only minimally enlarged. The patients have no chromosomal abnormalities or other evidence of myelodysplasia.^{91,92} Marrow examinations show a spectrum of abnormalities, ranging from normal cellularity to selective hypoplasia of the neutrophilic series. In most cases, quantitative marrow studies show the ratio of immature to mature cells is increased, suggesting loss of cells during the maturation process, that is, ineffective granulocytopenesis.⁹³ Antineutrophil antibodies, autoantibodies, including antinuclear or antimitochondrial antibodies, are absent.⁹⁴ Chronic idiopathic neutropenia in adults is the result of accelerated apoptosis of neutrophils and their precursors mediated via the Fas ligand or interferon- γ .⁹⁵ The disease mechanism, that is, activation of the extracellular apoptotic pathway, is similar to the mechanism described for patients with systemic lupus erythematosus.⁹⁶

For most patients, the clinical course can be predicted from the level of blood neutrophils, marrow examination, and prior history of fevers and infections. In general, patients with the lowest levels of blood and marrow neutrophils have the most frequent problems. Long-term observations show, however, that some patients have very low blood neutrophil levels for long periods with few or no infections. Evolution to acute leukemia or aplastic anemia generally does not occur. G-CSF increases neutrophils in most patients and is a useful therapy for patients with recurrent fever and infections.^{37,97}

DISORDERS AFFECTING NEUTROPHIL UTILIZATION AND TURNOVER

Mechanisms of Immune Neutropenia

Immune disorders primarily alter the distribution of neutrophils in the blood and accelerate neutrophil turnover. Antineutrophil antibodies cause transfusion reactions, alloimmune neonatal neutropenia, and autoimmune neutropenia. Antigen-antibody complexes, autoantibodies, and cytokine-mediated cellular injury are possible contributors to neutropenia of systemic lupus erythematosus and Felty syndrome. The association of neutropenia with increased numbers of circulating large granular lymphocytes demonstrates that cellular and humoral immune mechanisms can cause neutropenia (Chap. 94).

Neutrophils share surface antigens with other tissues including the i-I antigens and human leukocyte antigens (HLAs). They also have some specific antigens, including NA-1, NA-2 (now recognized as isotypes of Fc γ RIII or CD16), NB-1, NC-1, and NC-9a.^{98–100} A number of other

antigens can be identified on neutrophils and neutrophil precursors with monoclonal antibodies. The clearest associations of autoantibodies and neutropenia are with NA-1 and NA-2.¹⁰¹

Several tests are available for detecting antineutrophil antibodies, including agglutination and microagglutination, cytotoxicity, direct and indirect immunofluorescence, direct and indirect antiglobulin assays, and tests involving the binding of staphylococcal protein A to immunoglobulins on the surface of cells.¹⁰¹ The agglutination tests are the oldest methods and depend on the propensity of immunoglobulin-coated cells to aggregate. Immunofluorescence tests utilize antihuman γ -globulin tagged with a fluorescein label. These tests can be adapted for quantitative studies with fluorescence-activated cell sorting. Immunofluorescence and staphylococcal protein A-binding tests also can be adapted for examining immunoglobulins bound to single cells, including marrow cells. Direct methods are used to detect the antibodies on the patient's neutrophils. Indirect methods are used to test the patient's plasma or serum against panels of normal cells. Use of paraformaldehyde to expose antigens and to preserve the neutrophils for multiple tests has been especially helpful. Appropriate controls are essential for proper interpretation of these studies. Measurements of apoptosis and cytokine-mediated cellular injury are done through research laboratories.

Causes of Immune-Mediated Neutropenia

Alloimmune Neonatal Neutropenia Newborn infants may have neutropenia for a variety of reasons.¹⁰² In some cases, the disorder results from transplacental passage of maternal immunoglobulin (Ig) G antibodies that bind to the infant's neutrophil-specific antigens, usually the Fc γ RIIIb (HNA1 or CD16b) isotype inherited from the infant's father.^{103,104} Other antigens, such as NB1 glycoprotein (NB1 or CD177), HNA-3a(5b), HLA, and unknown antigens, also may be involved.¹⁰¹ Overall, this disorder occurs in approximately 1 in 2000 neonates. The disorder usually lasts 2 to 4 months until the passively acquired antibody is lost.

Immune neonatal neutropenia may be severe or relatively mild. It often is not recognized until bacterial infections occur in an otherwise healthy infant. The hematologic picture usually consists of severe neutropenia with normal to increased lymphocytes and normal monocytes, erythrocytes, and platelets. Marrow cellularity is normal or increased, with reduced numbers of mature neutrophils. Alloimmune neonatal neutropenia may be confused with neonatal sepsis because the latter condition also causes severe neutropenia. The diagnosis of alloimmune neutropenia usually is made using neutrophil agglutination or immunofluorescence tests. Treatment should be conservative; antibiotics are used only when necessary. Exchange transfusions to decrease antibody titers or neutrophil transfusions from the patient's mother are rarely needed.

Autoimmune Neutropenia Neutrophil autoantibodies can decrease neutrophil survival and impair neutrophil production. From a clinical perspective, however, distinguishing autoimmune neutropenia from chronic idiopathic neutropenia often is difficult.¹⁰⁵ Patients diagnosed with autoimmune neutropenia have one or more positive tests for antineutrophil antibodies. Their cytopenia is selective; other blood cell counts are normal or near normal. Marrow morphology (Fig. 65–3), colony forming cells, and other tests, including antinuclear antibody tests, are normal. In general, therapy should be conservative and expectant. Intravenous γ -globulin may transiently increase neutrophils, but the therapy is expensive and relatively ineffective. The response to glucocorticoid therapy is unpredictable. Daily or alternate-day G-CSF is effective but should be reserved for patients with recurrent infections. Spontaneous remissions appear to occur much more commonly in children than adults.^{106,107}

Figure 65-3. Morphology of a marrow sample from a patient with autoimmune neutropenia, demonstrating a normal maturation of neutrophil precursors.

Systemic Lupus Erythematosus Total leukocyte counts usually are between 2 and $5 \times 10^9/L$ and neutrophils are less than $1.8 \times 10^9/L$ in approximately 50 percent of patients with systemic lupus erythematosus.^{108–110,123} Mild neutropenia often is accompanied by monocytopenia and lymphocytopenia, anemia, thrombocytopenia, and mild degrees of splenomegaly. Marrow cellularity and maturation of cells usually are normal. An increased amount of IgG is present on the surface of neutrophils, and immune complexes are increased within the neutrophils.¹¹⁰ Fas and tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) mediate many of the clinical features of autoimmune diseases, including apoptosis of neutrophils in systemic lupus erythematosus. Glucocorticoids, G-CSF, and GM-CSF elevate neutrophils in most patients with lupus, including patients on immunosuppressive therapies, but the mild neutropenia of these patients usually does not require treatment.¹¹⁰

Rheumatoid Arthritis, Sjögren Syndrome, and Felty Syndrome Leukopenia in association with rheumatoid arthritis is unusual, occurring in less than 3 percent of large series of patients.¹²⁴ Approximately 1 percent of patients with rheumatoid arthritis develop additional features of Felty syndrome (splenomegaly, deforming rheumatoid arthritis, and leukopenia). Usually, these patients have had active, deforming arthritis and very high rheumatoid factor titers. The neutropenia may be moderate to severe; occasionally patients are seen with no circulating neutrophils. The marrow usually is normal or hypercellular but occasionally is hypocellular. Granulopoiesis usually is marked by sufficient precursors but few band or segmented neutrophils. No clear relationship between spleen size and the neutrophil count is evident.

The incidence of bacterial infections in patients with Felty syndrome is low until the neutrophil count is less than $0.2 \times 10^9/L$, which has long suggested that neutrophils are made but that their blood kinetics are altered. The altered kinetics may result from high levels of circulating and intracellular immune complexes and IgG on the surface of neutrophils. Cellular injury via Fas-mediated apoptosis is an additional mechanism for cell loss from the marrow and blood.¹²⁵

In Sjögren syndrome, approximately 30 percent of patients have moderate leukopenia. The total leukocyte count usually is 2 to $5 \times 10^9/L$ with a normal differential count.^{115,126} Rarely, severe neutropenia occurs in association with recurrent bacterial infections.

Therapeutic options for management of neutropenia in these autoimmune disorders include methotrexate, glucocorticoids, G-CSF, GM-CSF, splenectomy, and biologic agents such as rituximab and

tocilizumab.^{116,117} Results with these therapies are unpredictable.^{122,127} Many specialists prefer weekly methotrexate because of its ease of administration, efficacy, and low toxicity.¹¹⁸ G-CSF or GM-CSF can increase neutrophils but may exacerbate arthralgias.¹¹⁹ Combinations of these agents is another good alternative. Splenectomy is followed by a rapid increase in counts in approximately two-thirds of cases, but approximately two-thirds of patients who respond to splenectomy have recurrence of neutropenia.¹²⁰ A subset of patients with Felty syndrome have a high blood concentration of large granular lymphocytes with a phenotype characteristic of immature natural killer cells.¹²¹ These patients tend to respond poorly to therapies directed toward increasing neutrophil levels but may respond to combinations of methotrexate and G-CSF. Several factors in addition to neutropenia predispose these patients to infections, including monocytopenia, hypocomplementemia, circulating immune complexes, and treatment with glucocorticoids or cytotoxic drugs. In general, treatments to correct neutropenia should be reserved for patients with documented infections.

Other Causes of Neutropenia Associated with Splenomegaly In 1942, Wiseman and Doan¹²² described a disorder they called primary splenic neutropenia. Since then, a variety of diseases have been recognized as also possibly causing this type of neutropenia, or pseudo-neutropenia. Diseases associated with splenomegaly and neutropenia include sarcoidosis, lymphoma, tuberculosis, malaria, kala azar, and Gaucher disease. Usually thrombocytopenia and anemia are present as well. Immune mechanisms in patients with inflammatory diseases are similar to the mechanisms observed in patients with systemic lupus erythematosus and Felty syndrome may be operative. In other patients, sluggish blood flow through the spleen with passive trapping of neutrophils in the congested red pulp probably is the primary cause. For the most part, the neutropenia in these patients is not sufficiently severe to be of clinical consequence. Removal of the spleen to raise the neutrophil count is rarely indicated.

DRUG-INDUCED NEUTROPENIA

Idiosyncratic drug reactions cause neutropenia with an estimated annual frequency of three to 12 cases per 1 million population.^{123–125} In 1922, Schultz¹²⁸ reported six cases of severe sore throat and prostration with absent blood neutrophils, which led rapidly to sepsis and death. A few years later, this syndrome was associated with the coal tar–derived drug aminopyrine.¹²⁷ Over the past 50 years, scores of other drugs have been recognized to cause this syndrome.

Two main types of idiosyncratic drug-induced neutropenia are recognized.^{128,129} One type is a dose-related toxicity resulting from interference of the drug with protein synthesis or cell replication. This effect often is nonselective. It can involve the hematopoietic stem cell and highly proliferative cells in other organs, such as the epithelial cells of the gastrointestinal tract. Prototype drugs for this type of reaction include phenothiazines, antithyroid drugs, chloramphenicol, and clozapine.^{130,131} Similar effects on marrow cells may be mediated through free radicals and drug metabolites. Patients receiving multiple drugs and patients having high plasma concentration of drugs as a result of the dose administered, slow metabolism, or renal excretory impairment are more prone to these reactions.¹³⁰

A second type of drug-induced neutropenia may not be dose related. The neutropenia is thought to be allergic or immunologic in origin, similar to drug-induced skin reactions and drug-initiated, antibody-mediated erythrocyte destruction. Many drugs can trigger this form of neutropenia.¹³² Women are affected more often than men. Older patients are affected more frequently than younger patients. Patients with a history of allergies, including allergies to other drugs, are affected more often than individuals without allergies. Neutropenia may occur

at any time, but tends to occur relatively early in the course of treatment with drugs to which the patient has been previously exposed.

Our basic understanding of drug-induced neutropenia is limited, partly because of the unpredictable occurrence of cases, the myriad agents involved, and the lack of good animal models for research. Clinical studies suggest the rate of recovery can be roughly predicted from the degree of marrow hypoplasia present when neutropenia is discovered. In patients with sparse marrow neutrophils but normal-appearing precursor cells (promyelocytes and myelocytes), neutrophils reappear in the blood approximately 4 to 7 days after the offending drug is stopped. Often an increase in the blood monocyte count heralds marrow recovery, and an “overshoot” with marked neutrophilia follows. When early precursor cells are severely depleted, recovery may require considerably more time.

Symptomatic patients with drug-induced neutropenia usually present with fever, myalgia, and sore throat, but usually no rash or evidence of allergy elsewhere.¹²⁷ Blood examination shows few or absent neutrophils. Mild lymphopenia may be observed, but other cell counts usually are normal. A high level of suspicion and careful clinical history are critical to identifying the offending drug. Differential diagnosis includes acute viral infections, particularly infectious mononucleosis and infectious hepatitis, and acute bacterial sepsis. If other hematologic abnormalities also are present, acute leukemia and aplastic anemia should be considered. Treatment usually consists of supportive care, including broad-spectrum antibiotics for febrile patients. Hematopoietic growth factors such as G-CSF or GM-CSF may be beneficial, but their use in this setting has not been established in randomized trials.¹³⁰ An alternative to discontinuing drugs such as clozapine is the addition of G-CSF treatment,^{127–129} although it is usually preferable to discontinue the suspected offending agent.

Table 65–1 lists some of the drugs frequently implicated in neutropenia. Given the rapidity of introduction of new agents, consult the manufacturer, a drug information center, or a poison control center when questions arise to learn if a drug can cause neutropenia.

NEUTROPENIA WITH INFECTIOUS DISEASES

Neutropenia can result from acute or chronic bacterial, viral, parasitic, or rickettsial diseases. Several mechanisms are involved. Certain viral infections, such as infectious mononucleosis, infectious hepatitis, Kawasaki disease, and HIV infection, may cause severe or protracted neutropenia and pancytopenia resulting from infection of hematopoietic precursor cells. Other agents, such as *Rickettsia* and *Bartonella*, can infect endothelial cells. These agents may cause leukopenia, neutropenia, thrombocytopenia, and anemia as part of a generalized vasculitic process. Increased neutrophil adherence to altered endothelial cells may occur in dengue, measles, and other viral infections. With severe Gram-negative bacterial infections, neutropenia probably results from increased adherence to the endothelium and increased utilization at the site of infection. Some chronic infections causing splenomegaly, such as tuberculosis, brucellosis, typhoid fever, malaria, and kala azar, probably cause neutropenia because of splenic sequestration and marrow invasion and suppression.

CLINICAL APPROACH TO THE PATIENT PRESENTING WITH NEUTROPENIA

Ordinarily, patients with acute onset of severe neutropenia present with fever, sore throat, and evidence of inflammation beneath the skin or mucous membranes. New respiratory or abdominal symptoms should heighten concern of an urgent clinical situation. Immediate investigation

should include a careful history with particular attention to drugs. The physical examination should give careful attention to the oropharynx, sinuses, chest, abdomen, bones for evidence of tenderness, and size of the lymph nodes and spleen. Prompt blood counts and microbial cultures, institution of intravenous fluids, antibiotics, and other supportive measures may be lifesaving. In this situation, fever and infections usually result from surface bacteria sensitive to numerous broad-spectrum agents, unless the patient has been treated recently with antibiotics. A complete blood count should be obtained and a marrow examination considered, particularly if the cause of acute neutropenia is not known. The marrow may reveal fibrosis, selective or nonselective hypoplasia of marrow precursors, excessive blasts, or atypical cells. With this information in hand and supportive care started, further diagnostic tests can be considered.

Chronic neutropenia often is discovered as a chance finding at a routine examination or during the course of investigation of a patient with recurrent fevers and infections. Determining if the neutropenia is chronic or cyclic and the mean level of blood cell counts when the patient is afebrile and relatively well is useful. Other important hematologic and immunologic data include the absolute monocyte, lymphocyte, eosinophil, and platelet counts; hematocrit or hemoglobin determination; and immunoglobulin levels. Patients with hypergammaglobulinemia usually have chronic and recurrent inflammation; patients with hypogammaglobulinemia and neutropenia usually are very susceptible to recurrent infections. Morphologic examination of the blood and marrow can identify some causes of benign neutropenia in children, the Chédiak-Higashi syndrome, and myelokathexis. The marrow examination is most useful for ruling out leukemia and myelodysplastic disorders and assessing the severity of the marrow defect.

In patients with chronic neutropenia, measurement of antinuclear antibodies (ANA) and rheumatoid factor titers and other serologic tests for autoimmune diseases may be useful. Usually, neutropenia associated with these disorders occurs in patients with obvious and severe disease, but occasionally patients are seen with occult splenomegaly, high ANA and rheumatoid factor titers, and a few other symptoms. Examination of the blood and marrow for large granular lymphocytes may be helpful. Infectious and nutritional causes of chronic neutropenia are rare and usually are evident at the time of patient evaluation. In adults, differentiation between chronic idiopathic neutropenia and the myelodysplastic syndromes may be the most difficult. Abnormalities in other cell lines (e.g., anemia with poikilocytosis, anisocytosis, basophilic stippling, and thrombocytopenia, pseudo-Pelger-Huët cells), low proportions of blast cells in the marrow, dysmorphic granulocyte and erythroid precursors, and clonal chromosomal abnormalities indicate myelodysplasia, particularly in older patients. Investigations of the mechanism of neutropenia with marrow and blood kinetic studies, *in vitro* marrow cultures, measurements of marrow granulocyte reserves, and indirect measurements of marrow proliferative activity may be useful in defining mechanisms of neutropenia, but are not widely available.

● NEUTROPHILIA

Neutrophilia is defined as an increase in the absolute blood neutrophil count to a level greater than 2 SD above the mean value for normal individuals. For children age 1 month or older and adults of all ages, this level is approximately $7.5 \times 10^9/L$, combining bands and mature neutrophils (Chap. 2). At birth the mean neutrophil count is $12 \times 10^9/L$, and counts as high as $26 \times 10^9/L$ are regarded as normal (Chap. 7).

Several terms are used almost synonymously with neutrophilia, including *neutrophilic leukocytosis*, *polymorphonuclear leukocytosis*, and *granulocytosis*. *Leukocytosis* is used because an elevated number of

TABLE 65-1. Classification of Widely Used Drugs Associated with Idiosyncratic Neutropenia

ANALGESICS AND ANTIINFLAMMATORY AGENTS	ANTIMALARIALS
Indomethacin*	Amodiaquine
Gold salts	Chloroquine
Pentazocine	Dapsone
<i>Para</i> -aminophenol derivatives*	Pyrimethamine
Acetaminophen	Quinine
Phenacetin	ANTITHYROID DRUGS*
Pyrazolone derivatives*	Carbimazole
Aminopyrine	Methimazole
Dipyron	Propylthiouracil
Oxyphenbutazone	CARDIOVASCULAR DRUGS
Phenylbutazone	Captopril
ANTIBIOTICS	Disopyramide
Cephalosporins	Hydralazine
Chloramphenicol*	Methyldopa
Clindamycin	Procainamide
Gentamicin	Propranolol
Isoniazid	Quinidine
<i>Para</i> -aminosalicylic acid	Tocainide
Penicillins and semisynthetic penicillins*	DIURETICS
Rifampin	Acetazolamide
Streptomycin	Chlorthalidone
Sulfonamides*	Chlorothiazide
Tetracyclines	Ethacrynic acid
Trimethoprim-sulfamethoxazole	Hydrochlorothiazide
Vancomycin	HYPOGLYCEMIC AGENTS
ANTICONVULSANTS	Chlorpropamide
Carbamazepine	Tolbutamide
Mephenytoin	HYPNOTICS AND SEDATIVES
Phenytoin	Chlordiazepoxide and other benzodiazepines
ANTIDEPRESSANTS	
Amitriptyline	Meprobamate
Amoxapine	PHENOTHIAZINES*
Desipramine	Chlorpromazine
Doxepin	Phenothiazines
Imipramine	OTHER DRUGS
ANTIHISTAMINES—H ₂ BLOCKERS	Allopurinol
Cimetidine	Clozapine
Ranitidine	Levamisole
	Penicillamine
	Ticlopidine

*More frequently reported to cause neutropenia in epidemiologic studies.

NOTE: Documentation of the role of specific drugs in the causation of neutropenia is dependent on either (1) the frequency of the occurrence among patients, (2) the timing of the event in relationship to drug use, (3) the absence of alternative explanations, or (4) the inadvertent or intentional reuse of the drug (rechallenges) with a similar response. Readers who require supplementary lists of putative drugs involved in the development of neutropenia or wish to read original references for these interactions are referred to Refs. 123 and 124

Figure 65-4. Mechanisms of neutrophilia are shown schematically. The rate of flow of cells through each compartment is represented by the arrows. CP, circulating neutrophil pool; MaP, maturation (postmitotic) pool; M.P., mitotic pool; MP, margined neutrophil pool; SP, storage pool (marrow reserves).

neutrophils is the most frequent cause of an increased total white cell count. *Granulocytosis* is less specific than neutrophilia, because granulocytes include eosinophils and basophils as well as neutrophils. Extreme neutrophilia often is referred to as a *leukemoid reaction* because the height of the white cell count may suggest leukemia. This exaggerated reaction may be the result of segmented neutrophils or may be associated with band neutrophils, metamyelocytes, and myelocytes in smaller proportions.

In normal individuals, the neutrophil count follows a diurnal pattern of variation, with peak counts in the late afternoon. Neutrophil counts also rise slightly after meals, with erect posture, and with emotional stimuli. Ordinarily these changes are not sufficient to cause neutrophilia.¹³⁴

MECHANISMS OF NEUTROPHILIA

Under normal circumstances, neutrophils follow an orderly progression from the marrow through the blood to tissue sites of utilization.¹³⁵ Mild neutrophilia may occur by several mechanisms: increased cell production, accelerated release of cells from the marrow into the blood, shift within the circulation from the marginal to the circulating pool,

reduced egress of neutrophils from the blood to tissues, or a combination of these mechanisms. The time required for these events varies substantially. Shifts between the marginal and circulating pools take only a few minutes. Shifts of neutrophils from the marrow to the blood occur within a few hours. Increases in the production of neutrophils, even with intense stimulation, may take at least a few days (Fig. 65-4). With sustained moderate to marked neutrophilia the cause is virtually always increased production of neutrophils.

Acute Neutrophilia

Pseudoneutrophilia (Demargination) Vigorous exercise and acute physical and emotional stress can increase the number of blood neutrophils within a few minutes.¹³⁶ The response is mimicked by infusion of epinephrine and other catecholamines that increase heart rate and cardiac output.¹³⁷ The response is caused by a shift of cells from the marginal to the circulating pool; hence, it frequently is referred to as *demargination*. This response in humans is dependent partially on release of neutrophils from the spleen,¹³⁸ but redistribution from other vascular beds, particularly the pulmonary capillaries, is quantitatively more important. This mechanism can account for about a doubling in neutrophil count. Greater elevations in neutrophils cannot be ascribed

solely to this mechanism. The increase in lymphocytes, monocytes, and neutrophils that occurs with demargination may be helpful in distinguishing this type of neutrophilia from the response to infections, protracted stress, or glucocorticoid administration. With these conditions, neutrophil counts are elevated, but lymphocyte and monocyte counts generally are depressed.

Marrow Storage Pool Shift Acute neutrophilia occurs as a consequence of release of neutrophils from the marrow storage pool, the *marrow neutrophil reserves*.¹³⁹ This mechanism produces acute neutrophilia in response to inflammation and infections. The marrow reserve pool consists principally of segmented neutrophils and bands. Metamyelocytes are not released to the blood except under extreme circumstances. The postmitotic marrow neutrophil pool is approximately 10 times the size of the blood neutrophil pool, and approximately half of these cells are band and segmented neutrophils.¹³⁵ In neutrophil production disorders, chronic inflammatory diseases, and malignancies, and with cancer chemotherapy, the size of this pool is reduced and the capacity to develop neutrophilia is impaired. Exposure of blood to foreign surfaces, such as hemodialysis membranes, activates the complement system and causes transient neutropenia, followed by neutrophilia resulting from release of marrow neutrophils. Colony-stimulating factors (G-CSF and GM-CSF) cause acute and chronic neutrophilia by mobilizing cells from the marrow reserves and stimulating neutrophil production.^{140,141}

Chronic Neutrophilia

Chronic neutrophilia follows a prolonged stimulus to proliferation of neutrophil precursors. It can be studied experimentally with repeated doses of endotoxin, glucocorticoids, or colony-stimulating factors. Although the details of the mediators and mechanisms for the development of chronic neutrophilia are not understood fully, a general scheme for this response is now widely accepted (see Fig. 65-4). Expansion of

cell production follows stimulation of cell divisions within the mitotic precursor pool, that is, divisions of promyelocytes and myelocytes. Subsequently, the size of the postmitotic pool increases. The changes cause an increase in the marrow granulocytic to erythroid ratio. In humans, the neutrophil production rate increases severalfold with chronic infections. Even greater increases may occur in polycythemia vera, chronic myelogenous leukemia, and leukemoid reactions in response to nonhematologic malignancies¹⁴² and to exogenously administered hematopoietic growth factors such as G-CSF,^{140,141} with a maximum response taking at least 1 week to develop.

Neutrophilia resulting from decreased egress from the vascular compartment occurs infrequently. A prototype disorder illustrating this mechanism occurs in patients with the neutrophil cell membrane defect CD11a/CD18 deficiency.¹⁴³ The neutrophils do not adhere to the capillary endothelium normally, but cell production and marrow release apparently are normal. Because these patients cannot mobilize neutrophils to sites of inflammation when they develop infections, extreme neutrophilia is observed (Chap. 66). Glucocorticoids may produce a functionally similar state, with neutrophils accumulating in the blood, at least transiently, after each dose is administered.¹⁴⁴ In patients recovering from infections, as the “tissue demand” for neutrophils diminishes, the persistence of neutrophilia may be attributed to this same mechanism. In chronic myelogenous leukemia, accumulation of neutrophils with a longer than normal half-life in the blood partially explains the extreme neutrophilia.¹⁴⁵

DISORDERS ASSOCIATED WITH NEUTROPHILIA

Neutrophilia in Response to Inflammation and Stress

Table 65-2 lists the categories and causes of acute and chronic neutrophilia. Probably the most frequent causes of acute neutrophilia are exercise, emotional stress, and any other circumstance that raises

TABLE 65-2. Major Causes of Neutrophilia

Acute Neutrophilia	Chronic Neutrophilia
Physical stimuli Cold, heat, exercise, convulsions, pain, labor, anesthesia, surgery	Infections Persistence of infections that cause acute neutrophilia
Emotional stimuli Panic, rage, severe stress, depression	Inflammation Most acute inflammatory reactions, such as colitis, dermatitis, drug-sensitivity reactions, gout, hepatitis, myositis, nephritis, pancreatitis, periodontitis, rheumatic fever, rheumatoid arthritis, vasculitis, thyroiditis, Sweet syndrome
Infections Many localized and systemic acute bacterial, mycotic, rickettsial, spirochetal, and certain viral infections	Tumors Gastric, bronchogenic, breast, renal, hepatic, pancreatic, uterine, and squamous cell cancers; rarely Hodgkin lymphoma, lymphoma, brain tumors, melanoma, and multiple myeloma
Inflammation or tissue necrosis Burns, electric shock, trauma, infarction, gout, vasculitis, antigen-antibody complexes, complement activation	Drugs, hormones, and toxins Continued exposure to many substances that produce acute neutrophilia, lithium; rarely as a reaction to other drugs
Drugs, hormones, and toxins Colony-stimulating factors, epinephrine, etiocholanolone, endotoxin, glucocorticoids, smoking tobacco, vaccines, venoms	Metabolic and endocrinologic disorders Eclampsia, thyroid storm, overproduction of adrenocorticotropic hormone
	Hematologic disorders Rebound from agranulocytosis or therapy of megaloblastic anemia, chronic hemolysis or hemorrhage, asplenia, myeloproliferative disorders, chronic idiopathic leukocytosis
	Hereditary and congenital disorders Down syndrome, congenital

endogenous epinephrine, norepinephrine, or cortisol levels. Acute neutrophilia occurs in pregnant patients and may be especially notable at the time of entering labor. Acute neutrophilia occurs with induction of general or epidural anesthesia, with all types of surgery, and with other acute events such as seizures, gastrointestinal hemorrhage, subarachnoid hemorrhage, or other internal bleeding.

Neutrophilia occurs with many acute bacterial infections. It occurs less predictably with infections caused by viruses, fungi, and parasites. Many aspects of the complex interactions of microbes with the infected host are not fully understood. Most patients with Gram-positive infections, such as pneumococcal pneumonia, staphylococcal abscesses, and streptococcal pharyngitis, have neutrophilia. Infections caused by Gram-negative bacteria, particularly those resulting in bacteremia or septic shock, may cause neutropenia or extreme neutrophilia.¹⁴⁶ Increased circulating levels of activated complement components, G-CSF, tumor necrosis factor, and interleukin (IL)-1, IL-6, and IL-8 may cause this response. Bacterial infections that have an insidious onset and cause splenomegaly, such as typhoid fever and brucellosis, characteristically do not show neutrophilia except in the initial or disseminated phase. Miliary tuberculosis is an important cause of leukemoid reactions. Neutrophilia is far less common with viral infections. In general, neutrophilia is seen in infections producing substantial tissue injury, evoked by toxins produced by the infecting organisms. Damage to host tissues also is the presumed mechanism of neutrophilia in thermal burns, electric shock, myocardial infarction, pulmonary embolism, sickle cell crisis, and systemic vasculitis.

Many chronic noninfectious conditions cause neutrophilia. Probably the most frequent cause is cigarette smoking.^{147,148} Neutrophil counts of smokers are increased in proportion to the amount of exposure. Neutrophil counts of smokers inhaling two packs of cigarettes per day average twice the normal levels. Chronic inflammatory diseases, including dermatitis, bronchitis, rheumatoid arthritis, osteomyelitis, ulcerative colitis, and gout, may cause a persistent neutrophilia. Sweet syndrome is an unusual dermatologic condition manifested as intense neutrophil accumulation in the skin and persistent neutrophilia.¹⁴⁹

Neutrophilia in Association with Cancer or Heart Disease

Neutrophilia is associated with many nonhematologic malignancies, such as lung and gastrointestinal malignancies, particularly when they metastasize to the liver and lung.¹⁵⁰ In some cases, tumor cells produce colony-stimulating factors that presumably cause the neutrophilia by direct marrow stimulation. Tumor necrosis and superinfections are other possible mechanisms. Neutrophilia is unusual in brain tumors, melanoma, prostate cancer, and lymphocytic malignancies.

Neutrophilia is a marker for the occurrence and severity of a variety of illnesses. Neutrophilia is associated with an increased incidence and severity of coronary heart disease, independent of smoking status.^{151,152} Similarly, elevated white cell counts have been associated with increased cancer mortality, independent of smoking history. In patients with cancer, subarachnoid hemorrhage, and other serious inflammatory conditions, neutrophilia portends a less favorable prognosis.

Hereditary Neutrophilia and Neutrophilia as a Manifestation of a Hematologic Disorder

In addition to the myeloproliferative neoplasms, including chronic neutrophilic leukemia and neutrophilic chronic myelogenous leukemia (Chap. 89), several unusual hematologic conditions may be associated with neutrophilia. The mechanisms for most of these disorders remain obscure. In Down syndrome, transient neonatal leukemoid reactions resembling chronic myelogenous leukemia may occur.¹⁵³ This type of neutrophilia may be related to a defect in regulation of neutrophil

production caused by chromosome 21 trisomy, but the precise mechanism is unknown. Idiopathic neutrophilic leukocytosis with a negative family history and a similar condition of hereditary neutrophilia with an autosomal dominant pattern of inheritance have been reported^{154,155} but are very rare. An inherited activating mutation in the G-CSF receptor (*CSF3R*) gene induces chronic hereditary neutrophilia.¹⁵⁶ Careful clinical examination and followup almost always reveal the cause of the neutrophilia.

Neutrophilia Associated with Drugs

Many drugs cause neutropenia, but neutrophilia in response to drugs is uncommon except for the well-known effects of epinephrine, other catecholamines, and glucocorticoids. Lithium salts cause sustained neutrophilia.¹⁵⁷ The counts return to normal when the drug is discontinued. The drug increases levels of colony-stimulating factor. Cases of neutrophilia have been reported with ranitidine and quinidine therapy, but such reactions are very uncommon.

CLINICAL APPROACH TO PATIENTS WITH NEUTROPHILIA

In most instances, the finding of neutrophilia, band neutrophils, and toxic granules in the mature cells can be related to an obvious ongoing inflammatory condition. Often the finding of neutrophilia helps confirm the diagnosis of appendicitis, cholecystitis, or bacterial pharyngitis. When the cause of neutrophilia is not readily apparent, especially if the neutrophilia is associated with fever or other signs of inflammation, more subtle infections such as tuberculosis or osteomyelitis should be considered. In addition, a history of smoking and evidence for a chronic anxiety state or an occult malignancy should be sought. If neutrophilia is accompanied by myelocytes and promyelocytes, increased basophils, and unexplained splenomegaly, the diagnosis of a myeloproliferative disease (e.g., chronic myelogenous leukemia, idiopathic myelofibrosis, or polycythemia vera) should be considered. Measurement of leukocyte alkaline phosphatase activity can be a useful screening test in cases of moderate neutrophilia (15 to $25 \times 10^9/L$). Ordinarily the values are elevated with inflammation of any cause and in subjects receiving glucocorticoid therapy. The values are low in chronic myelogenous leukemia and variable with other myeloproliferative neoplasms. Serum vitamin B_{12} levels and B_{12} -binding proteins are elevated in both benign neutrophilia and chronic myelogenous leukemia. In unexplained neutrophilia, testing for the cytogenetic alterations and the *BCR* gene rearrangement (Chap. 89) and *JAK2* gene mutations (Chap. 84) are important in the diagnostic evaluation. Chapter 89 discusses the diagnosis of chronic myelogenous leukemia and other chronic myelogenous leukemia disorders with prominent neutrophilia.

Epidemiologic studies show an association of neutrophilia with adverse effects of smoking, obesity, coronary artery disease, cerebral vascular disease and malignancies.¹⁵⁸⁻¹⁶² In myeloproliferative neoplasms, neutrophilia is a predictor of thrombotic events.¹⁶³⁻¹⁶⁵ In patients with sickle cell disease, neutrophilia correlates with increased complications and severity of the disease.^{166,167} In these patients, treatment with hydroxyurea lowers the blood neutrophil counts, and has been shown in randomized trials to reduce some of the complications of the disease. In some inflammatory diseases, glucocorticoids, which raise blood neutrophils, and immunosuppressive therapies, which lower blood neutrophils, are used to reduce inflammation; this is because both of these classes of drugs reduce the deployment of neutrophils and other leukocytes to tissue sites of inflammation. For instance, glucocorticoids usually suppress the inflammation of the skin in Sweet syndrome. In most clinical settings, therapies to reduce the neutrophil count are generally not indicated.

CHAPTER 66

DISORDERS OF NEUTROPHIL FUNCTION

Niels Borregaard

SUMMARY

The neutrophil circulates in blood as a quiescent cell. Its main function as a phagocytic and bactericidal cell is performed outside the circulation in tissues where microbial invasion takes place. Neutrophil function is traditionally viewed as chemotaxis, phagocytosis, and bacterial killing. Although these conceptually represent distinct entities, they are functionally related, and rely to a large extent on the same intracellular signal transduction mechanisms that result in localized rises in intracellular Ca^{2+} , changes in organization of the cytoskeleton, assembly of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase from its cytosolic and membrane integrated subunits, and fusion of granules with the phagosome or neutrophil plasma membrane. Clinical disorders of the neutrophil may arise from impairment of these normal functions. The clinical presentation of a patient who has a qualitative neutrophil abnormality may be similar to that of one who has an antibody, complement, or toll-like receptor disorder. In general, evaluation for phagocyte cell disorders should be initiated among those patients who have at least one of the following clinical features: (1) two or more systemic bacterial infections in a relatively short time period; (2) frequent, serious respiratory infections, such as pneumonia or sinusitis, or otitis media, or lymphadenitis; (3) infections present at unusual sites (liver or brain abscess); and (4) infections associated with unusual pathogens (e.g., *Aspergillus* pneumonia, disseminated candidiasis, or infections with *Serratia marcescens*, *Nocardia* species, or *Burkholderia cepacia*).

Acronyms and Abbreviations: ADP, adenosine diphosphate; ARF, ADP-ribosylation factor; ASC, apoptosis-associated speck-like protein with a caspase recruitment domain; ATPase, adenosine triphosphatase; BPI, bacterial permeability-increasing protein; cAMP, cyclic adenosine monophosphate; cANCA, cytoplasmic antineutrophil cytoplasmic antibody; CARD, caspase activation and recruitment domain; c/EBP, CCAAT/enhancer binding protein; CGD, chronic granulomatous disease; CHS, Chédiak-Higashi syndrome; DAG, diacylglycerol; DOCK8, dedicator of cytokinesis 8; ESAM, endothelial cell-selective adhesion molecule; FAD, flavin adenine dinucleotide; FMF, familial Mediterranean fever; fMLP, formyl-methionyl-leucyl-phenylalanine; G6PD, glucose-6-phosphate dehydrogenase; GDP, glucose diphosphate; GPI, glycosylphosphatidylinositol; GTP, guanosine triphosphate; GTPase, guanosine triphosphatase; H_2O_2 , hydrogen peroxide; HBP, heparin-binding protein; HETE, hydroxyeicosatetraenoic acid; HLA, human leukocyte antigen; HNP, human neutrophil peptide (synonym: defensin); ICAM, intercellular adhesion molecule; IFN, interferon; Ig, immunoglobulin; IL, interleukin; IP_3 , inositol triphosphate; ITAM, immunoreceptor tyrosine-based activation motif; JAMS, junctional adhesion molecule A, B, and C; LAD, leukocyte adhesion deficiency; LFA-1, leukocyte function-associated antigen-1; LPS, lipopolysaccharide; LSP-1, lymphocyte-specific protein-1; LTB_4 , leukotriene B_4 ; Mal/TIRAP, MyD88-adaptor-like/

● NEUTROPHIL STRUCTURE AND FUNCTION

CHEMOTAXIS AND MOTILITY

The similarity between neutrophil locomotion and that of amebas was noted long ago.¹ Neutrophils respond to spatial gradients of chemotaxins with differences in concentration of chemotaxin of as little as 1 percent across the cell,² although there has been contention as to whether chemotaxis also requires temporal, as well as spatial, sensing.³ Even with populations of cells as “homogenous” as neutrophils, a broad range of responsiveness is found.⁴ During locomotion toward a chemotactic source, neutrophils acquire a characteristic asymmetric shape (Fig. 66-1). In the front of the cell is a pseudopodium, referred to as the *lamellipodium*, that advances before the body of the cell containing the nucleus and the cytoplasmic granules. At the rear of the moving cell is a knob-like tail, the uropod. The lamellipodium undulates or “ruffles” as the neutrophil moves, at a rate of up to $50 \mu\text{m}/\text{min}$. The membrane lipids also flow during locomotion,⁵ and enhanced cytosolic Ca^{2+} is observed along the membrane margin.⁶ The lamellipodium, which is very thin, forms immediately when the cell encounters a gradient of chemotactic factor. As the cell moves, the cytoplasm behind the lamellipodium streams forward, almost obliterating it. At this point, some granules appear to contact the cell periphery and release granule contents in response to chemotactic agents. The lamellipodium extends again and the process repeats itself. A flow of cortical materials, composed particularly of actin filaments, has been proposed to account for chemotaxis as well as other cellular movements.⁷ This may also account for changes in cell viscosity. Polarity and movement is orchestrated by the cytoskeleton through signals generated from receptor associated G-proteins in an intricate network that regulates both direction and intensity of movement.⁸⁻¹¹

INGESTION

When a neutrophil comes in contact with a particle, the pseudopodium flows around the particle, its extensions fuse, and it thereby encompasses the particle within the phagosome.¹ The ingestion phase can be

toll/interleukin-1 receptor domain containing adaptor protein; MAPK, microtubule-associated protein kinase; MBL, mannose-binding lectin; MMP, matrix metalloproteinase; MPO, myeloperoxidase; MyD88, myeloid differentiation factor 88; NADPH, nicotinamide adenine dinucleotide phosphate (reduced form); NBT, nitroblue tetrazolium; NEM, *N*-ethylmaleimide; NET, neutrophil extracellular trap; $\text{NF-}\kappa\text{B}$, nuclear factor- κB ; NGAL, neutrophil gelatinase-associated lipocalin; NK, natural killer; NSF, *N*-ethylmaleimide-sensitive fusion protein; NSP4, neutrophil serine protease 4; PA, phosphatidic acid; PAF, platelet-activating factor; PECAM, platelet endothelial adhesion molecule; phox, phagocyte oxidase; PI3K, phosphatidylinositol 3'-kinase; PIP_1 , phosphatidylinositol-4-monophosphate; PIP_2 , phosphatidylinositol-4,5-bisphosphate; PKC, protein kinase C; PLC, phospholipase C; PLD, phospholipase D; PLS, Papillon-Lefèvre syndrome; PSGL, P-selectin glycoprotein ligand; SGD, specific granule deficiency; SH3, Src homology 3; sLe^x, sialyl Lewis X; SNAP, soluble NSF attachment protein; SNARE, SNAP receptor; TIR, toll/interleukin-1 receptor; TLR, toll-like receptors; 7TMRs, seven *trans*-membrane-spanning domain proteins; TNF, tumor necrosis factor; TRAM, TRIF-related adaptor molecule; TRAPS, tumor necrosis factor receptor-associated periodic syndrome; TRIF, TIR domain-containing adaptor inducing interferon (IFN)- β ; VAMP-2, vesicle-associated membrane protein-2.

Figure 66-1. Cinemicrophotographic observation of granule lysis of a chicken neutrophil following phagocytosis of zymosan particles. Note the lysis of the cytoplasmic granule (G) against one of two ingested zymosan particles (Z). The dense body of the granule disappears from view in the interval of 5 s (original magnification $\times 1200$). (Reproduced with permission from Hirsch JG: *Cinemicrophotographic observations on granule lysis in polymorphonuclear leucocytes during phagocytosis*. *J Exp Med* 116:827–834,1962.)

said to extend from recognition to the end of pseudopodium fusion. The particle thus becomes enclosed within a phagosome into which granules are rapidly discharged, as illustrated in Fig. 66-1. As with locomotion, phagocytosis results in Ca^{2+} being released in the vicinity of the active membranes.⁶ The number of ingested particles may be eventually limited by the availability of plasma membrane.⁷ Locomotion is not a prerequisite for ingestion: If neutrophils collide with a particle not secreting a chemotactic substance, pseudopodia form abruptly at the contact point and envelop the particle.¹²

The formation of a lamellipodium is essential for neutrophil locomotion and is also required for ingestion. When dissolution of the lamellipodium occurs, the interior contents of the cell are allowed to contact the cell membrane. Granule discharge may occur. Fusion of membranes is a common feature of (1) ingestion, where pseudopodia fuse; (2) degranulation, where granules fuse with the phagosome; and possibly (3) locomotion, where some granules may fuse with the plasma membrane. Pseudopodia form whether neutrophils are suspended in liquid medium or are attached to a surface, but the cell can only move translationally when fixed to a surface; thus it crawls but does not swim. Such “stickiness” is also a phase of ingestion.⁷ The neutrophil membrane adheres firmly to particles they ingest, presumably to provide the frictional force needed to move pseudopodia around the particles. Thus, the formation of pseudopodia, membrane fusion, and membrane adhesiveness are all characteristics associated with the functional responses of neutrophils.

ADHESION

The dual neutrophil functions of immune surveillance and *in situ* elimination of microorganisms or cellular debris require rapid transition between a circulating nonadherent state to an adherent state, allowing the cells to migrate into tissues when necessary. Initially neutrophils appear at sites on the endothelium adjacent to the site of inflammation. Adhesion molecules on endothelium are induced by the inflammatory mediators tumor necrosis factor (TNF)- α and interleukin (IL)-1.

Lipopolysaccharide (LPS), released by local activated macrophages and microorganisms, results in local extravasation of the neutrophil. In postcapillary venules or in pulmonary capillaries the slow rate of blood flow, further reduced by vessel dilatation at sites of inflammation, permits a loose and somewhat transient adhesion referred to as “tethering,” and results in the rolling of the neutrophil along the endothelium.¹³ Extensions from the rear of the neutrophil wraps around the rolling neutrophils as so called slings and provide “crawler tracks” at their front that assists in adhesion to the endothelium.¹⁴ During this tethering step, neutrophils respond to ligands, primarily chemokines dispatched on the endothelial surface by a signaling event that acts to reorganize the neutrophil surface membrane, thereby exposing adhesion molecules, which, in turn, lead to sustained adhesion and spreading (Chap. 19).

NEUTROPHIL MICROVILLI AND THEIR DYNAMICS

Circulating neutrophils contain surface microvilli of a diameter of $0.3 \mu\text{m}$.¹⁵ Moesin, ezrin, and p205 radixin are actin-binding proteins associated with neutrophil plasma membranes and are important for organization of microvilli on the surface of the cell.^{16,17} These actin binding proteins tether the primary adhesion proteins exposed on the microvilli, L-selectin and P-selectin glycoprotein ligand 1 (PSGL-1).¹⁸ L-selectin and PSGL-1 are filamentous glycosylated proteins protruding from the tips of the microvilli. E-selectin ligand 1 (ESL-1) located in the side of microvilli,¹⁹ and CD44, located on the cell body, both serve as ligands for E-selectin.²⁰ L-selectin, like the other selectins, including P-selectin, which is expressed on platelets and endothelial Weibel-Palade bodies, and E-selectin, which is expressed in endothelial cells, bind with a variable affinity to sialyl fucosylated oligosaccharides including sialyl Lewis X (sLe^x), which is present on multiple specific glycolipids and glycoproteins on leukocytes and inflamed endothelial cells.²¹ When binding to their ligands, L-selectin, PSGL-1, ESL-1, and CD44 recruit Syk (spleen tyrosine kinase), a tyrosine kinase, which binds to the immunoreceptor tyrosine-based activation motif (ITAM). ITAMs are present in the cytoplasmic domains of surface membrane proteins, and Syk then orchestrates the further signaling to initiate cell activation.²²⁻²⁵

ROLLING AND TETHERING

P-selectin is mobilized rapidly to the endothelial cell surface following stimulation by thrombin, histamine, or oxygen radicals and interacts with neutrophil PSGL-1 to initiate neutrophil rolling.²¹ Rolling subsequently involves newly expressed E-selectin, which appears on endothelial cells 1 to 2 hours after cell stimulation by IL-1, TNF- α , or LPS. E-selectin counterreceptors include PSGL-1, ESL-1, and CD44.^{19,24} Both P- and L-selectin contribute sequentially to leukocyte rolling, but L-selectin is involved in the prolonged neutrophil sequestration on inflamed microvasculature. L-selectin is constitutively present on neutrophils and its binding capacity is rapid and transiently increased after neutrophil activation, possibly via receptor oligomerization. Activation of ADAM17, a matrix metalloproteinase expressed at the neutrophil surface, severs L-selectin from the surface of neutrophils and impairs their recruitment to endothelium.^{26,27} Thus far, only one inducible L-selectin counterreceptor has been identified on inflamed endothelium.²⁸ In addition to its binding to endothelial ligands, neutrophil PSGL-1 is a counterreceptor for L-selectin, which permits previously adherent neutrophils to recruit other neutrophils to inflamed endothelium (Chap. 19).^{13,21}

NEUTROPHIL ADHESION AND SPREADING

Figure 66-2 shows a sequence of molecular and biophysical events leading to neutrophil activation and increased adherence during acute

Figure 66–2. Neutrophil-mediated inflammatory response. (1) Egress of mature neutrophils from marrow to circulation. (2) Initial tethering and rolling are dominantly mediated by selectins present both on neutrophils and endothelial cells and their ligands. Invasion by bacteria stimulates tissues macrophages to secrete inflammatory cytokines, interleukin (IL)-1 and tumor necrosis factor, which, in turn, activate endothelial cells to express E- and P-selectin and IL-8. E- and P-selectin serve as counterreceptors for the neutrophil P-selectin glycoprotein ligand-1. (3) Activated endothelial cells express intercellular adhesion molecule (ICAM)-1 and ICAM-2, which serve as ligands for the neutrophil β_2 integrins. The β_2 integrins mediate tight adhesion and arrest of the leukocytes in cooperation with the selectins. Localized activation of neutrophils by juxtacrine signaling molecules or chemoattractants that bind to surface receptors is critical for inside-out signaling of β_2 integrins, making them adhesive for the ICAM ligands on the endothelium. (4) Neutrophil invasion through the vascular basement membrane with release of proteases and reactive oxidative intermediates that cause local destruction of the extracellular matrix which allows for migration of the neutrophils into tissues. (5, 6) Uptake of microorganisms into the phagocytic vacuole with concomitant degranulation both into the phagocytic vacuole (azurophil granules and specific granules) and to the exterior (specific granules and gelatinase granules). (7) A burst of transcriptional activity is initiated during diapedesis of neutrophils and during phagocytosis, which results in generation of chemokines such as IL-8, monocyte chemoattractant protein-1, macrophage inflammatory protein-1 α , and IL-1 β that may recruit additional cells of the immune system.⁵⁸ (8) Formation of neutrophil extracellular traps by extrusion of chromatin and cationic bactericidal granule proteins.²⁶² M Φ , macrophages; PMN, polymorphonuclear neutrophil.

inflammatory response *in vivo*. The inflamed endothelium produces chemoattractants such as platelet-activating factor (PAF), leukotriene B₄ (LTB₄), and various chemokines, immobilized by proteoglycans on the luminal surface of endothelial cells.²⁹ Among these chemokines, IL-8 specifically attracts neutrophils. IL-8 is synthesized by endothelial cells in response to IL-1, TNF- α , or LPS, and is stored in Weibel-Palade bodies; IL-8 can be released by histamine or thrombin.³⁰ Additionally, IL-8 can be internalized by endothelial cells and transcytosed from the abluminal surface via vesicular caveolae, and presented to the tips of microvilli of the endothelial cell luminal surface.³¹ The binding of signaling molecules such as PAF and IL-8 to surface receptors on the leukocytes activates them in a juxtacrine fashion and triggers changes in affinity or avidity of β_2 integrins, leukocyte function-associated antigen (LFA)-1 (CD11a/CD18), which is constitutively expressed on neutrophil plasma membranes, and Mac-1 (CD11b/CD18), which becomes incorporated in the neutrophil plasma membrane from secretory vesicles.^{13,21,32} β_2 Integrins are recognized by counterligands on endothelial cells, including members of the intercellular adhesion molecule (ICAM) family such as ICAM-1 and ICAM-2. The ICAM glycoproteins are induced by cytokines that include TNF and IL-1. The relative affinity of the β_2 integrins for ICAM is increased by exposure of neutrophils to numerous stimuli, including C5a, N-formylated bacterial peptides, IL-8, and LTB₄. The extracellular domains of unactivated integrins are

in a bent position and not able to bind ligands. Intracellular signals, such as those generated via Syk as discussed above, can transform the integrins into an extended but not fully open conformation, capable of ligand binding with weak affinity permitting the integrin (LFA-1) to participate in rolling³³ and an extended and fully open form capable of ligand binding with strong affinity, mediating firm adhesion. The molecular mechanisms have been worked out in great detail. In essence, tailins and kindlins are recruited and bound to membrane near phosphotyrosine (NPxY and NxxY) motifs present on the integrin β chains and twist the cytoplasmic domains of the α and β chains. This changes the conformation of the extracellular domains from the bent to the open state, thereby permitting binding to ligands, and in so doing transmit signals from outside to inside.^{21,34–36} Neutrophils integrate the signals of integrin engagement and those delivered simultaneously by inflammatory cytokines or chemoattractants to activate a cascade of intracellular events resulting in cell spreading (Fig. 66–2). The CD11b/CD18 integrin (MAC-1) is known to interact in *cis* fashion with glycosylphosphatidylinositol (GPI)-anchored membrane proteins such as Fc γ RIIIB (CD16), the LPS receptor CD14, and the urokinase plasminogen activator receptor (uPAR; CD87). Integrins behave as transducers mediating signals transferred by these GPI-linked receptors.³⁷ For instance, Fc γ RIIIB interaction with CD11b/CD18 promotes antibody-dependent phagocytosis, whereas CD14 interaction with CD11b/CD18 occurs in

the presence of LPS and LPS-binding protein to generate proinflammatory mediators, and uPAR interaction with CD11b/CD18 mediates neutrophil migration by recruiting and activating the urokinase-type plasminogen activator.²⁹

TRANSENDOTHELIAL MIGRATION

Fully extended and open integrins bind ICAM-1 firmly and thus mediate attachment of neutrophils to endothelial cells.³⁸ ICAM-1 and -2 direct the motion of neutrophils to points of egress from the vascular lining. The majority are guided to points where three or more endothelial cells join. Intracellular signals from ICAMs loosen the binding between endothelial cell junctions provided by homotypic interaction of VE-cadherins.³⁹

Platelet endothelial cell adhesion molecule 1 (PECAM-1), endothelial cell-selective adhesion molecule (ESAM), junctional adhesion molecule A, B, and C (JAMs), and CD99 also form homotypic interactions between endothelial cells; however, neutrophils also express these adhesion proteins and may displace the interendothelial cell homotypic binding with neutrophil-endothelial cell binding mediated by the same proteins. In this way neutrophils can “zipper” through^{40–42} and exit by this paracellular route. A minority of neutrophils exit by a transcellular route through so-called endothelial cups.⁴²

Pericytes are perivascular contractile cells that interact with endothelial cells and regulate vascular permeability. Neutrophils exit the vascular wall through gaps between pericytes.⁴³ Pericytes adopt different morphologies and distributions in different tissues. Such may explain differences in neutrophil recruitment to viscera.⁴⁴

Once out in tissues the forefront neutrophils generate IL-8 and LTB_4 in order to recruit an additional swarm of neutrophils to the area and recruit later incoming monocytes and macrophages.⁴⁵

NEUTROPHIL SURFACE PROTEINS

Several proteins associated with the surface of the neutrophil function in the normal housekeeping activities such as Na^+/K^+ adenosine triphosphatase (ATPase), but others serve specific functions such as L-selectin, PSGL-1, and integrins. The surface of neutrophils is highly dynamic as a result of the incorporation of membrane from intracellular vesicles and granules, a process that is known to add significantly to the total cell surface measured by an increase in electric capacitance.⁴⁶ A number of membrane-bound receptors are localized to secretory vesicles and incorporated into the surface membrane when secretory vesicles fuse with the plasma membrane, as occurs during diapedesis. This enhances the ability of neutrophils to respond to the signals presented by endothelial cells or present in the extravascular tissue.

Receptors for Recognition of Microbes

Neutrophils and other cells of the innate immune system recognize microbes through germline-encoded receptors, which recognize molecular patterns that are relative unique to pathogens and shared among groups of pathogens, so-called pathogen-associated molecular patterns (PAMPs). These pattern-recognition receptors (PRRs) include the membrane-bound toll-like receptors (TLRs) and C-type lectin receptors (CLRs), and the cytosolic nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs) and RIG-like receptors (RLRs).^{47–50} Although PRRs are highly expressed in myeloid cells, they are also widely expressed in cells that are regularly exposed to microorganisms, particularly in epithelial cells.

TLRs are type 1 transmembrane signaling receptors that are activated by dimerization induced by ligand binding.⁵¹ The TLRs may dimerize both as homodimers and heterodimers. TLRs that recognize

microbial membrane components are largely present on the cell surface, and include TLR2 that recognizes lipoproteins and lipopeptides in association with either TLR1 or TLR6. CD14 is known as an LPS-binding protein but is not itself able to signal and presents LPS to TLR4.⁵¹ TLR5 binds flagellin, and TLR11 binds profilin-like proteins of protozoa.⁵² TLRs that recognize viral components are largely expressed on intracellular vesicles that may fuse with phagosomes and include TLR3 (not present in neutrophils) that recognizes double-stranded RNA, TLR7/8 that binds viral single-stranded RNA,⁵³ and TLR9 that binds unmethylated CpG regions on DNA.⁵⁴

Ligand binding, that is, dimerization of TLRs leads to recruitment of one of four intracellular adaptor proteins to the TIR (toll/IL-1 receptor) domain of the TLR. These proteins include MyD88 (myeloid differentiation factor 88), Mal/TIRAP (MyD88-adaptor-like/toll-IL 1 receptor domain containing adaptor protein), TRAM (TRIF-related adaptor molecule), and TRIF (TIR domain-containing adaptor inducing IFN- β). While many TLRs (5, 7, 8, and 9) exclusively use MyD88, TLR2 requires both Mal and MyD88 and TLR4 can use either Mal (MyD88-adaptor-like) and MyD88 or TRAM and TRIF to signal to NF- κ B (nuclear factor- κ B) or interferon regulatory factor (IRF)-3.^{55,56,47}

CLRs comprise a heterogeneous group of *trans*-membrane receptors that bind carbohydrates such as mannose, fucose, and β -glucans present on a variety of microbes, fungi in particular. They signal largely via their cytosolic ITAMs and Syk to activate NF- κ B, nuclear factor of activated T cell (NFAT), and microtubule-associated protein kinases (MAPKs) resulting in production of proinflammatory cytokines.⁴⁸

NLR proteins are cytosolic proteins that are divided into five subfamilies, NLRA, NLRB, NLRC, NLRP, and NLRX.⁵⁰ Their N terminus contains either a caspase activation and recruitment domain (CARD) or a pyrin domain (PYD). The NLRC members NOD1 and NOD2 recognize peptidoglycans of both Gram-positive and Gram-negative bacteria and signal to activate the NF- κ B pathway. Other members of the NLRC and NLRP subfamily are essential in organizing the inflammasome. The NLRs multimerize through their CARDs into inflammasomes,⁵⁰ cytoplasmic structures that activate caspase-1, which, in turn, convert pro-IL-1 and pro-IL-18 to the mature proinflammatory cytokines that are secreted.⁵⁷

A variety of chemokine receptors are found on the surface of the neutrophil. These are in general G-protein-coupled receptors. Other G-protein-coupled receptors on neutrophils are the purine receptors for adenosine diphosphate (ADP) and ATP, the PAF receptor C5a, and formyl-methionyl-leucyl-phenylalanine (fMLP) receptors. Receptors not belonging to the G-protein-coupled receptor family include receptors for IL-1, IL-10, and TNF- α , and the growth factors receptors for granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF). Both growth factor receptors are important for myeloid development, and play an important role in enhancing neutrophil function and gene transcription in mature neutrophils. A burst of transcriptional activity is associated with the diapedesis of neutrophils into tissues, which results in downregulation of proapoptotic genes and upregulation of genes coding for antiapoptotic proteins, upregulation of genes encoding chemokines and cytokines that may recruit macrophages, T cells and additional neutrophils, and downregulation of genes encoding chemokine receptors (see Fig. 66–2).⁵⁸

Surface Components for Phagocytosis

Neutrophils express the Fc α receptor (CD89) for immunoglobulin (Ig) A and IgG receptors, Fc γ RIIA (CD32), and Fc γ RIII (CD16). Neutrophils also express receptors for the complement components, including CD1qR, CR1 (CD35), CR3 (CD11/CD18), and CR4. CR1 binds CD3b, C4b, and C3bi with decreasing affinity. CR3 recognizes

C3bi (a proteolytic fragment of C3b). Of particular importance is that both Fc γ receptors and GPI-coupled receptors appear to be localized to lipid rafts. Lipid rafts are important, but elusive structures that facilitate signal transduction leading to phagocytosis by promoting several membrane protein interactions. Initially the rafts were conceptually associated with caveolae, which are structures identified on endothelial cells and thought to be important for transendothelial cell traffic. The caveolae were identified by their high content of cholesterol lipids and the presence of the structural protein, caveolin. Rafts were subsequently identified on neutrophils, but these cells are devoid of caveolin.⁵⁹ Rafts are perhaps best viewed as patches of surface membrane that attract many hydrophobic proteins including signaling molecules such as tyrosine kinases and phosphatases. Other membrane protein receptors that are not normally associated with rafts may change their conformation and subsequently associate with rafts upon binding their ligands. This is particularly true for the Fc γ and GPI-coupled receptors.

SECRETORY VESICLES

Secretory vesicles are small intracellular vesicles that were discovered during the search for the structural basis for upregulation of a variety of surface molecules on neutrophils in response to nanomolar concentrations of fMLP and other chemotactic stimuli. They were initially identified by “latent” alkaline phosphatase.⁶⁰ Secretory vesicles of neutrophils should not be confused with the vesicles that carry cargo from endoplasmic reticulum and Golgi in the constitutive secretory pathway of other cells and that are sometimes also named secretory vesicles. Secretory vesicles of neutrophils are specialized endocytosis vesicles that are formed in the final stages of neutrophil maturation in the marrow. They contain plasma proteins, seemingly without any selectivity. Albumin thus serves as a marker for secretory vesicles and has allowed the identification of these as small intracellular vesicles that are scattered throughout the cytoplasm of neutrophils as is true for neutrophil granules. The plasma proteins inside secretory vesicles show no sign of degradation, thus no fusion takes place with lysosomal structures.⁶¹ Secretory vesicles behave like the traditional neutrophil granules. They require a specific signal for mobilization.⁶² Secretory vesicles are not important for their cargo (plasma proteins), but for their membrane which becomes fully incorporated into the plasma membrane of the neutrophil upon stimulation.^{61,63–66} Secretory vesicles host most of the neutrophil chemotactic and GPI-coupled receptors, TLRs, and one of the early acting downstream effectors, phospholipase D.⁶⁷ They enrich the plasma membrane with receptors for adhesion and signaling, and can be seen as the structural basis for transition of neutrophils from circulating quiescent cells that do not respond well to stimuli such as chemoattractants and objects to be phagocytosed, to highly responsive cells capable of establishing firm contact with endothelium. The signals generated by tethering of selectins or PSGL-1 to the endothelium are sufficient to mobilize secretory vesicles. Secretory vesicles are completely mobilized *in vivo* during neutrophil diapedesis.^{21,66}

The first identified marker of secretory vesicles, latent alkaline phosphatase, is known to be elevated in chronic myeloproliferative disorders except for chronic myelogenous leukemia (CML), but the content of secretory vesicles in neutrophils from patients with chronic myeloproliferative disorders is not different from normal neutrophils.^{68–70} The best marker for secretory vesicles is CD35, a transmembrane protein of 160 to 250 kDa that binds complement components C3b and C4b, because CD35, in contrast to alkaline phosphatase, is absent from the plasma membrane of unstimulated neutrophils, and because it is absent from granules (in contrast to $\alpha_M\beta_2$).^{32,65,71} It is not known whether secretory vesicles contain lipid rafts, but most GPI-linked proteins are raft-associated⁷² and are localized to secretory vesicles in neutrophils.

GRANULES

Nomenclature of Neutrophil Granules

The neutrophil is known for its granules. When Paul Ehrlich introduced aniline dyes in histochemistry and discovered the different subsets of leukocytes, the neutrophil granules were divided into those that took up the azure dye, the azurophilic granules, and the others, the specific granules.^{73,74} When the peroxidase reaction was introduced, the azurophil granules were found to be peroxidase-positive as a result of the presence of the major myeloid cell protein, myeloperoxidase (MPO), and the specific granules were thus named peroxidase-negative granules.^{75,76} Because the azurophil granules are formed first, in the promyelocyte, and the specific granules later, in the myelocyte, these are also termed primary and secondary granules, respectively. A tertiary granule subset was identified in human neutrophils and shown to contain gelatinase,⁷⁷ but the ultrastructure was not determined until the issue of the neutrophil gelatinase (matrix metalloproteinase [MMP]-9) as a possible complex with neutrophil gelatinase-associated lipocalin (NGAL) was identified.^{78,79}

Granules were initially viewed of as small bags that emptied their content of bactericidal substances onto the ingested microorganisms when granules fuse with the phagocytic vacuole during phagocytosis, but it later became clear that granules are not only important for their cargo, but also for their membranes, as they contain proteins that become incorporated into the membrane of the phagocytic vacuole and into the surface membrane when the granules are mobilized.^{80,81} If granules were classified by their content, both of matrix proteins and membrane proteins, the number of different granule subsets that exists in neutrophils would be meaninglessly high. Yet nature has provided a beautiful setting that allows the neutrophil to fine tune its response to a specific task. *A priori*, there would be two reasons for having different subsets of granules: One would be to ensure that proteins, which cannot coexist, are segregated; that is, protease-sensitive proteins are separated from proteases. The other reason would be to have proteins whose service is needed at one time separated from proteins whose service is needed at a different time.

Heterogeneity of Neutrophil Granules

Among the peroxidase-positive granules, subsets can be identified that are rich in defensins as well as some that are not.^{82,83} Functionally, no difference has been identified in terms of the regulation of exocytosis of these peroxidase-positive granule subsets.⁸⁴ Other constituents include the serine proteases elastase, cathepsin G, proteinase 3, and neutrophil serine protease 4 (NSP4), and the inactive serine protease azurocidin (aka CAP 37), the antimicrobial proteins BPI (bacterial permeability-increasing protein), lysozyme, and the α defensins, which are the dominating species.⁸⁰ Defensins are also named HNPs (human neutrophil peptides). The membrane of the azurophil granules contains CD63 (granulophysin) and CD68, but their role in neutrophil function remains unclear.^{85,86} Many of the proteins present in peroxidase granules are proteolytically processed both at the N-terminus and the C-terminus to the active mature forms, which are stored in the granule matrix.

Peroxidase-negative granules can be divided into three subsets based on the distribution of the two marker proteins lactoferrin and gelatinase: granules that contain lactoferrin, but no gelatinase (15 percent of peroxidase-negative granules), granules that contain both proteins (60 percent), and granules that are rich in gelatinase, but low (or absent) in lactoferrin (25 percent).⁸⁷ The latter are named gelatinase granules or tertiary granules, whereas those that contain lactoferrin are called specific or secondary granules. It is a characteristic of peroxidase-negative granules that the proteins present in their matrix are not proteolytically

processed. The MMPs of peroxidase-negative granules are stored as a proform,⁸⁸ as is the major bactericidal protein hCAP-18.^{89,90} No major differences have been identified in the content of membrane proteins of the peroxidase-negative granule subsets. All contain the flavocytochrome p22^{phox}/gp91^{phox} complex that is part of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, and all contain the major β_2 -integrin $\alpha_M\beta_2$ —and these are even shared with the membrane of secretory vesicles.^{32,91,92} The divalent cation transporter Nramp1 is localized only to gelatinase granules,⁹³ and the membrane MMP leukolysin (MMP-25)⁹⁴ is shared between gelatinase granules and secretory vesicles. However, the subsets differ markedly in their propensity for exocytosis. Following neutrophil stimulation, gelatinase granules are exocytosed to a larger extent than granules containing both lactoferrin and gelatinase, and these are more readily mobilized than granules containing lactoferrin but lacking gelatinase. These, in turn, are mobilized more readily than peroxidase-positive granules.^{62,66,79,87,95} This organization of granule subsets with different content and different set points to trigger exocytosis allows the neutrophil to mobilize MMPs and integrins necessary for movement through the basal membrane and tissue before the bactericidal peptides and serine protease are called to play, but it puts an enormous task on the organization of the biosynthetic apparatus to secure that the right granule proteins are targeted to the granules with a given trigger for exocytosis.

The content of isolated granules has been mapped by proteome analysis.⁹⁶ High-resolution mass spectrometry has identified 1300 proteins associated with neutrophil granules, plasma membranes and secretory vesicles and confirmed that localization is largely determined by time of biosynthesis.⁹⁷

Targeting by Biosynthetic Timing

The extreme heterogeneity of neutrophil granules and their individual control of exocytosis can be explained simply by timing of their biosynthesis (Fig. 66–3). Granule proteins are synthesized during myelopoiesis from myeloblasts to band cells and segmented neutrophils in the marrow.^{75,76,98} The window of biosynthesis of each granule protein is highly controlled by combinations of transcription factors that change as the cells differentiate and mature.^{99,100} If all granule proteins are targeted to granules during synthesis, the content of newly formed granules would change as the cell matures because the profile of biosynthesis changes. A global view of the change in transcriptional activity of neutrophil precursors during maturation in the marrow confirmed the association between granule localization and transcriptional activity.¹⁰¹ This simple mechanism largely explains the heterogeneity of granules¹⁰² and their contents, but it does not account for the differences in exocytotic rates among individualized subsets. By timing the biosynthesis of the proteins essential for fusion^{103,104} to granule membranes during maturation, it is possible to regulate the rates of exocytosis. Indeed, the v-SNARE (SNAP receptor), vesicle-associated membrane protein (VAMP)-2 is present in a higher density on gelatinase granules than on specific granules and is most highly expressed on secretory vesicles,^{105,106} which correlates with the ease of releasing granule subsets from the neutrophil following activation.

Sorting between the Constitutive and Regulated Exocytotic Pathway

Although the sorting by timing can explain the granule heterogeneity of neutrophil granules, it does not provide any clues to the mechanisms

Figure 66–3. Formation of granule subsets during myelopoiesis and regulation of granule protein transcription. Difference in the appearance and disappearance of transcription factors regulate the individual window of granule protein gene transcription and translation into protein that is targeted to forming granules, explaining the heterogeneity of neutrophil granules.

responsible for diverting newly synthesized proteins to granules as opposed to immediate (constitutive) secretion. Not all granule proteins are equally efficiently directed to granules. Lysozyme is poorly retained during biosynthesis.¹⁰⁷ This explains the high concentration of lysozyme in plasma.¹⁰⁸ MPO is efficiently retained and the plasma level of MPO is consequently very low. A particularly interesting observation pertains to α defensins. These are localized exclusively to azurophil granules, but their window of biosynthesis is very similar to that of lactoferrin,^{107,100} and defensins and lactoferrin are both controlled by the transcription factor C/EBP ϵ (CCAAT/enhancer binding protein ϵ), which is absolutely required for biosynthesis of specific granule proteins.^{109,110} The absence of defensins from specific granules, despite an active biosynthesis when other specific granule proteins are formed, is explained by a complete lack of sorting of defensins to granules in myelocytes.^{99,100,107} Only defensins synthesized at the late promyelocytic stage are routed to granules, whereas defensins synthesized at the myelocyte stage are secreted from cells after biosynthesis¹⁰⁷ and is present in relatively high concentrations in plasma.¹¹¹ The defensins that are targeted to granules are processed to mature defensins, whereas the defensins that are secreted remain unprocessed. Processing of defensins removes a charge neutralizing propiece, sorting of defensins and other granule proteins to granules may depend on their ability to interact with negatively charged proteoglycans that are present in the matrix of granules.^{112–114} Serglycin, an intracellular proteoglycan is present in Golgi and immature granules of promyelocytes and disappears as the cells mature.¹¹⁵ Serglycin is absolutely critical for confining a variety of mast cell proteins to the mast cell granules.¹¹⁶ Granulocytes from mice with a targeted disruption of the serglycin gene are morphologically normal and contain normal levels of granule proteins except elastase.¹¹⁷ CD63 was demonstrated to be involved in sorting of elastase to azurophil granules,¹¹⁸ but this may be indirectly via serglycin. An N-terminal sorting domain has been identified in serglycin and was shown to be essential for routing of serglycin to mast cell granules.¹¹⁹ No common denominator has been identified that can fully explain why neutrophil proteins are sorted to granules. Perhaps the lack of efficient sorting to granules may not solely be taken as inefficiency, but may be a way to secure a desirable level of antibiotic protein such as lysozyme¹⁰⁸ and hCAP-18¹²⁰ in plasma which renders the myeloid cells of the marrow a major secretory organ.

Control of Neutrophil Granule Protein Expression

The biosynthesis of neutrophil granule proteins is controlled at the transcriptional and not the translational level (see Fig. 66–3).^{98–100} Not all transcription factors that are responsible for biosynthesis of granule protein have been identified, and the role of an individual transcription factor may be difficult to identify from gene knockout studies as transcription factors may work at multiple stages during myelopoiesis. The transcription factor PU.1 is essential for myelopoiesis because knockout mice do not form myeloid progenitors beyond myeloblasts^{121,122}; but this does not preclude PU.1 from regulating transcription of individual granule proteins at a later stage of development.^{123–126} Figure 66–3 shows the profile of important myeloid transcription factors during maturation of normal myeloid cells in the marrow *in vivo*. *RUNX1* (AML-1), *c-MYB*, *CASP*, *C/EBP α* , *C/EBP γ* , *GATA-1*, and *ELF-1* gene products are all strongly expressed in the myeloblast and promyelocyte, and some of these are required for azurophil granule protein expression. Then *c-MYB*, *AML-1*, *GATA-1*, and *ELF-1* gene products are downregulated as the cells enter the myelocyte stage, heralded by a brisk and transient upregulation of *C/EBP ϵ* to initiate expression of peroxidase-negative granule proteins⁹⁹ in agreement with the lack of specific granules in *C/EBP ϵ -/-* mice and with the observation of a *C/EBP ϵ* mutation in patients with a rare specific granule deficiency.^{109,110,127,128} PU.1, *C/EBP β* , and *C/EBP δ* also appear at the promyelocyte myelocyte

transition, but in contrast to *C/EBP ϵ* , continue to increase as the cells mature to neutrophils. *ELF-1* reappears at the metamyelocyte stage followed by *C/EBP ξ* , *c-Jun*, and *c-fos* that are expressed at the band cell stage and increase in content as the cells mature.⁹⁹

MicroRNA

MicroRNAs (miRNAs) are important regulators of protein synthesis. In general, they bind to the 3'-end of mRNA and inhibit translation. Just like genes for granule proteins, mRNAs are expressed during maturation of neutrophils in the marrow depending on the stage of neutrophil maturation and can be classified into six groups, each with its characteristic expression profile.¹²⁹ So far, miRNAs have been shown to regulate proteins of importance for proliferation but not (yet) expression of individual granule proteins. Expression of the myeloid-specific miRNA-223 increases during maturation of neutrophils in the marrow, and after their release into the circulating. One of the targets of miRNA-223 is the *Mef2c* transcription factor. Mice that lack miRNA-223 expand granulopoiesis and the mature neutrophils mount an enhanced respiratory burst in response to phorbol myristate acetate (PMA), indicating that miRNA-223 acts as a negative regulator of granulopoiesis and neutrophil activation.¹³⁰ miRNA-130a is highly expressed in myeloblasts and promyelocytes and targets *SMAD4*, which, despite a high level of mRNA in promyelocytes, is not expressed at the protein level, and the cells are consequently insensitive to growth inhibition by transforming growth factor β (TGF- β)-induced growth inhibition. miRNA-130a also inhibits *C/EBP ϵ* which induces exit from cell cycle and growth arrest at the myelocyte stage. Hence, miRNA-130a seems important for the expansion of myeloblasts, promyelocytes and early myelocytes.^{131,132}

FUNCTION OF INDIVIDUAL GRANULE PROTEINS AND THEIR ROLE IN OXIDATIVE AND NONOXIDATIVE MICROBIAL KILLING

Proteins of Azurophil Granules

Table 66–1 lists the physical-chemical and functional properties of neutrophil granules.

The protein MPO is a marker of azurophil granules. It is formed as a 90-kDa precursor with an internal disulphide bridge that forms a link between the 57- and 13.5-kDa subunits that are generated by the proteolytic processing that takes place during routing to granules. The heme group, which is necessary for the reduction-oxidation (redox) functions of MPO, associates with the 90-kDa subunit.¹³³ This seems to be a necessary prerequisite for subsequent processing.¹³⁴ MPO reacts with H_2O_2 , formed by the NADPH oxidase, and increases the toxic potential of this oxidant. Through oxidation of chloride, tyrosine, and nitrite, the hydrogen peroxide (H_2O_2)-MPO system induces formation of hypochlorous acid (HOCl), other chlorination products, tyrosine radicals, and reactive nitrogen intermediates, each of which can attack the surface membrane of microorganisms.^{135,136} MPO may be found on endothelial cells during inflammation and can inactivate nitric oxide (NO).¹³⁷ In addition to the activities of MPO itself, MPO is known for the anti-MPO autoantibodies that are characteristic of the pANCA (perinuclear antineutrophil cytoplasmic antibodies) that are found in vasculitides, in particular those that primarily affect kidneys.^{138,139}

BPI is a 55-kDa protein with high homology to the LPS-binding protein of plasma. It is organized into two largely symmetrical subdomains, one of which is responsible for the binding of LPS and for the antimicrobial activity against Gram-negative microorganisms. In contrast to LPS-binding protein, which presents endotoxin to CD14 and elicits a proinflammatory response, BPI binds LPS independent of CD14 and neutralizes the effects of LPS.¹⁴⁰ A transgene expressing

TABLE 66-1. Physical-Chemical and Functional Properties of Neutrophil Granules

Granule Protein	Localization	Physicochemical Properties	Function
Myeloperoxidase	Azurophil granule (AG)	Heme protein, 90-kDa proform with an internal disulphide bond between the 57- and the 13.5-kDa subunits, generated by proteolytic processing that takes place during routing to granules	The MPO-halide-H ₂ O ₂ system generates hypochlorous acid (HOCl), other chlorination products, tyrosine radicals, and reactive nitrogen intermediates, each of which can attack the surface membrane of microorganisms
Bacterial permeability-increasing (BPI) protein	AG	55-kDa protein with high homology to the LPS-binding protein of plasma	BPI is organized into two largely symmetrical subdomains one of which is responsible for the binding of lipopolysaccharide (LPS) and for the antimicrobial activity against Gram-negative microorganisms
Defensins: three α -defensins; human neutrophil peptides (HNPs) 1-3	AG	7-kDa proforms processed by proteolytic cleavage to mature 3-kDa defensins that share a characteristic three disulfide bond motif: 1-6, 2-4, 3-5	Defensins are small, amphipathic, pore-forming, antibacterial cationic peptides with a broad spectrum of antibacterial activity
Serine proteases of azurophil granules: elastase, cathepsin G, proteinase 3, and neutrophil serine protease 4 (NSP4); azurocidin (CAP37 or heparin-binding protein [HBP]) is enzymatically inactive	AG	28-kDa proforms, processed to active proteases en route to azurophil granules	Serine proteases, but both elastase and cathepsin G have direct antibacterial activities that are not dependent on their enzymatic activity; proteinase 3 liberates the antibacterial peptide LL37 from hCAP-18; HBP is chemotactic for monocytes; HBP may open endothelial cell tight junctions
Lysozyme	AG ~30%; specific granules (SG) ~50%; gelatinase granules (GG) ~20%	Cationic antimicrobial peptide of 14 kDa; in contrast to many neutrophil granule proteins, lysozyme is inefficiently targeted to granules and circulates free in plasma in a substantial quantity that reflects the normal myelopoietic activity	Lysozyme cleaves peptidoglycan-polymers of bacterial cell walls and displays bactericidal activity toward the nonpathogenic Gram-positive bacteria <i>Bacillus subtilis</i> ; a particular high serum level is characteristic for the myelomonocytic leukemias
Lactoferrin	SG	78-kDa iron chelator; member of the transferrin protein family with a high affinity for iron and similar iron-binding characteristics as ferritin	The antibacterial activity of lactoferrin does not depend exclusively on its ability to sequester iron. Proteolytic fragments, some of which are known as lactoferricin, are directly bactericidal
Neutrophil gelatinase-associated lipocalin (NGAL) or siderochelin	SG	25-kDa N-glycosylated member of the lipocalin protein family	NGAL is the first known siderophore-binding eukaryotic protein; NGAL binds enterochelin/enterobactin with high affinity, and blocks growth of <i>Escherichia coli</i> by sequestering siderophore-iron complexes
hCAP-18	SG	18 kDa; only human member of the cathelicidin protein family	Stored and released intact; binds endotoxin; C-terminal antibactericidal peptide, LL-37 released by proteinase 3; active mainly against Gram-positive bacteria, is chemotactic for T cells, monocytes, and neutrophils, and has angiogenic properties
Neutrophil collagenase	SG	75-kDa matrix metalloproteinase 8 (MMP-8); like other MMPs, MMP-8 is stored inactive and must be N-terminally trimmed to remove the inhibitory peptide	Active against types I, II, and III collagen
Olfactomedin 4 (OLFM4)	SG	65-kDa protein that forms multimers by disulfide bonding	Function is unknown, but OLFM4 is present only in a subset (25%) of neutrophils
Gelatinase	GG	92-kDa MMP-9; stored inactive	Active against type IV collagen
Leukolysin, which is distributed among of resting neutrophils	SG ~10%; GG ~40%; secretory vesicles (SV) ~30%; plasma membranes (PM) ~20%	Leukolysin is a 56-kDa glycosylphosphatidylinositol (GPI)-anchored membrane-bound MMP (MT6-MMP/MMP-25)	Active against fibronectin, chondroitin sulfate proteoglycan, dermatan sulfate proteoglycan

(continued)

TABLE 66–1. Physical–Chemical and Functional Properties of Neutrophil Granules (Continued)

Granule Protein	Localization	Physicochemical Properties	Function
Cytochrome b ₅₅₈ (gp91 ^{phox} , p22 ^{phox})	SG ~60%; GG ~25%; SV ~15%	Heterodimeric flavoheme protein; 91-kDa glycoprotein subunit (heme-flavin binding); 22-kDa protein subunit, possibly heme binding	Together with p47 ^{phox} , p67 ^{phox} , and p40 ^{phox} , cytochrome b ₅₅₈ constitutes the superoxide generating nicotinamide adenine dinucleotide phosphate (NADPH) oxidase of phagocytes
CD11b/CD18 (Mac-1, Mo1, CR3, α _M β ₂)	SG ~60%; GG ~25%; SV ~15%	Most prominent β ₂ -integrin in neutrophils; CD11B = α _M and is a glycoprotein of 170 kDa; CD18 = β ₂ and is a glycoprotein of 95 kDa	Multifunctional integrin that functions as an adhesion receptor binding to members of the immunoglobulin family intercellular adhesion molecule (ICAM)-1, to fibronectin, collagen; is important in mediating firm adhesion to vascular endothelial cells; functions as a phagocytosis receptor for C3bi-coated particles
Pentraxin-3	SG	Pentamer of 47-kDa subunits	Binds complement C1q, selected microorganisms
Ficolin-1	GG	Multimer of 32-kDa subunits	Binds acetylated carbohydrates on microorganisms; may activate mannose-binding lectin-associated serine proteases
Arginase 1	GG	37-kDa glycoprotein	Degrades arginine, the substrate for nitric oxide (NO) synthase

high levels of BPI has enhanced resistance against endotoxin.¹⁴¹ Important effects not related to LPS have been described, such as chemotaxis, opsonization, and dendritic cell function, as reviewed in Ref. 142.

Defensins are small antibacterial cationic peptides with a broad spectrum of antibacterial activity.¹⁴³ They share a characteristic three-disulfide-bond motif.^{82,144,145} Based on this, mammalian defensins are divided into α defensins, β defensins, and the cyclical θ defensins.¹⁴⁶ Only α defensins are found in human neutrophils, and reside exclusively in azurophil granules. They are by far the dominating proteins of azurophil granules, yet are only expressed in a subset of granules that are formed late in the promyelocyte stage.^{83,100,107} Three defensins have been isolated from azurophil granules, HNP-1 to HNP-3.⁸² Large amounts of unprocessed defensin, that is, prodefensin, are secreted from late promyelocytes and myelocytes in the marrow and may serve as a marker of normal myelopoietic activity.¹¹¹ In contrast to lysozyme and MPO, prodefensins are not expressed by acute leukemia cells. A rise of prodefensin in plasma precedes detectable neutrophils by 6 days and is a measure of normal granulopoiesis which may be of clinical use in the setting of myeloablative treatment for acute leukemia.¹¹¹

The serine proteases of azurophil granules include elastase, cathepsin G, proteinase-3, and NSP4.^{147,148} Azurocidin, which is also named CAP37 or heparin-binding protein (HBP), is an enzymatically inactive serine protease.^{149–153} Both elastase and cathepsin G have direct antibacterial activities that are not dependent on their enzymatic activity. Proteinase 3 expression leads to autoantibodies against itself in Wegener granulomatosis, which is known as cANCA (cytoplasmic antineutrophil cytoplasmic antibody).¹⁵⁴ Proteinase 3 is also bound to the surface of circulating neutrophils at levels that vary considerably amongst individuals but are highly constant throughout life in a given individual. The binding is mediated by the NB1 antigen (CD177).^{155,156} A secreted precursor of proteinase 3 has been suggested to inhibit normal myelopoiesis¹⁵⁷ and to play a role in regulation of myelopoiesis. So far, the only specific substrate of proteinase 3 identified is the cathelicidin of specific granules hCAP-18. Proteinase 3 activates hCAP-18 by removing the cathelicidin part, and unleashing the antibacterial activity of the C-terminal LL-37 peptide.⁹⁰ Cathepsin C, also known as dipeptidyl

peptidase 1, removes two inhibitory N-terminal amino acids from the serine proteases prior to their storage in granules.¹⁵⁸ Patients with the Papillon-Lefèvre syndrome lack cathepsin C activity and are not able to store serine proteases in their neutrophils.¹⁵⁹ The condition is characterized by severe juvenile periodontitis and keratosis in hands and feet, but not by major systemic infections,¹⁶⁰ arguing against the notion the serine proteases are important for immune defense.¹⁶¹

The membrane of azurophil granules contains CD63 (granulophysin), which is implicated in transmembrane signaling with the β₂ integrins in the activated neutrophil.^{85,86,162} Also, the CD68 antigen^{100,163} and presenilin appear localized exclusively to the membrane of azurophil granules,¹⁶⁴ whereas stromatin is found in the membrane of all granules¹⁶⁵ and the vacuolar-type H⁺-ATPase is shared between azurophil, gelatinase granules and secretory vesicles.¹⁶⁶ These membrane proteins will translocate to the phagocytic vacuole or to the plasma membrane when neutrophils are activated and engaged in phagocytosis.

Proteins of Peroxidase-Negative Granules

For an overview, see Table 66–1.

Lactoferrin is the dominating protein of specific granules.¹⁶⁷ It is a 78-kDa iron-chelator, member of the transferrin protein family with a high affinity for iron and similar binding characteristics as ferritin.^{168,169} The antibacterial activity of lactoferrin does not depend exclusively on its ability to sequester iron because proteolytic fragments of lactoferrin, some of which are known as lactoferricin, are directly bactericidal.^{170,171}

NGAL, or lipocalin 2, is a 25-kDa N-glycosylated member of the lipocalin protein family.⁷⁹ Lipocalins are transport proteins that bind small and often lipophilic substances in their canonical lipocalin pocket.¹⁷² Some NGAL is associated with gelatinase (MMP-9) in a subset of specific granules,¹⁷³ but the majority is present either as a monomer or as a homodimer in specific granules. NGAL interferes with the activation and stability of MMPs,¹⁷⁴ but the major function of NGAL is to bind and sequester siderophores. NGAL binds enterochelin/enterobactin with high affinity, and blocks growth of *Escherichia coli* by sequestering siderophore-iron complexes,¹⁷⁵ which might not be only a neutrophil-specific antibacterial defense because NGAL can be induced in a variety of epithelial cells during inflammation by IL-1.¹⁷⁶ NGAL

has been demonstrated to play a protective role in infections against *E. coli*,¹⁷⁷ *Klebsiella pneumoniae*,¹⁷⁸ *Salmonella typhimurium*,¹⁷⁹ and *Mycobacterium tuberculosis*.¹⁸⁰ NGAL has effects not explained by sequestering bacterial siderophores and was shown to worsen the outcome of pneumococcal pneumonia by deactivating macrophages.¹⁸¹ It is possible that the ability of NGAL to bind endogenous siderophore-like structures and transport iron may explain some of these effects.¹⁸² Nramp1, the cation transporter, was initially identified first in macrophages as an essential resistance factor against mycobacterial infection. It is present in membranes of both specific and gelatinase-containing neutrophil granules.^{93,183}

Lysozyme is a cationic antimicrobial peptide of 14 kDa.¹⁸⁴ In agreement with its biosynthetic profile, lysozyme is present in all granule subsets, with peak concentrations in specific granules.^{100,108} Lysozyme cleaves peptidoglycan polymers of bacterial cell walls and displays bactericidal activity toward the nonpathogenic Gram-positive bacteria *Bacillus subtilis*.¹⁸⁵ Lysozyme also binds LPS¹⁸⁶ and reduces cytokine production and mortality caused by LPS in a murine model system of septic shock.¹⁸⁷ In contrast to many neutrophil granule proteins, lysozyme is inefficiently targeted to granules and circulates free in plasma in a substantial quantity that reflects the granulopoietic activity.^{107,108} Lysozyme is also secreted from activated macrophages,¹⁸⁸ and a particular elevated serum level is characteristic of the leukemias with a large proportion of monocytes.¹⁸⁹

hCAP-18,⁸⁹ also known as LL-37¹⁹⁰ or CAMP, is the only human member of a family of antimicrobial peptides known as cathelicidins. Cathelicidins are typically found in peroxidase-negative granules of mammalian neutrophils.¹⁹¹ hCAP-18 is a prominent protein of neutrophil specific granules present in equimolar concentrations with lactoferrin.¹⁹² It is also present in plasma at a substantial concentration bound to lipoproteins.¹²⁰ In general, cathelicidins are proantibiotic peptides that share a common and highly conserved 14-kDa N-terminal region known as the cathelin region, whereas the C-terminal regions vary extensively among the different cathelicidins. The C-terminal peptides must be liberated from the cathelin domain by proteolysis to become antibacterial. In most species this is carried out by elastase, but in human neutrophils this is done by proteinase 3 from azurophil granules. The liberated C-terminal peptide is known as LL-37.^{90,190} Like several other neutrophil proteins, hCAP-18 is formed by cells in other tissues, particularly epithelial cells.^{90,193–195} It is constitutively expressed in the testis and present in semen. Here, the activating protease is gastrin, a prostate protease that is active at low pH. This cleaves hCAP-18 to ALL-38, which has the same antibacterial spectrum as LL-37.¹⁹⁶ The cathelin part, which is released has some protease inhibitory activity by itself.¹⁹⁷ The LL-37 stimulates neutrophil, monocyte, and T-cell chemotaxis via the formyl peptide receptor-like-1.¹⁹⁸ In addition, hCAP-18/LL-37 has angiogenic¹⁹⁹ and endotoxin-neutralizing properties.²⁰⁰

Three MMPs have been identified in neutrophils: neutrophil collagenase (MMP-8,75 kDa), which is localized to specific granules,²⁰¹ gelatinase (MMP-9,92 kDa), which resides predominantly in gelatinase granules,^{78,202} and leukolysin (MT6-MMP/MMP-25,56 kDa), which is distributed among specific granules (approximately 10 percent), gelatinase granules (approximately 40 percent), secretory vesicles (approximately 30 percent), and the plasma membrane (approximately 20 percent) of resting neutrophils.^{94,203} The MMPs are stored as inactive proforms that are proteolytically activated following exocytosis. Together, the MMPs are capable of degrading major structural components of the extracellular matrix, including collagens, fibronectin, proteoglycans, and laminin, and they are believed to be of central importance for the degradation of vascular basal membranes and interstitial structures during neutrophil extravasation and migration.

Two pattern-recognition molecules, pentraxin 3 and ficolin1, are found in specific granules and gelatinase granules, respectively. Pentraxin 3, a member of the long pentraxins family, is synthesized in myelocytes and metamyelocytes and stored in specific granules of neutrophils. Pentraxin-3 binds the complement component C1q and mediates activation of the classical complement cascade. In addition, pentraxin-3 binds *K. pneumoniae* outer membrane protein A (KpOmpA) from Gram-negative bacteria, especially the *Enterobacteriaceae* species, and binds *Aspergillus fumigatus* conidia. Pentraxin-3 was shown to play a major role in uptake and killing of *A. fumigatus* conidia by neutrophils in a mouse model.^{204,205}

Ficolin-1 is present in gelatinase granules. Ficolin-1 binds acetylated carbohydrate structures on Gram-positive bacteria and can recruit mannose-binding lectin-associated serine proteases (MASPs) and activate the lectin complement cascade.²⁰⁶

Arginase-1 is a constituent of gelatinase granules²⁰⁷ and may participate in regulation of T-cell activities by removing arginine, the essential substrate for inducible nitrous oxide synthase. The product, proline, is essential for collagen synthesis and arginase-1 from neutrophils may thus support wound healing.

Olfactomedin 4, a 65-kDa specific granule protein, forms huge multimers, but only in approximately 25 percent of neutrophils, ranging from 5 to 40 percent between individuals and constant in each individual. The functional consequence is unknown.^{208,209}

Membrane proteins of peroxidase-negative granules are shared among the subsets of peroxidase-negative granules that can be distinguished based on their matrix proteins; that is, specific and azurophil granules. Two exceptions are Nramp1 and MMP-25, which are both present, predominantly in the membrane of gelatinase granules and secretory vesicles.^{93,94} Cytochrome b_{558} , which is comprised of gp91^{phox} and p22^{phox}, forms the membrane component of the NADPH oxidase and is a prominent membrane protein of peroxidase-negative granules.^{81,210} It codistributes with the major β_2 -integrin of neutrophils CD11b/CD18, with the major segment in specific granules, some in gelatinase granules, and some in secretory vesicles. Secretory vesicles are rapidly mobilized, and even though only 15 percent of the total cytochrome b_{558} and CD11b localizes to secretory vesicles, this is the fraction that is primarily translocated to the plasma membrane during neutrophil diapedesis.^{66,32} Hv1 is a voltage-gated proton channel situated in the plasma membrane and membranes of peroxidase-negative granules.²¹¹ Hv1 associates with nascent phagosomes, and neutralizes the negative charge induced by transport of electrons by the NADPH oxidase.^{212,213} The CD66 antigens found in the membrane of specific granules may play a role as bacterial receptors (galectin receptors) and generate signals to activate the NADPH oxidase.^{214,215}

STIMULUS-RESPONSE COUPLING BY NEUTROPHILS

Stimulus-response coupling by neutrophils has been the subject of intense research for many years. This work has been fruitful in illuminating some of the underlying causes of defects in cell activation. Studies of neutrophil degranulation and oxidative metabolism have also revealed transduction mechanisms common to a wide variety of other important secretory cell types, thereby greatly expanding the relevance of this work. This chapter considers next our current understanding of the activation process, which is shown schematically in Fig. 66–4.

RECEPTOR-LIGAND INTERACTIONS

Formyl Peptide Receptor

Neutrophil responses can be evoked by a variety of particulate and soluble stimuli. Opsonized particles, immune complexes, and

Figure 66-4. Signal transduction in neutrophils. G-protein-coupled receptors are seven transmembrane receptors that couple to heterotrimeric guanosine triphosphate (GTP)-binding (G) proteins. Agonist binding to the receptor triggers exchange of guanine diphosphate (GDP) for guanine triphosphate (GTP) on the $G\alpha$ subunit of the G-protein, and consequently, the dissociation of the α subunit for the $\beta\gamma$ -dimer. Both subunits can regulate the activity of multiple effectors such as phospholipase $C\beta$ (PLC β). PLC β cleaves an endogenous lipid, namely phosphatidylinositol bisphosphate (PtdInsP $_2$), yielding diacylglycerol (DAG) and inositol triphosphate (IP $_3$). IP $_3$ is known to liberate calcium from bound intracellular stores leading to a rise in intracellular-free calcium (Ca^{2+}). The increase in intracellular Ca^{2+} is augmented by an influx of Ca^{2+} from the extracellular space. Increased DAG, in concert with elevated Ca^{2+} can activate protein kinase isozymes α and β (PKC $\alpha\beta$) leading to their translocation to membranous sites. Phospholipase D (PLD) can be activated by PKC converting phosphatidylcholine to phosphatidic (PA) acid. Elevations in PA can mobilize the cytosolic proteins, p47, p67^{phox}, and p40^{phox} to bind to the membrane-bound proteins gp91^{phox} and p22^{phox}, which then reduces O_2 to O_2^- in the presence of NADPH.

chemokine and chemotactic factors produced during the inflammatory process activate neutrophils by binding to specific cell-surface receptors. Of the neutrophil chemotactic receptors, the *N*-formyl peptide receptor is the best characterized. *N*-formyl peptide, the synthetic analogues of bacterial *N*-formyl peptide products, induces a variety of neutrophil responses and has been extensively employed as activating stimuli. Specific receptors for the chemotactic peptide, fMLP, have been identified on the neutrophil surface,²¹⁶ and binding of the formyl peptide to its receptor correlates with its ability to induce chemotaxis and degranulation.²¹⁷ The formyl peptide receptor,²¹⁸ like the receptors for C5a, IL-8, LTB $_4$, and PAF, belongs to a family of seven *trans*-membrane-spanning domain proteins (7TMRs) that are coupled to heterotrimeric G-proteins (containing $G\alpha$ and β,γ subunits).^{219,213} Upon ligand binding, guanine diphosphate (GDP) bound to the $G\alpha$ subunit is exchanged with guanine triphosphate (GTP) and the β,γ subunits dissociate from the receptor and mediate downstream signaling. Phosphorylation of the receptors then augments their affinity for β arrestins. The association with β arrestins block association with β,γ subunits and mediate internalization of the receptors, but may also induce additional signals via β arrestins.^{220,221} The formyl peptide receptor has been studied in most detail in neutrophils. The receptor is highly glycosylated and has a relative molecular mass (Mr) of 50 to 70 kDa. It has been identified on the membranes of gelatinase granules and secretory vesicles, and shown to be mobilized to the cell surface following stimulation.²²²

C5a Receptor

Activation of the complement system generates C5a, a derivative of C5 and the most potent of the chemotactic proteins. C5a induces neutrophil chemotaxis, degranulation, and superoxide generation.^{222,223} Responses to C5a result from interactions with specific receptors on the cell surface.^{222,224} The receptor was identified as a single polypeptide in the plasma membrane with an apparent mass of 40 to 48 kDa.^{222,225} Binding studies show that there are 50,000 to 113,000 receptor sites per cell with a dissociation constant (Kd) of 2×10^{-9} M. The C5a receptor has been isolated and cloned, and is a member of the seven transmembrane-spanning class of G-protein-coupled receptors.²²⁶

Three other important G-protein-coupled receptors are for PAF, IL-8, and LTB $_4$. PAF and IL-8 receptors have been cloned.^{227,228} Their intracellular stores and signal transduction mechanisms are largely similar to those used by other G-protein-coupled receptors (e.g., fMLP).²²⁷ IL-8 has two related receptors, for which slightly different signal transduction pathways have been detected.²²⁹

C3 Receptors

Neutrophils also express receptors for the complement-derived chemotactic factors C3b and C3bi. Receptors for C3b and C3bi (also known as CR1 and CR3, respectively) are sparse on resting neutrophils, but increase significantly in numbers following activation with several stimuli because of incorporation from secretory vesicles (CR1 and CR3) and gelatinase and specific granules (CR3, which is the integrin Mac-1).^{32,71} The C3b receptor (CR1) is a glycoprotein with a molecular weight of 205 kDa and is located in secretory vesicles.^{65,71}

Integrins

CD11/CD18 integrins also play an important role in cell signaling. The adhesion of cells to surfaces or to other cells can either activate neutrophils directly or "prime" them for an enhanced response to other stimuli. For example, the oxidative burst of neutrophils is very different in cells that are suspended versus those that are adherent to surfaces.²³⁰ H_2O_2 production in response to chemotaxins is influenced by monoclonal antibodies to CD11b, but not CD11a.²³¹

Fc Receptors

Neutrophils possess three different receptors for immunoglobulins. Unstimulated cells express Fc γ RIIA and Fc γ RIII, also known as CD32 and CD16, respectively. Functionally, the most important of the two is the Fc γ RIII for clearing immune complexes,²³² and it is attached to the membrane by a GPI linkage.²³² The linkage is relatively labile, so the amount of Fc γ RIII on the membrane reflects a balance between shedding and mobilization from intracellular stores. Fc γ RIIA is a protein that spans the plasma membrane.²³³ The signal transduction pathways initiated by Fc γ RIII can crosstalk with the formyl peptide receptor, with CR3, and even with each other. A direct physical linkage between

CD11b and FcγRIIB has been demonstrated by experiments in which capping of one receptor results in co-capping a substantial fraction of the other receptor. CD11b can also interact with the transmembrane FcγRII, and both of these molecules can modify each other's signals.²³⁴

The tyrosine kinase Syk, plays a critical role in the phagocytic pathway mediated by FcγRIIA.²³⁵ A cytoplasmic amino acid motif, known as ITAM, is present on FcγRIIA and FcγRI/γ (a receptor found on IFN-γ-stimulated myeloid cells) and is essential for the phagocytic response during crosslinking of these two Fc receptors. Binding of Src family protein tyrosine kinases to the ITAM leads to activation of Src family protein tyrosine kinases and ITAM tyrosine phosphorylation. This serves to recruit phosphatidylinositol 3'-kinase (PI3K) and Syk, which when activated phosphorylates multiple substrates, including neighboring ITAMs. Syk is recruited from the cytosolic pool. The essential role for Syk-affecting signal transduction is reflected by ITAM-dependent activation of actin assembly. Other tyrosine kinases, including Src kinases, especially Lyn, facilitate the formation of the phagosome.²³⁶ Once active microfilaments are formed, they enhance the activity of phospholipase D (PLD) to generate phosphatidic acid (PA), a necessary phospholipid for phagocytosis to ensue.^{237,238}

Phospholipid Metabolism and Tyrosine Kinase Activation

The next step in signal transduction can be attributed to interactions of receptor-activated G proteins or through FcγRIIA and tyrosine kinases with phospholipases.^{239,240} For instance, a membrane-associated phosphoinositide-specific phospholipase is activated upon stimulation with chemotactic stimuli. In particular, phospholipase C (PLC) hydrolyzes phosphatidylinositol-4,5-bisphosphate (PIP₂) and phosphatidyl inositol-4-monophosphate (PIP₁) to the putative second-messenger products inositol 1,4,5-trisphosphate (IP₃) and 1,2-diacylglycerol (DAG) (see Fig. 66-4).²⁴¹ In neutrophils, IP₃ interacts with a specific intracellular receptor and stimulates the release of Ca²⁺, as well as opens Ca²⁺ channels on the plasma membrane, resulting in rises in intracellular Ca²⁺.²⁴² Activation of the small GTP-binding proteins of the Rac, Rho, and Cdc42 families regulates actin-dependent processes such as membrane ruffling, formation of pseudopodia, and stress fibers leading to cell adhesion and motility, and appears critical in neutrophil function,^{243,244} while working in concert with the phospholipases.

Even in the absence of PLC metabolism, there is a significant increase in DAG and Ca²⁺ intracellularly that accompanies phagocytosis.²⁴⁵ Ca²⁺ is necessary for granule phagosome fusion and DAG has been linked to both particle ingestion and degranulation.²⁴⁶ Both can be formed by the activation of PLD, which hydrolyzes phosphatidylcholine to produce PA and choline. Activation of PLD is mediated by Rho and/or ADP-ribosylation factor (ARF).²⁴⁷ Diacylglycerol is then generated by PA phosphohydrolase, which catalyzes the dephosphorylation of PA. The hallmark of the phosphatidylcholine-derived DAG is the presence of 1-*O*-alkyl linkages. During PA formation by the action of PLD on phosphatidylcholine, PA can act as a Ca²⁺ ionophore, thereby initiating fusogenic activity.²⁴⁸ Thus, the phosphatidylcholine acid generated during phagocytosis may promote fusion of neutrophil granules with newly formed phagosomes.

Another downstream target of DAG in phagocytosis is the activation of protein kinase C (PKC), particularly PKCδ, a Ca²⁺-independent isozyme of PKC found in neutrophils.²³⁷ PKCδ is one of four PKC isozymes that translocate to the plasma membrane during phagocytosis. During phagocytosis, PKCδ is translocated from the cytosol to the plasma membrane. Accompanying the translocation of PKCδ to the membrane, RAF-1 translocation is promoted. Following translocation of these two key components, mitogen-activated extracellular signal-regulated kinase (MEK) activation occurs, which is followed by activation of mitogen-activated protein (MAP) kinase/extracellular

signal-related kinase (ERK)-2 and then myosin light-chain kinase.²⁴⁰ Following phosphorylation of myosin, reorganization of the actin cytoskeletal occurs leading to phagocytosis. Concomitant with the activation of PLD, ceramide is generated by a neutral sphingomyelinase activity found in the plasma membrane of neutrophils and it is most likely important in attenuating the activity of the cells through inhibition of PLD.²⁴⁰ Following engagement of the Fc receptors and Syk activation in the neutrophil, PI3K is also activated. Inhibition of PI3K activity impedes phagocytosis.²³⁷

Arachidonate Metabolism In addition to their participation as putative second-messenger products in the stimulus-response coupling pathway, many lipid metabolites may be released from stimulated neutrophils, and, in turn, modulate cell function by interacting with receptors on other neutrophils. Phospholipase A₂, present on both the granules and plasma membranes of neutrophils,²⁴⁹ as well as the cytosol,²⁵⁰ is activated during neutrophil stimulation, yielding arachidonic acid as one of the major end products. Arachidonic acid is not only released from stimulated neutrophils, but also serves as a regulator of phospholipase A₂ (PLA₂) activity and as a stimulus for these cells.²⁵¹ Sensitivity of the cells to other stimuli can be enhanced with arachidonic acid and other long-chain fatty acids.²⁵²

Arachidonic acid can also be metabolized by the lipoxygenase pathway to produce hydroxyeicosatetraenoic acids (HETEs), including 5-HETE, 12-HETE, and 5,12-diHETE.²⁵³ These compounds have also been shown to induce several neutrophil responses.²⁵⁴ Stimulated neutrophils also produce the diHETE LTB₄ through the lipoxygenase pathway. LTB₄ and other leukotrienes can be released in response to a variety of stimuli.²⁵⁵ Receptors for LTB₄ have been partially purified, and their activation serves as a potent stimulus for chemotaxis and adherence.²⁵⁶

Another potent mediator of inflammation produced by stimulated neutrophils is 1-*O*-alkyl-2-acetyl-sn-glycerol-3-phosphoryl choline, also known as PAF.²¹ Not only is PAF synthesized by neutrophils and activated endothelial cells, but it induces degranulation, aggregation, and superoxide generation.²⁹ Inflamed endothelium generates PAF, which serves to immobilize neutrophils on the luminal surface of the endothelial cells, thereby facilitating the interaction of the neutrophil integrin receptors with the ICAM ligands on the endothelial cells.

Degranulation and Membrane Fusion

In stimulated cells the signal transduction cascade activates G proteins, followed by enhanced intracellular Ca²⁺, lipid remodeling, and protein kinase activation. These events culminate in secretion. This ultimate event—the fusion of granule membranes with phagosomes or the plasma membrane—occurs rapidly and is highly efficient.

Fusion Proteins Over the past 20 years the SNARE (soluble N-ethylmaleimide-sensitive factor attachment protein receptor) hypothesis has become the reigning paradigm for fusion of biomembranes.¹⁰⁴ The hypothesis is centered around the protein that is sensitive to N-ethylmaleimide (designated *NEM-sensitive fusion protein* or *NSF*) and several SNAREs on the participating membranes. The SNAREs are divided into the v-SNAREs, being found on vesicles or granules, and t-SNAREs, being found on the target plasma membranes. The SNARE hypothesis has proven to have great predictive value as the constellation of fusion proteins and their interactions appears in almost all species and tissues. Initial docking of granules with the membrane to which they fuse is likely mediated by Rab-GTPases. Once docking is obtained, SNAREs are recruited to both membranes and interact and mediate actual fusion assisted by SNARE-interacting proteins such as sSec1/Munc18 proteins and a local rise in Ca²⁺. Disassembly of the fusion complex is mediated by NSF in an ATP-dependent process.²⁵⁷ The t-SNARE

VAMP-2 is localized to the membranes of specific and gelatinase granule and secretory vesicles in resting human neutrophils,^{105,106} and the t-SNARE syntaxin 4 is associated with the plasma membrane as shown by immunoelectron microscopy. Munc18-3 may interact with syntaxin 4 and regulate fusion of secondary and gelatinase granules. VAMP-7 is associated with azurophil granule fusion and Munc18-2 may interact with syntaxin 3 and regulate azurophil granule fusion.^{258,259}

Neutrophil Extracellular Traps

What previously was considered pus was identified as a highly bactericidal structure composed of strands of chromatin and bactericidal neutrophil granule proteins attached.^{260,261} These NETs (see Fig. 66-2) are extruded from neutrophils in a process called *netosis* and represent one of three death programs of neutrophils: apoptosis, necrosis, and netosis. Neutrophils only undergo netosis if they have mounted a respiratory burst.²⁶² Elastase and MPO are also required for netosis.²⁶³ The NADPH oxidase activity of stimulated neutrophils thus serves two purposes, namely to generate reactive oxygen species for microbial killing and to induce formation of the bactericidal NETs after the intact neutrophil has ceased to function. This, in turn, means that patients with defective NADPH oxidase assembly (patients with chronic granulomatous disease [CGD]) lack both the ability to generate microbicidal oxygen species and the ability to form the NETs. Patients with the Papillon-Lefèvre syndrome (PLS) lack elastase and are incapable of generating NETs. PLS patients do not have a major immune defect and their symptoms are largely related to periodontal infections, in contrast to CGD patients. Negative effects of NETs have been noted as NETs may induce thrombosis.²⁶⁴ Neutrophils are able to generate NETs and maintain their structural integrity as an anucleate cell still capable of migration and phagocytosis.²⁶⁵

CLINICAL DISORDERS OF NEUTROPHIL FUNCTION

CLASSIFICATION

Neutrophil dysfunction may arise from (1) the absence of antibodies or complement components required to opsonize microorganisms, an interaction that provides a chemotactic signal; (2) the abnormalities of cytoplasmic and granule movement that alter the chemotactic response or that result in abnormalities of the plasma membrane affecting the cells in terms of capability to modulate movement; and (3) defective microbicidal capability. Comprehensive reviews of these syndromes are available to the interested reader.²⁶⁶⁻²⁶⁸

ABNORMALITIES OF THE SIGNAL MECHANISM AS A RESULT OF ANTIBODY AND COMPLEMENT DEFECTS OR IMPAIRMENT OF PATTERN RECEPTOR RECOGNITION

Because the synergistic action of immunoglobulins and complement proteins creates the opsonins that coat microorganisms and stimulate the development of chemotactic factors, a deficiency of either one may result in impaired neutrophil function. The most profound disturbances arise from abnormalities in C3, because this protein is the focal point for generation of opsonins and chemotactic factors (Chap. 19).²⁶⁹⁻²⁷¹ Opsonins such as C3b, generated from cleavage of C3, serve to coat bacteria. Opsonization in general refers to the coating of pathogens by serum proteins such that they are more likely to be ingested. Activation of C3 can occur in the absence of an antibody or the classical complement

components C1, C2, and C4; thus, disorders of these latter molecules result in less-severe clinical conditions. C3 deficiency is inherited as an autosomal recessive disorder. Homozygotes have undetectable serum levels of C3 and suffer from recurrent severe pyrogenic infections, whereas asymptomatic heterozygotes have half the normal values.

A functional deficiency of C3 protease resulting in severe pyrogenic infections also is seen in patients with a deficiency in C3b inactivator, a protein inhibitor of the alternative complement pathway. Unchecked activation of this pathway leads to hypercatabolism of C3 and factor B.²⁷² Properidin deficiency also results in a functional deficiency in C3.²⁷³ Properidin is a serum protein that belongs to the alternative complement pathway; it is involved in the stabilization of the enzyme complex C3bBb. The protein is a multimeric glycoprotein with a subunit Mr of 56,000, the gene of which has been cloned.²⁷⁴ Absence of properidin is associated with severe, often fatal, pyrogenic infections, often with meningococci.

Approximately 5 percent of the population have low serum levels of mannose-binding lectin (MBL),²⁷⁵ a serum lectin secreted by the liver that binds mannose sugars present and on the surface of bacteria, fungi, and some viruses. MBL is one of the soluble collectin effector proteins that contribute to the basic armamentarium of innate immunity. MBL can function as an opsonin when bound to the surfaces by activating the complement cascade. A deficiency of MBL has been reported in infants with frequent unexplained infection, chronic diarrhea, and otitis media.²⁷⁵ Other studies have identified an increased susceptibility to infection by specific pathogens in MBL-deficient individuals, including human immunodeficiency virus, *Plasmodium falciparum*, *Cryptosporidium parvum*, and *Neisseria meningitidis*.²⁷⁶ The deficiency in MBL largely results from three relatively common single-point mutations in exon 1 of the gene, which leads to the failure of MBL to activate complement.²⁷⁷ In addition, the protein also modulates disease severity, at least in part through complex, dose-dependent influences on cytokine production.

Phagocytes, including neutrophils, express a large number of cell surface proteins that play crucial functional roles in their biology. Microbial PRRs are an essential component of innate immunity, in which they recognize and detect PAMPs, resulting in activation of neutrophils and other phagocytes. The mammalian TLR family comprises an important class of PRRs, which recognize a wide range of microbial pathogens and pathogen-related products. At least 12 different TLRs that can be found on mononuclear phagocytes have been described.²⁷⁸ TLRs signal via MyD88, an adapter protein. MyD88 deficiency in humans can lead to recurrent infections with both Gram-positive and Gram-negative infections, thereby indicating a role for both mononuclear cells and neutrophils in host defense in the MyD88-deficient state.²⁷⁹

Because a large number of chemoattractants are generated during inflammation, it is difficult to establish the relative significance of a given individual component. Furthermore, chemotactic factors and opsonins are involved in the activity of both neutrophils and mononuclear phagocytes. Therefore, it is not clear whether the clinical consequences of disorders involving these substances are unique to one or the other of these phagocytic cells. Patients with antibody- or complement-deficient syndromes suffer mainly from infections with encapsulated pathogens such as *Haemophilus influenzae*, pneumococci, streptococci, and meningococci.²⁸⁰ Furthermore, splenectomized individuals deprived of an organ rich in mononuclear phagocytes have a small, but finite risk of sepsis because of the same microorganisms. Encapsulated pathogens characteristically are not associated with neutropenic states. Antibody coating of encapsulated organisms facilitates their ingestion by mononuclear phagocytes, but may be less important for their ingestion by neutrophils.

ABNORMALITIES OF THE CELLULAR RESPONSES AS THE RESULTS OF DEFECTS IN CYTOPLASMIC MOVEMENT

Degranulation Abnormalities

Chédiak-Higashi Syndrome

Definition and History This rare autosomal recessive disease was initially recognized as one in which neutrophils, monocytes, and lymphocytes contained giant cytoplasmic granules.²⁸¹ Chédiak-Higashi syndrome (CHS) is now recognized as a disorder of generalized cellular dysfunction characterized by increased fusion of cytoplasmic granules.²⁸² Pigmentary dilution affecting the hair, skin, and ocular fundi results from pathologic aggregation of melanosomes and is associated with failure of decussation of the optic and auditory nerves (Table 66–2).²⁸³ Patients with this syndrome exhibit an increased susceptibility to infection, which begins in infancy. Infections most commonly involve the skin and respiratory systems. The susceptibility to infection can be explained in part through defects in neutrophil chemotaxis, degranulation, and bactericidal activity.²⁸¹ The presence of giant granules in the neutrophil interferes with their ability to traverse narrow passages between endothelial cells. Other features of the disease include neutropenia, thrombocytopeny,²⁸⁴ natural killer cell abnormalities,^{281,285} and peripheral neuropathies.²⁸⁶ Similar genetic syndromes have been described in mice, mink, cats, rats, cattle, and killer whales.²⁸⁶

Although CHS carries the names of Moises Chédiak and Ototaka Higashi, the disorder was first described by Béguez César, a Cuban pediatrician in 1943. Initially characterized by neutropenia and abnormal granules in leukocytes, the syndrome was further delineated in 1948 by Steinbrinck's description of a second case.²⁸⁷ In 1952, Chédiak reported the hematologic characteristics of the disorder,²⁸⁸ and in 1953 Higashi emphasized the giant peroxidase-containing granules within patients' neutrophils.²⁸⁹ Besides the susceptibility to infections, patients often suffer a fatal lymphohistiocytic infiltration known as the accelerated phase occurring months from birth to several years later.²⁹⁰

Epidemiology By 2008, 300 cases worldwide had been described, with concentrations in the United States, Japan, northern Europe, and Latin America.²⁸⁶ Patients of African descent have also been described.

Etiology and Pathogenesis CHS is caused by a fundamental defect in granule morphogenesis that results in abnormally large granules in multiple tissues.^{282,291} Giant granules are seen in Schwann cells, leukocytes, and macrophages of the liver and spleen, and certain cells of the pancreas, gastric mucosa, kidney, adrenal gland, and pituitary gland.²⁸⁶ Giant melanosomes form and prevent the even distribution of melanin, which results in pigmentary dilution of the hair, skin, iris, and optic fundus. Although the giant lysosomes are the primary morphologic feature of the disorder, only cells relying on the secretion by these lysosomes manifest pathologic defects. In the early stages of myelopoiesis some of the normal-size azurophil granules coalesce to form giant granules that result in large secondary lysosomes that contain reduced content of hydrolytic enzymes, including proteinases, elastase, and cathepsin G.²⁸¹ Many of the myeloid precursors die in the marrow, resulting in a moderate neutropenia, with white cell counts of about $2.5 \times 10^9/L$ and absolute neutrophil counts ranging from 0.5 to $2.0 \times 10^9/L$.²⁹⁰ The marrow itself appears normal to hypercellular. In spite of the normal ingestion of particles and active oxygen metabolism, these neutrophils kill microorganisms relatively slowly. This delay reflects a slow and inconsistent delivery of diluted amounts of hydrolytic enzymes from the giant granules into the phagosomes, which may predispose the host to bacterial infection.^{291,292} In this syndrome, monocytes have the same functional derangements as neutrophils,²⁸¹ and in an analogous fashion perforin-deficient natural killer (NK) cells show profoundly impaired cytotoxic activity and are unable to kill many targets.²⁹³

The CHS blood cell membranes are more fluid than cells of normal individuals,^{281,294} and the altered membrane structure could lead to defective regulation of membrane activation, as well as promoting fusion of neutrophil azurophilic granules with each other. Conceivably, changes in membrane fluidity may affect cell function by reducing expression of Mac-1 (CD11b/CD18). The altered membrane fluidity could result in elevated levels of intracellular cyclic adenosine monophosphate, which appears in this disorder and is reflected in the reduced chemotactic responses.²⁸¹

The gene that is mutated in CHS is *CHS1* (syn. *LYST*) found on chromosome 1q. Its size indicates a protein of more than 400 kDa is encoded.²⁹⁵ During early development, granule biogenesis is normal; with perforin in NK cells and granule enzymes in myeloid cells synthesized and routed correctly to the granules. However, once formed the granules fuse to form giant organelles.²⁹⁶ Several studies led to the suggestion that the enlarged lysosomes found in CHS cells are the results of abnormalities in membrane fusion, which could occur during the biogenesis of the lysosomes. It has been hypothesized that this *CHS1* protein interacts with attachment proteins on lysosomes (v-SNAREs) and that this mutated protein leads to indiscriminate interactions with v-SNARE to yield uncontrolled fusion of lysosomes with each other.²⁹⁷

Clinical Features Characteristically patients with CHS have light skin and silvery hair. They frequently complain of solar sensitivity and photophobia. Other eye findings can include horizontal or rotatory nystagmus. Infections are common and involve the mucous membranes, skin, and respiratory tract. They are susceptible to both Gram-positive and Gram-negative bacteria, as well as fungi, with *Staphylococcus aureus* being the most common infecting organism.²⁸⁶ Attenuated NK function probably contributes to the increased susceptibility to infection as well. Neurologic signs and symptoms are variable in CHS and may include a peripheral and cranial neuropathy, autonomic dysfunction, weakness, and sensory deficit; and ataxia may also be a prominent feature.

Patients with CHS have prolonged bleeding times with normal platelet counts, resulting from impaired platelet aggregation associated with a deficiency of the storage pools of ADP and serotonin.²⁸⁴ Electron micrographs reveal normal numbers of α granules in platelets, but decreased numbers of platelet dense bodies.²⁸⁶

The accelerated phase of CHS is characterized by lymphocytic proliferation in the liver, spleen, marrow, and central nervous system. The accelerated phase may occur at any age and is now recognized as a genetic form of hemophagocytic lymphohistiocytosis (HLH).²⁹⁸ Typically, the patient develops hepatosplenomegaly and high fever in the absence of bacterial sepsis. The pancytopenia becomes worse at this stage, producing hemorrhage and an increased susceptibility to infection. The onset of the accelerated phase may be related to the inability of these patients to contain and control the Epstein-Barr virus (EBV) leading to HLH (Chap. 70). The lymphocyte expansion into the tissue is associated with excessive cytokine production and massive tissue necrosis and organ failure leading to the propensity to recurrent bacterial and viral infections, fever, and prostration usually resulting in death.²⁹⁸ At autopsy, the lymphohistiocytic infiltrates in the liver, spleen, and lymph nodes are extensive, but not neoplastic by histopathologic criteria.²⁹⁸

Laboratory Features The laboratory test diagnostic for CHS is examination of granular cell morphology. The pathognomonic feature is giant peroxidase-positive granules that can be seen in neutrophils.²⁸⁹ A microscopic examination of hair shafts reveal large, speckled pigment clumps as opposed to the normal pattern of finally divided pigment of melanin spread along the length of the shaft.²⁸⁶ Similar giant granules can occasionally be present in CML and acute myelocytic leukemia.²⁸⁶ Molecular diagnosis of CHS remains difficult and is not commercially available. Heterozygotes for CHS are considered completely normal and cannot be detected clinically or biochemically.

TABLE 66–2. Clinical Disorders of Neutrophil Function

Disorder	Etiology	Impaired Function	Clinical Consequence
DEGRANULATION ABNORMALITIES			
Chédiak-Higashi syndrome	Autosomal recessive; disordered coalescence of lysosomal granules; responsible gene is <i>CHSI/LYST</i> which encodes a protein hypothesized to regulate granule fusion	Decreased neutrophil chemotaxis; degranulation and bactericidal activity; platelet storage pool defect; impaired NK function, failure to disperse melanosomes	Neutropenia; recurrent pyogenic infections, propensity to develop marked hepatosplenomegaly as a manifestation of the hemophagocytic syndrome
Specific granule deficiency	Autosomal recessive; functional loss of myeloid transcription factor arising from a mutation or arising from reduced expression of Gfi-1 or C/EBP ϵ , which regulates specific granule formation	Impaired chemotaxis and bactericidal activity; bilobed nuclei in neutrophils; defensins, gelatinase, collagenase, vitamin B ₁₂ -binding protein, and lactoferrin	Recurrent deep-seated abscesses
ADHESION ABNORMALITIES			
Leukocyte adhesion deficiency I	Autosomal recessive; absence of CD11/CD18 surface adhesive glycoproteins (β_2 integrins) on leukocyte membranes most commonly arising from failure to express CD18 mRNA	Decreased binding of C3bi to neutrophils and impaired adhesion to ICAM-1 and ICAM-2	Neutrophilia; recurrent bacterial infection associated with a lack of pus formation
Leukocyte adhesion deficiency II	Autosomal recessive; loss of fucosylation of ligands for selectins and other glycol conjugates arising from mutations of the GDP-fucose transporter	Decreased adhesion to activated endothelium expressing ELAM	Neutrophilia; recurrent bacterial infection without pus
Leukocyte adhesion deficiency III (LAD-1 variant syndrome)	Autosomal recessive; impaired integrin function arising from mutations of <i>FERMT3</i> which encodes kindlin-3 in hematopoietic cells; kindlin-3 binds to β -integrin and thereby transmits integrin activation	Impaired neutrophil adhesion and platelet activation	Recurrent infections, neutropenia, bleeding tendency
DISORDERS OF CELL MOTILITY			
Enhanced motile responses; FMF	Autosomal recessive gene responsible for FMF on chromosome 16, which encodes for a protein called "pyrin"; pyrin regulates caspase-1 and thereby IL-1 β secretion; mutated pyrin may lead to heightened sensitivity to endotoxin, excessive IL-1 β production, and impaired monocyte apoptosis	Excessive accumulation of neutrophils at inflamed sites which may be the result of excessive IL-1 β production	Recurrent fever, peritonitis, pleuritis, arthritis, and amyloidosis
DEPRESSED MOTILE RESPONSES			
Defects in the generation of chemotactic signals	IgG deficiencies; C3 and properdin deficiency can arise from genetic or acquired abnormalities; mannose-binding protein deficiency predominantly in neonates	Deficiency of serum chemotaxis and opsonic activities	Recurrent pyogenic infections
Intrinsic defects of the neutrophil, e.g., leukocyte adhesion deficiency, Chédiak-Higashi syndrome, specific granule deficiency, neutrophil actin dysfunction, neonatal neutrophils; direct inhibition of neutrophil mobility, e.g., drugs	In the neonatal neutrophil there is diminished ability to express β_2 integrins and there is a qualitative impairment in β_2 -integrin function; ethanol, glucocorticoids, cyclic AMP	Diminished chemotaxis; impaired locomotion and ingestion; impaired adherence	Propensity to develop pyogenic infections; possible cause for frequent infections; neutrophilia seen with epinephrine arises from cyclic AMP release from endothelium
Immune complexes	Bind to Fc receptors on neutrophils in patients with rheumatoid arthritis, systemic lupus erythematosus, and other inflammatory states	Impaired chemotaxis	Recurrent pyogenic infections

TABLE 66–2. Clinical Disorders of Neutrophil Function (Continued)

Disorder	Etiology	Impaired Function	Clinical Consequence
Hyperimmunoglobulin-E syndrome	Autosomal dominant; responsible gene is <i>STAT3</i>	Impaired chemotaxis at times; impaired regulation of cytokine production	Recurrent skin and sinopulmonary infections, eczema, mucocutaneous candidiasis, eosinophilia, retained primary teeth, minimal trauma fractures, scoliosis, and characteristic facies
Hyperimmunoglobulin-E syndrome	Autosomal recessive; more than one gene likely contributes to its etiology	High IgE levels, impaired lymphocyte activation to staphylococcal antigens	Recurrent pneumonia without pneumatoceles sepsis, enzyme, boils, mucocutaneous candidiasis, neurologic symptoms, eosinophilia
MICROBICIDAL ACTIVITY			
Chronic granulomatous disease	X-linked and autosomal recessive; failure to express functional gp91 ^{phox} in the phagocyte membrane in p22 ^{phox} (autosomal recessive); other autosomal recessive forms of CGD arise from failure to express protein p47 ^{phox} or p67 ^{phox}	Failure to activate neutrophil respiratory burst leading to failure to kill catalase-positive microbes	Recurrent pyogenic infections with catalase-positive microorganisms
G6PD deficiency	Less than 5% of normal activity of G6PD	Failure to activate NADPH-dependent oxidase, and hemolytic anemia	Infections with catalase-positive microorganisms
Myeloperoxidase deficiency	Autosomal recessive; failure to process modified precursor protein arising from missense mutation	H ₂ O ₂ -dependent antimicrobial activity not potentiated by myeloperoxidase	None
Rac-2 deficiency	Autosomal dominant; dominant negative inhibition by mutant protein of Rac-2-mediated functions	Failure of membrane receptor-mediated O ₂ generation and chemotaxis	Neutrophilia, recurrent bacterial infections
Deficiencies of glutathione reductase and glutathione synthetase	Autosomal recessive; failure to detoxify H ₂ O ₂	Excessive formation of H ₂ O ₂	Minimal problems with recurrent pyogenic infections

AMP, adenosine monophosphate; C, complement; CD, cluster designation; CGD, chronic granulomatous disease; ELAM, endothelial-leukocyte adhesion molecule; FME, familial Mediterranean fever; G6PD, glucose-6-phosphate dehydrogenase; GDP, glucose diphosphate; ICAM, intracellular adhesion molecule; Ig, immunoglobulin; IL, interleukin; LAD, leukocyte adhesion deficiency; NADPH, nicotinamide adenine dinucleotide phosphate; NK, natural killer.

Data from Remington JS Swartz MN: *Current Clinical Topics in Infectious Disease*, 6th ed. New York, NY: McGraw-Hill; 1985.

Differential Diagnosis The diagnosis of CHS should be considered in individuals with partial albinism, exaggerated bleeding, and recurrent infections. Patients with CHS must be distinguished from those patients with Griscelli syndrome (GS) and Hermansky-Pudlak syndrome (HPS).

GS is a rare disorder, arising from mutations in the *RAB27A* gene, and is defined by partial ocular and cutaneous albinism, variable cellular and humeral immunodeficiency, variable neurologic involvement, and the development of the accelerated phase. Individuals with GS lack giant granules in neutrophils and have large pigment clumps in hair shafts.²⁸⁶ HPS is a disorder of ocular and cutaneous albinism, bleeding diathesis arising from platelet dysfunction, and deposition of ceroid lipofuscin in various organs (Chap. 120). In contrast to CHS, HPS cells lack giant granules and the patients are not predisposed to recurrent infections.²⁸⁶

Therapy High-dose ascorbic acid (200 mg/day for infants, 2 g/day for adults) improves the clinical status of some patients with CHS in the stable phase.²⁸¹ Although there is controversy regarding the efficacy

of ascorbic acid, given the safety of the vitamin,²⁸⁶ it is reasonable to administer it to all patients. CHS presents a therapeutic dilemma, particularly when the accelerated phase begins. Prophylactic antibiotics do not prevent infections. The only potential for curative therapy for preventing the accelerated phase is marrow transplantation.²⁹⁹ Marrow transplantation reconstitutes normal hematopoietic and immunologic function and corrects the NK deficiency in patients before entering the accelerated phase.²⁹⁹ On the other hand, if the patient is actively in the accelerated phase, stem cell transplantation from a matched unrelated donor is associated with a poor prognosis.²⁹⁹ Ocular and cutaneous albinism are not corrected after transplantation, nor does transplantation prevent progressive neuropathies from occurring.³⁰⁰

Specific Granule Deficiency Specific granule deficiency (SGD) has been described in patients of both sexes and is inherited as an autosomal recessive disorder (see Table 66–2).²⁸¹ Besides the absence of specific granules, the nuclei of the neutrophils are bilobed. Patients are afflicted with recurrent infections primarily involving the skin and

lungs. *S. aureus* and *Pseudomonas aeruginosa* have been the most commonly observed pathogens, although *Candida albicans* also has been isolated. Specific granule-deficient neutrophils lack gelatinolytic activity in the tertiary granules; vitamin B₁₂-binding protein, lactoferrin, hCAP-18, and collagenase in the specific granules; and defensins in the primary granules.^{301–303} This disorder also extends to eosinophils that lack the characteristic eosinophil granule proteins: major basic protein, eosinophilic cationic protein, and eosinophil-derived neurotoxin (Chap. 62).³⁰⁴ Thus, the disorder is a global defect in phagocytic granules rather than limited to specific granules, as suggested by its name. Neutrophils from these patients are defective in chemotaxis, possibly related to the absence of the intracellular pool of leukocyte adhesion molecules that normally reside in the tertiary and specific granules, and exhibit a mild defect in bactericidal activity, possibly related to the deficiency of the granule constituents, lactoferrin and defensins.^{301,305} The impairment in granule protein synthesis affecting the granulocytic cells appears secondary to the functional loss of the myeloid transcription factor, *C/EBPε*, which was identified in two patients.^{109,306} In another case of SGD, the expression of the transcription factor growth factor independence-1 (*Gfi-1*) was markedly reduced along with a heterozygous mutation of *C/EBPε* gene.³⁰⁷ It was suggested that the combined abnormalities blocked specific granule expression leading to the expression of the SGD phenotype. The defect is restricted to blood cells, as normal lactoferrin secretion has been demonstrated in the nasal secretions of an SGD patient despite the abnormality demonstrated in his neutrophils.³⁰² The diagnosis of SGD is suggested by the presence of neutrophils devoid of specific granules but containing azurophilic granules on the blood film.²⁸¹ The diagnosis can be confirmed by demonstrating a severe deficiency in either lactoferrin or hCAP-18. An acquired form of SGD can

be observed in thermally injured patients or in individuals with myelodysplasia.^{281,308} Treatment of SGD is symptomatic, with the administration of parenteral antibiotics for acute infections and surgical drainage of refractory infections. With aggressive medical management, patients may survive into their adult years.

Adhesion Abnormalities

Leukocyte Adhesion Deficiency

Definition and History Leukocyte adhesion deficiency type I (LAD-1) is a rare autosomal recessive disorder of leukocyte function (see Table 66–2). More than 100 cases have been reported worldwide. The disease is characterized clinically by recurrent soft-tissue infections, delayed wound healing, and severely impaired pus formation despite striking blood neutrophilia.³⁰⁹ Individuals with this disorder have decreased or absent expression of a family of structurally and functionally related leukocyte surface glycoproteins designated CD11/CD18 complex (also referred to as the β₂-integrin family of leukocyte adhesive proteins; Table 66–3). These proteins include LFA-1 (CD11a/CD18), Mo-1 or Mac-1 (CD11b/CD18), p150,95 (CD11c/CD18), and p160,95 (CD11d/CD18).³⁰⁹ The CD11 subunits are integral membrane glycoproteins, each spanning the plasma membrane only once. They are approximately 40 percent homologous, suggesting that they arise from a common primordial gene.³⁰⁹ The three distinct genes encoding the α subunits occur in a cluster on chromosome 16, whereas the gene for the β subunit is located on chromosome 21.³¹⁰

The initial clinical description in 1979 described six children and two families with findings of delayed separation of the umbilical cord and delayed healing at the site of detachment of the cord, recurrent infections despite neutrophilia, neutrophilia persisting during

TABLE 66–3. Biologic and Clinical Features of Leukocyte Adherence Deficiencies 1 and 2

	Genetic Defect	Leukocyte Functional Abnormalities	Clinical Features	Diagnosis
LAD-1	Molecular mutations affecting expression of the β ₂ -integrin CD18	Neutrophils; adherence spreading, homotypic aggregation, chemotaxis receptor CR3 activities: C3bi binding affecting phagocytosis, respiratory burst, and degranulation in response to C3bi-coated particles*	Autosomal recessive; delayed umbilical cord separation; neutrophilia; defective neutrophil migration into tissue; recurrent bacterial infections; impaired wound healing	Flow cytometry for expression of CD11b/CD18 (Mac-1)
		Monocytes; adherence, CR3 activities		
		Lymphocytes; cytotoxic		
		T-lymphocyte activities; NK cytotoxic activities; blastogenesis		
LAD-2 (CDG-IIc)	Mutations affecting function of GDP-fucose transporter 1 resulting in defective glycosylation expression at the α _{1,3} -position of selectin ligands including sLe ^x and other fucosylated proteins requiring fucosylation	Neutrophils; rolling mediated by sLe ^x to endothelium; neutrophilia†	Autosomal recessive; recurrent bacterial infections, periodontitis; growth retardation; developmental retardation; Bombay red cell phenotype	Flow cytometry for leukocyte sLe ^x (CD15)

CDG-11c, congenital disorder of glycosylation type IIc; GDP, glucose diphosphate; NK, natural killer; sLe^x, sialyl Lewis X.

*These functional abnormalities and clinical features are a consequence of lack of the CD11b/CD18, which includes CD11a, CD11b, CD11c, and CD11d markers of four different α chains and the common β₂-chain CD18 of Mr 95 kDa.

†These functional abnormalities and clinical features are a consequence of lack of sLe^x expression on leukocytes.

infection-free periods, and impaired neutrophil chemotaxis.³¹¹ The molecular basis for LAD-1 was first suggested when neutrophils from a patient with the disorder was found to lack a high-molecular-weight membrane glycoprotein.³¹² This finding suggested that the lack of the membrane protein impaired the neutrophil's functional responses. In 1982, another patient was evaluated and it was confirmed that the membrane glycoprotein with a Mr of 150 kDa was missing.³¹³ The normal parents and siblings of the proband exhibited intermediate quantities of the glycoprotein, which suggested the existence of a heterozygous carrier state. The disorder then became known as LAD. Subsequently, in 1984, a glycoprotein 150 was identified as one subunit of a glycoprotein that had two subunits that served as a receptor for a plasma complement component.³¹⁴ This was followed by other investigations that found that two other related leukocyte membrane glycoproteins also were deficient. Each of the three glycoproteins was then determined to be heterodimers with one common subunit and one subunit unique to each glycoprotein.³¹⁵ Synthesis of a defective subunit common to the three glycoproteins of CD11/CD18 complex resulted in loss of expression of all heterodimers.³¹⁶ This observation provided the molecular explanation for the cellular defect. In 1985, the extent of clinical severity and magnitude of the cellular abnormalities were correlated with the degree of CD11/CD18 deficiency, thereby laying the groundwork for the direct relationship between the glycoprotein deficiency and the clinical presentation.³¹⁵

Etiology and Pathogenesis Each of these molecules contains an α and a β subunit noncovalently associated in an $\alpha\beta$ structure. They all have the same β subunit and are distinguished by their α subunits, which have different isoelectric points, molecular weights, and cell distribution (see Table 66-3).³¹⁵ The structure of CD11/CD18 has been deduced from molecular cloning of the various subunits.³¹⁵ The x-ray crystal structure and nuclear magnetic resonance analysis also reveal that activation signals lead to the separation of the α and β subunit cytoplasmic tails, thereby converting the bent conformation of each integrin with its headpiece near the plasma membrane into fully extended high-affinity structures in a switchblade-like movement.³¹⁷ These studies establish that the CD11/CD18 heterodimers are members of a large gene family involved in cell-cell and cell-matrix adhesion (integrins). Several subfamilies of integrins are described and classified according to the type of their highly homologous β subunits. The α subunits are also homologous to each other, but to a lesser degree than are the associated β subunits. Within each subfamily, a single β subunit usually is shared by several α subunits. Certain α subunits often share more than one β subunit, which alters their specificity for various ligands.³¹⁵ The molecular defect involves all four members of the CD11 integrin subfamily. In patients with LAD-1 who have been evaluated at the molecular level, absent, diminished, or structurally abnormal β subunits (CD18) were identified.³¹⁵ A heterogeneous group of mutations that are confined to the gene on chromosome 21q22.3 also was identified.³¹⁵ Many patients have point mutations that result in single amino acid substitutions in CD18, which predominantly reside between amino acids 111 and 361.³¹⁵ This peptide domain is highly conserved among all β subunits and appears to be important for interaction with the α subunit. Several affected individuals are compound heterozygotes for two different mutant alleles, whereas others are homozygotes for a single mutant allele. Messenger RNA splicing abnormalities that have been described in two kindreds can result in either deletion or insertion of amino acids in the conserved extracellular domain of CD18. Small deletions within the coding sequences of the CD18 gene disrupting the reading frame or a nucleotide substitution resulting in a premature termination signal has been described. Mutations in CD18 disrupt the association in the $\alpha\beta$ subunits so that maturation, intracellular transport, and all cell surface assembly of functionally active $\alpha\beta$ molecules fail to occur.³¹⁵

Approximately half of patients exhibit a low level of CD11/CD18 cell surface molecules and moderate disease, with the remainder having totally absent surface expression of these proteins, which accounts for a profound impairment of neutrophil and monocyte adherence and adhesion-dependent functions *in vitro*, including cell migration, phagocytosis, and complement- or antibody-dependent cytotoxicity.^{315,316}

The bulk of the neutrophil Mac-1 glycoprotein is stored inside the cell in the membrane of neutrophil specific and gelatinase granules and in secretory vesicles.^{32,318} Exposure of neutrophils to degranulating stimuli results in a 5- to 10-fold increase in the number of Mac-1 molecules on the cell surface, which parallels the fusion of granules to the plasma membrane.³¹⁸ Neutrophils from these patients fail to augment their surface adhesive glycoproteins, as the defect in β -subunit synthesis affects both membrane and granule pools of Mac-1.³¹⁹ In contrast to Mac-1 and p150,95, LFA-1 is predominantly confined to the neutrophil plasma membrane. Consequently, the cell surface levels of LFA-1 are not enhanced by neutrophil degranulation.

Lymphocytes deficient in CD11/CD18 are able to adhere to endothelial surfaces via the expression on lymphocytes of very-late antigen-4 (VLA-4) integrin (synonym: integrin $\alpha_4\beta_1$) receptors, which bind to the vascular cell adhesion molecule 1 (VCAM-1), found on the endothelial cells.³²⁰ This residual adhesion may account for the paucity of clinical symptoms related to lymphocyte function. The patients are not unusually susceptible to viral infection, although three patients had one or more episodes of aseptic meningitis.³¹⁵

The failure of the LAD-1 neutrophils to migrate to the sites of inflammation outside of the lung and peritoneum arises from their inability to adhere firmly to surfaces and undergo transendothelial migration from venules.³²¹⁻³²³ Failure of Mac-1-deficient neutrophils to undergo transendothelial migration occurs because β_2 integrins bind to ICAM-1 (CD54) and ICAM-2 expressed on inflamed endothelial cells.^{309,324} LAD-1 neutrophils are able to accumulate in the lung, perhaps through a process of movement mediated by "chimneying," which does not require functional integrins.³²⁵ Chemotaxis that occurs despite blockade of CD11/CD18 under special *in vitro* conditions has been dubbed "chimneying." The neutrophils that do arrive at inflammatory sites in the inflamed lung by CD11/CD18-independent processes fail to recognize microorganisms coated with the opsonic complement fragment C3bi (an important stable opsonin formed by the cleavage of C3b by C3b inactivator).^{313,326} Other neutrophil functions, such as degranulation and oxidative metabolism, normally triggered by C3bi binding are also diminished and markedly compromised in neutrophils from LAD-1.³⁰⁹ Similarly, the urokinase-plasminogen activator-receptor and the Fc γ RIII receptors, both phosphatidylinositol-linked proteins, are defective in their functions because these receptors transduce their signals through CD11/CD18.^{234,327} Monocyte function is also impaired. Monocytes of affected individuals have poor fibrinogen-binding function, an activity promoted by the CD11/CD18 complex^{309,328}; consequently, such cells are not able to participate effectively in wound healing. Thus, impairment in neutrophil function underlies the propensity to recurrent infections, which is the clinical expression of this disease. Similar genetic syndromes have been discovered in Irish Setter dogs and Holstein cattle.³¹⁵ A CD11/CD18-deficient mouse with 2 to 6 percent of normal β_2 -integrin expression has been produced by gene targeting.^{321,329}

Clinical Features Activated leukocytes of patients with the most-severe clinical form express less than 0.3 percent of the normal amount of the β_2 integrins, whereas those of patients with the moderate phenotype may express 2 to 7 percent of normal numbers of β_2 -integrin molecules.³⁰⁹ The severely affected patients suffer from recurrent and chronic or even gangrenous soft-tissue infections (subcutaneous tissues or mucous membranes), generally by bacterial or fungal microorganisms

such as *S. aureus*, *Pseudomonas* spp. and other Gram-negative enteric rods, or *Candida* spp. Patients with the moderate phenotype have fewer and less-severe infections. Infectious susceptibility and impaired wound healing are related to diminished or delayed infiltration of neutrophils and monocytes into extravascular inflammatory sites. In all patients surviving infancy, severe progressive generalized periodontitis is present. Individuals who are clinically well, but who are heterozygous carriers of LAD have been identified. Their stimulated neutrophils express approximately 50 percent of the normal amount of the Mac-1 α subunit and the common β subunit.³⁰⁹ The diagnosis of LAD-1 should be considered in infants with a paucity of neutrophils at sites of infection despite blood neutrophilia and have a history of delayed separation of the umbilical cord.

Laboratory Features The diagnosis is made most readily by flow cytometric measurement of surface CD11b in stimulated and unstimulated neutrophils using monoclonal antibodies directed against CD11b (Fig. 66-5). Assessment of neutrophil and monocyte adherence, aggregation, chemotaxis, C3bi-mediated phagocytosis, and cytotoxicity generally demonstrates striking abnormalities that are directly related to the molecular deficiency. Delayed-type hypersensitivity reactions are normal, and most individuals have normal specific antibody synthesis. The ability of lymphocytes to generate specific antibodies explains the self-limited course of varicella or viral respiratory infections. However, some patients have impaired T-lymphocyte-dependent antibody

responses, for example, to repeat vaccination with tetanus toxoid, diphtheria toxoid, and polio virus.

Patients with LAD-1 usually have blood neutrophil counts of 15 to $60 \times 10^9/L$. However, during infectious episodes, they commonly have neutrophil counts in excess of $100 \times 10^9/L$ and sometimes as high as $160 \times 10^9/L$. Granulocytic hyperplasia is a feature of the marrow examination which may relate to excessive production of IL-17 and G-CSF as a result of decreased uptake of apoptotic neutrophils by tissue macrophages.^{319,330} Despite elevated blood counts, there is a paucity of neutrophils in inflammatory skin windows and biopsies of infected tissues.

Differential Diagnosis Eight patients (four Arab, two Turkish, one Pakistani, one Brazilian) who had neutrophilia, recurrent bacterial infections, and an inability to form pus have been described.^{13,331,332} The patients also had the Bombay blood phenotype (deficiency in H blood group integrins), severe mental retardation, unusual facial appearance, microcephaly, cortical atrophy, seizures, hypotonia, and short stature (see Table 66-2). Functionally, the neutrophils were unable to adhere to E-selectin or cytokine-activated endothelial cells and exhibited impaired chemotaxis and an inability to roll on postcapillary venules *in vivo*. The patients are now classified as having LAD-2 or congenital disorder of glycosylation type IIc (CDG-IIc).³³³ In contrast to LAD-1, the patients' NK cell activity is normal. The LAD-2 neutrophils express normal levels of CD18 integrins, but are deficient in the carbohydrate structure sLe^x, which renders the cells unable to roll on activated endothelial

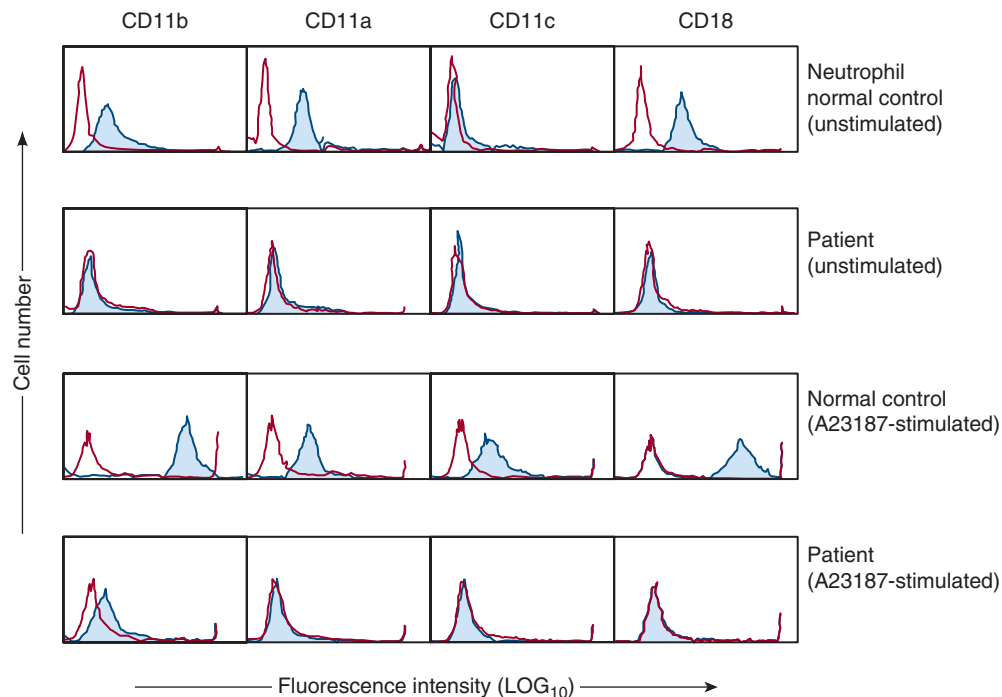

Figure 66-5. Specific diagnosis of CD11/CD18 glycoprotein deficiency by indirect immunofluorescence flow cytometric analysis. Blood neutrophils of a pediatric patient suspected of having CD11/CD18 glycoprotein deficiency and those of an abnormal individual were subjected to immunofluorescence staining for the expression of the CD11b, CD11a, CD11c, and CD18 epitope (crosshatched histograms) as compared with the background immunofluorescence staining by isotype-identical negative-control antibodies (open histograms). Neutrophils were either stained immediately after purification by Ficoll-Hypaque density centrifugation (unstimulated) or after exposure to calcium ionophore A23187 (1 mM) for 15 minutes at 37°C (A23187-stimulated). A23187 stimulation causes significant increase in CD11b and CD18 epitope staining (surface MO1 expression) by normal neutrophils as compared with unstimulated normal cells. A23187 stimulation also causes a small increase in the CD11b-epitope expression of patient cells (the CD11b crosshatched histogram becomes distinguishable from background staining after A23187 stimulation), suggesting that this patient has a “moderate” form of the disorder (capable of expressing small but detectable quantities of CD11/CD18 glycoproteins). Flow cytometric analysis was performed on a Coulter Electronics EPICS F C Flow Cytometer with a logarithmic amplifier. (Reproduced with permission from Todd R, Freyer DR: The CD11/CD18 leukocyte glycoprotein deficiency, *Hematol Oncol Clin North Am* 1988 Mar;2(1):13-31.)

cells expressing E-selectin (see Table 66–3). Thus, the neutrophils from the patients categorized as having a LAD-2 phenotype are unable to tether to inflamed venules, which is necessary for subsequent activation (Chap. 19). The LAD-2 can be explained by a congenital disorder of fucosylation of ligands for selectins and other glycoconjugates. Each of the three selectins binds with variable affinity to sialylated and fucosylated oligosaccharides, including sLe^x, which is present on multiple specific glycolipids and glycoproteins on leukocytes and activated endothelial cells.¹³ Neutrophils from LAD-2 subjects lack sLe^x, which leads to impaired neutrophil rolling on endothelial cells. Other fucosylated determinants, including the H, Lewis, and secretor blood group antigens, are lacking as well, suggesting a global defect in fucosylation. The diminished fucosylation arises from impaired transport of GDP-fucose from the cytoplasm to the Golgi lumen.³³¹ A human GDP-fucose transporter (GFTP) that localizes to the Golgi apparatus has been demonstrated to be defective secondary to distinct mutations in the *SLC35C1* gene encoding the transporter.¹³ When fibroblasts and lymphoblastoid cells derived from a LAD-2 patient were grown in the presence millimolar concentrations of fucose, cell-surface fucosylation could be restored. Following this observation oral administration of L-fucose to two Turkish patients led to normalization of neutrophil counts and functional E- and P-selectin ligands on myeloid cells accompanied by abatement of fevers and infections.¹³ Two Arab patients, in contrast to the Turkish patients who have different mutations of the gene encoding the putative GFTP, did not respond to oral fucose.³³² A Brazilian LAD-2 patient, like the Turkish patients, initially benefited from oral fucose; but, following expression of sLe^x on the myeloid cells, the patient developed autoimmune neutropenia.³³⁴ The diagnosis of LAD-2 can be made by flow cytometry analysis of CD15s (sLe^x) expression.

LAD-3, also known as LAD-1 variant syndrome, compromises two major hallmarks: a moderate LAD-1–like syndrome and severe Glanzmann-like bleeding diathesis (Chap. 120). Four patients have been described in whom the inheritance appears to be autosomal recessive and is associated with functional defects of the leukocyte and platelet integrins arising from intracellular signaling.³³⁵ The disease initially presents in early childhood and consists of the inability to form pus at sites of microbial infections, as well as a severe bleeding tendency. The neutrophils from the patients display defective adhesion and chemotaxis and are unable to undergo the respiratory burst when triggered by unopsonized zymosan. The molecular basis for LAD-3 arises from mutations in *FERMT3*, which encodes kindlin-3 in hematopoietic cells. Kindlin-3 binds to regions of the β -integrin tails and constitutes an essential element for transition of integrins from the bent and inactive to the extended an active conformation.³³⁶ Marrow transplantation can be curative.

Another rare cause of neutrophilia and an inability to form pus was observed in a patient with a mutation in the Rac2 GTPase, which is discussed below. The neutrophils from the patient had defects in both adhesion and chemotaxis (see Table 66–2).

Therapy, Course, and Prognosis Treatment of LAD-1 is largely supportive.^{309,315} Patients with a history of recurrent infections can be maintained on prophylactic trimethoprim-sulfamethoxazole. Marrow transplantation with human leukocyte antigen (HLA)-compatible siblings or parental donors has resulted in engraftment and restoration of neutrophil function and remains the treatment of choice for patients with a severe phenotype.³³⁷

The restoration of CD11/CD18 expression in CD34 peripheral stem cells from LAD-1 following transduction with a retrovirus bearing CD18 and induced to differentiate into neutrophils with growth factors indicates that LAD-1 is caused by a defective CD18 gene and provides a basis for somatic gene therapy, which was accomplished

in a dog model.^{338,339} Not only did the neutrophils express the integrins, but the cells demonstrated improvement in their functional responses, such as adhesion and the respiratory burst when challenged with ligands for CD11/CD18. These results indicate that *ex vivo* of the transfer gene for CD18 into LAD-1 CD34+ cells followed by reinfusion of the transfused cells may represent a therapeutic approach for LAD.

The severity of infectious complications correlates with the degree of β_2 deficiency. Patients with severe deficiency may die in infancy, and those surviving infancy have a susceptibility to severe, life-threatening, systemic infections. In patients with moderate deficiency, life-threatening infections are infrequent and survival relatively long.³¹⁹ LAD-1 can be diagnosed by prenatal screening.

Neutrophil Actin Dysfunction

These patients, like patients with LAD, have recurrent pyogenic infections from birth as a result of defective chemotactic and phagocytic response (see Table 66–2). In one patient, actin isolated from blood and neutrophils could not polymerize under conditions that fully polymerized the actin of neutrophils from normal individuals.³⁴⁰ Subsequent studies on the index patient's family confirmed that partial actin dysfunction was present in the parents and one sister.³⁴¹ One of the parents was found to be a heterozygote for LAD, and the other was not, but further studies established that LAD was not generally associated with defective actin filament assembly.^{342,343} The basis of the defective polymerization of actin in the index patient remains unknown, but this disorder of phagocytes is distinct from LAD.

Defective actin polymerization has been described in a 2-month-old infant with severe recurrent bacterial infections associated with impaired chemotaxis and phagocytic response.³⁴⁴ The patient's neutrophils showed increased expression of CD11b, distinguishing the patient's clinical problem from LAD-1. Morphologically, the neutrophils displayed thin, filamentous projections of membrane with an underlying abnormal cytoskeletal structure. Subsequently, a 47-kDa protein was purified that inhibited actin polymerization *in vitro*.³⁴⁵ Further biochemical studies revealed a markedly defective actin polymerization in the patient's neutrophils along with a severe deficiency of an 89-kDa protein and an elevated level of the 47-kDa protein. The 47-kDa protein was identified as LSP-1 (lymphocyte-specific protein-1), which is an actin-binding protein present in normal neutrophils. Overexpression of LSP-1 resulted in bundling of actin in cells, leading to an abnormal cytoskeletal structure and motility defects.³⁴⁶ Neutrophils from the patient's parents revealed a partial defect in actin polymerization accompanied by intermediate levels of LSP-1 and the 89-kDa protein. These observations suggest that the neutrophil actin dysfunction (NAD) known as NAD47/89 is an autosomal recessive disorder. Because actin dysfunction is lethal, treatment requires restoration of normal neutrophil function by marrow replacement from a normal donor. Marrow transplantation was successful.^{347,344}

DISORDERS OF NEUTROPHIL MOTILITY

Familial Mediterranean Fever

Definition and History Familial Mediterranean fever (FMF) is an autosomal recessive disease that primarily affects populations surrounding the Mediterranean basin. The disease is characterized by acute limited attacks of fever often accompanied by pleuritis, peritonitis, arthritis, pericarditis, inflammation of the tunica vaginalis of the testes, and erysipelas-like skin disease (see Table 66–2). The initial description occurred in 1908, identifying a Jewish girl who had episodic abdominal

pain and fever.³⁴⁸ Subsequently additional cases were identified,³⁴⁹ but it took nearly a half century to establish this disorder as familial Mediterranean fever.³⁵⁰

Epidemiology More than 10,000 patients worldwide are affected with FMF. It occurs predominantly in Sephardic Jews, Arabs, Turks, Italians, and Armenians.³⁴⁸ The disorder can occur in other populations, but it is unusual. The frequency of the susceptibility gene varies widely; it is very high among Armenians (ratio of persons with the gene to those without it is 1:7) and Sephardic Jews (1:5 to 1:16), but is lower in Ashkenazi Jews (1:135).

Etiology and Pathogenesis The pathologic findings in FMF are those of nonspecific acute inflammation affecting serosal tissues such as the pleura, peritoneum, and synovium. Neutrophilic infiltration predominates in the affected tissues. Physical and emotional stress, menstruation, and a high-fat diet may trigger the attacks.³⁵¹

The gene responsible for FMF has been identified to be located on chromosome 16. It encodes for a 781-amino-acid protein called *pyrin* or *marenostriin*.³⁵² The gene (*MEFV*) is predominantly expressed in neutrophils, eosinophils, monocytes, dendritic cells, and synovial and peritoneal fibroblasts, and its expression is upregulated by IFN- γ and TNF, and by the process of myeloid differentiation itself.³⁵³ Nearly all the 50 mutations in the *MEFV* gene are missense changes, most of which are clustered in on exon 2 and 10.³⁵⁴ Founder effects in FMF have been established, and the two most common mutations, V726A and M694V, originated in common ancestors who lived about 2500 years ago in the Middle East.³⁵²

Pyrin plays a role in controlling the activity of inflammasomes (see “Neutrophil Surface Receptors”). PYRIN, one of the four domains of pyrin, bears homology to a number of proteins involved in apoptosis and in inflammation, and is similar to a member of the six-helix-bundle death-domain superfamily that includes death domains and death effector domains known as CARDs.³⁵⁵ The PYD appears to allow for the interaction of macromolecular complexes by PYRIN–PYRIN interactions. This interaction has led to the identification of pyrin’s ability to interact specifically with another PYRIN-domain protein termed *apoptosis-associated speck-like protein with a CARD* (ASC).³⁵⁶ Besides the aminoterminal PYD, ASC has a C-terminal CARD domain that allows binding to the CARD of procaspase-1 (IL-1 β -converting enzyme), which results in procaspase-1 autoactivation.³⁵⁵ Activated caspase-1 then converts prointerleukin-1 β to IL-1 β , which is, in turn, secreted and interacts with the IL-1 receptor to mediate inflammation. It has been suggested that pyrin may act as an antiinflammatory molecule by inhibiting ASC-induced IL-1 processing, which, in turn, could be defective in FMF. This hypothesis is supported by observing increased IL-1 processing and heightened sensitivity to LPS and impaired apoptosis in peritoneal macrophages from pyrin knockout mice. The puzzle, however, remains as to why serosal tissues are the main targets of inflammation in FMF.

Clinical Features Febrile episodes in FMF may begin in infancy, but by age 20 years, 90 percent of patients have had their first attack. The duration and frequency of attacks may vary considerably, even in the same patient.³⁵¹ Acute attacks frequently last 24 to 48 hours and recur once or twice a month. In some patients, attacks may recur as frequently as several times a week, or as infrequently as once a year, and symptoms may persist as long as a week during individual episodes. Some patients experience spontaneous remission that persists for years, followed by recurrence of frequent attacks. Peritonitis caused by FMF may resemble an acute abdomen, thereby leading to potential uncertainties about the clinical management of the acute abdominal episode. Attacks of pleuritic pain occur in approximately 25 to 80 percent of patients. Symptoms of pleuritis may sometimes precede abdominal pain, and some patients experience pleuritic attacks

without abdominal symptoms. Recurrent pericarditis is rare. The course of peritonitis in FMF is similar to attacks at other serosal sites; however, it tends to appear at a late stage of the disease. Mild arthralgia is a common feature of febrile attacks, and monoarticular or oligoarticular arthritis may occur. Arthritis usually affects large joints, the knees in particular, and effusions are common. As many as one-third of the patients experience transient erysipelas-like skin lesions that appear typically on the lower leg, ankle, or dorsum of the foot. These lesions are circumscribed, painful, erythematous areas of swelling, which usually subsides within 24 to 48 hours.

In approximately 25 percent of affected patients, a form of renal amyloidosis develops in which the amyloid derives from a normal serum protein called serum amyloid A (amyloidosis of the AA type; Chap. 108). The amyloidosis progresses over a period of years to renal failure in almost all cases, and the cause of death in patients with FMF is usually attributed to this complication. It appears that polymorphisms in the gene for serum amyloid A increase the susceptibility to renal amyloidosis and that polymorphisms in a gene for the major histocompatibility complex class 1 α -chain influence the severity of the disease.³⁵⁰

Laboratory Features Laboratory findings in FMF are nonspecific. Nonspecific findings include increases in inflammatory mediators such as amyloid A, fibrinogen, and C-reactive protein during febrile attacks.³⁵⁰ Proteinuria greater than 0.5 g of protein per 24 hours in patients with FMF may suggest amyloidosis.

The cloning of the FMF gene now allows a reliable diagnostic test. Five founder mutations account for 74 percent of FMF carrier chromosomes from typical populations known to harbor the disease.³⁵⁷ Carrier rates for FMF mutations may be as high as 1:3 in some populations, suggesting that the disease is often underdiagnosed. Some amino acids that cause human disease are often present in wild-type in primates.³⁵⁸

Differential Diagnosis The TNF receptor–associated periodic syndrome (TRAPS) was first described in 1982 in a large Irish family.³⁵⁹ The affected family members had recurrent fever with localized myalgia and painful erythema. Differentiating this disorder from FMF was its response to corticosteroids and the autosomal dominant inheritance of the disorder. Affected patients can have attacks that last for at least 1 or 2 days, but prolonged attacks lasting longer than a week are common. Localized pain and tightness in one muscle group and a migratory pattern of the symptoms are prominent features. The disorder may be associated with colicky abdominal pain, diarrhea or constipation, nausea, and or vomiting. Painful conjunctivitis, periorbital edema, or both are common as well as chest pain secondary to sterile pleuritis.³⁵⁰ During febrile attacks, painless skin lesions may develop on the trunk or extremities and may migrate distally. Missense mutations in the gene for the type-1 TNF 55-kDa cell membrane receptor, which is required for diagnosis, have been identified. Patients with TRAPS respond dramatically to high doses of oral prednisone (>20 mg). In time, however, the responses wane, requiring higher doses of corticosteroids. Standard doses of a p75:Fc fusion protein, etanercept, administered subcutaneously twice weekly decreases the frequency, duration, and severity of attacks; thus, etanercept may provide a safer, more effective alternative than corticosteroids in controlling the disease.

Therapy Colchicine treatment is effective in FMF and may prevent the development of amyloidosis.³⁵¹ Prophylactic colchicine, 0.6 mg orally, two to three times a day, prevents or substantially reduces the acute attacks of FMF in most patients. Some patients can abort attack with intermittent doses of colchicine beginning at the onset of attacks (0.6 mg orally every hour for 4 hours, then every 2 hours for four doses, and then every 12 hours for 2 days). In general, patients who

benefit from intermittent colchicine therapy are those who experience a recognizable prodrome before developing fever and clear-cut acute symptoms.

Course and Prognosis The prognosis for normal longevity for patients has been excellent since the recognition that colchicine is an effective treatment of this disease. Most patients can be maintained almost entirely symptom-free. However, if amyloidosis develops, it may be followed by the nephrotic syndrome or uremia. Unless the patient receives a renal transplant, the likelihood of eventual death from renal failure is high.

Other Disorders of Neutrophil Motility

The directed migration of neutrophils from the circulation to an inflammatory site is a consequence of chemotaxis and leads to the accumulation of an exudate. For normal chemotaxis to occur, a complex series of events must be coordinated. Chemotactic factors must be generated in sufficient quantities to establish a chemotactic gradient. The neutrophils must have receptors for the chemotactic agents and mechanisms for discerning the direction of the chemotactic gradient. Depressed neutrophil chemotaxis has been observed in a wide variety of clinical conditions (see Table 66–2).³⁶⁰ These can be stratified as follows: (1) defects in the generation of chemotactic signals; (2) intrinsic defects of the neutrophil; and (3) direct inhibitors of neutrophil motility in response to chemotactic factors.

Older patients with chemotactic disorders may be infected by a variety of microorganisms, including fungi and Gram-positive or Gram-negative bacteria. *S. aureus* is the most frequent bacterial offender. Typically, the skin, gingival mucosa, and regional lymph nodes are involved. Respiratory tract infections are frequent, but sepsis is rare. Delayed or inappropriate signs and symptoms of inflammation are common. Although the cells move slowly in Boyden chambers or other chemotactic assays, they do accumulate in sufficient numbers in inflammatory sites to produce pus. However, detection of patients with neutrophils that have profound defects in chemotaxis usually is accomplished through other phagocytic assays.

Patients with the hereditary deficiency of complement factors C3, C5, or properdin exhibit an increased incidence of bacterial infections because they are unable to form the chemotactic peptide C5a.³⁶¹ The degree to which defective chemotaxis plays a role in C3 deficiency is unclear because opsonization and ingestion rates also are abnormal in these disorders. Frequently, chemotactic disorders are associated with other impaired neutrophil functions. For instance, both glycogen storage disease type 1b³⁶² and Shwachman-Diamond syndrome³⁶³ are chemotactic disorders frequently associated with an absolute neutrophil count below $0.5 \times 10^9/L$. Following restoration of a normal neutrophil count with G-CSF, the patients no longer are predisposed to recurrent bacterial infections in spite of a persistent chemotactic defect. Thus, a chemotactic defect observed *in vitro* does not correlate invariably with decreased resistance to bacterial infections *in vivo*.

Among the impaired defense mechanisms of the neonate is neutrophil adherence and chemotaxis, as demonstrated by the *in vitro* response of neonatal neutrophils to a variety of chemotactic factors.³²² The impaired motility of the neonatal neutrophils in part arises from the diminished ability to mobilize neutrophil β_2 integrins following neutrophil activation.³⁶⁴ Additionally, the neonatal neutrophil may have a qualitative defect in β_2 -integrin function, resulting in impaired neutrophil transendothelial migration for up to 1 month after birth.

At the other end of the spectrum, neutrophils from elderly loose focus during chemotaxis while their motility is unimpaired. This is caused by increased activity of PI3-K and results in less efficient bacterial killing and enhanced release of tissue destructive proteases. Inhibition of PI3K activity reverts this condition *in vitro*.³⁶⁵

Drugs and Extrinsic Agents That Impair Neutrophil Motility

Although many pharmacologic agents can influence neutrophil function, few drugs used in clinical medicine affect neutrophil behavior *in vivo*. Ethanol, an inhibitor of PLD, in concentrations that occur in human blood can inhibit neutrophil locomotion and ingestion.³⁶⁶ Glucocorticoids, especially at high and sustained doses, inhibit neutrophil locomotion, ingestion, and degranulation.³⁶⁷ Administration of glucocorticoids on alternate days does not interfere with neutrophil movement.³⁶⁸ Epinephrine does not have a direct effect on neutrophil adhesion but cyclic adenosine monophosphate (cAMP), which is released from endothelial cells following exposure to epinephrine, can depress neutrophil adherence.³⁶⁹ Similarly, elevated cAMP levels following epinephrine administration may impair neutrophil adherence, leading to diminished neutrophil margination and apparent neutrophilia. Immune complexes, as seen in patients with rheumatoid arthritis or other autoimmune diseases, also can inhibit neutrophil movement by binding to neutrophil Fc receptors.

Hyperimmunoglobulin E Syndrome

Definition and History Autosomal dominant hyperimmunoglobulin E syndrome (HIES) is a disorder characterized by markedly elevated serum IgE levels, chronic dermatitis, and serious recurrent bacterial infections.³⁷⁰ The skin infections in these patients are remarkable for their absence of surrounding erythema, leading to the formation of “cold abscesses.” The neutrophils and monocytes from patients with this syndrome exhibit a variable, but at times profound, chemotactic defect that appears extrinsic to the neutrophil (see Table 66–2).³⁷¹

The syndrome was originally described in 1966 in two red-headed, fair-skinned females who had “cold abscesses” and hyperextensible joints, which led to the appellation “Job’s syndrome.”³⁷⁰ Subsequently Buckley and coworkers documented the association of levels of immunoglobulin E with undue susceptibility to infection.³⁷²

Epidemiology Reports of more than 200 cases have been documented.^{372,373} HIES occurs in persons from diverse ethnic backgrounds and does not seem to be more common in any specific population.

Etiology and Pathogenesis Both males and females have been affected, as well as members of succeeding generations, indicating that the disorder is autosomal dominant with an incomplete penetrance form of inheritance.³⁷⁰ STAT3 mutations cause most, if not all cases of autosomal dominant HIES. All mutations have been missense mutations or in-frame deletions, leading to the formation of full-length mutant STAT3 protein, which exerts a dominant negative effect. STAT3 is a major transduction protein affecting pathways involving wound healing angiogenesis, immunity, and cancer. The more rare autosomal recessive form is caused by mutations in dedicator of cytokinesis 8 (DOCK8), a guanine nucleotide exchange factor.³⁷⁴

The mechanism of the immune deficiencies in HIES remains clouded. Several reports with limited numbers of patients have conflicted results as to whether a chemotactic defect exists and whether there is a T-helper 1/T-helper 2 cytokine imbalance.

Clinical Features HIES may begin as early as day 1 after birth.³⁷² The syndrome is characterized by chronic eczematoid rashes, which are typically papular and pruritic. The rash generally involves the face and extensor surfaces of arms and legs; skin lesions are frequently sharply demarcated and usually lack surrounding erythema. By 5 years of age all patients have had a history of recurrent skin abscess formation with recurrent pneumonias, along with chronic otitis media and sinusitis. Patients may also develop septic arthritis, cellulitis, or osteomyelitis. The major offending pathogen is generally *S. aureus*. Other pathogens commonly infecting patients are *C. albicans*, *H. influenzae*, and pneumococci. Other associated features include coarse facial features,

including a prominent forehead, deep set eyes, a broad nasal bridge, a wide fleshy nasal tip, mild prognathism facial asymmetry, and hemihypertrophy.³⁷⁰ There is a high incidence of scoliosis, hyperextensible joints, and delayed shedding of the primary teeth.³⁷⁰ Occasionally, unexplained osteopenia presents, which is often complicated by recurrent bone fractures. Additionally, there is an increased risk of both Hodgkin and non-Hodgkin lymphoma.

Laboratory Features Blood and sputum eosinophilia have been a consistent finding in all patients.³⁷⁰ Patient serum IgE levels range from three to 80 times the upper limit of normal. The serum IgE usually rises above 2000 IU/mL and often is elevated at birth. Upon reaching adulthood the IgE may decline over years, despite the clinical abnormalities of STAT3 deficiency. Usually patients have normal concentrations of IgG, IgA, and IgM, and may have elevated levels of IgD. Patients often have abnormally low anamnestic antibody response and poor antibody and cell-mediated responses to neoantigens. At times the neutrophils and monocytes of patients have a profound chemotactic defect.

Differential Diagnosis Autosomal recessive-HIES (AR-HIES) is a distinct clinical entity manifested by elevated IgE ligands, and recurrent skin and cutaneous viral infections and mutations in *DOCK8*.^{370,375}

Fatal sepsis occurs in AR-HIES from both Gram-positive and Gram-negative bacteria. Patients with AR-HIES have more symptomatic neurologic disease than STAT3 deficiency. Autoimmune hemolytic anemia may occur, but neutrophil chemotaxis is normal. The genetic mutation underlying AR-HIES remain unclear. Therapy remains supportive.

Therapy No known therapy is curative, and management decisions are based on the clinical findings. Prophylactic trimethoprim-sulfamethoxazole is effective in reducing infections with *S. aureus*.³⁷⁰ Type and route of antibiotic therapy are dictated by the results of the Gram stain and culture in patients with acute bacterial infections. Incision and drainage are essential for the management of abscesses, including superinfected pneumatoceles. Eczematoid dermatitis can be controlled with topical glucocorticoids to reduce inflammation and antihistamines to control pruritus. Intravenous immunoglobulin may decrease the number of infections for some patients. Attention needs to be paid to the scoliosis, fractures and degenerative joints by orthopedists. Retention of primary teeth requires dental expertise.

Course and Prognosis If the hyperimmunoglobulin E is recognized early in life and the patient is maintained on chronic anti-*Staphylococcal* antibiotic therapy, the prognosis remains good. Many such patients have reached maturity, indicating that the syndrome is compatible with prolonged survival. Conversely, if the diagnosis is delayed and the patient develops infected giant pneumatoceles, secondary fungal infections may occur, leading to a morbid state.

DEFECTS IN MICROBICIDAL ACTIVITY

Chronic Granulomatous Disease

Definition and History CGD is a genetic disorder affecting the function of neutrophils and monocytes. These phagocytic cells are able to ingest, but not kill, catalase-positive microorganisms because of an inability to generate antimicrobial oxygen metabolites (see Table 66-2). It is caused by mutations involving one of several genes encoding a component of the NADPH oxidase.³⁷⁶

In 1957, two pediatric groups caring for six male infants reported a clinical disorder of chronic suppurative lymphadenitis and recurrent fevers leading to premature deaths in the children.^{377,378} In the same time period, three observations assisted in providing the framework to understand the defect in the phagocytes of patients with CGD. Scientists described first that a striking increase in oxygen consumption

was found upon particle ingestion by phagocytes, which was not related to mitochondrial oxygen metabolism.³⁷⁹ Next, it was found that the process of phagocytosis was accompanied by the formation of large quantities of H_2O_2 in the cell.³⁸⁰ Subsequently, it was reported that homogenates of phagocytes consume oxygen when incubated with pyridine nucleotides.³⁸¹ These observations indicated that an oxidase enzyme or enzymes in the phagocytes were activated during phagocytosis to convert molecular oxygen into H_2O_2 . It was then established that phagocytes from patients with CGD could ingest, but could not kill, the catalase-positive organisms.³⁸¹ Building on previous studies that a neutrophil oxidase mediates the increase in oxygen consumption, a pyridine-dependent oxidase was found to be deficient in neutrophils of patients with CGD, which led to their inability to reduce the dye nitroblue tetrazolium (NBT) during phagocytosis of particles.³⁸² Collectively, these studies laid the groundwork for subsequent studies to unravel the biochemical and genetic defects in CGD.

Epidemiology The incidence of CGD in the United States is 1 per 200,000 livebirths, based on data from the National Institutes of Allergy and Infectious Disease Registry.³⁸³ Data from the Registry indicates that 86 percent of patients are male and 14 percent female; 80 percent are classified as white, 11 percent as black patients, and 3 percent Asians or mixed-race patients. Of the 340 patients in the Registry with adequate information for determination genetic transmission, 70 percent had the X-linked recessive form of the disease.

Etiology and Pathogenesis Several laboratory tests are used to classify forms of CGD and aid in understanding its pathogenesis (Table 66-4). The diagnosis of CGD is based on a compatible clinical history and demonstration of a defective respiratory burst. Several methods detect the production of reactive oxidants. The NBT method relies on the intracellular reduction of NBT by superoxide anion to a blue formazan precipitate that can be seen microscopically.³⁷⁶ More sensitive methods rely on the reaction of oxidants with specific chemiluminescent and fluorescent probes. The patients with CGD may have heterogeneous array of regular symptoms and severity, depending on which subunit is defective and on the nature of the genetic mutation.

Nicotinamide Adenine Dinucleotide Phosphate-Oxidase Function Engulfment of microbes by phagocytic cells is associated with a burst of oxygen consumption that is important for microbicidal killing and digestion. The respiratory burst is accompanied, not by mitochondrial respiration, but by a unique electron transport chain called the NADPH oxidase. Prior to stimulation, the components of the oxidase are physically separated into two major subcellular locations (Fig. 66-6). The membrane-bound portion of the NADPH oxidase contains a heterodimeric cytochrome b_{558} composed of a large, heavily glycosylated subunit with a Mr of 91 kDa, known as a gp91^{phox} (91-kDa glycoprotein of the phagocyte oxidase), and a 22-kDa protein known as p22^{phox}.^{376,384} Eighty to 90 percent of the cytochrome b_{558} is found in specific and gelatinase granules and secretory vesicles of the neutrophil and following neutrophil activation translocates to the plasma membrane.^{66,318} The heavy chain of cytochrome b contains sites for heme binding, flavin adenine dinucleotide (FAD) groups, and NADPH binding.³⁸⁵⁻³⁸⁸ The three-dimensional structure of cytochrome b_{558} indicates that the carboxyl-terminal half of the peptide contains sequences for flavin and NADPH binding.³⁸⁹ The amino half of the molecule is hydrophobic and contains the histidines that coordinate heme binding.³⁹⁰ The p22^{phox} also contains a site for heme binding.³⁸⁵ The synthesis of the p22^{phox} peptide is absolutely required for stability of gp91^{phox} and for oxidase activity in the membrane.³⁷⁶ The p22^{phox} also contains proline-rich regions that display consensus protein-protein interactions that provide a binding site for p47^{phox}.³⁹¹ Three other proteins vital to the function

TABLE 66-4. Diagnostic Classification of Chronic Granulomatous Disease

Affected Component	Inheritance	Subtype	Membrane-Bound Cytochrome b_{558} *	Cytosol $p47^{phox}$ *	Cytosol $p67^{phox}$ *
$gp91^{phox}$	X	$X91^0$	Not detectable	Normal	Normal
		$X91^+$	Normal quantity, but nonfunctional	Normal	Normal
		$X91^-$	Defective $gp91^{phox}$, which is poorly functional or expressed in a small fraction of phagocytes	Normal	Normal
$p22^{phox}$	A	$A22^0$	Not detectable	Normal	Normal
		$A22^+$	Normal quantity, but nonfunctional	Normal	Normal
$p47^{phox}$	A	$A47^0$	Normal quantity	Not detectable	Normal
$p67^{phox}$		$A67^0$	Normal	Normal	Not detectable

*Detected by spectral analysis or immunoblotting. In this nomenclature, the first letter represents the mode of inheritance (-linked [X] or autosomal recessive [A]). The number indicates the phox component, which is genetically affected. The superscript symbols indicate whether the level of protein of the affected component is undetectable (0), diminished (-), or normal (+) as measured by immunoblot or spectral analysis.

Figure 66-6. Possible mechanisms for the production of superoxide anion in neutrophils. Oxygen is reduced to superoxide (O_2^-) by a nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. The oxidase is a composite of (1) a 47-kDa cytosolic protein ($p47$); (2) a 67-kDa cytosolic protein ($p67$); (3) a 40-kDa cytosolic protein ($p40$); (4) a low-molecular-weight cytosolic G-protein, Rac2; and (5) a membrane-bound cytochrome b_{558} . Cytochrome b consists of a 22-kDa protein subunit ($p22$) and a 91-kDa glycoprotein subunit ($gp91$), both of which contain heme. The $gp91$ subunit is a flavin adenine dinucleotide (FAD)-dependent flavoprotein that contains the NADPH binding site and ultimately shuttles electrons to molecular oxygen, forming O_2^- , and (6) the cytosolic components translocate to the membrane and may serve to alter the tertiary structure of cytochrome b , to permit the flow of electrons from NADPH to O_2 . The $p47$ subunit is phosphorylated upon activation of the neutrophil. The $p40^{phox}$ component stabilizes the preactivation complex of $p67^{phox}$. The unstable superoxide anion (O_2^-) is converted to hydrogen peroxide (H_2O_2), either spontaneously or by the enzyme superoxide dismutase (SOD). H_2O_2 in the presence of myeloperoxidase (MPO) converts H_2O_2 to hypochlorous acid (HOCl). Both H_2O_2 and O_2^- can be transformed into hydroxyl radical (OH^\cdot). H_2O_2 can be reduced to H_2O and O_2 by the enzyme catalase or by glutathione (GSH), a product of the hexose-monophosphate shunt. These reactive oxygen species are responsible for microbial killing. Normal oxidative function of the NADPH complex requires fully functional individual components.

of this oxidase system reside in the cytosol of the resting phagocyte. Upon stimulation, translocation of p47^{phox} takes place. Phosphorylated p47^{phox} together with two other cytoplasmic components of the oxidase, p67^{phox}, and a low-molecular-weight guanosine triphosphate Rac-2, translocate to the membrane, where they interact with cytoplasmic domains of the transmembrane cytochrome b₅₅₈ to form the active oxidase.^{391,392} Both p47^{phox} and p67^{phox} contain SH3 (Src homology 3) domains that may participate in intramolecular and intermolecular binding with consensus proline-rich regions in p47^{phox}.³⁹² Phosphorylation, which occurs on serines in the cationic C-terminal region of p47^{phox}, serves to disrupt this intermolecular interaction, making the SH3 regions available for binding to p22^{phox}. Another cytoplasmic component with homology to p47^{phox} has been identified as p40^{phox}. p40^{phox}, like p47^{phox}, contains a PX domain, a motif that supports the binding to phosphoinositides on the cytosolic side of membranes.³⁹³ The p40^{phox} component stabilizes the cytoplasmic complexes of p67^{phox} and p47^{phox} on phagosomes. Its binding of phosphatidylinositol 3 phosphate also potentiates superoxide production upon neutrophil activation.³⁹⁴ Cytochrome b₅₅₈ spans the membrane, permitting NADPH to be oxidized at the cytoplasmic surface and oxygen to be reduced to form O₂⁻ on the outer surface of the plasma membrane or on the inner surface of the phagosomal membrane.³⁹⁵

Genetic Alterations Affecting Cytochrome b The most frequent form of CGD occurs in 70 percent of patients and is caused by mutations in the gp91^{phox} gene, termed *CYBB*, which is located on chromosome Xp21.1.^{376,396} These mutations lead to the X-linked form of the disease. Large interstitial deletions causing other X-linked disorders such as retinitis pigmentosa, Duchenne muscular dystrophy, McLeod hemolytic anemia, and ornithine transcarbamylase deficiency, have been reported in a few patients with X-linked CGD.^{383,397-399} Mutation analysis of the gene encoding gp91 and a large group of X-linked CGD kindreds has documented many distinct defects, including point mutations, inversions, deletions, or insertions that disrupt the reading frame and nonsense mutations that create a premature stop codon.³⁹⁶ Some splice-site defects have also been identified. In this situation, short deletions in gp91^{phox} mRNA are caused by point mutations that produce partial or complete exon skipping during mRNA splicing.⁴⁰⁰ This abnormality is a common cause of X-linked CGD. In the remaining patients, point mutations have been identified that generate either premature stop codons or amino acid substitutions that apparently disrupt protein stability or function and lead to a complete lack of detectable cytochrome b₅₅₈ protein in phagocytic cells in most patients with X-linked CGD. In some situations, low levels of functional cytochrome b are present, whereas in others, normal levels of dysfunctional cytochrome b₅₅₈ occur.⁴⁰¹ In the latter situation there is some clustering of defects in regions of known function, such as the NADPH- or flavin-binding consensus regions.⁴⁰² Approximately 10 to 15 percent of X-linked CGD arises from new germline mutations.⁴⁰³

A similar array of mutations has been identified in the 5 percent of CGD patients who have abnormalities in the p22^{phox} gene, termed *CYBA*, which is located on chromosome 16q24.^{376,402,404} In this autosomal disorder, mutations in the p22^{phox} gene result in deletions, frameshifts, and/or missense mutations. Patients with a defective p22^{phox} gene do not express the other cytoplasmic unit polypeptide. In one patient, p22^{phox} peptide was associated with normal amounts of cytochrome b with normal heme spectrum, but p47^{phox} translocation membrane did not occur and there was no oxidase activation because the mutation affected a proline-rich region thought to mediate binding to one of the SH3 domains of p47^{phox}. In gp91^{phox}-deficient patients, p22^{phox} mRNA is present, but it is not translated, which is consistent with the notion that either cytochrome subunit polypeptide is dependent upon the stable

expression of the other subunit.³⁷⁶

Genetic Alterations Affecting Cytosolic Proteins Two other proteins have been identified as being vital to the function of the NADPH-oxidase system. Their absence results in the syndrome of CGD.⁴⁰⁵ These proteins have molecular masses of 47 kDa and 67 kDa, respectively, and are located in the cytosol of resting cells. Defects in the genes for p47^{phox}, termed *NCF1*, which is found on chromosome 7q11, are responsible for the majority of all cases of autosomal recessive CGD, whereas inherited defects for the gene for neutrophil p67^{phox}, termed *NCF2*, account for a small subgroup of autosomal recessive CGD.³⁷⁶ The function of p47^{phox} and p67^{phox} in regulating the respiratory burst oxidase is thought to involve activation of the electron transport function of cytochrome b₅₅₈. The mutation analysis in patients with p47^{phox}-deficient forms of CGD reveals an unusual pattern, in that more than 90 percent of mutant alleles have guanine-thymine dinucleotide deletion at the start of exon 2, resulting in frameshift and premature stop.^{402,406} The truncated protein is unstable in that it cannot be detected immunologically. The majority of patients appear to be homozygous for this mutation without any history of consanguinity. The p47^{phox} gene occurs in an area of chromosome 7 that has a high degree of evolutionary duplication in normal individuals because a pseudogene highly homologous to the normal p47^{phox} gene exists in the normal genome in this region of duplication. The pseudogene contains the same GT deletion associated with most cases of p47^{phox} CGD. This implies that recombination of the normal gene and pseudogene with conversion of the normal gene to partial pseudotype sequence in that region may be responsible for the high relative rate of this specific mutation in diverse racial groups, which proved to be the case.⁴⁰⁷

A second rare form of CGD is caused by mutations in the gene for the p67^{phox} cytosolic component.⁴⁰¹ The p67^{phox} gene, which has been mapped to the long arm of chromosome 1, spans 37 kb and contains 16 exons. The mutations identified in p67^{phox}-deficiency CGD have included missense mutations and spliced junction mutations affecting mRNA processing, which led to nondetectable p67^{phox} protein by immunologic means.⁴⁰²

Mutation of *NCF4*, the gene encoding p40^{phox}, was reported in a child with granulomatous colitis. One allele had a frameshift mutation with a premature stop codon. The other had a missense mutation predicting an R105Q substitution in the PX domain which is responsible for binding to phosphatidylinositol 3 phosphate. The functional defect was inability to assemble the NADPH oxidase in the membrane of phagosomes but not on the plasma membrane.⁴⁰⁸

Predisposition to Infection Mutations in the gene for cytochrome b₅₅₈ or the cytosolic factors involved in activating the cytochrome are associated with the CGD phenotype. **Figure 66-7** shows schematically the manner in which the metabolic deficiency of the CGD neutrophil predisposes the host to infection. Normal neutrophils accumulate H₂O₂ and other oxygen metabolites in the phagosomes containing ingested microorganisms. MPO is delivered to the phagosome by degranulation and in this setting H₂O₂ acts as a substrate for MPO to oxidize halide to HOCl and chloramines, which kill the microbes. The quantity of H₂O₂ produced by the normal neutrophils is sufficient to exceed the capacity of catalase, a H₂O₂-catabolizing enzyme produced by many aerobic microorganisms, including *S. aureus*, most Gram-negative enteric bacteria, *C. albicans*, and *Aspergillus* spp. In contrast, H₂O₂ is not produced by CGD neutrophils, and any generated by the microbes themselves may be destroyed by their own catalase. Thus, catalase-positive microbes can multiply inside CGD neutrophils, where they are protected from most circulating antibiotics, and can be transported to

Figure 66-7. The pathogenesis of chronic granulomatous disease (CGD). The manner in which the metabolic deficiency of the CGD neutrophil predisposes the host to infection is shown schematically. Normal neutrophils accumulate hydrogen peroxide (H_2O_2) in the phagosome containing ingested *Escherichia coli*. Myeloperoxidase is delivered to the phagosome by degranulation, as indicated by the closed circles, and in this setting, H_2O_2 acts as a substrate for myeloperoxidase to oxidize halide to hypochlorous acid and chloramines, which kill the microbes. The quantity of H_2O_2 produced by the normal neutrophils is sufficient to exceed the capacity of catalase, a H_2O_2 -catabolizing enzyme of many aerobic microorganisms, including most Gram-negative enteric bacteria, *Staphylococcus aureus*, *Candida albicans*, and *Aspergillus* spp. When organisms such as *E. coli* gain entry into the CGD neutrophils, they are not exposed to H_2O_2 because the neutrophils do not produce it, and the H_2O_2 generated by microbes themselves is destroyed by their own catalase. When CGD neutrophils ingest streptococci (Strep.) or pneumococci, these organisms generate enough H_2O_2 to result in a microbicidal effect. On the other hand, as indicated in the middle figure, catalase-positive microbes, such as *E. coli*, can survive within the phagosome of the CGD neutrophil.

distant sites and released to establish new foci of infection.⁴⁰⁵ Activation of the oxidase also has a pronounced effect on the pH within the phagocytic vacuole. It is controversial whether activation of the respiratory burst is associated with an alkaline phase, but the pH of the phagocytic vacuole becomes more acidic in CGD patients than in normal patients.^{161,409} The alkaline phase may be important for the antimicrobial and digestive functions of the neutral hydrolases released from the cytoplasmic granules into the vacuole upon phagocytosis. In CGD, the phagocytic vacuoles remain acidic and the bacteria are not digested properly.⁴¹⁰ The impairment in the respiratory burst by CGD neutrophils leads to delayed neutrophil apoptosis and subsequent impaired clearance of degenerating neutrophils by CGD macrophages, which, in turn, predisposes the host to enhanced inflammation.⁴¹¹ CGD neutrophils are incapable of generating NETs and cannot trap microorganisms by this mechanism.⁴¹² The CGD macrophage is unable to clear CGD neutrophils because of a deficiency of intrinsic IL-4 production, which occurs because of defective phosphatidylserine exposure on CGD neutrophils, that is a necessary requirement to engage CGD macrophage phosphatidylserine membrane receptors and subsequent macrophage activation.⁴¹¹ In hematoxylin-and-eosin-stained sections from patients, macrophages eventually may contain a golden pigment, which reflects the abnormal accumulation of ingested material and also contributes to the diffuse granulomata that give CGD its descriptive name.⁴¹³ On the other hand, when CGD neutrophils ingest pneumococci or streptococci, these organisms generate enough H_2O_2 to result in a microbicidal effect.

Clinical Features Although the clinical presentation is variable, several clinical features suggest the diagnosis of CGD.³⁷⁶ Any patient with recurrent lymphadenitis should be considered to have CGD. Additionally, patients with bacterial hepatic abscesses, osteomyelitis at multiple sites or in the small bones of the hands and feet, a family history of recurrent infections, or unusual catalase-positive microbial infections all require clinical evaluation for this disorder. Table 66-5 lists the most

common clinical infections that afflict CGD patients and Table 66-6 cites their prevalence.

Among the various infections, only perirectal abscess, suppurative adenitis, and bacteremia/fungemia differ significantly in prevalence in the X-linked recessive and autosomal recessive CGD patients.³⁸³ Each of these conditions was twice as common in the X-linked form.

The onset of clinical signs and symptoms may occur from early infancy to young adulthood. Although the majority of patients with CGD (76 percent) are diagnosed before the age of 5 years, approximately 10 percent are not diagnosed until the second decade of life, and on rare occasions, not until the third decade or later.³⁸³ The organisms infecting CGD patients have changed considerably from those initially reported between 1957 and 1976. *Staphylococcus* caused most of the infections in the initial cases; *Klebsiella* and *E. coli* were then the next most common pathogens. Now *Aspergillus* is the prominent organism causing pneumonia and is the leading cause of death in patients.³⁷⁶ Invasive aspergillosis can occur in the first few months of life in healthy infants as well as in those with CGD. Although aspergillosis is the most common infecting fungus in CGD, *Candida* and several other fungal strains have been invasive in this disorder. *Burkholderia cepacia* is another leading cause of death in patients with CGD. *Serratia marcescens* is the third leading organism that commonly infects patients with CGD. Infections are characterized by microabscesses and granuloma formation. The presence of pigmented histiocytes is helpful in establishing the diagnosis. Patients may suffer from the consequences of chronic infections including the anemia of chronic disease, lymphadenopathy, hepatosplenomegaly, chronic purulent dermatitis, restrictive lung disease, gingivitis, hydronephrosis, and gastroenteric narrowing.³⁸³ Patients with CGD are also at risk for developing colitis and chorioretinitis, and discoid lupus erythematosus.³⁸³

Several mothers of patients in whom X-linked inheritance was established had an illness resembling systemic lupus erythematosus.³⁸³ Both X-linked and autosomal recessive patients with CGD also have a

similar disorder.⁴¹⁴ It may be that these mothers' and patients' cells are unable to clear immune complexes sufficiently, which is a characteristic feature of CGD cells *in vitro*.⁴¹⁵ Variant alleles of MBL and FcγRIIA especially in combination are associated with rheumatologic disorders in patients with CGD.⁴¹⁶

Laboratory Findings The defect in the respiratory burst is best determined by measuring superoxide or H₂O₂ production in response to both soluble and particulate stimuli.⁴¹⁷ A test that is being employed is the use of flow cytometry using dihydrorhodamine-123 fluorescence.⁴¹⁸ Dihydrorhodamine-123 fluorescence detects oxidant production because it increases fluorescence upon oxidation.⁴¹⁸ In most cases there is no detectable superoxide or H₂O₂ generation with either type of stimulus. In the variant form of CGD, however, superoxide may be produced at rates between 0.5 and 10 percent of control.⁴¹⁹

An alternative method for measuring respiratory burst activity is the NBT test. This assay is performed by microscopically assessing the ability of individual cells to reduce NBT to purple formazan crystals following stimulation. Commonly there is no NBT reduction with most forms of CGD. In some of the variant forms, however, a high percentage of cells may contain some formazan, a finding indicative of a greatly diminished respiratory burst in most of the neutrophils. This test also permits detection of the carrier state in X-linked CGD when as few as 5 to 10 percent of the cells are NBT-negative.⁴²⁰

Most sophisticated procedures can identify the molecular defect. Cytochrome b content can be measured in extracts of detergent-disrupted neutrophils by a spectrophotometric assay.⁴²⁰ Once the diagnosis of CGD is made, the genotype can be determined. A mosaic population of oxidation that has positive and negative neutrophils in a male patient's mother and sister strongly suggests X-linked CGD. Lack of a mosaic pattern among female relatives does not rule out the X-linked mode of inheritance because the defect can arise spontaneously. Prenatal diagnosis of CGD is established by analysis of DNA from amniocytes or chorionic villus samples.

Differential Diagnosis Leukocytes from patients with CGD have normal glucose-6-phosphate dehydrogenase (G6PD) activity. However, a few individuals with apparent CGD have been described who have neutrophils that lack or are almost lacking in G6PD activity.^{421,422} The erythrocytes of these patients also lack the enzyme, and the patients have chronic hemolysis. In the cases of severe neutrophil G6PD deficiency, an attenuated respiratory burst progressively decreases as a result of the depletion of intracellular NADPH, the primary substrate for the respiratory burst oxidase. CGD and G6PD deficiency can be distinguished from each other by the hemolytic anemia seen in the latter disorder and by the fact that erythrocyte G6PD activity is normal in CGD and markedly reduced in G6PD deficiency.⁴⁰¹ A variety of studies indicate that the small GTPase Rac-2 plays an essential role in activity of the NADPH and the actin cytoskeleton in human neutrophils.³⁸³ A toddler has been described as presenting with a perirectal abscess at 5 weeks of age. This patient subsequently had necrosis of the periumbilical skin and fascia, and his surgical wounds did not heal properly. Functionally his neutrophils had multiple defective components; for example, adhesion to ligands for sLe^x, chemotaxis, release of primary azurophil granules upon stimulation with chemotactic peptide, and failure to undergo the respiratory burst using the same stimulus.^{423,424} Molecular analysis identified the asparagine for aspartic acid mutation at amino acid 57 of one allele of the Rac-2 gene.^{423,424} Mutant Rac-2 did not bind GTP and it inhibited and behaved as a dominant negative to impair Rac-2-mediated activation of the respiratory burst.⁴²⁴ Fortunately, the youngster was successfully transplanted with marrow from a HLA-identical older brother.⁴²⁴

Therapy, Course, and Prognosis Allogeneic hematopoietic stem cell transplantation is the only recognized curative treatment for CGD. Reduced intensity conditioning stem cell transplantation from HLA-matched donors performed in 56 patients with intractable infections and severe inflammation carried a 2-year overall survival of 96 percent.⁴²⁵ However, vigorous supportive care along with the use of recombinant IFN continues to be the foundation of treatment.³⁷⁶ Cultures must be obtained as soon as infection is suspected, as unusual organisms are commonly the source of infection and may grow promptly *in vitro*. Most abscesses require surgical drainage for therapeutic and diagnostic purposes, and prolonged use of antibiotics is often required. If fever occurs, it is advisable to obtain certain studies that aid in the management of septic episodes. These include roentgenograms of the chest and skeleton and a computed tomography (CT) scan of the liver because of the frequency of pneumonia, osteomyelitis, and liver abscesses.³⁸³ Arrangements should be made for prompt medical attention at the first signs of infection. With early intervention, many lesions can be managed by conservative medical means. For example, enlarging lymph nodes often regress when treated with local heat and orally administered antistaphylococcal antibiotics. It is particularly important to obtain a microbiologic diagnosis, and fine-needle aspiration may be helpful in this regard. In general, antibiotic therapy for the offending organisms is indicated and purulent masses should be drained. The cause of fever and prostration cannot always be established, and empiric

treatment with broad-spectrum parenteral antibiotics is required. Often it is necessary to treat with antibiotics for a prolonged time until the initially elevated sedimentation rate approaches normal values. *Aspergillus* spp. infection requires treatment with amphotericin B or, in refractory cases, with granulocyte transfusions.³⁷⁶ Glucocorticoids also may be useful in the treatment of patients with antral and urethral obstruction. The risk of *Aspergillus* infection can be reduced by avoiding marijuana smoke and decaying plant material, such as mulch and hay, both of which contain numerous fungal spores.⁴²⁶ Long-term oral prophylaxis with trimethoprim-sulfamethoxazole (5 mg/kg per day of trimethoprim) is an accepted practice in the management of patients with CGD.³⁷⁶ Patients have prolonged infection-free periods, which result from the prevention of infections caused by *S. aureus*, without increasing the incidence of fungal infections. The use of itraconazole prophylactically has reduced the development of fungal infections.^{427,428}

IFN- γ (50 mcg/m², three times per week, subcutaneously) can reduce the number of serious bacterial and fungal infections.^{427,429} IFN- γ -enhanced neutrophil function *in vitro* has not been correlated with improvement in the activity of the neutrophil respiratory burst in patients totally lacking the ability to generate superoxide. On the other hand, its use increases the neutrophil expression of the high-affinity Fc γ receptor 1, as well as monocyte expression of Fc γ RI, Fc γ RII, Fc γ RIII, CD11/CD18, and HLA-DR.⁴³⁰ The IFN- γ protective effect in patients with CGD may involve improved microbial clearance, as suggested by the enhanced phagocytic activity by neutrophils of opsonized *S. aureus*. In rare, X-linked CGD patients able to generate some superoxide, IFN- γ programs granulocyte cells to increase their expression of cytochrome b, which results in normal superoxide generation.⁴³¹ With the use of current prophylactic treatments, the mortality in CGD has been reduced to two patient deaths per year per 100 patients followed.³⁷⁶

CGD patients with mutations that result in 5 to 10 percent of normal-functioning amounts of NADPH have a mild phenotype and better clinical prognosis than do patients with complete absence of any NADPH-oxidase activity.⁴³² Similarly, female carriers of X-linked CGD who have only 3 to 5 percent oxidase-normal neutrophils rarely get serious infections suggestive of the CGD clinical phenotype.⁴³³ Thus, even low levels or partial correction by gene therapy of CGD is likely to provide clinical benefits. In support of that hypothesis, mouse models of X-linked and p47^{phox}-deficient CGD have been developed by gene targeting.^{434,435} Studies in the gp91^{phox}- and the p47^{phox}-deficient mouse models of CGD show that retrovirus-mediated gene-therapy-targeting of marrow progenitor cells *ex vivo* can result in the correction of defects in oxidant production *in vivo* in blood neutrophils after radiation conditioning and transplantation of marrow stem cells.^{436,437} Protection from infection challenge occurred even when the oxidase-corrected cells comprised less than 10 percent of circulating neutrophils. These promising results suggest that somatic gene therapy can be employed to correct defective phagocyte oxidase function in selected patients with CGD. In a phase I clinical trial, gene therapy for p47^{phox}-deficiency CGD, five adult patients received intravenous infusions of autologous blood stem cells that were *ex vivo* transduced using a retrovirus encoding normal p47^{phox}.⁴³⁸ Although conditioning therapy was not given prior to the stem cell infusion, functionally corrected neutrophils were detectable in blood for several months.³³⁹ In another study, long-term high-level clinical beneficial correction in *ex vivo* gene therapy of X-linked CGD occurred in two adult patients.⁴³⁹ Nonablative busulfan conditioning was used to augment gene therapy correction. There needs to be caution regarding the long-term stability and safety of gene therapy. For instance, there are concerns about gene insertion rendering patients vulnerable to developing an hematological malignancy.

Myeloperoxidase Deficiency

The functional and immunochemical absence of the enzyme MPO from granules of neutrophils and monocytes, but not eosinophils, is inherited as an autosomal recessive trait, with a prevalence of 1:2000.⁴⁴⁰ MPO, an enzyme that catalyzes the production of HOCl in the phagosome. In MPO deficiency, the microbicidal activity of the neutrophils is reduced early after ingestion of microorganisms (see Table 66–2). However, normal microbicidal activity is observed in approximately 1 hour after a variety of organisms are ingested.⁴⁴⁰ Thus, the MPO-deficient neutrophil uses an MPO-independent system for killing bacteria that is slower than the MPO–H₂O₂–halide system, but that is eventually effective in eliminating bacteria. MPO-deficient neutrophils accumulate more H₂O₂ than do normal neutrophils; the higher peroxide concentration improves the bactericidal activity of the affected neutrophils. In contrast to the retardation of bactericidal activity, candidacidal activity in MPO-deficient neutrophils is absent.⁴⁴⁰ The most significant clinical manifestation in a few patients with diabetes mellitus and MPO deficiency has been severe infection with *C. albicans*. Because this is such a common disorder of phagocytes, it is important to note that the vast majority of patients with this genetic disorder have not been unusually susceptible to pyogenic infections and do not require therapy.

The complementary DNA encoding human MPO has been cloned and the gene structure, including promoter and regulatory elements, delineated.⁴⁴⁰ The gene consists of 12 exons and 11 introns and is located on the long arm of chromosome 17, and its expression is finely coordinated with expression of genes encoding other lysosomal proteins. Expression of genes for human neutrophil elastase and MPO is very similar; it is low in myeloblasts, peaks during the promyelocyte stage, and eventually drops to low levels in myelocytes. MPO is a symmetric molecule composed of four peptides, where each half consists of a heavy- and a light-chain heterodimer.⁴⁴⁰ Each heavy- and light-chain heterodimer starts as a single peptide that is cleaved during the post-translational process to yield the heavy and light chains that form half of the mature molecules. The two halves of the molecule are associated by a disulfide linkage between heavy-subunit residues at their residue C319.

The primary translation product of the gene is a single-chain peptide of 80 kDa that undergoes cotranslational glycosylation at several asparagine residues, followed by a series of modifications of these oligosaccharides. The apopromyeloperoxidase exists for a prolonged time in the endoplasmic reticulum, where it associates reversibly with several endoplasmic reticulum–resident proteins known as molecular chaperones.⁴⁴⁰ Subsequent to heme insertion, the enzymatically active promyeloperoxidase undergoes proteolytic cleavage of the pro region. Then, in a prelysosomal compartment, the single peptide is cleaved into the heavy and light subunits, which remain linked. During final sorting within the azurophil lysosome compartment, there is dimerization of half-molecules to form the mature MPO.

Most patients with MPO deficiency have a missense mutation in the gene that results in replacement of arginine 569 with tryptophan.⁴⁴⁰ The mutation results in a precursor that associates with molecular chaperones, but does not incorporate heme, resulting in a maturational arrest during processing at the stage of an inactive enzymatic apopromyeloperoxidase. Other patients are heterozygotes with one allele bearing the common mutation and the other being normal, resulting in a partial deficiency.⁴⁴¹ To date, four genotypes have been reported to cause inherited MPO deficiency, each of which results in missense mutations. In the genotype Y173C, a missense mutation results in replacement of a tyrosine at codon 173 with a cysteine residue resulting in the mutant precursor being retained in the endoplasmic reticulum by virtue of its prolonged interaction with the chaperone calnexin, and eventually

undergoing degradation in a proteasome.⁴⁴⁰ In this way, the quality control system operating in the endoplasmic reticulum retrieves misfolded MPO precursors from the biosynthetic pathway and creates the biochemical phenotype of MPO deficiency. In another patient, a missense mutation resulted in an intact MPO molecule that acquired heme but failed to undergo proteolytic processing to a mature molecule.

Acquired disorders are associated with MPO deficiency. Reported states include lead intoxication, ceroid lipofuscinosis, myelodysplastic syndromes, and acute myelogenous leukemia.⁴⁴² One-half of untreated patients with acute myelogenous leukemia and 20 percent of patients with CML may have MPO deficiency.⁴⁴²

Deficiencies of Glutathione Reductase and Glutathione Synthetase

Neutrophils contain enzymes capable of inactivating potentially damaging reduced oxygen byproducts. Disposal of superoxide anion is accomplished through superoxide dismutase, a soluble enzyme that converts superoxide to a H₂O₂. H₂O₂ is detoxified by catalase and by the glutathione peroxidase–glutathione reductase system, which converts H₂O₂ to water and oxygen.⁴⁴³ In addition to the soluble enzymes, cellular vitamin E serves as an antioxidant to prevent damage to the surface of activated neutrophils when releasing H₂O₂.⁴⁴³ Single cases of profound deficiencies in glutathione reductase⁴⁴⁴ and glutathione synthetase⁴⁴⁵ have been associated with impaired neutrophil bactericidal activity (see Table 66–2). Both deficiencies are associated with hemolysis under conditions of oxidative stress (Chap. 48). Glutathione synthetase deficiency also has been associated with intermittent neutropenia during times of mild infection. Vitamin E has been employed to ameliorate the hemolysis and improve neutrophil function in a patient with glutathione synthetase deficiency.⁴⁴⁵ Like patients with MPO-deficient neutrophils, the patients with glutathione reductase deficiency and glutathione synthetase deficiency are not unusually susceptible to bacterial infections.

● DIAGNOSTIC APPROACH TO THE PATIENT WITH SUSPECTED NEUTROPHIL DYSFUNCTION

An increased susceptibility to pyogenic infections must be viewed in light of a number of factors: (1) adequacy of host defense; (2) the microbes to which the host is exposed; and (3) the conditions of the exposure. It is not always easy to establish a diagnosis of a specific neutrophil dysfunction on clinical grounds alone. Patients with recurrent pyogenic infections often yield no clues as to why they are afflicted, and patients with established deficiency of a defense mechanism may have an unimpressive clinical history. On the other hand, patients may be suspected of having a neutrophil dysfunction if they have a history of frequent bacterial or severe infections. Recurrent pulmonary infections, hepatic abscesses, and perirectal abscesses also should alert the clinician to consider further diagnostic evaluation of neutrophil function. For example, the identification of unusual catalase-positive bacteria and fungi, such as *B. cepacia*, *S. marcescens*, *Nocardia*, and *Aspergillus*, could be indicative of CGD.

Because many of the tests of neutrophil function are bioassays with great variability, the results of the tests must be interpreted in light of the patient's clinical condition. For instance, isolated chemotactic defects usually do not explain the propensity for a patient to have recurrent severe infections. Furthermore, variation in bioassays is often intensified by inflammation or infection. Figure 66–8 is an algorithm for evaluation of the patient with recurrent infection.

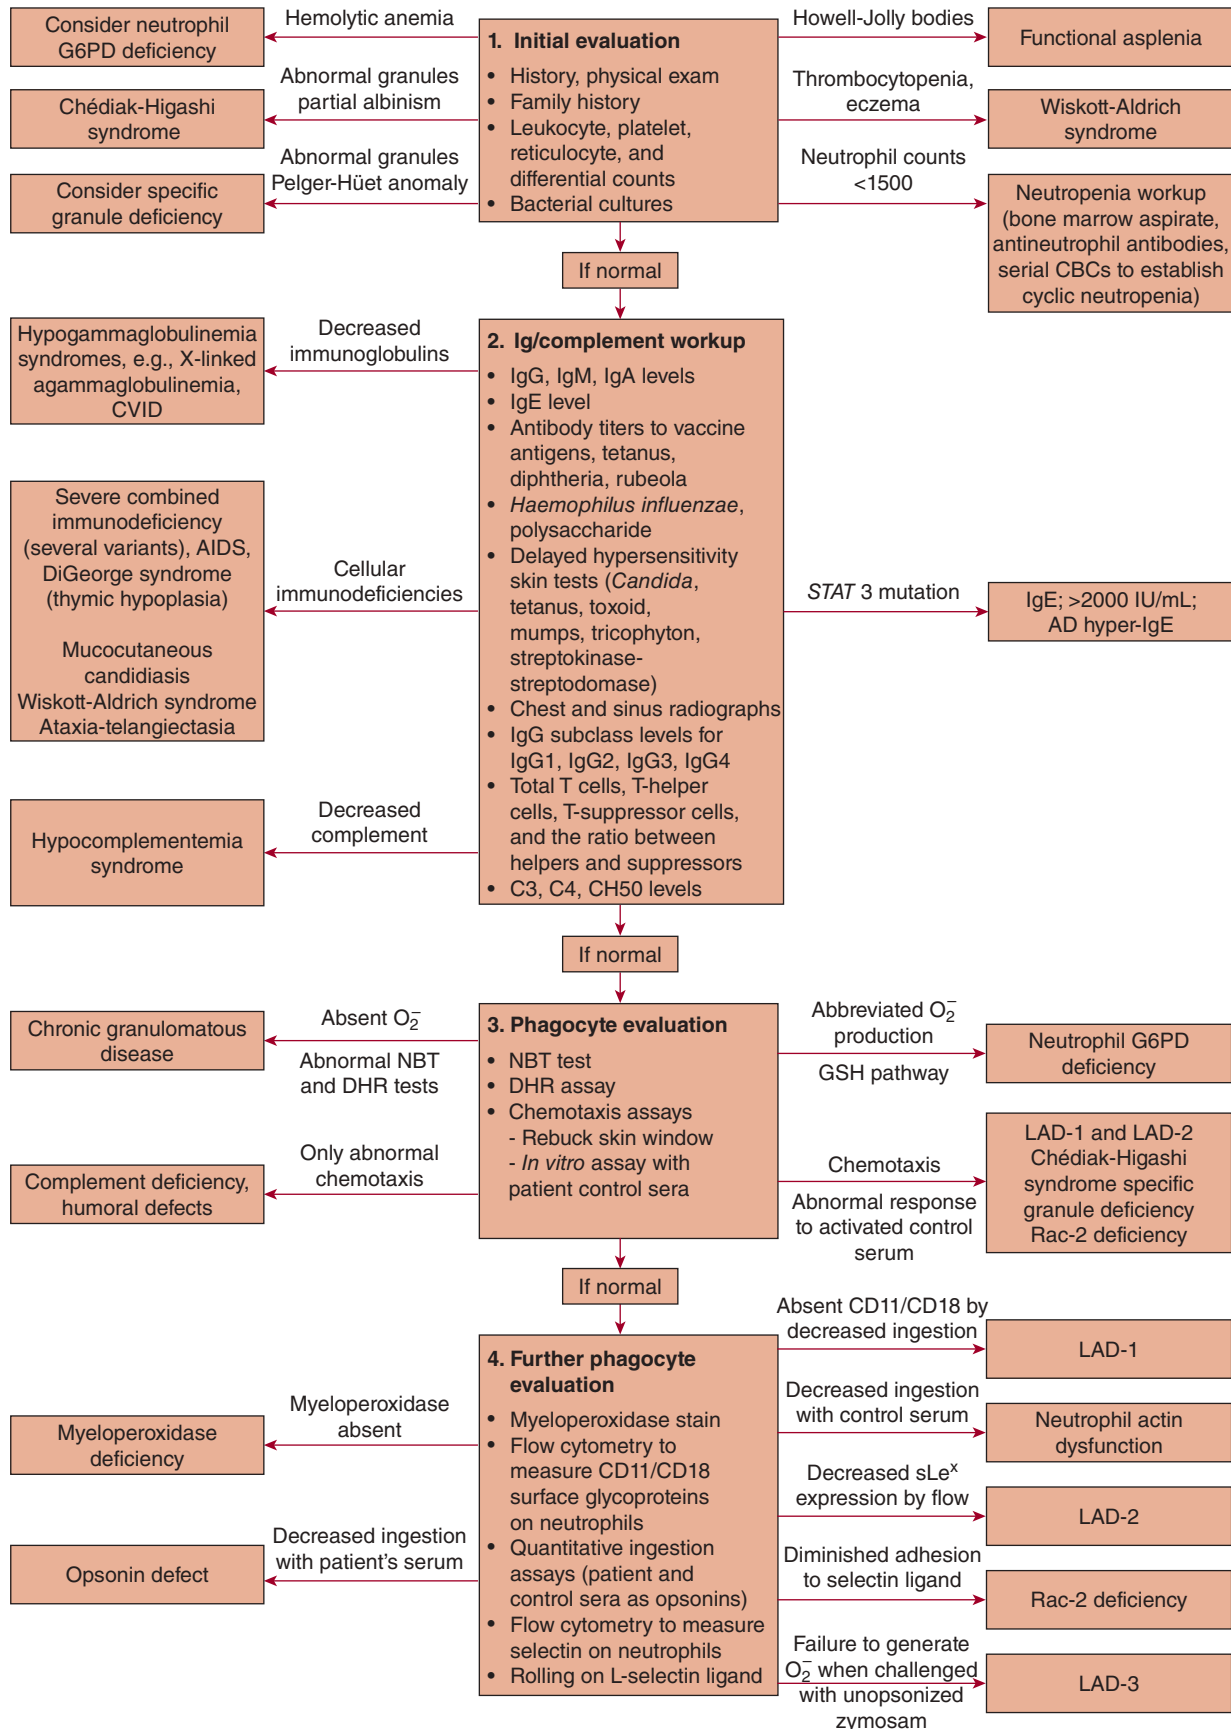

Figure 66–8. Algorithm for the workup of patients with recurrent infections. AD, autosomal dominant; CBC, complete blood count; CVID, common variable immunodeficiency; DHR, delayed hypersensitivity reaction; G6PD, glucose-6-phosphate dehydrogenase; GSH, glutathione; Ig, immunoglobulin, LAD, leukocyte adhesion deficiency; NBT, nitroblue tetrazolium; sLe^x, sialyl Lewis X.

CHAPTER 67

STRUCTURE, RECEPTORS, AND FUNCTIONS OF MONOCYTES AND MACROPHAGES

Steven D. Douglas and Anne G. Douglas

SUMMARY

The monocyte is a spherical cell with prominent surface ruffles and blebs when examined by scanning electron microscopy. As the monocyte enters the tissue and differentiates into a macrophage, the cell volume and number of cytoplasmic granules increase. Cell shape varies, depending on the tissue in which the macrophage resides (e.g., lung, liver, spleen, brain). A characteristic feature of macrophages is their prominent electron-dense membrane-bound lysosomes, which can be seen fusing with phagosomes to form secondary lysosomes. The latter contain ingested cellular and noncellular material in different stages of degradation. A broad range of surface receptors for many ligands, including the Fc portion of immunoglobulin, complement proteins, cytokines, chemokines, lipoproteins, and others, are on the cell surface. Macrophages differ in appearance, biochemistry, and function based on the environment in which they mature from monocytes. These differences are exemplified by the diversity among dendritic cells of lymph nodes, histiocytes of connective tissue, osteoclasts of bone, Kupffer cells of liver, microglia of the central nervous system, and macrophages of the serosal surfaces, each fashioned to meet the local needs of the mononuclear phagocyte system, which plays a role in inflammation and host defense against microbes. Modern cell biologic methods refined our knowledge of surface receptors, endocytosis, and lysosomal

Acronyms and Abbreviations: APC, antigen-presenting cell; CD, cluster of differentiation; CR, complement receptor; CSF, colony-stimulating factor; DC, dendritic cell; EGF, epidermal growth factor; EGF-TM7, epidermal growth factor—seven transmembrane; EMR2, epidermal growth factor—like module containing mucin-like hormone receptor—like 2; FcR, Fc receptor; GM-CSF, granulocyte-monocyte colony-stimulating factor; GPCR, G-protein—coupled receptor; HLA, human leukocyte antigen; IBD, inflammatory bowel disease; IFN, interferon; Ig, immunoglobulin; IL, interleukin; IMP, intramembrane particle; IRAK, interleukin receptor-associated kinase; LFA, lymphocyte function—associated antigen; LPS, lipopolysaccharide; m- ϕ , macrophage; MARCO, macrophage receptor with collagenous structure; M-CSF, macrophage colony-stimulating factor; MHC, major histocompatibility complex; MPO, myeloperoxidase; NF, nuclear factor; NLR, NOD-like receptor; NOD, nucleotide-binding oligomerization domain; PI3K, phosphatidylinositol 3-kinase; PS, phosphatidylserine; SR, scavenger receptor; TGF, transforming growth factor; TLR, toll-like receptor.

degradation, with emphasis on membrane flow and secretion. These pioneering studies culminated in the discovery of dendritic cells as potent, specialized antigen-presenting cells. Subsequent development of monoclonal antibodies and molecular cloning of surface proteins and cytokines, followed by microarray analysis and genomics, provided the sensitive and specific tools to analyze macrophage functions *in vitro* and *in vivo*. These studies have brought insights into macrophage cytotoxic and antimicrobial activities and, to a lesser extent, their trophic, homeostatic functions in the body. Macrophages play a major role in innate as well as adaptive immunity.

● MONONUCLEAR PHAGOCYTE SYSTEM OVERVIEW

Modern study of mammalian phagocytes began with Metchnikoff in the 19th century. An understanding of the ontogeny, kinetics, and function of phagocytic cells in animals led to the concept of the mononuclear phagocyte system.^{1,2} Kinetic studies indicate that marrow monoblasts and monocytes develop from the common myeloid progenitor, a derivative of the hematopoietic stem cell, and that tissue macrophages develop from monocytes that have migrated from the blood pool in response to chemotactic stimuli (Table 67-1 and Chap. 18). Tissue macrophages share many functional characteristics, such as phagocytic and microbial killing capabilities and adherence to glass or plastic surfaces *in vitro*. Vascular endothelium, reticular cells, and dendritic cells of lymphoid germinal centers usually are not included in the mononuclear phagocyte system, although the now obsolete term *reticuloendothelial system*³ denoted those cells as playing some complementary part with mononuclear phagocytes. In addition to developing the multitude of types of tissue macrophages, monocytes can differentiate into myeloid-derived dendritic cells.^{4,5}

● STRUCTURE

The blood monocyte is a medium to large motile cell that can marginate along vessel walls and has a propensity for adherence to surfaces. Monocytes respond to inflammation and chemotactic stimuli by active diapedesis across vessel walls into inflammatory foci, where they can mature into macrophages, with greater phagocytic capacity and increased content of hydrolytic enzymes. Free macrophages also are present in mammary glands, alveolar spaces, pleura, peritoneum, and synovia. The somewhat less-motile fixed-tissue macrophages are found in different tissues and serous cavities. The functions of mononuclear phagocytes include phagocytosis, killing, and digestion of microorganisms, particulate material, or tissue debris; secretion of chemical mediators and regulators of the inflammatory response; interaction (as dendritic cells) with antigen and lymphocytes in the generation of the immune response; cytotoxicity, such as killing of some tumor cells; and other functions specific for macrophages of particular tissues.

The development of techniques to isolate monocytes from blood of adult human subjects led to the discovery that monocytes are heterogeneous with regard to cell volumes. Isolation of purified monocytes by adherence to glass substrates or to gelatin-coated flasks or by centrifugal elutriation reveals distinct populations of monocytes.^{1,2} In addition to the usual 12- to 15- μ m diameter (when measured on a dried blood film) monocyte, so-called regular monocytes, a somewhat smaller cell that is less active than its larger, more mature counterpart has been identified. This cell is referred to as a small immature monocyte, but its functional significance is not clear.

TABLE 67-1. Distribution of Mononuclear Phagocytes

Marrow	Tissues
Monoblasts	Liver (Kupffer cells)
Promonocytes	Lung (alveolar macrophages)
Monocytes	Connective tissue (histiocytes)
Macrophages	Spleen (red pulp macrophages)
Blood	Lymph nodes
Monocytes	Thymus
Body cavities	Bone (osteoclasts)
Pleural macrophages	Synovium (type A cells)
Peritoneal macrophages	Mucosa-associated lymphoid tissue
Inflammatory tissues	Gastrointestinal tract
Epithelioid cells	Genitourinary tract
Exudate macrophages	Endocrine organs
Multinucleate giant cells	Central nervous system (microglia)
	Skin (histiocyte/dendritic cells)

Data from Lewis, C, McGee, JD: *The Macrophage*, 2nd ed., Oxford University Press, New York, NY, 1992; Gordon S, Fraser I, Nath D. et al: Macrophages in tissues and in vitro. *Curr Opin Immunol* 4:25-32, 1992; Lasser A: The mononuclear phagocytic system: A review. *Hum Pathol* 14:108-26, 1983.

Monocytes continuously emigrate from the blood into tissue, with a half-life in the blood of approximately 1 day in mice.⁶ Nondividing monocytes can be induced to differentiate into dendritic like cells in vitro. However, this process requires culture of the cells for 7 to 10 days with exogenous cytokines, typically interleukin (IL)-4 and granulocyte-monocyte colony-stimulating factor (GM-CSF).⁷ The major lineage regulator of nearly all macrophages is monocyte/macrophage colony-stimulating factor (M-CSF; also termed CSF-1) and its receptor (M-CSF R). The M-CSF R is a class III transmembrane tyrosine kinase receptor, which is expressed on most mononuclear phagocytes.⁸ In the presence of endothelial cells grown on an extracellular matrix, monocytes differentiate along two distinct pathways: toward dendritic cells or macrophages. Monocytes that migrate across endothelium in an abluminal to luminal direction differentiate into dendritic cells. In contrast, monocytes that remain in the subendothelial matrix differentiate into macrophages.

MORPHOLOGY OF MONOCYTE PRECURSORS

Monoblasts and promonocytes are the precursors of monocytes, bearing finely dispersed nuclear chromatin and nucleoli when observed in the stained film of the marrow. The monoblast is a very-low-prevalence marrow cell, indistinguishable by light microscopy from the myeloblast. Promonocytes are 12 to 18 μm in diameter (as measured on dried blood films) and have characteristic deeply indented, irregularly shaped nuclei with condensed chromatin, and numerous cytoplasmic microfilaments.

In animal studies, a small percentage of marrow cells are phagocytic, synthesize DNA, adhere to glass surfaces, and contain nonspecific esterases.⁹ These cells have been referred to as *promonocytes* and are considered as intermediate between monoblasts and the monocytes of the blood.⁹ Cytochemical studies identify the promonocyte in normal human marrow. Promonocytes have deeply indented and irregularly shaped nuclei and bundled and scattered single filaments in the cytoplasm. These morphologic features distinguish the promonocyte

from the progranulocyte.^{10,11} Peroxidase is present throughout the cell secretory apparatus in all cisternae of the rough-surfaced endoplasmic reticulum, the Golgi complex, associated vesicles, and all immature and mature granules. Cytochemical reaction products for acid phosphatase and arylsulfatase also are deposited throughout the secretory apparatus of the promonocyte.

MORPHOLOGY OF MONOCYTES

Light Microscopy

The morphology of monocytes has been investigated by light and phase-contrast optics,¹² scanning and transmission electron microscopy, and freeze-fracture and freeze-etch procedures.¹³

On the stained blood film the monocyte has a diameter of 12 to 15 μm (Fig. 67-1). The monocyte nucleus occupies approximately half the area of the cell and usually is eccentrically placed. The nucleus most often is reniform, but may be round or irregular. It contains a characteristic chromatin net with fine strands bridging small chromatin clumps. Chromatin aggregates are arranged along the internal side of the nuclear membrane. The cytoplasm is spread out, stains grayish-blue with Wright stain, and contains a variable number of fine, pink-purple granules, which at times are sufficiently numerous to give the entire cytoplasm a pink hue. Clear cytoplasmic vacuoles and a variable number of larger azurophilic granulations often are encountered in these cells.

Phase Microscopy

The monocyte nucleus has a distinct chromatin pattern on a cloudy background when examined by phase-contrast microscopy. The cytoplasm is clear gray. Mitochondria are extremely fine and occasionally form a small, juxtannuclear rosette surrounding the centrosome. The phase-dense cytoplasmic granules, varying in number, are generally at the limit of resolution of light microscopy and appear as fine intracytoplasmic dust. Monocytes contain several types of cytoplasmic vacuoles. The reniform nucleus with a juxtannuclear depression filled by a centrosome and its active undulating movement similar to that of other leukocytes are characteristic of the monocyte. The locomotion of the monocyte has the same pattern of undulating cytoplasmic veils seen in macrophages. The monocyte generally assumes a triangular shape as it moves, with one point trailing behind and the other two points advancing before the cell. Blood monocytes undergo adherence and cytoplasmic spreading following attachment to glass surfaces.¹⁴ The extent of spreading increases in the presence of antigen-antibody complexes, certain divalent metals, and proteolytic enzymes.^{14,15} The spread form of the monocyte reveals that the nucleus and granules are located centrally and the abundant hyaloplasm is in the periphery of the cell, terminating in a fringed border that displays undulating movement. The small monocyte may be difficult to distinguish from the large lymphocyte when examined by phase-contrast microscopy.

A striking feature on phase-contrast microscopy is the ruffled plasma membrane that forms prominent phase-dense folds at the cell surface and edges. Some cells have a dense thickening at the edge of the cytoplasm, with microextensions on the thickened edge.

Scanning Electron Microscopy

The monocyte surface has very prominent ruffles and small surface blebs.^{16,17} Extensive ruffling on the monocyte plasma membrane is of functional significance. The monocyte is both motile and phagocytic, and these functions require physical contact with particles or cell surfaces. Reduction in the radius of curvature of the cell surface

Figure 67-1. Blood films. This composite shows four examples of normal monocytes with different nuclear configurations. **A.** In this case, the nucleus is contorted on itself and the nuclear-to-cytoplasmic ratio is a bit higher than the average case. **B.** Another contorted nucleus with a lower nuclear-to-cytoplasmic ratio. Scattered vacuoles are common in monocytes collected in ethylenediaminetetraacetic acid (EDTA)-anticoagulated blood before film preparation. **C.** Characteristic reniform nuclear shape. **D.** Circular nuclear shape. Azurophilic granules are evident in the cytoplasm of monocytes. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

by formation of ruffles or microvilli may reduce repulsive forces when surface negative-charge groups on the cell approach and contact a negatively charged substratum or cell. In addition, redundancy of the cell membrane may provide reserve membrane required for locomotion and phagocytosis.

Transmission Electron Microscopy

The nucleus of the monocyte contains one or two small nucleoli surrounded by nucleolar-associated chromatin (Fig. 67-2).¹⁸ The cytoplasm contains a relatively small quantity of endoplasmic reticulum and a variable quantity of ribosomes and polysomes. The mitochondria are numerous, small, and elongated. The Golgi complex is well developed and is situated about the centrosome within the nuclear indentation. Centrioles and filamentous centriolar satellites are often visualized in this region. Microtubules are numerous, and microfibrils are found in bundles surrounding the nucleus. In cultured macrophages, collections of microfilaments are present underneath the plasma membrane near sites of cell attachment either to a substratum or to phagocytosable particles.¹⁹ The cell surface is characterized by numerous microvilli and vesicles of micropinocytosis. The cytoplasmic granules resemble the small granules found in the granulocytic series, measuring approximately 0.05 to 0.2 μm in diameter. They are dense and homogeneous and are surrounded by a limiting membrane. These granules, as with the lysosomal granules of other leukocytes, are packaged by the Golgi apparatus after their enzymatic content has been produced by the ribosomal complex of the cell.^{10,11} These cytoplasmic granules contain acid phosphatase and arylsulfatase and, therefore, are primary lysosomes. After endocytosis, lysosomes fuse with the phagosome, forming secondary lysosomes.

Some monocyte granules stain positive for peroxidase, whereas others are peroxidase negative.^{10,11}

Freeze-Fracture Microscopy

In this technique, a cell suspension is frozen, placed in a high-vacuum chamber, and struck with a blunt edge, thus producing a fracture that propagates through the frozen specimen. The utility of the procedure comes from the remarkable finding that when the fracture encounters a cell, the fracture tends to propagate along the interior of the plasma membrane and thus split the lipid bilayer into its two constituent layers. After fracture, the specimen is coated with platinum, which is electron dense when viewed with transmission electron microscopy. All cell types examined thus far by the freeze-fracture technique reveal intramembrane particles (IMPs) as the predominant topographic feature of the interior of the bilayer. Studies of the erythrocyte show that at least some particles contain intercalated membrane proteins, and this is assumed to be the case for nucleated cells as well. The distribution of IMPs is dramatically altered in a number of cell systems by physiologic stimuli, for example, hormonal stimulation.

Profound changes in the distribution of IMPs on mononuclear phagocytes occur following binding of antibody-coated erythrocytes.¹³ Because redistribution of IMPs also occurs in some non-phagocyte Fc receptor (FcR)-bearing cells¹³ and after exposure to aggregated immunoglobulin (Ig) G, this alteration in IMPs presumably reflects interaction with FcR. Freeze-etch electron micrographs of the monocyte show nuclear pores traversing both lamellae of the nuclear membrane and contours of cytoplasmic lysosomes and mitochondria (Fig. 67-3).

Figure 67-2. Transmission electron micrograph of a monocyte. The eccentric reniform nucleus has a thinly dispersed chromatin pattern. The Golgi complex (G) is in a juxtannuclear position. Small electron-dense granules can be seen evolving in the Golgi complex. Small amounts of rough endoplasmic reticulum (er) and polyribosomes (r) are present, particularly about the cell periphery. Mitochondria (m) are concentrated in the region of the Golgi apparatus; they also are scattered in the cell periphery. Lysosomes (L) are small, electron-dense granules surrounded by a limiting membrane. The irregular ruffled cell margin is apparent with numerous microprojections ($\times 24,000$).

HISTOCHEMISTRY OF MONOCYTES

Table 67-2 compares the hydrolytic enzyme contents of monocytes, neutrophils, and lymphocytes. Monocytes also give a weak but positive periodic acid-Schiff reaction (for polysaccharides) and Sudan black B reaction (for lipids). Nonspecific esterase²⁰⁻²² is frequently used as a marker for monocytes. Monocyte esterases are inhibited by sodium fluoride, whereas the esterases of the granulocytic series are not. The nonspecific esterase reaction is positive in promyelocytes and myelocytes; therefore, analysis of fluoride inhibition is necessary to distinguish marrow monocytes from early myelocytes. Monocyte granules, although heterogeneous in size (0.3 to 0.6 μm), are not separable into populations by routine electron microscopic criteria. Identification of monocyte granule populations has depended on subcellular localization of monocyte enzymes by electron microscopic cytochemistry.¹⁰ Human marrow promonocytes and blood monocytes contain granules that comprise two functionally distinct populations.^{10,11} One population contains the enzymes acid phosphatase, arylsulfatase, and peroxidase. These granules are modified primary lysosomes and are analogous to the azurophil

granules of the neutrophil. The monocyte azurophil granule population is heterogeneous in cytochemical reactivity for peroxidase, acid phosphatase, and arylsulfatase.^{23,24} Moreover, primary granules that are morphologically identical with other vesicles can be identified as lysosomes cytochemically. The other population of monocyte granules lacks alkaline phosphatase²³ and is not strictly analogous to the specific granules of neutrophils.

MORPHOLOGY OF MACROPHAGES

Macrophage characteristics are heralded by a significant increase in cell size, increase in the number of cytoplasmic granules, increase in the heterogeneity of cell size and shape, and increase in the number of cytoplasmic clear vacuoles in comparison to monocytes.

Light and Phase-Contrast Microscopy

In vitro culture of monocytes purified from adult human blood has provided an opportunity to observe the maturation of these cells into mature macrophages. The macrophages of the pulmonary alveoli,

Figure 67-3. Freeze-etch electron micrograph of a monocyte. Fracture plane displays the large nucleus (N), with multiple nuclear pores (np) and the two lamellae of the fractured nuclear membrane (nm) evident in some regions. Membrane and cleaved surfaces of mitochondria (m) and lysosomal granules (L) can be identified in the cytoplasm.

peritoneal and pleural cavities, and inflammatory exudates are hypermature cells that have undergone *in vivo* stimulation and maturation. This process results in enhanced bactericidal activity^{1,2} because of augmentation of lysosome number and acid hydrolase content. Macrophages display attributes of morphologic specialization specific to their location and function. The fixed macrophages of the spleen (littoral

cells) are involved in the sequestration and destruction of effete or abnormal red cells and exhibit stages of erythrophagocytosis and intracytoplasmic aggregates of ferritin (Chap. 6). The macrophages of the marrow, the “nurse cells” of the erythroblastic island, play a similar role in erythrophagocytosis and iron storage and transfer (Chaps. 5 and 31). Hepatic macrophages (Kupffer cells), found in liver sinusoids, also phagocytize red cells and other cellular elements and are important sites of iron storage. Macrophages of the pulmonary alveoli, the lamina propria of the gastrointestinal tract, and the peritoneal and pleural fluids reflect in their morphology a specific function of phagocytosis of microorganisms, cells, and cellular and noncellular debris, characteristic of the specific organ location.

Most macrophages are 25 to 50 μm in diameter on Wright or hematoxylin-and-eosin-stained films (Fig. 67-4). They have an eccentrically placed reniform or fusiform nucleus with one or two distinct nucleoli and finely dispersed, loosely stranded nuclear chromatin that tend to clump in the nuclear interior and along the internal aspect of the nuclear membrane (Fig. 67-5A). A juxtannuclear clear zone (Golgi complex) is well defined when the Wright stain is used. The cytoplasm shows fine granules and multiple pink-purple, large azurophil granules. The cytoplasmic borders are irregularly serrated. Cytoplasmic vacuoles are present near the cell periphery, reflecting the active pinocytosis in these cells.

The surface antigen CD68, also known as *macrosialin*, is commonly used as a macrophage marker. Figure 67-5B shows an immunohistochemistry micrograph of a macrophage in a lymph node. The cytoplasm of the macrophage is intensely positive for CD68, while the surrounding lymphocytes are negative.

On phase-contrast microscopy, living macrophages are large cells with a propensity to adhere to and spread on glass surfaces. Thus, the cell organelles are concentrated within the central portion of the cell and clear veils of hyaloplasm spread about the cell, with intense ruffling of the membrane borders. Vesicles and contractile vacuoles are seen about the cell periphery and in the cell interior. The juxtannuclear clear zone bearing the centrosome and the Golgi complex is particularly dynamic and displays an undulating motion.

TABLE 67-2. Cytochemical Reactions of Leukocyte Enzymes

Chemical	Monocytes	Neutrophils	Lymphocytes
Acid phosphatase	++	+	+

Electron Microscopy

Scanning electron micrographs of macrophages adherent to glass surface show membrane ruffling and pseudopodia (Fig. 67-6). Transmission electron microscopy of monocyte-derived macrophages show a variable degree of differentiation, nuclear “maturity,” ribosomes,

mitochondria, and lysosome content, and the nucleus varies in shape from horseshoe to fusiform (Fig. 67-7). Clear spaces between membrane-fixed chromatin aggregates mark the sites of nuclear pores that are relatively abundant on freeze-etch electron micrographs of macrophages and monocytes (see Fig. 67-3). Polyribosomes and scant smooth

The macrophage develops prominent peripheral membrane ruffling and numerous microadhesion points to the surface coated with immune complexes.

and rough endoplasmic reticulum are seen about the cell periphery. A well-developed Golgi complex is in a juxtannuclear location. It often is multicentric and contains a concentration of vesicles, some with dense inclusions that mark them as early lysosomes. A relatively constant feature of cells engaged in endocytosis is the large number of microvilli at the cell surface. The degree of development of this surface adaptation

is related to the phagocytic activity of the cell and its rate of pinocytosis. The number and size of mitochondria vary with the phagocytic and hence metabolic activity of the cell. Mitochondria tend to be grouped about the region of the Golgi complex, although several usually are seen dispersed about the cell periphery, presumably supplying energy for the active endocytic processes occurring there.

Figure 67-7. Electron micrograph of monocyte-derived macrophage cultured *in vitro* for 9 days. G, Golgi zone; N, nucleus. Arrow on right indicates endoplasmic reticulum; arrow on left indicates mitochondria; open arrow indicates lysosomes ($\times 7600$).

The most constant and characteristic ultrastructural features of macrophages are the electron-dense membrane-bound lysosomes that often can be seen fusing with phagosomes to form secondary lysosomes. Within the secondary lysosomes, ingested cellular, bacterial, and non-cellular material can be seen in various stages of degradation, often recognizable as degenerating mitochondria or nuclear material. These secondary lysosomes also contain partially degraded material from the late stages of the endocytic process, often appearing as multilamellar lipid bodies. Microtubules and microfilaments are prominent in macrophages. Actin- and myosin-like proteins have been isolated from monocytes and partially characterized. Resting macrophages have irregular cell borders and pseudopodia pushed out in all directions. Their cytoplasm has rough endoplasmic reticulum and Golgi complex in the perinuclear area. Lipid globules, primary lysosomes, and mitochondria are characteristically prominent. Activated monocytes/macrophages are motile cells that extend a leading pseudopod as they move forward.²⁵

RECEPTORS

MEMBRANE RECEPTORS AND OTHER SURFACE PROTEINS OF MONOCYTES AND MACROPHAGES

Monocyte/macrophage cells have surface receptors that have been characterized by their binding to specific monoclonal antibodies. These receptors (Fig. 67–8) are markers for origin, growth,

differentiation,²⁶ activation, recognition, migration, and function of the monocyte/macrophage. Monocytes have been classified into distinct subtypes based on surface expression of CD14 and CD16, molecules that form part of the lipopolysaccharide (LPS) toll-like receptor (TLR) and one of the immunoglobulin FcRs, respectively. These include CD14+ -bright/CD16- monocytes, CD14+ -dim/CD16+ monocytes, and CD14-dim/CD16+ monocytes. Monocyte heterogeneity was initially divided into the CD14+ -bright/CD16- negative cells, which comprise 90 to 95 percent of total circulating monocytes (classical monocyte)²⁷—CD14-bright or dim refer to the fluorescence magnitude of staining using a specific CD14 monoclonal antibody. The minor subset is CD14-dim, CD16-positive, and less phagocytic than the classical monocyte. The classical monocyte produces reactive oxygen species (ROS) and cytokines in response to TLR engagement. The minor subset selectively secretes tumor necrosis factor (TNF)- α , IL-13, and CCL2 in response to viruses and immune complexes containing nucleic acids via TLR-7, TLR-8, MyD88-MEK (myeloid differentiation factor 88-MAPK kinase), and AHD.²⁸ This minor subset, CD14-dim,²⁹ is competent in (SR [scavenger receptor]) function of vascular, intraluminal debris and uptake of immune complexes.³⁰ In addition, their phenotype is related to the ability to produce and secrete select cytokines.³¹

Macrophages are proficient at endocytosis (both fluid phase and receptor-mediated) and are highly professional phagocytes of particulates of all origin, organic (cellular, microbial) as well as inorganic foreign materials.³² In contrast, when dendritic cells (DCs) mature into antigen-presenting cells (APCs), they have reduced uptake capacity

Figure 67–8. Schematic of selected molecules of varied structure and functions of monocyte receptors and surface antigens. (Used with permission of S. Seif, GraphisMedica, 2014.)

and induce an adaptive immune response or tolerance. Immature DCs display active macropinocytosis and capture exogenous materials for cross-presentation.³³ It is convenient to classify plasma membrane uptake receptors as opsonic and nonopsonic TLRs and non-TLR-dependent. The latter category includes a range of SRs^{34,35} and a family of lectin-like, carbohydrate recognition molecules.^{36,37} Given the complex ligands presented on the surface of microorganisms and damaged host cells, or generated within the vacuolar system after uptake, these receptors frequently cooperate with one another.

Fc Receptors

FcRs for IgG are expressed on the surface of mononuclear cells, macrophages, granulocytes, and platelets.^{38,39} FcRs are divided into three distinct classes: FcRI, FcRII, and FcRIII (Fig. 67–9). These receptors have broad ranges of expression on different cells. The first IgG receptor, FcRI (CD64), is a receptor found on monocytes, macrophages, and activated neutrophils. This receptor binds monomeric IgG through the Fc portion of the molecule. This Ig receptor has increased

expression on activated monocytes and macrophages. CD64 allows for receptor-mediated endocytosis of IgG–antigen complexes for presentation to T cells, can trigger the release of cytokines and ROS, and can play a role in granulocyte-mediated antibody-dependent cytotoxicity. The second IgG receptor, FcRII (CD32), is a widely distributed receptor present on many cell types, including monocytes, platelets, neutrophils, B cells, some T cells, and some capillary endothelium. This receptor can bind complexed IgG rather than monomeric IgG. This FcR regulates B-cell function when coengaged with the B-cell receptor for antigen, namely, surface Ig. It also can induce mediator release from myeloid cells and phagocytosis of Ig-coated particles *in vitro*. Finally, this FcR also can target antigen into presenting pathways. The third IgG receptor, FcRIII (CD16), is expressed by neutrophils, natural killer cells, and tissue macrophages.⁴⁰ This receptor can bind Ig in immune complexes and Ig bound to cell-surface membranes. It is the main FcR responsible for antibody-dependent cellular cytotoxicity. All three FcRs specifically bind the human IgG subclasses IgG₁ and IgG₃ (Chap. 75). The interaction of FcR on

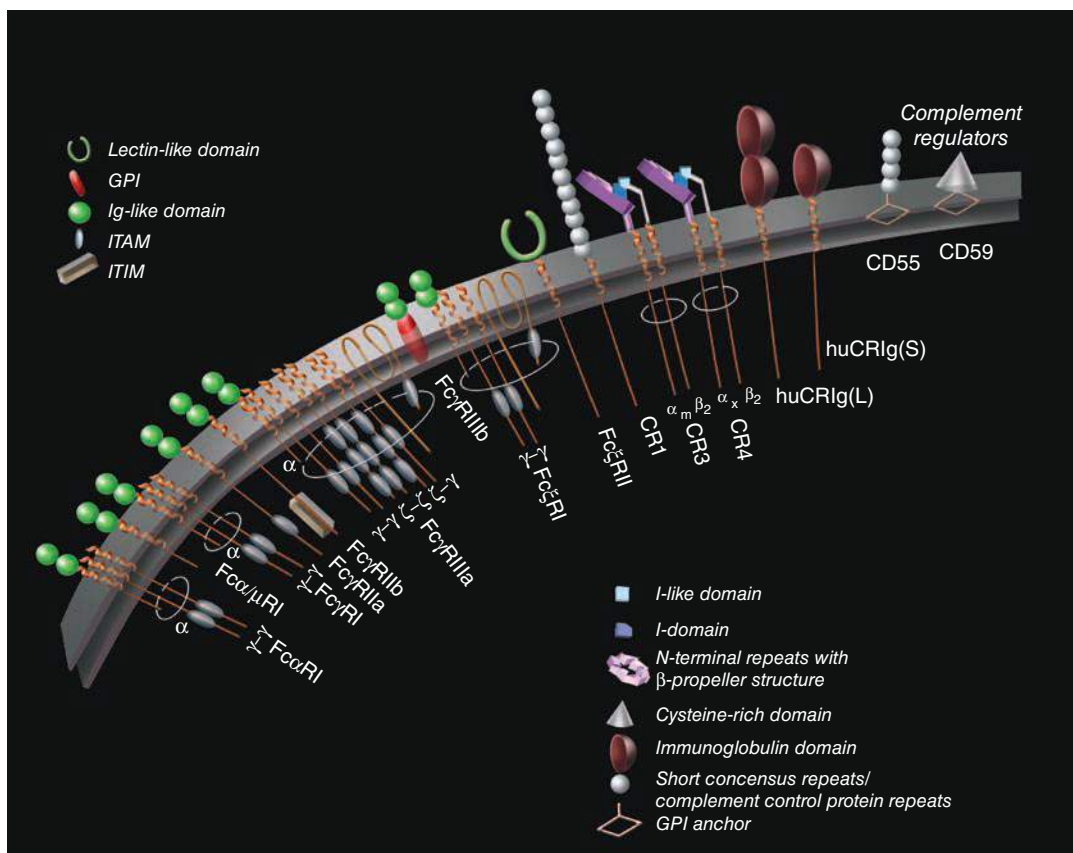

Figure 67–9. Human Fc receptors and complement. Myeloid cells express a range of classical Fc receptors that initiate a variety of cellular responses, including phagocytosis, antibody-dependent cell-mediated toxicity, antigen presentation, respiratory burst, and release of inflammatory mediators. Immunoglobulin (Ig) subclasses are bound by extracellular domains; signaling via cytoplasmic immunoreceptor tyrosine-based activation motif (ITAM) or immunoreceptor tyrosine-based inhibition motif (ITIM) is mediated by associated membrane-spanning polypeptides. Activation and inhibitory receptors are usually coexpressed on the cell surface and function in concert, determining the magnitude of effector cell responses. Complement receptors (CRs) and membrane regulators are expressed by *m-φ*-CR. CR1 is broadly expressed by nucleated cells, acting as a “sink” for activated complement. CR3 (CD11b/CD18), a phagocytic receptor for C3bi-coated particles, and CR4 (CD11c/CD18) are β_2 integrins, which, together with lymphocyte function-associated antigen (LFA)-1 (CD11a/CD18), mediate adhesion of myeloid cells to endothelium and extracellular matrix and migration. Human CR immunoglobulin (huCRIg) are long (L) and short (S) forms of the complement-binding receptor on Kupffer cells that mediate uptake of opsonized bacteria. CD55 and CD59 are glycosylphosphatidylinositol (GPI)-anchored regulators of complement activation. (Used with permission of S. Seif, GraphisMedica, 2014.)

macrophages with immune complexes results in cell “activation,” with an increase in phagocytosis, superoxide production, and prostaglandin and leukotriene release.

Complement Receptors

Activation of the complement system results in liberation of numerous ligands that bind to specific receptors on mononuclear phagocytes. Four receptors that bind fragments of the complement component C3 have been identified (see Fig. 67–9).⁴¹ Complement receptor (CR) 1 (or CD35) binds dimeric C3bi and is found on both monocytes and macrophages. CR3 (or CD11b) binds the complement fragment C3b. CR3 is a heterodimeric glycoprotein that is composed of two noncovalently linked polypeptides. The α chain of the polypeptide has an Mr of 185,000, and the β subunit has an Mr of 95,000. This receptor and the leukocyte antigens lymphocyte function-associated antigen (CD11a) and alpha-X integrin chain (CD11c) compose a family of heterodimers that share a common β subunit (CD18).⁴² This family is designated the *leukocyte integrin* (β_2) subfamily.⁴³ These heterodimers are involved in cell–cell interactions, including leukocyte trafficking into the tissues, binding of opsonized particles and plasma proteins, and attachment to various substrates. They also may modulate intercellular adhesion. Elimination of the integrin β_2 subunit causes leukocyte adhesion deficiency.⁴⁴

The classical opsonins, which promote the uptake of particles, are antibody, IgG complexed with antigens, and complement, activated by the classical pathway (antibody-dependent IgM or IgG) or recognized directly via the lectin-carbohydrate-stimulated alternative pathway. Fc and CRs are heterogeneous in structure, expression, and function, activating or inhibiting macrophage responses,^{45,46} as illustrated in Fig. 67–9. Other opsonins include fibronectin and milk-fat globulin.⁴⁷ Through their expression of various opsonic receptors, monocytes, macrophages, and DCs perform versatile roles in innate and adaptive immunity,⁴⁸ in antigen clearance and destruction, in autoimmunity, and in pathogenesis of a range of inflammatory and infectious disorders. Genetic polymorphisms influence the expression and functions of FcRs in homeostasis and disease. Although prominent in host protection, invading microorganisms may be able to exploit, even subvert these receptors to facilitate their entry and survival.⁴⁹ Opsonic receptors play an important role in clearance of hematopoietic cells, for example, antibody-coated platelets, giving rise to thrombocytopenia, and in therapeutic antibody treatment, for example, to facilitate engraftment. Antibody engineering has provided novel therapeutic agents to minimize undesirable consequences, such as cell activation. The initiation or avoidance of complement activation in particular controls an important effector pathway in tissue injury and repair.

Toll-Like Receptors

The family of TLRs, identified on macrophages in mammals, is a pattern-recognition receptor that bind structurally conserved molecules derived from microorganisms, including endotoxins (LPS) and viral nucleic acids. TLRs are now considered key molecules responsible for alerting the immune system to the presence of microbial infections. For example, TLR4 is part of a recognition couple for LPS. Pathogen recognition by TLRs activates the innate immune system through the signaling pathway and provokes inflammatory responses, such as cytokine production.⁵⁰ These are shown schematically in Fig. 67–10 to illustrate their diverse structures and signaling pathways.

The discovery of TLR has transformed the study of innate immunity, inflammation, and adjuvant actions on APC.^{51–53} Receptor structures, heterogeneity of expression, microbial and endogenous ligands, and signaling have been defined, and knowledge of their regulation

has begun to offer agents to manipulate TLR signaling in humans. The discovery of inborn errors, such as the interleukin receptor-associated kinase (IRAK)-4 deficiency,⁵⁴ and the role of toll-interleukin receptor adaptor protein (TIRAP) function in *Plasmodium falciparum* infection,⁵⁵ for example, have illustrated their role in human disease. Several concepts have emerged. From the original studies on LPS recognition and signaling by the multiprotein complex formed by CD14, LPS binding protein, and MD2, and the clarification of the distinct adaptor pathways (MyD88 [myeloid differentiation factor 88], TIRAP/MAL [MyD88 adaptor-like], TRIF [TIR domain-containing adaptor inducing interferon (IFN)- β], and TRAM [TRIF-related adaptor molecule]), the recognition and sensing of TLR ligands have become clear. The tertiary structure of TLR4 has been reported.⁵⁶ TLRs are expressed either on the plasma membrane of myeloid and other cells, or within the vacuole, especially in the case of TLRs 3, 7, and 9, which are implicated in viral nucleic acid recognition. Crosstalk among nuclear factor (NF) κ B, IFN, and mitogen-activated protein kinase (MAPK) kinase pathways has also become apparent.⁵⁷ TLRs collaborate with other recognition receptors,⁵⁸ such as dectin-1. Furthermore, a role has been proposed for TLR signaling in nontranscriptional activities, such as the kinetics of phagosome maturation in macrophages.⁵⁹

Non-Toll-Like, Nonopsonic Receptors

The study of lectins and SRs has lagged behind that of the above receptors, but is gaining ground, documenting receptor expression and ligands, mainly in mouse models of inflammation and infection.^{35,60,61} These receptors are present on macrophages and DCs, and variably on monocytes and neutrophils. They are implicated in the recognition and uptake of microbial and host ligands, and vary in their ability to activate host defense functions. Figure 67–11 and Table 67–3 illustrate the functional attributes of these receptor systems. The mannose receptor is mainly involved in endocytosis, with a predominant intracellular localization.^{62,63} The multilectin mannose receptor displays dual functions, contributing to the clearance of mannose-terminal lysosomal hydrolases and of neutrophil granule glycoproteins such as MPO, as well as of hormones (e.g., thyroglobulin) and exocrine secretion products (e.g., amylase). It plays a role in the capture and transport of mannose-terminal glycoproteins to targets in spleen (marginal metallophilic macrophages) and in lymph nodes (subcapsular sinus macrophages) that express sulfated receptors for its cysteine-rich domain. The outcome of such targeting is either silent disposal or, if combined with TLR stimulation, induction of an immune response.⁶⁴ In common with several other nonopsonic receptors, it can play dual, even opposing actions in host protection or in pathogenesis, as shown by ongoing studies in mice.

Dectin-1 is a lectin-like receptor that is widely expressed on myeloid cells, with a single immunoreceptor tyrosine-based activation motif (ITAM)-like motif in its cytoplasmic tail.⁶⁵ It recognizes β glucans, abundant in fungal walls, including bioactive zymosan particles, and has been implicated in innate resistance to fungal infection. Dectin-1 activates syk and caspase activation and recruitment domain (CARD)-9, regulating various effector pathways such as TNF- α , leukotriene production, and T-helper (Th) 17 cell activation, with heterogeneity in responses by macrophages and DCs. Dectin-1 collaborates with TLR 2/6 in the response to zymosan. Other lectins expressed by macrophages include sialic acid recognition molecules, Siglec-1 (sialoadhesin),⁶⁶ an extended Ig superfamily plasma membrane protein implicated in cell–cell interactions (Chap. 68 discusses a possible role in the hematopoietic system).

SRs are a diverse family of structurally unrelated, promiscuous receptors, with a predilection for polyanionic ligands, expressed by

Figure 67-10. The main toll-like receptor (TLR) signaling pathways and adaptor molecules. The pathways that are activated by the different receptors are multiple and complex. For example, TLR signaling involves not only nuclear factor- κ B (NF- κ B) activation, but also mitogen-activated protein kinases, phosphatidylinositol 3-kinase, and several other pathways that markedly affect the overall biologic response to the activation of TLRs. Dectin-1 (a β -glucan receptor) is shown as an example of various signaling-competent cell-surface pattern-recognition receptors. ASC, apoptosis-associated speck-like protein containing a caspase activation and recruitment domain; CARD, caspase activation and recruitment domain; ds, double-stranded; type I IFN, type I interferon; IFN, interferon; I κ B, inhibitor of NF- κ B; IL, interleukin; IPAF, interleukin-1 β -converting enzyme-protease activating factor; IRF, IFN-regulatory factor; LPS, lipopolysaccharide; MDA5, melanoma differentiation-associated gene 5; MyD88, myeloid differentiation primary response gene 88; NALP, NALP leucine-rich repeat and pyrin-domain-containing protein; NOD, nucleotide-binding oligomerization domain; RICK, receptor-interacting serine/threonine kinase; RIG-I, retinoic acid-inducible gene I; ss, single-stranded; TBK1, TANK-binding kinase 1; TIRAP, toll/IL-1R (TIR) domain-containing adaptor protein; TRAM, TRIF-related adaptor molecule; TRIF, TIR domain-containing adaptor protein inducing IFN- β ; SYK, spleen tyrosine kinase. diverse microorganisms, apoptotic cells, and modified host lipoproteins.³⁴ SR-A I/II and MARCO (macrophage receptor with collagenous structure) (class A SR) are collagenous transmembrane receptors that mediate endocytosis, phagocytosis, and cell adhesion. SR-A I/II is upregulated by M-CSF and MARCO by TLR and MyD88-dependent microbial ligands, triggers of innate immune activation.⁶⁷ A number of naturally occurring ligands for SR-A have been identified, including apolipoprotein A₁ and *Neisserial* outer-surface proteins,⁶⁸ as well as previously described lipid A, lipoteichoic acid, and modified (acetylated) low-density lipoproteins, among others. After initial interest primarily in its role in atherogenesis (Chap. 134), attention has also focused on innate immune functions in bacterial infection.

Class B SRs, such as CD36 and SR-BI, have distinct structures and have been implicated in mycobacterial recognition as well as in the uptake and exchange of lipids.^{69,70} CD36, together with thrombospondin,

plays a role in apoptotic cell uptake⁴⁷ and has been implicated in macrophage fusion. Other SRs, expressed on a variety of cells as well as macrophages, have similar roles in clearance.

Human Leukocyte Antigen Class II Receptors

Monocytes and macrophages serve an important function as APCs. They bear the class II glycoproteins of the major histocompatibility gene complex, human leukocyte antigen (HLA)-DR, HLA-DP, and HLA-DQ. Expression of major histocompatibility complex (MHC) class II antigens on macrophages from different tissues varies widely. Splenic macrophages contain a high percentage of HLA-DR-positive cells (50 percent), whereas peritoneal macrophages have relatively few (10 to 20 percent).⁷¹ The proportion of Ia-positive alveolar macrophages is only approximately 5 percent.⁷² Lymphokines, primarily IFN- γ , can induce macrophages to express higher levels of MHC class II antigens,

Figure 67-11. Macrophage nonopsonic and regulatory receptors. See text for further details. EGF-TM7, epidermal growth factor-seven transmembrane; MARCO, macrophage receptor with collagenous structure; Siglec, sialic acid-binding immunoglobulin-like lectin.

whereas prostaglandin E, α -fetoprotein, and glucocorticoids downregulate HLA-DR antigen expression on macrophages.

CD11

CD11 defines a family of three accessory adhesion surface glycoproteins: CD11a, CD11b, and CD11c. These proteins are distinct α subunits for three heterodimeric surface glycoproteins, each sharing a common β subunit, designated CD18. The α subunits have different isoelectric points, molecular weights, and cell distribution (Chap. 15).⁷³ Whereas CD11a is expressed on all leukocytes, CD11b and CD11c are expressed predominantly on monocytes and macrophages, a minor subset of B lymphocytes, and most polymorphonuclear leukocytes. CD11b is expressed on more than 95 percent of fresh human monocytes and macrophages but declines rapidly on cells maintained *in vitro*. Antibodies specific for CD11b, such as OKM1 or Mo1, may block this CR's ability to bind to CD3b.⁷⁴ Accordingly, these antibodies strongly inhibit CR-mediated rosetting of erythrocyte-IgM antibody-complement complexes.

CD14 and CD16

The CD14 molecule is one of the most characteristic surface antigens of the monocyte lineage. It is a polypeptide of 356 amino acids that is anchored to the plasma membrane by a phosphoinositol linkage.⁷⁵ It is expressed strongly on the surface of monocytes and weakly on the surface of granulocytes and most tissue macrophages. It can be detected on some nonmyeloid cells (e.g., hepatocytes and some epithelial cells). CD14 functions as a receptor for endotoxin (LPS). LPS binds to a serum

protein, LPS-binding protein, which facilitates the binding of LPS to CD14. The coreceptor MD2 and TLR4 also are vital in this process. When LPS binds to CD14/MD-2/TLR4 expressed by monocytes or neutrophils, the cells become activated and release cytokines such as TNF and upregulate cell surface molecules, including adhesion molecules. *In vitro*, soluble CD14 binds to LPS, and the complex stimulates cells that do not express CD14 to secrete cytokines and coregulate adhesion molecules.⁷⁶

A subset of human blood monocytes that express low levels of CD14 molecules and high levels of the Fc γ receptor III (Fc γ RIII) CD16 has been identified.^{77,78} These CD14+CD16+ monocytes resemble alveolar but not peripheral macrophages. CD14+CD16+ monocytes represent 5 to 10 percent of blood monocytes in normal individuals and can be dramatically expanded in pathologic conditions, such as sepsis, HIV infection, and cancer. CD16+ monocytes produce high levels of proinflammatory cytokines.

CD4

T lymphocytes express several surface receptors. The surface antigen CD4 is expressed primarily in T-helper lymphocytes (Chap. 76). CD4 and its corresponding messenger RNA have been demonstrated on monocytes, macrophages, and the monocyte-like cell line U-937.^{79,80} Although CD4 is present at low concentrations in blood monocytes, the proportion of cells that display this plasma membrane determinant ranges from less than 5 percent to 90 percent. The CD4 molecule is involved in induction of T-lymphocyte helper functions (T_H) and T proliferative responses to antigen stimulation; however, its role

TABLE 67-3. Ligands for Selected Nonopsonic, Non-Toll-Like Receptors

Class	Receptor	Microbial Ligands	Endogenous Ligands	Function	
Scavenger receptors	SR-A I/II	Gram+/- bacteria	Apoptotic cells	Phagocytosis	
		Lipoteichoic acid	Modified low- and high-density lipoproteins (LDL, HDL, apolipoprotein A ₁ , apolipoprotein E)	Endocytosis	
		Lipid A	AGE-modified proteins	Foam cell formation	
	MARCO	<i>Neisserial</i> surface proteins	β -Amyloid	Adhesion	
		Gram+/- bacteria	Marginal zone B lymphocytes	Adhesion	
		Trehalose dimycolate	Uteroglobin-related protein	Phagocytosis	
	CD36	<i>Neisserial</i> surface proteins			Innate activation
Diacylated lipopeptide from Gram+ bacteria			Apoptotic cells (with thrombospondin and vitronectin receptor)	Uptake, exchange of lipids, adhesion	
<i>Plasmodium falciparum</i> -parasitized erythrocytes		HDL			
Lectins	Dectin-1	β -Glucan	Outer rod segments		
			T lymphocytes (noncarbohydrate)	Fungal uptake and immunomodulation	
	DC-SIGN	Mannosyl/fucosyl glycoconjugates viruses (e.g., HIV-1, Dengue)	ICAM 2/3	Adhesion	
			T lymphocytes	Endocytosis	
	Mannose receptor	Mannosyl/fucosyl	Lysosomal hydrolases	Endocytosis	
	C-type lectin domains	Glycoconjugates on bacteria, viruses, fungi, parasites	Thyroglobulin	Adhesion	
	Cysteine-rich domain		Ribonuclease B	Antigen targeting	
	Fibronectin type II domain		Amylase	Adhesion	
				Sulfated carbohydrates in marginal zone (spleen) and subcapsular sinus (lymph node)	
				Collagens	

AGE, advanced glycation end product; DC-SIGN, dendritic cell-specific intercellular adhesion molecule-3-grabbing nonintegrin; ICAM, intercellular adhesion molecule; MARCO, macrophage receptor with collagenous structure; SR, scavenger receptor.

in the function of monocyte/macrophages has not been determined. An important aspect of the monocyte/macrophage phenotype is the presence of CD4 molecules on the surface of monocytes that can act as receptors for HIV type 1 (HIV-1). HIV-1 uses the CD4 receptors as an entry pathway for infection of monocyte/macrophages.^{79,80}

Chemokine Receptors

Chemokines mediate their activities by binding to target cell surface chemokine receptors that belong to a large family of G-protein-coupled,

seven transmembrane domain receptors. Human monocytes/macrophages express several chemokine receptors (Table 67-4). The chemokine receptor CCR5 has been implicated in HIV-1 infection of monocytes/macrophages.⁸¹⁻⁸⁵ CCR5 is a major coreceptor on monocytes/macrophages for M-tropic HIV-1 infection. At least one copy of a 32-nucleotide deletion within the CCR5 gene (CCR5 Δ 32) has been found in approximately 4 to 16 percent of individuals, depending on their background; when in the homozygous state, individuals are highly protected against acquisition of HIV.^{86,87}

TABLE 67-4. Surface Receptors of Monocytes and Macrophages

Fc Receptors	Transferrin and Lactoferrin Receptors
IgG _{2a} , IgG _{2b} /IgG ₁ , IgG ₃ , IgA, IgE	Lipoprotein lipid receptors
Complement receptors	Anionic low-density lipoproteins
C3b, C3bi, C5a, C1q	PGE ₂ , LTB ₄ , LTC ₄ , PAG
LPS receptors	Apolipoproteins B and E (chylomicron remnants, VLDL)
CD14	
Cytokine receptors	Receptors for coagulants and anticoagulants
MIF, MAF, LIF, CF, MFF, TNF- α , IL-1, IL-2, IL-3, IL-4, IL-10, IL-18, INF- α , INF- β , INF- γ , GM-CSF, M-CSF/CSF-1	Fibrinogen/fibrin
	Coagulation factor VII
Chemokine receptors	α_1 -Antithrombin
CCR1, CCR2A, CCR2B, CCR3, CXCR4, CCR5	Heparin
Macrophage growth factor receptors	Integrins (CD11b, CD18)
M-CSF, GM-CSF	Fibronectin receptors
Receptors for peptides and small molecules	Laminin receptors
Neurokinin-1	Mannosyl, fucosyl, galactosyl residue
H ₁ , H ₂ , 5-HT	α_2 -Macroglobulin-proteinase complex receptors
1,2,5-Dihydroxy vitamin D ₃	Toll-like receptors
N-formylated peptides	TLR2, TLR4, TLR5, TLR9
Enkephalins/endorphins	Others
Substance P	Cholinergic agonists
Hemokinin-1	α_1 -Adrenergic agonists
Arg-vasopressin	β_2 -Adrenergic agonists
Hormone receptors	
Insulin	
Glucocorticoids	
Angiotensin

To illustrate the dynamic interaction of macrophages and virus, a video showing an HIV-1 infected human macrophage sensing its environment was captured from a spinning disk confocal microscope using a 100 \times objective by Raphael Gaudin (see <http://www.cellimagelibrary.org/images/41568#.VAR6eNcDfRo>.email).

FUNCTION

Monocytes respond to activating signals, for example, chemokines, through chemokine receptors, setting in motion a series of adhesion and migration events associated with diapedesis.⁸⁸ They play a direct role in

sepsis and in more poorly defined changes associated with intravascular coagulation and platelet activation. Their phagocytic potential is mainly expressed after adherence to the vascular endothelium. Monocytes are relatively resistant to virus infection, compared with more differentiated macrophages. These cells selectively adhere to lipid- and platelet-activated endothelium, a precursor to atherogenesis.⁸⁹ Although metabolic, microbial, or environmental stimuli are normally required to induce monocyte activation, once activated monocytes express a greater potential for cytotoxicity and antimicrobial functions than resident tissue macrophages.

Figure 67-11 schematically shows select surface receptors related to monocyte function. These include chemokine recognition, adhesion,

and immunoregulatory molecules. Receptors involved in microbial recognition and innate immunity (e.g., cluster of differentiation [CD]14),⁹⁰ phagocytosis (e.g., FcR, CR), secretory, and killing mechanisms are described, as are cytokine production and responses. Intracellular granule contents of monocytes include myeloperoxidase (MPO) and lysozyme, although these are less studied than in neutrophils.

MOTILITY OF MONOCYTES AND MACROPHAGES

An effective monocyte response to infection is predicated upon the ability to migrate and accumulate at sites of inflammation and infection. Monocytes are capable of both random and directed movement. Random migration is nondirected movement that occurs in the absence of attracting substances. Directed movement, as a result of chemotaxis, refers to monocyte migration that occurs in response to soluble factors or stimuli and that is mediated by different types of receptors on phagocyte cell surfaces. A number of different methods have been used to study macrophage movement both *in vivo*⁹¹ and *in vitro*.⁹²

Monocytes and macrophages are unusual among hematopoietic cells in that they are motile (ameboid type), migratory, yet capable of sessile, “fixed” life in tissues as resident and more newly recruited cells. Although not as motile as neutrophils, and more difficult to study in physiologically relevant assays *in vitro*, they display lineage-specific, as well as shared, yet distinct properties with DCs, which can be considered as more motile, less-adherent cells specialized for antigen capture and delivery to naïve and primed lymphocytes.⁹³ They also share receptors and cytoskeletal properties with fibroblasts. Apart from diapedesis in response to endothelial and extravascular signals, monocytes and their progeny display polarization and specialized adhesion structures, most evident in the tight seal of osteoclasts to bone surfaces, so as to localize secretion of powerful catabolic products.

Adhesion is a defining event in the differentiation of monocytes, profoundly influencing the organization of the cell, its plasma membrane, cytoplasm, and nuclear transcription machinery, as well as regulating posttranslational modification of the proteome. Monocytes express diverse integrins, implicated in outside-in as well as inside-out signaling.⁹⁴ Particularly important are the β_2 -integrin heterodimers, restricted to myeloid cells, as opposed to β_1 and β_3 integrins shared with mesenchymal and other cells. The β_2 integrins, lymphocyte function-associated antigen (LFA)-1 (CD11a/CD18), CR3 (CD11b/CD18), and CD11c/CD18, have been of great value in studies of monocyte/macrophage adhesion. Inhibitory and stimulatory monoclonal antibodies have been generated, and rare inborn errors of metabolism, such as the leukocyte adhesion deficiency syndrome, caused by a genetic deficiency of the common β_2 chain, result in defective myeloid cell recruitment to inflammatory stimuli.

The well-known sequence paradigm of rolling (mediated by L-selectin), more stable adhesion (mediated by β_2 integrins), and diapedesis has been extensively studied in neutrophils (Chap. 19), and is thought to be similar for monocyte recruitment in response to chemokines, as described in Chap. 68. Monocyte-specific and constitutive migration through different tissue compartments (marrow, blood, tissues) are still poorly understood. An unresolved question is whether circulating monocytes are already “bar coded” for entry to special tissues, such as the CNS, or whether cells enter tissues stochastically from blood.

The control of monocyte motility in relation to chemotaxis continues to be studied.⁹⁵ In particular, the energetics and role of mitochondria in aerobic and hypoxic conditions deserve further study. Mitochondria are prominent in DCs and play a wider role than anticipated in innate

resistance to viral infection and in cytosolic stress. Several well-known G-protein-coupled receptors (GPCRs), including the array of selective, shared, even redundant chemokine receptors, β -adrenergic receptors, and others contribute to the regulation of directed migration and other cellular functions (Table 67-5).^{96,97} In addition, a newly defined family of GPCR with large extracellular domains, includes myeloid-restricted members of the epidermal growth factor-seven transmembrane (EGF-TM7) subfamily with multiple EGF (epidermal growth factor) repeats. EMR2 (epidermal growth factor-like module containing mucin-like hormone receptor-like 2) and CD97, structurally related to the F4/80 antigen marker discussed in Chap. 68, likely support additional important monocyte functions.⁹⁷ Their ligands include complement regulatory molecules (CD55, associated with paroxysmal nocturnal hemoglobinuria; Chap. 40) and chondroitin sulphate B, a matrix component. EMR2 expression on myeloid cells is upregulated by septic shock, its ligation on neutrophils potentiates a range of cellular responses.

The roles of phosphoinositide metabolism, diacylglycerol generation, calcium fluxes, and phosphorylation/dephosphorylation in regulating actin assembly have been studied in human and mouse cells, using mainly neutrophils as a prototype.⁹⁵ Genetic models of value for macrophage studies include src kinase knockout animals and the Wiskott-Aldrich syndrome. Small guanosine triphosphatases (GTPases; rac, rho, cdc42) have been implicated in diverse myeloid functions, including cell spreading and membrane ruffling. Specialized adhesion structures that deserve further study in macrophages include focal adhesion, podocyte formation (particularly prominent in osteoclasts) and possible participation in tight junctions; hemiconnexons have been reported in macrophages in marrow stroma. CR3 contributes to divalent cation-dependent adhesion of monocytes and macrophages to artificial, serum-coated substrates, such as bacteriologic plastic and the class A SR and MARCO (see “Non-Toll-Like, Nonopsonic Receptors” above), which mediate divalent cation-independent adhesion to serum-coated tissue culture plastic *in vitro*. However, the basis of the remarkable, even unique, protease-resistant adhesion of macrophages to foreign materials remains mysterious. Improved imaging studies, combined with genetic manipulations, will bring further insights into the regulation of monocyte/macrophage adhesion and migration *in vivo*.

INTERACTION WITH COAGULATION CASCADE

Monocytes and resident macrophages line the sinusoids of liver (Kupffer cells) and spleen and readily recognize activated platelets, binding them for clearance and destruction. In addition, monocytes produce potent procoagulants, such as tissue factor, initiating a clotting cascade which, if dysregulated, can lead to diffuse intravascular coagulation during septic shock. Following injury and inflammation, monocytes/macrophages produce urokinase, to generate plasmin, in concert with endothelial cell-derived tissue plasminogen activator.⁹⁸ Macrophage production of urokinase is regulated by phagocytic and other stimuli, and the active enzyme can bind to receptors (urokinase plasminogen activator receptor) on the cell surface in a complex interaction with protease-anti-protease complexes, thus localizing fibrinolysis, which is important in wound repair.

The nature and source of the lipid tissue factor produced by monocytes is not well characterized. The cells also produce a complex mix of lipid metabolites, consisting of labile prostaglandins, leukotrienes, and thromboxanes, by utilization of arachidonate-derived precursors and substrates for phospholipase and cyclooxygenase-processing enzymes, among others.

TABLE 67–5. Selected G-Protein–Coupled Receptors Implicated in Functions of Monocytes and Macrophages

RECOGNITION AND CLEARANCE OVERVIEW

Resident macrophages of the liver and marrow, as well as in lung and other nonhematopoietic tissues, play a major role in the recognition, phagocytosis, and endocytosis of foreign particles and macromolecules, as well as of modified host components. Clearance can be silent, even suppressing inflammation, mediated by transforming growth factor (TGF)- β generation, as observed after the uptake of apoptotic cells by macrophages.⁹⁹ Production of hematopoietic cells is balanced by their programmed senescence and increased destruction, which can be enhanced in response to microbial and other toxic substances. Macrophages initiate and perpetuate inflammation, both acute and chronic, as a result of their biosynthetic and secretory responses to injurious particles. Uptake and vacuole formation sequester the membrane-enclosed contents for digestion and possible antigen processing and presentation, a specialized property of DCs after their further differentiation from active endocytic to APCs.³³ Specialized studies show that blood-derived monocytes have unique functions. For example, in the human disorder multiple sclerosis and the model experimental autoimmune encephalitis, monocyte-derived macrophages initiate demyelination at nodes of Ranvier; whereas, microglia derived from yolk-sac progenitors during embryogenesis are relatively inert at disease onset.³¹ To illustrate the role of macrophages in the recognition and clearance of foreign substances, images of macrophage spreading

and engulfment of erythrocytes can be visualized by scanning electron microscopy, and the sequence of engulfment by phase-contrast optics (see video talk on macrophage phagocytosis at <http://hstalks.com/?t=BL1473311>).

In addition, interest has grown explosively in cytosolic recognition systems, designed to protect the cell from various infectious and lytic agents.^{100–102} The process of autophagy shares aspects with both membrane-bound and cytoplasmic organelle injury, and has become of great current interest because of its contribution to pathogenesis of infectious, malignant, and inflammatory syndromes.¹⁰³

APOPTOSIS

Macrophages take up large numbers of naturally dying cells, hematopoietic and others, through a complex mechanism involving multiple, often redundant nonopsonic receptors.^{47,99} A possible role for complement has also been proposed. [Figure 67–12](#) illustrates receptors and ligands that have been implicated. Apart from the SRs already discussed, they include receptors for opsonins and for milk-fat globulin, as well as for the vitronectin receptor. Phosphatidylserine (PS) expressed on the outer leaflet of apoptotic cells, contributes to apoptotic cell recognition, but its role is probably more complex as apparently healthy cells can express patches of PS on their surface and PS recognition plays a role in CD36-dependent macrophage–macrophage fusion.¹⁰⁴ The recognition

Figure 67–12. Phagocytic receptors for apoptotic cell phagocytosis. Macrophages and immature myeloid dendritic cells (DCs) are the main immune cells involved in the clearance of apoptotic cells. They express broadly similar multiple receptors that can bind directly or via opsonic-soluble proteins, for example, mannose-binding lectins (MBLs) to ligands. Phosphatidylserine (PS) becomes exposed on the outer surface of the apoptotic cell and a receptor for this ligand has been long sought. A new receptor (TIM4, and related TIM1) was discovered on resident $m\phi$, with specificity for PS. Other $m\phi$ populations utilize MFGE8 (a milk-fat globulin protein secreted by $m\phi$) as an opsonin. Discrimination of non-self and altered self may involve combinations of different phagocyte receptors. Apoptotic cell uptake results in an antiinflammatory response by $m\phi$ (e.g., release of transforming growth factor [TGF]- β and prostaglandin E_2), but has also been implicated in cross-presentation by DCs. For further details see Ref. 47. (Reproduced with permission of Savill J, Dransfield I, Gregory C, et al: A blast from the past: clearance of apoptotic cells regulates immune responses. *Nat Rev Immunol* 2002 Dec;2(12):965-975.)

mechanisms for uptake of necrotic cells and enucleated erythroblast nuclei by macrophages are not clear (Chap. 15).

ENDOCYTOSIS, PHAGOCYTOSIS, AND KILLING

Apart from the above ligands, macrophages express receptors for endocytosis of growth factors, cytokines, peptides, and lipids. Macrophages express a functional folate receptor that is induced during activation and can be used to target drugs or tracers to macrophages *in situ*.¹⁰⁵ Hemoglobin-haptoglobin complexes are internalized by CD163, a glucocorticoid-regulated receptor with a remarkable SR-cysteine extracellular domain structure.¹⁰⁶ CD163 is also upregulated by substance P.¹⁰⁷

The cell biology of endocytosis and of phagocytosis is illustrated in Figs. 67–13 and 67–14. Apart from size and resultant involvement of the cytoskeleton, they have much in common; vesicle/phagosome formation, falling pH and initial digestion, fusion with secretory vesicles derived from the Golgi, and maturation to form secondary lysosomes/

phagolysosomes with a more acidic pH, and further digestion.^{108,109} Apart from selective fusion with intracellular vesicles, there is extensive membrane flow, recycling, and fusion. Small GTPases play an important role in the control of membrane traffic.¹¹⁰ Early estimates revealed that a substantial fraction of surface membrane is internalized constitutively by endocytosis.

Studies that used opsonic receptors to examine the uptake mechanism of antibody-coated erythrocytes via opsonic receptors gave rise to the zipper hypothesis: local segmental engagement of FcR, and circumferential flow of macrophage pseudopodia around the particle, followed by fusion at the tip, closure, and ingestion. Subsequent studies by several groups documented the role of phosphatidylinositol 3-kinase (PI3K) and phosphoinositides in the initial fusion and subsequent associations between the actin cytoskeleton and cellular membranes.¹¹¹ Latex has provided a useful test particle to isolate latex-containing phagolysosomes by flotation. Proteomic analyses¹¹² demonstrated the protein composition of phagosomes and drew attention to functional constituents in the phagolysosomal membrane.

Figure 67-13. Phagocytosis and endocytosis pathways. Particulates are taken up by actin-dependent sequential maturation processes, involving membrane fusion and fission, which intersect with the endocytic pathway at several stages. Cytosolic small guanosine triphosphatases (rabs) determine organelle-specific interactions. Membrane is recycled to the plasma membrane, with processed antigen. Progressive acidification and delivery of lysosomal hydrolases result in terminal degradation. Compartment membranes express marker proteins such as lysosomal-associated membrane protein (LAMP)-1; the pan-macrophage CD68 antigen is associated with late endosomes and lysosomes.

These observations have provided the basis for numerous investigations regarding the interactions of diverse microorganisms with the vacuolar system, which are often necessary for pathogen survival and establishment of intracellular infection (Fig. 67-15). Organisms can inhibit acidification and fusion (*Mycobacterium*),^{101,113} multiply within secondary lysosomes (*Leishmania*),¹¹⁴ escape free into the cytosol (*Listeria*),¹¹⁵ or translocate their genomes into the cytoplasm by fusion (enveloped viruses); other organisms induce variations on this theme; for example, *Brucella* seeks out the endoplasmic reticulum after entry and *Legionella* can enter macrophages by inducing a phagosome membrane of unusual composition.¹¹⁶ Nonpathogenic organisms or pathogens taken up via opsonic receptors or after IFN- γ activation undergo a different fate, with killing and destruction.

The zipper mechanism, with tight apposition of membrane to the particle's surface ligands, does not apply to all forms of ingestion. For example, complement opsonized particles seem to sink into the cytoplasm, and other phagosomes can be spacious. A number of key methods of visualization¹⁰⁹ illustrate the dynamic nature of phagocytosis. Figure 67-14 illustrates some of the signaling pathways that control the cytoskeleton.

Macrophages are rich in lysosomal digestive enzymes,³³ activated by a falling pH of approximately 6.5 within the mature vacuole. Unless captured as peptides by MHC molecules, a feature of antigen processing by DCs, macromolecular substrates can be degraded to their constituent amino acids, sugars, or nucleic acid bases. Early studies¹¹⁷ probed the permeability of the lysosomal vacuolar membrane. If the

content cannot be fully degraded because of its nature (e.g., sucrose), overload (e.g., lipid), or owing to a genetic deficiency in a catabolic enzyme (lysosomal storage diseases), it accumulates within residual lysosomes, altering macrophage gene expression and secretory output, thus mediating chronic inflammation or metabolic forms of modified inflammation, such as atherosclerosis, foam cell formation and Gaucher disease. Figure 67-16A illustrates the uptake of senescent erythrocytes, the breakdown of heme and storage of Fe²⁺.¹¹⁸ Figure 67-16B shows how phagocytosis by DCs can bring about processing and cross-presentation of exogenous antigens.¹¹⁹ By comparison (Fig. 67-16C), autophagy is the envelopment of damaged intracellular organelles and cytoplasm by cytoplasmic membrane, and sequestration within a digestive vacuole, resembling heterophagy (Chap. 15).¹¹⁶ Its biochemical and cellular basis has become of interest because of its apparent relevance to cancer, infections such as tuberculosis and Legionnaire disease, and inflammatory syndromes such as inflammatory bowel disease (IBD).

Although the phagocytic mechanism has been investigated in depth, we do not understand fully how the process of internalization is controlled. For example, ingestion can be thwarted by attempts to ingest too large a particle or foreign surface, or by close apposition of plasma membrane to noninternalizable immune complexes. This results in redirecting secretory vesicles to the surface, reminiscent of osteoclast adhesion. In other circumstances, as in response to foreign bodies, and especially mycobacteria, and in the presence of

Figure 67-14. A model for Fc γ R-mediated phagocytosis. **A.** Signaling upstream and downstream of Rho guanosine triphosphatases during Fc γ R-mediated phagocytosis. Immunoglobulin (Ig) G bound to antigen on the particle binds to Fc γ RI receptors at the surface of the m ϕ and induces their aggregation (shown in red). This activates a Src family tyrosine kinase (probably Lyn). Lyn phosphorylates the receptor γ chain (phosphotyrosine residues in the γ chains are depicted as red diamonds) and Syk. Syk is activated and recruited to the phosphotyrosine residues of the γ chain through its two SH2 (Src homology 2) domains. Cdc42 activation by an unknown guanine–nucleotide exchange factor (GEF) allows the recruitment of WASP (Wiskott–Aldrich syndrome protein). In turn, WASP activates the Arp2/3 complex that triggers actin polymerization to generate the protrusive force for pseudopod extension (red arrowheads). Activation of a Rac1 GEF, possibly Vav, by tyrosine phosphorylation in conjunction with PI3 kinase products (PIP₃) promotes GDP/GTP (guanosine diphosphate/guanosine triphosphate) exchange on Rac1. GTP-bound Rac1 interacts with and activates the serine/threonine kinase Pak1, which may induce the actinomyosin contractility involved in phagosome closure. **B.** In the next step, Fc γ RI is rapidly down-modulated and returned to an inactive state (shown in blue), resulting in actin filament disassembly. According to this model, actin assembly proceeds as a wave at the distal rim of the pseudopodia, while actin depolymerization occurs rearward. Polyphosphoinositide phosphatases such as the SH2 domain-containing SHIP, which selectively hydrolyze PIP₃, may contribute to down-modulation. Modulation of Fc γ RI activation may also involve tyrosine phosphatases such as SHP-1, which associates with Fc γ RIIB, a member of the Fc γ R family that may be coligated with Fc γ RI. In addition, PEST family phosphotyrosine phosphatases (PTPases) may contribute to dephosphorylation by interacting with PSPIP, a cytoskeletal protein that interacts with WASP. GAPs may also contribute to down-modulation by returning Cdc42/Rac1 to the inactive, GDP-bound state. Eventually, cytoskeletal proteins are shed from the ingestion site to leave the phagosome free in the cytosol (not shown here). (Reproduced with permission from Chimini G, Chavrier P: Function of Rho family proteins in actin dynamics during phagocytosis and engulfment. *Nat Cell Biol* 2000 Oct;2(10):E191–E196.)

the Th2 cytokines IL-4 and/or IL-13, individual macrophages can fuse to form giant cells, with a common cytoplasm and multinucleation. Several fusogenic surface molecules have been identified and DNAX-activating protein (DAP) 12 expression and signaling is important in generating a fusogenic differentiation phenotype in macrophages.¹²⁰

INFLAMMASOME

The recognition of the multiprotein inflammasome complex¹⁰¹ has stimulated intense interest in the recognition by cytosolic proteins of foreign nucleic acid, uric acid-induced injury, and breakdown products of microbial walls, for example, muramyl dipeptide. More complex peptidoglycan structures can also be recognized

by surface receptors in *Drosophila*. Several reviews chart the rapid growth in our knowledge of inflammasome function in health and disease.^{100,102,121,122} Figure 67-17 illustrates selected nucleotide-binding oligomerization domain (NOD)-like and related receptors (NLRs) with nucleotide oligomerization and other characteristic domains. Mutations in NLR have been implicated in IBD, in periodic familial Mediterranean fever, and in a range of autohyperinflammatory syndromes.¹²³ More specifically, NOD-2 has been implicated in Crohn disease.^{124,125} Excessive caspase activation and IL-1 β release can be countered therapeutically with IL-1 receptor antagonists. Figure 67-18 illustrates the role of inflammasome activation in intracellular infection. Antiviral production of IFN- α and - β involves retinoid-inducible gene (RIG)-I-like helicases, indicating a role for mitochondria in cytosolic sensing.

Figure 67-15. Selected pathogens evade distinct phagocytic mechanisms. Pathogens have developed several mechanisms to enter and survive inside macrophages. *Legionella pneumophila* resides and multiplies in a vacuole studded with ribosomes as a result of interaction with the rough endoplasmic reticulum. The organism secretes effector molecules via its type IV secretion system into the cell, which inhibit phagosome/lysosome fusion. The *Francisella tularensis* phagosome acquires the early endosome markers EEA1 and Rab5 and then matures into a late endosome defined by the presence of the markers Lamp1, Lamp2, and Rab7. The late endosome does not acidify and the phagosomal membrane is disrupted, releasing the bacteria into the cytosol. The *Mycobacterium tuberculosis* phagosome acquires the early endosome marker Rab5 but excludes the late endosomal Lamps and Rab7. This organism also produces effector molecules that block fusion with the lysosome and resides and replicates in this early endosome. Acidification of the *Listeria monocytogenes* phagosome is essential for the perforation of the phagosomal membrane and escape of the bacteria into the cytosol. Here they mobilize the actin polymerization machinery to move within the cell and then from cell to cell. *Candida albicans* undergoes a conversion from a unicellular form to a multicellular hyphal form, which allows this fungus to escape the macrophage. The *Leishmania mexicana* phagosome develops into an acidic phagolysosome containing Rab7 where the parasite is able to survive and replicate. Viruses such as the influenza virus are able to inhibit the activation of antiviral mechanisms, such as the activation of IFN regulatory function proteins that induce IFN production upon viral infection, and enter the nucleus. Cytomegalovirus (not shown) incapacitates a range of major histocompatibility complex-antigen presenting pathways. (Used with permission of S. Seif, GraphisMedica, 2014.)

GENE EXPRESSION, SYNTHESIS, AND SECRETION

The development of microarray technology has had a dramatic impact on the analysis of macrophage gene expression in response to a wide range of stimuli, including microbial ligands, cytokines, and immunomodulators. Macrophages are able to express a large number of genes and are extremely versatile in their responses to environmental cues. It has been possible to discern signatures of particular agonists, for example, IFN- α and - β and IL-4, but many caveats remain in the interpretation of such data. Heterogeneity of cellular origin, differentiation stage, and populations from diverse origins, as well as substantial species differences, make it difficult to compare results within and among experiments. Validation of more quantitative messenger RNA analysis of protein synthesis and modification is difficult, although proteomic analysis is gaining ground. The study of macrophage chromatin organization in relation to gene expression is in its infancy.

There is extensive crosstalk between the secretory and endocytic pathways.¹²⁶ Table 67-6 is a selected list of secretory products. This includes lysozyme, a major myelomonocytic product that is

constitutively expressed *in vitro*, but upregulated in granulomata *in vivo*. The secretion pathway of lysozyme in monocytes and macrophages has not been defined. The well-known pro- and antiinflammatory cytokines are better characterized, both in terms of regulation and the secretion pathway.¹⁰⁹ The response to IL-6 and TNF- α secretion in model systems shows a more complex pathway than previously recognized.^{127,128} In addition to these and other important growth and differentiation factors that regulate angiogenesis, for example, macrophages are able to produce and secrete enzymes and proenzymes for a range of activities, as well as their inhibitors, for example, proteinases and antiproteinases. Although the amounts of complement proteins produced, for example, are relatively small, they can be significantly concentrated in a local microenvironment. In addition, macrophages can produce a range of antimicrobial peptides and lytic agents, but their most important killing mechanisms depend on oxygen¹²⁹ and nitrogen metabolites,^{109,114} which are illustrated in Figs. 67-19 and 67-20. Regulation of the nicotinamide adenine dinucleotide phosphate oxidase and of inducible nitric oxide synthase has been studied extensively in mice and humans through biochemical and genetic approaches. Apart from their antimicrobial activity, nitrogen metabolites contribute to signaling pathways.¹³⁰ IFN- α and - β play

Figure 67-16. **A.** Macrophages have an important role in iron metabolism by processing effete erythrocytes, internalized by phagocytosis, and returning iron to the blood (through ferritin) for reuse. Dissociation of iron linked to heme on erythrocytes requires the action of heme oxygenase (HO), an enzyme present in the endoplasmic reticulum (ER). The process allowing the transfer of heme oxygenase from the ER to the phagosomal lumen is so far unknown. **B.** Presentation of antigens from intracellular pathogens is mainly carried out by major histocompatibility complex (MHC) class II molecules loaded in phagosomes. Presentation of some pathogen antigens could also involve MHC class I molecules. Current models indicate that antigens generated by hydrolases in the phagosomal lumen could use SEC61 for translocation to the cytoplasm. After processing by the proteasome, antigens could be translocated to the phagosomal lumen through the transporter for antigen processing (TAP) complex where loading onto MHC class I or MHC class II molecules would occur. Transport to the cell surface from the phagosomal lumen could take place by using the existing membrane recycling machinery, involving the small GTP-binding proteins Rab4 and Rab11. **C.** Autophagy is a conserved membrane traffic pathway that equips eukaryotic cells to capture cytoplasmic components within a double-membrane vacuole, or autophagosome, for delivery to lysosomes. Although best known as a mechanism to survive starvation, autophagy is now recognized as a mechanism to combat infection by a variety of intracellular microbes.

Figure 67-17. Nucleotide-binding and oligomerization domain (NOD)–leucine-rich repeat (LRR) and inflammasome structures. NOD-like receptors (NLRs) have three structural domains: The LRR domain at the C-terminus, the NACHT (domain present in NAIP, CIITA, AHD, HET-E, TP-1) domain, and the N-terminal domain that can be a pyrin domain (PYD), a caspase activation and recruitment domain (CARD), or a baculovirus inhibitor-of-apoptosis protein repeat domain (BIR). The LRR domain is considered as the ligand-sensing motif, thus involved in the interaction with pathogen-associated molecular patterns (PAMPs), in analogy to toll-like receptors (TLRs). The NACHT domain is responsible for the oligomerization and activation of NLRs. The PYD or CARD domain of NLR is the link to downstream adaptors (such as apoptosis-associated speck-like protein containing a CARD [ASC]) or effectors (such as caspase-1). The BIR domain is proposed to act as caspase inhibitor. During NACHT LRR protein (NALP) and NALP1 inflammasome activation, NALP3 or NALP1 interact through PYD–PYD homotypic interactions with ASC, resulting in its activation. Subsequently, the CARD domain of ASC interacts with the CARD domain of caspase-1 and mediates its activation. NALP1 may also activate directly the caspase-5 through its C-terminal CARD domain. In contrast, NALP3 does not simultaneously activate caspase-5, but NALP3 can recruit a second caspase-1 through the CARD domain of CARD inhibitor of nuclear factor- κ B-activating ligand (CARDINAL), a component of the NALP3 inflammasome. Interleukin-1 β -converting enzyme (ICE)-protease activating factor (IPAF), that can on its own sense PAMPs, possesses a CARD domain at the N-terminal and thus may directly activate caspase-1 without ASC recruitment (“IPAF inflammasome”). (Reproduced with permission of Sidiropoulos PI, Goulielmos G, Voloudakis GK, et al: *Inflammasomes and rheumatic diseases: evolving concepts*. *Ann Rheum Dis* 2008 Oct;67(10):1382-1389.)

Figure 67-18. Knockout studies show that IPAF (interleukin-1 β -converting enzyme-protease activating factor) is essential for the activation of caspase-1 by *Salmonella typhimurium*, *Shigella flexneri*, and *Legionella pneumophila* in order to induce the release of interleukin (IL)-1 β , IL-18, and macrophage cell death. Sensing intracellular *S. typhimurium* seems to be mediated by the detection of monomeric flagellin that is secreted by the bacterial type III secretion system (and is dependent on the protein SipB from *S. typhimurium*) by IPAF. The type III secretion system protein IpaB is involved in sensing *S. flexneri*. Sensing intracellular *L. pneumophila* seems to be mediated by the detection of monomeric flagellin that is secreted by the type IV secretion system by NAIP5 (neuronal apoptosis inhibitor protein 5), which, in conjunction with IPAF, induces caspase-1 activation and restricts the growth of these pathogens in macrophages. Although a specific NLR (nucleotide-binding oligomerization domain-like receptor) protein that detects cytosolic *Francisella tularensis* has not yet been identified, the adaptor molecule ASC (apoptosis-associated speck-like protein containing a CARD) seems to be essential for counteracting infections with *F. tularensis*. CARD, caspase activation and recruitment domain; LRR, leucine-rich repeat; NACHT, domain present in NAIP, CIITA, HET-E, and TP-1; PYD, pyrin domain. an important role in macrophage antiviral activities¹³¹ and perhaps in the cellular response to bacteria.¹³² These cytokines also contribute significantly to immune and inflammatory pathways, as well as cancer immunoediting¹³³ and autoimmunity.¹³⁴

Macrophages may be able to produce IFN- γ , for example, under particular circumstances, but *in vivo* most of the cytokine derives from other sources. IFN- γ has a major impact on macrophage function (the initial name of IFN- γ was macrophage activating factor), including priming of biosynthetic and functional responses associated with cytotoxicity and inflammation in cell-mediated immunity (Fig. 67-21).¹³⁵ Table 67-7 summarizes the markers and functions associated with various forms of macrophage activation and deactivation, as described in Chap. 68.¹³⁶ Intracellular GTPases have been implicated in cell activation by IFN- γ , for example, and in relation to IBD.^{121,124,125} Similarly, the Th2 cytokines IL-4 and IL-13 induce characteristic changes in macrophage phenotype, which are associated with an alternative activation pathway. The cellular biology of alternatively activated macrophages is modified

extensively (Fig. 67-22).¹³⁷ Macrophages also express a range of inhibitory proteins, such as members of the suppressor of cytokine signaling family, that suppress cytokine production, in addition to IL-10¹³⁸ and TGF- β . Lipid metabolites, mainly derived from arachidonate and other lipid precursors, provide another potent source of inflammatory and immunomodulatory products.¹³⁹ The suppressive functions of monocytes and macrophages in chronic infections and experimental tumors require further study, including the development of new phenotypic markers in mice and humans.

CELLULAR INTERACTIONS

In addition to cytokine and other soluble afferent and efferent responses, macrophages are able to directly interact among themselves, with all other cell types in the body, both viable and injured, as well as with all kinds of microorganisms. Their interactions are reciprocal and regulated, contributing to homeostasis and to pathogenesis, both

TABLE 67-6. Selected Secretion Products of Macrophages

Proteins	Product	Comment
Enzymes	Lysozyme	Bulk product
	Urokinase-type plasminogen activator	Regulated by inflammation
	Collagenase	Regulated by inflammation
	Elastase	Regulated by inflammation
	Metalloproteinases	Also inhibitors
	Complement	All components and regulators
	Arginase	Alternative activation
	Angiotensin-converting enzyme	Induced glucocorticoids, granulomas
	Chitotriosidase	Gaucher disease, lysosomal storage
Inhibitors	Acid hydrolases	All classes (mainly intracellular)
	TIMP	
Chemokines	Many C-C, C-X-C, CX ₃ C; e.g., MCP, RANTES, IL-8	Initiates acute and chronic recruitment of myeloid and lymphoid cells
Cytokines	IL-1 β , TNF- α	Pro- and antiinflammatory
	IL-6, IL-10, IL-12, IL-17, IL-18, IL-23	Also antagonists, e.g., IL-1Ra
	Type I IFN	Autocrine and paracrine amplification
Apolipoproteins	Apolipoprotein E	Local source, marrow origin after adoptive transfer
Growth/differentiation factors	TGF- β	Also other family members (activins), myeloid growth and differentiation
	M-CSF	
	GM-CSF	
	FGF	Fibrosis
	PDGF	Repair
	VEGF	Angiogenesis
Opsonins	Fibronectin, pentraxin (PTX3)	Also uncharacterized receptor on M ϕ
Soluble receptors	Mannose receptor	Soluble mannose receptor
Cationic peptides	Defensins	Subpopulations and species variation
Lipids	Procoagulant	Initiation clotting
	Arachidonate metabolites:	Pro- and antiinflammatory mediators
	Prostaglandins	
	Leukotrienes	
	Thromboxanes	
	Resolvins	
Metabolites	Reactive oxygen intermediates	
	Reactive nitrogen intermediates	
	Haem breakdown (bile pigments)	
	Iron, B ₁₂ -binding protein	
	Vitamin D metabolites	

FGF, fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; MCP, monocyte chemoattractant protein; M-CSF, macrophage colony-stimulating factor; PDGF, platelet-derived growth factor; RANTES, regulated on activation, normal T-cell expressed, presumed secreted; TGF, transforming growth factor; TIMP, tissue inhibitor of metalloproteinase; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

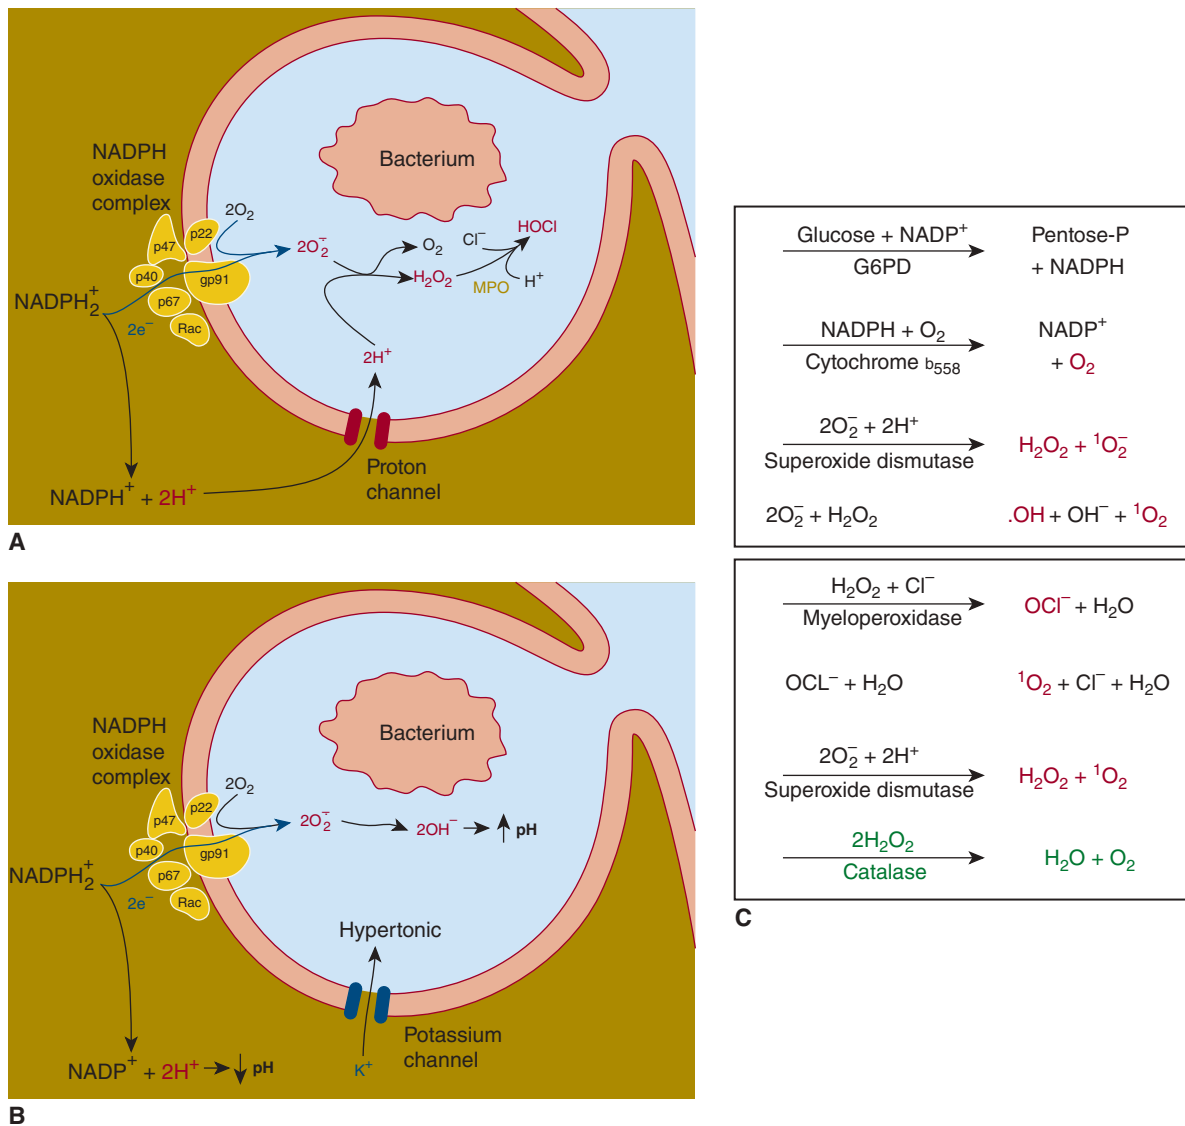

Figure 67-19. The respiratory burst in a phagocyte is triggered when a bacterium is phagocytosed. During the phagocytosis of bacteria by macrophages and neutrophils, the phagosome membrane pinches off and the microbe is endocytosed along with a small volume of extracellular fluid. The mechanisms discussed here are based on studies in neutrophils and are still controversial.¹¹² Electrons are removed from nicotinamide adenine dinucleotide phosphate (NADPH) in the cytoplasm and transferred through the gp91*phox* component (which includes flavin adenine dinucleotide and two hemes) across the membrane, where they reduce extracellular (or intraphagosomal) O_2 to O_2^- . Protons left behind in the cell are extruded through voltage-gated proton channels (red). Some of the reactive oxygen species (ROS) derived from O_2^- are indicated. Spontaneous or superoxide dismutase-catalyzed disproportionation of O_2^- produces hydrogen peroxide (H_2O_2), which may be converted to HOCl (hypochlorous acid, or household bleach) by myeloperoxidase (MPO). **A.** Traditional view of the respiratory burst with charge compensation by proton channels. A perfect match of one proton per electron results in no change in membrane potential, intracellular pH (pHi), or external pH (pHo) and little change in ionic strength. Because proton channels are separate molecules and for the most part operate independently of NADPH oxidase, perfect 1:1 stoichiometry is not obligatory. The large depolarization that occurs during the respiratory burst in intact neutrophils and eosinophils is likely the most important factor that causes proton channels to open, although both pHi and pHo tend to change in a direction that causes proton channels to open. That depolarization occurs demonstrates unequivocally that proton efflux initially lags behind electron efflux. **B.** If any fraction of the total charge compensation were mediated by K^+ efflux, pHi would fall, pHo (or phagosomal pH) would increase, and the osmolality of the phagosomal contents would increase. In this model, the elevated pH and osmolality of the phagosomal contents are crucial to activating proteolytic enzymes that actually kill bacteria, as opposed to ROS, which are said to be inert. **C.** Respiratory burst reactions. During phagocytosis glucose is metabolized via the pentose monophosphate shunt and NADPH is formed. Cytochrome b_{558} , which was part of the specific granule, combines with the plasma membrane NADPH oxidase and activates it. The activated NADPH oxidase uses oxygen to oxidize the NADPH. The result is the production of superoxide anion. Some of the superoxide anion is converted to H_2O_2 and singlet oxygen by superoxide dismutase. In addition, superoxide anion can react with H_2O_2 resulting in the formation of hydroxyl radical and more singlet oxygen. The result of all of these reactions is the production of the toxic oxygen compounds superoxide anion (O_2^-), H_2O_2 , singlet oxygen (${}^1\text{O}_2$) and hydroxyl radical ($\text{OH}\cdot$). As the azurophilic granules fuse with the phagosome, myeloperoxidase is released into the phagolysosome. Myeloperoxidase uses H_2O_2 and halide ions (usually Cl^-) to produce hypochlorite, a highly toxic substance. Some of the hypochlorite can spontaneously break down to yield singlet oxygen. The result of these reactions is the production of toxic hypochlorite (OCl^-) and singlet oxygen (${}^1\text{O}_2$). (A and B, modified with permission from Decoursey TE: Voltage-gated proton channels and other proton transfer pathways, *Physiol Rev* 2003 Apr;83(2):475-579.)

Figure 67–20. The role of nitrogen metabolism in mφ function. Interferon-γ (IFN-γ) enhances the activity of nitric oxide synthase 2 (NOS2) to generate nitric oxide, and inhibits arginase. Interleukin (IL)-4 and IL-13 promote arginase-dependent formation of L-ornithine and, ultimately, fibroblast proliferation and collagen production. GM-CSF, granulocyte-macrophage colony-stimulating factor; TNF, tumor necrosis factor. (Adapted with permission from Hesse M1, Modolell M, La Flamme AC, et al: Differential regulation of nitric oxide synthase-2 and arginase-1 by type 1/type 2 cytokines in vivo: granulomatous pathology is shaped by the pattern of L-arginine metabolism. J Immunol 2001 Dec 1;167(11):6533-6544.)

Figure 67–21. Signaling pathways induced by type I and type II interferon (IFN). The type I IFNs (IFN-α and IFN-β) bind a receptor that consists of the subunits IFN-α receptor (IFN-αR)-1 and IFN-αR2, which are constitutively associated with tyrosine kinase 2 (TYK2) and Janus kinase (JAK) 1, respectively. Type I IFN-induced JAK-STAT (signal transducer and activator of transcription) signaling is propagated similarly to IFN-γ-induced JAK-STAT signaling (below). Activated TYK2 and JAK1 phosphorylate STAT1 or STAT2. Type I IFN-induced signaling then induces homodimerization of STAT1 and heterodimerization of STAT1 and STAT2. STAT1 and STAT2 associate with the cytosolic transcription factor IFN-regulatory factor 9 (IRF9), forming a trimeric complex known as IFN-stimulated gene factor 3 (ISGF3). On entering the nucleus, ISGF3 binds IFN-stimulated response elements (ISREs). Studies of gene-targeted mice have shown that JAK1, STAT1, STAT2, and IRF9 are required for signaling through the type I IFN receptor. TYK2 is required for optimal type I IFN-induced signaling. IFN-γ signaling: IFN-γ induces reorganization of the IFN-γR subunits, IFN-γR1 and IFN-γR2, activating the Janus kinases JAK1 and JAK2, which are constitutively associated with each subunit, respectively. The JAKs phosphorylate a crucial tyrosine residue of IFN-γR1, forming a STAT1-binding site; they then tyrosine phosphorylate receptor-bound STAT1, which homodimerizes through Src homology 2 (SH2) domain-phosphotyrosine interactions and is fully activated by serine phosphorylation. STAT1 homodimers enter the nucleus and bind promoters at IFN-γ-activated sites (GASs) and induce gene transcription in conjunction with coactivators, such as CBP (cyclic adenosine monophosphate-responsive-element-binding protein [CREB]), p300, and minichromosome maintenance-deficient 5 (MCM5). IFN-γ-mediated signaling is controlled by several mechanisms: by dephosphorylation of IFN-γR1, JAK1, and STAT1 (mediated by SH2 domain-containing protein tyrosine phosphatase 2 [SHP2]); by inhibition of the JAKs (mediated by suppressor of cytokine signaling 1 [SOCS1]); by proteasomal degradation of the JAKs; and by inhibition of STAT1 (mediated by protein inhibitor of activated STAT1 [PIAS1]). (Reproduced with permission from Platanius LC: Mechanisms of type-I- and type-II-interferon-mediated signalling. Nat Rev Immunol 2005 May;5(5):375-386.)

TABLE 67-7. Immunomodulation of Macrophage Phenotype

Stimulus	Category	Markers	Function
Microbial (bacterial)	Innate activation	Induction of MARCO	Enhanced phagocytosis
		Costimulatory molecules	Antigen presentation
		CD200	Inhibition (CD200R)
IFN- γ	Classical activation	Induction MHC II	Cell-mediated immunity/delayed-type hypersensitivity
		Potentialiation innate markers	
		- TNF- α	Proinflammatory
		- iNOS induction	Antimicrobial (NO) signaling
		- NADPH, respiratory burst	Host defense, inflammation
		LGP47 induction	Association with phagosome/intracellular pathogen killing
		Downregulation of MR	Unknown
IL-4/IL-13	Alternative activation	Enhanced MR	Endocytosis
		Induction arginase	Humoral immunity
		Induction YM1, FIZZ1 (mouse)	Th2-responses, allergy, antiparasitic
		Induction CCL17 (MDC) and CCL22 (TARC)	Immunity, repair/fibrosis
		Fusion, giant cell formation	
Immune complexes	Upregulation	CD23 (Fc ϵ)	
Immune complexes	Modified activation	Selective IL-12 downregulation, IL-10 induction	
IL-10	Deactivation	Downregulation MHC II	
TGF- β	Deactivation	Downregulation of proinflammatory NO and ROI	
Glucocorticoids	Deactivation	CD163 induction, monocyte recruitment down-regulated, ACE induction, Stabilin induction	Antiinflammatory
			Homeostatic clearance of hemoglobin/haptoglobin complexes

IFN, interferon; IL, interleukin; iNOS, inducible nitric oxide synthase; MARCO, macrophage receptor with collagenous structure; MDC, macrophage-derived chemokine; MHC, major histocompatibility complex; MR, mannose receptor; NADPH, nicotinamide adenine dinucleotide phosphate; NO, nitric oxide; ROI, reactive oxygen intermediate; TARC, thymus and activation-regulated chemokine; TGF, transforming growth factor; TNF, tumor necrosis factor.

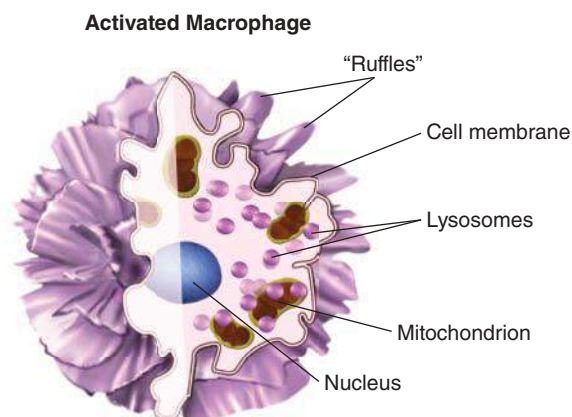

Figure 67-22. Schematic cross-section of “activated” macrophage, showing ruffling of cell membrane and cellular organelles (also see Fig. 67-15). (Used with permission of S. Seif, GraphisMedica, 2014.)

Figure 67-23. Hypoxia induces marked changes in the phenotype of macrophages. Macrophages upregulate hypoxia-inducible transcription factor (HIF)-1 and HIF-2 in hypoxia, which translocate to the nucleus to induce the expression of a wide array of target genes. Several important cell-surface receptors are upregulated in hypoxia, including the glucose receptor GLUT-1 (for increased glucose uptake as the cell switches to anaerobic glycolysis to make ATP in the absence of oxygen), the chemokine stromal cell-derived factor-1 (SDF-1) receptor CXCR4, and the angiopoietin receptor Tie-2. Hypoxia also stimulates the expression of a wide array of other protumor cytokines, enzymes, and receptors, grouped here according to their known function in tumors. Downregulation of a factor or tumor-associated macrophage function is indicated by an *arrow*. Ag, antigen; COX, cyclooxygenase; FGF, fibroblast growth factor; HGF, hepatocyte growth factor; MIF, macrophage migration inhibitory factor; MMP, matrix metalloproteinase; PDGF, platelet-derived growth factor; PGE₂, prostaglandin E₂; TF, tissue factor; uPA/R, urokinase-type plasminogen activator receptor; VEGF, vascular endothelial growth factor. Microenvironmental factors regulating macrophage function in breast tumours: hypoxia and angiopoietin-2*. *Breast Cancer Res* 2007;9(3):209.)

acutely and following persistent injury, to chronic inflammation. Storage of poorly degraded materials in lysosomes, for example, results in sustained production of degradation products, whereas massive, acute responses have a profound impact on the systemic circulation, endocrine and nervous systems, and on metabolic pathways. Short-range interactions include giant cell formation during granulomatous inflammation, and also contact-dependent immunoregulation by surface molecules such as CD200/CD200R and SIRP α /CD47.¹⁴⁰ Matrix and other surface interactions regulate the induction or suppression of adaptive immune responses, as well as of other functions. The availability of oxygen plays an important role in macrophage interactions with a range of other cells, both normally and in a range of pathologies inducing inflammation, repair, and malignancy (Fig. 67-23).

RELEVANCE TO HEMATOPOIETIC FUNCTIONS AND DISORDERS

In addition to their essential role in host defense (innate and acquired immunity), inflammation, and repair, macrophages contribute to hematopoiesis, as well as to the turnover of hematopoietic cells and their products. Macrophages can be induced to take up folate, sense and respond to oxygen levels, and promote vascular growth, regulating the integrity of the hematopoietic microenvironment. However, they also play a central effector role in pathogenesis. Their surface expression and secretion of TNF- α , other proinflammatory cytokines, enzymes, and metabolites contribute to vascular injury and increased permeability of the microvasculature, as well as to local and systemic catabolic effects associated with chronic inflammation. In this regard, anti-TNF- α therapy is of considerable value in selected inflammatory conditions and has been extended to the treatment of cancer and rheumatologic conditions.¹⁴¹⁻¹⁴⁴ Stromal and other resident macrophage populations provide a niche for acute and persistent infections in marrow and elsewhere, and these macrophages also contribute to trophic support of hematopoietic malignancies, such as multiple myeloma. The macrophage, therefore, provides an important target cell for selective therapeutic intervention, without undue enhancement of vulnerability to infection. Additional molecular targets are needed, based on more detailed

analysis of macrophage functions within their native hematopoietic tissue environment. A deeper understanding of macrophage physiologic functions and of their role in a broad range of diseases should lead to the development of fresh insights into the pathogenesis and management of hematologic disorders.

CHAPTER 68

PRODUCTION, DISTRIBUTION, AND ACTIVATION OF MONOCYTES AND MACROPHAGES

Steven D. Douglas and Anne G. Douglas

SUMMARY

Monocytes and macrophages play an important role in human biology, both as a component of the hematopoietic system and within the stroma and tissue microenvironment where they contribute trophic and clearance functions. They constitute a widely dispersed cellular system throughout the body, interacting with host cells and foreign invaders through their versatile biosynthetic and secretory responses, to maintain physiologic homeostasis. They are specialized migratory or sessile phagocytes, present within the circulation and extravascular tissue compartment, contributing to diverse pathologic processes directly and through their production of bioactive products. Because of their extensive heterogeneity and plasticity, the centrality of monocytes and their progeny has not always been recognized by hematologists. The origin, life span, and functions of the monocyte are the focus of this chapter, including their relevance to health and disease in humans, based on current understanding of their properties. The relationship of monocytes and macrophages to dendritic cells, and monocyte-derived cells with a specialized immunologic role in T-lymphocyte activation, are described. Together, macrophages and dendritic cells are major antigen-presenting cells, contributing to host defense, innate and acquired immunity, and inflammation, as well as noninfectious disease processes, both within and outside the lymphohematopoietic organs.

METHODS OF MONOCYTE AND MACROPHAGE STUDY

There has been a resurgence of interest in the *in situ* analysis of macrophages.¹ Genetic/ribonucleic acid interference manipulation, more recently with macrophage-specific/restricted promoters, has been

Acronyms and Abbreviations: CR, complement receptor; DC, dendritic cell; DC-SIGN, dendritic cell-specific intercellular adhesion molecule-3-grabbing nonintegrin; EMR, epidermal growth factor module-containing mucin-like hormone receptor; FACS, fluorescence-activated cell sorting; FcR, Fc receptor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN- γ , interferon- γ ; IL, interleukin; LPS, lipopolysaccharide; M-CSF, macrophage colony-stimulating factor; MARCO, macrophage receptor with a collagenous structure; MR, mannose receptor; PRR, pattern recognition receptor; Sn, sialoadhesin; SR-A, scavenger receptor A; TGF, transforming growth factor; TLR, toll-like receptor; TNF- α , tumor necrosis factor- α .

used to knock down macrophage genes or messenger RNA, and to mark cells with fluorescent labels such as green fluorescent protein. Of particular value in tracing their origins and distribution has been the use of fractalkine receptor-transgenics,² and myeloid-specific lysozyme-Cre for targeted ablation.³ Random chemical mutagenesis has been spectacularly successful in validating known, and discovering novel, gene targets that affect macrophage functions.^{4,5} A wider range of experimental models (*Drosophila*, zebra fish) have facilitated interspecies comparisons of macrophage migration and phagocytosis *in vivo*.^{6,7} The analysis of microRNA expression⁸ and functions is still in its infancy and is likely to generate important insights into monocyte/macrophage gene expression in health and disease. Combined with improved imaging methods (fluorescent, nuclear magnetic resonance imaging-based, 2-photon microscopy), new insights have been obtained regarding the dynamic behavior of macrophages and dendritic cells (DCs) *in vivo*.⁹ There has been progress in provoking embryonic and induced pluripotent stem cell differentiation into macrophages and DCs *in vitro*, opening the possibility of introducing mutations into human genes, to complement the naturally occurring material derived from human inborn errors and resultant genetic diseases.¹⁰

Although individual-labeled cells can be followed in accessible tissues or *ex vivo*, the resolution, isolation, and characterization of important embedded macrophage populations are limiting. Methods of isolation from solid organs, for example, brain and even liver and gut, are prone to artifact, and macrophages are profoundly affected by removal from their natural tissue environment. Many of the genetic manipulations introduced by transgenesis are leaky and not uniform, not surprising in the light of macrophage heterogeneity. Although the fate of recently recruited cells from blood into tissues can be tracked more easily, the slowly turning over resident populations are less easily accessed, resulting in bias. Finally, there are intrinsic difficulties with human experimentation *in vivo*. Induced skin blisters, for example, make it possible to collect fluid and cells from sites of inflammation.¹¹ However, the low frequency of monocytes compared with neutrophils limits the use of *ex vivo* indium-labeled cells for transfer studies *in vivo*.

PRODUCTION

DEVELOPMENT OF MONOCYTES AND MACROPHAGES

Macrophages and related amoeboid phagocytic cells, ancient in the evolution of multicellular organisms, are the main leukocytes responsible for innate immunity and tissue remodeling, as documented by Metchnikoff in his pioneering studies on invertebrates,¹² and confirmed by contemporary studies on *Drosophila melanogaster*.⁷ In mammals, much of our knowledge of macrophage ontogeny derives from studies in the mouse. After origins from an aortic mesonephric site, the best understood phases of macrophage development occur during midfetal development, in the yolk sac, followed by fetal liver, spleen, and marrow, before and after birth.¹³ The association of macrophages with definitive erythropoiesis is a striking feature of fetal liver hematopoiesis from approximately day 12 of mouse development; macrophages then, for the first time, become intimately associated with nucleated erythroblasts, reaching a peak of hematopoietic cluster formation at day 14. The role of stromal macrophages in hematopoiesis within the adult is illustrated and discussed further in this chapter.

The association of macrophages with erythroblasts is mediated by surface adhesion molecules,¹⁴ including a poorly characterized divalent cation-dependent receptor and the sialic acid-binding molecule sialoadhesin (Siglec1).¹⁵ The potential trophic functions of stromal

macrophages in marrow erythropoietic islands is poorly understood, as is the considerable role of macrophages in iron and heme metabolism. Macrophages interact with cells in numerous ways; however, during erythropoiesis a special phagocytic process allows for the removal of pyknotic erythroid nuclei during the final stages of erythropoiesis. The mechanism of recognition of membrane-bound erythroid nuclei is not clear, nor its relationship to the uptake of apoptotic cells elsewhere during development. The production of granulocytes from progenitors also involves macrophage–myeloblast clusters and similar adhesion receptors. Once fetal liver hematopoiesis declines before and after birth, the macrophages in the liver adopt the features of resident Kupffer cells. The stromal macrophages associate with developing blood cells within islands of clustered cells, a feature of hematopoiesis throughout life.¹⁶ During fetal life, monocytes and macrophages are distributed through the developing vasculature, providing amoeboid, phagocytic cells implicated in tissue remodeling, for example, sculpting of digits,¹⁷ and growth of the central nervous system.¹⁸ Blood monocytes seed resident tissue macrophage populations throughout the organism, and these cells proliferate more readily in the fetus than in later life; the adhesion molecules, chemotactic signals, and receptors involved during this constitutive phase of distribution are poorly defined, but it is independent of the β_2 -integrin CD11b/CD18, which plays a role in myelomonocytic cell recruitment induced by inflammation in the adult.¹⁹ The appearance of macrophages during development has been correlated with fibrous scar formation after injury.¹⁷ In sum, macrophages play a major role during

development, both in hematopoiesis and in extravascular tissues, and much remains to be learned regarding their properties in the fetus.

Growth, Differentiation, and Turnover

Figure 68–1 gives an overview of differentiation of monocytic cells in the adult.²⁰ The origins of monocytes from multipotential (progenitors colony-forming units, spleen [CFU-S]) and committed hematopoietic precursors (colony-forming units, culture [CFU-C]) and the role of lineage-restricted growth factors such as monocyte/macrophage colony-stimulating factor (M-CSF; also termed CSF-1) and granulocyte-macrophage (GM)-CSF have been studied extensively, but new details are still emerging. Both transcription factor c-Myb and receptor FLT3, M-CSF-dependent myeloid lineages (monocyte and dendritic) occur. These cell types may have different responses to tissue damage and infection.²⁰ Monocytes share precursors with other hematopoietic cells and are closely related to granulocytes. Monocytic precursors are the source of adult tissue macrophages, as well as of myeloid DCs and osteoclasts. Their relationship to B lymphocytes and to plasmacytoid DCs is still unclear, as plasmacytoid DCs express a range of myeloid as well as lymphoid markers. There is a considerable body of knowledge about the specific growth factors and their receptors, and growing knowledge of the nature and role of transcription factors involved in monocyte/macrophage differentiation.²¹ Genetic and cellular abnormalities in growth and differentiation pathways underlie myeloid leukemogenesis, though rarely giving rise to monocytic leukemia.

Figure 68–1. Differentiation of the macrophage/dendritic cell (DC) progenitor and origin of macrophage and DC subsets. CDP, common dendritic cell precursor; CMP, common myeloid progenitor; GMP, granulocyte/macrophage progenitor; HSC, hematopoietic stem cell; HSPCs, hematopoietic stem and progenitor cells; MDP, macrophage/DC progenitor; pDC, plasmacytoid dendritic cell. For further details see Ref. 20. (Used with permission of S. Seif, *GraphisMedica*, 2014.)

MATURATION AND DIFFERENTIATION OF MONOCYTES AND MACROPHAGES

The classic studies of Lewis and Lewis²² in 1926, Maximow²³ in 1932, and Ebert and Florey²⁴ in 1939, showed that monocytes transform into macrophages and multinucleated giant cells *in vitro*. Macrophages can be produced from monocytes or hematopoietic progenitor cells culture in cytokines, such as GM-CSF or M-CSF.

The alterations of ultrastructure during transformation into macrophages, epithelioid cells, and giant cells have been described using purified populations of monocytes and *in vitro* culture techniques.²⁵ As the monocyte matures into the macrophage, the cell enlarges in size, and the lysosomal content and the amount of hydrolytic enzymes within the lysosomes (e.g., phosphatases, esterases, β -glucuronidase, lysozyme, arylsulfatase) increase. At the time, the size and number of mitochondria increase, their energy metabolism increases concomitantly. Production of lactate also increases. The Golgi complex, which packages lysosomes, increases in size and vesicle complexity (Chap. 67). Several stimuli induce formation of multinucleated giant cells from monocytes.²⁶

Growth Factors

M-CSF and GM-CSF are the major growth factors implicated in monocyte and macrophage differentiation. Other cytokines, such as interleukin (IL)-3 and IL-4, result in minimal monocyte proliferative

expansion, and their genetic elimination has no effect on the lineage. M-CSF promotes survival as well as growth and differentiation of macrophages, exclusively, acting through a specific receptor (CSF-1R), encoded by the protooncogene *c-FMS*, which has been extensively used as a lineage marker for fluorescence-activated cell sorting (FACS) analysis (CD115) and transgenesis.^{27,28} The role of M-CSF has been reviewed²⁹ and its role in macrophage and osteoclast development is illustrated in Fig. 68–2. The naturally occurring mouse mutant, *op/op*, gives rise to M-CSF deficiency and osteopetrosis, with marked or partial deficiency in monocyte and selected tissue macrophage populations; DC numbers are unaffected.³⁰ Unlike PU.1 deficiency, the *op/op* mouse is viable, though its reproductive ability is impaired, because M-CSF also plays an important role in the reproductive system. Uterine epithelium is a rich source of M-CSF, inducing monocyte-macrophage recruitment, growth and differentiation, and upregulating scavenger receptor (SR) expression, cell adhesion, and endocytosis of modified low-density lipoproteins and other polyanionic ligands. M-CSF is produced in a soluble and membrane-bound forms, is present in plasma, and has been implicated in atherosclerosis and tumor-dependent recruitment of monocytes and macrophages. The size of the growth burst induced by M-CSF depends on the stage of differentiation of the target cell, decreasing markedly as the precursors mature into monocytes and macrophages. Adhesion and inflammatory stimuli enhance the response to growth factors and can result in macrophage proliferation at peripheral sites, for example, in granulomata.

Figure 68–2. Regulation of macrophage and osteoclast development by macrophage colony-stimulating factor (M-CSF). Circulating M-CSF, produced by endothelial cells in blood vessels, together with locally produced M-CSF regulates the survival, proliferation, and differentiation of mononuclear phagocytes and osteoclasts. The cytokine synergizes with other hematopoietic growth factors (HGFs) to generate mononuclear progenitor cells from multipotent progenitors, and with receptor activator of nuclear factor- κ B ligand (RANKL) to generate osteoclasts from mononuclear phagocytes. *Brown arrows* indicate cell differentiation steps; *blue arrows* indicate cytokine regulation. (Used with permission of S. Seif, GraphisMedica, 2014.)

GM-CSF has a broader myeloid target profile. It is produced by many cells, including macrophages themselves, especially after inflammatory stimuli such as lipopolysaccharide (LPS), and it enhances production of monocytes and macrophages with a different morphology to that induced by M-CSF. GM-CSF is required for myeloid DC differentiation *in vitro* and has been widely used, alone and in combination with cytokines such as IL-4 or transforming growth factor (TGF)- β , to produce DC from mouse marrow or from human monocytes in cell culture.^{31,32} Its targeted deletion in mice or genetic loss of function mutants of its specific receptor chain in humans results in pulmonary alveolar proteinosis, associated with defective alveolar macrophage metabolism of pulmonary surfactant.³³

Survival, Differentiation, and Turnover Overview

Once the cells have acquired the characteristics of mature monocytes/macrophages, they display considerable heterogeneity in morphology and phenotypic plasticity. In general, their proliferative potential is limited, and their life span can vary from less than 1 day to many months, depending on their microenvironment, infections, and other stimuli. Although terminally differentiated, macrophages remain extremely active in messenger RNA and protein synthesis, with complex, often characteristic profiles of gene expression, depending on innate and acquired immune stimuli and cellular interactions. Tissue macrophages are relatively resistant to apoptosis, compared with neutrophils, but this feature changes during infection. Their active membrane turnover and endocytosis make them susceptible to toxic agents, making them targets for clearance by surviving macrophages. Sublethal injury and infection can also induce autophagy, increasingly recognized as an important component of inflammatory and infectious diseases.

The remarkable ability of macrophages to undergo homotypic cell–cell fusion results in giant cell formation. This is a feature of osteoclast differentiation, depending on M-CSF and the tumor necrosis factor (TNF) family member receptor activator of nuclear factor- κ B ligand (RANKL), which act on monocytic precursors to yield catabolic cells able to excavate and remodel living bone. Local adhesion and ruffling of their plasma membrane are associated with focal, polarized release of H⁺ and hydrolytic enzymes by monocyte-derived osteoclasts. The attempted uptake of non- or poorly degradable foreign materials induces “foreign-body giant cells,” with distinct properties; macrophage-derived giant cells are also characteristic of granulomatous diseases such as tuberculosis (Langerhans giant cells; Fig. 68–3) and parasitic infections (e.g., schistosomiasis). Mycobacterial and ill-defined host lipids are able to induce giant cell formation *in vitro*. The mechanism of fusion involves cellular differentiation to induce a fusogenic phenotype and

A

surface glycoprotein interactions with a selected substratum; T-helper type 2 (Th2) cytokines, such as IL-4 and IL-13, act through a common receptor chain and signaling pathway to enhance macrophage fusion.³⁴ DNA synthesis, a feature of high-turnover granulomata associated with infection, can result in abortive cell division and cell death. These macrophage-derived giant cells are distinct from syncytia induced by fusogenic virus infection, especially paramyxoviruses and retroviruses such as the human immunodeficiency virus.

HETEROGENEITY

Monocytes are defined as the population of differentiated cells present in the circulation, with classical morphologic features (Chap. 67), and include the less-well defined precursors able to give rise to myeloid DCs and osteoclasts. Because of their ready availability from human blood and the sensitive methods now available to analyze their phenotype *ex vivo* (FACS, microarray, immunochemistry, and cytochemistry), human monocytes have been more amenable to study, whereas in the mouse, analysis of precursor–product relationship and tissue distribution have provided new insights into the fate and heterogeneity of the circulating population. The number of monocytes in the circulation depends on constitutive, steady-state production and delivery from marrow, possibly from marginated pools in spleen, as well as adhesion and diapedesis in response to unknown stimuli and enhanced recruitment in response to peripheral stimuli such as infection and inflammation. M-CSF and glucocorticoids affect their level and phenotype, as do metabolic stimuli; Chap. 70 describes clinical conditions that give rise to monocytosis. The biochemical properties and functions of monocytes are described in Chap. 67. They are relatively radioresistant once entering the circulation, where they persist for 12 to 48 hours as motile cells, with an ability to engulf particles and to adhere transiently or more stably to arterial as well as microvascular endothelium, thus modulating their phagocytic ability. Depending on interactions with the vessel wall and local differentiation, monocytes are able to crawl along and patrol the intravascular surface utilizing CD11a, a β_2 -integrin–dependent property.²⁰ Mature macrophages lining the endothelium can also detach and recirculate, for example, filled with lipid stores as foam cells in atherosclerosis, and circulate heavily laden with erythroid breakdown products in malaria.

The presence of significant numbers of immune cells and molecules in adipose tissue suggest vibrant interactions between the immune and metabolic systems. In obesity, the inflammatory infiltrate and activation state of macrophages in adipose tissue may contribute to insulin resistance. The cellular localization and inflammatory potentials of macrophages,³⁵ as well as the ratio of macrophages to adipocytes,³⁶ differ in obese and lean mice. In lean mice, macrophages in the adipose tissue have the alternate or M2 phenotype (ARG1+CD206+CD301+), are uniformly distributed, and serve a protective function as they are less inflammatory and promote insulin sensitivity by producing IL-10; however, in obese mice, macrophages distribute around necrotic adipocytes, and induce inflammation and insulin resistance.^{35,37} CC-chemokine receptor 2 (CCR2) and its ligand (CCL2) are critical for macrophage recruitment to adipose tissue.³⁸ Metabolic disease can be viewed as maladaptive consequence of inflammation-induced insulin resistance, which may beneficially conserve energy resources for the immune system combatting infection for brief periods.^{39–43}

The precursors of myeloid DC and osteoclasts may represent a subpopulation of monocytes, whose further differentiation depends on cytokines and local factors in the vessel wall, marrow, and other tissues. *Ex vivo* substantial numbers of monocytes give rise to myeloid DC after treatment with GM-CSF and IL-4.³² Monocytes that differentiate into macrophages do not recirculate for the most part, but persist for varying times as “resident” tissue cells that turn over locally, especially in lymph

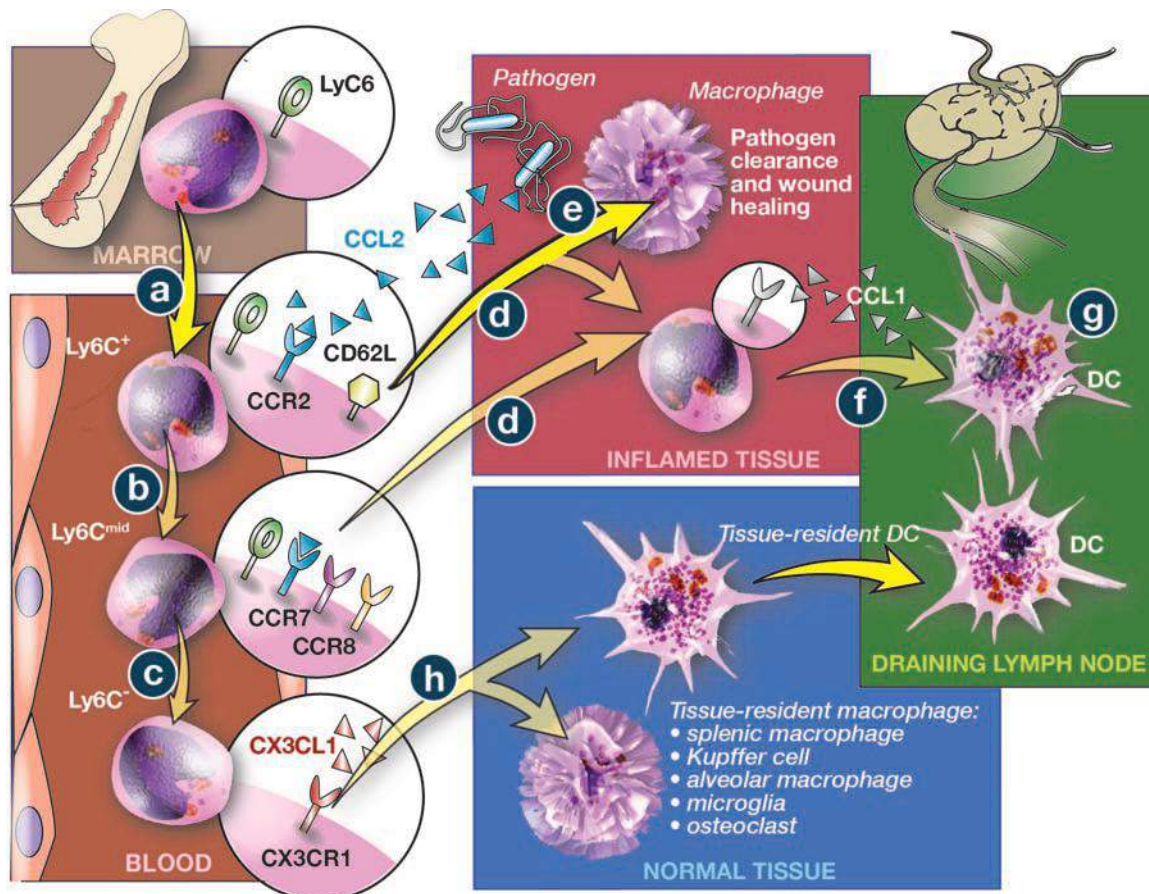

Figure 68-4. Heterogeneity of monocytes in blood and the contribution of different subsets to resident and inflammatory macrophages and DCs in tissues. For further details see Ref. 34. (Used with permission of S. Seif, GraphisMedica, 2014.)

nodes. It is not known if the constitutive exit from blood is a stochastic process or specific to particular tissues.

Phenotypic heterogeneity of monocyte populations has become a topic of intense interest, thanks to the availability of surface antigens/receptors such as CD14, CD16 (human), and Ly6C (mouse), and analysis of chemokine/receptor expression, especially fractalkine receptor (CX₃CR) and CCR2.³⁴ Figure 68-4 illustrates the subsets and tissue progeny established by the use of genetically manipulated mice and Table 68-1 compares expression of markers to characterize monocyte subsets in mouse and human blood. The relationship of monocyte precursor subsets that give rise to inflammatory tissue macrophages and DCs is better defined than is that of those that give rise to resident cells, which turn over more slowly. Current studies aim to elucidate the subset origin of other recruited populations, for example, in atherosclerosis, normal CNS, and tumors, and in response to metabolic, traumatic, or degenerative injury. Conceptually, it is still not clear how stable these apparently distinct subsets are or whether they represent part of a continuous phenotypic spectrum, arising by modulation of subpopulations rather than irreversible, true differentiation. Separation and microarray analysis of freshly isolated monocytes will yield further information regarding this question, providing novel markers and diagnostic signatures. Removal from an *in vivo* environment, as well as *in vitro* artifacts, can profoundly alter the phenotype and function of monocytes in such studies. Imaging and *in situ* analysis may enable single-cell direct studies of their fate.

Monocyte/macrophages have a major role in the development and progression of cardiovascular disease.^{44,45} In acute myocardial infarction

macrophages with an M1 proinflammatory profile migrate to the cardiac tissue and are involved in cardiac remodeling (Chap. 134).⁴⁶

In atherogenesis, there is recruitment of monocytes into the vascular wall at sites of turbulent flow. Once within the subendothelial tissue, the monocytes differentiate into macrophages and engulf oxidized low-density lipoprotein accumulated in arteries, leading to foam cell formation, atheroma development, and the secretion of profibrotic agents by adjacent vascular smooth muscle cells, resulting in a fibrous cap formation. Thus, vascular wall macrophages are key factors in initiating the atherosclerotic lesion. Moreover, macrophages activate the coagulation cascade (Chap. 67) inducing thrombus formation and vascular occlusion.

Resident Macrophage Populations in Adult Tissues Overview

It is important to describe first the nature of those macrophages present throughout the body as resident populations, in the absence of overt inflammation, before considering the altered monocyte-derived macrophages recruited to local sites by infectious or sterile inflammatory (e.g., metabolic) stimuli. The properties of such elicited macrophages are well established and are described in Chap. 67. However the functions of resident macrophages, especially in different organs, are still mysterious and are considered in outline here, with further details in Chap. 67.

The use of differentiation antigens such as F4/80 and cd68 (mouse) and CD68 (human) has made it possible to define resident macrophage populations in mouse tissues,⁴⁷ and to compare their anatomic relationships in the two species (Table 68-2). F4/80 (EMR1), a member of a family of epidermal growth factor-7 transmembrane (EGF-TM7)

plasma membrane molecules, is broadly present and almost exclusive to macrophages (Fig. 68-5A to C).^{48,49} It is related to G-protein-coupled chemokine receptors in structure, but has a large epidermal growth factor (EGF) domain extracellular extension, thought to be involved in adhesion to extracellular matrix. The human members of this family are more broadly present on myeloid cells; EGF module-containing mucin-like hormone receptor 2 (EMR2) is a useful tissue marker for human macrophages, although it is also present in neutrophils and immature DCs (Fig. 68-5A). Additional macrophage antigen markers useful for immunocytochemical and FACS analysis include Siglec1 (Fig. 68-5D), a sialic acid-binding lectin, the β_2 integrins

TABLE 68-2. Selected Markers of Mononuclear Phagocytes and Related Cells

Cell Type	Antigen Markers	Other Properties
Monocytes/macrophages	F4/80 (mouse) EMR2 (human) CD68 CR3 (CD11b) Sialoadhesin (Siglec-1) Scavenger receptors (SR-A, MARCO) Mannose receptor M-CSF receptor	Opsonic phagocytosis; lysozyme secretion; abundant acid hydrolases

ATPase, adenosine triphosphatase; DC, dendritic cell; DC-LAMP, dendritic cell lysosomal-associated membrane protein; DC-SIGN, dendritic cell-specific intercellular adhesion molecule-3-grabbing nonintegrin; EMR, epidermal growth factor module-containing mucin-like hormone receptor; M-CSF, macrophage colony-stimulating factor; MARCO, macrophage receptor with collagenous structure; MHC, major histocompatibility complex; TRAP, tartrate-resistant acid phosphatase.

NOTE: Marker expression is variable, depending on cell localization, maturation, and activation. Some markers are also present on other myeloid cells, e.g., polymorphonuclear cells, and selected endothelial cells.

CD11b/CD18 (Mac1, CR3), and CD11c, present on DCs and selected, especially alveolar, macrophages.⁵⁰ Receptor antigen markers include SR-A,⁵¹ a broadly expressed macrophage receptor additionally found on sinusoidal endothelium, whereas MARCO (macrophage receptor with collagenous structure), a related collagenous SR, is more restricted in expression.⁵² Additional markers include lectins such as the macrophage mannose/fucose receptor (MR; Fig. 68-5E).⁵³ CD163, a receptor for hemoglobin-haptoglobin complexes, is induced by glucocorticoids,⁵⁴ IL-10,⁵⁴ and substance P.⁵⁵ Complement receptors (CRs) and Fc receptors (FcRs) are described in Chap. 67.

The resident macrophages in tissues constitute a major dispersed organ system, responsive to endogenous and exogenous stimuli; they are highly active in uptake of particles and soluble ligands, providing not only sentinels for defense at portals of entry, but also mediating the

Figure 68-5. Immunocytochemical detection of macrophages in human (A) and mouse (B to E) lymphohematopoietic tissues. A. Tonsil. EMR2-positive macrophages are scattered throughout follicles and interfollicular areas. B. Liver. Kupffer cells are F4/80+, unlike sinusoidal endothelium and hepatocytes. C to E. Spleen. C. Red pulp macrophages express F4/80, unlike marginal zone cells. Macrophages in T-cell area are F4/80-, except for periarteriolar processes. D. Marginal metallophilic macrophages express sialoadhesin (Siglec1) strongly; red pulp macrophages are weakly positive. E. A subset of marginal metallophilic macrophages binds a chimeric protein probe of the cysteine-rich domain of the MR-human Fc. For details see Ref. 91. (A, used with permission from T. Marafioti. B to E, reproduced with permission from Taylor PR, Zamze S, Stillion RJ, et al: Development of a specific system for targeting protein to metallophilic macrophages. Proc Natl Acad Sci USA 101(7):1963–1968, 2004.)

clearance of damaged or dying cells and modulating the properties of viable neighboring cells. In sum, these cells provide a homeostatic, trophic function that is often overlooked in considering their role in cytotoxicity and antimicrobial host defense. The properties of macrophages in hematomalymphoid organs and other tissues, with special relevance to hematologic aspects, are discussed in detail.

● DISTRIBUTION

HEMATOPOIETIC ORGANS

Marrow

It is often overlooked that mature macrophages are important constituents of the hematopoietic stroma,⁵⁶ along with fibroblastic mesenchymal cells, osteoblasts, and endothelial cells, contributing to hematopoiesis beyond their own differentiation (Figs. 68–6A to E and 68–7). Stromal macrophages in hematopoietic island clusters associate with developing erythroid and other granulocytic cells through nonphagocytic, cell–cell adhesion receptors, such as sialoadhesin and a divalent cation-dependent receptor, as described for fetal liver. The potential trophic functions provided by stromal macrophages are ill-defined but include surface-expressed and secreted growth factors and cytokines. Stromal macrophages are actively endocytic and clear erythroid nuclei and apoptotic hematopoietic cells as required, rapidly degrading them for possible reutilization of iron and other nutrients. Stromal macrophages also interact with less-differentiated hematopoietic precursors through release of potent secretory products, such as IL-1, and with lymphocytic populations, including plasma cells, through IL-6. They are targets for infectious agents, for example, mycobacteria, lentiviruses, and retroviruses, and serve as reservoirs in many chronic infections, while

expressing a reduced killing capacity, as demonstrated for other resident macrophage populations.

Several monocyte and macrophage populations coexist in the marrow compartment; a network of stromal macrophages, clustered in hematopoietic islands, the developing monocytes, as well as osteoclasts and isolated macrophages in apposition to bone surfaces. Mature macrophages in human marrow contain prominent inclusions in storage disorders, such as Gaucher disease and hemosiderosis. Hemophagocytosis, a consequence of perforin deficiency in some patients, and seen in genetic syndromes and postviral infection, is a striking manifestation of excessive macrophage cytopathic activity in the marrow.^{57,58} Uptake of opsonized platelets by macrophage FcR and CRs in stromal and other resident tissue macrophages are important features of thrombocytopenic syndromes.

The hematopoietic stem cell lineage which gives rise to monocyte-macrophages and myeloid DCs also leads to production of the osteoclast lineage.^{59,60} Following interaction via Stat4 and RANKL (regulator of activation of nuclear factor- κ B), a member of the superfamily of TNE, cells undergo differentiation, fusion, attachment to bone as osteoclasts and then function in bone remodeling.⁶¹

A common marrow progenitor cell that gives rise to both monocytes and DCs has been defined,²⁰ including both classical DCs and the plasmacytoid DCs.^{62,63} This common marrow progenitor cell circulates in the blood and seeds lymphatic tissues.^{62,63} These short-lived, migratory cells modify T-cell responses and, unlike Langerhans cells, are replaced by bloodborne precursors.^{41,42} The central activity of immature classical DCs is phagocytosis, while that of mature classical DCs is cytokine production.^{62,63}

Dendritic cells that occur in lymphoid and nonlymphoid organs have a major role in processing and presenting antigens, leading to

Figure 68-6. Stromal macrophages in human marrow associate with developing hematopoietic cells in islands/clusters. Immunocytochemical staining with antimacrophage monoclonal antibody Y1/82A of marrow section reveals a network of arborizing stromal macrophages uniformly distributed throughout the marrow interstitium (alkaline phosphatase–antialkaline phosphatase [APAAP] stain; hematoxylin counterstain). **B.** Marrow cells depleted of red cells and other single cells are enriched for cell clusters, most of which are erythroid clusters with a central stromal macrophage (arrows; Giemsa). **C.** Isolated erythroid cluster with intermediate and late normoblasts surrounding a central stromal macrophage (Giemsa). **D.** Isolated mixed cluster with both myeloid and erythroid cells attached to a central stromal macrophage. A dividing cell (arrow) is seen (Giemsa). **E.** Isolated erythroid clusters from a pathologic marrow sample show intense staining for hemosiderin of stromal macrophages with cellular processes extending between attached erythroblasts (Perl acid ferrocyanide reaction; counterstain neutral red). **F.** Immunocytochemical stain with antibody Y1/82A of isolated erythroid cluster. Both the stromal macrophage cell body and processes (arrows) between attached erythroblasts are visible (APAAP stain; hematoxylin counterstain). Bar = 50 μm . (Reproduced with permission from Lee, S.H. et al.: Isolation and immunocytochemical characterization of human bone marrow stromal macrophages in hemopoietic clusters. *J Exp Med* 168(3):1193–1198, 1988.)

unique T cell function. The “classical” DC develops from a precursor which is dependent on the growth factor receptor.^{62–64}

Spleen

From the macrophage point of view, the spleen is the most complex organ in the body.^{65,66} Our knowledge is based mainly on the mouse and we know there is considerable species variation,⁶⁷ as well as constitutive hematopoiesis in mouse spleen. Subpopulations observed in the mouse by marker and genetic knockout experiments include (1) macrophages in the red pulp, white pulp, and in the marginal zone, itself M-CSF dependent,³⁰ and (2) heterogeneous, more phagocytic “metallophilic” macrophages in the outer marginal zone. Characteristic phenotypic markers are available to identify macrophages in mouse spleen (see Fig. 68–5C to E). The F4/80 antigen and the mannose receptor (MR) are restricted to mature macrophages in the red pulp, whereas CD68 is a marker for all macrophages, as well as DCs, although the mainly intracellular expression of CD68 is less prominent in DCs. There are several well-characterized markers for mouse metallophilic macrophages, including sialoadhesin (Sn), a poorly characterized protein recognized by the MOMA-1 monoclonal antibody, and ligands for MR cysteine-rich domain-Fc chimeric proteins (see Fig. 68–5E). The splenic marginal zone macrophage population develops postnatally,⁶⁸ in parallel with antipolysaccharide responses to encapsulated bacteria. Functions of splenic marginal zone macrophages include clearance of senescent erythrocytes and neutrophils (red pulp), targeting of circulating antigens and pathogens (marginal zone), interferon (IFN) production, induction of secondary adaptive immune responses, regulation of hematopoiesis, and iron storage. Markers for the outer marginal zone macrophages include MARCO and SIGNR1, a mouse homologue of dendritic cell-specific intracellular adhesion molecule-3–grabbing nonintegrin (DC-SIGN). The spleen is also a site for storage and rapid deployment of monocytes, which participate in wound healing and play a role regulation of inflammation.⁶⁹

Lymph Nodes

Lymph node macrophages are also heterogeneous, with distinctive Sn subcapsular cells, corresponding to marginal metallophilic in their marker expression, and F4/80+ macrophages in germinal follicles and in the hilus. Macrophages in T-lymphocyte-rich areas are F4/80– or dim, as in T-cell areas in spleen, but express CD68. It is thought that antigen enters lymph nodes via afferent lymphatics and two photon experiments have defined the possible transfer of viral and other antigens and immune complexes to B lymphocytes after capture by the subcapsular sinus macrophages.⁷⁰ Their contributions to the initiation of adaptive immune responses, compared with DCs, are unclear. Tingible body macrophages arise from the clearance of apoptotic B cells in germinal centers, as in the spleen.

Nonlymphohematopoietic Organs

In bulk, the gastrointestinal tract represents the largest accumulation of F4/80+ macrophages in the body, extending throughout the upper and lower gut. The small intestine is essentially sterile, and the abundant F4/80+ resident macrophages in the lamina propria express a distinct phenotype, ascribed to TGF- β production by adjacent cells.^{56,71–73} The liver contains an abundant population of sinusoidal F4/80+ Kupffer cells, which share some properties (FcR, MR, SR-A) with sinusoidal endothelium, which lacks F4/80. The skin has F4/80+ epidermal Langerhans cells and F4/80+ dermal macrophages, which can migrate to draining lymph nodes and differentiate into antigen-presenting DCs.^{74,75} The lung has a distinctive F4/80– or dim alveolar macrophage population, as well as interstitial F4/80+ macrophages. Alveolar macrophages are CD11c+ and express a range of nonopsonic phagocytic

Figure 68-7. Sialoadhesin (Siglec1) (arrowheads) is clustered at sites of stromal macrophage adhesion to developing cells (**B**, granulocytes; **C**, eosinophils) but diffusely present in association with erythroblasts (**A**). For details see Ref. 93. (Reproduced with permission from Crocker PR, Werb Z, Gordon S, et al: Ultrastructural localization of a macrophage-restricted sialic acid binding hemagglutinin, SER, in macrophage-hematopoietic cell clusters. *Blood* 76(6):1131–1138, 1990.)

receptors (MR, SR-A), as well as FcR, but lack CR3. These cells also contain particle debris, cigarette smoke residue, and abundant lysozyme, because of exposure to irritants and uptake of carbon and dust particles, as well as of mucosal secretions in the airway.

The central nervous system contains an extensive network of F4/80+ CR3+ microglia, derived from monocytes during development, when they remove apoptotic neurons.¹⁸ They differentiate into characteristic membrane-rich arborized forms within the neuropil and persist throughout adult life. Their function is obscure but may involve homeostasis and catabolism of neurotransmitters. In addition, there are perivascular F4/80+ macrophages (also MR+ SR-A+) and other F4/80+ populations in the meningeal space and choroid plexus. The endocrine, exocrine, reproductive, and urinary tracts all contain macrophage populations at sites of phagocytosis (ovary, testes) and hormonal metabolism (adrenal, thyroid, for example).⁷¹ Precise characterization of these cell types using monoclonal antibodies with specificity for human cell types in tissue requires further analysis.

● ACTIVATION STATE

RECRUITMENT OF MONOCYTES IN RESPONSE TO INFLAMMATION AND TUMORS

The stimuli that give rise to induced recruitment of monocytes, with or without accompanying myeloid and/or lymphoid cells, and the mechanisms involved are better understood than those of constitutive tissue localization. Bacterial infections induce enhanced myelomonocytic cell recruitment and follow the stages established for neutrophils, transient arrest, and rolling on the microvascular endothelium, mediated by L-selectin, and initiated by chemotactic stimuli acting via G-protein-coupled chemokine receptors (Fig. 68-8). The β_2 integrins CD11a/CD18 and CD11b/CD18 mediate more stable adhesion. This is followed by diapedesis and interactions with CD31. Receptors implicated in subsequent extravascular migration are less defined but may include the fractalkine receptor, and intravascularly, β_1 - and β_2 -integrin, CD44, and

EMR2. The evidence for an important role of L-selectin and β_2 integrins in human phagocyte recruitment to inflammatory stimuli comes from human inborn error syndromes, mouse genetic experiments, and antibody inhibition. The role of the common β_2 -integrin chain (CD18) and definition of leukocyte adhesion deficiency syndrome provided a powerful paradigm for further experimental study of CD11/CD18.^{76,77} Cellular signaling gives rise to dynamic changes in migration/adhesion and cytoskeletal reorganization outlined further in Chap. 67. Studies of tumor-associated macrophages (TAMs) in mouse model systems, particularly mammary cancer, have identified a population of unique macrophages. The TAMs develop from marrow-derived macrophages that are inflammatory phenotypes and are recruited to the tumor.^{78,79}

Mononuclear cell recruitment without that of other myeloid cells is a feature of viral infection and modified forms of inflammation observed in metabolic diseases, atherosclerosis, storage disorders, autoimmunity, and tumors. Different chemokine receptors and cell adhesion molecules account, in part, for more selective monocytic recruitment, although some are shared. The phenotypic heterogeneity in monocyte subsets is characterized by quantitative differences in expression of plasma membrane molecules resulting in differential recruitment of subsets in response to different stimuli. Once in the tissues, their subsequent fate also varies markedly, depending on the local environment, where newly recruited monocytes respond to tissue-specific factors. A striking example is that observed in the neutrophil, where monocytes can differentiate over a few days into highly arborized, activated microglia, resembling locally reactivated resident microglia.¹⁸ Thus, it becomes progressively more difficult to distinguish newly recruited from initially resident cells through marker analysis. Direct observation by fluorescent imaging *in vivo* may define precursor-product relationships more clearly. Similar issues arise in other organs, for example, lung, liver, gut, and even in skin, where static observations can be misleading. There are also common features of recruited cells irrespective of the local tissue environment, including the expression of CD11b/CD18 and monocytic adhesion molecules, and metabolic markers, such as the ability to undergo a respiratory burst and an increased proliferative potential and

Figure 68–8. Recruitment. Stages of monocyte adherence to endothelium and diapedesis, induced by inflammatory stimuli. The model is mainly based on the recruitment of neutrophils, with which it shares many features, although monocyte-specific chemokines, receptors, and adhesion ligands exist, especially in constitutive and noninfectious, metabolic forms of inflammation. PECAM, platelet endothelial cell adhesion molecule.

high cell turnover rate. These monocytic markers tend to decline upon further macrophage differentiation, and in the case of myeloperoxidase may not be renewed after degranulation.

HETEROGENEITY OF MACROPHAGES IN TISSUES: IMMUNOMODULATION

Characterization of the macrophages found in tissues has yielded insights into their versatility in response to microbial constituents and cytokines produced by lymphoid, other immune and nonimmune cells. Adhesion to extracellular matrix, metabolites, vascular, and hormonal changes all influence the macrophage phenotype. This variety of stimuli can selectively activate or deactivate macrophage gene and protein expression, regulating their function. Figure 68–9 illustrates some of the stereotypic signature phenotypes, and Chap. 67 further describes the innate recognition mechanisms and functional responses.

Broadly considered, it is convenient to distinguish several clusters of activation properties; innate, classical, and alternative activation, and deactivation. The definition of activation has a long and confusing history, has mainly been based on limited models of analysis, typically peritoneal macrophages *in vivo* and *in vitro*, and on studies with macrophage-like cell lines. The advent of microarrays and of proteomics and systems biology has generated increasingly detailed information. It makes sense to schematize the interactions of monocytes and macrophages with microorganisms, microbial products, and Th1/Th2 lymphocytes, although this is subject to revision as CD4 T-lymphocyte

heterogeneity continues to grow in complexity, with the description of Th17, FoxP3+, and other regulatory T cells. Further details are given in Chap. 67.

INNATE ACTIVATION

For this discussion, innate activation is defined as direct microbial stimulation by intact bacteria or their constituents, such as LPS acting via toll-like receptor (TLR) sensors, in the absence of the major Th1/2 cytokines. For example, ethanol-killed *Neisseria meningitidis*, a potent immunomodulator with adjuvant-like properties, stimulates the expression of two useful markers on macrophages: MARCO and CD200. Expression of MARCO, a class A SR, is remarkably specific for macrophages (and DCs) and is regulated developmentally on the outer marginal zone macrophages, but it is inducible on most macrophage populations by TLR and myeloid differentiation factor 88 (MyD88)-dependent bacterial stimuli. It is a phagocytic and adhesion receptor providing an adaptive, enhanced ability to take up *Neisseria* and other bacteria, after innate activation. CD200, an immunoglobulin (Ig) superfamily member, is widely expressed on many cells, but not on resident macrophages, and part of an immunoregulatory receptor pair with CD200 R, is also induced on macrophages by innate stimuli.

Lectins, such as Dectin-1, control innate activation of macrophages by β glucans in fungal walls,⁸⁰ in collaboration with TLR pathways, as discussed in Chap. 67. TLR-independent innate activation by viruses, parasites, and other pathogen-associated stimuli requires further study.

Figure 68-9. Immunomodulation of macrophage phenotype by cytokines, microbial constituents, and glucocorticosteroids. CCL, chemokines; CR, complement receptor; DC-SIGN, dendritic cell-specific intercellular adhesion molecule-3-grabbing nonintegrin; EMR, epidermal growth factor module-containing mucin-like hormone receptor; FPR1, formyl-peptide receptor 1; FPR-L1, formyl-peptide receptor-like 1; GC, glucocorticoids; IL, interleukin; IFN γ , interferon- γ ; LPS, lipopolysaccharide; MARCO, macrophage receptor with a collagenous structure; MRC-1, mannose receptor C-type 1; NO, nitric oxide; PECAM, platelet endothelial cell adhesion molecule-1; ROS, reactive oxygen species; SR-A, scavenger receptor A; TLR, toll-like receptor; TNF- α , tumor necrosis factor- α . Further details on innate modulation of phenotype by microbial products are given in Chap. 67. CYTOKINE-INDUCED PRIMING AND ACTIVATION: CLASSICAL AND ALTERNATIVE ACTIVATION

Investigations in normal humans, pathologic states, and animal models have led to the characterization of different states of macrophage polarization (Fig. 68-10).⁸¹ The terms macrophage “activation” and “polarization” require well-defined nomenclature and experimental guidelines. It has been recommended that the term “activation” be used to refer to perturbation of macrophages with exogenous agents the same way that many authors use “polarization.”⁸² Studies of *in vitro*, *ex vivo*, and *in vivo* cells from animals and humans have led to descriptions of complex cellular structural, biochemical, and functional activation states of macrophages. Consequently, it is essential to describe the properties of the macrophage its activation/polarization state. There are various nomenclatures and Fig. 68-10 indicates the major features of the M1–M2 dichotomy. This dichotomy, however, is more of a continuum and there are transitional states. The most useful approach is to describe the spectrum of activation states by cell isolation technique, membrane receptors, cytokines, chemokines, and metabolic markers, and when possible, genetic modifications producing shifts in activation phenotype. This approach is essential for deciphering the role of monocyte-macrophages in disease pathogenesis.

Macrophage polarization usually is driven by unique pattern recognition receptors (PRRs). Classical activation of macrophages or M1 in general⁸³ have a proinflammatory profile. This pathway is triggered by IFN- γ followed by a microbial stimulus, LPS. The M1 macrophage is characterized by high antigen presentation and production of IL-12, IL-23, nitric oxide, and proinflammatory cytokines, including IL-1, TNF- α , IL-6, and CXCL-1, -2, -3, -5, -8, -9, and -10. The pathway to the

alternative M2 macrophage is mediated by IL-4, IL-10, and IL-13. These cells demonstrate enhanced expression of Dectin-1, MR C1 (CD206), CD163, CCR2, CXCR1, CXCR2, and DC-SIGN.⁸⁴ M2 produce high levels of IL-10 and low-levels of IL-12.⁸⁵ IFN- γ , produced mainly by natural killer cells and activated Th1 CD4+ and CD8+ cytotoxic lymphocytes, induces a set of macrophage biosynthetic and effector responses, known as classical activation, because of its well-established role in enhanced macrophage functions in cell-mediated immunity, inflammation, and host defense, particularly against intracellular pathogens. Full activation of effector functions, such as the respiratory burst and generation of oxidative nitrogen metabolites, depends on a two-stage mechanism of priming by the cytokine, via specific IFN- γ receptors, followed by a local stimulus, LPS, or other TLR ligands. Although essential for host defense, including against opportunistic pathogens such as found in patients with the acquired immunodeficiency syndrome, classical activation is responsible for tissue injury and its consequences in inflammatory bowel disease, tuberculosis, and rheumatoid arthritis, although additional immunopathogenic agents, such as immune complexes, also contribute. Biochemical and cellular aspects of classical activation are described in Chap. 67.

The Th2 cytokines IL-4 and IL-13, acting via a common receptor chain as well as distinct receptors, induce a characteristic signature of altered gene expression in macrophages known as alternative activation.^{86,87} Such primed macrophages can be induced to respond further to local, TLR-dependent phagocytic stimuli to secrete enhanced levels of proinflammatory cytokines, analogous to classically activated macrophages. Alternative activation is associated with allergy and parasitic infection, and has been implicated in humoral immunity, control of Th1-dependent inflammation, and host defense to extracellular pathogens, such as helminths. It can promote repair or, if excessive, fibrosis.

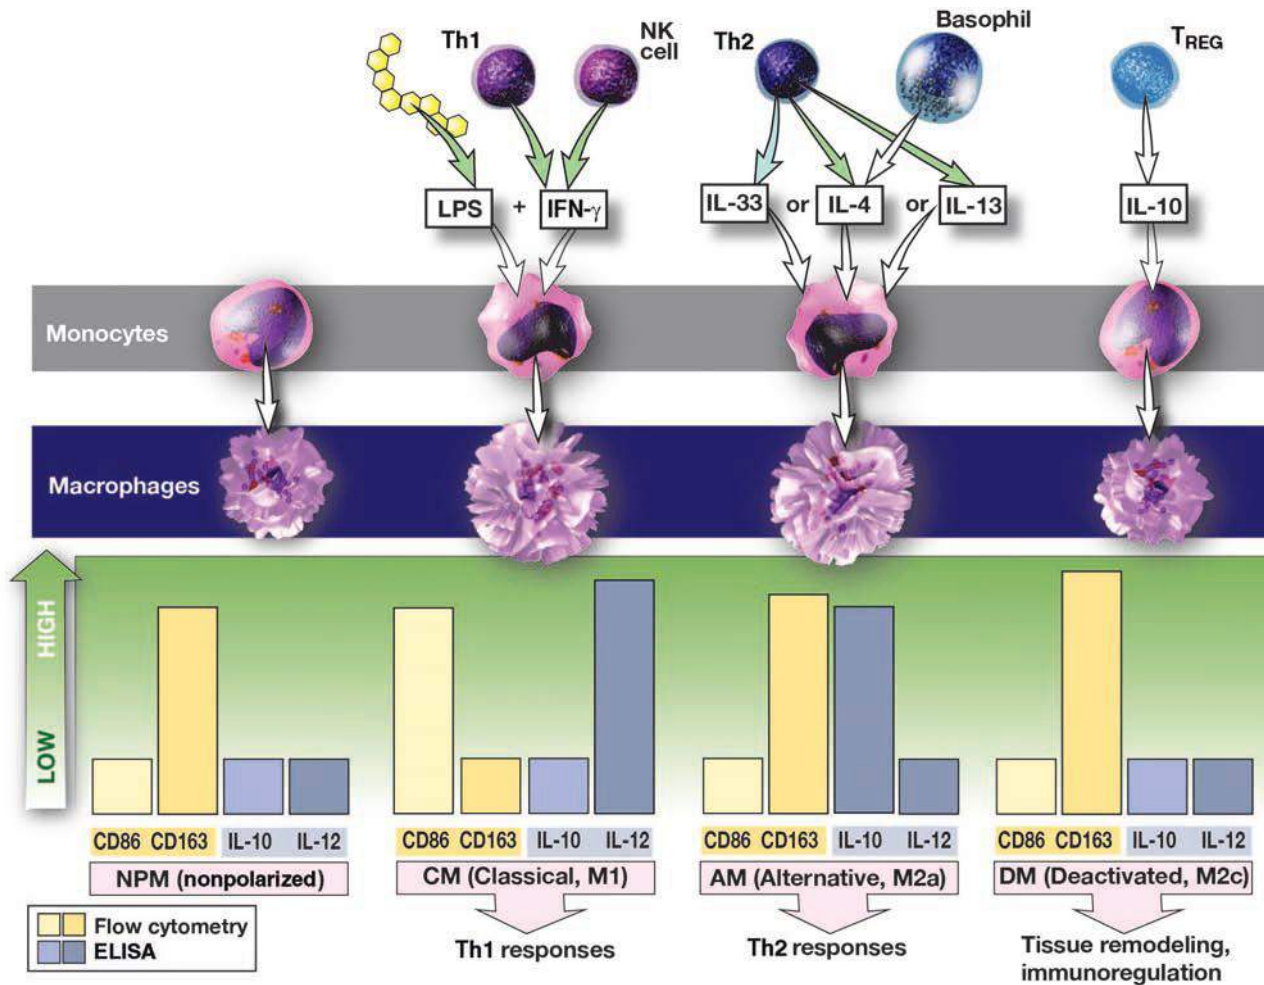

Figure 68–10. Schema of states of monocyte-macrophage activation. AM, alternative M2A; CM, classical (M) activation; DM, M2C deactivated; NPM, nonpolarized. Membrane markers expression in yellow. Flow cytometry and cytokines enzyme-linked immunosorbent assay (ELISA) in blue. IFN- γ , interferon- γ ; IL, interleukin; LPS, lipopolysaccharide; NK, natural killer; Th1/Th2, T-helper type 1/2; T_{REG}, T regulatory cell. (Used with permission of S. Seif, GraphisMedica, 2014.)

Other forms of alternative activation have been described after stimulation of macrophages by immune complexes, acting via FcR. A major G-protein-coupled receptor that is important in macrophage activation is the Neurokinin-1 receptor.⁸⁸ This receptor, which has a full-length form and a truncated splice variant, is important in macrophage signaling and calcium fluxes.^{89,90} An important caveat is that there are substantial species differences in the marker changes depending on the differentiation and prior activation state of the macrophages.

IL-10 is a major deactivating cytokine for macrophages, produced by the macrophages themselves, as well as by Th2 lymphocytes and other sources. Acting through its own receptor, it counteracts IFN- γ , and can potentiate IL-4-induced actions. Other antiinflammatory regulators of macrophages activation include glucocorticoids and prostaglandin E₂. Although less-well defined, the overall gene and protein expression profiles of macrophages are also markedly influenced by the extracellular matrix, hormones, and other immunomodulators, so that modified forms of inflammation are associated with macrophages present in lipid-rich environments, tumors, and metabolic diseases. Finally, cell-cell interactions, as well as intracellular regulatory networks, profoundly influence the functions of macrophages, and are described in Chap. 67.

CHAPTER 69

CLASSIFICATION AND CLINICAL MANIFESTATIONS OF DISORDERS OF MONOCYTES AND MACROPHAGES

Marshall A. Lichtman

SUMMARY

Disorders that exclusively result in abnormalities of monocytes, macrophages, or dendritic cells are uncommon and usually are referred to, pathologically, as histiocytosis. These disorders can be inherited, such as familial hemophagocytic lymphohistiocytosis; inflammatory, such as infectious hemophagocytic lymphohistiocytic syndrome; or clonal (neoplastic), such as Langerhans cell histiocytosis. They can result from an inherited enzyme insufficiency in macrophages that lead to exaggerated storage of macromolecules, such as in Gaucher disease. Monocytes are critical sources for proinflammatory and inflammatory cytokines and, when inappropriately activated, can result in the lymphohistiocytic hemophagocytic syndrome with fever, intravascular coagulation, and organ pathology. A variety of hematopoietic neoplasms may have a phenotype characterized by a large proportion of monocytes. Idiopathic (clonal) monocytosis is a rare manifestation of a myelodysplastic syndrome. Some cases of myelogenous leukemia have progenitor cells that mature preferentially into leukemic monocytes, including acute monoblastic or monocytic leukemia, chronic myelomonocytic leukemia, and juvenile myelomonocytic leukemia. Two acquired diseases, hairy cell leukemia and aplastic anemia, result in a severe depression of blood monocytes (along with other blood cell types). Mutations in *GATA2* are associated with severe monocytopenia and mycobacterial infections (the MonoMAC syndrome). Inherited disorders affecting white cells, such as chronic granulomatous disease and Chédiak-Higashi syndrome, result in impaired monocyte function. Monocyte dysfunction may accompany a variety of severe illnesses, such as sepsis, trauma, and cancer. Monocytes also contribute to a variety of diseases, such as Crohn disease and rheumatoid arthritis, by virtue of their being a principal source of tumor necrosis factor. Monocytes play a pathogenetic role in other complex, acquired disorders, such as thrombosis and atherogenesis. Table 69–1 catalogues the qualitative and quantitative abnormalities of monocytes, macrophages, and dendritic cells.

Acronyms and Abbreviations: CD, cluster of differentiation; GM-CSF, granulocyte-macrophage colony-stimulating factor; HLA-DR, human leukocyte antigen-D related; IL, interleukin; MonoMAC, monocytopenia and mycobacterial infections syndrome; TNF, tumor necrosis factor.

CLASSIFICATION

Classification of monocytic disorders is difficult because few abnormalities result solely in a disturbance of monocytes or macrophages. However, the presence of monocytopenia, monocytosis, histiocytosis, or qualitative disorders of monocytes may be an important diagnostic feature or contribute to the functional abnormality in the patient.

The terms *histiocyte* and *macrophage* are synonymous. The latter term is customary when discussing the biology of the cells of the *mononuclear phagocyte system*, which is the total pool of marrow, blood, and tissue monocytes and macrophages, formerly referred to as the *reticuloendothelial system*. In disease nosology, the terms *histiocyte* and *histiocytosis* continue to be used for diseases that principally involve cells derived from blood monocytes, that is, macrophages and monocyte-derived dendritic cells.

The physician should consider the absolute monocyte count and not the percent of cells that are monocytes when evaluating the differential blood cell count before concluding that there is an inappropriate content of blood monocytes (Chap. 70).

Table 69–1 lists a classification of monocyte and macrophage disorders of relevance to hematologists.

MONOCYTOPENIA

Table 69–1 contains several important causes of monocytopenia. Two notable examples of disorders accompanied by severe monocytopenia are aplastic anemia and hairy cell leukemia. Pancytopenia is usual in both conditions, but the predisposition to serious infection is heightened by the deficiency in monocyte production. In hairy cell leukemia, the severe monocytopenia represents an important diagnostic clue because of its constancy. A syndrome of profound monocytopenia, often a monocytosis, associated with susceptibility to mycobacterial avian complex, fungal, and disseminated papilloma virus infections, and subsequent development of myelodysplasia or acute myelogenous leukemia in some cases, was first described in 2010 (see Table 69–1). It is accompanied by blood B-cell lymphopenia and decreased circulating and tissue dendritic cells, but not by hypogammaglobulinemia or a deficiency of tissue macrophages or skin Langerhans (dendritic) cells. It is the result of mutations of *GATA2* that impair transcription of its mRNA and is usually inherited as an autosomal recessive or can occur sporadically. The mutations of *GATA2* were found in germline and hematopoietic tissues, adding it to the familial leukemia genes, as well as to a slow onset (sometimes decades), complex immunodeficiency state.

MONOCYTOSIS AND HISTIOCYTOSIS

Table 69–1 contains a comprehensive list of causes of monocytosis. Monocytosis is often the manifestation of an inflammatory or a neoplastic disease. Certain hematopoietic tumors, especially acute monocytic and chronic myelomonocytic leukemia, have as their principal manifestation a predominance of monocytic cells in marrow and blood. Occasionally, chronic monocytosis can precede the onset of acute myelogenous leukemia, representing an uncommon manifestation of the myelodysplastic syndromes. Dendritic cell variants of acute myelogenous leukemia have also been discovered since the advent of immunophenotyping and genotyping of acute leukemias. The precise derivation of these myeloid dendritic cells is uncertain (i.e., granulocytic or monocytic). In some cases of monocytic leukemia, the malignant clone does not appear to include progenitors of red cells and platelets. Such cases are not likely to be the result of a mutation of a multipotential hematopoietic cell. This type of progenitor cell monocytic leukemia and other histiocytic or dendritic cell tumors support the concept that primitive

cells, committed to the monocyte-macrophage lineage, can undergo malignant transformation (Chaps. 83 and 88).

Several uncommon types of histiocytosis are serious systemic diseases that may masquerade as malignant disease. However, in such cases the cytopathologic changes in monocytes or macrophages do not constitute a malignant transformation and are not monoclonal. Familial and sporadic hemophagocytic lymphohistiocytosis, infection-induced hemophagocytic syndromes, and sinus histiocytosis with massive lymphadenopathy are among such disorders (Chap. 71). Infectious hemophagocytic histiocytosis caused by Epstein-Barr virus may be a

hybrid disease because of the association with an underlying monoclonal or oligoclonal proliferation of virus-infected lymphocytes. The striking activation of macrophages and the resulting cytokine elaboration and organ pathology seen in some patients with juvenile rheumatoid arthritis, referred to as the “macrophage-activation syndrome,” is closely related to other types of hemophagocytic syndromes (Chap. 71). Pediatric rheumatologists refer to the hemophagocytic syndrome in patients with juvenile rheumatoid arthritis as the “macrophage activation syndrome,” but the clinical expression is closely analogous to other acquired hemophagocytic lymphohistiocytic syndromes. In these

hemophagocytic syndromes, it is currently thought that the inherited or acquired inability of natural killer cells and cytotoxic T lymphocytes to modulate and, eventually, abrogate the immune response is responsible for the pathologic events of cytokine storm, fever, intravascular coagulation, organ dysfunction, and intense hemophagocytosis. Tumors of histiocytes (or dendritic cells) are rare, but can be classified into several groups with a combination of morphologic and immunophenotypic markers (Chap. 71).

● QUALITATIVE DISORDERS OF MONOCYTES

Inherited abnormalities can result in dysfunctional macrophages (see Table 69–1). In these situations the abnormality is usually shared by other leukocytes, as in chronic granulomatous disease, which results from a defect in oxygen-dependent microbial killing. In Chédiak-Higashi disease, defective macrophages result from an abnormality in their cell and granule membranes (Chap. 66). An indomethacin-sensitive monocyte-killing defect in children is associated with a predisposition to atypical mycobacterial disease. Also, inherited or enzyme deficiencies in macrophages can result in accumulation of undegraded macromolecules, leading to various types of storage diseases. A classic example is Gaucher disease, a disorder that results from an inherited deficiency of the enzyme glucocerebrosidase, in which tissue damage results from the engorgement of macrophages with the enzyme substrate. Recombinant glucocerebrosidase, which enters macrophage lysosomes by endocytosis, can ameliorate this macrophagic disease (Chap. 72).

Acquired functional abnormalities of monocytes occur in a variety of diseases and circumstances (see “VII. Monocyte and Macrophage Dysfunction” in Table 69–1). Monocyte dysfunction occurs after severe trauma, sepsis, in other critically ill patients, and in patients with metastatic cancer. Monocyte production of interleukin (IL)-12 or maturation to dendritic cells also can be impaired in cases of severe trauma, critical illness, or metastatic cancer.

Some factors, such as IL-10, impair monocyte functions. A viral IL-10–like molecule encoded by the Epstein-Barr virus *BCRF1* gene also might play a role in the pathogenesis of that virus infection, and may act, in part, by inhibiting monocyte function. Tobacco smoking and marijuana smoking can result in impairment of alveolar macrophage function. In several diseases, including chronic lymphocytic leukemia, Kawasaki disease, Whipple disease, and malakoplakia, specific abnormalities of monocyte function play a significant role in the immune impairment in each disorder.

● CLINICAL MANIFESTATIONS OF MONOCYTE DISORDERS

MONOCYTOPENIA OR MONOCYTE DYSFUNCTION

Isolated monocytopenia in the absence of any other blood cell deficiency or immune deficiency has not been reported. The manifestations of such a clinical state (pure amonocytosis) must be inferred. Neutrophils, endothelial cells, and other cell types can substitute, in part, for some monocyte functions. Monocytes have antibacterial, antiviral, antifungal, and antiparasitic capabilities. They are effective phagocytes that are involved in the ingestion and inactivation of microbes, such as mycobacteria, *Listeria*, *Brucella*, trypanosomes, and other granuloma-producing organisms. Thus, their deficiency

or functional abnormality predisposes to such infections. In association with the amonocytosis of the MonoMAC (monocytopenia and mycobacterial infections) syndrome, opportunistic infections with mycobacteria, fungi, and viral organisms are characteristic. Macrophages can serve as a reservoir for the human immunodeficiency virus and are the principal locus for the virus in the brain and in neural tissue.

Deficiency in a specific subset of macrophages, the osteoclasts, results in *osteopetrosis*, an imbalance in bone metabolism that favors accretion. Osteoclasts normally play a key role in the closely regulated process of bone resorption and accretion, mediating the former process. Monocyte derivatives are, thereby, involved in the development of osteoporosis and other metabolic bone diseases in which the balance tips toward resorption. Bisphosphonates can inhibit osteoclast action by interfering with its function of bone resorption and by inhibiting the mevalonate pathway to geranylgeranyl diphosphate, which prevents the transformation of monocytes to osteoclasts. Thus, the deleterious clinical manifestations of macrophages are being subdued by making the monocyte a target of therapy, in this case the prevention and amelioration of postmenopausal osteoporosis, tumor-induced bone lysis, and Paget disease, as well as of others.

Macrophages and their derivatives, monocyte-derived dendritic cells, process and present antigens and play a role in immune regulation. In complex systems, such as that of antibody production, abnormal macrophages might lead to defects in humoral immunity. Activated monocytes secrete more than 50 chemical mediators or monokines, which, among other things, play a vital role in cellular immunity and inflammation. In effect, they are a critical endocrine (hormone-elaborating) apparatus. The absence of monocytes from the inflammatory response and the failure to elaborate, or the inappropriate elaboration, of monokines such as IL-1, α_1 -proteinase inhibitor, prostaglandins, leukotrienes, plasminogen activator, elastase, tumor necrosis factor (TNF), IL-6, IL-12, and other cytokines, may cause or contribute to disease manifestations. A deficiency or impairment of monocytes has the potential of influencing several functions and systems, because monocytes are such important sources of inflammatory cytokines (Chap. 67). In contrast, the unregulated activation of monocytes can lead to deleterious cytokine elaboration. Central to this process is TNF. The monocyte is a major source of TNF, which is a principal proinflammatory cytokine, triggering the elaboration of IL-1, IL-6, and others. Monocyte-derived TNF is also the primary chemical inducer of granuloma formation. The appreciation of its latter roles resulted in therapy to sequester TNF by antibody neutralization or receptor blockade and has resulted in substantial therapeutic effects in adult and juvenile rheumatoid arthritis, psoriasis, psoriatic arthritis, and Crohn disease. The side effects of such therapy confirm the key role of TNF in suppression of intracellular pathogens, such as *Mycobacterium tuberculosis* (potentiation of microbial diseases by TNF sequestrants), and in the role of the monocyte in modulating demyelination (exacerbation of multiple sclerosis in patients treated with anti-TNF). The therapeutic administration of granulocyte-monocyte colony-stimulating factor (GM-CSF) also activates monocytes to elaborate cytokines, and this effect is being used to augment cancer vaccine therapy.

Monocytopenia and decreased monocyte entry into inflammatory sites occur after glucocorticoid administration. This may explain why patients treated with glucocorticoids are predisposed to infections in which monocytes play a protective role, such as those resulting from fungal, mycobacterial, and other opportunistic organisms. Dysfunctional monocytes, incapable of killing ingested microorganisms, are present in chronic granulomatous disease (Chap. 66), as well as in hematopoietic stem cell diseases, such as monocytic variants of acute myelogenous leukemia.

TISSUE EFFECTS OF MONOCYTOSIS

Benign monocytosis is not associated with specific clinical manifestations. All forms of myelogenous leukemia with a predominance of monocytes are associated with a predisposition to troublesome tissue infiltrates, especially in the skin, gingiva, lymph nodes, meninges, and anal canal. The higher the monocyte count and the higher the proportion of leukemic monocytes, the more prevalent is tissue infiltration. In some cases, the tissue infiltration of leukemic monocytes can produce symptoms: lung dysfunction, laryngeal obstruction, and intracranial vessel rupture, as well as others. Release of procoagulants leading to intravascular coagulation also occurs in myelogenous leukemia with a high proportion of monocytes. The hyperleukocytic syndrome can occur in acute monocytic leukemia with markedly elevated white cell counts (Chaps. 83 and 88).

EFFECTS OF HISTIOCYTOSIS

Hemophagocytic lymphohistiocytosis usually refers to the accumulation of activated macrophages (histiocytes) in tissue sites. The cells become intensely cytophagocytic; ingestion of red cells and occasionally of leukocytes, platelets, erythroblasts in marrow, or cells in other tissue sites is an important feature of these inflammatory histiocytoses (Chap. 71). Because morphology has been misleading, the diagnosis of histiocytosis requires identification of specific cell markers. A histiocytosis may be inflammatory (polyclonal) or neoplastic (clonal). Because tissue macrophages can take on highly specialized phenotypes and localize in different tissues, histiocytosis is further defined by whether they carry markers of these cell types (e.g., Langerhans cells, interdigitating dendritic cells; Chap. 71).

THROMBOATHEROGENESIS

The complex interrelationships among monocytes, atherogenesis, and coagulation are discussed in several other chapters in the text (Chaps. 115 and 134). Monocytes may play a central role in the pathologic aspects of both processes, as a repository for tissue factor, inflammatory cytokines, and a key element in the inflammatory precursor lesions of atheroma formation (Table 69–1, sections VIII and IX).

BLOOD DENDRITIC CELLS

Dendritic cells and macrophages belong to a family of antigen-presenting cells and in the laboratory can be generated from a common precursor. So-called monocyte-derived dendritic cells are easily produced in the culture vessel by the appropriate cytokines. Indeed, the use of GM-CSF as an adjuvant in cancer vaccines may relate in part to the cytokine's ability to activate monocytes and foster conversion to dendritic (antigen-presenting) cells *in vivo* (Chaps. 26 and 27). Dendritic cells can be defined by phenotype into two principal types—myeloid and lymphoid (plasmacytoid) dendritic cells—of which there are likely subtypes. Monocyte-derived dendritic cells are a subset of the myeloid type (Chap. 20).

Flow cytometry using cluster of differentiation (CD) markers and antidendritic cell surface antibodies have permitted the enumeration of myeloid (human leukocyte antigen-D related [HLA-DR]+, CD11c+, CD123–) and lymphocytic-plasmacytoid (HLA-DR+, CD11c–, CD123+, CD303+) dendritic cells in human blood in normal subjects and subjects with disease. Their centrality in the immune response as premier antigen-presenting cells may result in nonspecific alterations in their blood concentration or function in many generalized or localized inflammatory, infectious, and neoplastic diseases. Plasmacytoid dendritic cells may be decreased in numbers with aging, further impairing

the immune response of older individuals (Chap. 9). Dendritic cells are also profoundly decreased in patients with hairy cell leukemia and are dysfunctional in patients with chronic lymphocytic leukemia.

CHAPTER 70

MONOCYTOSIS AND MONOCYTOPENIA

Marshall A. Lichtman

SUMMARY

The blood monocyte is in transit between the marrow and tissues where it transforms (matures) into a macrophage. In tissues, the monocyte develops a phenotype characteristic of the specific tissue of residence (e.g., Kupffer cells of liver, microglia of brain, osteoclasts of bone). Because the monocyte participates in virtually all inflammatory and immune reactions, its concentration in the blood may be increased in many such conditions, including autoimmune diseases, gastrointestinal disorders, sarcoidosis, and several viral and bacterial infections. Monocytosis, an increase in the blood absolute monocyte count to more than $800/\mu\text{L}$ ($0.8 \times 10^9/\text{L}$), may occur in some patients with cancer and several unrelated conditions, such as postsplenectomy states, inflammatory bowel disease, and some chronic infections (e.g., bacterial endocarditis, tuberculosis, and brucellosis). The inconsistency and unpredictability in the blood monocyte concentration among patients with the same disease is a function of its relatively small blood pool size, the damping effect of a large tissue pool, its relatively long life span, the number and complexity of effectors in the relevant cytokine network that can influence the response, and the ability to expand macrophage numbers by local mitosis in tissues. The most striking increase in blood monocyte concentration occurs with hematopoietic malignancies, especially clonal monocytosis, and monocytic or myelomonocytic leukemia. Depression, myocardial infarction, parturition, thermal injuries, and marathon competition are closely associated with monocytosis. [Table 70–1](#) is a comprehensive list of causes of monocytosis. Monocytopenia is notable in patients with aplastic anemia or hairy cell leukemia as a feature of pancytopenia. Although other cytopenias accompany the monocytopenia, the latter contributes significantly to the predisposition to infection and in hairy cell leukemia is an aid to diagnosis because of its constancy. The MonoMAC syndrome, the result of *GATA2* mutations, is associated with extreme monocytopenia and amonocytosis.

The blood monocyte is a cell in transit from marrow to tissues.¹ There are two major populations of blood monocytes based on physical properties: a smaller population thought to represent a less-mature stage, has a higher buoyant density, a smaller cell volume, lacks Fc receptors,

Acronyms and Abbreviations: CD, cluster of differentiation; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; LPS, lipopolysaccharide; M-CSF, monocyte/macrophage colony-stimulating factor; MDS, myelodysplastic syndrome; MonoMAC, monocytopenia and *Mycobacterium avium* complex; NK, natural killer.

and has greater tumoricidal activity; the larger population represents a more-mature stage, has a lower buoyant density, has a larger cell volume, displays Fc receptors, expresses more peroxidase activity, secretes larger amounts of interleukin (IL)-1, presents antigen, and mediates antibody-dependent cell-mediated cytotoxicity more efficiently. The larger population, classical monocytes that are highly phagocytic and proinflammatory, composes approximately 90 percent of blood monocytes, and strongly expresses CD14 (lipopolysaccharide receptor) but does not express CD16 (FcγRIII), designated the CD14⁺⁺CD16⁻ subset. These monocytes carry chemokine receptors CCR2^{hi}CX3CR1^{lo}. Of the remaining monocyte population, approximately 5 percent exhibit strong expression of CD14 and modest expression of CD16, the CD14⁺⁺CD16⁺ “intermediate” subset, which expresses the chemokine receptors CCR2^{mid}CX3CR1^{hi}CCR5^{mid}, are proinflammatory and less phagocytic, and the “nonclassical” subset, which exhibits strong expression of CD16, the CD14⁺CD16⁺⁺ subset, which expresses the chemokines CCR1^{lo}CX3CR1^{hi}, the so-called patrolling subset.² The latter subset contains dendritic cell precursors.³ The major subsets can each be further stratified based on the expression of CD64 (FcγRI) (Chaps. 67 and 68).⁴

In tissues the monocyte is capable of transformation, under the influence of local environmental factors, into a macrophage. The monocyte plays an important role in acute and chronic inflammatory reactions, including granulomatous inflammation; immunologic reactions, including those involved in delayed hypersensitivity; tissue repair and reorganization; atheroma and thrombus formation; and the reaction to neoplasia and allografts. Because of the key role of monocytes in a variety of pathophysiologic reactions, a modest elevation in blood monocyte count can occur in many disparate conditions. In addition, in circumstances in which large increases in the number of macrophages are required in tissue sites, the demand may be met by local proliferation of macrophages and not be reflected either in an increased transit of monocytes through the blood compartment from marrow to tissue or in an increased concentration of blood monocytes.⁵ Occasionally, T-cell clones release only macrophage/monocyte colony-stimulating factor (M-CSF), which can stimulate the growth of macrophage colonies, providing a model for local control of macrophage proliferation.⁶

● NORMAL BLOOD MONOCYTE CONCENTRATION

In the first 2 weeks of life, the average absolute blood monocyte count is approximately $1000/\mu\text{L}$ ($1 \times 10^9/\text{L}$; Chap. 7). There is a gradual decline in the normal monocyte count to a mean of $400/\mu\text{L}$ ($0.4 \times 10^9/\text{L}$) in adulthood, at which time monocytes constitute 1 to 9 percent (mean: 4 percent) of blood leukocytes (Chap. 2). Monocytosis is present when the absolute count exceeds $800/\mu\text{L}$ ($0.8 \times 10^9/\text{L}$) in adults. Men tend to have slightly higher monocyte counts than women.⁷ Increments in the number of blood monocytes correlate directly with increases in the total blood monocyte pool and the monocyte turnover rate.⁸ The blood monocyte count cycles with a periodicity of 5 days.⁹ Older persons have a decrease in the proportion of CD14⁺⁺CD16⁻ to CD14⁺CD16⁺ monocytes as compared to younger persons, although the functional significance of this difference has not been established.¹⁰

● DISORDERS ASSOCIATED WITH MONOCYTOSIS

Table 70–1 outlines the diseases reported to be associated with monocytosis. In one review, hematologic disorders represented more than 50 percent, collagen vascular diseases approximately 10 percent, and malignant disease approximately 8 percent of cases of monocytosis.¹¹

--	---

HEMATOLOGIC DISORDERS

Approximately 25 percent of patients with a myelodysplastic syndrome have an increase in the absolute monocyte count.¹²⁻¹⁶ Occasional patients with a myelodysplastic syndrome may develop an absolute monocyte count as high as 30,000/ μ L (30×10^9 /L). Chronic monocytosis may be the principal feature of a clonal myeloid disease and precede by years the development of acute myelogenous leukemia. Patients with myelodysplasia and monocytosis have a high propensity to evolve into acute or chronic myelomonocytic leukemia. Monocytosis, as a feature of primary myelofibrosis, may be a harbinger of rapid progression.¹⁷ The number of promonocytes and monocytes in blood and marrow may be increased in patients with acute myelogenous leukemia of the monocytic^{18,19} or myelomonocytic type.²⁰ Acute myelogenous leukemic cells with a histiocytic (macrophagic)²¹ or dendritic cell phenotype have been described.²²⁻²⁴ Patients with chronic myelomonocytic leukemia

have, by definition, an increased absolute number of monocytes in the blood ($\geq 1.0 \times 10^9$ /L). The monocytosis may be more striking in some cases.²⁵⁻²⁷ Juvenile myelomonocytic leukemia, also, is defined in part by the increased number of monocytes in the blood and marrow.²⁸ In some cases of acute monocytic leukemia, the monocytes are immature and have features of monoblasts or promonocytes, but in some cases they are indistinguishable by light microscopy from normal blood monocytes. Some automated instruments are dependent on the α -naphthol acetate esterase reaction to detect the proportion of monocytes in white cell differential counts. These instruments may underestimate leukemic monocytes counts, especially in cases of chronic myelomonocytic leukemia, because the leukemic monocytes have a decreased activity of the enzyme.²⁵ An uncommon variant of Ph-positive chronic myelogenous leukemia (CML), expressing a p190 BCR-ABL transcript, is associated with a striking monocytosis in approximately 50 percent of cases.^{29,30}

Monocytosis occurs in a number of neutropenic states: cyclic neutropenia,³¹ chronic granulocytopenia of childhood,³² familial benign chronic neutropenia,³³ infantile genetic agranulocytosis,^{34,35} and chronic hypoplastic neutropenia.³⁶ In human cyclic neutropenia, monocyte oscillation is reciprocal to the neutrophil cycle; the peak monocytosis, which often exceeds 2000/ μ L (2.0×10^9 /L), occurs at the end of the neutropenic period. Monocytes often stay above 500/ μ L (0.5×10^9 /L) throughout the cycle. In the variety of other neutropenias mentioned, monocytopenia is often preserved in the face of neutropenia. Transient elevations of the monocyte count have been reported in the acute phases of drug-induced agranulocytosis.³⁷⁻³⁹ Monocytosis characteristically appears later in the recovery phase of agranulocytosis and may be a harbinger of recovery.^{37,40,41} Some observers dispute the validity of the latter observation.⁴²

Monocytosis can occur with lymphomas and can increase with exacerbation of disease activity.⁴³ Monocytosis has been noted in approximately 25 percent of cases of Hodgkin lymphoma, although it does not correlate with prognosis.^{43,44} In contrast, one treatise on the disease reports the hematologic values of patients with Hodgkin lymphoma at the time of diagnosis; only 4 of 100 have nominal increases in absolute blood monocyte counts.⁴⁵ A statistically significant increase in blood monocyte concentration has been reported in myeloma and has been correlated with the presence of λ light-chain-containing monoclonal immunoglobulin.^{46,47} Rare cases of M-CSF secreting lymphoid tumors have been associated with monocytosis.^{48,49} Monocytosis at diagnosis has been correlated with decreased survival in several lymphoma types and chronic lymphocytic leukemia.^{50,51} Pseudolymphoma syndrome, induced by drugs such as carbamazepine, phenytoin, phenobarbital, and valproic acid, is associated with monocytosis.⁵²

SPLENECTOMY

Monocytosis is a common feature in individuals who have had splenectomy.^{53,54}

INFLAMMATORY AND IMMUNE DISORDERS

Connective tissue diseases, including rheumatoid arthritis,⁵⁵ systemic lupus erythematosus, temporal arteritis, myositis, and periarteritis nodosa, may be associated with monocytosis, although monocytosis is not common in these diseases.¹¹ The usual alterations of the white cell count in systemic lupus erythematosus, for example, are neutropenia and lymphopenia, but 10 percent of patients have a mild monocytosis.⁵⁶ An elevation of the blood monocyte count occurs in sarcoidosis⁵⁷ and is inversely related to a reduction in circulating T lymphocytes.⁵⁸

Infectious diseases are an uncommon cause of monocytosis. Only a few instances of infection were noted in a comprehensive review of causes of monocytosis, including tonsillitis, dental infection, recurrent liver abscesses, candidiasis, and one instance of tuberculous peritonitis.¹¹ Tuberculosis was once a leading cause of monocytosis, because of the role of monocytes in granuloma (tubercle) formation. Neither the monocyte count nor the ratio of monocytes to lymphocytes correlates with the stage or activity of tuberculosis.⁵⁹⁻⁶¹ *Mycobacterium fortuitum* infection, usually in the setting of AIDS, also is associated with monocytosis.⁶²

Monocytosis is found in 15 to 20 percent of patients with subacute bacterial endocarditis,^{63,64} but is not correlated with the presence of bacterial macrophages, which may be present in this disease.⁶⁵

A number of infections formerly thought to be associated with monocytosis are not, when examined systematically. These include rickettsial diseases, leishmaniasis, typhoid fever, malaria, and disseminated candidiasis, brucellosis,⁶⁶ and dengue hemorrhagic fever.⁶⁷

A monocytosis in the resolution phase of acute infections has been noted,⁶⁸ and monocytosis occurs in cases of neonatal, primary, and secondary syphilis.^{69,70} Certain viruses, especially cytomegalovirus varicella-zoster virus, and influenza virus induce an increase in blood monocytes.⁷¹⁻⁷³

GASTROINTESTINAL DISEASES

Sprue, ulcerative colitis, regional enteritis, and alcoholic liver disease are associated with monocytosis.^{11,74,75}

NONHEMATOPOIETIC MALIGNANCIES

Sixty percent of patients with nonhematologic malignancy exhibit a monocytosis that is independent of the presence or absence of metastatic disease.⁷⁶ An inverse relationship of monocyte count (elevated) and T-lymphocyte concentration (decreased) has also been noted in patients with malignant disease.⁷⁷ Reports of hematologic values in metastatic colon cancer and soft-tissue sarcoma have emphasized the frequency of monocytosis in patients with cancer.^{78,79} Consequently, if *unexplained* monocytosis persists, malignancy should be considered.

EXOGENOUS CYTOKINE ADMINISTRATION

The administration of granulocyte-macrophage colony-stimulating factor (GM-CSF),⁸⁰ IL-10,⁸¹ or granulocyte colony-stimulating factor (G-CSF)^{82,83} may result in mild increases in blood monocyte counts. Administration of M-CSF^{84,85} results in an invariable increase in blood monocytes. Doses of 40 to 120 mcg/kg per day result in the peak increase, which may reach three- to fourfold baseline, in approximately 8 days. Administration of human macrophage inflammatory protein-1 α to patients or normal volunteers is associated with a brief monocytopenia followed by a monocytosis that is proportional to the dose administered.⁸⁶

MYOCARDIAL INFARCTION

Monocytosis occurs after myocardial infarction, reaching a peak on day 3. A correlation exists between serum creatine kinase activity and monocyte count, suggesting a relationship between extent of infarction and monocytosis.⁸⁷ After myocardial infarction, persistent monocytosis is correlated with pump failure.⁸⁸⁻⁹⁰ Monocytosis is a frequent finding after cardiopulmonary bypass surgery.⁹¹ In the latter circumstance, CD14 (lipopolysaccharide [LPS] receptor) is markedly decreased on the monocyte surface and plasma-soluble CD14 is increased, changes compatible with monocyte activation.

MISCELLANEOUS CONDITIONS

Other disorders associated with monocytosis include tetrachloroethane poisoning.⁹² Monocytosis is a frequent finding at the time of parturition.^{93,94} An increase in blood monocytes occurs in healthy volunteers^{95,96} and in patients with myelodysplastic syndrome (MDS)^{97,98} who are given moderately high, therapeutic-level doses of glucocorticoids. Psychiatric depression is associated with a conjoint increase in neutrophils and monocytes.⁹⁹⁻¹⁰¹ The monocytosis in depressive and anxiety disorders is associated with high plasma levels of β endorphins and dysfunctional (hypophagocytic) monocytes.¹⁰¹ Thermal injury is accompanied by monocytosis.^{102,103} Competitive marathon runners have a monocytosis associated with elevated plasma levels of several cytokines, including M-CSF.^{104,105} An increase in blood monocytes accompanies several rare syndromes: holoprosencephaly,¹⁰⁶ Kawasaki disease,¹⁰⁷ and Wiskott-Aldrich.¹⁰⁸

● BLOOD MONOCYTE SUBSET COUNTS IN DISEASE

Differential monocyte subset responses (CD14⁺⁺CD16⁻ vs. CD14⁺CD16⁺) without deviation of total monocyte counts outside the normal range have been observed in older subjects and those with sepsis, AIDS, allergic disorders, dermatitides, hemodialysis, and atherosclerosis.^{4,10,91,109} These monocytic subset variations usually are not measured in clinical laboratories and, as yet, have little diagnostic or prognostic importance.

● DISORDERS ASSOCIATED WITH MONOCYTOPENIA

Table 70-2 lists the disorders associated with monocytopenia. Although monocytopenia may occur in any hematopoietic multipotential cell disease associated with pancytopenia (e.g., acute myelogenous leukemia), a decrease in monocytes is notable and constant in aplastic anemia¹¹⁰ and hairy cell leukemia,¹¹¹ in which monocytopenia can be a helpful diagnostic clue and also a contributor to the predisposition to infection, which is an important, morbid feature of the disease. Monocytopenia occurs in a small proportion of patients with chronic lymphocytic leukemia and these patients may have a higher frequency of infections, especially by viruses.¹¹² Severe thermal injuries also can result in monocytopenia.¹¹³ Cyclic neutropenia is also notable for intermittent periods of monocytopenia.¹¹⁴ Rare cases of conjoint severe neutropenia and monocytopenia occur.¹¹⁵ Transient monocytopenia is a feature of hemodialysis, but monocyte counts return to normal within hours after the procedure ends.¹⁰⁹

In contrast, to reports of monocytosis noted above in “Inflammatory and Immune Disorders,” automated blood cell counts in large numbers of subjects find that a decreased absolute monocyte count is frequent in patients with rheumatoid arthritis¹¹⁶ or systemic lupus erythematosus,¹¹⁷ and in those with human immunodeficiency virus infection.¹¹⁸ One has to presume that these contrasting results relate to stage or activity of disease at the time of measurement.

In 2010, a disease was described in which extreme monocytopenia, and sometimes a monocytosis, was the most striking abnormality in the blood counts.¹¹⁹ It has been named the *MonoMAC syndrome* because of the monocytopenia (mono) and the frequency of *Mycobacterium avium* complex (MAC) opportunistic infections, although persistent fungal and viral infections (especially papillomavirus), also occur. Marked decreases in blood B-cell, natural killer (NK)-cell, and dendritic cell counts are characteristic.^{120,121} The disease is the result of mutations in the *GATA2* gene that decrease transcription of the gene message.¹²² It may present as an atypical type of MDS with a hypocellular marrow, but with striking dysmorphic megakaryocytes and micromegakaryocytes,

or with acute myelogenous leukemia.¹²³ Because of the *GATA2* gene product's role in the development of the vascular and lymphatic systems, some cases may have the triad of lymphedema, monosomy 7, and myelodysplasia or acute myelogenous leukemia, designated the Emberger syndrome.¹²⁴⁻¹²⁷ Hematopoietic stem cell transplantation has been successful in restoring normal immunohematopoiesis in some of the patients so treated.¹²⁸

Glucocorticoid hormones produce a monocytopenia, transiently, approximately 6 hours after administration to human volunteers^{129,130} or to patients.⁹⁵ Administration of interferon- α and tumor necrosis factor- α may also cause monocytopenia.¹³¹ Monocytopenia may follow radiotherapy.¹³²

● BLOOD DENDRITIC CELL COUNTS

Blood dendritic cells are composed of two phenotypic subtypes: myeloid-derived (HLA-DR⁺CD11c⁺CD123⁺) and lymphoid-plasmacytoid-derived (HLA-DR⁺CD11c⁻CD123⁺). The total blood dendritic cell count can be measured by flow cytometry.¹³³⁻¹³⁵ Dendritic cells make up approximately 0.6 percent of blood cells (range: 0.15 to 1.30 percent) and represent 14×10^6 cells/L (range: 3 to 30×10^6 cells/L). Approximately one-third of these cells are a lymphoid-plasmacytoid-derived type and two-thirds are a myeloid-derived type.¹³⁵⁻¹³⁷ Fluctuations in blood dendritic cells are often independent of changes in total blood monocyte count. Blood dendritic cell counts decrease with aging¹³⁸ and increase with surgical stress¹³⁷ (and presumably other stressful reactions) in relation to plasma cortisol levels.

CHAPTER 71

INFLAMMATORY AND MALIGNANT HISTIOCYTOSIS

Kenneth L. McClain and Carl E. Allen

SUMMARY

Diseases of the histiocyte (i.e., macrophage or dendritic cell) lineage can be divided into four groups based upon the final maturation steps from their myeloid progenitor cells: (1) Langerhans cell histiocytosis (LCH), (2) malignant histiocytoses or dendritic cell sarcomas, (3) juvenile xanthogranuloma/Erdheim-Chester disease, Rosai-Dorfman disease, and (4) hemophagocytic lymphohistiocytosis syndromes. Storage diseases of macrophages are discussed in Chap. 72. The distinction among these diseases is based upon clinical characteristics and histopathologic staining for unique surface markers. LCH may present at birth or in adulthood with skin rash, bone pain, draining ears, oral ulcers, gingivitis, pulmonary dysfunction, chronic diarrhea, diabetes insipidus, and marrow or liver failure. Therapy for LCH in children has been studied in clinical trials by the Histiocyte Society. Treatment for adults is based primarily on case series. Although relapses are not typically rapidly fatal, they are associated with a higher risk of endocrine and central nervous system complications. The diagnostic criteria for the malignant histiocytosis have been clarified by cell-surface marker studies. Treatment options and prognosis vary widely. Erdheim-Chester disease and juvenile xanthogranuloma are phenotypically similar, but are treated differently. Erdheim-Chester disease is found almost exclusively in adults and juvenile xanthogranuloma occurs primarily in children. Rosai-Dorfman disease presents with massive cervical lymphadenopathy in most patients, but may also involve other parts of the body. There are several treatment options for Rosai-Dorfman disease, Erdheim-Chester disease, and juvenile xanthogranuloma, but no clinical trials of specific drugs have been published. Hemophagocytic lymphohistiocytosis (HLH) is characterized by pathologic inflammation and may present with infections, hepatitis, meningitis, or autoimmune diseases. Without therapy, HLH is almost universally fatal. Most patients who receive prompt diagnosis and treatment with immune suppression therapy survive.

Acronyms and Abbreviations: AHSCT, allogeneic hematopoietic stem cell transplantation; ALL, acute lymphoblastic leukemia; ATG, antithymocyte globulin; CD, cluster designation; CT, computed tomography; DC, dendritic cell; DI, diabetes insipidus; DLCO, diffusing capacity in lung for carbon dioxide; ECD, Erdheim-Chester disease; FEV₁, forced expiratory volume in 1 second; HLA-DR, human leukocyte antigen-D related; HLH, hemophagocytic lymphohistiocytosis; IFN, interferon; IL, interleukin; JXG, juvenile xanthogranuloma; LC, Langerhans cell; LCH, Langerhans cell histiocytosis; M-CSF, macrophage colony-stimulating factor; MRI, magnetic resonance imaging; NK, natural killer; PET, positron emission tomography; RDD, Rosai-Dorfman disease.

CLASSIFICATION OF THE HISTIOCYTOSIS

The general description of cells in the monocyte-macrophage system (mononuclear phagocyte system) has been largely clarified (Chaps. 67 to 69), although some ambiguity remains. Nomenclature committees remain loyal to the term “histiocyte,” a designation assigned in the 19th century to tissue macrophages, although the “histiocytosis” umbrella includes functional and neoplastic disorders of a broad range of cells in the monocyte, macrophage, and dendritic cell (DC) lineages. The distinctions among diseases in this category are determined by (1) clinical findings, (2) histopathology, (3) immunocytology to define the antigens on the surface of the pathologic cells, and (4) cytogenetic or genetic features (Table 71-1).

The histiocytic disorders have been classified based upon whether they are (1) DC related, (2) monocyte-macrophage related, or (3) malignancies of macrophages or DCs (Table 71-2).^{1,2} Evolving understanding of myelomonocytic differentiation, as well as cellular origins of histiocytic disorders, will likely necessitate revision of these classifications in the near future.

The pathologic cells in Langerhans cell histiocytosis (LCH) lesions have phenotypic similarity to epidermal Langerhans cells (LCs), which has led to the hypothesis that LCH is derived from aberrant activation and/or neoplastic transformation of the epidermal LCs.³ LCH originates from aberrant proliferation and differentiation of myelomonocytic precursors.^{4,5} Regardless of ontogeny, LCH lesions are characterized by pathologic DCs with phenotypic similarity to epidermal LCs, including positive staining with anti-CD207 (antilangerin) and the presence of Birbeck granules identified by electron microscopy.^{6,7} Birbeck granules are racket-shaped inclusions that are thought to be involved in antigen processing. Cells staining with anti-CD207 and/or anti-CD1a are required for the diagnosis of LCH. Other antigens, such as S100 or HLA-DR (human leukocyte antigen-D related) are not specific for LCH. The histiocytes in Erdheim-Chester disease (ECD) and juvenile xanthogranuloma (JXG) have phenotypic similarity to the dermal-interstitial dendrocyte that stains with antibodies to CD68, fascin, and factor XIIIa. However, the DCs in these disorders also express surface CD163 that is characteristic of macrophages.

Malignant histiocytosis (or “histiocytic sarcoma”) has evolved as a diagnosis of exclusion involving malignant histiocytes that lack markers for anaplastic large cell lymphoma or other hematologic malignancies. Malignant histiocytosis represents a spectrum of malignancies that presumably derive from DCs of different lineages at different stages of differentiation. Human DCs are defined as hematopoietic cells expressing high levels of major histocompatibility complex II (MCHII) and CD11c while lacking other specific lineage markers. Under normal conditions, these cells reside in tissue or circulate in the blood. Once stimulated by antigen, they migrate to lymphoid tissue and interact with effector or suppressor T cells. Malignant histiocytoses are variable and share surface markers with DC subsets: follicular DC “sarcoma” (CD21+, CD35+), interdigitating DC “sarcoma” (CD14+), and Langerhans cell “sarcoma” (CD1a+).

The monocyte-macrophage disorders include Rosai-Dorfman disease (RDD) and hemophagocytic lymphohistiocytosis (HLH). RDD, also known as sinus histiocytosis with massive lymphadenopathy, has the telltale histopathologic finding of intact lymphocytes in the cytoplasm of macrophages (emperipolesis), a feature that must be present to diagnose this disorder. HLH is distinct among the diseases discussed in this chapter in that the macrophages are nonneoplastic, otherwise normal histiocytes, characterized by a pathologic reaction to aberrant stimuli.

● LANGERHANS CELL HISTIOCYTOSIS

HISTORY

LCH has a complicated history that underlies the current clinicopathologic approach to the disease. What has come to be identified as LCH was first described in case reports and series in the early 1900s.⁸ By the 1950s, patterns of clinical presentations had been categorized as Hand-Schüller-Christian (multifocal eosinophilic granulomas) and Letterer-Siwe (disseminated disease including marrow, spleen and liver). However, these apparently disparate entities were found to share the same histopathology: histiocytes with abundant cytoplasm and reniform nuclei among an inflammatory infiltrate that could include lymphocytes, eosinophils and macrophages. Lichtenstein hypothesized that these clinical disorders must be linked by a common etiology, and proposed the designation “Histiocytosis X,” with “X” indicating incomplete knowledge of pathogenesis and cell of origin. Two decades later, Birbeck granules, which had previously been identified only in epidermal LCs, were identified in DCs of LCH lesions by electron microscopy. Nezelof and colleagues therefore extended Lichtenstein’s hypothesis that this spectrum of disorders arises from the epidermal Langerhans cell.³ Histiocytosis X has since been regarded as “Langerhans cell histiocytosis.”

EPIDEMIOLOGY AND INHERITANCE

The incidence of LCH is 2 to 10 cases per 1 million children younger than age 15 years.^{9–11} A survey of LCH patients in France revealed an incidence of 4 to 6 per 1 million in children younger than age 15 years. The male-to-female ratio is close to 1 and the median age of presentation is 30 months, although patients may present with the disease from birth through the ninth decade. Identical and fraternal twins with early onset of LCH have been described. There are occasional reports of affected nontwin siblings and multiple cases in one family, although it is not clear if this is significantly greater than one would expect by chance.¹²

The relatively high rate of high-risk multisystem LCH in identical twins compared to presumed fraternal twins may be explained by shared precursor cells as well as the possibility of shared genes. An increased frequency of family members with thyroid disease,¹³ family members with other cancers,¹⁴ *in vitro* fertilization,¹⁵ and parental exposure to metal¹⁶ have also been reported as potential associations. Although inheritance of penetrant mendelian “LCH genes” in the majority of cases seems unlikely, it remains possible that there are inherited genes associated with increased risk of developing LCH.

Molecular Pathology

The focus of studies and reviews on LCH over the past decades has been on either an immune or a neoplastic disorder. The competing models have been (1) an inappropriate activation of an otherwise normal epidermal LC or (2) a neoplastic transformation of the epidermal LC. Twenty years ago, CD1a+ cells from LCH lesions were described as clonal, based on non-random X inactivation.^{17,18} Subsequently, somatic activating mutations in the *BRAF* oncogene were reported in 57 percent of LCH histopathologic specimens,¹⁹ with subsequent studies validating the recurrent *BRAF*^{V600E} mutation at high frequency.^{5,20–22} *BRAF* is the central kinase of the RAS/RAF/MEK/ERK pathway, which is essential to numerous cell functions and is frequently mutated in cancer cells.²³ Significance of *BRAF*^{V600E} as a driver mutation in LCH is supported by early reports of clinical responses to *BRAF* inhibition in adults with combined LCH and ECD.²⁴ Other recurrent somatic mutations in LCH may be uncovered.

Cell of Origin

The cell of origin of LCH has been assumed to be the epidermal LC based on phenotypic similarities discussed above. However, the transcriptome of CD207+ cells from LCH lesions is more consistent with an immature myeloid DC phenotype than with the transcriptome of epidermal LCs.⁴ Furthermore, DC maturation may be heterogeneous within lesions, with variable CD1a+/CD207– populations.^{25,26} Immunohistochemical staining antibodies specific for *BRAF*^{V600E} revealed that the mutations are not limited to CD207+ cells within LCH lesions, but also are found in CD207-negative subpopulations.²¹ Using the *BRAF*^{V600E} mutation as a “bar code,” cells that carry the mutation were identified in circulating myelomonocytic precursors in blood and in hematopoietic stem cells in marrow aspirates of patients with clinical high-risk LCH, but not in patients with single-lesion low-risk LCH. The functional significance of this observation was supported by the ability of forced expression of *BRAF*^{V600E} in myelomonocytic precursors (CD11c+ cells) to induce a disseminated LCH-like phenotype in mice.⁵ We therefore hypothesize that the state of differentiation of the cell in which LCH arises determines the clinical manifestations of the disease; pathologic ERK (extracellular signal-regulated kinase) activation in stem cell or early myelomonocytic precursor resulted in disseminated high-risk disease whereas ERK activation in tissue-restricted precursor resulted in localized disease. These observations define LCH as a myeloid neoplasm.

Inflammation and Langerhans Cell Histiocytosis

Although ERK hyperactivation may drive differentiation and proliferation of myelomonocytic precursors in LCH, the mechanisms that drive inflammation in the LCH lesions are not currently understood. The LCH DCs make up a median of 8 percent of the cells within lesions.⁵ Like physiologically activated DCs, they express high levels of T-cell costimulatory molecules and proinflammatory cytokines.^{4,27,28} The LCH lesion's inflammatory infiltrate includes lymphocytes, macrophages, and eosinophils in variable proportions, with enrichment of regulatory CD4+CD25+ T cells (T regs).²⁹ Dozens of cytokines, chemokines,

and cytokine and chemokine receptors have been hypothesized to play roles in LCH pathogenesis, creating a local “cytokine storm” as well as increased circulating proinflammatory cytokines, including tumor necrosis factor α , soluble interleukin (IL)-2 receptor α , RANKL (receptor activator of nuclear factor- κ B ligand), osteoprotegerin, and osteopontin.^{4,30,31} Although MAPK (mitogen-activated protein kinase) pathway activation in maturing DCs may drive differentiation of LCH DCs, inflammation likely plays a role in the clinical manifestations and possibly also in tumor maintenance: A unique phenomenon in LCH is that disruption of solitary LCH lesions often results in spontaneous resolution, even without clean margins.

CLINICAL FEATURES

LCH usually presents with a skin rash or painful bone lesion. Systemic symptoms of fever, weight loss, diarrhea, edema, dyspnea, polydipsia, and polyuria may also occur.

In LCH, involvement of specific organs at the time of diagnosis determines the designation “high-risk” or “low-risk.” Organs that indicate high-risk of progression include liver, spleen, and marrow. Organs that indicate low-risk of progression include skin, bone, lung, lymph nodes, and pituitary gland. Patients may present with disease in one site or organ (single site or single system) or in multiple sites or organs (multisystem). Treatment decisions for patients are based on whether or not organs that indicate high-risk or low-risk of progression are involved, and if LCH presents as a single site or as a multisystem disease. Patients can have LCH of the skin, bone, lymph nodes, and pituitary in any combination and still be considered to have a low-risk of progression.

Single-Site Disease Presentation

In this situation the disease presents with involvement of one site, which can be skin, oral mucosa, bone, lymph nodes, pituitary, or thymus.

Skin Lesions simulating seborrheic dermatitis of the scalp may be mistaken for prolonged “cradle cap” in infants. The lesions may be localized to intertriginous areas or may be diffuse (Fig. 71–1). The most common skin flexures affected are the groin, the perianal area, back of the ears, the neck, the armpits, and, in women, the crease below the breasts. Infants may also present with brown to purplish papules over any part of their body. This latter manifestation may be self-limited as

Figure 71–1. Photographs demonstrate variability in clinical presentations of Langerhans cell histiocytosis skin lesions.

the lesions often disappear during the first year of life with no therapy. However, these patients should be evaluated for other sites of disease which may coexist with skin lesions as multisystem LCH. Some reports describe multisystem LCH arising after presenting with lesions limited to the skin,^{32,33} although infants with skin lesions were not observed to develop disseminated disease in a relatively large institutional series.³⁴ In a report of 61 neonatal LCH cases, nearly 60 percent had multisystem disease and 72 percent had high-risk organ involvement.³⁵ The overall survival was poorer in neonates with high-risk organ involvement compared to infants and children with the same extent of disease. Response to therapy at 12 weeks was more important than patient age in determining outcome. A review of 71 children with skin involvement revealed that those without other organ systems involved had nearly a 90 percent progression-free survival after initial therapy or observation. Often dermatologists or general practitioners who see a patient with skin LCH do not perform a complete evaluation searching for LCH in other sites. Thus, we found that 40% of patients referred for apparent “skin only” LCH did have other sites of disease when a complete evaluation was done.³⁴

Isolated skin involvement is rarely observed in children older than 18 months of age.³⁴ Children and adults may develop red papular lesions in the scalp, skin of the groin, abdomen, back, or chest that resemble the diffuse rash of *Candida* infection. Seborrhea-like involvement of the scalp may be mistaken for a severe case of dandruff in older individuals. Ulcerative lesions behind the ears, involving the scalp, skin of the genitalia, or perianal region are often misdiagnosed as bacterial or fungal infections.

Oral Mucosa Presenting symptoms include gingival hypertrophy, ulcers of the soft or hard palate, buccal mucosa, or on the tongue and lips. Lesions of the oral mucosa may precede evidence of LCH elsewhere.³⁶

Bone The most frequent site of LCH in children is a lytic lesion of the skull which may be asymptomatic or painful.³⁷ LCH can occur in any bone. The most frequently involved sites are skull, femur, ribs, vertebrae, and humerus. Spine lesions are most often located in the cervical vertebrae and are frequently associated with other bone lesions. Proptosis from a LCH mass in the orbit mimics rhabdomyosarcoma, neuroblastoma, and benign fatty tumors of the eye. Some skull lesions are not only lytic but may have an accompanying mass that impinges on the dura. Whether or not this affects risk of progression or not is unknown. Lesions of the facial bones (orbit, mastoid), or anterior or middle cranial fossae (e.g., temporal, sphenoid, ethmoid, or zygomatic bone) comprise the “CNS-risk” sites. These patients have a threefold increased risk for developing diabetes insipidus (DI) and an increased risk of other CNS disease (see “Central Nervous System and Endocrine System” below).

Lymph Nodes and Thymus Cervical nodes are the ones most frequently involved and may be soft or hard-matted masses with accompanying lymphedema. An enlarged thymus or mediastinal node involvement can mimic lymphoma or an infectious process and may cause asthma-like symptoms. Biopsy of the node or mass with histologic examination and microbial cultures is helpful even in patients with known LCH as lymphadenopathy may represent LCH, coexisting neoplastic disease, or infection.³⁸

Pituitary Gland The posterior pituitary gland can be affected in LCH patients causing central DI (see “Endocrine System” below). Anterior pituitary involvement may result in impaired growth and sexual maturation.

Multisystem Disease

In multisystem LCH, the disease presents in multiple organs or body systems, including liver and spleen, marrow (high-risk sites) or bones, lungs, skin, lymph nodes endocrine system, gastrointestinal system (low-risk sites), and CNS (intermediate-risk site depending on extent).

Liver and Spleen Patients with liver and spleen involvement have a significantly increased risk of death from LCH. Hence, these are considered “high-risk organs.”³⁹ Hepatic infiltration by LCH lesions can be accompanied by dysfunction, leading to hypoalbuminemia with ascites, hyperbilirubinemia, and clotting factor deficiencies. Sonographic imaging, computed tomography (CT), or magnetic resonance imaging (MRI) of the liver may show hypochoic or low-signal intensity along the portal veins or biliary tracts when the liver is involved.⁴⁰ One of the most serious complications of hepatic LCH is cholestasis and progressive sclerosing cholangitis.⁴¹ The median age of children with hepatic LCH is 23 months. Patients generally present with hepatomegaly with or without splenomegaly, elevated alkaline phosphatase, liver transaminases, and γ -glutamyl transpeptidase. Biopsies may or may not show CD207+ DCs.⁴² A classic histologic feature is the collection of lymphocytes around bile ducts. Seventy-five percent of children with sclerosing cholangitis do not respond to chemotherapy and ultimately require liver transplantation.⁴¹

Massive splenomegaly may lead to consumptive cytopenias and respiratory compromise. Splenectomy may ameliorate severe thrombocytopenia, but the effect is generally not sustained with progressive hepatomegaly and inflammation in the setting of uncontrolled disseminated LCH.

Lung The lungs were once considered a high-risk organ; however, review of a large series of patients shows that the treatment outcome for patients with lung and bone involvement is not statistically different from those with only bone LCH.⁴³ The lungs are less frequently involved in children (13 percent) than in adults (60 percent), in whom smoking is a key etiologic factor.⁴⁴ In young children with diffuse disease, therapy can halt tissue destruction and normal repair mechanisms may restore some lung parenchyma and function. “Spontaneous” pneumothorax can be the first sign of LCH in the lung. Patients also present with cough, tachypnea, or dyspnea. Ultimately, widespread fibrosis and destruction of lung tissue leads to severe pulmonary insufficiency. Declining diffusion capacity may also herald the onset of pulmonary hypertension.⁴⁵ Chest radiographs may show a nonspecific interstitial infiltrate. A high-resolution CT image of the chest is needed to visualize the cystic and nodular pattern of LCH that leads to the destruction of lung tissue.

Marrow Involvement of the marrow is considered an indicator of high risk. Most patients with marrow involvement are young children who also have diffuse disease in the liver, spleen, lymph nodes, and skin with significant thrombocytopenia or neutropenia, though some may also have scattered marrow involvement with more mild cytopenias.^{46,47} An institutional study found patients with high-risk LCH with the *BRAF*^{V600E} mutation to have 0.2 to 2.1 percent of cells from the marrow aspirate carry the mutation, with only four of seven cases being reported as having abnormal histology.⁵ LCH patients sometimes present with hemophagocytosis in the marrow.⁴⁸ The presence of CD1a+/CD207+ in the marrow or at other sites identifies hemophagocytic syndrome as secondary to LCH rather than from primary HLH (discussed in the section “Hemophagocytic Lymphohistiocytosis” below).

Endocrine System DI is the most frequent endocrine manifestation of LCH. Patients may present with an apparent “idiopathic” DI and sometimes with an enlarged pituitary gland or stalk before other LCH lesions are identified. Approximately half of these patients will have other lesions diagnostic of LCH within a year of identifying the DI.⁴⁹ A review of patients with DI and enlarged pituitary glands found the three most likely diagnoses were germinoma, LCH, and lymphoma.⁵⁰ DI followed the initial LCH diagnosis at other sites by a mean of 1 year and growth hormone deficiency occurred on the average 5 years later. Historically, the 10-year risk of pituitary involvement has been reported as 24 percent.⁵¹ In one series, this incidence of DI did not decrease

in chemotherapy-treated patients (see “Central Nervous System and Diabetes Insipidus” below). In another study the incidence of DI decreased from 40 to 20 percent after 6 months of treatment with vinblastine and prednisone for patients at risk for CNS involvement.⁵² However, after a year of this treatment, the incidence of DI was decreased to 12 percent.³⁹

Craniofacial Lesions Patients with multisystem disease and craniofacial involvement at the time of diagnosis, particularly of the ear, eye, and oral region, carried a significantly increased risk of developing DI (relative risk: 4.6).⁵³ This risk increased when the disease remained active for a longer period of time or reactivated. The risk for development of DI in this population was 20 percent at 15 years after diagnosis. Up to 56 percent of DI patients will develop anterior pituitary hormone deficiencies (growth, thyroid, or gonad-stimulating hormones) within 10 years of the onset of DI.⁵⁴

Gastrointestinal System A few patients with diarrhea, hematochezia, perianal fistulas, or malabsorption have been reported.^{55,56} Diagnosing gastrointestinal lesions in LCH is difficult because of the patchy involvement. Endoscopic evaluation may reveal CD1a+/CD207+ cells in the intestinal mucosa, though LCH involvement may be patchy and require multiple biopsies to detect.

Central Nervous System and Diabetes Insipidus DI (considered both an endocrine and a CNS manifestation of LCH) can present as an early or late condition. DI caused by damage to the posterior pituitary is the most frequent initial sign (and early manifestation) of LCH in the CNS. Pituitary biopsies are rarely done and only if the stalk is larger than 6.5 mm or there is a hypothalamic mass. The pituitary enlargement may spontaneously decrease or respond to chemotherapy.⁵⁷ However, a review of 22 patients with pituitary enlargement of 6.5 mm or greater revealed that despite regression of the mass with therapy, all had anterior pituitary deficiencies as well as MRI evidence of the CNS neurodegenerative syndrome (see “Other Chronic Central Nervous System Disease Manifestations” below) and 17 (77 percent) developed clinical signs of neurodegeneration.⁵⁸ Most often the diagnosis of LCH is established by biopsy of skin, bone, or lymph node of a patient who also has the pituitary abnormalities.

Other Chronic Central Nervous System Disease Manifestations LCH patients may develop mass lesions of the choroid plexus, or gray or white matter.⁵⁹ These lesions may contain CD1a+ DCs as well as CD8+ lymphocytes.⁶⁰ A chronic CNS problem that develops in 1 to 4 percent of LCH patients is the “LCH CNS neurodegenerative syndrome” manifested by dysarthria, ataxia, dysmetria, and, sometimes, behavior changes.^{61,62} The brain MRI in these patients shows hyperintensity of the dentate nucleus and white matter of the cerebellum on fluid-attenuated inversion recovery (FLAIR) and T2-weighted images or hyperintense lesions of the basal ganglia on T1-weighted images (Fig. 71–2). Atrophy of the cerebellum also may be seen.⁵⁹ The radiologic findings may precede the onset of symptoms by many years or can be found coincidentally. Among 83 LCH patients who had at least two MRI studies of the brain for evaluation of craniofacial lesions, DI, other endocrine deficiencies, or neuropsychological symptoms, 57 percent had radiologic neurodegenerative changes at a median time of 34 months after diagnosis. Of these patients, one-quarter had clinical neurologic deficits develop 3 to 15 years after LCH diagnosis.⁶²

LABORATORY FEATURES

LCH is defined by characteristic inflammatory lesions including histiocytes expressing CD1a and CD207 (Fig. 71–3).¹ Patients with high-risk disease may present with anemia and thrombocytopenia caused by marrow involvement and/or inflammation.^{46,47} An elevated sedimentation rate and thrombocytosis has been reported to correlate with active

Figure 71–2. Radiologic evidence of Langerhans cells histiocytosis and CNS neurodegenerative syndrome. T2-weighted magnetic resonance image of the brain of a patient with Langerhans cells histiocytosis showing hyperintense changes of the cerebellar white matter.

LCH, but these associations are variable.⁶³ When the liver is involved hypoalbuminemia, elevated liver enzymes, and elevated bilirubin may be observed. Intestinal involvement may also cause hypoalbuminemia. Lytic lesions of the bone are identified by plain films, CT imaging, MRI, bone scan, or positron emission tomography (PET) scan. PET scans are useful for detecting lesions not found by bone scan or plain films and comparison PET scans are particularly good for providing evidence of healing after 6 to 12 weeks of therapy.⁶⁴ An institutional series found the presence of the somatic mutation in LCH lesions to correlate with

Figure 71–3. Biopsy of a bone lesion in a patient with Langerhans cell histiocytosis. Langerhans cells cytoplasm and membrane stain positively for CD207 (immunoperoxidase stain with hematoxylin and eosin [H&E] counterstain).

higher risk of initial treatment failure, and circulating cells with the *BRAF*^{V600E} mutation to correlate with active disease, though these observations remain to be validated in prospective trials.⁵

DIFFERENTIAL DIAGNOSIS

It is not unusual for infants with LCH skin lesions to have symptoms for longer than 1 year prior to having a diagnostic biopsy.³⁴ The varied cutaneous presentations of LCH may mimic a fungal diaper rash, seborrheic scalp rash or cradle cap, congenital viral infections, neuroblastoma, contact dermatitis, or psoriasis (see Fig. 71-1). Women or men with genital lesions may be thought to have a sexually transmitted disease or other infection. Oral lesions mimic other ulcerative conditions, gingival infections, or dental caries. Copious white or green discharge from the ears resembles otitis externa. Lytic bone lesions are often thought to be evidence of a malignancy such as neuroblastoma, rhabdomyosarcoma, or Ewing sarcoma. Collapsed vertebrae from LCH may mimic tuberculosis bone disease, trauma, or osteomyelitis. The interstitial infiltrates found in LCH patients with pulmonary involvement may resemble a viral pneumonia. An enlarged thymus or mediastinal lymph nodes can cause respiratory distress and wheezing similar to asthma. Enlarged lymph nodes from LCH mimic any infiltrative condition such as lymphomas, other histiocytic diseases, infections, or immune-related conditions. Likewise, hepatosplenomegaly of LCH patients can result from the same conditions. Chronic diarrhea in LCH patients may initially be considered to be an infectious or inflammatory bowel disease. Isolated DI with enlargement of the pituitary may suggest a germinoma, lymphoma, or hypophysitis. LCH should be strongly considered when symptoms of other more common conditions do not respond to therapy.

Occasionally infiltrates of LC are found in various malignancies and as such represent an attempt of the immune system to respond to that disease.⁶⁵⁻⁶⁷ Similarly LCH may be found in the thymus of patients with myasthenia gravis.⁶⁸

TREATMENT

Pediatric Patients

The current optimal treatment of childhood and adults LCH patients, as with other rare conditions, is on clinical trials. The U.S. National Cancer Institute website (<http://www.cancer.gov/cancertopics/pdq/treatment/lchistio/HealthProfessional>) and the Histiocytosis Association (<http://www.histio.org; 1-856-589-6606>) also may be useful resources.

Patients with only skin LCH, some single-bone lesions (non-CNS-risk), and isolated DI have not been studied in Histiocyte Society clinical trials, but are discussed in this section.

Skin-Limited Lesions Skin-limited lesions may require therapy if they are symptomatic. One approach is topical glucocorticoids,³³ although rarely effective. Other approaches with reported efficacy include oral methotrexate (20 mg/m² weekly)⁶⁹ or oral thalidomide (50 to 200 mg daily).⁷⁰ Topical application of nitrogen mustard may be effective for cutaneous LCH that is resistant to oral therapies, but is contraindicated for large areas of skin.⁷¹ Psoralen plus long-wave ultraviolet A radiation (PUVA) has been used as well.⁷² The approach is limited by the severity and distribution of the skin involvement.

Single Skull Lesions of the Frontal, Parietal, or Occipital Regions, or Single Lesions of Any Other Bone Curettage or curettage plus injection of methylprednisolone may be used.⁷³

Vertebral or Femoral Bone Lesions at Risk for Collapse Isolated radiation therapy is indicated for patients with single bone lesions of a vertebrae or the femoral neck, which are at risk of collapse.^{74,75} When instability of the cervical vertebrae and neurologic symptoms are present, bracing or spinal fusion may be needed.⁷⁶ Certain skull lesions, not in the CNS-risk region, could also be considered for radiation therapy.

Skull Lesions in the Mastoid, Temporal, Orbital or Base of Skull Bones (CNS-Risk Lesions) The purpose of treating these patients with systemic therapy is to decrease the risk of developing DI. In a large series of patients with CNS-risk lesions who received little or no chemotherapy there was a 20 to 50 percent incidence of DI compared to incidence rates of 10 percent in patients treated with systemic chemotherapy.⁵² The current standard of care, based on the LCH-III study, is to treat patients with single or multifocal lesions in CNS risk sites for 12 months with intravenous vinblastine and oral prednisone: weekly intravenous vinblastine (6 mg/m²) for 7 weeks, with daily oral prednisone (40 mg/m²) for 4 weeks followed by a 2-week taper. If there is a good response by 6 weeks, then vinblastine frequency is decreased to every 3 weeks. After the first 6 weeks, oral prednisone is given for 5 days at 40 mg/m² every 3 weeks with the vinblastine intravenous. Patients with suboptimal responses by 6 weeks are given an additional 6 weeks of weekly intravenous vinblastine.³⁹

Multiple Bone Lesions or Combinations of Skin, Lymph Node, or Pituitary Gland Involvement with or Without Bone Lesions Patients should be treated for 12 months with intravenous vinblastine and oral prednisone as outlined for the CNS-risk lesions. Both shorter (<6 months) treatment strategies and treatment with only a single agent (e.g., prednisone) are associated with inferior outcomes. A 37 percent reactivation rate with a two-drug regimen has been reported, versus 50 to 80 percent with only surgery or single-drug treatments.^{39,53,77}

Spleen, Liver, or Marrow (May or May Not Include Skin, Bone, Lymph Node, or Pituitary Gland Involvement) The standard therapy used for LCH in high-risk organs (spleen, liver, and/or marrow) is based upon the LCH-III results in which oral mercaptopurine was added to intravenous vinblastine/oral prednisone regimen, outlined for the low-risk patients above.³⁹ The addition of oral or intravenous methotrexate did not improve the overall survival or risk of reactivation. Another more intensive regimen (JLSG-96) has been reported that includes intravenous cytarabine, intravenous vincristine, oral prednisolone, and methotrexate for good responders or a salvage therapy with intravenous daunorubicin, intravenous cyclophosphamide, intravenous vincristine, and oral prednisolone for poor responders.⁷⁸ Both treatments lasted 7.5 months. **Table 71-3** compares the results of the LCH-III and JLSG-96 trials.

Central Nervous System Treatment of mass lesions, including enlargement of the hypothalamic-pituitary axis, parenchymal mass lesions, and leptomeningeal involvement, with cladribine has been effective. Doses of cladribine ranged from 5 to 13 mg/m² given intravenously at varying frequencies.⁷⁹

TABLE 71-3. Comparison of Treatment Outcomes in High-Risk Langerhans Cell Histiocytosis Patients

	LCH-III*	JLSG-96
Number of patients	235	59
Median age at diagnosis	1.1	0.9
Therapy duration (mo)	12	7.5
Initial response	70-72*	76
Reactivations	25-29	45
Survival	88	97

LCH-III, Histiocyte Society Langerhans cell histiocytosis treatment protocol III; JLSG-96, Japan Langerhans Cell Histiocytosis Study Group protocol 96.

*Arm A (velban/prednisone) vs. Arm B (velban/prednisone/methotrexate).

Reports for treatment of the CNS neurodegenerative syndrome have been limited to case series and pilot studies. Strategies include oral dexamethasone, intravenous cladribine, oral all-*trans* retinoic acid, intravenous immunoglobulin, and intravenous cytarabine.^{80–82} All-*trans* retinoic acid was given at a dose of 45 mg/m² daily, orally, for 6 weeks, then 2 weeks a month for 1 year. Intravenous immunoglobulin, 400 mg/m² monthly. Some investigators have given chemotherapy along with the IVIG. The chemotherapy plan was prednisolone 2 mg/kg 5 days a month with or without oral or IV methotrexate 20 mg/m² one day every 2 weeks, daily oral 6-mercaptopurine 1.5 mg/kg/day, or monthly vinblastine 6 mg/m²/dose once monthly for a year. MRI findings were stable, but clinical efficacy was difficult to judge as patients were reported to have no progression in their neurologic symptoms. Intravenous cytarabine with or without intravenous vincristine was effective in decreasing neurologic symptoms and improving the MRI images in five of eight patients who were stable for longer than 8 years.

Recurrent, Refractory, or Progressive Childhood Langerhans Cell Histiocytosis

Recurrent “Low-Risk” Organ Involvement The optimal therapy for patients with relapsed or recurrent disease has not been determined. Patients with recurrent bone disease who reoccur more than 6 months after stopping vinblastine and prednisone can benefit from treatment with a “reinduction” of intravenous vinblastine, weekly, and daily oral prednisone for 6 weeks. If there is no active disease, or at least very little evidence of active disease, then treatment can be changed to every 3 weeks with the addition of oral methotrexate weekly and oral 6-mercaptopurine nightly. Three approaches (1) intravenous cladribine, (2) intravenous vincristine and intravenous cytarabine, and (3) intravenous clofarabine are effective regimens for patients with recurrent bone disease.^{83–85}

A phase II trial of oral thalidomide for LCH patients (10 low-risk patients; 6 high-risk patients) who failed primary and at least one secondary regimen showed a complete response in 4 of 10 and partial responses in 3 of 10 low-risk patients. However, dose-limiting toxicities and extraordinary cost limit the overall usefulness of thalidomide.⁷⁰

Recurrent High-Risk Organ Involvement A new treatment plan is indicated when a patient with multisystem involvement progresses after 6 weeks of standard treatment, or has not had a partial response by 12 weeks. Data from the LCH-III study showed only 57 percent survival for this group. A prospective trial with cladribine (5 mg/m² per day, intravenously, for 5 days monthly for 6 months) had high rates of response in patients with recurrent and refractory low-risk, but not high-risk, LCH.⁸⁵ Another regimen for patients with refractory high-risk LCH is treatment with a highly intensive strategy based on acute myelogenous leukemia protocols. Treatment with high-dose cladribine (9 mg/m² per day) coupled with cytarabine (1 g/m² per day) for 5 days for at least 2 months resulted in increased overall survival and cure in previously refractory patients. However, there was also a relatively high treatment-related mortality.⁸⁶ Institutional case series with intravenous clofarabine (25 mg/m²/day for 5 days/month) have promising results in patients who have failed multiple previous strategies with manageable toxicities.^{87–89} There is considerable interest in use of the BRAF inhibitors for treatment of refractory and recurrent LCH in patients with the BRAF^{V600E} mutation. There are pediatric and phase I studies for several anti-BRAF compounds. Concern for more widespread use in the setting of pediatric LCH is tempered by the toxicity profile that includes high incidence of squamous cell carcinoma in melanoma patients.⁹⁰ There is only one published report on use of oral vemurafenib for two adult patients who had LCH and ECD with positive responses.⁹¹

Allogeneic hematopoietic stem cell transplantation (AH SCT) has been used for patients with multisystem high-risk organ involvement that is refractory to chemotherapy. Reduced-intensity conditioning

regimens are curative and associated with less toxicity and improved survival.⁹²

Options No Longer Considered Effective Treatments for LCH in any location that have been used in the past but are no longer recommended include cyclosporine and interferon (IFN)- α . Extensive surgery is also not indicated. It is critical that LCH bone lesions (especially skull and mandible) not be treated by excision with wide margins. Even large defects may remodel to near normal architecture following resolution of LCH follow chemotherapy and/or curettage. Similarly, surgical resection or radiotherapy of groin or genital lesions is contraindicated as chemotherapy can heal skin lesions.

COURSE AND PROGNOSIS

LCH patients with low-risk disease treated with vinblastine and prednisone have a 99 percent chance of survival, but more than 50 percent fail to be cured with initial therapy. Nearly 100 percent of these patients are ultimately cured of LCH, though many require multiple courses of salvage therapy. Patients with high-risk disease who do not respond adequately by 12 weeks of treatment now have an 87 percent chance of long-term survival, but also often require salvage therapy as described earlier.

PERMANENT CONSEQUENCES AND LATE EFFECTS OF TREATMENT

Disease-associated sequelae remain a major challenge for patients with LCH, with risk of complications increasing with multisystem, high-risk, and prolonged duration of active disease. Children with low-risk organ involvement (skin, bones, lymph nodes, or pituitary gland) treated for 6 months have a 24 percent chance of developing long-term sequelae.⁹³ Those with DI are at risk for panhypopituitarism and should be monitored carefully for adequacy of growth and development. In a retrospective review of 141 patients with LCH and DI, 43 percent developed growth hormone deficiency.⁵⁴ The 5- and 10-year risks of growth hormone deficiency among children with LCH and DI were 35 percent and 54 percent, respectively. There was no increased reactivation of LCH in patients who received replacement growth hormone compared to those who did not.

Patients treated before 2000 with multisystem involvement had a 71 percent incidence of long-term problems.^{93,94} Hearing loss has been found in 13 percent of children treated for LCH. Neurologic symptoms secondary to vertebral compression of cervical lesions have been reported in LCH patients with spinal lesions. Cognitive defects and MRI abnormalities may develop in some long-term survivors with CNS-risk skull lesions.⁹⁵ Some patients have markedly abnormal cerebellar function and behavior abnormalities, while others have subtle deficits in brain stem-evoked potentials and short-term memory.⁹⁶

Orthopedic problems from lesions of the spine, femur, tibia, or humerus may be seen in 20 percent of patients. These problems include vertebral collapse or instability of the spine that may lead to scoliosis, and facial or limb asymmetry.

Diffuse pulmonary disease may result in poor lung function with higher risk for infections and decreased exercise tolerance. These patients should be followed with pulmonary function testing including the diffusing capacity of carbon monoxide and ratio of residual volume to total lung capacity.⁴⁵

Liver disease may lead to sclerosing cholangitis which responds to chemotherapy in only 25 percent of cases and liver transplantation usually is indicated.⁴¹

Dental problems characterized by loss of teeth have been significant for some patients, usually related to overly aggressive dental surgery.⁹³

Marrow failure secondary to LCH or from therapy is rare but is associated with a higher risk of malignancy. Patients with LCH may have a higher than normal risk of developing secondary cancers.⁹⁷ Leukemia (usually acute myelogenous) occurs after treatment as does lymphoblastic lymphoma. Concurrent LCH and a malignancy have been reported in a few patients, and some patients have had their malignancy initially followed by development of LCH. Three patients with T-cell acute lymphoblastic leukemia (T-ALL) and aggressive LCH, for which the two disorders had shared clonal markers have been reported.^{98,99} Two cases had clonality of the same T-cell receptor genotype. The authors considered the plasticity of lymphocytes permitting development into LCs. The other patient with LCH after T-ALL had the same T-cell receptor gene rearrangements and activating mutations of the *NOTCH1* gene in the patient's DCs and acute lymphoblastic leukemia (ALL) blasts. A series of four patients with acute leukemia of ambiguous or myeloid lineage with intermingling LCH cells have been reported.¹⁰⁰ The authors speculated the two diseases shared a common hematopoietic stem cell as had been suggested earlier during investigation of the *BRAF*^{V600E} mutation in the marrow of LCH patients.⁶

ADULT LANGERHANS CELL HISTIOCYTOSIS

Incidence

It is estimated that one to two adult cases of LCH occur per 1 million population.¹⁰¹ The true incidence of this disease is difficult to assess because large published studies usually are from referral centers and the disorder often is underdiagnosed. A survey from Germany reported that 66 percent of the adult LCH patients were women with an average age of 43.5 years.¹⁰²

Pathogenesis

There are no studies to compare the biology of LCH in adults and children. The association of adult pulmonary LCH with smoking and evidence that the incidence of *BRAF*^{V600E} mutations in adult LCH tissue is not the same as in the pediatric population indicates some differences. The LCs in adult lung lesions are mature DCs expressing high levels of the accessory molecules CD80 and CD86, unlike LCs found in other lung disorders.¹⁰³ Molecular studies have shown pulmonary LCH in adults is primarily a reactive process, rather than a clonal proliferation as seen in childhood LCH.¹⁰⁴ Subsequent investigations by this group with the Ion AmpliSeq technology showed two of five adult pulmonary LCH patients had the *BRAF*^{V600E} mutation.¹⁰⁵ An analysis of *BRAF*^{V600E} expression by immunohistochemistry (IHC) and molecular techniques (allele-specific polymerase chain reaction [PCR] and Sanger sequencing) has also been reported for a series of adults with isolated pulmonary LCH and others with nonpulmonary lesions.¹⁰⁶ Of the pulmonary LCH cases 7 of 25 (28 percent) were positive for *BRAF*^{V600E} expression by IHC. The cumulative pack-years of smoking was significantly higher in the *BRAF*-positive adult pulmonary LCH patients than in the wild-type *BRAF* cases. Only 19 of 54 (35.2 percent) of the nonpulmonary cases had the *BRAF* mutation. The frequency of *BRAF*^{V600E} mutation in North American pediatric series ranged from 57 to 65 percent based on deep sequencing and quantitative PCR.^{5,19} It is possible that technical differences in sensitivity underlie the relatively decreased reported frequency of *BRAF*^{V600E} in adult cases of LCH. Further studies in adult patients will be needed to determine if age or ethnicity influence the role of *BRAF* mutations in LCH pathogenesis.

Clinical Findings

Adult LCH patients may have symptoms and signs for many months before a definitive diagnosis is made and treatment instituted. LCH in adults is often similar to that in children, except that isolated adult pulmonary LCH is closely associated with smoking. Presenting symptoms

are (in order of decreasing frequency) dyspnea or tachypnea, polydipsia and polyuria, bone pain, lymphadenopathy, weight loss, fever, gingival hypertrophy, ataxia, and memory problems. Among the signs of LCH are skin rash, scalp nodules, soft-tissue swelling near bone lesions, lymphadenopathy, gingival hypertrophy, hepatosplenomegaly. Patients who present with isolated DI should be carefully observed for onset of other symptoms or signs characteristic of LCH. At least 80 percent of patients with DI had involvement of other organ systems: bone (68 percent), skin (57 percent), lung (39 percent), and lymph nodes (18 percent).¹⁰⁷

Many patients have a papular rash with brown, red, or crusted areas ranging in size from a pinhead to a dime. In the scalp the rash is similar to seborrhea. Skin in the inguinal region, genitalia, or around the anus may have open ulcers that do not heal after antibacterial or antifungal therapy. In the mouth, swollen gums or ulcers along the cheeks, roof of the mouth, or tongue occur. In a series of 18 patients with skin LCH collected from 5 centers in the Netherlands followup revealed 5 developed malignancies which included 2 with myelomocytic leukemia, 1 with histiocytic sarcoma, and 2 with lymphomas. A literature review produced 6 additional cases of adults who had skin LCH and subsequently developed hematologic malignancies.¹⁰⁸

The sites of bone involvement in adults differ from that of children. Lesions in the mandible occur in 30 percent of adults versus in 7 percent of children, and skull lesions in occur 21 percent of adults versus in 40 percent of children.^{102,109} The frequency of LCH lesions in the vertebrae (13 percent), pelvis (13 percent), extremities (17 percent), and ribs (6 percent) of adults is similar to that found in children.

Pulmonary LCH is slightly more prevalent in smokers than in non-smokers and the male-to-female ratio may be near unity depending on the incidence of smoking in the population studied.^{44,102,110} Patients with pulmonary LCH usually present with cough, dyspnea, or chest pain, although nearly 20 percent of adults with lung involvement have no symptoms.¹¹¹ The sudden onset of chest pain may indicate a spontaneous pneumothorax. The most frequent pulmonary function abnormality finding (80 percent of patients) with pulmonary LCH is a reduced carbon monoxide diffusing capacity.^{112,113} A long-term retrospective study of 49 pulmonary LCH patients showed that lung function deteriorated within 2 years in 60 percent of patients and the forced expiratory volume in 1 second (FEV₁) and diffusing capacity in lung for carbon dioxide (DLCO) were the parameters that most often declined.¹¹⁴ Airway obstruction was the most important functional pattern observed, which correlated with the percent predicted FEV₁. In this series, the investigators found pulmonary function tests much better than serial CTs for following the disease course and response to therapy. A high-resolution CT scan can uncover cysts and nodules, usually in the upper lobes characteristic of LCH. Despite the typical CT findings, a lung biopsy is needed to confirm the diagnosis.¹¹⁵ The presence of cystic abnormalities on high-resolution CT scans does not predict which patients will have progressive disease.¹¹⁶ Adults with pulmonary LCH can have multisystem disease, including bone (18 percent) or skin (13 percent) lesions and DI (5 percent).

Therapy

Although adult patients have been treated with vinblastine and prednisone, vinblastine often causes significant neuropathy in adults when given weekly for 6 weeks, and glucocorticoids are not tolerated as well by adults as children. Alternative approaches in adults for initial therapy include either intravenous cytarabine or intravenous cladribine. The latter is effective for adults with skin, bone, lymph node, and probably pulmonary and mass lesions in the CNS.^{79,117,118} A review of 58 adults with bone lesions compared the efficacy and toxicity of intravenous vinblastine plus oral prednisone to intravenous cladribine or cytarabine.¹¹⁹ In this retrospective review, cytarabine had the best outcomes, with 21

percent of treated patients unresponsive and 20 percent with grades 3 to 4 hematologic toxicity as opposed to intravenous vinblastine plus oral prednisone after which there was an 84 percent of patients without a satisfactory response and 75 percent grades 3 to 4 neurotoxicity. Patients receiving cladribine had an inadequate response 59 percent of the time and had a 37 percent incidence of hematologic toxicity. The relatively promising efficacy and safety of cytarabine in adults with LCH should be confirmed in a prospective study.

As in pediatric cases, extensive or mutilating surgery to remove skin lesions, teeth or jaw bones is not indicated. Systemic chemotherapy will cause bone lesions to regress and the involved teeth and jaw bones can reform. Oral thalidomide and oral methotrexate have also been effective in adults with skin disease.^{69,70} Anecdotal reports have described the successful use of the intravenous bisphosphonate pamidronate in controlling severe bone pain in patients with multiple osteolytic lesions.^{120,121}

A consensus document authored by experts treating adults with LCH with guidelines for evaluation and management has been published.¹²² A clinical trial for adults with LCH was conducted for an agent that inhibited AKT signaling activity, with responses in some patients.¹²³ There are no current clinical trials for adult LCH patients, although some studies enrolling patients for treatment with MAPK pathway inhibitors may include LCH among the diagnoses being studied.

Adult Langerhans Cell Histiocytosis Patients with Lung Disease and Who Smoke Cigarettes Most adult patients with LCH have gradual disease progression with continued smoking. The disease may regress or progress with the cessation of smoking.¹²⁴ Lung transplantation may be necessary for adults with extensive pulmonary destruction from LCH.¹²⁵ A multicenter study documented a 54 percent survival at 10 years after lung transplantation, with 20 percent of patients having recurrent LCH, which did not impact on survival, but longer followup of these patients is needed.

MALIGNANT HISTIOCYTIC DISEASES

DEFINITION AND HISTORY

The original description of this group of malignant histiocytosis is attributed to Scott and Robb-Smith who, in 1939, reported cases of a rapidly fatal disease with jaundice, lymphadenopathy, anemia, leucopenia, and hepatosplenomegaly that they called *histiocytic medullary reticulosis*.¹²⁶ They believed the malignant cell was a histiocyte based upon the accepted morphologic criteria of that time. Advanced immunohistochemical techniques resulted in identifying cells as either lymphocytes or histiocytes. The disease was labeled *giant cell reticulosis* and the cells *reticulum cells* based upon their large size, but revealed little as to the place of these cells in the immune system. Later, Rappaport introduced the term *malignant histiocytosis*,¹²⁷ as he believed the morphologic characteristics identified the histiocyte as the malignant cell. There has been considerable debate about the identity of malignancies of LC histiocytes as the majority of patients with “histiocytic lymphoma or malignant histiocytosis” reported in the literature had one of the variants of large cell lymphoma.^{128,129} By excluding patients with anaplastic large cell lymphomas and other T- or B-lineage large cell lymphomas, the resulting number with malignancies of histiocytes becomes very small. Favara and colleagues suggested that such diseases should be considered sarcomas of histiocytic or macrophage-related lineage. An updated review of the histologic features of these neoplasms based upon the 2008 World Health Organization (WHO) Classification has been published.¹³⁰ One of the major changes is that the 2001 WHO definition of histiocytic sarcoma (HS) stated that the neoplasms could not have

clonal B/T-cell receptor gene rearrangements. Now because more cases of “transdifferentiation” between lymphoid malignancies and HS are being recognized, these gene rearrangements are being included among HS. Among the prior or subsequent malignancies associated with HS are B- or T-lymphoblastic lymphoma/leukemia, mature B-cell lymphomas, follicular lymphoma,^{100,131} chronic lymphocytic leukemia with *BRAF*^{V600E} mutation in both malignancies,^{100,132} mantle cell lymphoma, extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue, splenic marginal zone lymphoma, and diffuse large B-cell lymphoma. A series of four cases of HS with acute leukemia of ambiguous or myeloid lineage have also been reported.¹⁰⁰

Acute myelogenous leukemias with a dominant monocytic phenotype represent the other group of malignant disorders involving monocytic cells. Descriptions of the clinical presentation, biology, and treatment of the monocytic leukemias and large cell lymphomas are presented elsewhere in this book (Chaps. 88 and 98, respectively).

Histologically, the tumors consist of large, overtly malignant-appearing cells in a diffuse, noncohesive array often in the lymph node sinuses or paracortical areas. They are round to oval and sometimes spindle shaped. Hemophagocytosis may be seen. The nuclei may be oval, indented, convoluted, or irregular, and may display mild to severe atypia.¹³⁰

The markers most specific for histiocytic cells include monocyte/macrophage colony-stimulating factor (M-CSF) receptor, lysozyme, Ki-M8, S100+, Ki-M4, cathepsins D and E, CD21-, and CD35-. If a dendritic-histiocytic cell proliferation meets a combination of criteria as “malignant,” such as having a clonal cytogenetic abnormality, aneuploid DNA profile, malignant histiocytomorphology, other evidence of monoclonality, and an aggressive clinical course, it is classified as a HS.

An international panel of experts reviewed 61 cases of tumors of histiocytes and accessory DCs.¹³³ Seventeen cases (27 percent) were classified as HS and were CD68+, lysozyme+, CD1a-, S100-/+ , CD21-, and CD35-. LC tumors (24 cases, 38 percent) were CD68+, lysozyme-/+ , CD1a+, S100+, and CD21/35-. Interdigitating DC sarcomas (four cases, 7 percent) were CD68+/- , lysozyme-, CD1a-, S100-/+ , and CD21/35-. Follicular DC tumors (13 cases, 21 percent) were CD68+/- , lysozyme-, CD1a-, S100-/+ , and CD21/35+. Four cases were unclassifiable. The 2008 WHO classification added immunostaining with anti-CD163, a hemoglobin scavenger receptor, as a criterion, which identifies monocytes and histiocytes and is more specific than anti-CD68. HS found with or subsequent to B-cell lymphomas may have that tumor’s immunophenotype and particular features such as BCL6 nuclear staining and BCL2 protein expression. *BRAF*^{V600E} mutations were reported in five of eight patients with HS and 5 of 27 with follicular DC sarcoma by Sanger sequencing and quantitative PCR.^{100,134}

EPIDEMIOLOGY

Although malignant dendritic/histiocytic cell tumors affect all age groups, the median age is 33 years.¹³³ Males are affected more often than females and most patients had HSs and LC tumors. One review of more than 2000 lymphoma cases found eight patients (0.4 percent) with HSs.¹³⁵ Another review found 1 percent of all hematolymphoid neoplasms to be HS with a median age at diagnosis of 46 years.¹³⁰

CLINICAL FEATURES

Systemic symptoms of fever, headache, malaise, weight loss, dyspnea, and sweating occur in patients with diffuse disease.^{133,135,136} Lymphadenopathy is the most common presenting feature, but involvement of the spleen, gastrointestinal tract, skin, and soft tissue are common. Marrow involvement occurs in approximately 25 percent of the patients.

Dendritic or Langerhans Cell Sarcomas

Histologic differentiation of dendritic-LC sarcomas from HS include long DC processes, convoluted nuclei, more intense S100 staining and weaker CD68 staining. These patients may have fever or weight loss. They usually present with erythematous nodules or a skin rash, and may also have involvement of bone, lymph nodes, lung, liver, or brain.^{137,138} A series of histiocytic-DC sarcomas in patients with follicular lymphomas showed a clonal evolution from the B-cell lymphoma to myeloid-derived sarcomas.

Extranodal Histiocytic Sarcomas

These tumors occur equally in males and females and present at a median age of 55 years.¹³⁹ Tumors are found in the soft tissue of extremities, the gastrointestinal tract, the nasal cavity, and the lung, sometimes with involvement of regional lymph nodes. Gastrointestinal masses were usually painful. Extremity tumors often present as painless masses. Patients had symptoms or signs for 1 month to 2 years before diagnosis. Most tumors are localized at the time of diagnosis.

Interdigitating Dendritic Cell Sarcomas

Interdigitating DC sarcomas may occur as extranodal tumors in children and primarily affect lymph nodes in adults.¹⁴⁰ A report of four pediatric cases had involvement of the chest wall, vertebrae, lymph nodes, marrow, and pelvic space. Of the other seven pediatric and 26 adult cases, 17 had extranodal presentations. Many of the 17 cases had intestinal or mediastinal tumors. These tumors were very aggressive in a third of cases.^{141,142}

Follicular Dendritic Cell Tumors

The malignant cells in these patients are spindle to ovoid forming fascicles, storiform patterns and whorls which stain with CD21, CD23, and CD35. These malignancies affect males and females equally and present at a median age of 47 years (range: 14 to 77 years).¹⁴¹ Nodal and extranodal sites can be affected. Most frequent nodal presentations are cervical, axillary, and supraclavicular; mediastinal and mesenteric nodes can also be affected. These tumors are usually slow growing and painless. Although local invasion is common, metastasis to sites other than the lungs is uncommon.

LABORATORY FINDINGS

Patients with diffuse disease may have pancytopenia, although leukocytosis occurs in some as a secondary response. Hemophagocytosis is occasionally seen in the marrow. An elevated lactate dehydrogenase and erythrocyte sedimentation rate may be found.

DIFFERENTIAL DIAGNOSIS

A diagnostic biopsy with a full immunophenotype panel should be done for these rare tumors, which have been mistaken for Hodgkin lymphoma, anaplastic large cell lymphoma, or large cell lymphomas of T- or B-cell subtypes. The DC neoplasms do not express T- or B-lymphocyte markers and do not have rearrangements of immunoglobulin or T-cell receptor genes.^{133,142,143} Malignant fibrous histiocytoma, fibrosarcoma, leiomyosarcoma, rhabdomyosarcoma, or melanoma may simulate interdigitating DC sarcoma, as well as inflammatory pseudotumor. Although follicular DC sarcoma and histiocytic lymphoma may have a similar presentation, the specific immunophenotype of the tumors helps differentiate them from interdigitating DC sarcoma. Thymomas, meningiomas, and malignant fibrous histiocytomas can mimic follicular DC sarcoma, but they lack CD21 and CD35.

TREATMENT, COURSE, AND PROGNOSIS

Therapy for dendritic and LC sarcomas has usually been unsuccessful.¹⁴⁴ However, case reports of long-term remissions with oral thalidomide,^{145,146} intravenous alemtuzumab,¹⁴⁷ or intravenous MAID (mesna, doxorubicin [Adriamycin], ifosfamide, and dacarbazine)¹⁴⁸ have been published. In some instances, surgical resection of a localized mass with radiotherapy has been successful.

Interdigitating DC sarcomas, also, have been treated successfully with surgery alone or a combination of surgery and radiotherapy, when the tumor is localized.¹⁴⁰ Patients with stage III/IV tumors generally do not respond to multidrug chemotherapy, such as intravenous cyclophosphamide, doxorubicin, and vincristine and oral prednisone with or without the addition of intravenous actinomycin D.

MALIGNANT FIBROUS HISTIOCYTOMA AND GIANT CELL TUMOR OF THE BONE

Gene-profiling experiments have shown that these tumors are not derived from histiocytes, but are poorly differentiated fibrosarcomas, myosarcomas, fibromyxosarcomas, or liposarcomas.¹⁴⁹⁻¹⁵¹ They are treated with a similar approach as are osteosarcomas.¹⁵²⁻¹⁵⁴

ERDHEIM-CHESTER DISEASE

DEFINITION AND HISTORY

In 1930, two cases of "lipid granulomatosis" were described by William Chester and Jakob Erdheim and later designated as *Erdheim-Chester disease*.¹⁵⁵ The histopathologic characteristics of ECD overlap xanthogranuloma and distinctions between the two are made on the basis of clinical and radiologic findings. Lipid-laden histiocytes with foamy or eosinophilic cytoplasm infiltrate bones and various organs and generate a fibroblastic response that leads to critical organ failure. The histiocytes are CD68+, CD163+, factor XIIIa+, CD1a-, and S100-, and do not contain Birbeck granules. Touton-like giant cells are commonly found.

EPIDEMIOLOGY/ETIOLOGY

This disease primarily affects adults (mean age: 53 years; range: 7 to 84 years) with a predominance of males (73 percent).¹⁵⁶ There is no known etiology. Cells from ECD biopsies have been found to be clonal in three of five cases tested and polyclonal in two.¹⁵⁷⁻¹⁵⁹ Elevated levels of osteopontin in ECD tissue have been found at diagnosis, which then declined after treatment with prednisolone.¹⁶⁰ It is difficult to judge the exact role of osteopontin in ECD as it has many functions as a noncollagenous, extracellular matrix protein that may affect cell adhesion, migration, and other functions. Immunohistochemical staining of ECD tissue shows expression of CCL2 (monocyte chemoattractant protein 1), CCL4 (macrophage inflammatory protein-1 β [MIP-1 β]), CCL5 (RANTES [regulated upon activation, normal T-cell expressed and secreted]), CCL20 (MIP-3 α), and CCL19 (MIP-3 β), along with their receptors CCR1, CCR2, CCR3, CCR5, CCR6, and CCR7.¹⁶¹ Elevated expression of an IFN- γ -inducible protein, IL-6, and RANKL has been described. The latter two factors are important for bone remodeling. Biopsies of 32 of 37 patients with ECD had prominent staining for the platelet-derived growth factor receptor- β . The inflammatory nature of ECD is indicated by an elevation of cytokines in a cohort of 37 patients. A T-helper type 1 (Th1)-associated signature in ECD patients was associated with

elevation of IFN- α , IL-12, monocyte chemoattractant protein-1 (MCP-1), IL-4, and IL-7, but there was little difference in the levels of these before and after treatment with IFN- α .

Discovery of *BRAF*^{V600E} mutations in LCH and ECD has opened important research initiatives as well as the possibility of targeted therapy. Thirteen of 24 (54 percent) ECD patients and 38 percent of LCH patients had this mutation.¹⁶² An *NRAS* mutation has also been found in ECD, further documenting the importance of the MAPK pathway.¹⁶³ The frequent occurrence of lesions classified as LCH and ECD in the same patient, along with common finding of *BRAF*^{V600E} mutation, suggests a common cell of origin in some patients.¹⁶⁴

CLINICAL FEATURES

A consensus paper on the evaluation and treatment of ECD has been published with helpful summaries of clinical, laboratory, and radiologic findings.¹⁶⁵ Many patients have fever, weakness, and weight loss. The clinical findings include CNS symptoms (50 percent), bone pain (40 percent), xanthelasma (27 percent), exophthalmos (27 percent), and DI (22 percent).¹⁶⁶ Some patients have cerebellar signs and focal neurologic deficits.¹⁶⁷ Fifty percent of patients have extraskeletal disease. It is unusual for lymph nodes, liver, spleen, or axial skeleton to be affected, whereas these areas are frequently affected in LCH and RDD. Retroperitoneal and renal involvement occurs in one-third of ECD patients and causes abdominal pain, dysuria, and hydronephrosis. Pulmonary involvement may present in 20 percent of patients and results in dyspnea. Skin manifestations of ECD include xanthomatous lesions that may begin as reddish-brown papules similar to xanthoma disseminatum. Cardiac dysfunction occurs because of circumferential sheathing of the aorta, and aortic branches, including coronary arteries, but often is not symptomatic. There may also be endocardial, myocardial, or pericardial involvement, leading to pericardial effusions with the risk of tamponade.^{168,169}

CNS involvement may occur in up to 50 percent of ECD patients. Cerebellar and pyramidal symptoms are the most frequent, but headaches, neuropsychiatric or cognitive difficulties, and cranial nerve palsies are reported.¹⁷⁰ Parenchymal CNS lesions causing disability are a poor prognostic indicator.¹⁷¹ ECD may infiltrate any CNS location within or outside the neuraxis, including the pachymeninges, and are similar to meningiomas, sarcoidosis, Wegener granulomatosis, RDD, or LCH. Orbital involvement causes proptosis and pituitary infiltration leads to DI in nearly 25 percent of patients.

LABORATORY FEATURES

There are no specific laboratory findings, but elevated sedimentation rate and alkaline phosphatase have been reported in approximately one-fifth of cases. The consensus publication on ECD provides a list of baseline radiologic tests which include PET/CT, MRI brain with contrast and attention to the pituitary, cardiac MRI, and when indicated clinically, MRI of the orbits with contrast, renal artery ultrasound, high-resolution CT of the chest, pulmonary function tests, testicular ultrasound, and electromyography. Radiographs show bilateral patchy osteosclerosis of the metaphysis and diaphysis of the femur, proximal tibia, and fibula in nearly 100 percent of patients. Lytic lesions are found in approximately one-third of patients. Chest CT imaging findings include diffuse interstitial infiltrates, and pleural and interlobular septal thickening.¹⁶⁹ Perirenal infiltration, extending through the fat of the anterior or posterior pararenal spaces, leading to the classic “hairy kidney” appearance (>60 percent of patients) and circumferential sheathing of the aorta (>60 percent of patients), as well as retroperitoneal

fibrosis-like infiltrates (20 percent), can be seen on an abdominal CT scan and MRI of the heart.

DIFFERENTIAL DIAGNOSIS

Although histologically distinct, the clinical features may suggest LCH, RDD, JXG, or xanthoma disseminatum. Some clinical features overlap with sarcoidosis, amyloidosis, Paget disease, Ormond disease (idiopathic retroperitoneal fibrosis), and Whipple disease (intestinal lipodystrophy). The histologic features can be confused with Gaucher disease, Niemann-Pick disease, mucopolysaccharidosis, or malakoplakia.¹⁷²

THERAPY

Subcutaneous IFN- α and pegylated IFN- α are considered the first-line treatments for ECD.¹⁷³ Survival has been improved using doses of 3 million units, 3 times a week.^{174–178} When the standard dose is ineffective, increasing the IFN- α dose to greater than 18 million units per week or use of pegylated IFN- α to a dose greater than 180 mcg/wk is recommended. Treatments have been extended for as long as 3 years. Patients treated with the high-dose regimens had a stabilization of CNS disease in 64 percent and of cardiac involvement in 79 percent.

Earlier published treatment results include a review of 37 patients treated with glucocorticoids, usually 1 mg/kg per day, orally, resulting in decreased exophthalmos or general symptoms in 20 patients.¹⁵⁶ Among these patients, glucocorticoids were effective in six patients, transiently effective in four, and ineffective in eight. Of eight patients treated with a variety of chemotherapy agents and glucocorticoids, four had improvement. Radiation was ineffective for orbital masses, but transiently relieved bone pain. A series of six patients treated with oral imatinib mesylate reported two had stable disease and one an initial response before worsening.¹⁷⁹ Some patients have been treated effectively with intravenous cladribine.¹⁸⁰ Anticytokine treatments with anakinra, infliximab, and tocilizumab have had varying degrees of success in a limited number of patients. Anakinra is given at 1 to 2 mg/kg per day, intravenously, and may work best for patients with bone pain and other systemic symptoms.^{181–183} However, it seems to be less effective than IFN- α . The same can be said for the anti-tumor necrosis factor α drugs, intravenous infliximab and intravenous etanercept.

Clinical trials currently open to open to ECD patients include:

- NCT01524978 Vemurafenib: anti-*BRAF*^{V600E}
- NCT01727206 Tocilizumab: anti-IL-6 (phase II clinical trial)
- ACTRN12613001321730: Sirolimus and prednisone (prospective trial)

COURSE AND PROGNOSIS

Nearly 60 percent of ECD patients die of their disease; 36 percent die within 6 months. The mean survival duration is less than 3 years. Cardiac, pulmonary, and renal failure are the primary causes of death.

JUVENILE XANTHOGRANULOMA

DEFINITION AND HISTORY

JXG is a histiocytic disorder that affects the skin with multiple nodules in the head, neck, and trunk primarily in children, although adults can also be affected.¹⁸⁴ The lesional cells are derived from dermal dendrocytes. Systemic involvement occurs in a few cases. Rudolf Virchow may have been the first to describe a child with what he called “cutaneous xanthomas” in 1871.

EPIDEMIOLOGY

Children with solitary lesions have a median age of onset of 2 years with a male-to-female ratio of 1.5:1. Children with multiple lesions have a median age of onset of 5 months and have a male-to-female ratio of 12:1. No population study of JXG has been reported, so the precise incidence is unknown. However, a review of JXG from the Kiel Pediatric Tumor Registry recorded 129 (0.52 percent) cases of JXG and 800 (3.3 percent) cases of LCH among 24,600 children over a 36-year period.

ETIOLOGY AND PATHOGENESIS

There is no known cause of JXG. Patients with JXG and neurofibromatosis types 1 and 2, as well as the triad of the aforementioned diseases with juvenile chronic myelogenous leukemia, have been reported.^{185–187} These and other cases have suggested an increased risk of leukemia in neurofibromatosis patients with JXG, but there is no rigorous proof for this association.^{188,189}

CLINICAL FEATURES

The majority of patients are children younger than 2 years of age who have solitary skin nodules on their head, neck, or trunk.^{184,190} The lesion is most often the same color as surrounding skin, but may be erythematous or yellowish. Rarely, nodules may be in the subcutaneous fat, deep soft tissue, or skeletal muscle. Organ involvement is rare, but has been reported in the soft tissue, CNS, bone, lung, liver, spleen, pancreas, adrenal, intestines, kidneys, lymph nodes, marrow, and heart.^{184,190,191} Systemic symptoms and signs occur only if these organ systems are involved.

LABORATORY FEATURES

Immunohistochemical staining of biopsies is necessary to differentiate JXG from other histiocytic lesions. JXG classically stains with a macrophage marker such as antibodies to CD68 or Ki-M1P, factor XIIIa, fascin, vimentin, and often CD4. They are negative for S100 and anti-CD1a. There are three characteristic histologic patterns: early JXG, classic JXG, and transitional JXG.¹⁹⁰ Early JXG is characterized by small- to intermediate-size mononuclear histiocytes in sheet-like infiltrates. The cells in this category have only small quantities of lipid in the cytoplasm and Touton-type giant cells are absent. This type has relatively more mitoses than the others, but there is no cytologic atypia. Classic JXG exhibits abundant vacuolated, foamy histiocytes with Touton giant cells (lipid-laden histiocytes with multiple nuclei and a small amount of centrally oriented cytoplasm). Transitional JXG has a predominance of spindle-shaped cells resembling benign fibrous histiocytoma with foamy histiocytes and occasional giant cells.¹⁹⁰ Biopsies also contain lymphocytes, eosinophils, and occasionally Charcot-Leyden crystals. If the marrow is involved, patients may have cytopenias. Liver infiltration may cause elevation of liver enzymes, hypoalbuminemia, and an elevated erythrocyte sedimentation rate. Pituitary involvement may lead to DI. Hypercalcemia has been reported. CNS lesions can lead to hydrocephalus, seizures, and developmental delay.

DIFFERENTIAL DIAGNOSIS

LCH is the disease most often confused with JXG. Other disorders to be considered include fibrohistiocytic lesion not otherwise specified, reticulohistiocytoma, hemangioendothelioma, Spitz nevus, malignant fibrous histiocytoma, and rhabdomyosarcoma or other malignancies.

THERAPY

Patients with a single or only a few lesions need no therapy. An excisional biopsy can be used, if desired for cosmetic reasons. For the rare patients who have systemic disease and require treatment a wide variety of chemotherapy and radiotherapy regimens have been reported.^{191–193} Inclusion of a vinca alkaloid and a glucocorticoid is associated with better overall response rates than single agents. A child with CNS JXG who failed to respond to vinblastine was successfully treated with cladribine.¹⁹⁴ A series of four children with systemic and CNS JXG were successfully treated with clofarabine.⁸⁴

COURSE AND PROGNOSIS

Patients with only skin or soft-tissue involvement all survive and in a majority of cases, the lesions spontaneously disappear over time. Infants with large retroperitoneal masses, liver, marrow, or CNS involvement usually survive with chemotherapy treatment. Two of 17 patients with multisystem JXG reported in the literature died despite multiagent chemotherapy.¹⁹²

● SINUS HISTIOCYTOSIS WITH MASSIVE LYMPHADENOPATHY (ROSAI-DORFMAN DISEASE)

DEFINITION AND HISTORY

Rosai and Dorfman recognized this nonmalignant proliferation of histiocytes as a unique histopathologic entity, which is part of the differential diagnosis of massive lymphadenopathy.¹⁹⁵ Although this disease is self-limited in some patients, others with airway obstruction, multiple bone lesions, orbital or brain tumors require therapy.^{84,196}

EPIDEMIOLOGY

RDD is found throughout the world as a disease of children and young adults (mean age: 20.6 years). Most of our knowledge about it is the result of analysis of the 423 cases in the registry developed by Rosai and Dorfman in which there was no gender, ethnic, or socioeconomic predilection. Persons of African and European descent are equally represented; people of Asian descent less so. In cases of digestive system disease, males and persons of African descent were more commonly affected.¹⁹⁷ Intracranial disease is found in patients with a mean age of 37.5 years. There is an apparent increase in rheumatologic disorders and hemolytic anemia among these patients.^{198,199} Germline mutations in the nucleoside transporter SLC29A3 have been described in patients with rare familial syndromes that include lymphadenopathy characteristic of RDD.²⁰⁰

ETIOLOGY AND PATHOGENESIS

Although associations with various herpes virus infections have been reported, these most likely represent detection of lymphocytes or macrophages harboring these viruses with no relation to etiology. A model for the key histopathologic finding, emperipolesis of lymphocytes by macrophages, has been proposed.²⁰¹ These authors hypothesized that macrophage-activating cytokines could stimulate the macrophages to ingest lymphocytes. The cells in the lesions of this disorder are polyclonal.²⁰²

CLINICAL FEATURES

Massive, painless bilateral cervical adenopathy is the presenting finding in 87 percent of patients. Some have fever, night sweats, malaise, and

weight loss. A few patients have polyarthralgia, rheumatoid arthritis, glomerulonephritis, asthma, and diabetes mellitus. Painless maculopapular eruptions, sometimes reddish or bluish, or yellow xanthomatous rashes occur in 16 percent of patients. Subcutaneous nodules can be found anywhere in the body. Another 16 percent of patients have nasal cavity and paranasal sinus involvement with obstruction of the airways, epistaxis, septal displacement, and mass lesions infiltrating the sinuses. Ten percent have eyelid or orbital masses with proptosis. Unlike patients with LCH, patients with RDD uncommonly (10 percent) have osteolytic bone lesions. These have irregular borders, but may have sclerotic margins. Bilateral parotid or submandibular gland swelling may also be present. Less than 10 percent of patients have CNS, intracranial, epidural, or dural masses, as solitary or multiple lesions leading to headaches, nerve palsies, or syncope. Other organ system involvement in 1 to 3 percent of cases includes the kidney, genitourinary tract, lungs, larynx, liver, tonsil, breast, gastrointestinal tract, and heart. Up to 43 percent of patients have lymphadenopathy coupled with extranodal involvement of the skin, soft tissue, upper respiratory tract, bone, eye, or retroorbital tissue.²⁰³

LABORATORY FEATURES

Patients may have a hemolytic anemia or anemia of chronic disease, elevated erythrocyte sedimentation rate, and polyclonal hyperimmunoglobulinemia. Elevation of liver enzymes and other laboratory abnormalities depend on the organs involved.²⁰⁴ Hepatic features include capsular and pericapsular fibrosis. The lymph node sinuses are enlarged by a proliferation of histiocytes with large round or oval vesicular nuclei and a prominent nucleolus. Mitoses are rare. The cytoplasm is pale and eosinophilic, although some may have a foamy cytoplasm. The key diagnostic finding is intact lymphocytes in macrophages (active ingestion, or emperipolesis, the penetration of a smaller cell into larger one). Because the lymphocytes are inside vacuoles, they are not degraded. Accompanying the histiocytes are numerous plasma cells. The pathologic macrophages in this disease infiltrate the sinuses of lymph nodes and are phagocytosing lymphocytes and plasma cells as well as erythrocytes. Although the histiocytes are S100-positive, they are CD1a-negative, unlike the LCs, which are positive for both markers. The macrophages express CD68, CD14, CD15, lysozyme, transferrin receptor, IL-2 receptor, and CD163.¹⁹⁶

DIFFERENTIAL DIAGNOSIS

Any other cause of lymphadenopathy, such as infections, lymphomas, leukemias, Gaucher disease, melanoma, and other malignancies, should be ruled out by a biopsy. The massive cervical lymph nodes are strikingly similar to those of patients with the autoimmune lymphoproliferative syndrome.²⁰⁵ Inflammatory pseudotumor and RDD have been found in the same patient suggesting a histologic continuum.²⁰⁶

Clinicians should be aware that the sinuses of many reactive lymph nodes contain macrophages (histiocytes) and pathologists will report that presence as “sinus histiocytes or sinus histiocytosis.” This is not evidence for RDD because in those cases the sinus histiocytes do not have lymphocytes within their cytoplasm.

THERAPY

Many cases are self-limited and do not require therapy. Surgery may be useful for symptomatic treatment of local large lymph nodes. Multiorgan involvement or dysfunction, and association with immune dysfunction are poor prognostic indicators and indicate the necessity of treatment.²⁰⁷ Several therapies have been used, including glucocorticoids and chemotherapy, with success in some cases. Several case reports have described improvement or cure of patients with the disease

with oral dexamethasone, oral methotrexate, oral 6-mercaptopurine, intravenous cladribine, or intravenous vinorelbine plus methotrexate.^{208–211} Intravenous clofarabine may be the best therapy for patients with bone and CNS involvement.⁸⁴

COURSE AND PROGNOSIS

Most patients will have a slow but steady decrease in the size of their lymph nodes over months to years. For those patients requiring treatment because of impingement on vital organs responses are variable. Because no clinical trials have been done, treatment has been based on anecdotal reports.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

DEFINITION AND HISTORY

Farquhar and Claireux first described this disease in siblings in 1952.²¹² Although many case reports using several eponyms ensued, Henter and Elinder provided a logical organization of the diverse clinical presentations.²¹³ HLH is an aggressive and potentially fatal syndrome that results from inappropriate prolonged activation of lymphocytes and macrophages. The name describes the characteristic (but not diagnostic) pathologic finding of macrophages engulfing all types of blood cells in marrow, lymph nodes, spleen, or liver biopsies (see Fig. 71–3). HLH is also known as autosomal recessive familial HLH, familial erythrophagocytic lymphohistiocytosis, viral-associated hemophagocytic syndrome, and infection-associated hemophagocytosis. “Primary” or “familial” HLH has been used to describe young children with HLH with known gene mutations or a family history of HLH. Older children with HLH, or children without identifiable mutations, are sometimes described as having “secondary” or “acquired” HLH with the assumption that the condition is caused by infection or other stimulus and not a result of genetic predisposition. The same mutations may be present in both situations, and there is no rapid and definitive gene-testing strategy to distinguish the two groups. In general, presentation and outcome are the same for primary and acquired HLH.²¹⁴ Hypomorphic mutations in HLH-associated genes and compound heterozygous mutations have been described in patients who develop HLH at an older age or in the context of autoimmune disease.^{215,216} Thus, this distinction is not clinically useful in the acute setting as they both must be diagnosed promptly and treated aggressively.

EPIDEMIOLOGY

The incidence of HLH in Sweden was estimated at 1.2 children per 1 million children per year, or 1 in 50,000 livebirths with equal sex distribution.²¹³ At the Texas Children’s Hospital, HLH was diagnosed in 1 of 3000 inpatient admissions in a 2-year study.²¹⁷ The incidence in adults is unknown and the outcomes may be worse than for children.²¹⁸ Many adult patients with HLH also have lymphoma.²¹⁹

ETIOLOGY AND PATHOGENESIS

Defects in the function of natural killer (NK) cells and cytotoxic T cells have been found in HLH patients. This results in the inappropriate activation of T cells and macrophages, which produce proinflammatory cytokines, including IFN- γ , tumor necrosis factor- α , IL-6, IL-10, IL-12, and soluble IL-2 receptor- α (sCD25).^{220,221} In an animal model, perforin deficiency leads to inability to “prune” antigen-presenting DCs, resulting in increased activation of cytotoxic CD8+ T cells.²²² The hypercytokinemia and pathologic activation of T cells and macrophages result in multiorgan dysfunction that can rapidly lead to death.

Perforin Expression

Perforin was identified as a candidate HLH gene by gene mapping and was confirmed by poor expression of perforin in NK cells and cytotoxic T lymphocytes of HLH patients.^{223,224} Some HLH characteristics were reproducible in *PRF1* knockout mice.²²⁵ Perforin is secreted from NK cells and cytotoxic T cells upon activation by target cells and introduces pores in the target cell membrane, allowing granzyme to enter and trigger apoptosis.²²⁶

Other Defects Causing Hemophagocytic Lymphohistiocytosis

Mutations in other genes encoding proteins involved in NK and cytotoxic T-cell-mediated killing of target cells also have been discovered in patients with HLH, including *UNC13D* (encodes MUNC13-4), *STX11* (encodes syntaxin 11), and *UNC18B* (encodes STXB2).²²⁷ Mutations in the gene that encodes RAB27a (protein that controls secretion of lytic granules) have also been identified in patients with Griscelli syndrome.²²⁸

Immune Deficiencies Associated with Hemophagocytic Lymphohistiocytosis

Patients with other immune deficiencies associated with lysosomal trafficking defects (e.g., Chédiak-Higashi syndrome, Hermansky-Pudlak syndrome type II) also have a high frequency of HLH.²²⁹ HLH, often associated with infection by the Epstein-Barr virus, is the most common fatal complication of X-linked lymphoproliferative disease (*XLP1/SH2D1A* and *XLP2/XIAP*).²³⁰

CLINICAL FEATURES

Initial signs and symptoms of HLH mimic more common problems (e.g., fever of unknown origin or sepsis).²³¹ Confounding diagnoses such as infection, autoimmune disease, hepatitis, multisystem organ failure, encephalitis, and malignancy do not exclude a diagnosis of HLH. Important clues include an acutely ill patient with unexplained fever, rash, or neurologic symptoms. A medical history of immune deficiency should bring HLH to mind. Family history of consanguinity, recurrent spontaneous abortions, or HLH in siblings (or symptoms suggesting undiagnosed HLH) may be suggestive of a risk for HLH.

Prominent early clinical signs in one study included fever (91 percent), hepatomegaly (90 percent), splenomegaly (84 percent), neurologic signs (47 percent), rash (43 percent), and lymphadenopathy (42 percent).²³² Another study found 75 percent of patients with HLH to have CNS symptoms that may mimic encephalitis.²³³ Patients with HLH develop liver failure with markedly elevated conjugated bilirubin, pancytopenia, coagulopathy, renal failure heralded by hyponatremia, and pulmonary failure similar to acute respiratory distress syndrome with interstitial infiltrates on chest radiography.²³¹

Diagnostic Criteria

The cumulative experiences from the first prospective international treatment protocol sponsored by the Histiocyte Society, HLH-94, as well as other observations and studies, have led to the Histiocyte Society treatment protocol HLH-2004, which includes diagnostic guidelines (Table 71-4).²³⁴ The HLH criteria are derived from retrospective analysis of patients treated on HLH-94 and describe patients with extreme pathologic inflammation and associated defects in cytotoxic immune function.

Biallelic mutations in HLH-associated (or monoallelic in case of X-linked genes) are diagnostic for HLH, but generally not helpful for acute management although genetic results are becoming available more quickly. More rapid flow cytometry studies can identify absence of protein expression of *PRF1*, *SAP* (*XLP1*), or *XIAP* (*XLP2*).²³⁵ Flow

TABLE 71-4. Clinical Criteria for Diagnosis of Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) diagnosis is established with at least five of the following:

- Fever
 - Splenomegaly
 - Cytopenias in at least two cell lines:
 - Hemoglobin <90 g/L
 - Platelets <100 × 10⁹/L
 - Neutrophils <1 × 10⁹/L
 - Hypertriglyceridemia and/or hypofibrinogenemia:
 - Fasting triglycerides >3 mmol/L (>265 mg/dL)
 - Fibrinogen <1.5 g/L
 - Hemophagocytosis in marrow or spleen or lymph nodes
 - Low or absent activity of natural killer cells (specialized laboratory test)
 - Ferritin >500 mcg/L (>2000 mcg/L may be more specific)
 - Soluble cD25 (soluble interleukin-2 receptor) >2400 U/mL
- or
- HLH-associated gene mutations

cytometry degranulation assays that measure membrane CD107a are also effective for identifying patients with lymphocytes with impaired cytotoxic function.²³⁶

Hemophagocytosis is sometimes misunderstood as pathognomonic and necessary for the diagnosis of HLH, but biopsies fail to demonstrate hemophagocytosis in approximately one-third of patients (Fig. 71-4).²³⁷ HLH changes over time such that the cytokine stimulation resulting in hemophagocytosis may be modest early in the disease, or the marrow may progress to become aplastic with few macrophages available to engage in hemophagocytosis. Repeat marrow aspirates and biopsies, as well as lymph node or liver biopsies, may be helpful. Finding hemophagocytosis is highly suggestive of HLH, but is neither necessary nor sufficient to make the diagnosis. Cerebrospinal fluid should be tested in patients with signs of CNS abnormalities; pleocytosis, hyperproteinemia and hemophagocytosis support HLH with CNS involvement.

Figure 71-4. Hemophagocytosis by macrophages. Marrow aspirate treated with Wright-Giemsa stain illustrating prominent hemophagocytosis of multiple cell types by macrophages (arrows) in the marrow of a patient with hemophagocytic lymphohistiocytosis.

LABORATORY FEATURES

Ferritin

Although no one diagnostic criterion is sufficient to make the diagnosis of HLH, a highly elevated serum ferritin along with four other criteria is strongly indicative. A ferritin concentration of greater than 500 mcg/L was included in the HLH-2004 diagnostic criteria because a survey found that most children with infectious diseases had levels less than that level and those with rheumatologic diagnoses only rarely had higher levels. Ferritin concentrations greater than 500 mcg/L were 100 percent sensitive for HLH in a retrospective review over a 2-year period.²¹⁷ However, at this level there is considerable overlap with other disorders. Ferritin concentrations more than 10,000 mcg/L were 90 percent sensitive and 96 percent specific for HLH with very minimal overlap with sepsis, infections, and liver failure. Analysis of ferritin values in an extended cohort suggests that 2000 mcg/L may be a more appropriate measure for diagnosis of HLH than 500 mcg/L.²³⁸

The following tests should be done on a previously healthy patient who presents with persistent fevers, hepatosplenomegaly, and cytopenia of at least two cell lines: serum ferritin, aspartate aminotransferase/alanine aminotransferase, lactate dehydrogenase, bilirubin, coagulation studies, fibrinogen, triglycerides. A marrow biopsy and aspirate is needed, as well as a lumbar puncture for spinal fluid examination. NK cell function, perforin expression of T cells and NK cells, and sCD25 concentrations should be evaluated, usually requiring access to specialty laboratories, if there is clinical suspicion for HLH. Following daily serum ferritin levels is useful because rapidly rising ferritin is a strong indicator of HLH, and inferior outcomes are associated with slow normalization.²³⁹ It may be necessary to repeat the marrow biopsy or biopsy an enlarged liver or lymph nodes, if the first marrow biopsy fails to show hemophagocytosis and clinical suspicion of HLH is high.

DIFFERENTIAL DIAGNOSIS

Patients with fever of unknown origin, moderate infections, sepsis, multiorgan dysfunction, hepatitis, anemia and thrombocytopenia, and autoimmune phenomena such as Kawasaki disease, lupus erythematosus, or rheumatoid arthritis may present with features that overlap the diagnostic criteria for HLH. These may represent alternative or concurrent diagnoses. One must consider HLH if no clear diagnosis is established of the above mentioned entities is evident and the patient is deteriorating. Identification of an underlying immune deficiency such as X-linked lymphoproliferative disease (Chap. 80), Griscelli syndrome (Chap. 80), or Chédiak-Higashi syndrome (Chap. 80) should increase the suspicion of HLH. Epstein-Barr virus, cytomegalovirus, and other herpes virus infections are the most frequent viral infections associated with HLH. A wide variety of bacterial fungal and protozoal infections may also lead to HLH.

THERAPY

Before treatment with immune-modulating therapy fewer than 10 percent of patients with HLH survived.²⁴⁰ After case reports and case series described patients successfully treated with strategies that included aggressive immune suppression, podophyllotoxin derivatives, or a combination of immune suppression with etoposide, a prospective treatment protocol was developed that included induction therapy with oral or intravenous dexamethasone and intravenous etoposide, followed by continuous treatment with oral cyclosporine and pulses of dexamethasone and intravenous etoposide.^{241–243} Patients with CNS symptoms or cerebrospinal fluid lymphocytosis or pleocytosis also received intrathecal methotrexate. Patients with resistant disease, recurrent disease, or familial HLH underwent AHST. The overall estimated 3-year survival

on the HLH-94 protocol was 55 percent.²⁴³ In a study of patients with Epstein-Barr virus-associated HLH, early administration of intravenous etoposide was associated with improved outcomes.²⁴⁴ Etoposide was recently demonstrated to have specific cytotoxicity to activated T cells, which may explain why it is effective in HLH.²⁴⁵

A second protocol, HLH-2004, containing minor modifications from the first included starting oral cyclosporine at the onset of induction therapy, adding glucocorticoids to intrathecal therapy in patients with CNS disease, adding etoposide to conditioning in patients who undergo AHST, and considering depletion of T cells in patients who receive stem cells from unrelated donors.²⁴³ At this time, we consider HLH-94 the standard of care. Data are not yet available to evaluate the benefits of early cyclosporine, and it has known risks including increasing susceptibility to posterior reversible encephalopathy syndrome (PRES).²⁴⁶

Intravenous antithymocyte globulin (ATG) has been used as a primary treatment of 38 cases of familial HLH.²⁴⁷ It was intended that all of these patients undergo AHST, which ultimately cured 16 of 19 cases. ATG was ineffective for patients who had been previously treated with etoposide, dexamethasone, and cyclosporine and who had relapsed while on therapy.

A study that is open as of this writing, hybrid immunotherapy for HLH (HIT-HLH; clinicaltrials.gov: NCT01104025) combines strategies of early immune suppression with ATG and prolonged immune suppression with etoposide.

A significant number of patients with HLH will fail to respond to initial therapy or will develop recurrent episodes of inflammation while awaiting AHST. Treatment failures and recurrences are associated with very high rates of mortality. Escalation of dexamethasone and etoposide is a typical first step for patients with recurrence. Additional salvage strategies that have been reported include infliximab, dalizumab, anakinra, and other agents.²³¹ A retrospective multiinstitutional study reported that 77 percent of patients who received alemtuzumab therapy for refractory or recurrent HLH survived to AHST.²⁴⁸ A clinical trial is currently open to test the efficacy and safety of inhibition of IFN- γ in patients with HLH with recurrent inflammation (clinicaltrials.gov: NCT01818492).

AHST may be indicated for patients with familial HLH or with gene defects, CNS disease, or who relapse either on or off HLH therapy. Long-term survival was 50 to 65 percent with myeloablative conditioning, but patients experience significant treatment-related morbidity and mortality.^{214,249} Institutional series have demonstrated improved survival and decreased treatment-associated complications with reduced intensity conditioning (RIC) strategies that include alemtuzumab. RIC strategies are associated with improved survival.^{248,250} A multicenter clinical trial (Reduced Intensity Conditioning for Children and Adults with Hemophagocytic Syndromes or Selected Primary Immune Deficiencies [RICHI]) is currently testing the safety and efficacy of RIC with “intermediate” timed alemtuzumab.²⁵¹ (clinicaltrials.gov: NCT01998633)

Patients with HLH are generally acutely ill, and therapies for HLH may exacerbate cytopenias and susceptibility to opportunistic infections. Patients may require multiple transfusions of red cells, platelets, and fresh frozen plasma. Prophylaxis against *Pneumocystis carinii* infection with sulfamethoxazole and against fungi with fluconazole is necessary. Newly diagnosed HLH patients should have human leukocyte antigen typing done and a donor search initiated in case AHST is required for therapy.

Macrophage Activation Syndrome

This nomenclature describes patients with symptoms and signs of HLH in the setting of juvenile rheumatoid arthritis or systemic lupus erythematosus.²⁵² Similar to classic HLH, macrophage activation is

characterized by proliferation of macrophages and T cells. Patients present with continuous fever, purpura, hepatosplenomegaly, mental status changes, cytopenias, coagulopathy, and hypofibrinogenemia. Laboratory findings may include defective NK cell function and low perforin expression, as seen in HLH. In the setting of pathologic inflammation driven by autoimmune disease, patients may be successfully treated with therapy targeted against the underlying autoimmune disease.²⁵³ Treatment with dexamethasone and etoposide therapy is recommended if patients fail to improve after a brief trial of therapy appropriate for rheumatologic disease.

COURSE AND PROGNOSIS

Patients with HLH are often critically ill, functionally immunosuppressed, and receive toxic chemotherapy. They should be treated at institutions familiar with the complications of chemotherapy and immune suppression. Splenectomy is recommended only in the case of life-threatening respiratory compromise. Some patients have an initial good response to therapy with etoposide and dexamethasone, but then have progressive disease as evidenced by elevation of the serum ferritin, worsening coagulopathy, or need for increased respiratory, blood pressure, or renal support. Although it may seem counterintuitive to treat critically ill patients with immune suppression, patients with HLH require this approach to have a chance to survive to clear the inflammatory trigger or overcome inherited immune defects with AHSCT.

CHAPTER 72

GAUCHER DISEASE AND RELATED LYSOSOMAL STORAGE DISEASES

Ari Zimran and Deborah Elstein

SUMMARY

Gaucher disease and Niemann-Pick disease are the two lipid storage disorders that are most likely to be encountered by the hematologist because both may cause hepatosplenomegaly and cytopenias.

Gaucher disease is a common autosomal recessive lipid storage disorder, with an increased prevalence among Ashkenazi Jews, in whom the estimated birth occurrence is 1 in 850. Deficiency of the enzyme β -glucocerebrosidase results in accumulation of the sphingolipid glucocerebroside in the cells of the macrophage-monocyte system. Patients with the most prevalent form, type 1, have no primary neuronopathic symptoms, whereas there is involvement of the central nervous system in type 2 and type 3. Diagnosis of Gaucher disease depends on demonstration of decreased enzymatic activity of β -glucocerebrosidase combined with identification of mutations in the β -glucocerebrosidase gene at the DNA level, usually with elevation of biomarkers, such as chitotriosidase as ancillary confirmation and means of followup. Disease manifestations include hepatosplenomegaly, thrombocytopenia, anemia, osteopenia/osteoporosis with pathologic fractures and osteonecrosis, and, less commonly, pulmonary infiltration. Many patients, especially those homozygous for the common N370S mutation, are putatively protected against neurologic involvement, albeit there is evidence of a genetic risk factor for Parkinson disease. Generally, many patients with type 1 may be asymptomatic or so mildly affected that they may not present until their fifth or sixth decade and do not require disease-specific therapy, whereas for those with more severe signs and symptoms, enzyme replacement therapy (currently three infusible enzymes) is available. Substrate reduction therapy is an oral modality but is associated with a more problematic safety profile. Pharmacological chaperones and oral enzyme are being tested.

Niemann-Pick disease is a heterogeneous group of autosomal recessive disorders. Type A and type B result from deficiency of the enzyme sphingomyelinase, whereas type C results from mutations in the *NPC1* or *NPC2* gene, which appears to be involved in cholesterol trafficking and resulting in accumulation of cholesterol as well as sphingomyelin. Type A is a lethal infantile form with marked progressive neurologic involvement. Type B is a later-onset form with no neurologic involvement but hepatosplenomegaly in many patients. Patients with type C disease manifest progressive neurologic involvement and hepatosplenomegaly, but may survive into adulthood. The marrow of these

Acronyms and Abbreviations: cDNA, complementary DNA; ERT, enzyme replacement therapy; MRI, magnetic resonance imaging; PC, pharmacologic chaperone; SRT, substrate reduction therapy.

patients contains typical foam cells with small droplets in the cytoplasm and sea-blue histiocytes. Substrate reduction therapy was approved for patients with type C disease in 2008 in Europe; pharmacologic chaperone therapy is being attempted.

Fabry disease, Wolman/cholesteryl ester storage disease (CESD), and GM_1 -gangliosidosis are other lipid storage diseases characterized by hepatosplenomegaly; GM_2 -gangliosidosis by hepatomegaly only. CESD patients may result in anemia and have sea-blue histiocytes. They are usually not cared for by hematologists and will not be discussed in this chapter.

DEFINITION OF GLYCOLIPID STORAGE DISEASES

The glycolipid storage diseases are hereditary disorders in which one or more tissues become engorged with specific lipids, because of deficiencies of the lysosomal enzymes required for hydrolysis of one of the glycosidic bonds. Figure 72-1 shows the catabolic pathway of glycosphingolipids and lists the diseases that are involved in impaired degradation because of specific enzyme deficiencies. The type of lipid and its tissue distribution have a characteristic pattern in each disorder. This chapter deals mainly with Gaucher disease, in which glucocerebroside is stored. It is a common lysosomal storage disorder and also the one with the most hematologic features. The second storage disorder with some hematologic features is Niemann-Pick disease, in which the accumulated material is sphingomyelin and/or cholesterol. The remaining lysosomal diseases (Fabry disease, Wolman/cholesteryl ester storage disease, and GM_1 - and GM_2 -gangliosidosis), in which there is hepatosplenomegaly but few hematologic abnormalities, are not reviewed in this chapter.

GAUCHER DISEASE

HISTORY AND DEFINITION

Gaucher disease was first described by P.C.E. Gaucher in 1882, who thought that the large splenic cells of a young woman seen postmortem were evidence of a primary neoplasm.¹ The term *Gaucher disease* appeared first in 1905, when the autosomal recessive genetic nature of the disorder was elucidated.² In 1934, it was shown that glucocerebroside is the storage material in Gaucher disease,³ and in 1965, the primary defect was recognized as a deficiency of glucocerebrosidase resulting in an impairment of degradation of glucocerebroside.^{4,5} Enzymatic purification ultimately led to the cloning of the gene in 1985,^{6,7} unraveling of its structure, and identification of many glucocerebrosidase mutations.⁸ Disease-specific enzyme replacement therapy (ERT) was first introduced in 1991.⁹

EPIDEMIOLOGY

Gaucher disease is inherited as an autosomal recessive disorder. Although panethnic, type 1 is most common among the Ashkenazi Jews, with a carriership prevalence of 1 in 17 and an expected frequency of the disease in 1 in 850 livebirths.¹⁰ Two distinct forms of Gaucher disease, type 3b and type 3c, are also relatively common in Norrbottnia in northern Sweden,¹¹ and near the Palestinian town of Jenin, respectively.¹² In the general population, the estimated frequency (based on large-scale neonatal screening projects in three countries) is in the range of 1 in 50,000 to 1 in 100,000 persons.¹³

Some mutations result from recombinant events between the functional gene and its pseudogene.⁸ Since 2000, approximately 20 of these mutated enzymes have undergone crystallography showing the divergence of ligands in the active site and with various degrees of glycosylation.²³

Among Ashkenazi Jews, the predominant mutation is N370S which accounts for approximately 75 percent of mutant alleles among Jewish patients and approximately 30 percent of the alleles among non-Jewish patients. Homozygosity for N370S is characterized by relatively milder phenotypes (although the phenotype is very heterogeneous and severe cases are seen²⁴). N370S has heretofore been considered “protective” against the development of neuronopathic features. The second common mutation found almost exclusively among Ashkenazi Jews is one that usually causes a severe phenotype. Five or six common mutations account for approximately 97 percent of alleles among Jews, but account for less than 75 percent of alleles among non-Jews.^{8,25–27} Although controversial, premarital/prenatal screening for common mutations has become frequent among Ashkenazi Jews.^{28,29}

The second most common mutation is L444P, which when homozygous accounts for most patients with the neuronopathic type 3 disease, and is the most prevalent mutation in Asians, Arabs, and Norrbottnians. Patients with the unique variant of progressive calcifications of cardiac valves, type 3c, are uniformly homozygous for a point mutation D409H.¹²

Despite some relationship between specific mutations and the clinical course, genotype–phenotype correlation is imperfect. Elucidation of the three-dimensional structure of the glucocerebrosidase by crystallography has also not improved prediction of disease severity based on the location of mutations in the native protein.³⁰

The majority of the mutations cause glucocerebrosidase misfolding, which may lead to early degradation of the enzyme in the

endoplasmic reticulum.^{31,32} The investigation of the proteotoxic effect of the misfolded mutant enzyme in the endoplasmic reticulum has led to the development of the new therapeutic modality of pharmacologic chaperones (PCs). PCs are targeted to stabilize the mutated glucocerebrosidase and allow its appropriate trafficking from endoplasmic reticulum to Golgi and, finally, to the lysosome.

CLINICAL FEATURES

Three major types of Gaucher disease are differentiated clinically based on absence (type 1) or presence of neurologic features (types 2 and 3).³³ Table 72–1 summarizes key clinical, genetic, and demographic features. Although it has been suggested that there is a phenotypic continuum,^{34,35} it is still useful to think of Gaucher disease as three distinct forms to facilitate genetic counseling and management decisions.

There is variability in disease severity of all types of Gaucher disease. Type 1 disease may be asymptomatic and be discovered in the course of population surveys of Ashkenazi Jews,²⁸ or incidentally during evaluation of an unrelated hematologic disorder.

Fatigue

Fatigue is a common complaint, usually not invariably related to anemia, but also quite common in nonanemic patients and may be a result of elevated inflammatory cytokines.³⁶

Organomegaly

In symptomatic patients, the spleen is typically enlarged,³⁷ whether barely palpable or massively enlarged causing positional symptoms, such as early satiety or abdominal discomfort. Splenic infarction and subcapsular hematoma are uncommon. Hepatomegaly is usually asymptomatic, but it may cause abdominal discomfort and in splenectomized

TABLE 72–1. Characteristics of the Three Types of Gaucher Disease

	TYPE 1		TYPE 2		TYPE 3		
	Asymptomatic	Symptomatic	Neonatal	Infantile	3a	3b	3c
Subtype							
Common genotype	N370S/N370S or 2 mild mutations	N370S/other or 2 mild mutations	Two null or recombinant mutations	One null and one severe mutations	None	L444P/L444P	D409H/D409H
Ethnic predilection	Ashkenazi Jews	Ashkenazi Jews	None	None	None	Norrbottnians, Asians, Arabs	Palestinian Arabs, Japanese
Common presenting features	None	Hepatosplenomegaly, hypersplenism, bleeding, bone pains	Hydrops fetalis; congenital ichthyosis	SNGP, strabismus, opisthotonus, trismus	SNGP; myoclonic seizures	SNGP; hepatosplenomegaly growth retardation	SNGP; cardiac valves' calcifications
CNS involvement	None	None	Lethal	Severe	SNGP; slowly progressive neurologic deterioration	SNGP; gradual cognitive deterioration	SNGP; brachycephalus
Bone involvement	None	Mild to severe (variable)	None	None	Mild	Moderate to severe; kyphosis (gibbus)	Minimal
Lung involvement	None	None to (rarely) severe	Severe	Severe	Mild to moderate	Moderate to severe	Minimal
Life Expectancy	Normal	Normal/near-normal	Neonatal death	Death before age 3 years	Death during childhood	Death in mid-adulthood	Death in early adulthood

SNGP, supranuclear gaze palsy.

Figure 72-2. **A.** Histologic section of “Gaucheroma” showing hemorrhagic mass with nucleated red blood cells covered by a fibrous capsule. **B.** Histologic section at a higher magnification showing nucleated red blood cells admixed with numerous Gaucher cells. (Used with permission of Prof. Eliezer Rosenmann, Shaare Zedek Medical Center, Jerusalem, Israel.)

patients or others with very severe disease, liver fibrosis and later cirrhosis,³⁸ with or without portal hypertension, may occur; hepatocellular carcinoma may evolve.³⁹ An increased incidence of nonalcoholic fatty liver disease has been observed.⁴⁰

Lymphadenopathy

Lymphadenopathy has been described,⁴¹ including a severe protein-losing form,⁴² which is a clinical management problem.

Hemorrhagic Events

Epistaxis, easy bruising, and hemorrhage after surgical or dental procedures and bleeding during labor are common presenting symptoms. These manifestations usually are related to thrombocytopenia as the result of hypersplenism or marrow replacement by Gaucher cells, but platelet dysfunction and decreased levels of coagulation factors have also been described and hence should be assessed prior to surgical procedure or before delivery.^{43–45} Coagulation factor deficiencies may result from liver disease or consumption coagulopathy.

Anemia

Reduced hemoglobin levels are also primarily a result of hypersplenism and marrow replacement by Gaucher cells, but additional causes include iron deficiency, vitamin B₁₂ deficiency, and autoimmune hemolysis.^{46,47}

Gaucheromas

“Gaucheromas” (Fig. 72–2), which are possibly extraosseous in origin⁴⁸ and/or may mimic a malignant process,^{49,50} appear idiosyncratically, but possibly after some invasive procedure such as hip surgery; these have been described to be at increased risk of hemorrhaging when manipulated.

Pulmonary Disease

Severe pulmonary disease with cyanosis and clubbing occurs in some patients with advanced liver involvement, and is usually a consequence of hepatopulmonary syndrome with or without infiltration of the lungs by Gaucher cells.^{51,52} Mild pulmonary hypertension may be detected by echocardiography,⁵³ but may (rarely) be severe especially among

splenectomized patients⁵⁴; it has not been reported in children.⁵⁵ Pulmonary function tests may reveal abnormalities, such as reduced diffusion capacity in approximately two-thirds of patients.⁵⁶

Bone Disease

Bone involvement is usually the main cause of morbidity in symptomatic patients and can occur in any long bone.⁵⁷ Patchy areas of bone demineralization and infarction are seen (Fig. 72–3A), and asymptomatic widening of the distal femur known as *Erlenmeyer flask* deformity is very common (Fig. 72–3B). Bone metabolism markers indicate that bone resorption predominates,⁵⁸ but the overall mechanisms underlying development of bone lesions are poorly understood. Children may have delayed bone age and delayed eruption of the teeth.⁵⁹ Bone pain is probably the most troublesome symptom of Gaucher disease. Bone pain may be related to the pathologic processes evident by radiography, magnetic resonance imaging (MRI), and computerized tomography, or have the character of a “crisis,” which is a self-limiting, albeit exquisitely painful event, associated with signs of acute local and/or systemic inflammation (Fig. 72–3D). Aseptic necrosis of large joints, mainly the femoral heads but also the shoulders and knees (and rarely even in smaller joints) and vertebral collapse are particularly common typically among untreated patients with genotypes resulting in more severe phenotypes (Fig. 72–3C and E).

Gynecologic Manifestations and Fertility

Gynecologic and obstetric problems are common and are mainly related to bleeding tendency,⁶⁰ which may explain why females are more likely to be diagnosed. Delayed menarche and menorrhagia are common, and increased risk of recurrent abortions has been reported.⁶¹ Fertility is unaffected in males and females.

Ophthalmologic Disorders

Organs other than the spleen, liver, bones, and lungs may be affected. Many patients have pinguecula and a few a pterygium at the corneoscleral limbus.⁶² Additional findings include uveitis and preretinal white spots in rare cases.⁶³

Figure 72-3. Gaucher-related skeletal involvement including (A) humerus with chevron or herring-bone pattern; (B) Erlenmeyer flask deformity of the proximal femur; (C) plain radiograph of osteonecrosis of the left hip; (D) magnetic resonance image of pelvis and thighs that was performed 2 weeks after bone crisis of the right thigh. Bone edema is seen in the upper part of the femur at the level of lesser trochanter. Chronic marrow signal changes are seen in both femurs; (E) vertebral collapse. (Used with permission of Dr. Ehud Lebel, Shaare Zedek Medical Center, Jerusalem, Israel.)

Kidney Disease

Renal manifestations are rare and limited to case reports of nephrotic syndrome and renal cell carcinoma.⁶⁴ Nonetheless, many patients seem to have benign urinary hyperfiltration.⁶⁵

Neurologic Findings

Neurologic symptoms constitute the hallmark of types 2 and 3 diseases.⁶⁶ Particularly notable and pathognomonic are oculomotor abnormalities, especially supranuclear gaze palsy (SNGP), which is typically noted horizontally,⁶⁷ but might occur in the vertical plane as well. Patients with type 2 disease develop hypertonia of the neck muscles with extreme arching of the neck (opisthotonus), bulbar signs, limb rigidity, seizures, and sometimes choreoathetoid movements. In these patients, the SNGP becomes a fixed convergent squint, often facilitating differentiating between type 2 patients, who are terminal by 2 to 3 years of age, and the severe type 3a patients, who may survive longer. Patients with type 3a disease exhibit progressive neurologic abnormalities such as myoclonus and dementia.⁶⁸ Patients with type 3b disease display aggressive visceral and skeletal involvement but neurologic manifestations are largely limited to horizontal SNGP.⁶⁸ Patients with type 3c disease exhibit SNGP, mild visceral involvement, and fatally progressive calcifications of mitral and tricuspid valves and of the large arteries.^{12,68–70}

Several neurologic abnormalities have been observed in patients with type 1 disease, including peripheral neuropathy^{71,72} and an increased prevalence of Parkinson disease (the latter also among carriers of a single mutation).^{73–77} Carriers of severe mutations (e.g., null alleles) were reported to have a 13.6-fold increased risk of Parkinson disease compared to controls, whereas carriers of the more benign mutations have a 2.2-fold increased risk.⁷⁸ A meta-analysis of patients with Parkinson disease has confirmed this strong association between mutations in the glucocerebrosidase gene and Parkinson disease, which is marked by an earlier age of onset and higher prevalence of cognitive changes.^{78,79}

Predisposition to Infections

An increased tendency to infections is sometimes seen, occurring among splenectomized patients or severely affected patients, some of whom may have defective neutrophil chemotaxis.^{80,81} Bacterial osteomyelitis is most often iatrogenic following surgical intervention at the site of a bone crisis. In children, linear growth retardation is common regardless of disease severity,⁸² but a compensatory “catch-up” growth may occur by early adulthood.⁸³

Predisposition to Neoplasia

There is a higher prevalence of neoplastic disorders in patients with Gaucher disease.^{84,85} Myeloma has been established to be more prevalent.^{84,85} Other hematologic malignancies,⁸⁶ hepatocellular carcinoma, and renal cell carcinoma, may also have increased prevalence.⁸⁷ Although elevated levels of interleukin-6 in patients with Gaucher disease may link Gaucher disease and myeloma,⁸⁸ there is no explanation at present for increased incidence of other types of cancer. Some malignancies may be less common.⁸⁷ The impact of ERT on either an increased or decreased development of malignancies has not been determined.

LABORATORY FEATURES

Blood Counts

The complete blood count in patients with Gaucher disease may be normal or may reflect the effects of hypersplenism. A normocytic, normochromic anemia is frequently present, but hemoglobin levels only rarely fall below 8 g/dL. A modest reticulocytosis is often present in anemic patients. The white cell count may be decreased to as low as $1.0 \times 10^9/L$, but milder degrees of leukopenia are more common. The differential count is normal, but splenectomized patients tend to show a lymphocytosis. A defect of leukocyte chemotaxis which may be corrected by ERT,⁸⁹ and in some patients is associated with a tendency to bacterial infections⁹⁰; monocyte dysfunction has also been reported.⁸¹ Thrombocytopenia is typically more prominent than anemia.⁴⁶ In an anemic patient with an intact spleen and normal range platelet counts, there is probably an alternative reason for the low hemoglobin level, unrelated to Gaucher disease. Thrombocytopenia may be quite severe, even in an otherwise mildly affected patient. In splenectomized patients, anemia is more likely in the absence of thrombocytopenia; white cell count and platelet counts are usually higher than normal. Severe anisocytosis and poikilocytosis also occur in splenectomized patients, with many target cells, some nucleated red cells and Howell-Jolly bodies. During bone crises, leukocytosis, thrombocytosis, and elevated erythrocyte sedimentation are seen. Other markers of inflammation have been noted regardless of disease severity: elevated fibrinogen levels, elevated high-sensitivity C-reactive protein, and increased adhesion and aggregation of red blood cells.^{90,91}

Other Hematologic Findings

Clotting factor abnormalities may be induced by activated macrophages^{41,42} or may be found when there is liver involvement. Factor IX deficiency may be a laboratory artifact related to the effect of

accumulated lipid on platelet membranes.⁹² Factor XI deficiency is common among Ashkenazi Jewish patients because of its high coincidental prevalence in this ethnic group.⁹³

Bleeding tendency may also result from defective aggregation or adhesion of platelets³³ and therefore platelet function and/or thromboelastography should be tested before surgical and dental procedures and labor.^{44,94}

Biochemical and Immunologic Findings

In most patients, liver function tests are within normal limits but in conjunction with more severe disease, splenectomy, and/or comorbidities (hepatic B and/or C, or autoimmune diseases) abnormal liver function tests may be seen. Because of the increased prevalence of cholelithiasis,^{95,96} cholestatic findings may occur. Renal function tests are usually normal.⁶⁴

Many patients present with polyclonal gammopathies. Monoclonal gammopathies are found in 1 to 20 percent of patients, particularly older patients.^{79–82} Increased levels of autoantibodies have been reported,⁹⁷ and may indicate coincide with autoimmune diseases such as Hashimoto thyroiditis, rheumatoid arthritis, or immune hemolytic anemia.

Biochemical abnormalities have been used as surrogate markers in Gaucher disease. In the past, increased activities of serum acid phosphatase, angiotensin-converting enzyme, serum ferritin, and other hydrolases, such as β -hexosaminidase or β -glucuronidase, were used.

Other biomarkers correlate better with the extent of glucocerebroside storage. The most widely used biomarker is chitotriosidase,⁹⁸ which is undetectable in healthy subjects (its physiologic role is unknown), but is elevated, often several thousand-fold, in patients with Gaucher disease. Chitotriosidase measurement is useful for monitoring both untreated patients, to assess stability *versus* deterioration, and treated patients, to assess response to therapy. A change in chitotriosidase levels rather than absolute values is used for monitoring. In approximately 6 percent of people, it is undetectable, and for those patients, measurements of chemokine CCL18/PARC which is predominantly produced by Gaucher cells, can be used.⁹⁹

A potentially more sensitive and more specific biomarker has been identified: the lyso-glucosylsphingosine (lyso-Gb1),¹⁰⁰ which may be preferred as a more reproducible biomarker, using a more operator-friendly assay.

Serum iron levels may be low in patients because of iron deficiency related to bleeding or chronic inflammation. Deficiencies of vitamin B₁₂¹⁰¹ and vitamin D¹⁰² have been described, albeit these are also very common in the general population. Serum ferritin levels are usually elevated.

Gaucher Cells

Gaucher cells, found mainly in the marrow, spleen, and liver (Fig. 72–4), have small, usually eccentrically placed nuclei and cytoplasm with

Figure 72–4. **A.** “Gaucher cell” from the marrow of a patient with Gaucher disease. **B.** Histomicrograph of a Gaucher spleen with marked infiltration of the red pulp by Gaucher cells. **C.** Liver infiltrated by Gaucher cells (the pale pink cells). (Marrow image used with permission of Prof. Chaim Hershko, Shaare Zedek Medical Center, Jerusalem, Israel; spleen and liver images used with permission of Prof. Gail Amir, Hadassah Medical Center, Jerusalem, Israel.)

characteristic crinkles or striations. The cytoplasm is stained by the periodic acid-Schiff technique. Electron microscopy demonstrates cytoplasmic spindle- or rod-shaped, membrane-bound inclusion bodies 0.6 to 4 μm in diameter, consisting of numerous small tubules, 130 to 750 \AA in diameter, that are composed of twisted multilayers in negatively stained preparations.¹⁰³

DIFFERENTIAL DIAGNOSIS

Diagnosis

The diagnosis of Gaucher disease should be considered in (1) any patient who presents with unexplained splenomegaly, thrombocytopenia, frequent nosebleeds, anemia, acute or chronic bone pain; (2) children with short stature for their age; and (3) nontraumatic avascular necrosis of a large joint at any age, especially if it is associated with any of the above features.

A definitive diagnosis requires a reduced enzymatic activity of β -glucocerebrosidase in leukocytes,^{104,105} cultured fibroblasts, or amniocytes obtained during prenatal diagnosis. Measurement of glucocerebrosidase levels is supplemented by mutational analysis. This is important for prognosis, particularly in children, and for detection of carriers among affected families. While rapid polymerase chain reaction-based tests are often performed for five or seven common mutations, especially among Ashkenazi Jews as a “first-pass,” it is highly recommended to perform whole-genome sequencing¹⁰⁶ to rigorously establish the molecular diagnosis.

Marrow aspiration as a means of diagnosis is only indicated when other hematologic diseases must be considered.^{94,105} Gaucher cells are often sparse and thorough examination under low-power may be required to find them. Cells indistinguishable by light microscopy from typical Gaucher cells may also be seen in patients with other disorders such as chronic myelogenous leukemia, Hodgkin lymphoma, myeloma, and acquired immunodeficiency syndrome. The latter patients do not lack the ability to catabolize glucocerebroside, but the great inflow of globoside into phagocytic cells exceeds their capacity to hydrolyze glucocerebroside, forming “pseudo-Gaucher cells.”

Prenatal diagnosis can be established by examining cultured amniocytes obtained by amniocentesis for measurement of glucocerebrosidase activity¹⁰⁴ or by examining amniocytes or chorionic villi DNA for known mutations.

Heterozygote Detection

Heterozygotes for Gaucher disease have neither Gaucher cells in their marrow nor stigmata of Gaucher disease (other than the increased risk of Parkinson disease). Existence of a carrier state can be demonstrated by reduced glucocerebrosidase activity to approximately 50 percent of normal values. However, regardless of methodology, enzyme activity among heterozygotes overlaps the normal range and hence definitive diagnosis of heterozygous status only can be made by mutational analysis. Currently various methodologies are being developed to allow noninvasive prenatal diagnosis of monogenic diseases like Gaucher disease; the most promising of these is molecular analysis of cell-free fetal DNA.¹⁰⁷

THERAPY

Symptomatic Treatment

Symptoms and signs related to massive enlargement of the spleen (e.g., pancytopenia, early satiety, abdominal discomfort, and growth retardation in children) can be resolved by splenectomy. However, because of the efficacy of ERT, splenectomy should only be a last resort as it often induces progressive liver and bony complications, and increases

the risk of infection with encapsulated organisms. Partial splenectomy has not proved useful, with both regrowth of the remnant and risk of osteonecrosis.

When bone lesions result in fractures or osteonecrosis (see Fig. 72–3D), orthopedic procedures may be required. Joint replacement is generally uneventful, with good functional outcome and quality of life. The success of arthroplasties is enhanced by adherence to preoperative protocols including assessment of bleeding tendency, prophylactic use of antibiotic therapy, particularly in splenectomized patients, and early post-operative ambulation.¹⁰⁸

Deficiencies of iron, vitamin B₁₂, or vitamin D should be corrected and calcium supplementation is recommended in patients with osteoporosis receiving bisphosphonates.¹⁰⁹ Use of erythropoietin may be required for management of anemia because of marrow failure.¹¹⁰

Enzyme Replacement Therapy

The use of alglucerase,⁹ the first mannose-terminated, placental-derived enzyme, was approved in 1991, and the recombinant form, imiglucerase, albeit with one amino acid R495H that differs from the wild-type protein owing to a cloning artifact in the original complementary DNA (cDNA), was introduced in 1994.¹¹¹ Two intravenous preparations, one with the perfect native-enzyme sequence developed in a human cell line, velaglucerase alfa,¹¹² and the other, a carrot root cell-derived with the imiglucerase core sequence, taliglucerase alfa,¹¹³ have completed phase 3 clinical trials and are available. Phase 2 clinical trials with taliglucerase alfa are currently underway in which the same carrot cells, expressing taliglucerase alfa, are used as vehicle for oral delivery of the enzyme.

The response to ERTs is most gratifying.^{9,111–116} Decreased spleen and liver volumes and increased hemoglobin levels and platelet counts usually occur within 6 months of therapy with biweekly doses between 15 and 60 U/kg. Platelet counts in patients with massively enlarged spleens may require longer periods to respond, but improvement continues within the first 2 years of therapy. Thereafter, patients treated with imiglucerase stabilize even while on the same dose.¹¹⁶

The bone response is slower and less predictable. Osteonecrosis and lytic lesions do not respond to ERT. Quantitative chemical shift imaging, a sensitive modality to show changes in the marrow, including response to ERT (Fig. 72–5),¹¹⁷ is a resource available in only one site worldwide and, hence, various other imaging modalities, especially MRI-based modalities, but also bone densitometry and plain radiographs, are used as needed to document skeletal status.

ERT may or may not improve pathologic pulmonary findings. Because the enzyme is a large molecule, it does not cross the blood-brain barrier, and hence, does not impact neuronopathic features.^{118,119}

All ERTs are safe, having few side effects that are usually transient.^{112,113,120} Hypersensitivity reactions have been reported with each type of ERT, but only rare cases of anaphylaxis. Most patients with such reactions may continue ERT with or without premedication; it is advisable to avoid the administration of glucocorticoids for this purpose because of an increased risk of osteonecrosis. For each ERT there is a different percent of patients who may develop antibodies either shortly after initiation of treatment or over time.

Another side effect is weight gain with some concerns about changes in insulin resistance and the development of metabolic syndrome,¹²¹ including steatohepatitis. Because of the excellent safety profile, many patients receive therapy at home¹²² and many female patients are comfortable continuing with ERT during pregnancy and lactation.^{123,124} The effects of treatment are unaffected by switching from imiglucerase to velaglucerase alfa¹²⁵ or taliglucerase alfa.¹²⁶

The two major disadvantages of ERTs are the apparent lifetime dependency on intravenous infusions and the extremely high cost.

Figure 72-5. Color-coded fat fraction measurements using quantitative chemical shift imaging in an adult patient with type 1 Gaucher disease. Annual measurements show increase in fat fraction with specific therapy (mean value in 1994 = 0.11; mean value in 2001 = 0.45). (Used with permission of Dr. Mario Maas, Academic Medical Center, Amsterdam, The Netherlands.)

Guidelines and/or expert opinions usually recommend the use of relatively high doses.^{127,128} Yet, it is evident that for most symptomatic patients, there is no justification for doses higher than 30 to 60 U/kg per month, and for patients with asymptomatic type 1 disease, ERT should not be encouraged.¹²⁹

Substrate Reduction Therapy

The possibility that decreasing the formation of glucocerebroside from ceramide and glucose, referred to as *substrate reduction therapy* (SRT),¹³⁰ might favorably impact disease parameters was proposed in the 1970s.¹³¹ Oral miglustat (*N*-butyldeoxynojirimycin),¹³⁰ a glucose analogue that inhibits glucocerebroside synthase, has been licensed for treatment of patients for whom ERT is not suitable or not a therapeutic option according to the two preeminent regulatory authorities' definitions. This circumscribed approval stems from inferior efficacy of miglustat relative to ERT and a problematic safety profile including peripheral neuropathies, tremor, and memory impairment. Miglustat is effective in reducing hepatosplenomegaly in Gaucher disease when given as 100 mg, three times daily.¹³² Response to miglustat is dose-dependent; lower doses yield suboptimal improvement without reducing frequency of side effects.¹³³ Miglustat has also been studied as maintenance therapy in patients previously treated with imiglucerase.¹³³ A practical advantage was that it could be considered in type 3 patients because as a small molecule it crosses the blood–brain barrier and impacts neurologic signs. Unfortunately, a clinical trial failed to achieve the end points and, hence, there is no indication for this drug in neuronopathic Gaucher disease.

Another SRT, a ceramide analogue, eliglustat tartrate,¹³⁴ has been granted FDA approval. However, it has a more problematic safety profile compared to ERT (including cardiac events), the efficacy parameters.¹³⁵ The robust database derived from long-term followup from phase 2 and from three different phase 3 clinical trials¹³⁶ indicates it can be useful. However, unlike miglustat, it cannot cross the blood–brain barrier and should be targeted to type 1 patients only.

Pharmacologic Chaperones

A new approach to lysosomal storage diseases is “chaperone therapy.” PC therapy is based on *in vitro* experiments showing that some misfolded mutants of glucocerebrosidase are destroyed prior to their export from the endoplasmic reticulum to the lysosome.^{137,138} Under these circumstances, a reversible inhibitor stabilizes the mutant enzyme, enabling its passage to the lysosome without losing activity. Clinical trials with the first PC for Gaucher disease, isofagomine tartrate which had been shown to increase mutant enzyme activity in cells, tissues,¹³⁹ and healthy volunteers during the phase 1 trial, failed in the phase 2 clinical trial when only 1 of 18 patients with type 1 showed a beneficial effect.¹⁴⁰

Another PC, ambroxol, an expectorant that is available without prescription in many countries and has decades-long safety experience,

was administered in a pilot study to adult type 1 patients¹⁴¹; clinical trials in type 3 patients are planned.

Organ Transplantation

Because the macrophage is derived from hematopoietic stem cells, allogeneic hematopoietic stem cell transplantation should cure Gaucher disease. Although some enthusiasm was expressed for this approach, the short-term risks of transplantation markedly limit the number of suitable candidates. Effective ERT further limits the appropriateness of transplantation. Liver transplantation has been performed in a few patients with severe hepatic failure.¹⁴²

COURSE AND PROGNOSIS

Age of onset, severity of clinical manifestations, and degree of progression are partially related to genotype. Patients homozygous for the N370S mutation tend to present with symptoms and signs at an older age with relatively milder manifestations, and usually have a relatively stable disease. By contrast, compound heterozygotes for N370S and a “severe” mutation (such as N370S/84GG or N370S/L444P) usually present with the disease during childhood, and if untreated, progress continuously with both visceral and skeletal complications.^{108,143,144} Patients homozygous for the L444P mutation will develop neuronopathic disease with deteriorating neurologic signs and symptoms and their life span is reduced.⁶⁵

Although the genotype of the patient provides a benchmark for prognosis, there is much variability in patients with the same genotype, including between siblings with the same genotype. The availability of ERT has changed the natural course of the disease allowing normal growth and development in most patients, even in those with “severe” genotypes. Nevertheless, some patients still develop skeletal complications despite ERT and there is concern regarding development of associated diseases, such as myeloma, other malignancies, or Parkinson disease.¹²⁰

Prior to the availability of ERT, patients with severe type 1 or type 3, died at an early age because of liver disease, bleeding, or sepsis. With the advent of ERT, typical causes of death are malignancy, cardiovascular disease, and cerebrovascular disease.¹⁴⁵ In type 2 disease, death usually results from neurologic complications within the first 4 years of life⁶⁵; there is also a lethal neonatal variant. Total absence of glucocerebrosidase may not be compatible with life.

● NIEMANN-PICK DISEASE

HISTORY AND CLASSIFICATION

In 1914, Niemann, a Berlin pediatrician, reported the case of an infant who died at age 18 months with a disorder that seemed atypical for Gaucher disease because of its early onset and rapid course.¹⁴⁶ In 1927, Pick identified this as a unique disorder of rapid, progressive

neurodegeneration in infants.¹⁴⁷ The first adult patients identified had massive hepatosplenomegaly but no neurologic involvement. The predominant phospholipid accumulating in this disorder is sphingomyelin. In 1966, a deficiency of sphingomyelinase activity was demonstrated in a patient with Niemann-Pick disease.¹⁴⁸ Niemann-Pick is not a single entity; it comprises a group of disorders in which sphingomyelin storage occurs. Type A and type B disease, the classic forms of the disorder, represent an infantile neuronopathic and a later-onset nonneuronopathic form, respectively.¹⁴⁹ Type C, the most common form of Niemann-Pick disease, is a neuronopathic disorder, usually with an onset in early childhood, that results from an abnormality in cholesterol transport.¹⁵⁰ The sphingomyelinase gene is normal in type C disease, but mutations occur in one of two genes which have been designated *NPC1* and *NPC2*; the proteins they code may function in closely related steps of cholesterol transport. The designation type D disease was once applied to a population isolate in Nova Scotia¹⁵¹ but because these individuals also have an *NPC1* mutation, this term is no longer used.

EPIDEMIOLOGY

Niemann-Pick type A and type B diseases, also referred to as acid-sphingomyelinase deficiency, are panethnic disorders. There is a relatively high prevalence of type A disease among Ashkenazi Jews with a carrier rate of approximately 1 in 90.¹⁵² Three mutations account for 90 percent of Ashkenazi Jewish patients. Type B is common among individuals from the Maghreb region and the Arabian peninsula,¹⁵³ with three and two mutations accounting for 75 percent and 85 percent of Turkish and Arabic patients, respectively. Type C disease is relatively common in a Nova Scotia isolate,¹⁵¹ in a Hispanic population from the Upper Rio Grande Valley in the United States,¹⁵⁴ and in Western Europe.¹⁵⁵ The prevalence of Niemann-Pick type C disease in European populations is estimated to be 1 in 120,000 to 1 in 150,000 Europeans.¹⁵⁶

ETIOLOGY AND PATHOGENESIS

Type A and type B are autosomal recessive diseases caused by loss of function mutations in the gene for sphingomyelinase,¹⁵⁷ which is required for cleaving the bond between ceramide and phosphorylcholine (see Fig. 72-1). Nonsense mutations seem to cause the more severe type A disease, while missense mutations are found in the milder type B disorder.¹⁵⁷ Although sphingomyelinase is believed to be a part of an apoptosis-signaling pathway by generating ceramide from sphingomyelin,¹⁵⁸ no relationship between disease severity and this pathway has been established.

Type C disease also is an autosomal recessive disorder and is caused by mutations in either the *NPC1*^{159,160} or *NPC2*¹⁶⁰ gene. The function of the proteins encoded by these genes is unknown, but was suggested to be related to intracellular cholesterol transport.^{160,161} The *NPC1* gene encodes for a multi-pass transmembrane protein that localizes to the late endosome. The *NPC2* protein is soluble. The *NPC1* mutations account for more than 95 percent of cases.¹⁶¹ There are only a few cases of *NPC2* mutations manifested in neonates by severe liver and lung involvement, and progressive neurologic involvement leading to death by 4 years of age; there is a juvenile form in which there seems to be good genotype-phenotype correlation.¹⁶² *NPC1* deficiency is associated with induction of autophagy by the class III-P13K (phosphatidylinositolide 3'-kinase)/beclin-1 complex.¹⁶³ A naturally occurring murine model of the disease exists.¹⁶⁴

PATHOLOGY AND CLINICAL MANIFESTATIONS

The most characteristic histopathologic feature of the various forms of Niemann-Pick disease is the presence of foam histiocytes (Fig. 72-6), mainly in lymphoid tissues, but these may be present throughout the body. The foam cells contain largely sphingomyelin and cholesterol, the storage of cholesterol being more prominent in type C disease.

Type A disease presents in infancy. During the first months of life, affected infants gain weight at a diminished rate, the abdomen enlarges, and development is delayed. The patients usually cannot sit and lose physical capabilities already achieved and become blind and deaf. Some infants have a protracted course of jaundice of unknown cause. During the second year of life, the child lies still with nearly flaccid hyporeflexic extremities; there is massive hepatosplenomegaly, mild lymphadenopathy, and often a fine xanthomatous rash. Bone lesions may occur.

Type B disease usually presents in the first decade of life with hepatosplenomegaly, but may not be noted until adulthood. Neurologic manifestations are usually absent. Pulmonary infiltrates are common. The absence of a cherry-red spot in the macula and longer life expectancy differentiate type B from type A. Sea-blue histiocytes are sometimes found in the marrow, and a number of patients had been diagnosed as having sea-blue histiocytosis before a deficiency in sphingomyelinase was demonstrated.¹⁶⁵

Patients with type C disease often have neonatal jaundice, normal early childhood, and then develop hypotonia, dementia, ataxia, dysarthria, dystonia, seizures, gelastic cataplexy, and cognitive decline.¹⁶⁵ Hepatosplenomegaly is common.¹⁴⁹ Presentation may be at any age, even in the seventh decade,¹⁶⁵ but the "classic" description is of

Figure 72-6. Typical foam cell from the marrow of a patient with Niemann-Pick disease.

juvenile dystonic lipidosis with neonatal icterus and hepatosplenomegaly. In infants and toddlers, hepatosplenomegaly may be the only sign. In patients with a later-onset, there are variable presentations, but psychiatric signs and symptoms (disinhibition and deteriorating executive function) predominate.¹⁶⁵

LABORATORY FEATURES AND DIFFERENTIAL DIAGNOSIS

Hemoglobin values may be normal, or mild anemia may be present. Approximately 75 percent of lymphocytes contain one to nine vacuoles with a diameter of 2 μm . Electron microscopy reveals that these vacuoles are lipid-filled lysosomes.¹⁶⁶ The marrow contains typical foam cells whose diameter ranges between 20 and 100 μm . Small droplets are scattered throughout the cytoplasm (see Fig. 72–6). The cytoplasm of these cells stains only very faintly with the periodic acid-Schiff reagent. Phase microscopy of unstained preparations clearly reveals droplets in the cytoplasm of Niemann-Pick foam cells that distinguish them from Gaucher cells. Sea-blue histiocytes may be present in the spleen and marrow.^{158,164}

Type A and type B disease can be distinguished from other disorders by identification of the lipid as sphingomyelin and by demonstration of sphingomyelinase deficiency in leukocytes or cultured fibroblasts.^{166,167} Patients with type A disease have acid sphingomyelinase activity levels less than 5 percent of normal in *in vitro* cultures of lymphoblasts or fibroblasts. In type B disease, acid sphingomyelinase activity levels range between 2 and 10 percent of normal levels. Monospecific antibodies against sphingomyelinase are used to differentiate between type A and type B disease.¹⁶⁸ Heterozygotes may be detected by measurement of sphingomyelinase activity of cultured fibroblasts.¹⁶⁹ For patients with type C disease, the presence of foam cells is the only indication of the disease.

Prenatal diagnosis of the three types of the disease is possible, but is difficult in type C.¹⁷⁰

TREATMENT

There is no effective treatment for types A and B disease, but there has been an announcement of a successful phase 1b trial with ERT for type B disease and plans for continuation into a phase 2 trial.¹⁷¹

Splenectomy is only rarely required, because death usually occurs from other manifestations of the disease before hypersplenism becomes clinically important. Liver transplantation in type A disease corrects hepatic pathology but has little long-term benefit¹⁷²; similarly, allogeneic hematopoietic stem cell transplantation does not ameliorate the neurologic deterioration in type B disease,¹⁷³ nor does it affect the course of type C disease.¹⁷⁴ Somatic cell gene therapy has been attempted in knockout type B mice¹⁷⁵ and was effective in ameliorating visceral signs but had no effect on neurologic signs.

SRT was attempted in a patient with type C disease.¹⁷⁶ Depletion of glycosphingolipids by miglustat¹³⁰ despite having no direct effect on cholesterol metabolism, corrected abnormal lipid trafficking¹⁷⁷ and indicated that glycosphingolipid accumulation is a primary pathogenic event in type C disease.

A clinical trial using miglustat at a dose of 200 mg three times daily in an open-label 12-month trial with extension to 66 months in juvenile and adult patients with type C disease and in some children, resulted in improvement or stabilization.¹⁷⁷ Subsequent long-term exposure in adults, and some children¹⁷⁹ led to its commercial approval and use clinically in many countries. Miglustat improved neurologic manifestations such as ambulation, manipulation, speech, and swallowing; there are some gastrointestinal side effects.^{177–179}

COURSE AND PROGNOSIS

The prognosis in type A Niemann-Pick disease is dire; death nearly always occurs before the third year of life. Patients with type B disease may survive into childhood or longer and there is now hope for a disease-specific ERT. Patients with type C disease usually die in the second decade of life, but some patients with mild disease have a normal life span. New hope for patients with type C emanates from the potential for identification of disease-specific oxysterols as both biomarkers¹⁸⁰ of the disease and as harbingers of PC therapy for misfolded variants.¹⁸¹

CHAPTER 73

THE STRUCTURE OF LYMPHOCYTES AND PLASMA CELLS

Natarajan Muthusamy and Michael A. Caligiuri*

SUMMARY

Lymphocytes are a heterogeneous population of blood cells that can be distinguished from other leukocytes by their characteristic morphology and structural features. Mature lymphocytes can be divided into several functional types and subtypes based on their organs of development and function. The major classes of lymphocytes include T cells, B cells, and natural killer (NK) cells. T lymphocytes develop in the thymus (Chaps. 6, 74, and 76) and are exported to the blood and lymphoid organs. They are responsible for cell-mediated cytotoxic reactions and for delayed hypersensitivity responses (Chap. 76). T lymphocytes also produce the cytokines that regulate immune responses and provide helper activity for B cells. B lymphocytes can capture, internalize, and present antigens to T cells and are the precursors of immunoglobulin-secreting plasma cells (Chap. 75). NK cells account for innate immunity against infectious agents and transformed cells that have altered expression of transplantation antigens (Chap. 77). Blood T and B lymphocytes are indistinguishable by light and electron microscopy. NK cells tend to be larger cells with relatively large granules scattered in their cytoplasm. B cells can mature into plasma cells upon activation by engagement with antigen or with certain B cell mitogens. Although the different lymphocyte subpopulations appear similar by morphology they have distinct surface and intracellular protein expression patterns. These subpopulations, as defined by antigen expression, reflect different functional subsets, maturation stages, and activation stages. This chapter describes the light and transmission electron microscopic structures of lymphocytes and plasma cells and the major structural features reflected by surface antigens that are characteristic of each lymphocyte type. The chapter also provides information on biophysical and biochemical features of human lymphocytes.

Acronyms and Abbreviations: ADAM, a disintegrin and a metalloprotease; BTK, Bruton tyrosine kinase; CD, cluster of differentiation; Ig, immunoglobulin; lck, leukocyte tyrosine kinase; LGL, large granular lymphocyte; MHC, major histocompatibility complex; NK, natural killer; TCR, T-cell receptor; TdT, terminal deoxynucleotidyl transferase; T_{HH}, follicular helper T cells; Th, T helper cells; T_{REG}, T-regulatory cell; ZAP-70, zeta-associated protein of 70 kDa.

DEFINITION AND HISTORY

Lymphocytes and plasma cells first were described in 1774 and 1875, respectively.¹ Studies during the subsequent 75 years with improved histologic techniques and light microscope optics furthered understanding of the lymphoid organs and the distribution of lymphocytes.^{2–6} By the mid-20th century, awareness that the immune system had at least two components—one governing humoral immunity and one governing cellular immunity—led to early concepts of different lymphocyte subsets. Also, at the same time came the discovery that the thymus and bursa of Fabricius in birds were the source of what came to be known as T (thymic-derived) and B (bursa-derived) lymphocytes, respectively, and that the marrow was the bursa equivalent in humans (human B cells therefore could represent marrow-derived cells). This discovery coupled with descriptions of inherited absence of the thymus leading to loss of cellular immunity but retention of humoral immunity and cases of retention of cellular immunity in children who were deficient in antibody production, eventually led to our current understanding of the division of labor among what originally appeared to be a common lymphocyte pool, morphologically. The later advent of monoclonal antibodies against numerous surface antigens coupled with flow cytometry, *in vitro* functional assays, molecular techniques to distinguish between B cells and T cells, and experiments using inbred strains of mice brought us to our current state of knowledge of the immune response and its abnormalities.

Flow cytometry identifies a multitude of lymphocyte subsets based on antigen expression patterns. These immunophenotypic subsets correlate closely with function as determined by *in vitro* and *in vivo* testing. T lymphocytes, B lymphocytes, and natural killer (NK) cells represent three major blood lymphocyte functional subsets. The marrow and thymus contain precursor cells that resemble lymphocytes but lack function without differentiation and maturation into various lymphocyte subsets. Plasma cells are terminally differentiated B lymphocytes that produce immunoglobulin and mostly reside in marrow, lymph nodes, and other lymphoid tissues. (Chap. 6).

MICROSCOPY AND HISTOCHEMISTRY OF NORMAL BLOOD LYMPHOCYTES

LIGHT MICROSCOPY

Classic studies of blood and tissues defined lymphocytes as spherical and/or ovoid cells that have diameters from 6 to 15 μm when flattened on glass slides.⁴ Some of these studies described two separate broad types of lymphocytes based on size: small lymphocytes with diameters of 6 to 9 μm and large lymphocytes with diameters of 9 to 15 μm . Patients with acute viral illnesses have increased numbers of circulating large, “reactive,” lymphocytes. Other illnesses, such as infection with *Bordetella pertussis* and autoimmune disorders, can cause blood to have increased small lymphocytes or lymphocytes with plasma cell-like morphology (Chap. 78). The mean absolute number of circulating small lymphocytes in normal adults is $2.5 \times 10^9/\text{L}$ (Chap. 2).⁷ Children have higher lymphocyte counts that trend downward until they reach adult levels at approximately 8 to 10 years of age (Chap. 7).⁸

Most lymphocytes in normal blood are small with an ovoid or kidney-shaped nucleus that stains purple, has densely packed nuclear chromatin, and occupies approximately 90 percent of the cell area (Fig. 73–1A and B) by Romanowsky polychromatic stains (e.g., Giemsa or Wright) of air-dried films. A small rim of cytoplasm stains light blue. Nucleoli rarely are observed in Wright-stained films, but nucleoli in these cells may become visible in certain preparations, such as cytopspin slides, or after prolonged storage in anti-coagulated blood collection tubes.

*This chapter was written by H. Elizabeth Broome in the 8th edition and some of the text and images have been retained.

Figure 73-1. Wright-Giemsa stained blood films showing (A) a normal, small lymphocyte, monocyte, and segmented neutrophil; (B) normal small lymphocyte and two medium-sized lymphocytes; (C) neutrophil and two lymphocytes with morphologic features characteristic of *Bordetella pertussis* infection (small size, cleaved nuclei, and scant cytoplasm); (D) reactive lymphocytes; and (E) large granular lymphocyte and small lymphocyte. Wright-Giemsa stained marrow films showing (F) normal plasma cell; (G) two normal plasma cells, one nucleated red cell, and one neutrophil; and (H) two plasma cells with one containing many Russell bodies.

A minority of lymphocytes in normal blood have morphology that defines them as large granular lymphocytes (LGLs).⁹ These LGLs are slightly larger than most lymphocytes, having an increased area of light blue or clear cytoplasm. LGL cytoplasm contains a number of coarse pink granules, usually 5 to 15 per cell, and occasional clear vacuoles. In a normal adult, approximately 5 percent but up to 10 to 15 percent of blood lymphocytes are LGLs (see Fig. 73-1E).⁹ The LGLs in blood are composed of NK cells and a subset of cluster of differentiation (CD) 8+ T lymphocytes, indistinguishable by their morphology.

PHASE-CONTRAST MICROSCOPY

Active movement of lymphocytes is studied by phase-contrast, or interference-contrast, microscopy. Lymphocytes move slowly with a “hand mirror” appearance. Cytoplasmic spreading does not occur. However, during cell movement, a thickening occurs in the cytoplasmic rim, which houses most of the cell’s organelles, including the Golgi apparatus.

TRANSMISSION ELECTRON MICROSCOPY AND CYTOCHEMISTRY

The blood lymphocyte measures approximately 5 μm in spherical diameter as visualized by transmission electron microscopy.¹⁰ The nucleus has an abundance of electron-dense, condensed heterochromatin, a feature characteristic of nonproliferating cells. The nucleoli are round in section, approximately 0.5 to 1.4 μm in diameter. They are composed of three distinct and concentrically arranged structural units: the central region or agranular zone; the middle, fibrillar region; and the granular zone, which contains intranucleolar chromatin. The lymphocyte’s nuclear membrane contains nuclear pores and a perinuclear space.

The cytoplasmic organelles of the lymphocytes are characteristic of eukaryotic cells. Some organelles, such as the Golgi zone, are poorly developed. The cytoplasm contains free ribosomes, occasional

ribosome clusters, and strands of rough-surfaced endoplasmic reticulum (Fig. 73-2). Centrioles, mitochondria, microtubules (diameter approximately 0.25 μm), and microfilaments (diameter approximately 0.07 μm) are present in the cytoplasm adjacent to the cell membrane. The cytoplasm also contains lysosomes, which are approximately 0.4 μm in diameter, are electron opaque, and contain classic lysosomal enzymes (e.g., acid phosphatase, β -glucuronidase, and acid ribonuclease).¹¹ The lymphocyte plasma membrane stains with colloidal iron, a marker for membrane sialic acid. Lymphocyte cell membranes and cell coat glycoproteins are shown with other electron-dense markers, including phosphotungstic acid, lanthanum colloid, and ruthenium red.

Most T lymphocytes have a localized “dot” pattern when stained for acid phosphatase, acid and neutral nonspecific esterases, β -glucuronidase, and *N*-acetyl- β -glucosaminidase.¹² LGLs stain for acid hydrolases with a dispersed, granular reaction pattern.¹³ B lymphocytes either lack esterase and acid phosphatase or show minimal scattered granular staining.

SCANNING ELECTRON MICROSCOPY

Scanning electron microscopy provides three-dimensional information.¹⁴ However, the resolution achieved with scanning electron microscopy, approximately 0.1 μm , is considerably less than that possible with transmission electron microscopy, generally 0.002 to 0.0039 μm . Normal blood lymphocytes, washed and collected on silver membranes and fixed in glutaraldehyde, have a spherical topography with varying numbers of stubby or finger-like microvilli (Fig. 73-3).¹⁵ In contrast, monocytes are much larger, have few microvilli, and display ruffled membranes and ridge-like profiles (Chap. 67).

Lymphocyte microvilli contain parallel bundles of actin filaments that undergo continuous assembly and disassembly.¹⁶ The function of lymphocyte microvilli probably includes segregating surface receptors involved in extravasation. Two receptors involved in the initial rolling phase of extravasation, L-selectin and $\alpha\beta_7$ integrin,¹⁷ localize to microvillar tips. In contrast, the β_2 integrins that mediate stable adhesion

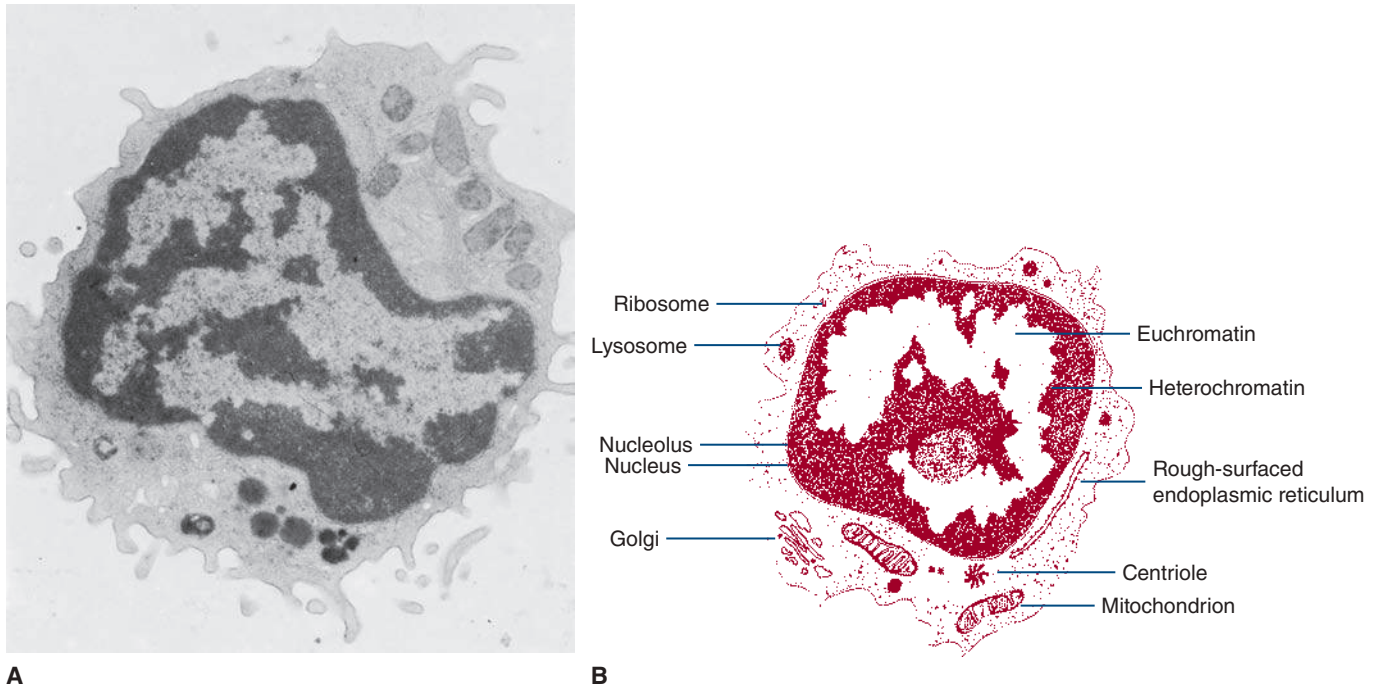

Figure 73-2. **A.** Transmission electron micrograph of normal human blood lymphocyte ($\times 12,000$). **B.** Diagrammatic representation of normal blood lymphocyte, with organelles labeled.

and diapedesis localize to nonprotrusive regions of the cell surface. This spatial separation of surface receptors might enable a temporal segregation of adhesive function during extravasation. Lymphocytes expressing chimeric L-selectin constructs that no longer localize to microvilli do not roll on L-selectin ligands, supporting this hypothesis.¹⁸

MORPHOLOGIC CHANGES ASSOCIATED WITH ACTIVATION

Lymphocyte stimulation is associated with a complex sequence of morphologic and biochemical events. Activation of B and T lymphocytes results in the transformation of the small, resting lymphocyte into proliferating large cells with abundant highly basophilic cytoplasm, irregularly condensed or smudged chromatin, and round to slightly irregular

Figure 73-3. Scanning electron micrograph of normal blood lymphocytes separated by the Ficoll-Hypaque method. Cells show varying numbers of microvilli ($\times 5000$). (Used with permission of Dr. Aaron Polliack of the Department of Hematology, Hebrew University Hadassah Medical School, Jerusalem, Israel.)

nuclear outlines (see Fig. 73-1D). Nucleoli may be evident by light microscopy in these cells, but they usually are not prominent. Infection with *B. pertussis* causes an increase in blood lymphocytes with a particular activated morphology characterized by small size, scant cytoplasm, and cleaved nuclei with mature chromatin (see Fig. 73-1C).

Activated lymphocytes proliferate and mature into effector lymphocytes and memory cells. Effector cells include helper T cells, cytolytic T cells, and plasma cells (see Figs. 73-1F and G, 73-4, and 73-5). *In vitro*, plant lectins, bacterial products, polymeric substances, and enzymes activate lymphocytes and cause mitosis. Such agents are called *mitogens*. Some mitogens are specific for either B or T lymphocytes, whereas other mitogens stimulate both.¹⁹

Approximately 4 hours after mitogen stimulation, lymphocytes show increased nucleolar size and an increase in the number and concentration of granules in the granular zone. These changes are followed by an increase in fibrillar zones and increased intranucleolar chromatin. Nucleolar chromatin becomes more electron lucent or dispersed. From 48 to 72 hours following the addition of phytohemagglutinin, the volume of the cytoplasm increases. In addition, the cytoplasm contains an increased number of ribosomal clusters and more rough-surfaced endoplasmic reticulum. The activated cell has increased numbers of lysosomes and a larger Golgi complex with more components.²⁰ Under some circumstances (e.g., cultures of human lymphocytes stimulated for 7 to 10 days with pokeweed mitogen), some B cells form well-developed Golgi and plasmacytoid features.²¹ Similar plasmacytoid cells are observed in antigen-stimulated lymph nodes, during graft rejection *in vivo*, and in some *in vitro* systems, including the mixed lymphocyte culture. In lymph nodes, the stimulated lymphoid cells may be referred to by various pathologists as lymphoblasts, immunoblasts, centroblasts, or large lymphoid cells. Morphologic criteria for these cells overlap.

Following stimulation with antigen or mitogens, the lymphocyte enters the cell cycle. The fate and function of lymphocytes that traverse the cell cycle can be divided into two pathways. Some lymphocytes undergo several mitotic cycles and then return to the G_0 phase, indistinguishable in morphology from the original nonactivated cells.

Figure 73-4. Transmission electron micrograph of lymphocyte from normal individual incubated with phytohemagglutinin²⁰ for 3 days. The transformed cell has a large Golgi zone (G) and many ribosomal aggregates (arrows). The nucleus is euchromatic (x7500).

Figure 73-5. Transmission electron micrograph of plasmacytoid cell present in culture of lymphocytes from a patient with chronic lymphocytic leukemia incubated with pokeweed mitogen for 7 days. The nucleolus (N) and rough-surfaced endoplasmic reticulum (arrows) are evident (x9000). (Reproduced with permission from Cohnen G, Douglas SD, Konig E, Brittinger G: Pokeweed mitogen response of lymphocytes in chronic lymphocytic leukemia: A fine structural study, *Blood* 1973 Oct;42(4):591-600)

Some of them then become memory cells, programmed to remember the stimulating antigen and thus respond more rapidly to reexposure to the original antigen. Alternatively, they become terminally differentiated effector lymphocytes, such as plasma cells or cytotoxic T cells (Chaps. 75 and 76).

● MICROSCOPY AND HISTOCHEMISTRY OF PLASMA CELLS

MORPHOLOGIC STUDIES

Plasma cells derive from small B lymphocytes after activation in the correct environment. The characteristic feature of plasma cells is abundant cytoplasmic and secretory immunoglobulin (Ig). A fully mature plasma cell lacks surface Ig expression. Each plasma cell has the same clonal rearrangement of its V(D)J (variable diversity joining) Ig genes as its predecessor B lymphocyte (Chap. 75). Several mitotic divisions may occur during cellular differentiation from the resting lymphocyte to the plasmablast to the immature plasma cell. Immature plasma cells can undergo successive waves of mitosis in the medullary cords of lymph nodes in response to antigen.²² Cell transfer experiments demonstrated that these transformed cells later mature into antibody-producing plasma cells.²³

Pokeweed mitogen induces B lymphocytes to transform into plasma cells after 7 to 10 days of culture.²⁴ These plasma cells infrequently contain large electron-dense inclusions (Russell bodies), which may measure 2 to 3 μm in diameter (see Fig. 73-1H).²⁵ Russell bodies, cytoplasmic Ig in the endoplasmic reticulum, sometimes are dissolved during the staining procedure. They usually occur in pathologic states but may be found in plasma cells from normal lymph nodes or marrow.

LIGHT MICROSCOPY, HISTOCHEMISTRY, AND ELECTRON MICROSCOPY

The mature plasma cell has a characteristic basophilic cytoplasm and an eccentric nucleus when treated with a polychrome stain. The nuclear polarity is attributable to a large paranuclear zone, which corresponds to the Golgi apparatus. The typical mature plasma cell spread on a slide usually is round or oval and has a diameter of 9 to 20 μm , with a mean cell diameter of 14 μm and a mean nuclear diameter of 8.5 μm (see Fig. 73-1F and G).²⁶ The nuclear heterochromatin is coarse and distributed in a pattern that sometimes resembles the spokes of a wheel (cartwheel nucleus) on paraffin sections. Normal plasma cells may occasionally have two or more nuclei. Cytochemical features of plasma cells include positive staining for β -glucuronidase and mitochondrial enzyme markers. They do not stain for peroxidase or nonspecific esterase.²⁷

Plasma cells in patients with certain diseases may have different histochemical properties. Plasma cell size and morphology may be altered substantially in myeloma and macroglobulinemia (Chaps. 107 and 109, respectively). Plasma cells with two or three nuclei are more frequent in marrows from patients with plasma cell dyscrasias. Periodic acid-Schiff stains may reveal cytoplasmic or nuclear inclusions in clonal plasma cells.²⁸ Under some circumstances, amyloid inclusions in plasma cells have been detected by electron microscopy.²⁹ In hemochromatosis and hemosiderosis, plasma cells may contain hemosiderin when examined by electron microscopy.³⁰

The plasma cell is packed with a rough-surfaced endoplasmic reticulum having numerous attached ribosomes as seen by electron microscopy. A large, circumscribed Golgi zone forms a paranuclear halo when observed by light microscopy. The nucleus has dense areas of heterochromatin. The Golgi zone contains lamellae, vesicles, vacuoles, and a number of granules. Mitochondria are located between the strands of endoplasmic reticulum.³¹

ANTIGENS OF HUMAN LYMPHOCYTES

B LYMPHOCYTE ANTIGENS

Figure 73–6 summarizes the expression of antigens on cells of the B-lymphocyte lineage, including committed progenitor B cells and pre-B cells. Chapter 74 discusses these cells and the maturation stages they represent. Figure 73–6 also lists antigens that are expressed or increased upon B-cell activation. Of the B-cell-associated antigens that are commonly used, only a few are restricted to cells of the B lineage. Of these antigens, only CD20, CD22, and Pax 5 are not found on other cell types. Pax 5, a transcription factor, is a “master regulator” of B-cell development^{32,33} that is expressed from the precursor stage through all B-cell maturation until it is lost at the plasma cell stage. Demonstration of monoclonal surface Ig allows diagnosis of clonal, neoplastic B cells. CD20 is the target of rituximab, a monoclonal antibody commonly used for treatment of B-cell neoplasms. CD19 is restricted mostly to B cells, but may be expressed weakly by follicular dendritic cells. CD19 is expressed by B cells at all stages of maturation, including the committed B-cell progenitor and most normal plasma cells. As such, it is the best-defined pan-B-cell surface antigen.

In addition to the CD antigens and Igs, B cells express the three major histocompatibility complex (MHC) class II antigens: DR, DP, DQ. These antigens are heterodimers of heavy chains and light chains that are encoded by genes within the D complex of the human leukocyte antigen (HLA) complex (Chap. 137). MHC class I antigens are expressed on all nucleated cells.

B-1 B Cells and CD5+ B Cells

B-1 B cells have distinctive activation requirements and high levels of CD44 and interleukin (IL)-5 receptor α (IL-5R α). They proliferate more rapidly than other B cells to stimuli such as IgM crosslinking, possibly because of having constitutively activated nuclear signal transducer and activator of transcription 3 (STAT3).³⁴ Many, but not all, B-1 cells express CD5, a 67-kDa transmembrane glycoprotein that is more brightly expressed by T cells. These cells are designated CD5 B cells.³⁵ B-1 B cells do not express other T-cell markers but do express all other pan-B-cell surface antigens. Various agents modulate B-cell expression of CD5.³⁶ B-1 B cells are found in umbilical cord blood,³⁷ adult blood, the pleura and peritoneum, and all major secondary

lymphoid organs; they are rare in the marrow.³⁸ These cells apparently are enriched for cells that spontaneously produce polyreactive autoantibodies.^{39–41}

Plasma Cells

Many B cell differentiation antigens are not expressed by the mature plasma cell, including CD20, Pax-5, surface Ig, and HLA class II antigens (see Fig. 73–6). Of the cells of the B lineage, plasma cells are distinctive in that they express CD138 and bright CD38.⁴² Clonal plasma cell neoplasms usually have antigen expression distinct from normal plasma cells including aberrant expression of CD20, CD28, CD56, and CD117. Clonal plasma cells usually aberrantly lack expression of CD19 and CD27.⁴³

T-LYMPHOCYTE AND NATURAL KILLER CELL ANTIGENS

Figure 73–7 and Table 73–1 summarize the expression of antigens on cells of the T-lymphocyte and NK lineages. All lymphocyte progenitors originate in the marrow, but T lymphocytes have their own special organ for maturation—the thymus—whereas NK cells appear to differentiate in secondary lymphoid tissue (Chap. 6).

Thymocyte

The thymus promotes the development of antigen-specific T lymphocytes and eliminates self-reactive T lymphocytes. There are three general stages of thymocyte maturation based on the surface CD4 and CD8 expression: double negative, double positive, and single positive. These stages have corresponding anatomic localization within the thymus with the least-mature double-negative cells located in the subcapsular area and the most-mature single-positive cells located in the medulla (Chap. 6). The most immature T lymphocytes in the thymus populate the subcapsular areas and express CD2, CD5, and CD7, antigens present on T lymphocytes of all stages. Capsular, “double-negative” thymocytes also express CD1a, cytoplasmic CD3, and terminal deoxynucleotidyl transferase (TdT). The majority of thymocytes are at the “double-positive” stage within the cortical area. These are the cells undergoing positive selection. Once the thymocytes achieve their “education” without dying, they mature to the single-positive stage in the medulla. These varying stages of immature T-cell maturation in the thymus have corresponding cell phenotypes in T-lymphoblastic leukemia/lymphoma.

Figure 73–6. Clinically useful antigens expressed during B-lymphocyte maturation. The intensity of the antigen expression at each stage of B-lymphocyte maturation is depicted by gradient density of bars on the graph. c, cytoplasmic; s, surface.

*CD7 is expressed on most, but not all, mature T lymphocytes.

Figure 73-7. Clinically useful antigens expressed during T-lymphocyte maturation. The intensity of the antigen expression at each stage of T-lymphocyte maturation is depicted by gradient density of bars on the graph.

Mature T Lymphocytes

Small, mature T lymphocytes are the most common lymphocytes in blood. T lymphocytes recognize antigen in the context of the MHC through binding with the T-cell receptor (TCR). Signaling from the TCR involves many membrane proteins, including CD3, a three-subunit complex expressed by early thymocytes and mature T cells.⁴⁴ It is tightly linked to the T-cell antigen receptor (Chap. 76). Most T lymphocytes have the α/β TCR on their surface, but a few percent of blood lymphocytes have the γ/δ TCR.

CD4 and CD8 Lymphocyte Subsets

Mature T cells express either CD4 or CD8, but not both. CD4, a member of the Ig supergene family, is a single-chain transmembrane glycoprotein.⁴⁵ CD8 is a 34-kDa dimeric transmembrane glycoprotein.⁴⁶ Most T cells express the α and β subunits of CD8. CD4 and CD8 act as coreceptors during T-cell activation by antigen. CD4 recognizes MHC II and CD8 recognizes MHC class I (Chap. 76). CD4 also is a coreceptor for the

human immunodeficiency virus⁴⁷ (Chap. 81), as are CCR5 (chemokine receptor 5) and CXCR4 (chemokine-related receptor). The majority of CD8 cells are cytolytic when appropriately activated.

Subsets of CD4+ T cells have helper function for activation and maturation of cytolytic cells or B cells. Other CD4 subsets have regulatory activity including the T-regulatory (T_{REG}) cells that induce immune tolerance, and follicular T-helper (T_{FH}) cells that promote B cell maturation and differentiation in germinal centers. T_{REG} and T_{FH} cells have unique phenotypes. T_{REG} cells express the low affinity receptor for IL-2 (CD25); and the transcription factor forkhead box P3 (FoxP3).⁴⁸ Follicular helper T- T_{FH} cells express CD10 and CD57. Malignant counterparts to both subsets occur. Adult T-cell leukemia/lymphoma expresses both CD25 and FoxP3 and is associated with marked immunosuppression.⁴⁹ Angioimmunoblastic T-cell lymphoma has characteristic clonal T cells that express CD10 and CD57 just like T_{FH} cells, and this lymphoma is associated with polyclonal hypergammaglobulinemia and the expansion and proliferation of both B cells and CD21+ follicular dendritic cells.⁵⁰ T-helper-17 (Th17) cells that secrete IL-17 exhibit critical roles in mucosal defense and in autoimmune disease pathogenesis.⁵¹

TABLE 73-1. Mature Natural Killer and T-Lymphocyte Subsets

NK or T-Cell Subset	Antigens
CD4+ helper T cells	CD2, CD3, CD4, CD5, CD7, and TCR α/β Subsets selectively express CD10, CD25, ⁴⁹ CD57, ⁹⁹ and FoxP3 ¹⁰⁰
CD8+ cytolytic T cells	CD2, CD3, CD5, CD7, CD8, and TCR α/β Subsets selectively express CD16, ⁵⁵ CD56, CD57, cytolytic enzymes ¹⁰¹
NK cells	CD2, CD7, KIRs (multiple), NKp46 (NCR1) Negative for CD3, TCR (α/β or γ/δ) Subsets express either CD16-negative, dim and CD56 bright, or CD16 bright and CD56 dim ⁵⁴ Cytolytic enzymes
γ/δ T cells	CD2, CD3, CD7, TCR γ/δ Usually negative for CD4 Subsets express CD5, CD8, and cytolytic enzymes

CD, cluster of differentiation; KIR, killer cell immunoglobulin-like receptor; NK, natural killer; TCR, T cell receptor.

Natural Killer Cells

The NK cell is defined as an effector cell that is not MHC restricted and has the capacity for spontaneous cytotoxicity toward various target cells (Chap. 77). Most NK cells have LGL morphology (see Fig. 73-1E).⁵² However, not all NK cells have LGL morphology, and not all LGL cells are NK cells. Many are cytolytic T lymphocytes. Cytolytic T lymphocytes and NK cells share many granule contents that can be detected by immunohistochemistry or flow cytometry. These include TIA-1, an RNA binding protein, and several granzymes, which are granule enzymes with serine protease activity.

Despite their relative morphologic homogeneity, NK cells comprise several subpopulations with distinct phenotypes. Human NK cells characteristically express CD16 (Fc γ RIII) and CD56 but not TCR α/β or TCR γ/δ , CD3, or CD4.^{53,54} CD8 is found on approximately 30 to 50 percent of NK cells. CD8 on NK cells is dim by flow cytometry and is of the β -homodimer form. CD16 (Fc γ RIII) is a low-affinity receptor that binds to IgG, which is bound specifically to antigens present on cells targeted for destruction in antibody-dependent cell-mediated cytotoxicity.⁵⁵ CD16 is expressed on all NK cells, neutrophils, and tissue macrophages. CD56 is the neural cell adhesion molecule and is seen on most NK cells in either low ("dim") or high ("bright") density.^{53,56} This 200-kDa protein is expressed at higher levels following activation.

LYMPHOCYTE SURFACE ANTIGENS

Lymphocyte subsets generally cannot be distinguished from one another by morphology. Most resting lymphocytes appear as small round cells with a dense nucleus and little cytoplasm. However, this homogeneous appearance is deceptive, as these cells comprise many functionally distinct subpopulations.

These subsets can be distinguished through the differential expression of cell-surface proteins, each of which can be recognized by a specific monoclonal antibody. Coupled with the biochemical analyses of the surface molecules that are recognized by each of these antibodies, many lymphocyte surface antigens have been defined.

Typically, it is necessary to monitor for coexpression of two or more cell-surface proteins to define a functional subset of lymphocytes. The same cell-surface protein is often expressed by more than one cell subset. For example, both helper and cytotoxic T cells express CD3, the proteins associated with the TCR for antigen (Chap. 76). Expression of both CD3 and CD4 helps to distinguish mature Th cells from cytotoxic T cells that express CD3 and CD8, and from other cells, such as dendritic cells, that express CD4 but lack expression of CD3 (Chap. 76). As noted above (see “CD4 and CD8 Lymphocyte Subsets”), T_{REG} cells are defined by the coexpression of CD3, CD4, CD25, and cytoplasmic FoxP3.⁴⁸ For these and other types of lymphocytes, it is the expression of a characteristic constellation of surface and cytoplasmic molecules, rather than the expression of any one particular marker, that generally helps to distinguish one subset of lymphocytes from another.

Fluorescent probes also can be used to identify antigen-specific lymphocytes.⁵⁷ Each clone of B lymphocytes expresses Ig capable of binding a particular antigen (Chap. 75). The frequencies of B cells specific for one antigen are estimated to range from 1 in 100,000 to 1 in 1,000,000 cells or less. Populations of lymphocytes enriched for B cells binding to a specific antigen can be stained using antigen coupled to probes, allowing for the detection and isolation of antigen-specific B cells using flow cytometry.⁵⁸ Alternatively, flow-based techniques can be used to monitor for antigen-specific B cells that are activated by contact with antigen.⁵⁹ T lymphocytes, however, generally recognize antigen in the form of peptides nested into molecules of the MHC (Chap. 76). Thus identification and isolation of antigen-specific T cells require more complex probes using multimeric complexes comprised of specific peptide antigen complexed with the relevant MHC molecule.⁵⁷

COMPOSITION OF LYMPHOCYTES

Unfortunately, few studies of the composition and biochemistry of lymphocytes have used purified lymphocyte subpopulations. Because mature helper T cells are the predominant blood lymphocyte of normal adults, many reported biochemical parameters are most relevant to this subpopulation.

ION AND WATER CONTENT

The resting blood lymphocyte has a mean cell volume of 200 μm^3 and contains 71 \pm 1.2 percent by weight of water.⁶⁰ The total lymphocyte cation content is 35 femtomoles (fmol) per cell, of which 22 to 28 fmol per cell is potassium, and 7.9 \pm 3.2 fmol per cell is sodium.⁶⁰ Lymphocyte membranes have both voltage-gated and calcium-activated potassium channels that regulate cell volume. Pharmacologic inhibition of these channels blocks T-cell activation. The calcium content of resting lymphocytes has been estimated at 580 to 800 pmol/10⁶ cells.⁶¹ Cytosolic free calcium concentrations are relatively low in resting lymphocytes (approximately 0.1 μM) but increase severalfold after activation.⁶²

LYMPHOCYTE MEMBRANE

The lymphocyte plasma membrane is composed of equal parts of weight of protein and glycosphingolipids and 6 percent by weight of carbohydrate.⁶³ The molar ratio of cholesterol to phospholipid is approximately 0.5.^{64,65} Phosphatidylcholine is the predominant phospholipid in the lymphocyte plasma membrane, but phosphatidylethanolamine, phosphatidylinositol, phosphatidylserine, and sphingomyelin are also present. Approximately half the membrane fatty acids are saturated. The membrane proteins are usually glycosylated.

The glycosphingolipids and protein receptors of lymphocytes often are organized in glycolipoprotein microdomains termed *lipid rafts*.^{66,67} Such lipid rafts sequester various protein receptors, coreceptors, and accessory molecules that together are involved in lymphocyte cell signaling, cytoskeletal reorganization, and/or membrane trafficking.⁶⁸ As such, the surface molecules on lymphocytes are not randomly distributed.

Extracellular Membrane-Associated Enzymes (Ectoenzymes)

Exposed on the exterior surface of lymphocytes are several enzymes called *ectoenzymes* (Table 73–2). Generally, the number of surface enzyme molecules is low compared with that of other surface molecules, such as those involved in lymphocyte adhesion. This probably reflects the fact that these molecules are catalytic and have a higher functional specific activity than do molecules involved in adhesion events, where multiple interactions over large surface areas are required. As such, it is possible that many more enzymes are present than the ones currently recognized because they are expressed at levels that are not detectable by conventional methods using monoclonal antibodies and flow cytometry.

Some of the surface enzymes are involved in nucleotide metabolism (see Table 73–2). For example, CD73 is an ecto-5'-nucleotidase that catalyzes the 5' dephosphorylation of purine and pyrimidine ribo- and deoxyribonucleoside monophosphates to nucleosides that can be taken up by transport systems.⁶⁹ This ecto-5'-nucleotidase is attached to the plasma membrane by a glycerol phosphatidylinositol anchor. In addition, lymphocytes express CD26,⁷⁰ which is a membrane protein that can associate with adenosine deaminase, the levels of which are increased after activation.⁷¹ The shedding of adenosine deaminase by stimulated cells may explain why plasma levels of this enzyme are increased in early HIV infection and in other diseases associated with immune activation.⁷²

The ectoenzymes of nucleotide metabolism may regulate lymphocyte and granulocyte function at sites of inflammation. Activated T lymphocytes can release ATP, which, in turn, can bind to specific plasma membrane ATP receptors.⁷³ In addition, CD38 can catalyze the transient formation of cyclic adenosine 5'-diphosphate-ribose, a new second-messenger molecule directly involved in the control of calcium homeostasis by means of receptor-mediated release of calcium from ryanodine-sensitive intracellular stores.⁷⁴ The consequent increase in calcium mobilization and phospholipid breakdown can provoke activation or death, depending on the target cell. Subsequently, the dephosphorylation of ATP generates adenosine, which can interact with A2 receptors on the plasma membranes of neutrophils, monocytes, and lymphocytes.⁷⁵ The engagement of A2 receptors elevates adenosine 3',5'-cyclic phosphate levels, counteracting the effects of ATP on cell activation. The deamination of adenosine permits the cycle to begin anew.

The ectodomains of several other surface antigens can possess proteolytic activity. For example, CD10 (or CALLA) also has neutral endopeptidase activity,⁷⁶ and CD26 has dipeptidyl peptidase IV activity.⁷⁷ These enzymes may play a role in modulating the binding of lymphocytes to other cells and to the extracellular matrix. In addition, inhibition of the

TABLE 73–2. Ectoenzymes Expressed by Lymphocytes

Surface Molecule	Enzymatic Activity	Function	Reference
CD10	Neutral endopeptidase, EC 3.4.24.11	Metalloproteinase that may also play a role in the metabolic stability of glucagon-like peptide-1	76
CD13	Aminopeptidase N, EC 3.4.11.2	Aminopeptidase involved in trimming peptides bound to major histocompatibility complex class II molecules and cleaving macrophage inflammatory protein (MIP)-1 chemokine to alter target cell specificity. Also served as Rc for coronavirus	102
CD26	Dipeptidylpeptidase IV, EC 3.4.14.5	Serine peptidase that may be involved in T-cell signaling and T-cell activation	77
CD38	ADP ribosyl cyclase, EC 3.4.14.5	Ectoenzyme with NAD glycohydrolase, ADP ribosyl cyclase, and cyclic ADP ribose hydrolase activities	74
CD39	Ecto (Ca ²⁺ , Mg ²⁺)-apyrase (ecto-ATPase)	Ectoenzyme with ADPase and ATPase activities that plays a role in regulating platelet aggregation	103
CD73	Ecto-5'-nucleotidase	Ecto-5'-nucleotidase that may play a role in T-cell signaling	69
CD143	Peptidyl-dipeptide hydrolase (angiotensin-converting enzyme)	Peptidyl-dipeptide hydrolase that is involved in the metabolism of vasoactive peptides angiotensin II and bradykinin	104
CD156a	ADAM8 metalloprotease	Matrix metalloprotease that may play a role in leukocyte extravasation	78
CD156b	ADAM17 metalloprotease	Metalloprotease that cleaves membrane-bound tumor necrosis factor and transforming growth factor- α to release the soluble cytokine	79
CD157	ADP ribosyl cyclase and cyclic ADP ribose hydrolase	ADP ribosyl cyclase and cyclic ADP ribose hydrolase that may play a role in lymphocyte development. Like CD38, this enzyme also is involved in the metabolism of NAD	105

ADAM, a disintegrin and a metalloprotease; ADP, adenosine 5'-diphosphate; ADPase, adenosine 5'-diphosphatase; ATPase, adenosine 5'-triphosphate; CD, cluster of differentiation; NAD, nicotinamide adenine dinucleotide.

catalytic activity of CD26 can provoke many cellular effects, including induction of tyrosine phosphorylation and p38 mitogen-activated protein kinase activation, as well as suppression of DNA synthesis and reduced production of various cytokines. As such, these ectoenzymes could play an important role in lymphocyte activation.

Some membrane-bound proteases have a disintegrin and a metalloprotease domain, termed ADAM (a disintegrin and a metalloprotease).⁷⁸ One such member of this family of proteins is the tumor necrosis factor- α converting enzyme, otherwise known as ADAM17 (CD156b).⁷⁹ These enzymes cleave other surface molecules, such as tumor necrosis factor, thereby releasing the soluble active cytokine. In addition, they may play an important role in modifying the activity of cytokines or other cell-surface molecules that are present in the vicinity of the plasma membrane.

Intracellular Membrane-Associated Enzymes

Transmembrane proteins that have cytoplasmic regions with kinase or phosphatase activities are common in biology although relatively few of these are restricted to lymphocytes. Nevertheless, many cytoplasmic domains of transmembrane proteins interact directly with enzymes that are restricted or preferentially expressed by lymphocytes or lymphocyte subsets (Chaps. 75 and 76). B lymphocytes, for example, selectively express Bruton tyrosine kinase (BTK), a tyrosine kinase that plays a critical role in signal transduction via surface Ig receptors.⁸⁰ Moreover, mutations that disrupt the function of such kinases can impair B-cell development, leading to dysregulated B-cell function or immune deficiency.⁸¹ On the other hand, T-cell development and function rely heavily on cytoplasmic receptor-associated tyrosine kinases, such as the

zeta-associated protein of 70 kDa (ZAP-70), leukocyte tyrosine kinase (lck), or fyn. ZAP-70 interacts with the ζ -chain (CD247) of the TCR for antigen,⁸² whereas the latter enzymes, lck and fyn, are Src family tyrosine kinases that interact with cytoplasmic domains of various accessory molecules, including CD2, CD4, CD8, CD44, CD50, and/or CD137.⁸³ Through such interactions, these receptor protein tyrosine kinases play important roles in signal transduction following immune recognition and/or cognate intercellular immune interactions.

In addition, lymphocytes possess an important class of intracellular molecules, known collectively as adaptor proteins, that have no intrinsic enzymatic activity.⁸⁴ These adaptor proteins can serve as a scaffolding for the assembly of kinases and other signaling molecules following antigen-receptor ligation. One important adaptor protein expressed in B lymphocytes is B-cell linker protein (BLNK; Chap. 75).⁸⁵ On the other hand, T cells use a distinct adaptor protein called linker for activation of T cells (LAT).⁸⁶ These molecules couple proximal biochemical events initiated by surface-receptor ligation with more distal signaling pathways by recruiting other cytosolic proteins (Chaps. 75 and 76).

● CYTOPLASMIC STRUCTURES

CYTOMATRIX

Beneath the lymphocyte's plasma membrane is a fully developed cytomatrix with several different structural and mechanical proteins, including tubulin, actin, myosin, tropomyosin, α -actinin, filamin, and a spectrin-like molecule, which are important in the formation of the immunologic synapse that forms during cognate intercellular interactions.⁸⁷ These are

arranged into typical microfilaments, microtubules, and intermediate filaments. Lymphocyte activation by antigens or mitogens can lead to changes in the interaction of membrane components with the cytoskeleton, allowing for antigen processing, Ig secretion, or cell-mediated cytotoxic reactions.⁸⁸

ORGANELLES

In large part the composition and metabolism of long-lived blood T lymphocytes reflect their resting state. The T cells have a high nuclear-to-cytoplasmic ratio, few ribosomes or mitochondria, and scant endoplasmic reticulum. Glycogen stores are meager. The DNA content of the resting small lymphocyte, 8 pg per cell, is the same amount in other diploid cells. In contrast, the RNA content averages 2.5 pg per cell, yielding an RNA-to-DNA ratio of approximately 0.32.⁸⁹ This value is less than in most other human cells, as a result of the small amount of ribosomal RNA in most lymphocytes.

In contrast to most lymphocytes, however, plasma cells have a high RNA-to-DNA ratio. These cells are the end products of B-cell differentiation and are committed to the synthesis, assembly, and secretion of Ig. Accordingly, these cells have a well-developed rough endoplasmic reticulum and Golgi apparatus, but lack many of the surface receptors found on most lymphocytes. Mature plasma cells are probably terminally differentiated and have a low rate of DNA synthesis and abundant RNA, reflecting the plasma cell's high-level synthesis of Ig.

Lysosomes

The few lysosomes in blood lymphocytes contain several different acid hydrolases, including acid phosphatase, β -glucuronidase, β -galactosidase, β -hexosaminidase, α -arabinosidase, α -galactosidase, α -mannosidase, α -glucosidase, and β -glucosidase.^{90–92} Acid hydrolase activities are generally higher in T cells than in non-T lymphocytes. Lysosomal acid esterase, assayed histochemically with α -naphthyl acetate as substrate, has a characteristic punctate appearance in mature T lymphocytes.⁹³ Secretory lysosomes are specialized organelles that combine catabolic functions of conventional lysosomes with the capacity to be secreted upon induction.⁹⁴ An example of such secretory lysosomes are the specialized cytoplasmic granules of T cells and NK cells that are responsible for the cytotoxic effector function of these cells.

Cytoplasmic Granules

In contrast to other lymphocytes, cytotoxic T lymphocytes and NK cells possess abundant cytoplasmic granules. These contain a pore-forming proteolytic enzyme, termed *perforin*, and a series of serine proteinases with specific proapoptotic activity, called *granzymes*.⁹⁵ To protect against possible autolysis by granule contents, cytotoxic lymphocytes possess serine-proteinase inhibitors, termed *serpins*.⁹⁶ As an additional safeguard, the granzymes of resting lymphocytes are stored as inactive proenzymes.

Cytotoxic lymphocytes rely primarily on the perforin/granzyme system to kill their targets.⁹⁷ Upon contact with its target cell, the cytotoxic lymphocyte converts the granzymes into active forms by a lysosomal cysteine protease called dipeptidyl peptidase I.⁹⁸ Then perforin introduces a pore in the membrane, allowing the activated granzymes and other granule contents to pass into the cytoplasm and then the nucleus of the cell targeted for destruction.⁹⁵ *In vitro* studies indicate that granzyme nuclear import is independent of ATP, cannot be inhibited by nonhydrolyzable guanosine triphosphate analogues, and involves binding within the nucleus, unlike conventional signal-dependent nuclear protein import. The perforin-dependent nuclear entry of granzymes precedes the nuclear events of apoptosis, such as DNA fragmentation and breakdown of the nuclear envelope (Chap. 15).

ACKNOWLEDGMENTS

CHAPTER 74

LYMPHOPOIESIS

Christopher S. Seet and Gay M. Crooks

SUMMARY

Lymphopoiesis refers to the process by which the cellular components of the immune system (i.e., T cells, B cells, and natural killer cells, and certain dendritic cells) are produced during hematopoietic differentiation. This process begins with the hematopoietic stem cell and continues through progenitor stages down a series of mostly diverging lineage pathways, ultimately resulting in the remarkable diversity and flexibility of the immune system. Although the more terminal events in lymphocyte differentiation and function have been defined in detail (Chaps. 75 to 77), the earliest events during which hematopoietic stem cells undergo lymphoid lineage commitment are less-well understood and still controversial. Although the conceptual framework for the questions of lymphoid commitment has been established largely on studies in the mouse, experimental systems now exist to better understand how such events are controlled in humans. This chapter summarizes what is known about the ontogeny of lymphoid development and the control of lymphoid differentiation, and discusses some of the persisting controversies in the field.

● LYMPHOPOIESIS DURING PRENATAL DEVELOPMENT

Blood is formed from a succession of sites during embryonic and fetal development, beginning outside the embryo in the yolk sac. Soon afterward, hematopoiesis begins in the embryo proper, initially in the para-aortic splanchnopleura (PAS) and aorto-gonad-mesonephros (AGM) regions, then the fetal liver, spleen, and finally the fetal marrow (Chap. 7). With each change of anatomical site, the range of hematopoiesis becomes progressively more complex and similar to that of the adult (Fig. 74–1).

When assigning hematopoietic function to each developmental stage, it is important to distinguish the lineage “potential” of stem and progenitor cells that arise from certain areas (i.e., the ability to generate specific lineages *in vitro* from immature cells removed from a region) from the spontaneous physiologic production of lineages in each region. With this distinction in mind, the onset of lymphopoiesis

Acronyms and Abbreviations: AGM, aorto-gonad-mesonephros; BM, bone marrow; BCR, B-cell receptor; CLP, common lymphoid progenitor; CT, computed tomography; DC, dendritic cell; DN, double negative; E, days of gestation; EBF, early B-cell factor; FACS, fluorescence-activated cell sorting; FLT3, Fms-like tyrosine kinase 3; HSC, hematopoietic stem cell; Ig, immunoglobulin; IL, interleukin; JAK3, Janus kinase 3; LMPP, lymphoid-primed multipotent progenitor; LSK, $lin^{neg}sca-1+c-kit+$; NK, natural killer; PAS, para-aortic splanchnopleura; SCID, severe combined immunodeficiency.

during embryogenesis lags behind development of the myeloid and erythroid lineages. Although myeloid, erythroid, and natural killer (NK) cells can be produced from all extraembryonic and embryonic sites, B and T lymphocytes are predominantly generated from so-called definitive hematopoietic stem cells (HSCs) in the embryo proper.¹

MURINE HEMATOPOIETIC DEVELOPMENT

Most of the studies exploring embryonic and fetal hematopoiesis have been performed using mouse models. Although the timing of each developmental stage has been carefully mapped, it has long been a source of controversy as to whether hematopoiesis in the embryo is initiated from colonizing precursors from the extraembryonic yolk sac, or whether the embryonic sites of hematopoiesis arise independently from the yolk sac.^{2–6} This debate has implications for understanding the lineages generated at different sites of hematopoiesis and thus for tracing the ancestry of the lymphoid cells that are produced in the mammalian embryo. One reason for the difficulty in assigning the exact organ in which lineages are generated, is that each site of hematopoiesis is active during overlapping periods (see Fig. 74–1). In addition, once circulation has been established, it is difficult to rule out the possibility that stem cells and progenitors found in one location did not migrate from another. However studies using *Ncx1*^{-/-} mice, which lack both heart-beat and circulation,^{7,8} are beginning to dissect the autonomous lineage potentials of these distinct embryonic hematopoietic tissues.

The first wave of hematopoiesis in the mouse begins in the extraembryonic tissue of the yolk sac by 7.5 days of gestation (E7.5), before circulation is established.^{9,10} This initial stage of so-called primitive hematopoiesis produces mostly erythrocytes and macrophages. Although lymphocytes are not detectable at this time,¹⁰ the contribution of first-wave progenitors to downstream fetal lymphopoiesis has been suggested by the identification of a lymphomyeloid progenitor in the E9.5 yolk sac, which expresses Rag-1, one of the earliest lymphoid-specific events,¹¹ as well as of a distinct progenitor with B-1/marginal zone B cell potential.¹² Further studies have identified both thymic-repopulating and multipotent potential in the yolk sac,^{13,14} indicating emerging changes to our understanding of primitive hematopoiesis. The murine placenta has also been identified as an autonomous source of multipotent hematopoietic cells as early as E8.5⁵; however, the direct contribution of either yolk sac or placental progenitors to definitive lymphoid development remains to be determined. Definitive HSCs that are capable of generating all lymphohematopoietic lineages first appear in the PAS/AGM region at E8.5 to E9.^{3,10} High-level, multilineage reconstituting activity typical of definitive HSC can be found in the murine AGM region by E10.5. However, although AGM cells can produce all lineages, including T and B lymphocytes *in vitro*, lymphocytes do not spontaneously develop in the fetus until hematopoiesis has begun in the fetal liver. Rag-1 expression, one of the earliest lymphoid-specific events, can be found in the E11 murine fetal liver.¹⁰ T-cell potential has been identified in the yolk sac and PAS as early as E8.25 to E9.5 of murine gestation¹³; however, T-cell differentiation *in vivo* begins with the colonization of the thymus around E11 by stem or progenitor cells that migrate to the thymus from the AGM, fetal liver, and, later still, the fetal marrow.^{15,16}

HUMAN HEMATOPOIETIC DEVELOPMENT

Hematopoietic cells have been identified in the human yolk sac as early as day 18 of embryonic life, at which time, like the mouse, they are almost exclusively comprised of erythrocytes and, to a lesser extent, monocytes and macrophages (see Fig. 74–1).¹⁷ Although no lymphocytes are seen in the yolk sac, yolk sac progenitors do have NK cell potential under certain *in vitro* conditions.^{17,18} The same yolk sac progenitors, however,

Figure 74-1. Timing of lymphohematopoiesis during prenatal development. Shown is the timeline for activity in each site of hematopoiesis in the embryo and fetus of (A) human and (B) mouse. B and T cells are first detected *in vivo* in fetal liver and thymus, respectively, at times shown. AGM, aorto-gonad-mesonephros; PAS, para-aortic splanchnopleura.

do not possess the capacity for B- or T-cell development, even when placed in culture conditions that permit lymphoid differentiation.¹⁸

As in the mouse, definitive hematopoiesis develops first in the AGM region derived from the splanchnopleura, as evidenced by the finding that the AGM is the site where CD34+ cells with the capacity for full lymphoid and myeloid differentiation are first found in the human embryo.^{18,19} The AGM develops at day 27 of gestation in the human, when human HSCs are generated as clusters of two or three cells arising from the endothelium specifically on the ventral surface of the preumbilical region of the aorta. These cells are clonogenic and highly proliferative, rapidly increasing to several thousand in number and spreading further along the aorta. However, hematopoiesis exists only transiently in the AGM, disappearing entirely by day 40.¹⁷ Although lymphoid cells can be produced in culture from cells extracted from the AGM,^{17,18} the HSC of the AGM do not produce mature cells *in situ*; instead their role is to migrate and colonize the fetal liver, producing the next wave of hematopoiesis. As in the mouse, recent studies have also detected multipotent progenitors with lymphoid potential in the human placenta. These reports suggest that hematopoietic stem/progenitor cells may also be generated *de novo* from the large vessels of the chorionic plate as early as week 5 of gestation, with multipotent HSC detectable at 15 weeks.^{20,21} However, the contribution of placental HSC to fetal liver or marrow colonization remains unclear.

Although blood cells are first detectable in the human fetal liver as early as day 23, they exist at this time only as erythroid and myeloid cells associated with hepatic sinusoids. These erythroid cells consist of megaloblasts expressing embryonic hemoglobins (globin chains ζ and ϵ), and no CD34+ cells are seen in the fetal liver during this early phase. It is likely that this first stage of fetal liver hematopoiesis is secondary to colonization of more mature cells from the yolk sac. By day 30, AGM-derived

CD34+ cells appear in the fetal liver,²² and by day 32, these cells are able to maintain long-term hematopoiesis *in vitro*.²² Erythroid cells in the fetal liver at this later stage of definitive hematopoiesis consist of enucleated macrocytes producing fetal hemoglobin (globin chains α and γ). In normal development, as with the yolk sac and AGM, hematopoiesis in the fetal liver is transient, disappearing by 20 weeks of gestation.¹

The final wave of hematopoietic development takes place in the fetal marrow, starting around 11 weeks of gestation. The initial cells seen in the marrow are CD15+ myeloid cells and glycophorin A+ erythroid cells, and hematopoiesis is again associated with the endothelium, taking place in the medullary sinusoids before osteoblast formation.²³ Eventually, CD34+ cells are found in the fetal marrow and behave functionally as true HSC, generating B, T, NK, and myeloid and erythroid lineages.¹ HSC have found their final niche, and lifelong, self-renewing lymphohematopoiesis resides permanently in the marrow thereafter.

THYMIC DEVELOPMENT

The human thymic microenvironment begins to develop at approximately 4 weeks' gestation and then undergoes three developmental phases.²⁴ The first phase occurs between 4 and 8 weeks' gestation, with the appearance of thymic epithelium arising as a product of the third and fourth pharyngeal pouches²⁵ and the expansion of thymic epithelial cells. The second phase occurs between 9 and 15 weeks' gestation and is characterized by the development of subcapsular, cortical, and medullary regions.²⁴ Thymic colonization by fetal liver-derived progenitors and lymphocyte production begins at approximately week 9.²⁵ The ability of thymocytes to respond to the mitogen phytohemagglutinin is detectable as early as 10 weeks' gestation,²⁶ and alloreactive, phenotypically mature T cells can be found by 13 to 16 weeks' gestation.²⁷

The third phase occurs from 16 weeks' gestation until age 1 to 2 years and is characterized by robust intrathymic T-cell maturation (Chaps. 6 and 76).

An exhaustive study of 136 human postnatal thymuses ranging from neonatal life to more than 90 years old, found that essentially all postnatal thymic growth (based on weight and volume) occurs during the first postnatal year, mostly in the first few months of life.²⁸ From the age of 12 months, the human thymus undergoes steady involution, with a reduction of thymocytes and thymic epithelium, particularly the medulla, and a corresponding increase in fatty infiltration of the perivascular space.²⁸

Whereas mice lose approximately 90 percent of the wet weight of the thymus during life, the increasing fatty infiltration in the perivascular space in the aging human thymus maintains the total size of the thymus in healthy people into late life.²⁸ Radiologic studies using computed tomography (CT) scans have confirmed that total thymic size remains stable in humans throughout life although parenchymal tissue atrophies dramatically (~95 percent; Chaps. 6 and 9).²⁹

B-CELL DEVELOPMENT

The hallmark characteristic of a mature B cell circulating in blood or residing in secondary lymphoid tissue is the expression of cell-surface immunoglobulin (Ig). The cell-surface Ig consists of μ , δ , γ , α , or ϵ heavy chains disulfide-linked to κ or λ light chains (Chap. 75). The cell-surface Ig and the associated signaling molecules $Ig\alpha$ (CD79a) and $Ig\beta$ (CD79b) are referred to as the *B-cell receptor* (BCR). Progenitor (pro-) B cells are defined by the absence of both cytoplasmic μ heavy chains and cell-surface BCR. Precursor (pre-) B cells are defined by the presence of cytoplasmic μ heavy chains in the absence of cell-surface BCR. This minimal definition of pro-B, pre-B, and B cells forms the basis of the current detailed model of human B-cell development.³⁰ B-cell development can be divided into two stages: an antigen-independent stage that occurs primarily in fetal liver and fetal and adult marrow, and an antigen-dependent stage that occurs primarily in secondary lymphoid tissue, such as spleen and lymph node.

The first B cells detectable in the human fetus are found in the fetal liver²⁵ at approximately 8 weeks' gestation, with the appearance of cytoplasmic IgM+ pre-B cells; by 10 to 12 weeks, surface IgM+ B cells are seen in the fetal liver³¹ and fetal omentum.³² B-cell and IgM production move to the fetal marrow and spleen by 17 weeks of gestation (Chaps. 6, 7, and 75).^{33,34} From the end of the second trimester throughout adult life, marrow is the exclusive origin of B-cell development.³⁵ The frequency of early B-lineage cells as a percentage of the total nucleated lymphohematopoietic cell pool is higher in fetal than in adult marrow. However, the ratio between pro-B, pre-B, and immature B cells and the mitotic activity within these fractions is relatively constant.³⁶

In murine B-cell development, two functionally and immunophenotypically distinct types of B cells, B-1 and B-2, have been described.³¹ Most B cells in adult mice are B-2 cells, which form part of the adaptive immune system by their ability to interact with T cells and undergo immunoglobulin heavy chain class switching. The B-1 cells make up approximately 5 percent of adult murine lymphocytes, but demonstrate a far less diverse immunoglobulin repertoire than the B-2 cells, responding to carbohydrate antigens and other T-cell-independent immunogens and forming part of the innate immune system. Murine B-1 cells are marked by their expression of CD11b, and are found in multiple sites, including the spleen, intestine, and the pleural and peritoneal cavities.^{37,38} The B-1 cells can be further divided into B-1a cells (which secrete immunoglobulins spontaneously) and B-1b cells (in which immunoglobulin production is induced) based on the expression of the marker CD5. The demonstration of a B-1a/marginal zone B-cell-restricted progenitor in the E9 extraembryonic yolk sac suggests the B-1

lineage may emerge prior to the development of the adaptive immune system.¹² At present, there is no clear evidence that humans have similar subpopulations of B-1 and B-2 cells during development.³¹

NATURAL KILLER CELL DEVELOPMENT

Functional NK cells can be detected in the human fetal liver as early as 9 to 10 weeks of gestation,²⁶ but NK cell differentiation can be induced *in vitro* from progenitors derived at all stages of hematopoietic development, even those from the yolk sac.^{1,17,18} Thus, the onset of NK potential is not equivalent to the full lymphoid potential of definitive hematopoiesis, as NK potential can be assigned to a range of progenitor types that exist at different stages, including primitive hematopoiesis. NK cell production can be considered as providing an essential defense mechanism for the developing mammalian embryo prior to development of more complex pathways of adaptive immunity.

DENDRITIC CELL DEVELOPMENT

Dendritic-like cells which express class II major histocompatibility (MHC) antigens are produced at all stages of embryonic and fetal hematopoiesis, being first detected in the human yolk sac and mesenchyme as early as 4 to 8 weeks, before development of the fetal marrow or thymus.³¹ Dendritic cells (DCs) are detectable at each site of hematopoiesis as soon as they become active, in the human fetal thymus at 11 to 14 weeks, marrow at 14 to 17 weeks, spleen at 16 weeks, and tonsils at 23 weeks.^{39,40} DC and macrophages are closely related and phenotypically similar (Chap. 67), both expressing MHC class II. Thus, clear discrimination of these two cell types can be difficult, particularly as many studies that provided information on human DC development were conducted before all the molecular and antibody tools for analysis of DC were available.

DIFFERENTIATION PATHWAYS FOR LYMPHOCYTE PRODUCTION

The conceptual framework for how the lymphocyte lineages are generated from HSC was developed largely from studies using genetically engineered mice and murine transplant models. Although necessary and useful as a starting point, caution should be exercised in translating the results of the murine studies to human lymphopoiesis, or in assuming for any species that only one pathway to lymphopoiesis exists at all stages of ontogeny.^{41,42} Additionally, the conclusions about lineage relationships of isolated populations are influenced by limitations inherent in any of the *in vitro* or *in vivo* assays employed to examine differentiation potential.⁴³

For several decades, our understanding of hematopoiesis has been built on a hierarchical schema in which all the pathways of differentiation lead away from a multipotent HSC, and progress through discrete progenitor stages that mark each branch-point of lineage commitment (Chap. 18). In the classical paradigm, the earliest differentiation "decision" made by an HSC is to enter one of two pathways, marked by either a common lymphoid progenitor (CLP) or a common myeloid progenitor (CMP), which has full myeloid and erythromegakaryocytic differentiation potential (Fig. 74-2).⁴⁴ With each successive stage of differentiation, lineage-specific cell-surface markers and transcription factors are upregulated, and alternative lineage potentials are lost. Consequently, the CLP is defined as a single cell that can give rise to all lymphoid lineages (B, T, and NK), but cannot generate myeloid, erythroid, or megakaryocytic lineages. The concept of progenitor populations marking two mutually exclusive differentiation pathways, one limited to myeloid and erythromegakaryocytic potential and the second defining

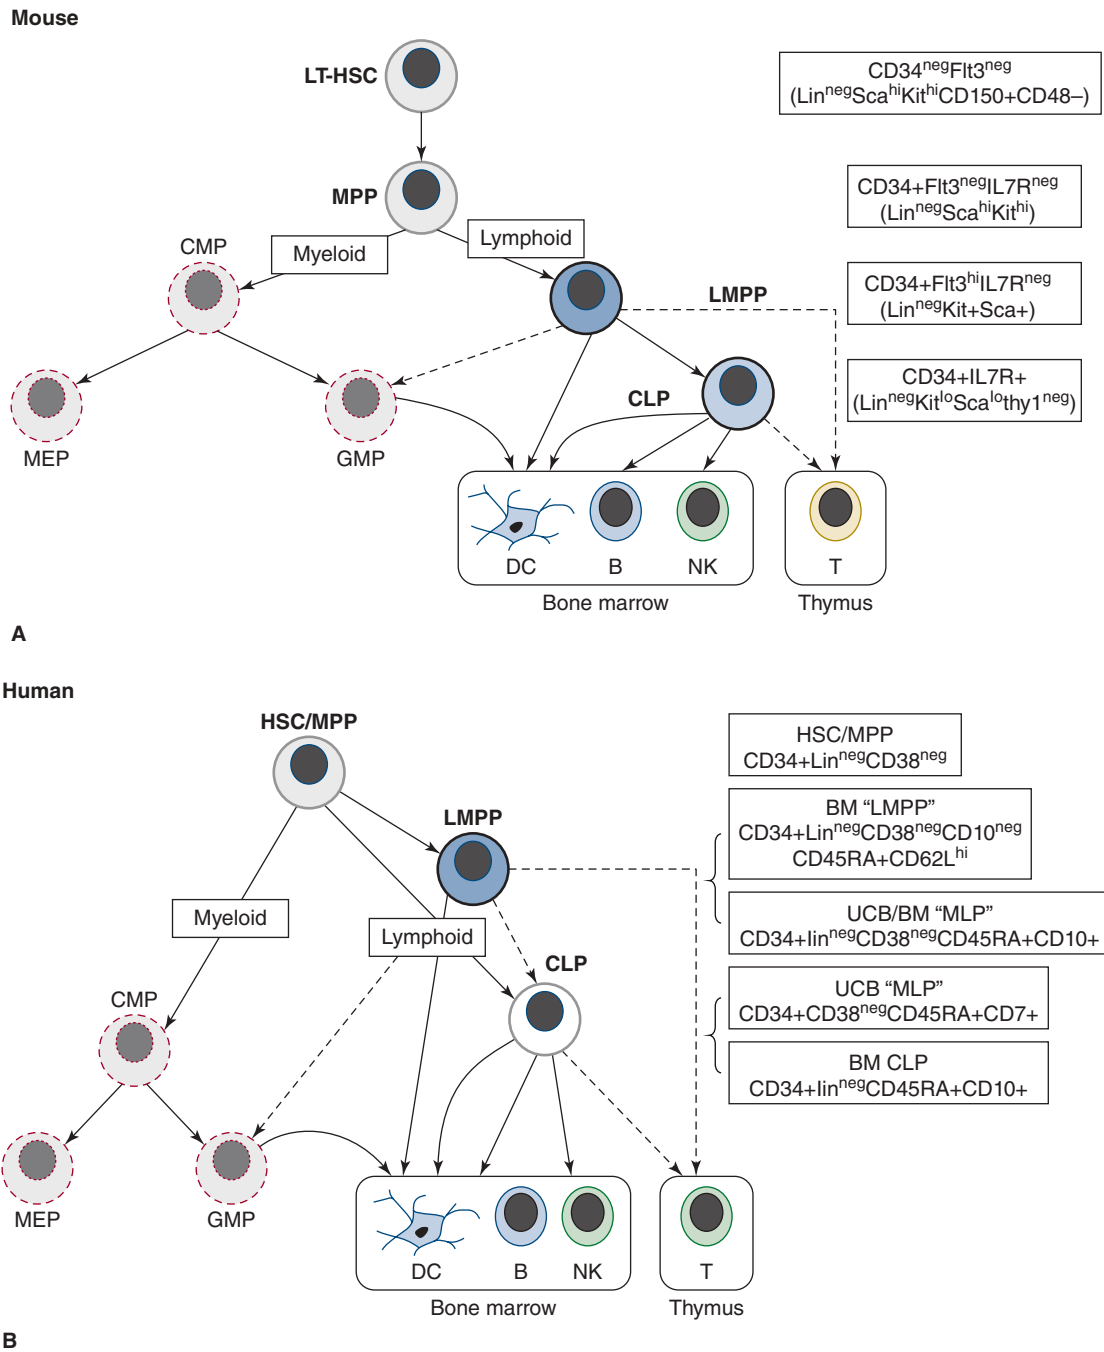

Figure 74-2. Postnatal pathways of lymphopoiesis in mice and humans. The key immunophenotype used to isolate each population is shown in boxes on the right. In parentheses under the main immunophenotypes are other markers also associated with each population. The exact relationship between lymphoid-primed multipotential progenitors (LMPPs) and common lymphoid progenitors (CLPs), and between LMPPs and myeloid progenitors remains controversial, as does the main cell type that initiates thymopoiesis (all shown as dashed lines). In both mice and humans, dendritic cells (DCs) can be produced *in vitro* from all prospectively identified lymphoid progenitors as well as myeloid progenitors. **A.** Murine lymphoid progenitor pathways. Populations with multilineage potential include long-term hematopoietic stem cells (LT-HSCs) and multipotential progenitors (MPPs). FLT3⁺ LMPPs, have full lymphoid (T-, B-, and natural killer [NK] cell developmental potential) and limited myeloid (nonclonogenic, mostly monocyte) potential. In the CLP, all myeloid potential is lost and full lymphoid potential remains. **B.** Human lymphoid progenitor pathways. Populations with multilineage potential include HSC and LMPP (aka multilymphoid progenitor [MLP]), which have full lymphoid (T-, B-, and NK cell developmental potential) and limited myeloid (mostly monocyte) potential. The CD10⁺ CLP has predominantly B, and some NK and T potential and is almost devoid of myeloid potential. Alternative phenotypic markers reported for each progenitor type with similar lineage potential are shown. BM, marrow; GMP, granulocyte-macrophage progenitor; MEP, megakaryocyte-erythroid progenitor.

lymphoid commitment, was held long before cells that satisfied the criteria of CLP were identified.^{45–47} In contrast, the existence of single clonogenic cells with myeloid, erythroid, and megakaryocyte lineages was shown more than three decades ago through the use of *in vitro* clonal assays to demonstrate so-called colony-forming unit-granulocyte erythromyeloid megakaryocyte,⁴⁸ and later confirmed using markers to prospectively isolate such cells in mice⁴⁹ and humans.⁵⁰ The lymphocyte lineages were assumed to be closely related because of a number of associations, for example, common anatomical sites of T and B lymphopoiesis (spleen, lymph nodes; Chap. 6), similar molecular mechanisms that regulate T-cell receptor and B-cell immunoglobulin rearrangements (Chaps. 75 and 76), and severe B- and T-lymphoid defects that result from single genetic mutations in mice (Chap. 80).⁵¹

Development of flow cytometry (synonym: fluorescence-activated cell sorting [FACS]) made possible the isolation of rare hematopoietic cell populations and the subsequent interrogation of lineage potential using *in vitro* cultures and *in vivo* reconstitution studies (Chap. 18). Primitive multilymphoid progenitors with little or no clonogenic myeloid or erythroid potential have now been isolated from human tissue using flow cytometry with combinations of various cell-surface markers.^{52–54} However, it seems likely that lineage relationships are less-strictly organized than once believed. Studies in mice show that the erythroid and megakaryocytic lineages can branch off at an earlier point in hematopoiesis, and that lymphoid (i.e., T, B, and NK) and myeloid (or at least monocytic) lineages can arise from the same pathway through a so-called lymphoid-primed multipotent progenitor (LMPP).⁵⁵ It remains unclear which of these lineage differentiation pathways are most physiologically significant during steady-state hematopoiesis, but it is likely that more than one pathway can exist simultaneously and alternative pathways may predominate during different stages of ontogeny and from different sites of hematopoiesis.

MURINE LYMPHOID PROGENITORS

In 1997, investigators working with murine marrow cells, isolated progenitors that possessed no myeloid or erythromegakaryocytic potential, but when transplanted into irradiated recipients could rapidly restore T-, B-, and NK cell lineages.⁵⁶ Clonal *in vitro* and *in vivo* studies showed that all lymphoid lineages were derived from a single common progenitor, thus proving the existence of the long-assumed CLP and supporting the classical model of lymphopoiesis. This study isolated cells based in part on expression of interleukin-7 receptor alpha (IL-7R α).⁵⁶ The IL-7R α + CLP do not express hematopoietic markers associated with fully differentiated lineages (they are called “lineage negative” or “lin^{neg}” cells). As an indication that they are more differentiated than multilineage HSCs, expression of certain HSC-related cell-surface markers (Sca-1, Thy-1, c-kit) is downregulated.⁵⁶ Thus the full immunophenotype assigned to the murine CLP is Lin^{neg} IL-7R α + Thy-1^{neg} Sca-1^{lo} c-kit^{lo}. This contrasts the murine CLP immunophenotype with that of the murine HSC, which is found within the Lin^{neg} IL-7R α ^{neg} Thy-1^{lo} Sca-1^{hi} c-kit^{hi} population.⁵⁶

Work with murine marrow has prompted a reexamination of when the lymphoid lineage pathways diverge from those of the myeloid and erythroid lineages (see Fig. 74–2). A population from murine marrow cells, defined largely by expression of the receptor FLT3 (Fms-like tyrosine kinase 3), has been shown to possess full lymphoid and some myeloid potential, but not erythroid or megakaryocytic potential.^{55,57} These lin^{neg}sca-1+c-kit+CD34+FLT3^{hi} (synonym: LSK CD34+FLT3^{hi}) cells are primed for lymphoid commitment in that they have down-regulated genes involved in erythromegakaryocytic differentiation and upregulated lymphoid-associated genes.⁵⁸ They have thus been termed LMPPs.^{55,58} Although they are able to generate monocytes and granulocytes *in vitro*, their differentiation potential is nonetheless skewed

heavily to lymphoid cells; after transplantation into irradiated recipients, LSK CD34+FLT3^{hi} cells rapidly reconstitute B and T lymphopoiesis. However, unlike the multipotent LSK CD34+FLT3^{neg} cells, reconstitution of myeloid lineages *in vivo* from LSK CD34+FLT3^{hi} is very limited, and importantly lacks granulocytic potential.⁵⁵ Indeed, subsequent *in vivo* fate-mapping studies have questioned the physiologic importance of a lymphomyeloid differentiation pathway to steady-state myeloid development, both in the marrow and thymus.^{59,60}

One confusing factor in defining lineage potential is the ability of both myeloid and lymphoid progenitor populations to differentiate into DCs, at least *in vitro* (Chap. 21).^{61–63} As *in vitro*-derived DC express many cell-surface markers common to myeloid antigen-presenting cells, irrespective of the lineage of origin, the extent to which identification of *in vitro* myeloid potential is confounded by a DC program is unclear.

HUMAN LYMPHOID PROGENITORS

The CD34 cell-surface marker is expressed on human HSCs and on a variety of different types of hematopoietic progenitors, including those restricted to lymphoid development (Chap. 18).^{64,65} CD34 has been combined with additional cell-surface markers to identify human multilymphoid progenitors, for example, CD10,^{52,66} CD7,^{53,54,67,68} and CD45RA.^{52,67} Similar to the mouse CLP, in addition to the upregulation of expression of the aforementioned markers, lymphoid commitment is accompanied by downregulation of certain HSC cell-surface markers, such as c-kit and Thy-1.⁴¹

As in murine studies, no one marker used in isolation is able to define a human lymphoid progenitor.⁶⁵ For example, although the expression of CD7 can be used to define a subset of CD34+lin^{neg}CD38^{neg} cells in cord blood that are multilymphoid progenitors without myeloid or erythroid potential,^{53,54} CD34+lin^{neg}CD38+CD7+ cells from cord blood have full lineage (lymphoid, myeloid, and erythroid) potential. Furthermore, when comparing the progenitor populations identified in human studies with those described from murine experiments it is important to recognize that species differences exist between cell-surface markers.⁴¹ For example, IL-7R α expression is used to define murine CLP,⁵⁶ but CD34+lin^{neg}CD38^{neg}CD7+ multilymphoid progenitors in human cord blood do not express IL-7R α ,⁵³ and CD34+lin^{neg}CD38+IL-7R α + cells in human cord blood have both myeloid, lymphoid and even some erythroid potential. A different ontogeny and source of hematopoietic cells will also introduce unexpected variations of progenitor immunophenotype and function.⁴¹ Whereas most murine studies have been conducted with adult murine marrow, most human studies have been performed with umbilical cord blood, a more logistically available source containing progenitors that are significantly more proliferative than marrow.⁶⁹ Again using the example of the CD34+lin^{neg}CD38^{neg}CD7+ multilymphoid progenitor, although this immunophenotype can be used to identify multilymphoid progenitors in cord blood,⁵³ the same markers cannot be used in human marrow because CD34+lin^{neg}CD38^{neg} marrow cells do not express CD7. Two candidates for the human equivalent of the murine LMPP have been described, both of which coexpress FLT3: one in the marrow identified as CD34+lin^{neg}CD38+CD45RA+ and high expression of CD62L (L-selectin)⁷⁰; and another in the marrow and cord blood characterized as a CD34+lin^{neg}CD38^{neg}Thy-1^{lo/neg}CD45RA+ multilymphoid progenitor (MLP).⁷¹ The hierarchical relationship of these two populations to each other, or to the marrow CD34+lin^{neg}CD38+CD45RA+ CLP is unclear; and as in the murine system, the physiologic contributions of a lymphomyeloid developmental pathway to steady-state hematopoiesis has yet to be determined. Adding to the concept of possible independence of dendritic cell development, DC potential has been found in all the primitive human lymphoid progenitors reported.^{52,53,67,70–72}

THYMIC PROGENITORS

It was long assumed that lymphoid commitment in the marrow precedes thymic seeding and T-cell development. However, despite the clear existence of lymphoid-committed progenitors within the marrow, the dominant cell type that migrates from the marrow and seeds the thymus to initiate thymopoiesis is still a matter of controversy. As described above, a variety of marrow-derived lymphoid-restricted progenitors and LMPPs are each able to generate T cells *in vitro* and *in vivo*. However, careful examination of the thymus has revealed primitive progenitors that have not only lymphoid, but also myeloid and erythroid potential. Such rare cells have been identified in murine thymus, where they are referred to as early thymic progenitors (ETP),⁷³ and also in human thymus, where they have the phenotype CD34+lin^{neg}CD1a^{neg}CD7^{neg}.^{74,75} The lineage potential of such cells as well as the sharing of many cell-surface markers and similar gene expression profile to HSCs, suggest strongly that HSCs or at least multipotent progenitors are able to seed the thymus directly without a preceding stage of lymphoid commitment in the marrow. Which of these alternative progenitor types are dominant in terms of their contribution to steady-state thymopoiesis is yet to be determined⁷⁶; however, it is likely that early thymic progenitor lineage potential is itself dynamic, based on colonization of the murine thymus with temporally distinct waves of both lymphoid-restricted and multipotent thymic-seeding progenitors during embryonic development.⁷⁷

CHALLENGES IN FUNCTIONAL CHARACTERIZATION OF LYMPHOID PROGENITORS

The accurate assignment of lineage potential to immunophenotypically defined progenitors requires clonal analysis. Although clonal assays for myelo-erythromegakaryocytic progenitors have existed for more than 30 years,⁴⁸ the ability to differentiate HSCs along lymphoid pathways has been relatively recent, particularly for human studies.⁴³ *In vitro* assays for human lymphoid potential became available when it was observed that selected murine stromal cell lines were capable of supporting B-cell, NK cell, and DC differentiation from primitive human HSCs.^{78–80} T-cell differentiation systems are more complex, requiring an *in vitro* model that recapitulates the unique environment of the thymus. Originally this was only possible using the fetal thymic organ culture method, a system in which large numbers of murine or human progenitors are seeded into whole thymic lobes in so-called hanging drop cultures.⁸¹ A more efficient *in vitro* system for studying murine and human T-cell differentiation has been developed using a murine stromal monolayer that expresses the Notch ligand Delta-like 1 (“OP9-DL1 stroma”).⁸² However, none of the *in vitro* T-cell culture systems simultaneously support B-cell development, making proof of full T- and B-lymphoid potential at a clonal level technically problematic. *In vivo* transplantation of a single murine HSC can prove multilineage potential at a clonal level, but this also is technically difficult, especially when studying progenitor populations that are not self-renewing. *In vivo* studies with human cells are particularly challenging as they rely on xenogeneic transplant models with low engraftment efficiency.^{41,43}

REGULATION OF LYMPHOPOIESIS

CYTOKINES IN LYMPHOPOIESIS

The many cytokine pathways that regulate lymphoid development, differentiation, and function are too numerous and complex for a full description here. However, the cytokine receptors of the common gamma (γ_c) chain family should be mentioned particularly because

of their biologic importance in lymphopoiesis and their clinical relevance in primary immune deficiency disease. The γ_c subunit is a signaling component of six different cytokine receptors, interleukin (IL)-2,⁸³ IL-4,^{84,85} IL-7,^{86,87} IL-9,⁸⁸ IL-15,⁸⁹ and IL-21,⁹⁰ all of which act on different stages and pathways involved in lymphopoiesis.^{51,91,92} All six γ_c -dependent receptors are unique in their activation of the Janus kinase 3 (JAK3) tyrosine kinase, a molecule that directly interacts with γ_c to mediate signaling.⁹³ In addition to the γ_c subunit, each of these receptors are comprised of an α subunit through which specific ligands bind; IL-2R and IL-15R also share a common β subunit.⁵¹

Null mutations of γ_c result in severe combined immunodeficiency (SCID) syndromes in mice and humans. However differences in the specific lineages affected reveal important species differences in cytokine dependency.⁵¹ The most important of these differences is in the requirement for IL-7 signaling in human and murine B-cell development. Adult murine B-cell development has an absolute requirement for IL-7 to IL-7R interaction and subsequent downstream signaling involving the γ_c subunit of the IL-7R and JAK3.⁹⁴ In contrast, IL-7 is not essential for human B-cell development. X-linked SCID patients with mutations in the γ_c cytokine-receptor subunit exhibit profound thymic hypoplasia and an absence of NK cells but normal or elevated numbers of B cells.⁵¹ SCID patients with mutations in JAK3^{95,96} or the IL-7R⁹⁷ also have normal numbers of blood B cells. Although B-cell numbers are normal, B-cell function in patients with γ_c -deficient SCID is not normal and patients are hypogammaglobulinemic, presumably partly as a result of the role of IL-4 in B-cell function and the absence of T-cell interactions in antibody production. These collective results indicate IL-7 is not essential for at least the numerically normal development of human B cells.

NK cells are absent in patients with γ_c -deficient and JAK3-deficient SCID, but are normal in IL-7R α deficiency.^{65,97,98} NK cells are also absent in mice deficient in IL-15,⁹⁹ IL-15R α ,¹⁰⁰ or IL-2R β (a subunit shared by IL-2R and IL-15R),¹⁰¹ demonstrating the essential role of IL-15, but not IL-7, in NK cell development. Although no null mutations for IL-15 or its receptor have been described in humans, a familial NK cell deficiency has been described in humans in which the response to IL-15 and IL-2 appears to be subnormal.¹⁰²

The production of both B and NK cells in patients with IL-7R α deficiency, shows that in humans IL-7 is not required for the earliest stages of lymphoid commitment or growth of CLPs. This point is further supported with the finding that multilymphoid CD34+CD38^{neg}CD7+ progenitors in human cord blood do not express IL-7R α ,⁵³ and that early lymphoid progenitor subsets are preserved in the marrow of γ_c and JAK3-deficient patients.¹⁰³ In contrast to B cells and NK cells, however, T-cell development is absolutely dependent on IL-7 in both mice and humans.⁹¹ In both species, mutations of any portion of the IL-7 signaling pathway, that is, γ_c , IL-7R α , or JAK3, completely prevents T-cell development.⁵¹ IL-2, in contrast, although an important cytokine in proliferation and function of mature T cells, is not essential for thymopoiesis; mutations in IL-2,¹⁰⁴ IL-2R α , or IL2R β ¹⁰⁵ result in functional T-cell defects, but T cells are not absent.

TRANSCRIPTIONAL REGULATION IN LYMPHOPOIESIS

The hierarchical differentiation pathways that lead irreversibly to the diverse array of functionally specialized mature lymphocytes are regulated by groups of genes expressed and repressed in a complex, precisely orchestrated sequence. As with cytokine regulation, our understanding of which transcriptional factors control each stage of differentiation has been developed using a combination of gene expression analyses in isolated progenitors and precursors, and an examination of the functional consequences of genetic mutations in mice and humans. The review

in this chapter focuses on genes that regulate the earliest commitment decisions in the production of lymphoid progenitors; regulation of later differentiation stages in each lineage is discussed in Chaps. 75 to 77, respectively.

The complex interplay between groups of genes involved in hematopoietic differentiation has been likened to a multidimensional network whose “regulatory space” is formed by a dynamic balance between certain transcriptional regulators.¹⁰⁶ Expression analysis of multiple genes in defined progenitor populations demonstrates levels of promiscuity at early stages of hematopoiesis, that preclude assignment of any unique gene expression pattern to each stage.^{106–108} As differentiation proceeds, a more specific “genetic fingerprint” for each lineage develops.

Regulation of Early Lymphoid Commitment

Ikaros Although no single gene has been identified as a lymphoid-specific master regulator, several transcription factors have been shown to be essential for the early stages of lymphopoiesis. The gene *Ikaros*, which encodes a family of DNA-binding zinc finger proteins, was identified in murine knockout studies as essential for all fetal lymphopoiesis.^{109,110} However, in the postnatal setting, the role of *Ikaros* is more complex and less specific. Adult *Ikaros*^{null} mice completely lack B cells, and although T cells are produced, their differentiation is abnormal.¹¹¹ A murine study has suggested that *Ikaros* is not required for the initial lymphomyeloid versus myeloerythroid commitment decision, and that not only lymphoid differentiation, but also certain fate choices in the myeloerythroid pathway are affected by *Ikaros*.¹¹² As the expression of two key lymphoid cytokine receptors, FLT3 and IL-7R α , is dependent on *Ikaros*, and as these markers are used to isolate murine LMPP and CLP, respectively, it is still not completely clear at which exact lymphoid progenitor stage *Ikaros* exerts its effects.¹¹² In addition to lymphoid progenitors, *Ikaros* isoforms are also expressed in HSCs, and myeloid lineages in mice^{112–116} and humans.^{116,117} Although *Ikaros* may act as a typical transcription factor in some settings, *Ikaros* also affects gene expression through its role in chromatin formation.¹¹⁸

Pu.1 The transcription factor PU.1 is essential for normal B- and T-lymphocyte development, but its effects are highly dose dependent. At high levels of PU.1, key myeloid regulatory genes are upregulated and macrophage differentiation is induced preferentially over lymphoid differentiation.¹¹⁹ Low-level expression of PU.1, however, is essential for lymphopoiesis.^{120,121} Mice in which PU.1 is completely absent lack B cells and have abnormal fetal thymopoiesis. However, studies with mice in which PU.1 is deleted specifically in B-lineage cells show that PU.1 is not essential for B-cell differentiation beyond the pre-B stage.¹²² It is likely that the critical role for PU.1 in murine lymphopoiesis lies in its upregulation of expression of the receptor for IL-7, which as mentioned above, is a key cytokine in both B and T lymphopoiesis in mice.¹²⁰

E2A E2A (encoded by *TCF3*) generates two basic helix-loop-helix proteins, E12 and E47, through differential splicing.¹²³ Murine studies suggest that E2A is necessary for lymphoid priming of multipotent progenitors and that the E2A proteins prime expression of a number of lymphoid-associated genes.¹²⁴ There is a dose-dependent requirement for E2A expression in the development of LMPP and CLP.¹²⁴ Both B- and T-lineage commitment are severely reduced in the absence of E2A, but *Ikaros* and PU.1 expression are normal.^{124–126} E2A affects B lymphopoiesis in part through upregulation of early B-cell factor (EBF)¹²⁷ and T lymphopoiesis through upregulation of expression and function of the key T-cell specification factor Notch 1.¹²⁸

Regulation of B-Cell Commitment

The transcription factors *Ikaros*, PU.1, E2A, EBF, and Pax5 are essential for normal B-cell differentiation. Mice that have functional deletions

in any one of these genes have severely abnormal B-cell development; however, of these genes, only EBF and Pax5 are B-cell specific within the hematopoietic system.

Pax5 Pax5 is expressed specifically in B-lineage-committed progenitors and is required for normal expression of the B-lineage genes CD19 and CD79a.¹²¹ Pax5^{-/-} mice are blocked at the pro-B cell stage, but express most early B-cell-related genes.¹²⁹ Although Pax5 can activate a small subset of B-lineage genes, its main function in B-cell differentiation appears to be the suppression of T-cell and myeloid transcriptional programs at the murine pro-B-cell stage, thus enforcing commitment to the B lineage.^{121,129,130} Consistent with this role, PU.1, E2A, and EBF function earlier than Pax5 in B lymphopoiesis, and forced expression of Pax5 does not rescue the B-cell defect seen in EBF^{-/-} mice or PU.1^{-/-} mice.¹²¹

Ebf EBF (encoded by *EBF1*) is a helix-loop-helix zinc finger protein that activates a B-lineage transcriptional program, and induces B lymphoid in preference to myeloid development, in part by antagonizing the expression of genes encoding alternative lineages such as C/EBP α (CCAAT/enhancer binding protein), Id2, and PU.1,¹³¹ and, in part, by inducing Pax5 expression.¹²¹ *Ebf1*^{-/-} lymphoid progenitor populations from mice lack the ability to generate B cells but retain the ability to generate T, NK, and myeloid cells.¹³¹ Overexpression of EBF in multipotent progenitors promotes B-cell production at the expense of myeloid differentiation.¹³¹ EBF and E2A function cooperatively in early B lymphopoiesis¹²⁴; however, overexpression of EBF can rescue B-cell differentiation in E2A-deficient mice, including activation of Pax5.¹³² Pax5 overexpression however cannot rescue the B-cell defect in EBF^{-/-} mice,¹²¹ demonstrating a critical, Pax5-independent role of EBF in early B-cell fate decisions.

Regulation of T-Cell Commitment

Notch Upon arrival into the thymus, multipotent progenitors from the marrow become rapidly committed to the T- and NK-cell pathways. The most important environmental cue for T-cell commitment is delivered by the thymic epithelium in the form of the Notch ligands, Delta-like 1 (*DLL1*) and Delta-like 4 (*DLL4*).¹³³ Binding of one of these ligands to the Notch 1 receptor expressed on the surface of thymocyte precursors causes activation of intracellular Notch and a series of transcriptional programs turn on to switch lineage fate toward the T lineage at the expense of B-cell development.¹³³ In mice, Notch is absolutely required for T-cell differentiation and proliferation, including β selection.¹³⁴ Analogous to control of early B cell differentiation by E2A, Notch signaling activates a transcriptional network which includes factors critical for lineage specification (GATA-3, TCF-1), and commitment (BCL11b).¹³⁵ However, although Notch signaling is necessary for murine thymopoiesis it is not sufficient for activation of the full complement of T-cell genes.¹³⁶ The ability of hematopoietic progenitors to respond to Notch signaling and commit to T-lineage fate depends on a balance between positive and negative regulators. Combinations of at least four other transcription factors are required to initiate T-cell development: PU.1, *Ikaros*, Runx family factors, and E2A.^{124,133} In addition, leukemia-lymphoma-related factor (LRF/Pokemon, encoded by *Zbtb7a*) must be downregulated to allow Notch signaling to induce T-cell fate decisions.¹³⁷ Notch signaling also plays important roles at later stages of thymocyte differentiation.¹³³

The effects of Notch signaling have been extensively studied in mice, but the exact stages and processes regulated by Notch appear to differ between mice and humans. For example, using *in vitro* studies of human T-cell development, it appears that while Notch is essential for early thymocyte proliferation, it is not required for β selection or T-cell receptor $\alpha\beta$ differentiation.^{138,139} As with so much of the information described in this chapter, the most important challenge that lies ahead is

to translate the detailed mechanistic framework developed from murine studies into careful investigations of human lymphopoiesis.

GATA-3 GATA-3 is a key transcriptional factor for T-cell development, and is essential at various stages of differentiation. However, in addition to T cells, GATA-3 is also expressed in uncommitted HSCs, CLPs, and even in nonhematopoietic cells, and its effects are complex and highly dose-dependent.^{33,135,140}

Tcf-1 TCF-1 (encoded by the *TCF7* gene) is a transcription factor essential for T-cell development, and is directly activated by Notch signaling.^{141,142} In ETPs, TCF-1 promotes cell survival as well as activation of T-lineage specific genes, including *Gata3* and *Bcl11b*.^{141,142} Induction of a T-cell specific transcriptional program by TCF-1 can occur even in the absence of Notch signaling; however, it cannot activate the essential T-lineage gene *Ptcr*,¹⁴² indicating that, as in B-cell development, T-cell specification occurs through both hierarchical and combinatorial transcription factor interactions.

Bcl11b BCL11B was identified as a transcription factor required for the normal generation of $\alpha\beta$ T cells during β selection; however, upregulation of Bcl11b first occurs at the earlier CD4^{neg}CD8^{neg} (double negative)-2 (DN2) stage, likely through transcriptional activation by TCF-1.¹³⁵ In DN2 cells, Bcl11b appears to contribute minimally to the T-lineage specification program governed by Notch/E2A/GATA-3/TCF-1 activity, but rather is required for the suppression of stem/multipotent progenitor-associated genes, which marks the loss of myeloid potential and final commitment to the T-cell lineage.¹⁴³

CHAPTER 75

FUNCTIONS OF B LYMPHOCYTES AND PLASMA CELLS IN IMMUNOGLOBULIN PRODUCTION

Thomas J. Kipps

SUMMARY

Much of our immune defense against invading organisms is predicated upon the tremendous diversity of immunoglobulin molecules. Immunoglobulins are glycoproteins produced by B lymphocytes and plasma cells. These molecules can be considered receptors because the primary function of the immunoglobulin molecule is to bind antigen. A single person can synthesize 10 to 100 million different immunoglobulin molecules, each having a distinct antigen-binding specificity. The great diversity in this so-called humoral immune system allows us to generate antibodies specific for a variety of substances, including synthetic molecules not naturally present in our environment. Despite the diversity in the specificities of antibody

Acronyms and Abbreviations: ADCC, antibody-dependent cellular cytotoxicity; AID, activation-induced deaminase; BACH2, basic leucine zipper transcription factor 2; BCL-6, B-cell chronic lymphocytic leukemia/lymphoma 6; BiP, immunoglobulin-binding protein; Blimp-1, B-lymphocyte-induced maturation protein-1; BLNK, B-cell linker protein; BTK, Bruton tyrosine kinase; C, constant; CDR, complementarity determining region; CRI, cross-reactive idiotype; CSR, class switch recombination; D, diversity; DLBCL, diffuse large B-cell lymphoma; DNA-PK, DNA protein kinase; E2F1, E2F transcription factor 1; EBF1, early B-cell factor 1; ERGIC, ER-Golgi-intermediate compartment; FR, framework region; H, heavy; HMG, high-mobility group protein; Ig, immunoglobulin; IL, interleukin; IRF4, interferon regulatory factor 4; ITAM, immunoreceptor tyrosine-based activation motif; κ , immunoglobulin kappa light chain; Kde, kappa-deleting element; λ , immunoglobulin lambda light chain; L, light; MTF, microphthalmia-associated transcription factor; MYBL1 and 2, v-myb myeloblastosis viral oncogene homologues 1 and 2; NHEJ, nonhomologous DNA end-joining; PAX5, paired box gene 5; PDI, protein disulphide isomerase; PLC, phospholipase C; POU2AF1, Pou domain, class 2, associating factor 1; POU2F2, Pou domain, class 2, factor 2; PRDM1, positive regulatory domain 1-binding factor-1; RAG, recombination-activating gene; RSS, recombination signal sequence; SCID, severe combined immunodeficiency; SHP-1, Src homology 2 domain-containing protein tyrosine phosphatase-1; SHIP-1, phosphatidylinositol-3,4,5-trisphosphate 5-phosphatase 1; TCFE2A, transcription factor E2a; UNG, uracil-DNA glycosylase; V, variable-region gene; V(D)J, exon created by a rearranged immunoglobulin heavy-chain variable-region gene, diversity gene segment, and joining gene segment; XBP1, X-box binding protein-1.

molecules, the binding of antibody to antigen initiates a limited series of biologically important effector functions, such as complement activation and/or adherence of the immune complex to receptors on leukocytes. The eventual outcome is the clearance and degradation of the foreign substance. This chapter describes the structure of immunoglobulins and outlines the mechanisms by which B cells produce molecules of such tremendous diversity with defined effector functions.

● IMMUNOGLOBULIN STRUCTURE AND FUNCTION

BASIC STRUCTURE

All naturally occurring immunoglobulin molecules are composed of one or several basic units consisting of two identical heavy (H) chains and two identical light (L) chains (Fig. 75-1).¹ The four polypeptides are held in a symmetrical, Y-shaped structure by disulfide bonds and noncovalent interactions.²⁻⁴ The internal disulfide bonds of the heavy and light chains cause the polypeptides to fold into compact globe-shaped regions called domains, each containing approximately 110 to 120 amino acid residues. Each domain is composed of β -pleated sheets that are stabilized by a conserved disulfide bond (Fig. 75-1). The light chains have two domains; the heavy chains have four or five domains. The aminoterminal domains of the heavy and light chains are designated the variable (V) regions because their primary structure varies markedly among different immunoglobulin molecules. The carboxy-terminal domains are referred to as constant (C) regions because their primary structure is the same among immunoglobulins of the same class or subclass. The amino acids in the light- and heavy-chain variable regions interact to form an antigen-binding site. Each four-chain immunoglobulin basic unit has two identical binding sites. The constant-region domains of the heavy and light chains provide stability for the immunoglobulin molecule. The heavy-chain constant regions also mediate the specific effector functions of the different immunoglobulin classes (Table 75-1).

LIGHT CHAINS

Immunoglobulin light chains have an approximate Mr of 23,000. They are divided into two types, κ and λ , based upon multiple amino acid sequence differences in the single constant-region domain.⁵ The λ chains are divided further into subclasses. The proportion of κ -to- λ chains in adult human plasma is approximately 2:1. The immunoglobulin light-chain constant region has no known effector function. Its main purpose may be to allow for proper assembly and release of an intact immunoglobulin molecule. Soon after synthesis, the antibody light-chain constant region associates with the nascent immunoglobulin heavy chain (see Fig. 75-1), releasing the latter from the immunoglobulin-binding protein (BiP). BiP is a heat shock protein that, in the absence of antibody light chain, binds the first constant-region domain of the newly synthesized heavy chain, thereby retaining the heavy-chain polypeptide in the cell's endoplasmic reticulum.⁶

HEAVY CHAINS

Immunoglobulin heavy chains have an Mr of 50,000 to 70,000, depending upon the number and length of the constant-region domains. The five major isotypes of heavy chains— γ , α , μ , δ , and ϵ —determine the five corresponding classes of immunoglobulin (Ig): IgG, IgA, IgM, IgD, and IgE. The individual immunoglobulin molecules of each isotype may contain either κ or λ light chains, but not both. Tables 75-1 and 75-2

Figure 75-1. Model of an immunoglobulin (Ig) G molecule. The light-chain domains V_L and C_L and the heavy-chain domains V_H , C_{H1} (or C_{H1}), C_{H2} (or C_{H2}), and C_{H3} (or C_{H3}) are labeled inside the respective immunoglobulin domain. Dotted red colored lines indicate intrachain and interchain disulfide bonds. The aminoterminal (N) and carboxyl-terminus (C) of each polypeptide are indicated. The hinge region also is indicated. Digestion by pepsin cleaves the molecule at the carboxyl side of the hinge region, which generates Fc and $F(ab')_2$ fragments, as indicated on the right. The $F(ab')_2$ fragment is bivalent, as it is held together by the disulfide bridges in the hinge region. On the other hand, digestion of the molecule by papain degrades the Fc portion and generates monovalent Fab fragments, as the cleavage site for papain is on the aminoterminal side of the disulfide bridges of the hinge region.

summarize the distinct physical and functional properties of the human immunoglobulin classes.

IgG

Approximately 80 percent of the immunoglobulins in adult plasma are IgG. The IgG molecule is composed of the basic 150-kDa immunoglobulin four-chain structure plus approximately 3 percent carbohydrate. Near the junction of the two arms of the Y-shaped immunoglobulin molecule, the two heavy chains interact to form a flexible “hinge” region (see Fig. 75-1). Exposed between constant-region globular domains, the hinge region is attacked readily by the proteolytic enzyme papain or pepsin. Figure 75-1 shows the cleavage sites. Digestion of IgG with papain yields three fragments. The single Fc piece contains the carboxy-terminal region of both heavy chains. The two identical $F(ab)$ pieces contain the entire light chain and the aminoterminal portion

of the heavy chain. The Fc-regions also contain a binding epitope for the neonatal Fc receptor (FcRn), responsible for the extended half-life, placental transport, and bidirectional transport of IgG to mucosal surfaces.⁷ As such, IgG molecules effectively penetrate extravascular spaces and readily cross the placental barrier to provide passive immunity to the newborn.

IgG is the predominant antibody produced during the secondary immune response to antigen. The average half-life of circulating IgG molecules is approximately 21 days, although the exact value varies among the IgG subclasses (Table 75-3). Within the IgG class are four major subclasses, designated IgG₁, IgG₂, IgG₃, and IgG₄.⁷ The most abundant subclass is IgG₁, which constitutes 60 percent of the total IgG in plasma. All IgG subclasses have a similar molecular mass except for IgG₃, which has a much longer hinge region than any other IgG subclass. The IgG₃ hinge region is approximately four times as long as the IgG₁ hinge, containing up to 62 amino acids (including 21 prolines and 11 cysteines), forming a polyproline helix with limited flexibility. Because of this, IgG₃ myeloma protein may aggregate spontaneously to produce a hyperviscosity syndrome.

Each subclass has a distinct heavy-chain constant region and mediates different effector functions (see Table 75-3). Whereas IgG₁ and IgG₃ proteins activate complement via the classic pathway, IgG₂ molecules fix complement poorly and IgG₄ proteins not at all.

Antibody responses to soluble protein antigens and membrane proteins primarily induce IgG₁, but also lower levels of the other subclasses, mostly IgG₃ and IgG₄. On the other hand, IgG antibody responses to bacterial capsular polysaccharide antigens typically are restricted to IgG₂; IgG₂ deficiency can result in the virtual absence of IgG anticarbohydrate antibodies. Viral infections generally induce IgG antibodies of the IgG₁ and IgG₃ subclasses, with IgG₃ antibodies appearing first in the course of the infection. The IgG₄ subclass typically is produced in response to allergens. Because IgG₄ has relatively low affinity to activating FcγRIII, but relatively high affinity to the inhibiting FcγRII, it may serve to prevent excessive immune responses against sterile antigens, such as bee venom, which do not pose infectious threats. As such, IgG₄ has been called a “blocking antibody” in the context of allergy, where it may compete with IgE for allergen binding.

For antigens found on pathogens, the bound IgG can: (1) tag the pathogen for ingestion and destruction by phagocytes, a process called *opsonization*; (2) activate complement; and/or (3) direct antibody-dependent cell-mediated cytotoxicity (ADCC). Either aggregated IgG

or antigen-antibody complexes may bind to specific receptors for the Fc fragment, designated FcγRI (CD64), FcγRII (CD32), and FcγRIII (CD16). Of the IgG subclasses, IgG₁ binds best to FcγRI (CD64) and FcγRII (CD32), with affinities (dissociation constant [Kd]) of 10 nM and 50 μM, respectively (see Table 75-3). IgG₁ and IgG₃ bind equally well to FcγRIII (CD16), with a Kd of 2 μM (see Table 75-3). This is the Fc receptor expressed by natural killer (NK) cells (or K cells), which mediate ADCC. Proteins of the IgG₄ or IgG₂ subclass bind poorly to FcγRI (CD64) and bind not at all to FcγRIII (CD16) (see Table 75-3). IgG₁ is the most proficient subclass at directing ADCC. For this reason, most of the therapeutic monoclonal antibodies are of the IgG₁ subclass, which can be modified further to enhance their capacity to direct ADCC.⁸

IgA

IgA composes only approximately 13 percent of plasma immunoglobulin (see Table 75-1), even though the production of IgA exceeds that of any other immunoglobulin isotype, accounting for 60 to 70 percent of antibodies produced each day.⁹ The relatively low amount in plasma is a result of the high amount of IgA secreted into the gastrointestinal tract. It is estimated that a normal 70-kg adult secretes approximately 2 g of IgA per day.⁹ IgA also circulates in the plasma as a monomer, dimer, or higher polymer containing approximately 8 percent carbohydrate. Within the IgA class are two major subclasses, designated IgA₁ and IgA₂. The most abundant subclass is IgA₁, which constitutes approximately 85 percent of the total IgA in plasma. The half-life of circulating IgA of either subclass is approximately 6 days.

The primary role for IgA is in mucosal immunity.¹⁰ Plasma cells in the lamina propria secrete IgA as a dimer that is held together by a J (joining) chain. The secreted IgA can bind to a *poly-Ig receptor*, which is an integral membrane glycoprotein expressed on the basal membrane of mucosal cells. Following the binding of IgA, the mucosal epithelial cells mediate endocytosis and transport of the IgA-poly-Ig receptor complex

^aDepending on the IgG₃ allotype.

[†]Two allotypic variants of FcγRIIa exist: H131 and R131.

[‡]Two allotypic variants of FcγRIIIa exist: F158 and V158.

in vesicles that are exported to the epithelial luminal surface. Here the poly-Ig receptor is proteolytically cleaved, releasing the extracellular domain, which remains complexed with the secreted IgA as a 70-kDa *secretory protein* that can protect the secreted IgA molecule from proteolytic digestion by enzymes in the intestinal lumen. This modified form of IgA, comprised of an IgA dimer bound to the J chain and secretory protein, is the principal antibody in saliva, tears, colostrum, and the fluids of the gastrointestinal, respiratory, and urinary tracts.

IgA can direct various effector functions by cells that bear specific Fc receptors for IgA (FcαR). FcαRI is the principal myeloid IgA receptor and is responsible for directing various IgA-mediated effector responses, such as respiratory burst, degranulation, and phagocytosis by granulocytes, monocytes, or macrophages. Another IgA receptor specific for the secretory protein can elicit powerful effector responses from eosinophils.¹¹ On the other hand, IgA antibodies do not cross the placenta, fix complement via the classic pathway, or bind efficiently to cell surfaces. Their main function may be to prevent foreign substances from adhering to mucosal surfaces and entering the blood.

Defective glycosylation of IgA₁ can lead to the most common form glomerulonephritis, namely *Berger disease* or *IgA nephropathy*. This is an autoimmune disorder in which neopeptides caused by defective galactosylation of O-linked glycans in the hinge region of human IgA₁ are recognized by antiglycan IgG or IgA₁ antibodies.¹² Some of the resultant immune complexes in the circulation escape normal clearance mechanisms, deposit in the renal mesangium, and induce glomerular injury.¹³

Another nephritis associated with glomerular IgA deposits is *Henoch-Schönlein purpura*, a condition that most commonly presents with a characteristic pruritic skin rash, arthritis, and abdominal pain in children or young adults (Chap. 122).

IgM

In a normal adult, approximately 6 percent of the total plasma immunoglobulins belong to the IgM class (see Tables 75-1 and 75-2). IgM molecules classically are termed macroglobulins because of their large molecular weight. Circulating IgM molecules contain 12 percent carbohydrate and are formed through the linkage of five identical immunoglobulin units by disulfide bonds and by a J chain (Fig. 75-2).¹⁴ IgM represents the predominant immunoglobulin class formed during a primary immune response. IgM macroglobulins do not penetrate easily into extravascular spaces or readily cross the placenta. Compared to monomeric IgG antibodies, pentavalent IgM antibodies fix complement more efficiently. A single IgM molecule on the surface of a red blood cell can initiate complement-mediated hemolysis. IgM is catabolized rapidly, with a plasma half-life of only 6 days. The monomeric form of IgM, with only two heavy and two light chains, is the major immunoglobulin expressed on the B-cell surface (Fig. 75-3). The IgM monomer represents the ligand-binding part of the receptor. The component that is responsible for signal transduction consists of two glycoproteins, CD79a and CD79b. The cytoplasmic domains of CD79a (Ig- α) and CD79b (Ig- β) contain tyrosine motifs responsible for transduction of signal from the receptor.¹⁵

IgD

IgD is a trace serum protein that composes less than 1 percent of plasma immunoglobulins. IgD is expressed on most peripheral B cells, as is IgM, where it may function as a B-cell membrane receptor for antigen that facilitates recruitment of B cells into specific antigen-driven responses. The molecule has the basic four-chain constant region and contains 11 percent carbohydrate (see Tables 75-1 and 75-2). IgD antibodies are sensitive to proteolytic degradation. They do not penetrate extravascular spaces efficiently, cross the placental barrier, or fix complement via the classic pathway. However, circulating IgD may bind to

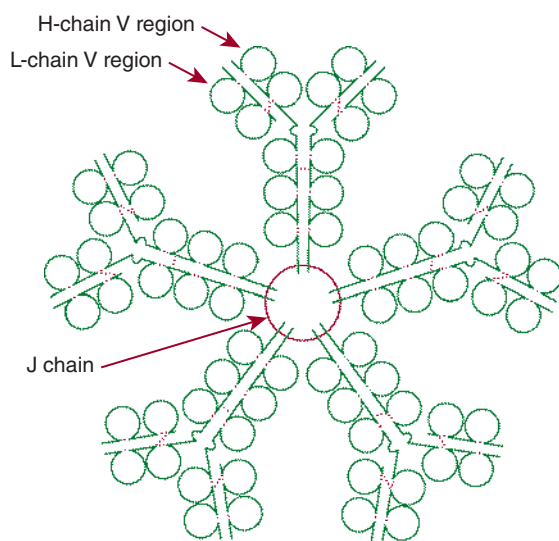

Figure 75-2. Schematic of an IgM pentamer. IgM has 10 binding sites for antigen, each composed of a heavy-chain variable region (H-chain V region) and a light-chain variable region (L-chain V region). Five bivalent IgM molecules are held together by the single joining (J) chain. Broken red colored lines indicate intrachain and interchain disulfide bonds.

Figure 75-3. Schematic of membrane IgM and its associated accessory proteins Ig- α (CD79a) and Ig- β (CD79b). The light-chain domains V_L and C_L and the heavy-chain domains V_H , C_{H1} (or C_{H1}), C_{H2} (or C_{H2}), C_{H3} (or C_{H3}), and C_{H4} (or C_{H4}) are labeled inside the respective immunoglobulin domain. Each of the cytoplasmic domains of Ig- α (CD79a) and Ig- β (CD79b) has an immunoreceptor tyrosine-based activation motif (ITAM) depicted by a green rectangle. These ITAMs play a critical role in the signaling events that are initiated by ligation of surface immunoglobulin by antigen. Dotted red colored lines indicate intrachain and interchain disulfide bonds.

basophils through a calcium-mobilizing receptor, which, upon cross-linking, can trigger antimicrobial, proinflammatory responses.¹⁶ Moreover, crosslinking of basophil-bound IgD also could induce basophils to produce interleukin (IL)-4, IL-13, B-cell activating factor (BAFF, CD272), and a proliferation inducing-ligand (APRIL, CD276), factors that, in turn, could enhance B-cell activation and isotype switching. This might explain why mice made deficient in IgD have fewer B cells, delayed affinity maturation, and weaker production of immunoglobulin isotypes, such as IgE, which are highly dependent on such cytokines.¹⁷

IgE

Although four human IgE isoforms can be produced by alternative splicing of the epsilon primary transcript,¹⁸ each isoform appears to have similar function. IgE has been called reaginic antibody to denote its association with immediate hypersensitivity. It normally constitutes only 0.004 percent of total plasma immunoglobulin (see Tables 75-1 and 75-2). In patients with parasitic infestation and in some children with atopic diseases, plasma IgE levels may rise to 5 to 20 times normal. The IgE molecule consists of a four-chain basic unit plus 12 percent carbohydrate. Monomeric IgE binds via the Fc region to high-affinity receptors on the surface membranes of basophils and mast cells. When bound to tissue mast cells, IgE has a much longer half-life than in plasma, in which its half-life is only approximately 2 days (see Table 75-2). Crosslinking of cell-bound IgE antibody by antigen induces the release of vasoactive amines, lipid-derived inflammatory mediators, proteases, proteoglycans, and cytokines, such as tumor necrosis factor- α (cachectin), interferon- γ , granulocyte-macrophage

colony-stimulating factor, and IL-1, IL-3, IL-4, IL-5, and IL-6. These substances act on adjacent cells and may regulate the metabolism of the connective tissue extracellular matrix. These lipid mediators and biogenic amines may produce the rapid components of immediate hypersensitivity, such as vascular leakage, vasodilation, and bronchoconstriction. The released cytokines, on the other hand, are responsible for the late phase of the immediate hypersensitivity response. The physiologic function of this response is not clear. Instead, the immediate hypersensitivity response may represent a pathologic systemic exaggeration of a local physiologic process that ordinarily contributes to the inflammatory response to invading organisms.

SURFACE IMMUNOGLOBULIN

Any one of the immunoglobulin isotypes may serve as a B-cell membrane receptor for antigen.¹⁵ However, most B cells express surface IgM with or without IgD. Each immunoglobulin is expressed on the surface membrane as a monomer complexed noncovalently with disulfide-linked heterodimeric glycoproteins that, together with surface immunoglobulin, form the B-cell antigen-receptor complex (see Fig. 75-3). For surface IgM, each heterodimer is composed of CD79a, an IgM α -chain of 33 kDa, complexed with CD79b, an Ig β -chain of 37 kDa. CD79a interacts with the transmembrane domain and C_H4 domain of the immunoglobulin molecule, which mediates B-cell receptor clustering and signaling in response to antigen (see Fig. 75-3).¹⁹ The CD79a chain is a product of the human mb-1 gene (designated *CD79a*) located at 19q13.2, whereas CD79b is the product of *CD79b* located on a different chromosome at 17q23. B cells that lack expression of CD79a or CD79b cannot express surface immunoglobulin. CD79a/CD79b are necessary, not only for transport of the assembled immunoglobulin to the cell surface but also for signal transduction following surface immunoglobulin-receptor cross-linking by antigen. Patients with inherited defects in CD79a have an immune deficiency that is indistinguishable from that of classic X-linked agammaglobulinemia (Chap. 80).²⁰ The cytoplasmic tails of CD79a and CD79b each contain immunoreceptor tyrosine-based activation motifs (ITAMs). Such motifs are found in the cytoplasmic domains of several immune system signaling molecules, including those of the T-cell receptor complex (Chap. 76).

B cells can become activated following ligation of their surface immunoglobulin receptors by antigen, which typically is presented on the surface of dendritic cells or macrophages.²¹⁻²⁴ This can cause microclustering of the immunoglobulin receptor complex into the *immunologic synapse*, which accumulates src family tyrosine kinases (e.g., Lyn, Blk, and Fyn), which can phosphorylate tyrosine residues in the ITAMs of CD79a and CD79b. In turn, the phosphorylated ITAM binds cytoplasmic signaling molecules, the most important of which is p72^{Syk}, a 72-kDa tyrosine kinase. Following its recruitment to the activated immunoglobulin receptor complex, p72^{Syk} itself becomes activated through phosphorylation, allowing it to phosphorylate the cytosolic adapter protein BLNK (B-cell linker protein, also known as SLP-65, BASH, or BCA).²⁵ BLNK serves as a docking site for a number of important signaling molecules, including Bruton tyrosine kinase (BTK), Vav-1, Vav-2, and phospholipase C gamma (PLC γ).²⁶ Dual phosphorylation and activation of PLC γ by BTK and p72^{Syk} allows PLC γ to effect hydrolysis of the polyphosphoinositides into inositol-1,4,5-trisphosphate and diacylglycerol, which, in turn, increase intracellular Ca²⁺ and activate protein kinase C and Ras, respectively. The importance of these activation events in B-cell signaling and development is underscored by patients with inherited defects in BTK, who lack B-cell development and have X-linked agammaglobulinemia (Chap. 80). Furthermore, inhibitors of BTK demonstrate

clinical activity in the treatment of patients with various B-cell malignancies, which appear dependent upon constitutive signaling via the immunoglobulin receptor.²⁷

To mitigate the problem of accidental initiation of signal transduction, the signaling cascade is subject to negative controls. The quantity and quality of immunoglobulin receptor signaling are modulated by several transmembrane proteins that are associated with the immunoglobulin-CD79a/CD79b receptor complex.²⁸ These associated proteins can be either costimulatory (e.g., CD19) or inhibitory (e.g., CD22, CD32 [Fc γ RII], CD72). In contrast to CD79a and CD79b, CD22 and CD72 have cytoplasmic domains with immunoreceptor tyrosine-based inhibitory motifs. When immunoreceptor tyrosine-based inhibitory motifs are phosphorylated by activated Lyn kinase, the domains recruit Src homology 2 (SH2) domain-containing protein tyrosine phosphatase 1 (SHP-1), otherwise known as protein tyrosine phosphatase 1c,^{29,30} or phosphatidylinositol-3,4,5-trisphosphate 5-phosphatase (SHIP-1).³¹ Bound SHP-1 or SHIP-1 can remove the phosphate group from the phosphorylated (and thereby activated) tyrosine kinases, returning these kinases to their inactive state so that they no longer trigger B-cell activation. The importance of SHP-1 in limiting B cell activation is demonstrated by mutant mice that lack this phosphatase.³² The B lymphocytes of such animals are stimulated by much lower concentrations of antigen than the B lymphocytes of normal mice, causing excessive B-cell proliferation, autoimmune disease, and early mortality.

GENETICS OF IMMUNOGLOBULINS

IMMUNOGLOBULIN GENE COMPLEXES

Immunoglobulin genes are inherited in three unlinked gene complexes: one for the heavy-chain classes, one for κ light chains, and one for λ light chains. The immunoglobulin heavy-chain gene complex is located at band q32 of the long arm of chromosome 14. This complex is composed of 39 functional heavy-chain variable-region (V_H) genes, more than 120 nonfunctional V_H pseudogenes, 25 functional diversity (D) segments, six functional J_H minigenes, and exons encoding the constant regions for each of the immunoglobulin heavy-chain isotypes (Fig. 75-4).³³ The κ light-chain gene complex is contained within band p12 on the short arm of chromosome 2. This gene complex consists of approximately 40 functional κ light-chain variable-region genes ($V\kappa$ genes), more than 30 nonfunctional $V\kappa$ pseudogenes, five $J\kappa$ segments, one constant-region exon, and one kappa-deleting element (Kde) (Fig. 75-5). Many of the $V\kappa$ genes in the so-called p region most proximal to the $J\kappa$ segments are in the opposite orientation of the $J\kappa$ segments, thus requiring that the $V\kappa$ exons in the proximal region to undergo inversion during immunoglobulin gene rearrangement (Fig. 75-5). The λ light-chain gene complex is located at band q11.2 on the long arm of chromosome 22, 6 Mb from the centromere.³⁴ This gene complex consists of approximately 41 functional λ light-chain variable-region genes ($V\lambda$ genes), more than 30 $V\lambda$ pseudogenes, four functional λ constant-region genes (C λ 1, C λ 2, C λ 3, C λ 7), and three λ constant-region pseudogenes (C λ 4, C λ 5, C λ 6), each associated with one $J\lambda$ segment (Fig. 75-5). The constant-region elements of the heavy-chain gene complex are proximal to variable-region segments on chromosome 14, whereas the constant-region segments of the two light chains are in the opposite orientation, telomeric to the variable-region genes.

Each germline V gene, D element, and J segment is flanked by recognition sequences that are necessary to direct site-specific recombination (Fig. 75-6). Such sequences consist of a highly conserved palindromic heptamer (5'-CACAGTG-3') a nonconserved spacer of 12 or 23 bp, and a conserved nonamer (5'ACAAAAACC-3').³⁵

Figure 75-4. Immunoglobulin heavy-chain (IGHC) gene complex. The heavy-chain genes encoding the constant regions are represented by blue boxes. Switch regions are represented by a filled circle upstream of the IGH genes. Enhancers are represented by light blue circles. Each *IGHV*, *IGHD* and *IGJH* gene is labeled on the right of each symbol. Functional *IGHV*, *IGHD*, and *IGJH* genes are represented by green boxes or blue and yellow lines, respectively. *IGHV*, *IGJH*, and *IGHC* pseudogenes are represented by red, orange boxes, or blue open boxes, respectively. *IGHV* and *IGHC* open-reading frames are represented by yellow and blue dashed boxes, respectively. Unrelated pseudogenes are represented by purple open boxes. Colors are according to IMGT color menu for genes. (Used with permission of Marie-Paule Lefranc. IMGT®, the international ImMunoGeneTics information system® <http://www.imgt.org>.)

Joining usually occurs only between segments flanked by recognition sequences with unequal spacers.³⁶ Each recognition sequence consists of a dyad symmetric heptamer, an A/T-rich nonamer, and a spacer region of conserved length, either 12 bp or 23 bp \pm 1 bp. This sequence is referred to as the 12/23 joining rule.³⁷ The consensus sequences for the heptamer (CACAGTG) and nonamers (ACAAAAACC) are optimal for rearrangement, but considerable deviation from the consensus sequence is observed and tolerated. Each spacer varies in sequence, but its length is conserved and corresponds to one or two turns of the DNA double helix. Each spacer brings the heptamer and nonamer sequences to one side of the DNA helix, where they are bound by the

Rag-1/Rag-2 protein complex that catalyzes recombination (Fig. 75-6). Similar recognition sequences flank the elements that rearrange to form the T-cell antigen receptor (Chap. 76). Because all segments of a particular type (e.g., $V\kappa$ gene segments) are flanked by one type of signal sequence and all the segments to which they should be joined (e.g., $J\kappa$ segments) are flanked by the opposite type of signal sequence, the 12/23 rule ensures that the joining is restricted to events that could be biologically productive. Such heptamer-spacer-nonamer sequences, often called recombination signal sequences (RSSs), are targets of lymphocyte-specific enzymes encoded by recombination activating genes *RAG1* and *RAG2*.³⁶

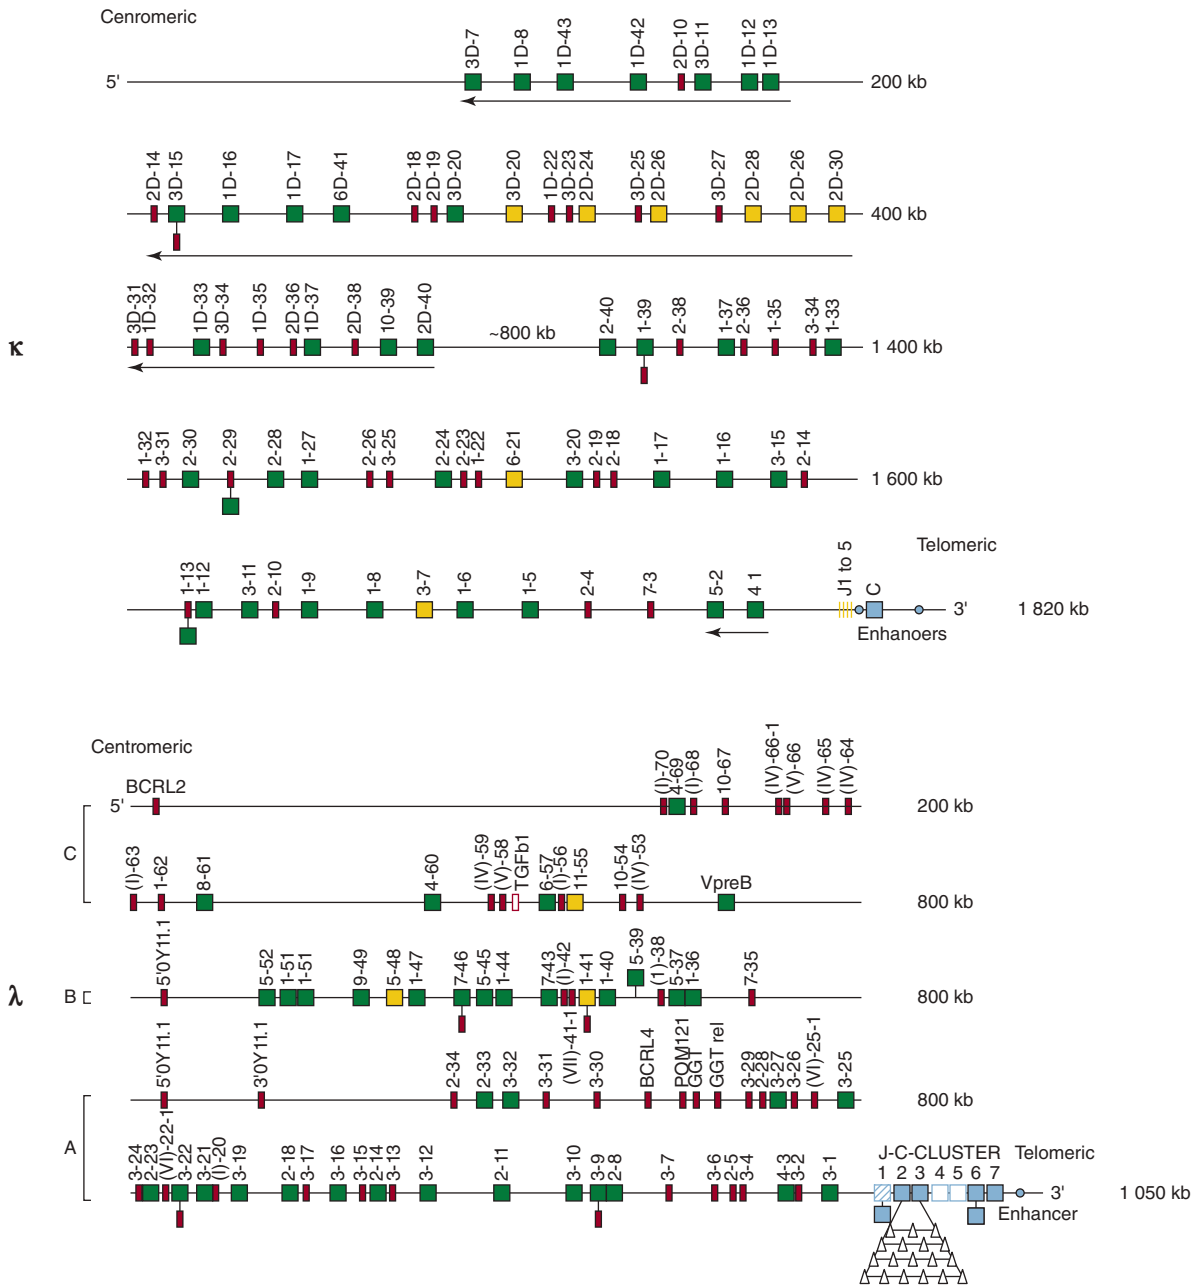

Figure 75-5. Immunoglobulin light-chain gene complexes. The *top panel* depicts the κ light-chain gene complex on chromosome 2p11-12. The *blue box* represents functional *IGLC* gene. The *IGKJ* gene segments are indicated by *yellow lines* labeled "J1 to 5." The κ light-chain enhancers are represented by *light blue circles*. *IGKV* functional genes, pseudogenes, and open-reading frames are indicated by *green, red, and yellow boxes*, respectively. The *IGKV* genes of the *p region* are designated by a number for the subgroup, followed by a hyphen and a number for the localization from 3' to 5' in the locus. The *IGKV* genes of the *d region* are designated by the same numbers as the corresponding genes in the *p region*, with the letter D added. *Arrows* show the *IGKV* genes whose orientation is opposite to that of the *IGKJ* gene segments. The *bottom panel* depicts the λ light-chain gene complex on chromosome 22q11.2. The *blue boxes* represent functional *IGLJ* and *IGLC* gene segments, whereas the *blue open boxes* represent *IGLJ* and *IGLC* pseudogenes. *IGLV* functional genes, pseudogenes, and open-reading frames are indicated by *green, red, and yellow boxes*, respectively. *IGLV* pseudogenes that could not be assigned to subgroups with functional genes are represented by *red boxes* and designated by a roman number between parentheses, corresponding to the clans, followed by a dash and a number for the localization from 3' to 5' in the locus. The *IGLV* genes are organized into three clusters, designated A, B, and C, which are indicated to the *left* of each cluster. Unrelated pseudogenes are represented by *purple open boxes*. The λ light-chain enhancer is represented by a *light blue circle*. Colors are according to IMGT color menu for genes. (Used with permission of Marie-Paule Lefranc. Figure 75-6. Schematic depicting the process of V(D)J recombination. The Rag-1/Rag-2 complex mediates **(A)** synapsis and **(B)** cleavage of the DNA at the boundaries of the heptamer/coding segments. **C.** The Artemis/DNA-PK (DNA protein kinase) endonuclease opens the hairpin and **(D)** the broken ends are then repaired by the proteins that mediate nonhomologous end-joining, namely the complex of Ku70, Ku80, DNA-PK, XRCC4, and Lig4.

● IMMUNOGLOBULIN GENE REARRANGEMENT AND EXPRESSION DURING B-CELL DEVELOPMENT

IMMUNOGLOBULIN GENE REARRANGEMENT

During B-cell ontogeny, the first immunoglobulin gene rearrangements generally occur within the heavy-chain gene complex (Fig. 75-7A). One or more D segments may rearrange and become juxtaposed with a single J_H element, generating a DJ_H complex that then may rearrange with one of the 39 functional V_H genes. Subsequently, gene rearrangements occur in the light-chain loci (Fig. 75-7B). One of the 40 functional V_K genes can rearrange with any one of five J_K segments. Should these gene rearrangements fail to generate a functional $V_K J_K$ exon, the Kde may rearrange to a site in or immediately downstream of the $V_K J_K$ exon,

thus deleting the κ light-chain constant-region exon.³⁸ Many of the proximal $IGKV$ genes in the so-called *p* region are in the opposite orientation of the $IGKJ$ segments, requiring that the V exons in this region undergo inversion during immunoglobulin gene rearrangement. A 650-bp sequence corresponding to DNase I hypersensitive sites HS1-2 within the $IGKV$ - $IGKJ$ intervening region binds a CCCTC-binding factor, which directs locus contraction and long-range $IGKV$ gene usage; its deletion results in a sevenfold increase in proximal $IGKV$ gene usage along with approximately 50 percent reduction in overall locus contraction.³⁹ Subsequent to κ light-chain gene rearrangement, one of the 41 functional $V\lambda$ exons can rearrange with any one of the four functional $J\lambda C\lambda$ exons to generate a gene that can encode a λ light chain (Fig. 75-7C).

Somatic V-region gene recombination involves introduction of double-strand DNA breaks at RSS, juxtaposition of the broken ends, and then religation through a process called *nonhomologous DNA end-joining* (NHEJ). The first cleavage step requires a specialized heterodimeric endonuclease complex comprised of Rag-1 and Rag-2 (see Fig. 75-6). Rag-1 and Rag-2 are encoded by adjacent genes located on the short arm of chromosome 11 (11p13-p12). Mice with either *RAG* gene knocked out cannot undergo immunoglobulin or T-cell receptor gene rearrangements and consequently fail to produce mature B or T lymphocytes.⁴⁰ Mutations that impair, but do not completely abolish, the function of Rag-1 or Rag-2 in humans result in a form of combined immune deficiency termed *Omenn syndrome*.⁴¹

The process of somatic DNA recombination is initiated when the Rag (recombination activating gene) endonuclease introduces DNA double-strand breaks (DSBs) at the border of two recombining gene segments and their flanking RSSs.⁴² DNA cleavage by Rag leads to four broken DNA ends that are repaired and joined through a process called NHEJ to form coding and signal joints.^{43,44} Occasionally these DSBs can be repaired aberrantly, leading to the formation of chromosomal lesions such as translocations, deletions, or inversions,^{45,46} often found in B-cell neoplasms. If the breakpoints of these chromosomal lesions lie near potential oncogenes or tumor-suppressor genes, they can lead to cellular transformation and lymphoid tumors. The mechanism of DNA rearrangement is similar for the heavy- and light-chain loci. However, only one joining event is needed to generate a light-chain gene, whereas two are needed to generate a complete heavy-chain gene. The most common mode of rearrangement involves the looping out and deletion of the DNA between two gene segments on the same chromosome; this occurs when the coding sequences of the two gene segments are in the same orientation in the DNA.⁴⁷ The 12- and 23-mer-spaced RSSs are brought together by interactions between proteins that specifically recognize the length of the spacer between the heptamer and nonamer signals, thus accounting for the 12/23 joining rule.^{36,48} The two DNA molecules then are broken and rejoined in a different configuration. By joining precisely in a head-to-head configuration, the ends of the heptamer sequences form a signal joint in a circular piece of extrachromosomal DNA that then is lost from the genome when the cell divides. However, the DNA that lies between the two gene segments is retained in an inverted orientation when a second mode of recombination occurs between two gene segments with opposite transcriptional orientations. Although this mode of recombination is less common, such rearrangements account for about half of all $IGKV$ -to- $IGKJ$ joins, as the transcriptional orientation of half of the human $IGKV$ gene segments is opposite to that of the $IGKJ$ gene segments.

The Rag-1/Rag-2 endonuclease complex recognizes either the 12-mer-spaced or 23-mer-spaced RSS and then introduces double-stranded DNA breaks (see Fig. 75-6). After introducing these breaks, the Rag-1/Rag-2 complex remains bound to the DNA.⁴⁹ Mutations that affect the ability of the Rag proteins to bind and maintain the broken

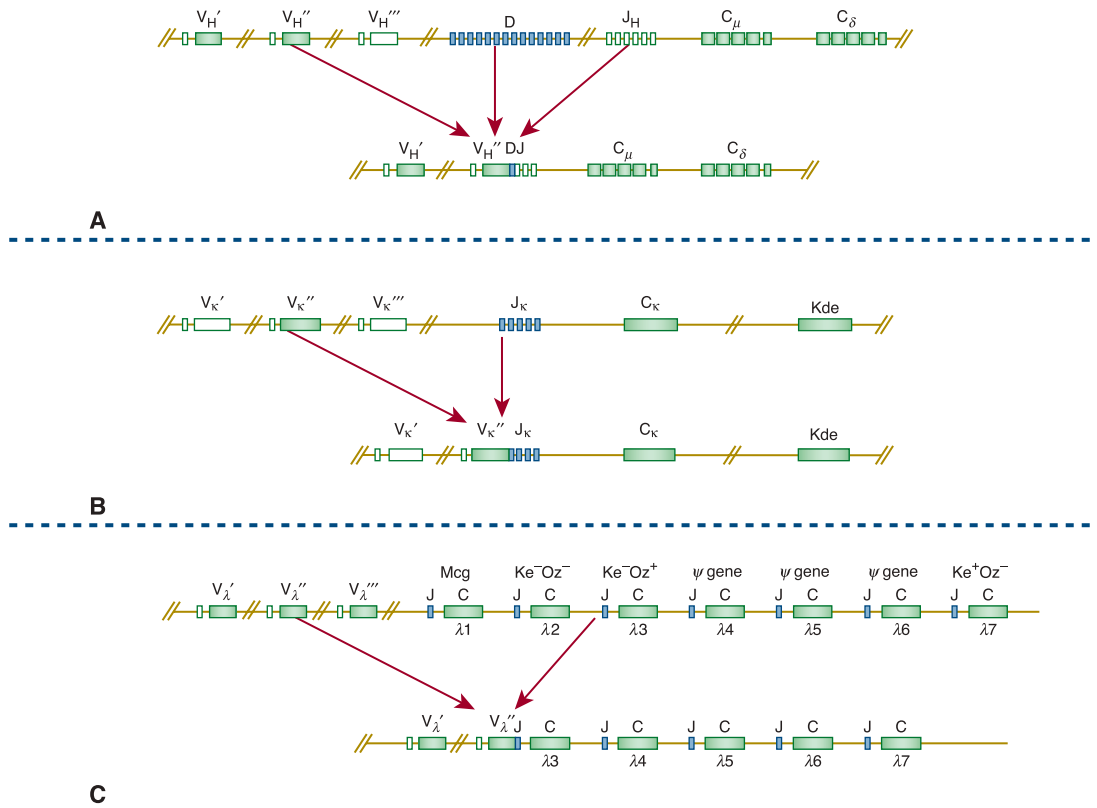

Figure 75-7. Immunoglobulin gene complexes and rearrangement. *Diagonal gold double lines* indicate a large DNA distance between the flanking genes depicted as *rectangular boxes* (not drawn to scale). The upper diagrams in **(A)**, **(B)**, and **(C)** show the germline DNA configuration of the immunoglobulin heavy-chain genes, κ light-chain genes, and λ light-chain genes, respectively. Exemplary immunoglobulin heavy-chain variable-region genes (V_H' , V_H'' , V_H'''), immunoglobulin κ light-chain genes (V_κ' , V_κ'' , V_κ'''), and immunoglobulin λ light-chain variable-region genes (V_λ' , V_λ'' , V_λ''') are depicted on the left side of each immunoglobulin gene complex. D denotes the diversity gene segments of the antibody heavy-chain locus. J_H , J_κ , and J_λ indicate the joining gene segments of the antibody heavy chain, κ light chain, and λ light chain, respectively. C_μ and C_δ denote the constant-region exons of the μ and δ heavy chains, respectively. Below each is a possible immunoglobulin gene rearrangement composed of a $V(D)J$ for the antibody heavy chain or a $V_\kappa J_\kappa$ or $V_\lambda J_\lambda$ for the κ or λ light-chain gene, respectively. Below the representative λ constant-region loci in **(C)** are listed the names of the λ nonallelic genetic markers Mcg , Ke^-Oz^- , Ke^-Oz^+ , and Ke^+Oz^- on $\lambda 1$, $\lambda 2$, $\lambda 3$, and $\lambda 7$, respectively. As indicated, $\lambda 4$, $\lambda 5$, and $\lambda 6$ are pseudogenes (ψ gene) that do not encode protein.

ends in a stable postcleavage complex can lead to misrepair of the DSBs, thereby enhancing the risk for oncogenic chromosomal aberrations.⁵⁰

Several proteins are involved in the processing and juxtaposition of the DSBs, including high-mobility group protein-1 (HMG1) and high-mobility group protein 2 (HMG2). HMG1 and HMG2 are widely expressed, abundant nuclear proteins that bind and bend DNA without sequence specificity, thereby playing an important role in the assembly of nucleoprotein complexes involved in DNA repair and transcription. HMG1 facilitates the bending of the DNA to allow the components of one DSB-Rag complex to bind and cleave the DNA at a different RSS,⁵¹ thus bringing together two disparate RSSs in accordance with the 12/23 joining rule.⁵²

The DSB-Rag complex also binds several other proteins, including Artemis, DNA-dependent protein kinase (DNA-PK), Ku70, Ku80, the human protein *X-ray repair complementing defective repair in Chinese hamster cells 4* (XRCC4), and DNA ligase IV (Lig4) (see Fig. 75-6).⁴³ DNA protein kinase (DNA-PK) is a serine-threonine protein kinase that is activated by DNA DSBs and is essential for the normal repair of DNA breaks induced by ionizing radiation, chemical agents, and during $V(D)J$ (exon created by a rearranged immunoglobulin heavy-chain variable-region gene, diversity gene segment, and joining gene segment) recombination.⁵³ Mice deficient in DNA-PK can make only trivial amounts of immunoglobulin or T-cell receptors and are called severe combined immunodeficiency

(SCID) mice.⁵⁴ Mice deficient in Artemis have a “leaky” SCID phenotype and develop some T and B cells in later life.⁵⁵ Ku-deficient mice also are deficient in T and B cells but have a small stature and other nonimmunologic defects, suggesting that these proteins also play important roles in normal development.⁵⁶ Defects resulting from mutation in Ku, XRCC4, Lig4, Artemis, or DNA-PK predispose to lymphomagenesis in mice.⁵⁷ The initial recognition and recruitment of these repair proteins to DSBs is heavily dependent on phosphorylation events (e.g., kinase activity and autophosphorylation of DNA-PK), but the downstream repair events appear more dependent on E3-ubiquitin ligases.⁵⁸

The process of recombination allows for generation of “junctional diversity” in the sequence of the rearranged gene segments. DNA ends generated by the Rag-1/Rag-2 endonuclease cleavage reaction each is fused by the NHEJ pathway involving the proteins mentioned in the preceding paragraph. The hairpinned termini of gene segments that give rise to the coding joint each is subsequently cleaved at random sites by an exonuclease. Cleavage of a hairpin away from its apex generates an overhanging flap that, if incorporated into the joint, results in addition of palindromic (P) nucleotides that contribute to junctional diversity (see Fig. 75-6). The opened hairpin ends can be modified further by nucleases that can remove a self-complementary overhang or cut further into the original coding sequence. In addition, a lymphocyte-specific enzyme, terminal deoxynucleotidyl transferase, can add

non-template-encoded (N) nucleotides (see Fig. 75–6). Finally, additional junctional diversity comes from the nucleolytic activities that remove potential coding end nucleotides prior to the final ligation of the DNA breaks into one intact recombination joint. Such processes contribute to immunoglobulin diversity and are the principal mechanism responsible for somatic diversification of the T-cell repertoire (see Chap. 76).

V(D)J recombination during lymphocyte development is regulated via transcription and through epigenetic changes that modulate the accessibility of particular loci or regions of loci to RAG.⁵⁹ Precursor B cells have high-levels of V_H germline transcripts immediately prior to V-to-DJ_H recombination.⁶⁰ Numerous epigenetic accessibility markers, such as the histone H3 lysine 4 trimethylation, are enriched around IGHJ in early pro-B cells in association with germline transcription.⁶¹ In addition, ubiquitination events can regulate recombination of immunoglobulin gene segments.⁶² The zinc finger region A of Rag-1 includes an N-terminal RING domain that acts as an E3-ubiquitin ligase, which can ubiquitinate a panel of targets for various downstream events.^{37,63–66} This region of Rag-1 also can interact with other E2 enzymes to ubiquitinate substrates involved in V(D)J recombination, such as histone 3.^{63,64} Ubiquitination of Rag-2 allows for rapid degradation of the protein upon entering S phase, thereby halting any potential off-target activities of Rag and limiting its capacity to induce V(D)J recombination during inappropriate phases of the cell cycle. Indeed, DNA breaks during S-phase are potentially harmful for cells, as such breaks can lead to deleterious translocations when misrepaired by homologous recombination (HR). It is therefore crucial to limit V(D)J recombination activity to cells within G₁ phase; this restriction appears to be controlled by Rag-2 degradation.⁶⁷

Under normal conditions, a B-lymphocyte or plasma cell synthesizes only one species of light chain and heavy chain, even though the cell has two different sets of immunoglobulin gene complexes that initially undergo seemingly independent immunoglobulin gene rearrangements. The specificity of the humoral immune response depends upon antigenic selection of unique clones of B cells, each clone expressing a homogeneous set of immunoglobulin receptors. Such restriction is achieved by limiting a given B cell to functional rearrangement and expression of only a single heavy-chain allele and a single light-chain allele. This phenomenon is called *allelic exclusion*. Although occasional neoplastic B-cell populations lack allelic exclusion and express both immunoglobulin alleles, allelic exclusion generally is observed with most B-cell tumors.⁶⁸

SURROGATE λ LIGHT CHAINS

Precursor B cells that only have rearranged D and J_H elements are referred to as progenitor B cells or “pro-B cells.” The term *pre-B cells* is reserved for precursor B cells that have completed immunoglobulin heavy-chain gene rearrangement and have a functional V(D)J complex. Both pro-B cells and pre-B cells have immunoglobulin light-chain loci in germline configuration.

Pre-B cells express some immunoglobulin μ chains in association with “surrogate” λ light chains. One of these proteins, called λ_5 , has similarity with known C λ light-chain domains. Another protein is called *VpreB* because it resembles a V domain but bears an extra N-terminal protein sequence. Both proteins are encoded by genes located on chromosome 22. The λ_5 gene is situated within a λ -like locus that is telomeric to the true λ light-chain locus. The gene encoding VpreB (VPREB1) is located within the cluster of immunoglobulin V λ genes (see Fig. 75–5), defined by breakpoints of chromosomal translocations found in a few leukemias and lymphomas. Together, VpreB and λ_5 pair with the μ heavy chains. Subsequent covalent linkages via an S-S bond

between the λ_5 and the first C_H1 domain of the μ H chain allow VpreB and λ_5 μ heavy chains to form a primitive immunoglobulin receptor that, with CD79a and CD79b, may be expressed on the surface membrane of the developing pre-B cell. Monoclonal antibodies that recognize λ_5 or VpreB specifically bind to pre-B cells and can react with B-lineage acute lymphocytic leukemia.⁶⁹

The pre-B cell receptor complex is expressed only transiently, as production of λ_5 ceases as soon as it is formed. Nevertheless, this protein plays an important role in normal B-cell development. When immunoglobulin μ chains form a complex with the “surrogate” λ light chains, the complementarity determining region 3 (CDR3) of the “surrogate” λ light chain covers the CDR3 of the heavy chain in the pre-B-cell receptor, allowing the pre-B cell to avoid antigen-specific selection.⁷⁰

In normal mice, the appearance of the pre-B cell receptor coincides with inactivation of the Rag-2 protein by phosphorylation and degradation of Rag-1 and Rag-2 mRNA, suggesting that this receptor plays a role in suppressing further immunoglobulin gene rearrangement. However, expression of the pre-B-cell receptor on the surface membrane is associated with cell activation and proliferation, leading to generation of small, resting pre-B daughter cells that again express Rag-1 and Rag-2. This situation leads to subsequent light-chain gene rearrangement. As such, expression of the pre-B-cell receptor appears to signal that a complete μ heavy-chain gene has been formed, that further rearrangements at this locus should be suppressed, and that development to the next stage can proceed. Therefore, the surrogate light chains play a critical role in normal B-cell development. This observation is underscored by studies on transgenic mice that lack functional λ_5 genes. In these mice, B-cell development in the marrow is blocked at the pre-B-cell stage, thereby markedly reducing the numbers of functional mature B lymphocytes in the blood and lymphoid tissues.⁷¹ Similarly, humans who have inactivating mutations in the λ_5 genes on both alleles of chromosome 22 have agammaglobulinemia and markedly reduced numbers of B cells.⁷²

HEAVY-CHAIN CLASS SWITCHING

During differentiation, a single B lymphocyte can synthesize heavy chains with different constant regions coupled to the same variable region through process called *class switch recombination*, which shares features of V(D)J recombination.⁷³ As pre-B cells develop into mature B cells, intact IgM monomers are inserted into the plasma membrane, followed by IgD molecules with the same antigen-binding specificity. The IgM and IgD constant-region genes are closely linked in embryonic DNA (see Fig. 75–4) and may be transcribed together. The differential splicing of the transcript allows simultaneous synthesis of the two immunoglobulin heavy chains from a single species of mRNA. As such, the expression of IgD that occurs during B cell maturation only rarely involves deletion of C μ .

The switch from IgM to IgG, IgA, or IgE requires active transcription of the downstream constant-region exons encoding the future immunoglobulin isotype. This process requires prior interaction of B lymphocytes with antigen or mitogen and ligation of CD40 via the ligand for CD40 (CD154) expressed by activated T cells. Patients with inherited defects in CD40 or CD154 have an immune deficiency (hyper-IgM syndrome type I) characterized by normal to high serum levels of IgM with extremely low serum levels of other immunoglobulin isotypes (Chap. 80).⁷⁴ Interleukins provided by antigen-reactive T lymphocytes strongly influence (1) which B cells differentiate into IgM-secreting plasma cells and (2) which B cells switch to synthesizing the heavy chain of another immunoglobulin isotype, such as IgG and IgA. Isotype switching to IgA occurs most efficiently in mucosal

lymphoid tissue, particularly in Peyer patches and mesenteric lymph nodes (Chap. 6).⁷⁵ Also, class-switched IgA plasmablasts have a propensity to migrate to the lamina propria of the intestine and to other mucosal sites.⁷⁶

Immunoglobulin class switch recombination (CSR) occurs in or near the switch region located in the intron between the rearranged $V(D)_H$ sequence and the μ gene and any one of similar regions located upstream of the C genes encoding each of the other heavy-chain isotypes, with the exception of the δ gene (see Fig. 77–4). The μ switch region, designated $S\mu$, consists of approximately 150 repeats of the sequence $(GAGCT)_n$ (GGGGGT), where n is generally 3 but can be as many as 7. The sequences of the other switch regions ($S\lambda$, $S\delta$, $S\epsilon$) are similar in that they also contain repeats of the GAGCT and GGGGT sequences. The switch in heavy-chain classes results from DNA recombination between $S\mu$, and $S\lambda$, $S\delta$, or $S\epsilon$, accompanied by the deletion of intervening DNA segments and the apposition of the previously rearranged variable-region gene next to the new constant-region gene.

In contrast to $V(D)J$ recombination, which mostly occurs in the G_0 and/or G_1 stage of the cell cycle, CSR seems to require DNA replication.⁷⁷ Also, unlike $V(D)J$ recombination, CSR requires expression of activation-induced deaminase (AID), an enzyme expressed in activated B cells that also is required for somatic hypermutation.⁷⁸ Patients with inherited defects in AID have an immune deficiency (hyper-IgM syndrome type II) characterized by relatively high serum levels of IgM and negligible serum levels of other immunoglobulin isotypes.⁷⁹ Specific inactivation of the C-terminal AID domain, encoded by exon 5 (E5), allows very efficient deamination of the AID target regions, but greatly impacts the efficiency and quality of subsequent DNA repair. Specifically eliminating E5 not only precludes CSR, but also causes an atypical, enzymatic activity-dependent, dominant-negative effect on CSR. This explains the autosomal dominant inheritance of AID variants with truncated E5 in patients with hyper-IgM syndrome type II and establishes that AID, through the E5 domain, provides a link between DNA damage and repair during CSR.⁸⁰

AID is expressed in germinal centers of peripheral lymphoid organs, the site where CSR occurs in B cells activated in response to antigen. AID most likely deaminates the closely positioned cytosines (dC) in the S-region DNA, converting the dC to uracils (dU), which, in turn, are removed by uracil-DNA glycosylase (UNG). The importance of UNG is underscored by patients who have inherited defects in this enzyme, resulting in an autosomal recessive form of the hyper-IgM immunodeficiency syndrome similar to that of patients with inherited defects in AID (see Chap. 80).⁸¹ The abasic sites generated by UNG are cleaved by AP endonuclease, resulting in closely positioned staggered nicks in the DNA that may result in double-stranded DNA breaks. The end processing, repair, and joining mechanisms for these DNA breaks apparently involve mechanisms and proteins similar to those involved in NHEJ used for $V(D)J$ recombination. Because the CSR occurs in the intron between the variable-region exon and the exon encoding the first constant-region domain, this process does not generate mutations in the regions encoding the variable or constant regions of the newly generated immunoglobulin heavy chain.

MECHANISMS FOR GENERATING ANTIBODY DIVERSITY

Several mechanisms contribute to the generation of diversity among immunoglobulin polypeptide variable regions. The mechanisms are (1) the presence in the germline DNA of multiple different V, J, and D gene segments; (2) the random joining of these DNA segments to produce a complete variable-region exon; (3) junctional diversity;

(4) the coming together of the heavy- and light-chain polypeptides to produce a complete immunoglobulin monomer capable of binding antigen; and (5) somatic mutations within the rearranged DNA segments themselves. Somatic mutations occurs through a process called somatic hypermutation.

Somatic hypermutation is not active in all B cells and cannot be triggered merely by mitogen-induced B-cell activation. However, during discrete stages of B-cell differentiation, expressed immunoglobulin V genes may incur new mutations at rates as high as 10^{-3} base substitutions per base pair per generation over several cell divisions, particularly during the secondary humoral immune response to antigen.⁸² Hypermutations begin on the 5' end of rearranged V genes downstream of the transcription initiation site and continue through the V gene and into the 3' flanking region before tapering off. As such, the mutations are clustered in the region spanning from 300 bp 5' of the rearranged variable-region exon to approximately 1 kb 3' of the rearranged mini-gene J segment. A high frequency of mutations are clustered around "hotspots" defined by the primary DNA sequence. The sequence RGYW (R = purine, A or G; Y = pyrimidine, C or T; W = A/T) and its complement, for example, is a hotspot for mutation that is conserved among species.⁸³

The process of somatic hypermutation requires the activity of AID through a process that has some similarity with CSR.^{84,85} In addition to having the hyper-IgM immunodeficiency syndrome type II, patients who have inherited defects in AID have B cells that lack the capacity to undergo somatic hypermutation (Chap. 80).^{79,86} As with CSR, somatic hypermutation requires active transcription of the genes undergoing mutation. AID most likely deaminates the cytosines in the region encompassing the rearranged variable-region gene, converting the dC to dU, which are converted to T after DNA replication, giving rise to C/G to T/A transitions. Alternatively, the dU are removed by UNG, resulting in abasic sites that subsequently are cleaved by AP endonuclease. This process generates staggered nick cleavage of the DNA. Repair of these staggered nicks may involve low-fidelity DNA synthesis, giving rise to frequent mutations. DNA cleaving enzymes and DNA repair enzymes (e.g., mismatch repair enzymes, base-excision repair enzymes, proteins involved in NHEJ) form a complex called the *mutasome*, which also apparently binds the target DNA to reduce its tendency to incur complete double-stranded DNA breaks.

Immunoglobulin enhancers may account in part for the preferential somatic hypermutation of immunoglobulin genes. Combinations of immunoglobulin enhancers target somatic mutation to immunoglobulin genes by recruiting AID and/or by making the immunoglobulin genes better substrates for mutation.⁸⁷ In addition, posttranslational AID ubiquitination has an important regulatory role during CSR and somatic hypermutation.^{88,89} Unlike Rag-2, AID protein stability is not associated with phases of the cell cycle, but rather with subcellular localization. In mouse B cells nuclear AID is subjected to rapid turnover upon polyubiquitination.⁸⁸

As a consequence somatic hypermutation, mostly transitional mutations are introduced at high frequency in the expressed immunoglobulin V genes and in other transcriptionally active genes with "hotspots," which can serve as a substrate for AID, UNG, and the *mutasome*.⁹⁰ Subsequent selection of the B cell and its daughter cells that express mutated V genes encoding an immunoglobulin variable region with improved fitness for binding antigen allows for "affinity maturation" of the antibodies expressed during the immune response to antigen, which typically is retained on follicular dendritic cells.⁹¹ Such selection enhances the frequency of nonconservative base substitutions in the DNA sequences encoding the CDR that serves as the contact site for antigen binding.⁸⁴

● IMMUNOGLOBULIN VARIABLE-REGION STRUCTURE

IMMUNOGLOBULIN VARIABLE-REGION SUBGROUPS

Despite the large number of different immunoglobulin variable regions that can be generated through the mechanisms just described, each antibody polypeptide can be assigned to one of a relatively small number of variable-region subgroups.⁵ Comparisons of the amino acid sequences of a large number of different monoclonal immunoglobulin proteins reveal four segments of limited amino acid sequence diversity between different antibody heavy- or light-chain variable regions. Each of these segments is designated as an immunoglobulin variable-region framework region (FR), see Fig. 75-7. Each immunoglobulin polypeptide can be assigned to one of a relatively small number of variable-region subgroups based upon the primary structure of its first three FRs. Moreover, each subgroup has characteristic FRs that distinguish it from other variable-region subgroups.

Satisfying expectations that immunoglobulin subgroups defined families of highly related antibody V genes, variable-region amino acid subgroup homologies extend to the nucleic acid sequence level.⁹²⁻⁹⁴ Cloned immunoglobulin V genes whose deduced amino acid sequences belong to a given subgroup generally share greater than 80 percent nucleic acid sequence homology. The human heavy-chain variable regions can be grouped into seven subgroups, whereas κ or λ light chains can be divided into six and 11 subgroups, respectively.

Crystallographic data of immunoglobulin variable regions indicate that amino acids within the first and third FRs of either the light or heavy chain form β bonds on the external surface of the molecule. These regions form relatively compact structures on the external solvent-accessible face of the antibody molecule that are not adjacent to the classic antibody-combining site for antigen. Accordingly, amino acid differences noted between the different variable-region subgroups are amenable to recognition by antisubgroup antibodies.

IMMUNOGLOBULIN IDIOTYPES

Antisubgroup antibodies must be distinguished from antiidiotypic antibodies. Positioned between the FRs are three segments of extreme hypervariability in both light- and heavy-chain sequences.² The third hypervariable region is generated through the recombinatorial process that joins the antibody light-chain V gene with the J segment of the light chain or the V_H gene with the somatically generated DJ_H segment of the antibody heavy chain. The diversity in first and second hypervariable regions in part reflects germline DNA-encoded differences between disparate antibody V genes, a diversity often noted even between V genes of the same subgroup.^{5,33} During an immune response, somatic hypermutation subsequent to V gene rearrangement also may play an important role in increasing the amino acid sequence diversity noted within these regions. These hypervariable regions on both chains fold together to form the antigen-combining site.³⁴ Hence, each of these regions of hypervariability is designated a CDR (see Fig. 75-7).

During secondary immune responses, extensive amino acid substitutions may occur in the CDRs. In contrast, amino acid replacement mutations occur much less frequently in the FRs than would be anticipated if the nucleic acid substitutions were occurring randomly. As a consequence, the subgroup determinants that characterize an entire variable-region subgroup may be relatively resilient to somatic hypermutation. On the other hand, the CDRs may form determinants of unique specificity that contribute to the epitopes recognized by antiidiotypic antibodies.

Despite the tremendous potential for diversity in Ig V gene expression and genetic polymorphism, antibodies produced by B-cell malignancies or normal B cells of unrelated persons may share common idiotypic determinants.⁹⁵ These common idiotypes, designated cross-reactive idiotypes (CRIs), were defined initially on IgM autoantibodies, such as rheumatoid factors. However, CRIs may be found on antibodies that do not have anti-self-reactivity. Molecular studies demonstrate that several of these CRIs represent serologic markers for expression of conserved immunoglobulin variable-region genes with little or no somatic mutation.

● IMMUNOGLOBULIN ALLOTYPES

HEAVY-CHAIN ALLOTYPES

Human immunoglobulins have inherited differences in structure, termed allotypes. These genetic markers usually are detected with agglutinating sera from individuals naturally immunized through transfusion or pregnancy. These antibodies recognize minor amino acid sequence variations in the constant regions of γ , α , and κ chains.⁹⁶ No definite allotypic differences have been detected on μ , δ , or λ chains. On ϵ chains, a monoclonal antibody to IgE defined an allotype that was common to persons of all races except for a few individuals of Asian or Melanesian background.

The α -chain allotypes, designated Am allotypes, are on the heavy chains of the IgA₂ subclass. The γ -chain allotypes are on the heavy chains of the IgG₁, IgG₂, and IgG₃ subclasses and are designated G₁m, G₂m, and G₃m, respectively. More than 24 Gm allotypic markers have been identified serologically. All the heavy-chain constant-region genes reside on chromosome 14. Therefore, different combinations of heavy-chain allotype markers are inherited as haplotypic units, in an autosomal codominant manner. The frequency of the various allelic markers differs among ethnic groups.^{4,96,97}

Particular immunoglobulin allotypes have been associated with susceptibility or resistance to infectious diseases or the relative immune response to particular vaccines.^{98,99} This could reflect linkage disequilibrium between particular polymorphic immunoglobulin variable region genes and constant region genes encoding particular immunoglobulin allotypes. Also, most humanized IgG₁ monoclonal antibodies licensed for therapy have κ light chains of the Km(3) allotype and γ_1 heavy chains of the G₁m₁₇ or G₁m₃ allotype.⁹⁶ As such, patients lacking such allotypes, who are treated with such monoclonal antibodies, may develop antiallotypic antibodies against G₁m or Km(3) determinants, respectively found on the heavy or light chain of the therapeutic antibody.¹⁰⁰

LIGHT-CHAIN ALLOTYPES

The κ light-chain allotypes are designated Km allotypes (formerly called inv). At least three major Km allotypes exist, designated Km(1), 1 Km(1,2), and Km(3), which may be recognized serologically or via molecular techniques.⁹⁸ Patients with B-cell malignancies who are treated with allogeneic hematopoietic stem cell transplantation have been noted to have better survival outcomes when there is disparity in the κ light-chain allotypes between donor and recipient, presumably because of an enhanced capacity to mount a graft-versus-leukemia effect.¹⁰¹

Seven $J\lambda$ -C λ gene segments are telomeric to the upstream V λ genes, but only four such segments are functional, namely J λ 1-C λ 1, J λ 2-C λ 2, J λ 3-C λ 3, and J λ 7-C λ 7 (see Fig. 75-5). These segments respectively encode the four identified isotypes of λ light chains, termed Mcg⁺Ke⁺Oz⁻, Mcg⁻Ke⁺Oz⁻, Mcg⁻Ke⁻Oz⁺, and Mcp⁺Ke⁺Oz⁻, which were

defined based on their reactivity with the Oz, Kern, Mcg, and Mcp antisera raised against λ Bence Jones proteins and that reflect minor non-allelic amino acid differences in the λ light-chain constant regions.¹⁰² A fifth type of λ light-chain, termed Mcg⁻Ke⁺Oz⁻ is highly homologous to Mcg⁻Ke⁻Oz⁻ and actually results from a polymorphic gene amplification in a functional polymorphic C λ 2 segment.¹⁰²

● IMMUNOGLOBULIN SYNTHESIS AND SECRETION

IMMUNOGLOBULIN SYNTHESIS

The total IgG content of the adult human body is approximately 75 g, of which 2.2 g is synthesized each day. Most immunoglobulin is produced by mature plasma cells, which have abundant rough endoplasmic reticulum, a well-developed Golgi apparatus, and high-level transcription of the immunoglobulin genes. The final mRNAs for immunoglobulin light and heavy chains are derived by the processing of large nuclear RNA transcripts. In plasma cells, the rearranged and spliced mRNA molecules for the heavy-chain and light-chain polypeptides are translated on separate ribosomal complexes.

The folding and assembly of intact immunoglobulin molecules occur in the endoplasmic reticulum (ER), which contains a large set of redox catalysts and chaperones that guide the folding of nascent proteins.¹⁰³ First, an aminoterminal leader peptide approximately 18 to 30 residues long is cleaved prior to the release of the completed light and heavy chains in the cisternae of the ER. The ER harbors a single prominent and highly conserved HSP70 family member, BiP, along with over 20 protein-disulphide-isomerase (PDI) oxidoreductases with CXXC active site motifs.^{104,105} The heavy-chain immunoglobulin polypeptides interact via their C_{H1} domains with BiP that allows for proper folding of the heavy-chain polypeptide and prevents its transport into the Golgi. The nascent immunoglobulin polypeptides also bind the various ER or ER-Golgi-intermediate compartment (ERGIC) proteins transiently, some shorter and some for longer periods, either simultaneously or in sequence, to allow for the proper folding and assembly of the IgM chains. For example, early in the process, GRP94 binds the nascent heavy chain after BiP to promote folding of H chains and assembly with L chains to HL “hemimers,” whereas much later, ERGIC53 acts after ERp44, when they assist assembly of H₂L₂ monomers into multimers.¹⁰⁶ The nascent immunoglobulin light chains can displace BiP and then spontaneously combine with the heavy chain to form immunoglobulin half molecules that are stabilized by disulfide bonds.¹⁰⁷ The process also requires the reduction-oxidation (redox) conditions generated by redox catalysts within ER, a requirement that has handicapped efforts to produce immunoglobulin in prokaryotic cell-free expression systems.¹⁰⁸ The joining of two identical half molecules by disulfide bonds yields a basic four-chain immunoglobulin unit, which then is allowed to transport to the Golgi for glycosylation.

Glycosyltransferase enzymes add a defined sequence of sugars to the assembled immunoglobulin unit to form branched-chain oligosaccharides composed of *N*-acetyl-glucosamine, mannose, galactose, fructose, and sialic acid. The oligosaccharides are attached covalently to the immunoglobulin heavy chain at several sites. The carbohydrate facilitates the transport of the antibody molecule across the plasma membrane and into the extracellular space and increases the solubility of the secreted protein.¹⁰⁹ Specific types of glycosylation also may improve the clinical activity of therapeutic monoclonal antibodies.^{7,110}

Five monomeric units of IgM combine to form a pentameric macroglobulin linked by disulfide bonds and a single J-chain polypeptide. Usually polymerization immediately precedes or occurs simultaneously

with IgM secretion. Similarly, IgA molecules form dimers and polymers linked by the J chain just prior to secretion from the plasma cell.

● REGULATION OF IMMUNOGLOBULIN SYNTHESIS

GENERATION OF PLASMA CELLS

A normal adult has some preexisting B lymphocytes that can produce immunoglobulin that can bind almost any foreign antigen. Such B cells can be recruited to the immune response against the antigen. In the presence of accessory T-follicular helper cells (T_{FH}; Chap. 76), an antigen-binding clone of B lymphocytes may transform into antibody-secreting plasma cells.¹¹¹

Transcription factors regulate this differentiation of B cells into antibody-secreting plasma cells. An important factor in plasma cell differentiation is the *B-lymphocyte-induced maturation protein-1* (Blimp-1),¹¹² which also is called the *positive regulatory domain 1-binding factor-1* (PRDM1) because it initially was identified by its ability to bind to the positive regulatory domain I of the human interferon- β promoter.¹¹³ Blimp-1 is a zinc finger-containing transcription factor encoded by *PRDM1* on human chromosome 6q21 that represses expression of genes encoding transcription factors that inhibit plasma-cell differentiation (e.g., *MYC*, B-cell chronic lymphocytic leukemia/lymphoma 6 [*BCL-6*], paired box gene 5 [*PAX5*], microphthalmia-associated transcription factor [*MITF*], and basic leucine zipper transcription factor 2 [*BACH2*]).¹¹² On the other hand, Blimp-1 directly or indirectly induces expression of other transcription factors that control genes encoding other transcription factors or proteins responsible for plasma-cell differentiation and/or immunoglobulin secretion (e.g., X-box binding protein-1 [*XBP1*], E2F transcription factor 1 [*E2F1*], *v*-myb myeloblastosis viral oncogene homologues 1 and 2 [*MYBL1/MYBL2*], early B-cell factor 1 [*EBF1*], Pou domain, class 2, factor 2, or associating factor 1 [*POU2F2/POU2AF1*], and transcription factor E2a [*TCFE2A*]). This capacity of Blimp-1 to repress and to activate expression of a variety of different transcription factors accounts for its capacity to orchestrate the dramatic changes in B-cell morphology and function associated with plasma-cell differentiation and high-level secretion of immunoglobulin protein. Mice with a conditional deletion of *PRDM1* encoding Blimp-1 in the B lineage demonstrate the critical requirement of Blimp-1 in plasma cell development.¹¹⁴ Although such mice have normal numbers of B cells and develop germinal centers in response to T-dependent antigens, they fail to generate plasma cells or to secrete normal levels of immunoglobulin in response to either T-independent or T-dependent antigens. Furthermore, other studies found that expression of Blimp-1 is required for the maintenance of long-lived plasma cells in the marrow and the long-term expression of antigen-specific immunoglobulin in the plasma.¹¹⁵

Some diffuse large B-cell lymphomas (DLBCLs) have deletions or inactivating mutations in *PRDM1*, suggesting that this gene also might act as a tumor suppressor.¹¹⁶ However, *PRDM1* mutations are not found in other lymphoid or myeloid leukemias, and myeloma cells and some DLBCLs express abundant levels of Blimp-1, making it appear unlikely that Blimp-1 suppresses tumor development *per se*.¹¹⁷ Moreover, the DLBCL cases that expressed Blimp-1 lacked detectable plasmacytic features and actually displayed more aggressive behavior.¹¹⁸ As such, B-cell expression of Blimp-1 appears necessary but not sufficient for plasma-cell differentiation.

The expression of Blimp-1 in B cells is regulated primarily at the level of *PRDM1* transcription, which requires activation by the transcription factor *interferon regulatory factor 4* (IRF4).¹¹² Transgenic mice

that have B cells with a conditional deletion of *IRF4* fail to generate immunoglobulin-secreting plasma cells.¹¹⁹ Substances that activate toll-like receptor 4 (TLR4) or toll-like receptor 9 (TLR9), such as lipopolysaccharide or CpG oligonucleotides, respectively, also can activate expression of Blimp-1.^{112,120} Mice lacking such toll-like receptors cannot mount effective antibody responses,¹²¹ except under certain conditions.¹²² Several cytokines, including IL-2, IL-5, IL-6, IL-10, and IL-21, also can induce expression of Blimp-1 when applied in the proper context. Indeed, such cytokines can have positive or negative effects on B-cell differentiation and/or survival depending upon the presence or absence of other signals. IL-21, for example, can induce expression of Blimp-1 and plasma cell differentiation primarily in memory B cells or B cells that previously had been activated via ligation of its B-cell receptor, namely surface immunoglobulin, when in the context of receiving T-cell helper signals, such as that caused by ligation of CD40.^{123,124} On the other hand, IL-21 can induce apoptosis of B cells that are activated via ligation of its surface immunoglobulin receptor in the absence of such T-cell helper signals.¹²⁴

MEMORY B CELLS

Following a T-cell dependent immune response to antigen, B cells that express high-affinity immunoglobulin for antigen also can differentiate into memory B cells.¹²⁵ Memory B cells differ from plasma cells in morphology and function. In contrast to plasma cells, memory B cells do not secrete immunoglobulin, but rather express surface immunoglobulin that can bind antigen and can be induced to differentiate rapidly into immunoglobulin secreting plasma cells after secondary challenge with antigen. Also, memory B cells may reengage the germinal center to undergo additional rounds of somatic hypermutation to enhance further the Ig repertoire.¹²⁶

Human memory B cells can be distinguished by their expression of CD27 and CD148.¹²⁷ Memory B cells also have increased expression of immune costimulatory molecules CD80 and CD86,¹²⁸ particularly following immune activation, which enhances their capacity to induce immune coactivation of T-helper cells (Chap. 76). In addition, memory B cells have high-level expression of antiapoptotic genes *BCL2* and *BCL-XL*,¹²⁹ which help enhance their long-term survival. Finally, memory B cells lack expression of *BCL-6*, which actually can repress memory B-cell development.¹³⁰ Because *BCL-6* also can repress expression of *PRDM1*, the lack of *BCL-6* expression makes memory B cells particularly amenable to stimulation by factors that induce expression of Blimp-1,¹¹⁹ thereby enhancing the capacity of memory B cells that express antigen-binding immunoglobulin to undergo rapid differentiation into plasma cells during the secondary immune response to antigen.¹³¹

CHAPTER 76

FUNCTIONS OF T LYMPHOCYTES: T-CELL RECEPTORS FOR ANTIGEN

Fabienne McClanahan and John Gribben*

SUMMARY

All T cells express a receptor for antigen that is formed by two polymorphic polypeptides that invariably are associated with a collection of invariant proteins, namely CD3 γ , CD3 δ , CD3 ϵ , and CD247. These invariant proteins are necessary for surface expression and signaling by the T-cell receptor. The two polypeptides that form the T-cell receptor on most T cells are termed α and β . A small subset of T cells has receptors formed by different polypeptides termed γ and δ . The polypeptides of the T-cell receptor have a diversity that is comparable to that estimated for immunoglobulin molecules. However, unlike immunoglobulins, the T-cell receptors recognize small fragments of antigen only if they are presented to them by defined major histocompatibility complex molecules on the plasma membrane of another cell, the antigen-presenting cell. The response of the T cell to antigen depends on the intensity of the signal generated by ligation of the T-cell receptor, and is modified by the simultaneous ligation of other accessory molecules. Interactions at the contact sites between T-cells and antigen-presenting cells are organized in the immunologic synapse. The outcome of T-cell antigen recognition can range from immune activation and T-cell proliferation to specific T-cell tolerance and/or programmed cell death.

Acronyms and Abbreviations: AP-1, activation protein-1; APC, antigen-presenting cell; CTLA-4, cytotoxic T-lymphocyte antigen 4; ERK, extracellular receptor-activated kinase; FOXP3, forkhead box P3; ICAM, intercellular adhesion molecule; IFN- γ , interferon-gamma; IL, interleukin; IPEX syndrome, immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome; ITAM, immunoreceptor tyrosine-based activation motif; ITIM, immunoreceptor tyrosine-based inhibitory motif; iT_{REG}, induced regulatory T cell; JNK, c-Jun N-terminal kinase; LAT, linker of activation of T cells; LFA, lymphocyte function associated; MAP, mitogen-activated protein; MHC, major histocompatibility complex; NFAT, nuclear factor of activated T cell; PKC, protein kinase C; PLC- γ_1 , phospholipase C-1 gamma; ROR γ t, retinoic acid-related orphan receptor γ thymus isoform; SAPK, stress-activated protein kinase; SH2 domain, Src homology 2 domain; SH3 domain, Src homology 3 domain; STAT, signal transducer and activator of transcription; T_{FH} cell, follicular helper T cell; TGF- β , transforming growth factor beta; Th17, CD4+ T-cell subset that produces cytokines of the interleukin-17 family; T_{REG}, CD4+CD25+ regulatory T cells; V-like, variable-region-like; VLA, very-late activation; ZAP-70, zeta-associated protein of 70 kDa.

T-LYMPHOCYTE ANTIGEN RECEPTORS

T-CELL RECEPTOR HETERODIMERS

The structural basis of T-cell recognition of antigen has been known since the 1990s, when a plethora of studies demonstrated that the proteins of the T-cell antigen receptor are structurally related to immunoglobulin molecules.¹ The T-cell receptor is formed by a heterodimer, that is, two disulfide-bond-linked polypeptides that are expressed on the cell surface and are associated with a collection of coreceptor accessory and invariant CD3 proteins. In contrast to immunoglobulins, the T-cell receptor is not secreted and also remains membrane bound throughout the activation process. In the majority of T cells, the T-cell receptor heterodimer consists of an α and a β chain, but a small subset of T cells expresses a $\gamma\delta$ heterodimer. Following the rule of allelic exclusion, each individual T cell expresses a single α and a single β chain (or a single γ or δ chain, respectively), and can either be $\alpha\beta$ or $\gamma\delta$. Each chain is composed of a *variable region*, consisting of a hydrophobic leader sequence of 18 to 29 amino acids and an aminoterminal domain of 102 to 119 amino acids, and a *constant region* with a carboxyl-terminal region segment of 87 to 113 amino acids. The variable region is responsible for the variation in the primary structure among different T-cell receptor polypeptides and represents the antigen-binding site, while the constant region is invariant among chains of the same class. Similar to other surface-membrane receptors, each chain is followed by a small connecting peptide, a transmembrane region of 20 to 24 amino acids, and a small cytoplasmic region of 5 to 12 residues at the carboxyl terminus anchoring the polypeptide in the cell membrane. The T-cell receptor chains fold into tertiary structures that are very similar to that of the light and heavy chains of the immunoglobulin molecule. Overall, the structural similarities between the T-cell receptor and immunoglobulins place the genes encoding these receptor proteins in the so-called immunoglobulin supergene family.

$\alpha\beta$ Heterodimers

More than 90 percent of mature T cells express an $\alpha\beta$ heterodimer, making this the major class of T-cell receptor. Without glycan side chains, each α or β polypeptide has a respective size of only 27 kDa or 32 kDa. However, within minutes after being translated into protein, both chains are glycosylated and assembled into a heterodimer composed of a single acidic α glycoprotein of 39 to 46 kDa linked to a more basic 40- to 44-kDa β -glycoprotein via a disulfide bond between the constant regions of the two chains (Fig. 76–1).

$\gamma\delta$ Heterodimers

Less than 10 percent of blood T cells and thymocytes exclusively express a $\gamma\delta$ heterodimer. Within the $\gamma\delta$ T-cell population, specific $\gamma\delta$ T-cell subsets can be defined by their T-cell receptor gene element usage, and their functionally distinct responses to infections with certain organisms such as *Listeria monocytogenes*.² Alternatively, $\gamma\delta$ T cells can be grouped according to their tissue location. In secondary lymphoid tissues, only 1 to 5 percent of the CD3-positive T cells express $\gamma\delta$ receptors. Murine studies demonstrate that many epithelial tissues, such as the epidermis, the intestine, the lung, and the uterus, are enriched for $\gamma\delta$ -expressing T cells, indicating that $\gamma\delta$ T cells are involved in the surveillance of body barriers.³

The amino acid sequence of the γ chain resembles the T-cell receptor β chain, whereas the amino acid sequence of the δ chain resembles the α chain. Like the homologous $\alpha\beta$ heterodimer, the $\gamma\delta$ heterodimer is also associated with the CD3 complex and is capable of initiating T-cell activation upon binding of specific ligands. Despite the similarities in chain structure and size, however, the tertiary structure of variable

*This chapter was written by Thomas J. Kipps, M.D., Ph.D. in the 8th edition and portions of that chapter have been retained.

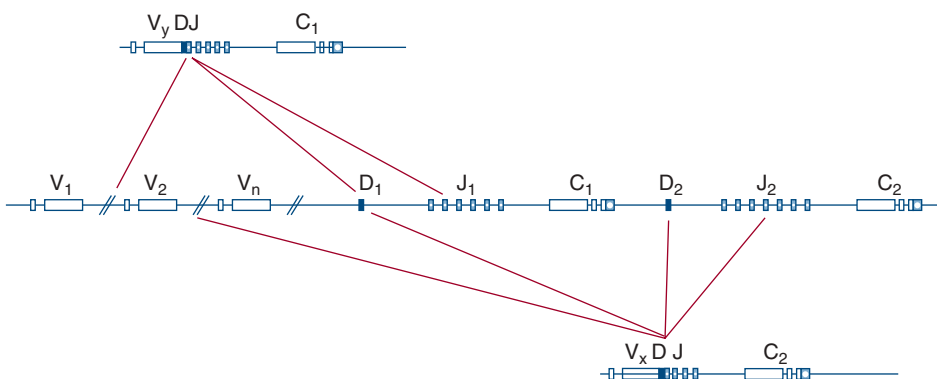

Figure 76-1. Schematic of the T-cell receptor (TCR) complex. The TCR is composed of the $\alpha\beta$ heterodimer, assembled by an α and a β chain, each of which consists of a variable (V) and a constant (C) domain. Both chains form loops and structurally resemble immunoglobulins. The TCR is accompanied by the invariant CD3 molecule, consisting of CD3 ϵ , CD3 δ , CD3 γ , and CD3. For clarity, CD3 ϵ /CD3 δ and CD3 γ /CD3 ϵ are depicted separately. An additional component of the CD3 molecule is the ζ chain (CD247) homodimer, which associates with the α and β chain upon stimulation. The *dotted lines* represent intrachain or interchain disulfide bridges, as indicated in the legend in the *lower left-hand corner*. The plasma membrane spanned by each of these chains is indicated. The boxes indicate the immunoreceptor tyrosine-based activation motifs (ITAMs) in the cytoplasmic domains of the CD3 polypeptides and the ζ chain.

regions of $\gamma\delta$ T-cell receptors has a closer resemblance to immunoglobulin variable regions than to the variable regions of $\alpha\beta$ T-cell receptors.

T-CELL RECEPTOR HETERODIMER GENE REARRANGEMENT

Similar to immunoglobulin genes, each chain of the T-cell receptors is encoded by distinct genetic elements that rearrange during development generating a diverse T-cell repertoire (Fig. 76-2).⁴ Located at band q35 on the long arm of chromosome 7, the β -chain complex has two closely linked genes, each capable of encoding the β -chain constant region. Each constant region gene is associated with a cluster of functional $J\beta$ -gene segments and a single $D\beta$ segment. The functional gene encoding the variable region of the β chain is constructed from the rearrangement of any of approximately 50 variable region gene segments to either one of the two $D\beta$ regions and one of 13 $J\beta$ regions.

The α -chain complex is located at band q11.2 on the long arm of chromosome 14 and thus is linked to the immunoglobulin heavy-chain complex. The α -chain gene complex consists of one constant region gene and at least 50 different variable region gene segments. The functional gene encoding the α -chain variable region is derived from the juxtaposition of any one of the variable region gene segments with one of the many $J\alpha$ segments through rearrangement that generally involves the deletion of the intervening DNA.

The organization of the γ and δ genes is similar to that of the α and β genes, but some significant differences exist. First, the gene complex encoding the δ genes is located entirely within the α -chain gene complex between the $V\alpha$ and $J\alpha$ gene segments. Consequently, any rearrangement of the α -chain genes inactivates the genes encoding the δ chain. Second, there are fewer V gene segments in the γ and δ gene complexes than at either the T-cell receptor α or β gene loci. The γ -gene complex on band p15 on the short arm of chromosome 7, for example, has only approximately 12 $V\gamma$ gene segments, two virtually identical $J\gamma$ segments, and two constant region gene segments. Moreover, there are only approximately four $V\delta$ gene segments, three $D\delta$ gene segments, three $J\delta$ gene segments, and a single constant region gene in the δ gene complex. Consequently, most of the variability in the γ and δ chains is found in the junctional region formed during the process of $\gamma\delta$ T-cell receptor gene rearrangement. The amino acids encoded by this region form the center of the T-cell receptor-binding site.

The identification of TCR gene rearrangements is also widely used for diagnostic and therapeutic purposes: In suspected lymphoproliferative disorders, PCR-based clonality testing has been standardized and guidelines and consensus reporting systems have been established.⁵ Moreover, the molecular analysis for clonal T-cell receptor gene rearrangements can be used to detect minimal residual disease in patients treated for clonal T-cell disorders, such as T-cell acute lymphoblastic

Figure 76-2. Schematic of possible rearrangements of the T-cell receptor (TCR)- β -chain genes. The TCR- β -chain genes in the germline DNA configuration are depicted in the *middle*. Possible recombination of either the first constant region (C_1 , *above*) or the second constant region (C_2 , *below*) with the variable region (V), diversity (D), or joining (J) segments are indicated by the *lines*.

leukemia (T-ALL), and guide clinical decision making and provide prognostic information.^{6,7}

ANTIGEN PRESENTATION TO T-CELL RECEPTOR HETERODIMERS

Despite their similarities in structure, there are important differences in the way that T-cell receptors and immunoglobulins recognize antigen: immunoglobulins can bind antigens directly, while T-cell receptors generally require that peptide antigens are bound to a molecule of the major histocompatibility complex (MHC) on the surface of another cell.^{8,9} MHC molecules, also known as histocompatibility antigens, are highly polymorphic glycoproteins, and have immunoglobulin-like structures themselves. There are two basic classes of MHC molecules: Class I MHC molecules generally bind and present *intracellular* proteins, that is, peptides that are derived from proteins synthesized and degraded in the cytoplasm of the cell. Class II MHC molecules generally bind peptides that are derived from *exogenous* proteins and degraded in intracellular vesicles. The human histocompatibility antigens HLA-A, HLA-B, and HLA-C are class I molecules, whereas HLA-D antigens DP, DQ, and DR are examples of class II molecules.

MHC class I molecules bind peptides that are usually 8 to 10 amino acids long. Their binding is stabilized by contacts in the free amino and carboxyl termini of the peptide and the peptide-binding groove of all MHC class I molecules. In addition, the peptide-binding groove is closed at both ends. The corresponding binding groove on class II molecules is open at either end, and peptides that bind to MHC class II molecules are generally at least 13 amino acids long. For both class I and class II molecules, the peptide binding groove is located in the central cleft between the two α helices of the MHC molecule. Steric factors, hydrogen bonding, and hydrophobic interactions between the peptide and the MHC molecule stabilize the peptide within this cleft and generate a tertiary structure that is further modified by amino acid residues of both the MHC and the peptide antigen.

MHC molecules are encoded by a family of MHC genes, which are located on chromosome 6 in humans (Chap. 137). MHC genes can be divided into three subgroups, with antigen presentation being encoded by class I (i.e., HLA-A, -B, -C) and class II (i.e., HLA-DP, DQ, DR) genes. Each of these gene loci exists in different alleles, and both maternal and paternal alleles are expressed concomitantly. The particular combination of class I and class II MHC alleles found on an individual chromosome is known as the MHC haplotype. Therefore, the number of different MHC molecules is greatly increased not only by MHC gene polymorphism, but also by codominant expression of MHC gene products. The resulting differences within MHC molecules are primarily found in the amino acids lining the clefts that hold the peptide antigen, allowing the MHC molecules encoded by each allele to bind a distinctive array of different peptides.

Structural studies show that the T-cell receptor can recognize both the MHC-bound peptide and the polymorphic amino acid residues themselves that surround the peptide-binding pocket.¹⁰ The specificity of a T-cell receptor (TCR) is defined both by the peptide it recognizes and by the MHC molecule binding it, and TCRs are therefore likely to engage a composite peptide/MHC receptor.^{11,12} Additional TCR-MHC binding parameters, such as ligands per cell or dissociation time defined by the affinity of antigen, also have an effect on subsequent T-cell activation, but their exact relationship remains largely controversial.¹³

Some T cells, however, do not recognize MHC-bound peptides. Instead they recognize antigens that are presented by MHC class I-like molecules encoded by genes that map outside the MHC region. One such family of molecules is called CD1. Despite structural similarities

with MHC class I molecules, CD1 molecules present larger extracellular peptides in a MHC class II-like fashion, and are also able to present glycolipids to T cells. Glycolipids are components of mycobacterial membranes; in cells infected with mycobacteria, the CD1 molecules are therefore able to bind and present membrane components such as lipoarabinomannan or mycolic acid. T cells that recognize these complexes play an important role in the immune response to *Mycobacterium tuberculosis*.^{14,15}

As discussed above, structural studies show that $\gamma\delta$ TCRs assume a different tertiary structure than $\alpha\beta$ TCRs. As a consequence, $\gamma\delta$ TCRs are able to recognize a wider variety of ligands, such as bacterial phosphoantigens, nonclassical MHC-I molecules and unprocessed proteins, which distinguishes them from the great majority of $\alpha\beta$ T cells.¹⁶ Other $\gamma\delta$ receptors can recognize determinants presented by CD1 molecules.¹⁷ A number of studies have described increased numbers of $\gamma\delta$ T cells in a variety of infectious and autoimmune diseases. Therefore, it is speculated that $\gamma\delta$ T cells link innate and adaptive immune responses under infectious and inflammatory conditions. In addition, it is hypothesized that $\gamma\delta$ T cells might play a role in novel T-cell-based immunotherapy strategies.^{18,19}

GENERATION OF T-CELL RECEPTOR DIVERSITY

TCR diversity is achieved by several mechanisms, some of which are the same as those that generate diversity among immunoglobulin molecules (Chap. 75). The joining of different V (variable), D (diversity), and J (joining) elements to produce a complete V gene, the presence of uncorrected errors made during the recombination of these genetic elements, and the combinatorial diversity afforded by the random pairing of two chains encoded by separated gene complexes all function to enhance the diversity of the T-cell antigen receptor repertoire. An important difference between T cells and B cells, however, is that B cells are capable of undergoing somatic hypermutation (Chap. 75). This process requires expression of activation-induced deaminase (AID) along with other enzymes expressed primarily by B cells within the germinal center of secondary lymphoid tissue during the immune response to antigen (Chaps. 6 and 75).

TCRs do not undergo somatic mutation, probably because of the central role they play in directing host immune defenses: During differentiation, immature $\alpha\beta$ T-cell precursors pass through the thymus, where they are educated to distinguish self from non-self by cell-surface proteins of the MHC (Chaps. 6 and 74). Because the ligand for the $\alpha\beta$ TCR is processed antigen presented by MHC molecules, close interaction with the MHC might be lost if the variable region of the TCR were allowed to diverge significantly from the inherited germline repertoire. Furthermore, somatic mutation of expressed TCR variable region genes may lead to constitutive T-cell activation to processed self-antigen presented by self-MHC molecules, which could lead to a breakdown in tolerance to self-antigens and autoimmunity.

THE INVARIANT CHAINS OF THE T-CELL RECEPTOR COMPLEX

COMPOSITION OF THE T-CELL RECEPTOR COMPLEX

The CD3 complex of polypeptides and CD247, also known as the zeta chain (ζ chain) of the TCR, are closely associated with and required for the surface expression of the polypeptide heterodimer.²⁰ Unlike the TCR heterodimers, these polypeptides are invariant and are found on

all T cells that express $\alpha\beta$ or $\gamma\delta$ heterodimers. The CD3 polypeptides are designated CD3 γ , CD3 δ , and CD3 ϵ . The CD3 ϵ chain couples with either the CD3 γ or the CD3 δ chain to generate heterodimers that each form a tight association with the $\alpha\beta$ (or $\gamma\delta$) receptor heterodimer on the T-cell surface (see Fig. 76–1). Each CD3 polypeptide has a negatively charged amino acid in the central portion of the hydrophobic transmembrane region that stabilizes the CD3 complex with the two chains of the TCR. The ζ chain (CD247), on the other hand, forms a disulfide-like homodimer that primarily associates with the two TCR chains and only weakly associates with the CD3 complex. As such, it cannot be coimmunoprecipitated easily with antibodies to the CD3 polypeptides. In addition, the ζ chain lacks a significant extracellular domain (see Fig. 76–1).

MOLECULAR FEATURES OF THE T-CELL RECEPTOR COMPLEX

The genes encoding CD3 γ , CD3 δ , or CD3 ϵ chains are clustered on the long arm of chromosome 11 in band q23. CD3 γ has a 16-kDa polypeptide backbone that is heavily glycosylated to assume a final molecular mass of 25 to 28 kDa. CD3 δ and CD3 ϵ are each 20 kDa in molecular mass. The CD3 δ is a glycoprotein consisting of 30 percent carbohydrate. In contrast, CD3 ϵ is not glycosylated. CD3 δ and CD3 γ are highly homologous at both the protein and nucleic acid sequence level. The nucleic acid sequence of each predicts CD3 δ and CD3 γ to have typical signal peptides, respective hydrophilic extracellular domains of 79 to 89 amino acids, hydrophobic transmembrane regions of 27 amino acids, and hydrophilic intracellular domains of 44 to 55 amino acids. CD3 ϵ is similar, with a 22-residue signal peptide, an extracellular domain of 104 amino acids, a transmembrane domain, and a comparatively long intracellular domain of 81 amino acids. Each CD3 polypeptide has one immunoglobulin-like domain in its extracellular domain that is defined by an intrachain disulfide bond (see Fig. 76–1), indicating that these polypeptides are members of the immunoglobulin superfamily. However, unlike the $\alpha\beta$ or $\gamma\delta$ chains of the TCR, there is no variability in the extracellular domains of the CD3 proteins, indicating that these molecules do not contribute to the specificity of antigen recognition.

The ζ chain has no sequence or structural homology to the other three CD3 chains. It is a nonglycosylated protein of 16-kDa molecular mass that is encoded by a gene found on chromosome 1. The ζ chain has only a very short extracellular domain of 6 to 9 amino acids, a transmembrane domain of 21 amino acids, and a long intracellular domain of 113 amino acids.

The cytoplasmic domains of all the CD3 polypeptides and the ζ chain each contain sequences termed immunoreceptor tyrosine-based activation motifs (ITAMs). Each ITAM contains two copies of the sequence tyrosine-X-X-leucine separated by six to eight amino acid residues, in which X represents an unspecified amino acid. The cytoplasmic domains of each CD3 polypeptide contain one ITAM, whereas each ζ chain contains three ITAMs (see Fig. 76–1). These sequences allow the CD3 proteins to associate with cytosolic protein tyrosine kinases following TCR ligation, thus transducing a signal to the interior of the T cell. The cytoplasmic domains of CD3 ϵ and CD3 ζ are particularly important in this regard.

SIGNAL TRANSDUCTION VIA THE T-CELL RECEPTOR COMPLEX

Although the major components of the TCR signaling machinery have been identified and mapped, key components continue to be discovered, adding to the complex network of TCR signal transduction. Signal transduction from the TCR heterodimer to intracellular proteins is mediated by the CD3 polypeptides and the ζ chain. Their spatial

organization and the mechanisms by which this is regulated are, however, still poorly understood.²¹ Upon binding to a specific ligand, the TCR $\alpha\beta$ (or $\gamma\delta$) heterodimer undergoes steric changes that result in the phosphorylation of the ITAMs of the ζ chain and each of the CD3 polypeptides (see Fig. 76–1). When tyrosine residues in the ITAMs become phosphorylated, they can act as docking sites for adapter proteins or tyrosine kinases, such as the zeta-associated protein of 70 kDa (ZAP-70), which possesses a Src homology 2 (SH2) domain and a Src homology 3 (SH3) domain. Following ligation of the TCR, Src family protein tyrosine kinases (e.g., Lck) are recruited and become activated. This differentially phosphorylates the ITAMs of the accessory molecules in the TCR complex.²² ZAP-70 is recruited to the phosphorylated ITAMs of the ζ chain via its SH2 and SH3 domains, and subsequently becomes activated. Activated ZAP-70 phosphorylates tyrosine residues in the intracytoplasmic segments of surface CD6 and membrane-anchored adapter protein called linker of activation of T cells (LAT), both of which constitute a device for the amplification and diversification of signals that are responsible for most of the responses that result from engagement of the TCR.²³

The network of proteins that interact with the LAT signalosome includes SLP-76, phospholipase C γ_1 (PLC- γ_1) and GRAP2. Activated PLC- γ_1 mediates hydrolysis of phosphatidylinositol-(4,5)-bisphosphate at the cell membrane, which generates the second messengers inositol-(1,4,5)-trisphosphate and polyunsaturated diacylglycerols, leading to a rapid increase in cytosolic free calcium and activation of the θ isoform of protein kinase C (PKC). Cytosolic free calcium binds to calmodulin, an ubiquitous calcium-dependent regulatory protein. The calcium-calmodulin complex activates the cytoplasmic phosphatase calcineurin, which, in turn, catalyzes the removal of an inhibitory phosphate group on the nuclear factor of activated T cells (NFATs) that retains NFAT proteins in the cytoplasm. Removal of the phosphates from NFAT1 and NFAT2 by activated calcineurin allows these transcription factors to translocate into the nucleus, where they enhance transcription of several activation-induced genes, including those encoding interleukin (IL)-2, IL-4, and tumor necrosis factor.²⁴ The importance of this pathway in T-cell activation is underscored by the strong immunosuppressive activity of calcineurin inhibitors such as cyclosporine and FK506, which are commonly administered in the clinic to treat autoimmune diseases and to prevent graft rejection.

In parallel, diacylglycerol in the plasma membrane recruits Ras-GRP1, a guanine nucleotide-exchange factor (GEF), which acts on Ras to activate extracellular receptor-activated kinase 1 and 2 (ERK1/2). Activated ERK phosphorylates Elk, which, in turn, stimulates transcription of Fos, a component of the activation protein-1 (AP-1) factor that is a necessary component of the transcription-factor complex required for expression of IL-2 and other critical T-cell proteins. LAT-bound SLP-76 also interacts with Nck and with Vav1 to promote reorganization of the actin cytoskeleton, and with FYB to increase the binding of the integrin CD58 (LFA-1) to its ligand intercellular adhesion molecule (ICAM)-1. DYN2, a member of the dynamin superfamily of large guanosine triphosphatases (GTPases), is also recruited by phosphorylated LAT molecules and participates in the generation of filamentous actin. Dedicator of cytokinesis 2 (DOCK2), another GEF, also activates GTPases of the Rac family, which, in turn, activate another mitogen-activated protein (MAP) kinase called p38, and initiate a parallel enzymatic cascade resulting in the activation of yet another MAP kinase called c-Jun N-terminal kinase (JNK), otherwise known as stress-activated protein kinase (SAPK). Activated JNK phosphorylates c-Jun, the second component of the AP-1 transcription factor required for IL-2 transcription. The guanosine triphosphate (GTP)-bound form of Rac also induces cytoskeletal reorganization, thereby facilitating the clustering of the TCR complex, accessory molecules, and other

accessory proteins at the site of contact between the T cell and the antigen-presenting cell (APC).

CD4 AND CD8

STRUCTURE OF CD4 AND CD8

CD4 and CD8 are glycoproteins that share structural features of other immunoglobulin superfamily receptor molecules. CD8 has two isoforms with different expression patterns and presumably different functions, and is expressed as a CD8 α /CD8 β heterodimer or as a CD8 α /CD8 α homodimer.²⁵ These chains are encoded by genes that are linked closely to the immunoglobulin κ light-chain locus at band p12 on the short arm of chromosome 2. The protein sequence of the aminoterminal domains of each CD8 chain shares greater than 28 percent homology with κ light-chain variable regions. Therefore, these domains are called the variable-region-like (V-like) domains. Following this V-like domain, the CD8 molecule has a short region rich in prolines, threonines, and serines that resembles the immunoglobulin hinge region. This region also contains sites for O-linked glycosylation. A hydrophobic transmembrane region anchors the hinge-like region. The CD8 molecule has a 25-amino-acid cytoplasmic tail consisting of highly basic residues. Two cysteines within the V-like domain form a disulfide bridge that stabilizes the immunoglobulin-like fold. An additional cysteine residue is located each within the V-like domain, the hinge region, the transmembrane segment, and the cytoplasmic domain. These cysteines form intermolecular disulfide bridges between two CD8 molecules, thereby stabilizing the CD8 α /CD8 β heterodimers or CD8 α /CD8 α homodimers on the T-cell surface. The cell surface CD8 heterodimer shares structural geometry with the heterodimers formed by the pairing of immunoglobulin light and heavy chains.

CD4, on the other hand, is expressed as a monomer on the surface of a subset of peripheral T cells, mononuclear phagocytes and some blood-derived dendritic cells. It is a 55-kDa monomeric glycoprotein that is encoded by a gene that maps to the short arm of chromosome 12. It consists of 5 external domains, a stretch of hydrophobic transmembrane residues, and a highly basic cytoplasmic tail of 38 residues. Similar to CD8, the aminoterminal domain of CD4 also has extensive homology to immunoglobulin light-chain variable regions. However, following this immunoglobulin-like domain is a domain of 270 amino acids that bears little resemblance to other proteins of the immunoglobulin superfamily.

The cytoplasmic regions of CD4 and CD8 are conserved among vertebrates, suggesting that they are essential for the function of these molecules. The cytoplasmic region of CD4 contains five serines and threonines, one or more of which is phosphorylated by PKC upon activation of T cells by phorbol esters or exposure to antigen. Subsequent to phosphorylation, the CD4 glycoprotein is internalized concomitant with T-cell activation. Similarly, the CD8 protein also possesses a highly charged and conserved cytoplasmic domain that may be involved in transmembrane signal transduction.

FUNCTION OF CD4 AND CD8

In addition to MHC antigen presentation, TCRs generally require activation via CD4 and CD8 as coreceptors. Imaging studies and affinity measurements have demonstrated that CD4 and CD8 molecules associate on the plasma membrane with components of the TCR and contribute to antigen recognition and stabilization of TCR–MHC interactions.²⁶ The adhesion between the CD3/TCR complex and the MHC glycoproteins expressed by an APC or target cell is more than 100-fold enhanced by CD8 or CD4, probably by focusing MHC molecules of the APC or target cell onto the T-cell surface, allowing for

specific recognition of “processed” antigen that is cradled within the MHC glycoproteins. However, CD4 and CD8 differ in their expression patterns (see section “Helper and Cytotoxic T Cells and CD4+ T Cell Subsets” below) and MHC-binding specificities: CD8 binds to the nonpolymorphic α_3 domain of the HLA class I molecule (HLA-A, -B, or -C), whereas CD4 binds to the nonpolymorphic β_2 domain of HLA class II molecules (HLA-DP, -DQ, and -DR).²⁷ Therefore, T cells expressing CD4 or CD8 generally recognize antigens presented by class II or class I MHC glycoproteins, respectively. This selectivity is underscored by studies on knockout mice that lack expression of either of these accessory molecules. Mice lacking CD4 or CD8 fail to develop class II-restricted or class I-restricted T cells, respectively, indicating that these coreceptors play essential roles in the maturation of T cells in the thymus. A similar defect is observed in patients with the bare lymphocyte syndrome who have a congenital immune deficiency caused by genetic defects in their capacity to make MHC class II molecules.²⁸ Although patients have normal numbers of B cells and T cells, they have markedly reduced numbers of CD4+ T cells, thus accounting in part for their profound immune deficiency.

In addition to serving as coreceptors, CD4 or CD8 molecules enhance antigen responsiveness by transducing a signal either directly or in concert with the CD3/TCR complex. This is mediated through their interaction with the SRC family tyrosine kinase Lck.²⁹ Lck is non-covalently associated with the cytoplasmic tails of CD4 and/or CD8. When a T cell recognizes a peptide presented by an appropriate MHC antigen, the interaction of CD4 or CD8 with the MHC molecule brings Lck close to the TCR complex. Lck then phosphorylates the tyrosine residues in the ITAMs of CD3 polypeptides and the ζ chain, thereby initiating the receptor signaling required for T-cell activation.

Finally, CD4 also is a cellular coreceptor for HIV.³⁰ Binding of CD4 along with chemokine receptors such as CCR5 or CXCR4 facilitates entry of the virus into host T cells and stimulates them in an antigen-driven immune response.³¹ Targeting HIV entry/fusion by specific monoclonal antibodies and/or inhibitors is, therefore, an important therapeutic approach in HIV.³² Additionally, CD4 is also of prognostic relevance, as disease progression correlates with depletion of blood T cells that express CD4 (Chap. 81).

T-CELL SUBSETS

PRECURSOR THYMOCYTES

T lymphocytes develop in the marrow from a common lymphoid progenitor that also gives rise to B lymphocytes. While B-lymphocyte precursors remain in the marrow, T-cell precursors migrate to the thymus, where they undergo distinct maturation steps and immunologic education. This is accompanied by characteristic TCR gene and surface expression changes of the CD3 complex, CD4, and CD8. At the early stage, thymocytes are double-negative and express neither CD4 nor CD8. This is a highly heterogeneous population, which includes $\gamma\delta$ T cells, $\alpha\beta$ T cells that also express the NK1.1 receptor commonly found on natural killer (NK) cells, and immature thymocytes that do not yet express a complete TCR molecule, but are thought to be precursors to the $\alpha\beta$ lineage. The latter start to express CD8 and CD4 and enter the double-positive stage, where they undergo positive/negative selection events and CD4/CD8 cell fate choice. This results in the generation of mature thymocytes and peripheral T cells that express either CD4 or CD8, but not both (Chap. 74).³³

HELPER AND CYTOTOXIC T CELLS

The mutually exclusive expression of CD4 or CD8 on mature T cells defines two major blood T-cell subsets: blood T cells that express CD8

normally constitute 25 to 35 percent of the peripheral T-cell population. They recognize antigens presented by MHC class I molecules and differentiate into cytotoxic CD8 T cells. Their main function is lysis of the target cell bearing the surface antigens for which a cytotoxic T cell is specific. Within this subset, there are a range of phenotypes defined both by function and expression of markers with an immunoregulatory function. Blood T cells that solely express the CD4 surface antigen are designated helper T cells. They normally comprise approximately 65 percent of blood T cells. Generally, their function is the production of lymphokines upon activation by foreign antigens presented by MHC class II molecules, regulating and/or assisting in the active immune response. Helper T cells can differentiate into several subtypes, each secreting different cytokines to facilitate a different type of immune response.

CD4+ T-CELL SUBSETS

Th1 and Th2 Cells

Based on distinct cytokine patterns upon activation, mature CD4+ T cells may be divided into subsets—the first of which identified were named *T-helper type 1 (Th1)* and *T-helper type 2 (Th2)*.³⁴ In general, Th1 cells are a major source of interferon- γ (IFN- γ), and also the major T-cell population involved in activating macrophages and clearing intracellular pathogens. Th2 cells are a major source of IL-4 and are important for the generation of immunoglobulin (Ig) E, the production of eosinophils, and the immune defense against infections by parasites. Both subsets are produced from a noncommitted population of precursor T cells. The process by which commitment develops is called *polarization*.

In addition to IFN- γ , Th1 cells produce lymphotoxin β , IL-2, and IL-12, whereas Th2 cells also produce IL-5, IL-13, and IL-25. Human Th1 and Th2 cells can also differ in the array of surface antigens or cytokine receptors they express. Th1 cells preferentially express CD26, membrane IFN- γ , the chemokine receptors CCR1 (CD191), CCR2 (CD192), CCR5 (CD195), CXCR3 (CD183), and CXCR6 (CD186), and the receptor for IL-12 (IL-12R or CD212). Higher levels of the lymphocyte activation gene 3 (LAG-3 or CD223), a ligand for MHC class II antigens that is structurally related to CD4, have also been described. Th2 cells preferentially express CD62L, the α chain of the IL-4 receptor (IL-4R α), the α chain of the IL-33 receptor (IL-33R α), CD30, and the chemokine receptors CCR3 (CD193), CCR4 (CD194), CCR8 (CDw198), and, to some extent, CXCR4 (CD184).^{35–37} Distinctive expression levels of these cytokine and chemokine receptors, along with distinctive binding activities for various endothelial selectins, most likely account for the differences in the response to cytokines and tissue-specific migration of these helper T-cell subsets.

The cytokines produced by each subset also stimulate polarization of additional T cells to the same subset, while inhibiting the polarization of the other subset. In naïve CD4+ T cells, the Th1 cytokine IFN- γ induces or activates the signal transducer and activator of transcription (STAT) 1, STAT4, and the T-box transcription factor T-BET, while simultaneously modulating IL-2 and Th2 cytokines, resulting in an attenuation of Th2 cell development (Fig. 76–3).³⁸ Several other studies demonstrate that T-BET also physically interacts with other transcription factors important for alternative T helper cell developmental decisions to functionally repress the opposing subtype specific gene expression programs and promote Th1 development.³⁹ Similarly, IL-4 activates or enhances the expression STAT5, STAT6, and GATA3, transcription factors that play important roles in Th2 cell development (Fig. 76–3).⁴⁰ Another Th2 cytokine, IL-10, inhibits Th1 cell activation, thereby limiting the production of Th1-type cytokines. Because of these self-amplifying and mutually excluding feedback loops, an immune

response becomes increasingly polarized once it develops along a Th1 or Th2 pathway, particularly upon protracted stimulation by chronic infection or prolonged exposure to environmental antigens. Other factors that drive polarization are chemokines (explaining the differential expression of chemokine receptors on Th1/Th2 cells), eicosanoids, oxygen free radicals, various inflammatory mediators, and direct cell-to-cell interaction with APCs.

Functionally, Th1 cells predominantly drive cellular immunity to fight viruses and other intracellular pathogens, eliminate cancerous cells, and stimulate delayed-type hypersensitivity (DTH) skin reactions. This is mostly achieved by stimulating macrophage Fc receptor expression, phagocytosis, and antigen presentation, enhancing the capacity of macrophages to kill intracellular pathogens. Th2 cells drive humoral immunity and upregulate antibody production to fight extracellular organisms. They initiate the antibody response to antigen by activating naïve antigen-specific B cells to produce IgM antibodies, subsequently stimulate the production of switched immunoglobulin isotypes, including IgA, IgE, and neutralize and/or weakly opsonize subtypes of IgG (Chap. 75), probably via IL-4 as a B-cell stimulatory/growth factor. In addition to stimulating the production of IgE antibodies, the cytokines made by Th2 cells induce differentiation of mast cells and eosinophils.³⁴

Several studies have indicated that Th2 polarization and accumulation at inflammatory sites is likely to trigger the hypersensitivity reaction in allergic diseases.⁴¹ On the other hand, these responses are protective against metazoan parasite infections such as helminths: Th2 responses are host protective while extracellular parasites migrate through the body, and reduce the number of parasites either through direct killing in the tissues or expulsion from the intestines.⁴² Other studies demonstrate that eosinophilia and elevated IgE that accompany infection with *Schistosoma mansoni* are caused by the induction of Th2-type cells in the immune response to parasite ova.⁴³ The Th2 polarization in these diseases/conditions is most likely a result of minimal IL-4 secretion during initial activation. If an antigen is present at high concentrations but does not trigger acute inflammation and attendant production of IL-12, the local concentration of IL-4 increases over time and induces a Th2 polarization of cells. On the other hand, pathogens that induce acute inflammation and/or engage toll-like receptors on accessory cells and macrophages can promote production of IFN- γ and IL-12, thereby stimulating development of the immune response along the Th1 pathway.³⁸ Immune responses restricted to Th1 cells, for example, are observed in patients with leprosy who have developed cellular immunity to *Mycobacterium leprae*⁴⁴ or *M. tuberculosis*,⁴⁵ in patients with *Yersinia enterocolitica*⁴⁶ or arthritis triggered by infection with *Borrelia burgdorferi*.⁴⁷

However, it is probably overly simplistic to view the Th1 pathway as being the more aggressive of the two, generating acute organ-specific autoimmune diseases and inflammations, while the Th2 pathway predisposes to atopic diseases and systemic autoimmune disease. For example, *Helicobacter pylori*-associated peptic ulcer can be regarded as a Th1-driven immunopathologic response to some *H. pylori* antigens, while deregulated and exhaustive *H. pylori*-induced T-cell-dependent B-cell activation can support the onset of low-grade B-cell lymphoma.⁴⁸ In addition, many chronic inflammatory and autoimmune conditions such as rheumatoid arthritis (RA), type 1 diabetes, and multiple sclerosis (MS) are mixed Th1/Th2 conditions, and a clear Th1/Th2 bias has also not been identified yet for many types of cancer.³⁴

CD4+CD25+ Regulatory T Cells

Another type of CD4 cells that suppresses rather than provides helper activity are regulatory T (T_{REG}) cells. T_{REGs} possess potent suppressive capacity and can exert diverse suppressive mechanisms allowing them

Figure 76-3. Differentiation of CD4+ T-cell subsets. During the course of the immune response, a naïve CD4+ T cell (top of figure) can differentiate into any one of several distinctive CD4+ T cells, as indicated beneath each differentiated cell type. Beneath the name of each T-cell subset is listed the transcription factor (if known) that is critical for the differentiation and maintenance of the subset. Interleukin (IL)-4 is critical for development of T-helper (Th)-2 cells (green), which triggers activation and/or induction of signal transducer and activator of transcription (STAT)5, STAT6, and GATA3, transcription factors that are important in Th2 differentiation. On the other hand, interferon- γ (IFN- γ) and IL-12 pattern the development of Th1 cells (light red) through the activation and/or induction of transcription factors STAT1, STAT4, and T-BET. IL-6 along with transforming growth factor beta (TGF- β) can induce blood CD4+ T cells to express the transcription factors STAT3 and ROR γ t (retinoic acid-related orphan receptor γ thymus isoform), which programs differentiation into Th17 cells, whereas TGF- β , retinoic acid (RA), and IL-2 induces these cells to express the transcription factors forkhead box P3 (FOXP3) and STAT5, which are required for differentiation into CD4+CD25+ regulatory T cells (T_{REG}) cells (red). IL-21 favors differentiation of naïve CD4 T cells into follicular helper T cells (T_{FH} , gold). Th9 cells (dark blue) are induced by IL-4 and TGF- β , express a combination of transcription factors and secrete IL-9. There is some plasticity in these differentiated T-cell subsets. IL-6 in combination may induce T_{REG} cells to differentiate into Th17 cells, whereas B cells stimulated via CD40-CD40-ligand (CD40L or CD154) may induce their differentiation into T_{FH} cells, as indicated by the dashed horizontal arrows.

to influence a very broad range of cell populations in a variety of anatomical locations and disease scenarios, both by direct cell-cell contact and the secretion of cytokines.⁴⁹ The cardinal phenotypic features of CD4+ T_{REG} cells include their constitutive expression of the transcription factor forkhead box P3 (FOXP3), their cell surface expression of CD25 (the low-affinity receptor for IL-2 and their cell surface and cytoplasmic expression of the coinhibitory receptor cytotoxic T-lymphocyte antigen 4 (CTLA-4 or CD152).⁵⁰

FOXP3 is an essential transcription factor required to manifest the T_{REG} cell phenotype,⁵¹ but it does not function alone and requires the expression of additional transcription factors to define the T_{REG} cell phenotype and to establish its characteristic transcriptional programme.⁵² Patients with the *immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome* (IPEX syndrome) are found to have germline mutations in the gene encoding FOXP3, which maps to the long arm of the X chromosome at Xp11.23 (Chap. 80).⁵³ T_{REG} developmental deficiency or dysfunction is a hallmark of IPEX, leading to severe, multiorgan, autoimmune phenomena. Patients typically have autoimmune skin conditions, such as bullous pemphigoid or alopecia universalis, and autoimmune endocrinopathies similar to those seen in patients with the *autoimmune polyendocrine candidiasis ectodermal dystrophy syndrome* (APECED syndrome), which is associated with genetic defects in the autoimmune regulator (*AIRE*) gene responsible for the generation of T-cell tolerance in the thymus (Chaps. 6 and 80).^{54,55} The IPEX syndrome demonstrates the importance of T_{REG} cells in maintaining tolerance to self-antigens and in preventing runaway immune responses to environmental antigens that might evolve into cross-reactive autoimmunity.

Additional key factors and signals required for T_{REG} cell development and survival include IL-2, transforming growth factor- β (TGF β) and co-stimulatory molecules.⁵⁶ It is also becoming clear that unique epigenetic changes that are partly induced by TCR signalling are typical of the T_{REG} cell lineage, and that they can be used to differentiate T_{REG} subpopulations such as thymus-derived T_{REG} (tT_{REG}) cells and peripherally derived T_{REG} (pT_{REG}) cells.^{57,58} These terms have replaced “natural FOXP3+ T_{REG} cells” and “induced or adaptive T_{REG} cells” to more accurately describe the anatomical location of their differentiation. tT_{REG} cells differentiate from CD4+CD8- T cells that have undergone positive and negative selection to self-antigens presented in the thymus (Chap. 6) and are thought to play a role in maintaining tolerance to self-antigens. pT_{REG} cells, on the other hand, differentiate upon antigen encounter under certain conditions and during normal homeostasis of the gut.⁵⁹ As such, pT_{REG} are thought to play an important role in the development and maintenance of mucosal immune tolerance and in the control of severe chronic allergic inflammation and “altered” self-antigens of inflamed tissues or neoplastic cells. They are also required to minimize tissue damage in inflammatory settings such as viral infection⁶⁰ or mediate tolerance to allografts.⁶¹ tT_{REG} and pT_{REG} cells have subtle differences in the methylation status of conserved noncoding sequence 2 (CNS2; also known as the T_{REG} cell-specific demethylated region [TSDR]) in the *FOXP3* locus, potentially influencing the stability of the cells under inflammatory or pathogenic conditions.⁶²

T_{REG} cells can specifically suppress immune responses via contact-dependent and cytokine-mediated mechanisms.⁶³ Upon activation through their TCR, T_{REG} s can (1) produce antiinflammatory cytokines (e.g., IL-10, TGF- β , or IL-35), (2) reduce the availability of IL-2

via absorption by the CD25 receptor, (3) lyse other immune effector cells via granzyme secretion or CD95-CD95L-mediated cell killing, (4) modulate the activation state and/or function of APCs and other immune effector cells, and/or (5) release suppressor factors, such as galectin-1⁶⁴ (a β -galactoside-binding protein that can bind and inhibit the function of many glycoproteins, including CD7, CD43, and CD45) and fibrinogen-like protein 2 (FGL2; a member of the fibrinogen family that mediates its suppressive effect through binding to low affinity Fc γ receptors expressed on APCs).⁶⁵ Consequently, T_{REG} cells can act directly against specific target antigens, while activating suppressive functions of other types of immune effector cells such as CD4+ and CD8+ cells.

Th17 T Cells

Naïve CD4+ T cells also can differentiate into Th17 T cells that play an important role in immune responses to certain extracellular pathogens and fungi.⁶⁶ These cells produce IL-17 (sometimes referred to as IL-17A) and a closely related cytokine, IL-17F, which can form biologically active homodimers or heterodimers and induce substantial tissue reactions because of the broad distribution of the IL-17 and IL-22 receptors. Principal cytokines involved in the differentiation of naïve blood CD4+ T cells into Th17 cells are IL-23 and IL-1 β (see Fig. 76-3), but a combination of TCR stimulation and the cytokines TGF- β and IL-6 are also required.⁶⁷ Prostaglandins, most notably prostaglandin E₂, can synergize with IL-23 and IL-1 β to drive differentiation of CD4+ T cells into Th17 cells.⁶⁸ These cytokines and factors can induce activation and/or expression of transcription factors that are distinct from those used by Th1 or Th2 cells, including the retinoic acid-related orphan receptor γ (ROR γ t) and STAT3 (see Fig. 76-3).^{69,70} which, in turn, can induce expression of IL-17 and IL-17F.^{71,72} However, for full commitment of precursors to the Th17 lineage, ROR γ t and STAT3 must act in cooperation with other transcription factors, including ROR α , interferon regulatory factor 4 (IRF4), and runt-related transcription factor 1 (RUNX1). Th17 cells also express high levels of the IL-23R, CCR4, CCR6, CXCR4, CD161, and multiple CD49 integrins, but not CCR2, CCR5, or CCR7.^{37,73,74} In contrast to Th1 or Th2 cells, Th17 cells do not elaborate IFN- γ or IL-4, both of which can inhibit expression of IL-17.⁷⁵

Th17 cells play a central role in inflammation and defense against intestinal bacteria, extracellular pathogens, and fungal infections, mostly via activation of neutrophils. Common pathogens that induce mainly Th17 responses include Gram-positive *Propionibacterium acnes*, gram-negative *Citrobacter*, *Klebsiella pneumoniae*, *bacteroides* and *Borrelia* species, and fungi such as *Candida albicans*.⁷⁶ Th17 cells are abundantly found in the intestinal lamina propria, where they are induced and stimulated by commensal bacteria, maintain epithelial integrity, and clear extracellular pathogens.⁷⁷

Th17 cells are the principal producers of IL-17 in response to specific immune stimulation, but NK and natural killer T (NKT) cells are also able to produce IL-17. IL-17 is a proinflammatory cytokine that has pleiotropic effects on multiple target cells, resulting in enhanced antigen presentation, antibody production, macrophage activation, cellular extravasation, and neutrophil migration.⁷⁸ In addition to IL-17 and IL-17F, Th17 cells elaborate other proinflammatory factors, including chemokines (e.g., CXCL8 [IL-8] and CCL20), cytokines (e.g., IL-6, tumor necrosis factor- α , IL-21, and IL-22), growth factors (e.g., granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor), acute phase proteins (e.g., C-reactive protein), and antimicrobial peptides and mucins.⁷⁶

The importance of Th17 cells in the defense against certain microorganisms is reflected in the rare primary immunodeficiency disorder called *autosomal dominant hyper-IgE syndrome*, in which a mutation in

STAT3 abrogates Th17 differentiation (Chap. 80).^{79,80} Patients lack Th17 cells and have an increased susceptibility to infection with the various species of *Staphylococcus* or *Candida*. Furthermore, the loss of intestinal commensal bacteria that are essential for the induction of Th17 cells through the use of antibiotics can cause depletion in intestinal Th17 cells, and might account in part for the increased incidence of gastrointestinal infections with *C. albicans* or *Clostridium difficile* observed in patients subjected to long-term, broad-spectrum antibiotic therapy.⁸¹ Because of their capacity to enhance inflammation in an antigen-specific manner, Th17 cells also have been implicated in the development and/or propagation of several autoimmune disease, such as rheumatoid arthritis,⁸² systemic lupus erythematosus (SLE),⁸³ MS,⁸⁴ inflammatory bowel disease,⁸⁵ glucocorticoid-resistant asthma,⁸⁶ and psoriasis.⁸⁷

T_{FH} Cells

T follicular helper cells (T_{FH} cells) constitute another subset of CD4+ T cells that regulates the development of antigen-specific B-cell immunity in the germinal center of secondary lymphoid follicles. T_{FH} cells express the CXCR5 chemokine receptor, allowing them to home to the CXCL13-rich B-cell zones of lymphoid follicles where they engage antigen-specific B cells in cognate intercellular interactions, and cell-surface proteins such as programmed cell death-1 (PD-1), inducible T-cell costimulator (iCOS), B- and T-lymphocyte attenuator (BTLA), and CD40L, which allow them to form stable contacts with antigen-primed B cells.⁸⁸ Such interactions play a critical role in B-cell differentiation into plasma cells or memory B cells in response to antigenic stimulation. In addition, T_{FH} cells secrete cytokines such as IL-4, IFN- γ , IL-10, and/or IL-21, which partly overlap with cytokines characteristic of other T-effector cells, helping to modify the differentiation fate of B lymphocytes (Chap. 75).

T_{FH} cells also express the cytoplasmic adaptor protein signal lymphocyte activation molecule (SLAM)-associated protein (SAP), required for lymphocyte interactions, and the transcription factor B-cell lymphoma 6 (BCL-6), required for T_{FH} cell differentiation. Several lines of evidence suggest that T_{FH} differentiation is a multistage process, but that dendritic cells (DCs) are crucial for CD4+ T cell priming and initial acquisition of T_{FH} cell characteristics, including the induction of BCL-6 expression.⁸⁹ The flexibility and plasticity of T_{FH} cells, which is mostly mediated by chromatin modifications, is underlined by the expression of a constellation of transcription factors, including BCL-6, BATF, STAT3, IRF4, c-Maf, and GATA-3, many of which are expressed by other Th effector subsets (see Fig. 76-3).

Th9 Cells

Another helper T-cell subset that has recently emerged are Th9 cells. In contrast to Th17 cells and T_{REGs}, they are induced by the combination of TGF- β and IL-4 and regulated by the transcription factors PU.1, STAT6, IRF4, and GATA-3.⁹⁰ They primarily produce IL-9, IL-10, and IL-21.⁹¹ Functionally, Th9 cells appear to be effector rather than regulatory, and they have been implicated in the development of allergic reactions, particularly in the lungs.⁹² Recent data indicates that Th9 cells *in vivo* might be implicated in tumor immunity in melanoma.^{93,94}

MEMORY T CELLS

Following a successful immune response to antigen including the exposure to and recognition of antigen, expansion of T-cell subsets and exertion of effector function, both naïve CD4+ and CD8+ T-cells can develop into long-lived memory T cells that provide enhanced protection from re-exposure to the same or a related pathogen.^{95,96} Memory

T-cell populations maintain the ability to both survive independently of cognate antigen⁹⁷ and self-renew in response to external homeostatic signals such as IL-15 and IL-7, hence maintaining themselves at stable levels for many years.⁹⁸ In addition, they have less-stringent requirements for activation and an enhanced capacity for lymphokine production upon rechallenge with the same antigen, and require a lower level of costimulatory factors.

Memory CD4⁺ or CD8⁺ T lymphocytes can also be distinguished from naïve cells based on their surface phenotypes of CD45 isoforms, rate of cycling, and migration. CD45, also known as leukocyte common antigen or T200, consists of a family of membrane glycoproteins, ranging from 180 to 220 kDa, that are expressed on all leukocytes.⁹⁹ Each member is the product of a single complex gene on chromosome 1 that contains 34 exons. Exons 3 through 7 may be spliced differently at the RNA transcript level to generate several distinct messenger RNA and protein products. The deduced amino acid sequences of these protein products have extracellular domains ranging from 391 to 552 amino acids, a transmembrane region, and a highly conserved cytoplasmic domain of 705 amino acids. This large cytoplasmic domain contains an intrinsic tyrosine phosphatase activity that is important in the regulation of various activation pathways involving tyrosine kinase activity, such as those involved in signal transduction via the TCR for antigen.¹⁰⁰ Different isoforms of CD45, designated as CD45R, have distinct expression patterns during lymphocyte ontogeny and activation. Therefore, cell subsets can be readily characterized by flow cytometry approaches using specific monoclonal antibodies. Naïve CD4⁺ T cells express CD45RA, whereas memory CD4⁺ T cells and CD8⁺ T cells express CD45RO. CD45RB can also be useful for distinguishing memory T cells. Within the CD4⁺ memory T-cell population, for example, there is an increase of helper activity associated with the shift from a CD45RB^{bright} to a CD45RB^{dim} phenotype.¹⁰¹

In addition, the distinct expression of chemokine receptors (CCRs) or homing molecules can be used to characterize T-cell subsets: relative to naïve T cells, memory T cells express lower levels of L-selectin (CD62L) and higher levels of CD29 and CD44.¹⁰² More recent studies demonstrate that memory cells can be further subdivided into CD44+CD62L+CCR7+ central memory T cells (T_{CM} cells) and CD44+CD62L-CCR7- effector memory T cells (T_{EM} cells).¹⁰³ Because of their constitutive expression of CCR7 and CD62L, T_{CM} cells home to secondary lymphoid organs, where they have little or no immediate effector function, but show greater sensitivity to antigenic stimulation in comparison to naïve T cells, are less dependent on costimulation, and upregulate CD40L to a greater extent. However, upon recognition of their cognate antigen, they have a high proliferative potential and can rapidly differentiate into large numbers of effector cells. T_{EM} cells, in contrast, have higher migratory potential and display immediate effector function. Therefore, T_{CM} cells are predominantly found in the CD4 lineage and are enriched in lymph nodes and tonsils, whereas T_{EM} cells are more frequent in the CD8 compartment in lung, liver, and intestines. Accordingly, CD8⁺ T_{EM} cells carry large amounts of perforin, and both CD4⁺ and CD8⁺ T_{EM} cells can produce IFN- γ , IL-4, and IL-5 within hours after following antigenic stimulation.

It has long been controversial whether memory T cells arise during the contraction phase and develop directly from effector cells, or whether they diverge early during an immune response, and arise in parallel with short-lived effector cells. Recent studies, however, have provided evidence for an early delineation of the effector versus memory T-cell fates regulated through specific transcription factors and cytokines, such as IL-7 receptor α -chain (IL-7R) expression, IL-2, IL-12, and T-BET, EOMES, and BLIMP-1.^{104,105}

T-CELL ACCESSORY MOLECULES

IMMUNE MODULATORY MOLECULES

CD28

CD28 is a 44-kDa disulfide-linked homodimer that is expressed on most resting T cells and plasma cells. Mature thymocytes have higher levels of CD28 than immature cells. Among human peripheral T cells, more than 90 percent of CD4⁺ T cells and approximately 50 percent of CD8 T cells express CD28. In general, activation of T cells induces enhanced expression of CD28, but ligation of CD28 leads to its transient downregulation.¹⁰⁶ CD28 is another member of the immunoglobulin superfamily and binds to both CD80 and CD86 using a highly conserved motif (MYPPPY) in a loop that resembles the third complementarity-determining region of immunoglobulin molecules. CD28 binds to CD80 with relatively low affinity (dissociation constant [K_d] = 4 μ M) and dissociates very rapidly (K_{off} = 1.6 s⁻¹),¹⁰⁷ and its binding to CD86 may be even weaker.¹⁰⁸

CD28 functions as a major costimulatory molecules that is essential for T-cell activation, probably in the context of TCR/CD28 microcluster formation.¹⁰⁹ Ligation of CD28 by CD80 or CD86 or by anti-CD28 antibodies activates distinct signaling pathways that function together with the signals induced by ligation of the TCR to allow for T-cell activation and proliferation.¹¹⁰ Following coligation of CD28, the Src kinases Lck and Fyn may phosphorylate a tyrosine within an ITAM found in the cytoplasmic domain of CD28, allowing the latter to bind and to activate phosphatidylinositide 3-kinase via its SH2 domains. CD28 signaling also facilitates GTP/guanosine diphosphate (GDP) exchange on Ras, resulting in activation of the MAP kinase pathway, activation of Akt kinase, and activation of the adapter protein Vav and the associated Rac pathway. These signals enhance the transcription of IL-2 and the stability of IL-2 transcripts, thereby stimulating T-cell proliferation.¹¹¹ Although mice lacking CD28 can mount effective T-cell responses, they are defective in T-cell-dependent antibody responses, suggesting that CD28 is necessary for T-cell-B-cell interactions and the proficient generation of antibody responses to antigen.¹¹²

The requirement for the same cell to present both the specific antigen and the costimulatory signal is crucial to prevent destructive autoimmune responses to self-tissues. This restricts the initiation of T-cell responses to APCs that express both the peptide antigen in the context of self-MHC molecules and the ligands for CD28, namely, CD80 and CD86. This is particularly important as not all self-reactive T cells undergo deletion in the thymus because not all self-peptides are presented in the thymus (Chap. 6). This is especially true for specialized tissues that express proteins that are never expressed in the thymus. If simultaneous ligation of the TCR and CD28 was not required, then T cells that recognize the self-peptide expressed by the MHC of such specialized tissues could become activated, leading to autoimmune rejection of the specialized tissue. Instead, ligation of the TCR in the absence of CD28 ligation leads to a state of hyporesponsiveness or anergy, in which the T cell expressing that receptor becomes refractory to activation.¹¹³ Anergized T-cell clones produce only negligible amounts of IL-2, which is crucial for clonal expansion following T-cell activation. Interestingly, clonal T-cell anergy was found not to be a terminal fate, as the addition of exogenous IL-2 during restimulation could reverse the phenotype.¹¹⁴ These characteristics are not limited to T cells, as anergic B cells also demonstrate some of the hallmark features, such as reduced proliferation and effector function. Anergy is an important basis for development of peripheral tolerance for self-antigens that are not expressed in the thymus (Chaps. 6 and 74).

CTLA-4 (CD152)

CTLA-4 (CD152) is another receptor for CD80 and CD86. It is a 50-kDa disulfide-linked homodimer that shares 31 percent identity with CD28. The gene encoding this receptor is closely linked with that encoding CD28 on the long arm of chromosome 2 at 2q33–q34. However, in contrast to the constitutive expression of CD28, T cells—with the exception of T_{REGs}—express CD152 only upon activation. Expression of CD152 peaks at approximately 24 hours after activation and then subsides by 72 hours but is always approximately 30- to 50-fold lower than that of CD28. CD28 ligation is particularly effective in inducing CD152.

CD152 binds to both CD80 and CD86 using the same highly conserved motif (MYPPPY) used by CD28, which, like CD28, is also in a loop that resembles the third complementarity-determining region of immunoglobulin molecules. However, despite its lower expression levels, CD152 binds to CD80 and CD86 approximately 20 times more avidly than CD28, with a K_d of 0.4 and 2.2 μ M, respectively.^{107,108} In contrast to CD28, ligation of CD152 transmits a negative signal to T-cell activation.¹¹⁰ Instead of an ITAM, CD152 possesses an immunoreceptor tyrosine inhibitory motif (ITIM) in its cytoplasmic domain. Ligation of CD152 induces tyrosine phosphorylation of the ITIM, which, in turn, recruits the tyrosine phosphatase SHP-2 that can deactivate the phosphorylated ITAMs of the ζ chains of the TCR complex. Mice made genetically deficient in CD152 develop a fatal lymphoproliferative disorder that is characterized by massive cell activation and infiltration into tissues, indicating that CD152 serves as an important brake on unregulated T-cell activation.¹¹⁵ Mice that are genetically modified to express only the extracellular domain of CD152 allowing the binding of CD80 or CD86, however, are protected from organ infiltration by T cells, suggesting that modulation of CD28 signals by competitive sequestration of its ligands can regulate tissue infiltration by autoreactive T cells.¹¹⁶

Moreover, anti-CD152 monoclonal antibodies that block the interaction of CD152 with CD80 and CD86 can enhance T-cell responses *in vitro* and *in vivo*. This has prompted their evaluation as immune-enhancing agents in models of autoimmune disease and in transplantation models,¹¹⁷ and more recently in clinical vaccine studies and trials in combination with the blockade of other immunomodulatory molecules.^{118,119}

Other Members of the CD28 Receptor Family

Homology-based cloning strategies have identified other proteins that are structurally related to CD28/CTLA-4 or its ligands CD80/CD86. These proteins are categorized as members of the CD28 or CD80 (B7) families, respectively, which belong to the immunoglobulin superfamily, a structurally and functionally highly heterogeneous family of T-cell cosignaling molecules.¹²⁰

Two other important members of the CD28 family are iCOS (CD278) and PDCD1 (CD279, PD-1). Whereas CD278 is found primarily on activated T cells, CD279 can be found on activated T cells, B cells, some myeloid cells, and NK cells. CD278 and CD279, respectively, bind to the iCOS-ligand (iCOS-L or CD275) and the PD-ligands PD-L1 (CD274) or PD-L2 (CD273).¹²¹ CD273, CD274, and CD275 belong to the CD80 (B7) family of surface molecules and are found or can be induced on B cells, APCs, and other nonhematopoietic tissues. CD278 primarily functions as a costimulatory molecule for cells bearing CD275.¹²² CD279 plays a negative regulatory role on activated T cells and modifies T cell/APC contact durations by inhibiting TCR stop signals.¹²¹ Like CD152, CD279 possesses an ITIM motif in its cytoplasmic tail that, upon phosphorylation, can recruit the tyrosine phosphatase SHP-2.¹²³ In this regard, CD279 may play a role similar to that of CD152, helping to brake cellular activation when bound to its ligands CD273 or CD274.

In general, the molecular mechanisms of T-cell costimulation and coinhibition are viewed as an evolving concept, as receptors and ligands exhibit great diversity in their expression, structure and function, and this is likely to be dependent on the context of anatomical location and the existence of underlying healthy and pathological immune responses.¹²⁰

T-CELL ADHESION MOLECULES

In addition to CD3/TCR molecules and CD4 or CD8, several other surface proteins are required for efficient T-cell antigen recognition.¹²⁴ Some of these surface proteins are termed adhesion molecules, as they facilitate the adhesion of the T cell to its appropriate APC or target cell (Fig. 76–4). Their main function is to permit the T-cell antigen receptor complex to interact better with the MHC glycoproteins of the other cell, allowing for efficient T-cell antigen recognition and activation. Each member of this group of accessory molecules has distinctive affinities for the surface molecules expressed by the APC or target cell, which is reflected by differential expression patterns on specific T-cell subsets. Adhesion and antigen response are largely considered the final step of the multi-stage T-cell trafficking process that involves migration, adhesion, and signaling.

Lymphocyte Function-Associated Glycoproteins

The lymphocyte function-associated (LFA) molecules are an important family of glycoproteins that facilitate efficient cell–cell adhesion.¹²⁴ The family consists of the three major surface molecules LFA-1, LFA-2 (CD2), and LFA-3 (CD58). LFA-1 belongs to a family of three related glycoproteins LFA-1, MAC-1 (CD11b/CD18), and gp150,95 (CD11c/CD18). These proteins also are called “integrins” because they are hypothesized to coordinate the binding of cells to other cell types and to extracellular proteins. Each protein consists of a distinct α subunit noncovalently associated with the β_2 subunit glycoprotein of 95 kDa, designated as CD18. Because they share a common β_2 subunit, these molecules also are referred to as the β_2 integrins. The α subunit of LFA-1, designated CD11a, is a 180-kDa glycoprotein. Coupled together with the common β_2 subunit, this 180-kDa molecule is expressed on more than one-third of all marrow cells, all T cells, all B cells, and all NK cells. The α subunit of MAC-1 is a glycoprotein of 170 kDa, designated CD11b. MAC-1 is expressed on NK cells, monocytes, macrophages, granulocytes, and small subpopulations of T and B cells. The α subunit of p150,95, designated CD11c, is a 150-kDa glycoprotein that is not expressed by T lymphocytes.

The shared β_2 subunit (CD18) has extensive sequence homology to the β_3 subunit (CD61) of the platelet adhesion receptor glycoprotein IIb/IIIa (CD41/CD61) and the β_1 subunit (CD29) of a family of related adhesion proteins, termed very-late-activation (VLA) antigens. Many of these receptors function in cell–cell interactions and recognize their ligands at sites that contain the amino acid sequence Arg-Gly-Asp. In addition, the α subunit provides some selectivity. LFA-1, because of its α subunit, binds best to cell-surface ligands called ICAMs, namely, ICAM-1 (CD54), ICAM-2 (CD102), and ICAM-3 (CD50). CD54 and CD102 are expressed on endothelial cells as well as APCs. The binding of LFA-1 on lymphocytes to these molecules allows lymphocytes to migrate through blood vessel walls. CD50 is expressed only on leukocytes, including T cells, and is thought to play an important role in the adhesion of T cells with LFA-1 expressed on APCs (see Fig. 76–4). The LFA glycoproteins are essential for proper T-cell function and host immunity, and integrin gene defects leading to leukocyte adhesion deficiencies result in severe immune deficiencies. In humans, three LADs (LAD I to III) have been described.¹²⁵

Figure 76-4. Schematic of a T-cell interactions with an antigen-presenting cell. The *thick green lines* depict the plasma membranes of the interacting cells. The molecules of the antigen-presenting cell, namely, lymphocyte function-associated antigen (LFA)-1, intercellular adhesion molecule (ICAM)-1 or ICAM-3, LFA-3, major histocompatibility complex (MHC) class II, and CD80 or CD86, are displayed on *top*, while the T-cell antigens, ICAM-2, LFA-1, CD2, CD4, the T-cell receptor (TCR) complex, and CD28, are shown on the *bottom* of the diagram. *Thin lines* connecting the stick figures indicate disulfide bridges. The TCR complex consists of the $\alpha\beta$ heterodimer that is noncovalently coupled with the δ , ϵ , γ , and ζ chains of CD3, as indicated. This complex can recognize peptide antigen (designated by the *diamond labeled P*) that is cradled by the α and β chains of the MHC class II molecule of the antigen-presenting cell. The avidity of this interaction is enhanced by CD4 on the T-cell surface that interacts with nonpolymorphic determinants on the MHC class II molecule. The interaction steps between the T cell and the antigen-presenting cell are listed at the *bottom* of the figure. T-cell molecules ICAM-2 (CD102), LFA-1 (CD11a/CD18), and CD2 bind to LFA-1, ICAM-1 (CD54) or ICAM-3 (CD50), and LFA-3 (CD58), respectively, that are present on the surface of the antigen-presenting cell. These molecules provide for better adhesion between the T cell and the antigen-presenting cell (adhesion), allowing for time for the TCR complex to find the MHC molecule bearing a specific peptide antigen (antigen recognition). Should the antigen-presenting cell express CD80 or CD86, then simultaneous ligation of CD28 will occur (costimulation), leading to activation of the reactive T cell.

Although clinically distinct, they exhibit several common features including recurrent bacterial infections and leukocytosis.

LFA-1, CD2, and CD50 binding partners are CD54, CD102, LFA-1, and CD58 on the APC (see Fig. 76-4). Binding prolongs the time the T cell is exposed to antigen, and allows to sample large numbers of MHC molecules on the plasma membrane of the APC for the presence of specific peptide antigen. When a naïve T cell recognizes its specific peptide in the context of the MHC, signaling through the TCR induces a conformational change in LFA-1 that greatly increases its affinity for CD54 and CD102. This stabilizes the association between the antigen-specific T cell and the APC. This association can last for several days during which time the naïve T cell proliferates, forming daughter cells that also adhere to the APC and that differentiate into armed effector T cells.

Very-Late-Activation Antigens

VLA received this terminology because the first identified VLA molecules, namely VLA-1 and VLA-2, initially were found on T cells only weeks after repetitive stimulation *in vitro*.¹²⁶ VLA molecules are β_1 integrins and share a common β_1 unit (CD29) that is paired with any one of six different α chains (α_1 to α_6), designated CD49a to CD49f. CD49a, CD49b, CD49c, CD49d, CD49e, and CD49f form molecules called VLA-1, VLA-2, VLA-3, VLA-4, VLA-5, and VLA-6, respectively, when paired with CD29. Despite their nomenclature, some of these VLA molecules, most notably VLA-4, are also expressed constitutively by some T cells and are rapidly induced on others. VLA-4 plays an important role in facilitating the attachment of cells that bear this molecule to the endothelium through its binding to vascular cell adhesion molecule-1

(VCAM-1), designated CD106. CD106 can be upregulated by various proinflammatory cytokines, allowing VLA-4 to play an important role in facilitating the homing of T cells to endothelium at sites of inflammation.

CD2

CD2 is a glycoprotein of approximately 50 kDa found on all T lymphocytes, large granular lymphocytes, and thymocytes.¹²⁷ CD2 facilitates cell-cell adhesion by binding to CD58, a 55- to 70-kDa surface glycoprotein that is expressed on erythrocytes and leukocytes as well as on endothelial, epithelial, and connective tissue cells (see Fig. 76-4). Monoclonal antibodies that bind CD2 may inhibit a variety of T-lymphocyte functions, including antigen-specific T-lymphocyte proliferative responses to lectins, alloantigens, and soluble antigens. Anti-CD2 inhibits cytotoxic T-lymphocyte-mediated cell killing by binding to the T cell rather than to the target, which generally does not express CD2. On the other hand, antibodies directed against CD58 inhibit cytotoxic T-lymphocyte-mediated cell killing by binding to CD58 on the target cell, thus blocking interaction of CD2 with CD58.

THE IMMUNOLOGICAL SYNAPSE

T-cell antigen recognition following the principles described above takes place within a contact zone termed the immunological synapse, which organizes the involved membrane proteins at the interface between the T cell and the APC. Immune synapse formation involves polymerization of F-actin and polarization of the cytoskeleton, resulting

in the redistribution of TCRs, costimulation, and accessory molecules into the region beneath the T-cell:APC contact site.¹²⁸ These molecules are segregated into central (cSMAC), peripheral (pSMAC) and distal (dSMAC) supramolecular activation clusters (SMACs). The cSMAC contains a concentration of TCR:CD3:peptide:MHC complexes, costimulatory molecules such as CD28, and signaling molecules such as PKC θ , while the pSMAC is enriched with adhesion molecules such as LFA-1. The dSMAC contains large glycoproteins such as CD45.¹²⁹ In addition to priming of T-cell responses, the immunological synapse is also important for effector functions.¹³⁰ For example, the pSMAC has been suggested to polarize cytotoxic granules released by cytotoxic CD8 T cells toward the target cells, therefore preventing the leakage of cytolytic granule contents to bystander cells, and the cSMAC is implicated as a site for receptor internalization and degradation.

CHAPTER 77

FUNCTIONS OF NATURAL KILLER CELLS

Giorgio Trinchieri, Richard W. Childs, and Lewis L. Lanier

SUMMARY

Natural killer (NK) cells, with a predominant morphology of large granular lymphocytes, represent a lineage of lymphoid cells with constitutive ability to mediate cytotoxicity toward pathologic target cells and secrete cytokines. NK cells participate in the innate resistance to microbial pathogens and malignancies; opposing effects of activating and inhibitory receptors regulate NK cell activity. Malignant expansions of NK cells, either acute or chronic, are rare, but represent well-identified clinical entities.

IDENTIFICATION AND DEFINITION OF NATURAL KILLER CELLS

DEFINITION

Natural killer (NK) cells were identified in the blood and lymphoid organs of humans and experimental animals as cells capable of killing tumors, virus-infected cells, and, in some instances, normal cells, in the absence of previous deliberate or known sensitization.^{1,2} NK cells are now considered to belong to the cellular subgroup that is characterized by the production of interferon (IFN)- γ within the family of innate lymphoid cells (ILCs), a family of developmentally related cells involved in innate immunity and tissue development.³ NK cells are defined as cytotoxic cells with the predominant morphology of large granular lymphocytes (LGLs) that: (1) neither productively rearrange any of the genes encoding the T-cell receptor (TCR) chains nor express on their surface the CD3-TCR complex; (2) express the CD56 (N-CAM), CD335 (NKp46), and CD16 (Fc γ RIIIA), antigens in humans, the NK1.1 (NKR-P1C), NKp46, and DX5 (VLA-2/CD49d) antigens in mice, and the NKR-P1 antigen in rats; and (3) can kill cells not expressing major

Acronyms and Abbreviations: ADCC, antibody-dependent cell-mediated cytotoxicity; AML, acute myelogenous leukemia; CAR, chimeric antigen receptor; CTL, cytotoxic T lymphocyte; GM-CSF, granulocyte-macrophage colony-stimulating factor; HLA, human leukocyte antigen; IFN, interferon; Ig, immunoglobulin; IL, interleukin; ILC, innate lymphoid cell; iNKT, invariant natural killer T cell; ITIM, immunoreceptor tyrosine-based inhibitory motif; KIR, killer cell Ig-like receptor; LCMV, lymphocytic choriomeningitis virus; LGL, large granular lymphocyte; MCMV, mouse cytomegalovirus; MHC, major histocompatibility complex; NK, natural killer; TCR, T-cell antigen receptor; TNF, tumor necrosis factor; TRAIL, TNF-related apoptosis-inducing ligand.

histocompatibility complex (MHC) class I or class II antigens. Thus, target-cell recognition by NK cells is distinct from cytotoxic T lymphocytes (CTLs), which recognize specific antigenic peptides bound to MHC class I molecules. Nonetheless, the presence of MHC class I on target cells affects NK cell recognition, in some cases inhibiting a NK cell response.

Certain T lymphocytes that express either $\alpha\beta$ or a $\gamma\delta$ TCR may exhibit, particularly upon activation, TCR-independent cytolytic activity that resembles that of NK cells and often express many of the same surface receptors as NK cells. Among the T lymphocytes in humans and mice that coexpress many of the NK cell antigens, invariant natural killer T (iNKT) cells express an invariant TCR that recognizes glycolipids presented by CD1d, a nonclassical MHC molecule, and upon stimulation rapidly produce large amounts of IFN- γ , granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin (IL)-4, and IL-13.⁴

MORPHOLOGY

Human LGLs are medium- to large-size lymphocytes with round or indented nuclei, condensed chromatin, and usually prominent nucleoli. The cytoplasm is abundant and contains a variety of organelles and granules (primary lysosomes) that, in addition to lysosomal enzymes, contain proteins important for cytotoxic function, such as serine esterases (granzymes) and pore-forming proteins (perforin).⁵ Although many NK cells have the morphology typical of LGL, a significant proportion of NK cells are agranular and indistinguishable from other lymphocytes.⁶

ORIGIN AND TISSUE DISTRIBUTION

NK cells originate in the marrow from the common lymphoid progenitor cell.⁷ Most have a life span ranging from a few days to a few weeks,⁸ but some may persist for months after exposure to viral challenge.⁹ In mice, the cytokine IL-15 plays a particularly important role in the differentiation and expansion of NK cells.¹⁰ NK cell differentiation does not require the thymus, although NK cell progenitors can differentiate in the thymus from precursors expressing IL-7R α CD127.¹¹ Secondary lymphoid tissues may also be a site of NK cell development in humans.¹² The increased number of NK cells and altered anatomical distribution in response to infection or other stimuli are the result of increased NK cell production in the marrow and proliferation of peripheral NK cells.

NK cells represent approximately 5 to 20 percent of blood lymphocytes.¹³ Immature NK cells express high amounts of CD56, lack CD16, and have low cytolytic capacity, whereas mature NK cells in blood express low amounts of CD56, high levels of CD16, and mediate potent lytic activity.¹⁴ NK cells are present in the red pulp of the spleen and are found at a low frequency in other lymphoid organs and marrow.² NK cells with a phenotype resembling the CD56^{high} peripheral subset have been detected in lymph nodes.¹⁵ Small numbers of NK cells can be identified in the liver (pit cells), lung, and intestinal mucosa.^{16,17} In response to type I IFN or viral or bacterial infections, NK cells accumulate in organs in which they normally are rare, particularly the liver, marrow, and lymph nodes where they may produce large amounts of cytokines.¹⁸ CD56^{bright} CD16⁻ NK cells are the predominant cell type present in the human early pregnancy decidua.¹⁹ Decidual NK cells produce cytokines that have tissue remodeling capacity, facilitate embryonic implantation, monitor mucosal integrity throughout the menstrual cycle, control trophoblast invasion during pregnancy, and modulate the maternal immune response against embryo antigens.¹⁹

MECHANISMS OF NATURAL KILLER CELL FUNCTIONS

CELL-MEDIATED CYTOTOXICITY

Cytotoxicity mediated by NK cells depends on binding to the target cells, followed by activation of the lytic mechanism, which usually involves release of perforin and granzymes from the granules.⁵ Cytotoxicity can also be mediated through the interaction of surface molecules, for example, the interaction of Fas ligand, membrane tumor necrosis factor (TNF), or TNF-related apoptosis-inducing ligand (TRAIL) on NK cells with their death-inducing receptors on target cells. Lysis of the target cells results from alteration of membrane permeability and induction of apoptosis.⁵

Several surface molecules on NK cells have been identified that activate the cytotoxic mechanism and induce cytokine secretion (Fig. 77-1).²⁰ One of these molecules is the low-affinity receptor for the Fc fragment of immunoglobulin (Ig) G (FcγRIIIA or CD16), which is expressed on most human circulating NK cells in association with the signal-transducing CD3ξ or FcεRIγ chains. When CD16 is cross-linked by IgG antibodies bound to a target cell surface, it triggers antibody-dependent cell-mediated cytotoxicity (ADCC). Natural killing can also be activated by several other receptors that recognize relevant ligands on the potential target cell. NKG2D, a receptor expressed on all NK cells, has been implicated in NK cell recognition of transformed and virus-infected cells.²¹ This receptor recognizes a family of MHC class I-related glycoproteins (including MICA, MICB, ULBP1–ULBP6), which are absent or expressed at only low levels on healthy cells but are induced or upregulated upon cell transformation or viral infection.²¹ Viruses, such as cytomegalovirus, have devised strategies to prevent the expression of NKG2D ligands in the infected cells,²² presumably to escape NK cell-mediated immunity. NK cells express many other activating receptors that have been implicated in their recognition of tumors, including DNAM-1 (CD226) and the “natural cytotoxicity” receptors NKp30, NKp44, and NKp46.²⁰

Figure 77-1. Schematic of selected inhibitory and activating natural killer (NK) cell receptors regulating NK cell responses.

NK cells preferentially kill certain tumor cells lacking expression of MHC class I molecules.²³ NK cells are regulated by positive signals initiated by activating receptors and negative signals transmitted by interactions between inhibitory receptors for MHC class I on the NK cells and autologous MHC class I molecules on potential target cells. NK cells may mediate immune surveillance against cells that lose expression of MHC class I. Numerous viruses inhibit the synthesis or transport of MHC class I proteins, presumably to avoid detection by CTL.²⁴ In addition, frequent loss of MHC class I expression on tumor cells has been documented.²⁵ However, NK cells are capable of killing cells expressing MHC class I if they receive sufficiently strong activation signals.

Two families of NK cell receptors for MHC class I have been identified in humans. The Killer cell Ig-like receptors (KIRs) are encoded by approximately 15 genes present on human chromosome 19q13.4.²⁶ KIR genes are highly polymorphic and evolve rapidly, diversifying by gene duplication and conversion events. Certain KIRs bind human leukocyte antigen (HLA)-C ligands, whereas other KIRs recognize certain alleles of HLA-B or HLA-A. Another class of NK cell receptors for MHC class I are heterodimeric glycoproteins composed of a CD94 subunit that is disulfide bonded to an NKG2A molecule.²⁰ The genes encoding CD94 (*KLRD1*) and NKG2A (*KLRC1*) are on human chromosome 12p12-p13 and are members of the C-type lectin superfamily. The CD94-NKG2A receptors bind to HLA-E, a unique MHC class I protein that displays peptides derived from leader segments from HLA-A, HLA-B, HLA-C, or HLA-G proteins.²⁷ When synthesis of HLA-A, HLA-B, HLA-C, or HLA-G is disrupted, possibly by viral infection or transformation of the host cell, HLA-E cannot be transported to the cell surface for presentation to the CD94-NKG2A receptor. The various KIR and CD94-NKG2A receptors are expressed on overlapping subsets within the NK cell population and on certain memory T cells, usually CD8⁺ T cells, although a minor subset of CD4⁺ T cells also express KIR. The inhibitory KIR and CD94-NKG2A receptors have an immunoreceptor tyrosine-based inhibitory motif (ITIM) sequence in their cytoplasmic domains, which binds to the cytoplasmic tyrosine phosphatase SHP-1, resulting in suppression of cytotoxicity and cytokine secretion.²⁰ Therefore, the functional behavior of NK and T cells expressing KIR or CD94-NKG2A is regulated by the balance of positive signals transmitted by a variety of activating receptors and negative signals provided by the inhibitory MHC class I receptors. Although the expression of NK cell inhibitory receptors is variegated and polymorphic, most NK cells express at least one inhibitory receptor recognizing self MHC and thus are not self-reactive. This is accomplished at least in part by the requirement of interaction of an inhibitory receptor with its ligands during NK cell development for full functional maturation and possibly expansion (NK cell “licensing”).²⁸

Certain receptors of the KIR and CD94-NKG2 families do not possess ITIM sequences and activate, rather than suppress, NK- and T-cell responses.²⁰ These receptors noncovalently associate with the homodimeric adapter protein DAP12.²⁹ Like the CD3ξ and the FcεRIγ subunits, DAP12 contains an immunoreceptor tyrosine-based activation motif (ITAM) in the cytoplasmic domain. Upon receptor ligation, DAP12 becomes tyrosine phosphorylated, recruits the ZAP70 and Syk cytoplasmic tyrosine kinases, and induces cellular activation.²⁹ The physiologic role of activating NK cell receptors for MHC class I has not been determined, but these receptors may have consequences in allogeneic marrow transplantation. In mice, an activating receptor in the Ly49 family (the functional counterpart of KIRs in humans) has been shown to recognize a viral glycoprotein encoded by cytomegalovirus and protects the mice from this pathogen.^{30,31} This finding suggests that certain activating KIRs in humans may also recognize pathogens.

Although resting blood NK cells are cytotoxic, their activity can be greatly enhanced both *in vivo* and *in vitro* by exposure to cytokines such

as IFN- α/β , IL-2, IL-12, IL-15, and IL-18.³²⁻³⁴ Resting NK cells constitutively express intermediate-affinity IL-2 receptors, and IL-2 induces the progression of most NK cells into the cell cycle.³⁵

PRODUCTION OF CYTOKINES

Many of the physiologic functions of NK cells are mediated at least partly by their ability to secrete cytokines. NK cells are powerful producers of IFN- γ and GM-CSF, and other cytokines and chemokines. Stimulation by cytokines, such as IL-2, IL-12, IL-18, TNF- α , and IL-1,^{2,33,36,37} and triggering by activating receptors, such as CD16 interacting with immune complexes, are among the stimuli that, acting individually or often in synergistic combination, induce NK cells to produce cytokines.^{2,38,39}

PHYSIOLOGIC ROLES OF NATURAL KILLER CELLS

INNATE RESISTANCE

Together with myeloid cells, NK cells are effectors of the innate or natural resistance, which represents the first line of defense against infection (Fig. 77-2). The ability of NK cells to participate in the resistance against infection by certain viruses is well documented in experimental animals and is strongly suggested by the recurrent viral infections in the rare patients with a selective deficiency of NK cells.⁴⁰ NK cells selectively kill virus-infected cells by a mechanism that is at least partly dependent on the production of IFN- α , a potent stimulator of NK cell activity.^{41,42} *In vivo* viral infection and type I IFN production usually are accompanied by rapid activation of, and increase in the number of, NK cells.¹⁸ The NK cell response to virus infection is followed by an antigen-specific T helper and CTL response, which peaks 7 to 9 days after infection.¹⁸ The early NK cell response induces a significant reduction in the titer of certain viruses, including mouse cytomegalovirus (MCMV).⁴³ NK cell

activation induced by viral infection may have beneficial or pathogenic effects.⁴⁴ After expansion in response to MCMV infection, NK cells expressing the activating Ly49H receptor persist for several months and respond rapidly to rechallenge with MCMV, thus possessing immunologic memory.⁹ Similarly, a subset of liver-resident NK cells can mediate antigen-specific contact hypersensitivity responses and immunologic memory.^{45,46}

NK cells enhance the response of phagocytic cells to microorganisms, especially intracellular bacteria and parasites, by producing high levels of the phagocyte-activating cytokines IFN- γ and GM-CSF in response to the microorganisms themselves or to factors, such as IL-12 and TNF- α , produced by infected phagocytic cells.^{47,48}

REGULATION OF ADAPTIVE IMMUNITY

NK cells, by interacting with infectious agents and antigens early during the immune response, have either stimulatory or inhibitory effects on the function of B and T cells and antigen-presenting cells.² Evidence for an enhancing effect of NK cells on B-cell responses has been shown both *in vitro* and *in vivo* by studies demonstrating that NK cells in the absence of T cells support antigen-specific B-cell responses, partly by producing IFN- γ .^{49,50} In certain infections, NK cells may be necessary for optimal induction of both a CD4⁺ and CD8⁺ T-cell response.^{51,52} NK cells stimulated by microorganisms or by cytokines, such as IL-12 and IL-18, produce large amounts of IFN- γ and other cytokines that facilitate T-helper cell type 1 development.^{53,54} The reciprocal activating interaction between NK cells and the antigen-presenting dendritic cells is important for the regulation of both innate resistance and the downstream adaptive response to pathogens.^{55,56}

MODULATION OF HEMATOPOIESIS

Experimental and clinical studies have demonstrated that NK cells are involved in the regulation of hematopoiesis.⁵⁷ The effect of NK cells

Figure 77-2. Schematic of some of the functions and regulatory pathways of natural killer (NK) cells as effector cells of natural resistance. In addition to mediating cytotoxicity, NK cells exert their physiologic roles by releasing several cytokines that affect the functions of other cell types, including hematopoietic progenitor cells. NK cell activity also is regulated by cytokines. Cytokines interferon (IFN)- α/β , interleukin (IL)-2, IL-15, and IL-12 enhance NK-cell-mediated cytotoxicity. IL-2, IL-12, IL-15, IL-18, tumor necrosis factor (TNF), and IL-1 induce NK cell lymphokine production. IL-2 and IL-12 induce NK cell proliferation. Blue arrows indicate conditions that activate NK cells whereas the red arrows indicate innate, proinflammatory, and immunoregulatory functions of NK cells. GM-CSF, granulocyte-macrophage colony-stimulating factor; M-CSF, macrophage colony-stimulating factor.

is mostly mediated by secretion of soluble factors. NK cells, constitutively or upon activation, produce several lymphokines, some with mostly inhibitory effects on hematopoiesis, such as TNF and IFN- γ , and some with mostly stimulatory effects, such as GM-CSF.^{36,58} The effector role of NK cells in rejection of parental marrow graft in irradiated F1 mice⁵⁹ and in suppressing erythropoiesis and phagocytosis in mice infected with lymphocytic choriomeningitis virus (LCMV)⁶⁰ demonstrate that *in vivo* activated NK cells can affect both allogeneic and syngeneic hematopoietic progenitor cells. Because of the ability of NK cells to kill transformed hematopoietic cells, NK cells have been postulated to play an important role in the graft-versus-leukemia reaction in allogeneic marrow transplantation but only a modest, if any, role in graft-versus-host disease.⁶¹ In haploidentical or mismatched hematopoietic transplantation, the presence on donor NK cells of the KIR not recognizing inhibiting ligands on host hematopoietic and malignant cells results in protection from leukemia relapse.⁶² A reduced incidence of graft-versus-host disease has also been observed and thought to result from the elimination of recipient antigen-presenting cells by donor NK cells.⁶²

● PATHOLOGIC ALTERATIONS IN NATURAL KILLER CELL NUMBER AND FUNCTIONS

NK cell function and NK cell numbers are often decreased in pathologic conditions, including cancer and AIDS.^{63,64} The reduced activity or number of NK cells may contribute to disease pathology by decreasing the innate resistance against tumor growth and metastasis in cancer patients or against opportunistic infections in AIDS patients. NK cell (and cytotoxic T-cell) hyporesponsiveness is observed in patients with Chédiak-Higashi syndrome,⁶⁵ a rare autosomal recessive disease associated with cellular dysfunction, including fusion of cytoplasmic granules and defective degranulation of neutrophil lysosomes. NK cell numbers are normal in these patients, but the NK cells present a single, large granule in the cytoplasm and have a severely reduced ability to mediate cytotoxicity.⁶⁵

Malignant acute expansion of NK cells is rare, more frequent in Asians than in whites, and often associated with Epstein-Barr virus infection.⁶⁶ Extranodal NK cell lymphomas occur in both the nasopharyngeal region and in nonnasal areas as an NK cell (CD2⁺, CD3⁻, CD56⁺, CD16⁻, CD57⁻) leukemia or lymphoma that mostly affects extranodal tissues.⁶⁷ It affects predominantly men in their fifth decade and usually has an extremely aggressive clinical course. Aggressive NK cell leukemia is a catastrophic disease that affects young adults and is characterized by the systemic presence of neoplastic NK cells in blood and marrow.⁶⁷ An entity previously known as “blastic NK cell lymphoma,” characterized by CD4⁺, CD56⁺ cells with dermal tropism, is now recognized to represent an expansion of plasmacytoid dendritic cells rather than NK cells.⁶⁷ A chronic monoclonal proliferative disorder of LGL with a clinical course that is often relatively indolent is more commonly observed.⁶⁸ Most patients have lymphocytic infiltration of the marrow. Severe neutropenia and anemia often are observed. Associated diseases, most commonly rheumatoid arthritis, hepatitis, or cancer, are present in up to half of patients.⁶⁸ Although cells from all these patients are characterized by a LGL morphology, in approximately two-thirds of the cases they represent a monoclonal expansion of CD8⁺ T cells, and in only less than one-third of cases they have the typical phenotype and genotype of CD3⁻, CD56⁺, CD57⁺, and, in some patients, CD16⁺ NK cells.⁶⁸

● NATURAL KILLER CELL THERAPY TO TREAT CANCER

TARGETING NK CELL RECEPTORS

Data showing recipients of KIR-incompatible donors have reduced relapse of acute myelogenous leukemia (AML) following mismatched allogeneic stem cell transplantation remain the most compelling evidence to support the antitumor activity of NK cells.⁶¹ Further, studies in mice showing Ly49-incompatible NK cells mediate graft-versus-tumor effects have led to clinical trials exploring adoptively infused allogeneic NK cells in patients with cancer. In humans, pilot studies have shown that adoptive transfer of IL-2-activated MHC-mismatched allogeneic NK cells can proliferate *in vivo* and can induce tumor regression in patients with AML and solid tumors.⁶⁹

A strategy to disrupt inhibitory KIRs to enhance NK tumor killing involves blocking KIRs with monoclonal antibodies or genetically silencing their expression. IPH2101 is a fully human IgG₄ antibody that binds to KIR2D, thus blocking its ability to suppress NK cell function. Studies in a mouse model showing that IPH2101 enhances NK-cell killing of KIR ligand-matched tumor cells has led to phase I studies evaluating the efficacy of IPH2101-mediated KIR2D blockade in patients with AML and other hematologic disorders.⁷⁰ Genetic disruption of the inhibitory receptor NKG2A has been shown to enhance NK cell killing of HLA-E-expressing tumors *ex vivo* and *in vivo* following their infusion into tumor-bearing mice.⁷¹

ADOPTIVE NATURAL KILLER CELL TRANSFER

Recently, methods have been developed to expand large numbers of human NK cells *ex vivo*, which provides the opportunity to study the efficacy of adoptive NK-cell immunotherapy in patients with cancer.⁷² Most expansion cultures utilize irradiated feeder cells such as Epstein-Barr virus-transformed lymphoblastoid cell lines or the human erythromyeloblastoid leukemia cell line K562 cells genetically modified to express membrane bound 4-1BB ligand, IL-15, or IL-21. Expanded NK cells have increased surface expression of NK activating receptors and cytotoxicity effector molecules. Compared to resting NK cells, expanded NK cells express higher amounts of IFN- γ , Fas ligand, and TRAIL, and have markedly enhanced cytotoxicity against K562 and other tumor cells compared to resting or short-term IL-2-activated NK cells. Phase I trials of infusing large numbers of these *ex vivo* expanded autologous NK cells are now ongoing in patients with a variety of different cancers.⁷³

Studies suggest that lenalidomide, an immunomodulatory drug derived from thalidomide, and several monoclonal antibodies blocking immune checkpoints, such as anti-PD-1, anti-PD-L1, and anti-CTLA-4, augment NK-cell-mediated ADCC.^{74,75} The advances in our ability to expand NK cells *ex vivo* now makes it feasible to combine these and other monoclonal antibodies with adoptive NK cell transfer to potentially augment their antitumor effects.

OVERCOMING DEFICIENT NATURAL KILLER CELL HOMING

Expanded NK cells are inefficient at homing to the marrow and lymph nodes where hematologic malignancies reside. A variety of techniques to improve NK cell homing to these target organs have been described.⁷² NK cell trogocytosis (the transfer of plasma membrane fragments from the presenting cell to the lymphocyte) of the membrane-bound chemokine receptor CCR7 expressed on K562 cells can be used to

increase NK cell CCR7 surface expression, improving their homing into the lymph nodes of athymic mice.⁷⁶ Nicotinamide, a specific inhibitor of nicotinamide adenine dinucleotide-dependent enzymes, substantially increases surface expression of CD62L on NK cells when added to cell cultures, improving their homing into the spleens and marrow of immunodeficient mice.

Recruitment of leukocytes to marrow is largely dependent on E-selectin binding.⁷⁷ *Ex vivo* expanded NK cells primarily express nonglycosylated ligands for E-selectin, potentially limiting their homing ability to the marrow. *Ex vivo* forced fucosylation of NK cells with fucosyltransferase VI enhances their E-selectin binding capacity *in vitro* and in mice improves their homing to the marrow.⁷² Forced fucosylation of NK cells is currently being studied as a novel approach to improve NK homing to the marrow to enhance NK cell killing of hematologic malignancies.

AUGMENTING NATURAL KILLER CELL TUMOR KILLING

Exposing tumors to drugs that enhance caspase activity or upregulate death receptors for the apoptosis-inducing ligands TRAIL or Fas-L is an alternative strategy to bolster the antitumor effects of NK cells.⁷⁸ The proteasome inhibitor bortezomib upregulates surface expression of the TRAIL receptor DR5, enhancing tumor susceptibility to NK-cell TRAIL-mediated apoptosis *in vitro* and *in vivo*.⁷⁹ In mice, eradicating regulatory T cells prior to adoptive NK cell infusions further potentiates this antitumor effect. Clinical trials evaluating the antitumor activity of *ex vivo* expanded adoptively infused NK cells following bortezomib treatment are ongoing.

Methods to transfect chimeric antigen receptors (CARs) into NK cells have been optimized to induce tumor-specific NK cell killing in clinical applications. CARs specific for antigens expressed on tumors such as CD19 on B-cell malignancies, HER2/ErbB2 on breast carcinomas, and GD2 on neuroblastoma tumors when transduced into NK cells enhance tumor killing by autologous NK cells.^{72,80} These findings, as well as studies showing the efficacy of T-cell based CAR therapy targeting CD19 in B-cell malignancies, suggest CAR-modified NK cells are worthy of exploration in the clinic (Chap. 26).

CHAPTER 78

CLASSIFICATION AND CLINICAL MANIFESTATIONS OF LYMPHOCYTE AND PLASMA CELL DISORDERS

Yvonne A. Efebera and Michael A. Caligiuri*

SUMMARY

This chapter outlines the major categories of lymphocyte and plasma cell disorders. The disorders are classified into three main groups. The first is composed of diseases caused by defects intrinsic to lymphoid cells. The second is caused by disorders that result from factors extrinsic to lymphoid cells. The third is composed of disorders caused by neoplastic or preneoplastic lymphoid cells and are outlined in Chap. 90 using the World Health Organization classification of tumors of lymphoid tissues. The clinical manifestations of diseases in any one of the three groups may be difficult to distinguish, but this grouping can provide a framework with which to proceed in evaluating patients with known or suspected lymphocyte and plasma cell disorders. This chapter introduces the framework and presents a roadmap to other chapters in this book that discuss each of the disorders in greater detail.

CLASSIFICATION

Lymphocyte and plasma cell disorders can be classified into three major groups (Table 78–1). The first group, listed under “primary disorders,” is composed of lymphocyte disorders caused by intrinsic defects in lymphoid cells that result in functional abnormalities of marrow-derived (B) lymphocytes, thymic-derived (T) lymphocytes, combined T and B (impaired humoral and cellular immunity), or natural killer (NK) cells. These disorders primarily result from inborn errors in lymphocyte metabolism (Chaps. 73 to 77 and 80) and/or receptor–ligand expression (Chaps. 17 and 80). The second group, listed under “acquired disorders,” consists of disorders caused by factors extrinsic to lymphocytes resulting in immune dysfunction. These conditions most commonly result from infection with viruses, or other cellular pathogens (Chaps. 79, 81, and 82), but they also may be caused by bacteria, drugs or systemic disease of nonlymphoid cells. The third group of diseases is composed of preneoplastic and neoplastic lymphocyte disorders and is discussed in detail in Chap. 90.

Acronyms and Abbreviations: GVHD, graft-versus-host disease; Ig, immunoglobulin; NK, natural killer; SCID, severe combined immune deficiency; Th, T helper; T_{REG}, CD4+ regulatory T cell.

*This chapter was prepared by Thomas J. Kipps in the 8th edition and much of the text has been retained.

Some categories of lymphocyte and plasma cell disorders may be difficult to distinguish clinically because lymphocyte disorders can have many clinical manifestations that are not restricted to cells of the immune system and disparate disorders can have similar clinical manifestations, with any one disorder associated with a diverse array of clinical pathologies.

In some cases, the classification of lymphocyte disorders is influenced by the manifestations of the disease. For example, autoimmune hemolytic disease (Chap. 54) and autoimmune thrombocytopenia (Chap. 117) are caused by inappropriate secretion of autoantibodies by B lymphocytes. The blood cell that is coated with autoantibody presumably is normal, yet we classify the disease that can result from hemolytic autoantibodies as an acquired hemolytic anemia because that aspect of the disease is more visible and better understood than is the inappropriate synthesis of antierythrocyte antibody by the disturbed lymphocyte population(s). These disorders are not considered here.

Many diseases, especially infection (e.g., tuberculous adenitis), inflammatory states (e.g., rheumatoid arthritis), autoimmune disease (e.g., systemic lupus erythematosus), and metastatic carcinoma can involve lymph nodes or the spleen as a secondary alteration. These disorders also may be associated with abnormal production of antibodies, such as those resulting in the lupus anticoagulant (Chap. 131). These disorders also are not considered here because the primary disease is not generally considered a lymphocyte disorder.

CLINICAL MANIFESTATIONS

B LYMPHOCYTE DISORDERS

Immunoglobulin Deficiency

The clinical manifestations of B-lymphocyte disorders include the consequences of B-lymphocyte deficiency, dysfunction, or malignant transformation. The manifestations may consist of a specific deficiency of one of the immunoglobulin (Ig) isotypes or of several or all Ig molecules (panhypogammaglobulinemia; see Chap. 75). Inability to synthesize or secrete antibodies impairs the clearance of pathogens because of the inability to opsonize microorganisms for phagocytosis, resulting in immune dysregulation and dysfunction (Chap. 80).

Abnormal Immunoglobulin Production

Primary defect in the B-cell clone or expansion of a clone in response to chronic antigen stimulation can result in excess production of Ig that in turn produces a monoclonal gammopathy (Chap. 106). Monoclonal gammopathy can result in B-cell neoplastic disease, such as plasma cell myeloma (Chap. 107), Waldenström macroglobulinemia (Chap. 109) or chronic lymphocytic leukemia (Chap. 92). Production of abnormal Ig molecules or Ig fragments can also be seen in association with chronic infection, leading to development of Ig heavy-chain disease (Chap. 110). Deposition of Ig or Ig fragments can contribute to primary amyloid formation (Chap. 108). Reactivity of the Ig with self-antigen(s), such as those found on the red cell membrane (Chap. 54), can result in systemic autoimmune disease.

T LYMPHOCYTE DISORDERS

Impaired Immunoregulation

The clinical manifestations of deficiencies or excesses of T-lymphocytes depend on the subset of T-lymphocytes involved. Delayed hypersensitivity normally is mediated by CD4+ helper T cells (Th cells) and, more specifically, Th1-type cells (Chap. 76). A deficit or functional disturbance in these T-cells can impair the cellular immune response to mycobacteria, *Listeria*, *Brucella*, fungi, or other intracellular

TABLE 78-1. Classification of Disorders of Lymphocytes and Plasma Cells**I. Primary disorders****A. B-lymphocyte deficiency or dysfunction (Chap. 80)^{1,2}**

1. Agammaglobulinemia
 - a. Acquired agammaglobulinemia³
 - b. Associated with plasma cell myeloma, heavy chain disease, light chain amyloid, Waldenström macroglobulinemia, or chronic lymphocytic leukemia (Chaps. 92 and 107–110)^{4,5}
 - c. Associated with celiac disease⁶
 - d. X-linked agammaglobulinemia^{7,8}
 - e. Autosomal recessive agammaglobulinemia⁹
 - f. Common variable immunodeficiency¹⁰
 - g. Transient hypogammaglobulinemia of infancy¹¹
 - h. Bloom syndrome¹²
 - i. Comel-Netherton syndrome¹³
2. Selective agammaglobulinemia (Chap. 80)
 - a. Immunoglobulin (Ig) M deficiency
 1. Selective IgM deficiency¹⁴
 2. Wiskott-Aldrich syndrome¹⁵
 - b. Selective IgG deficiency (Chap. 80)
 - c. Selective IgA deficiency^{16,17}
 - d. IgA and IgM deficiency¹⁸
 - e. IgA and IgG deficiency^{19,20}
 1. CD40/CD40L deficiency
 2. Activation-induced cytidine deaminase (AID) (uracil-DNA glycosylase [UNG], hyper-IgM₄) deficiency
 3. *PMS2* deficiency
3. Hyper-IgA^{21,22}
4. Hyper-IgD^{23–26}
5. Hyper-IgE syndrome (HIES; Chap. 80)²⁷
6. Hyper-IgE associated with HIV infection²⁸
7. Hyper-IgM immunodeficiency (Chap. 80)^{19,20,29}
8. X-linked lymphoproliferative disease^{30–32}

B. T-lymphocyte deficiency or dysfunction (Chap. 80)^{33,34}

1. Cartilage-hair hypoplasia (Chap. 80)^{35,36}
2. Lymphocyte function antigen-1 deficiency³⁷
3. Thymic aplasia (DiGeorge syndrome)^{38,39}
4. Thymic dysplasia (Nezelof syndrome)⁴⁰
5. Thymic hypoplasia^{41,42}
6. CD8 deficiency⁴³
7. CD3 γ deficiency⁴⁴
8. Winged helix deficiency (Nude)⁴⁵
9. Interleukin-2 receptor α chain (CD25) deficiency⁴⁶
10. Signal transducer and activator of transcription 5b (STAT 5b) deficiency⁴⁷
11. Schimke syndrome⁴⁸
12. Janus kinase 3 (JAK3) deficiency⁴⁹
13. γ c Deficiency
14. Wiskott-Aldrich syndrome (Chaps. 80 and 120)^{15,50}

15. Zeta-associated protein of 70 kDa (ZAP-70) deficiency (Chap. 80)^{51,52}
16. Purine nucleoside phosphorylase deficiency (Chap. 80)
17. Interleukin-7 receptor deficiency (Chap. 80)
18. Major histocompatibility complex class I or II deficiency (Chap. 80)
19. Coronin-1A deficiency (Chap. 80)
20. IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) syndrome caused by mutations in FoxP3 that cause a deficiency of CD4+ regulatory T cells (T_{REGS}) (Chaps. 76 and 80)
21. APECED (autoimmune polyglandular, candidiasis, and ectodermal dystrophy) syndrome caused by mutations in the autoimmune regulator gene (AIRE) gene (Chaps. 6, 76, and 80)
22. Autoimmune lymphoproliferative syndrome (Chap. 80)

C. Combined T- and B-cell deficiency or dysfunction (Chap. 80)

1. Ataxia-telangiectasia⁵³
2. Combined immunodeficiency syndrome (Chap. 80)⁵⁴
 - a. Adenosine deaminase deficiency^{55,56}
 - b. Thymic aplasia⁵⁷
 - c. CD45 deficiency⁵⁸
 - d. X-linked severe combined immunodeficiency syndrome⁵⁹
3. Major histocompatibility complex class II deficiency—bare lymphocyte syndrome (Chap. 80)⁶⁰
4. IgG and IgA deficiencies and impaired cellular immunity (type I dysgammaglobulinemia)⁶¹
5. Thymoma-associated immunodeficiency⁶²
6. Pyridoxine deficiency⁶³
7. Reticular agenesis (congenital aleukocytosis)⁶⁴
8. Omenn syndrome (Chap. 80)⁶⁵
9. Warts, hypogammaglobulinemia, infections, myelokathexis (WHIM) syndrome resulting from mutation in the *CXCR4* gene (Chap. 80)

D. Natural killer cells (Chaps. 77 and 94)

1. Chronic natural killer cell lymphocytosis^{72–74}

II. Acquired disorders**A. AIDS (Chap. 81)****B. Reactive lymphocytosis or plasmacytosis (Chap. 79)**

1. *Bordetella pertussis* lymphocytosis (Chap. 79)
2. Cytomegalovirus mononucleosis (Chap. 82)
3. Drug-induced lymphocytosis⁷⁵
4. Stress-induced lymphocytosis⁷⁶
5. Persistent polyclonal B-cell lymphocytosis⁷⁷
6. Postsplenectomy lymphocytosis⁷⁸
7. Epstein-Barr virus mononucleosis (Chap. 82)
8. Inflammatory (secondary) plasmacytosis of marrow
9. Large granular lymphocytosis (Chap. 94)
10. Other viral mononucleosis (Chap. 82)
11. Polyclonal lymphocytosis (Chap. 79)

(Continued)

organisms associated with formation of immune granulomas. Th2-type CD4+ Th cells, on the other hand, appear better suited to induce B-cell responses to antigen and direct the immune response against parasitic infestations (Chap. 76). Deficiency or defects in CD4+ regulator T cells (T_{REGs}) can result in autoimmune disease, whereas depletion or deficiency of Th17 cells can result in impaired resistance to opportunistic infection (Chap. 76). Depletion of CD4+ T cells in patients infected with human immunodeficiency virus accounts in large part for the acquired immune deficiency that develops in patients infected with the virus (Chap. 81).

T lymphocytes within a marrow allograft are responsible for initiation of the graft-versus-host disease (GVHD) (Chap. 23). Acute GVHD can lead to severe dermatitis, gastroenteritis, and hepatitis. Chronic GVHD can encompass a collage of connective tissue diseases, such as scleroderma, xerophthalmia, xerostomia, and pulmonary insufficiency, specifically bronchiolitis obliterans. Eosinophilia, hypergammaglobulinemia, development of autoantibodies, and plasmacytosis can occur. Infection with classic or opportunistic pathogens is a common complication of both acute and chronic GVHD. A similar qualitative reaction, albeit more limited, is seen in mononucleosis resulting from Epstein-Barr virus infection (Chap. 82).

COMBINED T- AND B-CELL DISORDERS

Combined T- and B-cell deficiency and dysfunction can result in heterogeneous group of disorders that affect both cellular and humoral immunity. The disorder can be severe (severe combined immune deficiency [SCID]) or mild depending on whether the defect is partial (hypomorphic defects) or complete (null or amorphic defects). Complete defects can result in early death, typically during the first year of life, from uncontrolled infection. An extreme form of SCID is the T-cell-negative, B-cell-negative, NK-cell-positive phenotype with children presenting early in life with severe infections, failure to thrive, and low-to-absent T- and B-cell numbers and function. Advances in gene therapy and allogeneic stem cell transplantation offer hope in some cases (Chap. 80).

NATURAL KILLER CELL DISORDERS

Chronic NK cell lymphocytosis is a rare proliferative disorder that can be distinguished from NK cell leukemia and lymphoma by its indolent nature (Chap. 77). Patients typically have neutropenia, anemia, vasculitic syndromes, fever of unknown origin, constitutional symptoms, cutaneous lesions and autoimmune disorders, including rheumatoid arthritis, Sjögren syndrome, and/or polymyalgia rheumatica. Studies seeking to define this condition as a clonal disorder using X-linked gene analysis have not yielded consistent findings (Chap. 77).

CHAPTER 79

LYMPHOCYTOSIS AND LYMPHOCYTOPENIA

Sumithira Vasu and Michael A. Caligiuri

SUMMARY

Lymphocytosis is defined as an absolute lymphocyte count exceeding $4 \times 10^9/L$, whereas *lymphocytopenia* is defined as a total lymphocyte count less than $1.0 \times 10^9/L$. Lymphocytosis can be categorized as either polyclonal or monoclonal. *Monoclonal lymphocytosis* reflects an underlying clonal lymphoid disease in which the numbers of lymphocytes are increased because of the acquisition of somatic mutations resulting in clonal expansion of a lymphocyte progenitor. This expansion can be stable, such as monoclonal B-cell lymphocytosis or a progressive malignancy such as acute lymphocytic leukemia, whereas *polyclonal lymphocytosis* is most commonly the result of stimulation or a reaction to factors extrinsic to lymphocytes, generally infections and/or inflammation. Lymphocytopenia, on the other hand, typically reflects depletion of T cells, the most abundant lymphocyte subtype in the blood. The most common cause of such T-cell depletion is a viral infection, such as infection with the human immunodeficiency virus, although other causes exist. This chapter outlines the conditions associated with abnormalities in the numbers of circulating lymphocytes in the blood. It also serves as a useful road map to other chapters in the book that describe in detail those conditions that commonly are associated with abnormalities in the absolute numbers of circulating lymphocytes.

LYMPHOCYTOSIS

DEFINITION

Lymphocytosis is defined as an absolute lymphocyte count exceeding $4 \times 10^9/L$, although somewhat higher threshold values (e.g., $>5.0 \times 10^9/L$) are sometimes used. The normal absolute lymphocyte count is significantly higher in childhood. Chapter 2 describes the methods for determining the absolute lymphocyte count and the normal range for such counts in older children and adults (see Chap. 2, Tables 2-1 and 2-2). Tables 7-3 and 7-4 in Chapter 7, provide the lymphocyte counts and lymphocyte subset counts in newborns and infants.

The blood film of patients with lymphocytosis should be evaluated for a predominance of reactive lymphocytes associated with infectious

mononucleosis (Chap. 82), large granular lymphocytes associated with large granular lymphocytic leukemia (Chap. 94), smudge cells associated with chronic lymphocytic leukemia (CLL; Chap. 92), or blasts of acute lymphocytic leukemia (Chap. 91). Chapter 73 provides a description of normal lymphocyte morphology.

Characterization of cell-surface markers is valuable in distinguishing primary lymphocytosis (leukemic) from secondary lymphocytosis (reactive). Improvements in flow cytometric techniques and reagents have allowed clinical laboratories to perform flow cytometric immunophenotyping to distinguish benign from neoplastic lymphoproliferative disease.¹ Analysis for immunoglobulin or T-cell receptor gene rearrangement also may provide evidence for monoclonal B-cell or T-cell proliferation, respectively.^{1,2}

PRIMARY LYMPHOCYTOSIS

Primary lymphocytosis defines conditions associated with an increase in the absolute number of lymphocytes secondary to an intrinsic defect in the expanded lymphocyte population (Table 79-1). These conditions also are referred to as *lymphoproliferative disorders* and most commonly are secondary to the neoplastic accumulation of monoclonal B cells, T cells, natural killer (NK) cells, or less fully differentiated cells of the lymphoid lineage. Table 79-1 lists the chapters describing each of these conditions.

Although patients with lymphocytosis secondary to lymphoproliferative disease generally maintain abnormal lymphocyte counts that rise over time, this finding is not invariable. Patients with large granular lymphocytic leukemia (Chap. 94) may have only transient lymphocytosis that is induced by stress or exercise.

Monoclonal B-Cell Lymphocytosis

The advent of multiparameter flow cytometric and molecular diagnostic techniques has identified a syndrome in patients who have expanded populations of monoclonal B cells without other associated clinical signs or symptoms.³ This condition, monoclonal B-cell lymphocytosis (MBL) has generated a series of clinical and biologic studies investigating the prognosis and implications of this condition. An absolute B-cell count of less than $5.0 \times 10^9/L$ rather than the absolute lymphocyte count is used to distinguish MBL from CLL (Chap. 92).⁴ This threshold is essentially arbitrary and is not based on objective clinical outcome data. MBL could be diagnosed in two situations: in subjects with a normal lymphocyte count via a screening assay (screening MBL) or during a clinical evaluation of lymphocytosis (clinical MBL).⁵⁻⁸ Screening MBL, also commonly referred to as low-count MBL (<500 monoclonal B cells per μL) is diagnosed when high-sensitivity flow cytometric techniques are used in unaffected sibling families with a genetic predisposition to CLL.⁹ Prevalence of screening MBL increases with age from 2.1 percent in individuals between 40 and 60 years of age up to 5 percent in individuals older than age 60 years.¹⁰ Single-cell analysis in familial CLL kindreds showed oligoclonality, suggesting a model of stepwise progression to CLL.¹¹ MBL also has been detected in blood donors, with a prevalence of 6.0 to 8.3 percent in donors age 45 years or older.¹² This study detected presence of a MBL clone in 149 of 2098 donors, showing that MBL prevalence is much higher in blood donors than previously reported.¹³ This finding has generated interest given a meta-analysis showing higher risk of non-Hodgkin lymphoma and CLL in patients who received blood transfusions.¹⁴ Individuals with known clinical MBL should not be considered suitable for blood donation. Whether this applies to screening MBL is a matter of investigation. The 10 percent prevalence of screening MBL among relatives of patients with CLL has led to questions concerning their suitability as stem cell donors for patients with CLL requiring allogeneic stem cell transplantation.¹⁵

Clinical MBL is more commonly encountered in clinical practice when patients are evaluated for lymphocytosis. A prospective study evaluated classic and new prognostic markers (*IGHV* mutational status and chromosomal abnormalities) in patients with clinical MBL and Rai stage 0 CLL.¹⁶ No significant differences were found either in *IGHV/IGHD/IGHJ* usage between the two patient groups. Similar gene and microRNA (miRNA) signatures were seen in both groups suggesting that the two conditions have an indistinguishable biologic profile but differ only in the initial size of the monoclonal population.¹⁷ This condition is biologically indistinguishable from CLL. Given the seriousness of a diagnosis of CLL, investigators have sought to evaluate how the B-cell clone relates to the clinical outcome of development into CLL.^{16,18} The consensus is that the risk of progression requiring CLL-specific treatment among individuals with clinical MBL is 1 to 2 percent per year compared to 5 to 7 percent per year for individuals with Rai stage 0 CLL.^{6,10,19–22} In contrast to this quantifiable progression for clinical MBL, progression to CLL is extremely rare among individuals with screening MBL.²³ In addition, a cohort study showed that clinical MBL was an independent risk factor for hospitalization for infection after controlling for age and gender compared to a control cohort.²⁴ Thus, individuals with clinical MBL should be followed with a physical examination and complete blood counts by a hematologist every 6 to 12 months, while longer followup intervals of 12 to 18 months are

recommended in screening MBL. Clinical MBL should also be counseled about screening for second primary malignancies. [Table 79–2](#) lists the features of screening MBL and clinical MBL.

Persistent Polyclonal Lymphocytosis of B Lymphocytes

Persistent polyclonal B-cell lymphocytosis (PPBL) is defined as a chronic, moderate increase in absolute lymphocyte counts ($>4 \times 10^9/L$) without evidence for infection or other conditions that can increase the lymphocyte count.²⁵ This type of lymphocytosis is a rare disorder that mostly affects middle-age women and is associated with smoking. It is characterized by the persistent expansion of CD27+immunoglobulin (Ig) M+IgD+ B cells, the presence of circulating binucleated lymphocytes and increased IgM serum levels.^{26,27} Such patients have an accumulation of polyclonal B cells that have an unusual binucleated appearance on the blood film.²⁸ Specific morphologic features predictive of the diagnosis include basophilic vacuolated cytoplasm and monocytoid changes.^{28,29} These lymphocytes typically have low-to-negligible expression of CD5 or CD23 found in patients with CLL and are polyclonal with respect to light-chain expression and immunoglobulin heavy-chain gene rearrangements ([Fig. 79–1](#)).^{30,31}

The B cells commonly express relatively high levels of IgD and CD27, a phenotype shared with that of memory B cells (Chap. 75).³² Consistent with this phenotype, the immunoglobulin variable-region

TABLE 79–2. Characteristics of Clinical and Screening Monoclonal B-Cell Lymphocytosis

	Clinical MBL	Screening MBL
Risk of transformation to CLL-requiring therapy	1–2% per year	Extremely rare

genes used by the B cells most commonly have evidence of somatic mutations, implying that the expanded B cells have undergone germinal center maturation in an immune response(s) to antigen(s).^{33,34} Analyses of the immunoglobulin variable-region genes expressed by memory-type B cells of patients failed to reveal evidence of positive antigenic

selection, suggesting that inappropriate clearance of B cells expressing low-affinity immunoglobulin receptors plays a role in this disorder.³⁵

The cause(s) of this type of lymphocytosis is unknown. Gender and genotype may be important in the pathogenesis, as the patients most commonly are young to middle-age women who often are human

Figure 79–1. Persistent polyclonal lymphocytosis of B lymphocytes. Blood film. **A** to **C**. Examples of the nuclear abnormality of lymphocytes in this disorder. The lymphocyte nucleus may be bilobed or segmented although not fully bilobed. Some are monolobed. **D**. Light chain analysis. Immunoenzymatic method. Cytocentrifuge cell preparation. leukocyte antigen (HLA)-DR7 positive.³⁶ In addition, there are shared cases among identical twins and in families.^{37,38} Moreover, evaluation of first-degree relatives of individuals with this type of lymphocytosis may identify new patients who have all the criteria for its diagnosis or have slight increases in serum IgM, suggesting a possible hereditary or genetic contribution to the pathogenesis.³⁹

Patients can have features resembling those of patients with various monoclonal B-cell malignancies. Patients may have mild splenomegaly.⁴⁰ Histologic examination of marrow and secondary lymphoid tissues from patients with progressive splenomegaly can reveal features resembling marginal zone B-cell lymphoma (Chap. 101).⁴¹ In possibly another manifestation of this syndrome, first identified in Japan as hairy B-cell lymphoproliferative disorder, the patients can present with anemia, thrombocytopenia, and splenomegaly and have an excess of polyclonal B lymphocytes that appear similar in morphology and immune phenotype to the neoplastic B cells in hairy cell leukemia (Chap. 93).^{42,43}

Although the lymphocytosis generally is not progressive, most patients have small numbers of blood B cells with chromosomal abnormalities. These abnormalities can include an additional isochromosome +i(3q) and premature chromosome condensation, and/or the t(14;18) translocation involving the *BCL-2* and immunoglobulin heavy-chain loci that typically is found in the neoplastic B cells of patients with follicular lymphoma (Chap. 99).⁴⁴⁻⁴⁷ In another study of 43 patients, two-thirds of patients had lymphocytes with independent chromosomal abnormalities, such as del(6q), +der, +8, or other polyploidy karyotypic abnormalities.^{48,49} In any one patient, these chromosomal abnormalities are restricted to B lymphocytes independent of their expression of immunoglobulin or light chains.⁵⁰ For cases associated with smoking, these cytogenetic abnormalities apparently persist after the discontinuation of tobacco use.^{36,51} The finding of such chromosome abnormalities is consistent with the notion that this disorder represents a preneoplastic state. Extensive proliferation of CD27+ IgM+IgD+ cells have been noted as well, which may explain the finding of splenomegaly.²⁶ Occasional reports of clonal immunoglobulin gene rearrangements in this disorder suggest that polyclonal expansion in some cases may be followed by the emergence of one predominant clone.⁴⁰ Moreover, a small proportion of patients ultimately develop monoclonal B-cell lymphoma or B-cell leukemia.^{40,52,53}

SECONDARY (REACTIVE) LYMPHOCYTOSIS

Secondary lymphocytosis defines conditions associated with an increase in the absolute number of lymphocytes secondary to a physiologic or pathophysiologic response to infection, toxins, cytokines, or unknown factors.

Infectious Mononucleosis

The most common reactive lymphocytosis is infectious mononucleosis (see Table 79-1). In cases of mononucleosis secondary to infection with Epstein-Barr virus (EBV), the atypical lymphocytes commonly consist of polyclonal populations of CD8+ T cells, γ/δ T cells, and CD16+CD56+ NK cells that are stimulated in response to EBV-infected B cells (see Chap. 82, Fig. 82-1).⁵⁴ A study prospectively evaluated university students to determine the incidence, risk factors, and virologic and immune correlates of disease severity.⁵⁵ During a median of 3 years of observation of EBV antibody-negative students, 66 subjects experienced primary infection. Of these, 77 percent had infectious mononucleosis, 12 percent had atypical symptoms, and 11 percent were asymptomatic. Although viremia was transient, median oral shedding was 175 days. Increases were observed in numbers of NK cells and CD8+ T cells but not in numbers of CD4+ T cells during acute infection. Severity of illness correlated with both blood EBV load ($P = 0.015$) and CD8+ lymphocytosis ($P = 0.0003$).

Acute Infection Lymphocytosis

Acute infection lymphocytosis is a disorder that occurs in children usually between the ages of 2 and 10 years. It is characterized by an increase in blood lymphocytes, often to 20 to 30 $\times 10^9/L$ ⁵⁶ and occasionally as high as 100 $\times 10^9/L$, which might be mistaken for acute leukemia.⁵⁷ The lymphocytes may vary in size but are otherwise similar to normal blood lymphocytes (Fig. 79-2). Patients usually are asymptomatic but may have fever, abdominal pain, or diarrhea. Lymph node enlargement and splenomegaly do not occur, and the patient's serum usually is negative for heterophile antibodies found in patients with infectious mononucleosis caused by EBV. In this regard, the disease resembles infectious mononucleosis caused by viruses other than EBV, such as cytomegalovirus (CMV; Chap. 82).⁵⁸⁻⁶⁰ Clinical symptoms last for a few days, but the lymphocytosis may persist for several weeks. Eosinophilia may be present. Examination of marrow from a few patients has shown minimal increases in lymphocytes, but marked infiltration with lymphocytes also has been observed. In some cases, the lymphocytosis has been found in association with acute infection by coxsackievirus B2.⁶¹

Bordetella pertussis

A marked increase in the number of lymphocytes occurs in patients infected with the Gram-negative bacterium *Bordetella pertussis*.⁶² Absolute lymphocyte counts range from 8 to 70 $\times 10^9/L$, with a mean of approximately 30 $\times 10^9/L$, involving all lymphocyte subsets.⁶³ A notable proportion of lymphocytes have cleaved nuclei, characteristic of the cells in cases of pertussis (see Chap. 73, Fig. 73-1C).

Lymphocytosis primarily results from failure of lymphocytes to leave the blood because of *pertussis toxin*, which is released by the bacteria.⁶⁴ Pertussis toxin is an adenosine diphosphate ribosylase that modifies G proteins in mammalian lymphocytes. This inhibits the capacity of lymphocytes to traffic from blood into lymphoid tissues, primarily through inhibition of chemokine receptors. Pertussis toxin also may stimulate egress of maturing T cells from the thymus and may bind to neuraminic acid residues of T-cell surface glycoproteins to induce T-cell activation.^{65,66} Despite high levels of vaccination, recent epidemics have been noted primarily as a result of waning immunity in adults who subsequently serve as a source of infection to household infants.⁶⁷

Large Granular Lymphocytosis

Large granular lymphocytosis can result from expansions of NK cells, CD8+ T cells, or, more rarely, CD4+ T cells.^{68,69} In the most common form, the lymphocytosis is secondary to CD3-CD16+CD56+ NK cells and is termed *NK lymphocytosis*, in which NK cell counts typically approximate 4 $\times 10^9/L$, but can sometimes exceed 15 $\times 10^9/L$.⁷⁰ The blood lymphocytes of patients with T-cell large granular lymphocytosis should be evaluated for clonal rearrangements in the T-cell receptor genes (Chap. 76),⁵¹ which would be indicative of T-cell large granular lymphocytic leukemia (LGLL); LGLL is a heterogeneous disorder characterized by an increase in the number of blood large granular lymphocytes between 2 and 20 $\times 10^9/L$ for more than 6 months without a clearly identified cause (see Chap. 94, Fig. 94-1).⁷¹ Currently NK cell lymphoproliferative disorder is considered as a provisional entity, distinct from T-LGLL and NK-LGLL in the 2008 WHO (World Health Organization) classification. A retrospective review compared clinical and pathologic features between patients with T-LGLL and chronic NK lymphocytosis.⁷² They noted that median age, association with autoimmune diseases and hematologic malignancies were similar between the two groups. However, neutropenia and association with rheumatoid arthritis was less prevalent in NK cell lymphoproliferative disorder than in T-LGLL.

Large granular lymphocytosis has been observed in 20 percent of allogeneic stem cell transplant recipients for a variety of malignancies with a median onset of 312 days from transplant.⁷³ CMV-seropositive

Figure 79-2. Blood films. **A.** Acute infectious lymphocytosis. The lymphocytosis in this disorder of childhood is composed of normal-appearing lymphocytes, which may vary somewhat in size as shown in the blood of this case. Note typical small lymphocyte with dense chromatin pattern and scant rim of cytoplasm and somewhat two larger lymphocytes with less-dense chromatin pattern. **B, C.** Reactive lymphocytes. Large lymphocytes with an increased proportion of cytoplasm with basophilic cytoplasmic edges, often engaging neighboring red cells. Nucleoli may occasionally be evident. This variation in lymphocyte appearance can occur in a variety of disorders that provoke an immunologic response, including viral illnesses. They are indistinguishable in appearance by light microscopy from the reactive lymphocytes seen in infectious mononucleosis, viral hepatitis, or other conditions such as Dengue fever. **D to F.** Plasma cytoid lymphocytes. In this type of reactive lymphocytosis, the lymphocytes are large and have deep blue-colored cytoplasm, approaching the coloration of plasma cell cytoplasm, but they retain the nuclear appearance, cell shape, and cell size of a medium-size lymphocyte, and they do not develop a prominent paranuclear clear zone or markedly eccentric nuclear position as do most plasma cells. They may be seen in a variety of situations including infections, drug hypersensitivity, and serum-sickness-type reactions. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

recipients and patients who developed CMV reactivation and chronic graft-versus-host disease (GVHD) were more likely to develop large granular lymphocytosis. GVHD is a condition occurring after allogeneic hematopoietic stem cell transplantation when alloreactive T lymphocytes from the graft attack host organs, resulting in protean manifestations in multiple organs, and can cause severe debilitation. Surprisingly, presence of large granular lymphocytosis was associated with an overall survival advantage (86.2 percent vs. 53.8 percent, $p < 0.0001$), lower nonrelapse mortality (3.2 percent vs. 27.3 percent, $p < 0.0001$) and lower relapse incidence (9.6 percent vs. 29.4 percent, $p < 0.0001$).

Expansion of NK cells or T cells may represent an exaggerated response to systemic infection and/or immune deregulation. T-cell large granular lymphocytosis may be secondary to an exaggerated cellular immune response to infection with human CMV.⁷⁴ Also, there is an association between NK lymphocytosis and strongyloidiasis.⁷⁵

Patients with NK lymphocytosis frequently have recurrent cutaneous lesions, such as livedoid vasculopathy, urticarial vasculitis, or complex recurrent aphthous stomatitis.^{76,77} Other reports noted an association between NK lymphocytosis and various cytopenias, including severe aplastic anemia.^{70,78} Large granular lymphocytosis also may be associated with rheumatoid arthritis. Occurring in less than 0.6 percent of patients with rheumatoid arthritis, large granular lymphocytic lymphocytosis almost invariably is associated with neutropenia in the absence of splenomegaly and thus may represent a subset of

Felty syndrome.^{79,80} Patients with autoimmune pure red cell aplasia or immune thrombocytopenia also may have large granular lymphocytosis secondary to expanded numbers of polyclonal T cells or NK cells.^{81,82}

Drug-Induced Lymphocytosis

Dasatinib and ibrutinib are associated with lymphocytosis when used for chronic myelogenous leukemia (CML) and CLL, respectively. In patients receiving dasatinib, expansion of highly differentiated CD8+ T lymphocytes or NK cells have been noted.⁸³⁻⁸⁵ Some studies associate oligoclonal expansions of these cells to clinical effects such as CMV reactivation and pleural effusion.⁸⁶ Clonal lymphocytosis usually has LGLL morphology and also show late differentiated (CD27-CD57+) phenotypes that seem predisposed to apoptosis and reduced NK-cell cytotoxicity. In addition to lymphocytosis, plasma levels of interleukin (IL)-6, monokines induced by interferon- γ (IFN- γ) and IL-2R were significantly increased in LGLL patients. IFN- γ is a soluble cytokine critical for innate and adaptive immunity against viral, bacterial and protozoal infections. IL-2 is also a cytokine that has effects on T lymphocytes and has key functions in tolerance and immunity. Some studies suggest that lymphocytosis after dasatinib is associated with a favorable response in CML.⁸⁷

Ibrutinib targets B-cell receptor signaling and has been approved for use in CLL.⁸⁸ After just one dose of ibrutinib, increases in the absolute lymphocyte count of up to 66 percent can occur, representing egress

of lymphocytes from nodal compartments.⁸⁹ Although this resolves within 8 months in most patients, a small minority has sustained lymphocytosis lasting more than a year. Biologic characterization of the lymphocytosis has shown that the persistent CLL cells do not proliferate and do not represent clonal evolution. The prolonged lymphocytosis likely represents a persistent quiescent clone and is not associated with a risk of relapse.⁹⁰

Stress Lymphocytosis

Transient stress lymphocytosis has been identified as a common cause of lymphocytosis in patients admitted to a hospital.⁹¹ Both trauma and non-traumatic stress have been associated with lymphocytosis.^{92,93} Trauma, surgery, acute cardiac failure, septic shock, myocardial infarction, sickle cell crisis, or status epilepticus may be associated with an elevated lymphocyte count, often greater than $5 \times 10^9/L$, which may revert to normal or below-normal levels within hours.^{94,95} The increased lymphocyte count appears promptly after the event and appears secondary to lymphocyte redistribution affecting all major lymphocyte subsets.⁹² A transient lymphocytosis can be induced by the redistribution of leukocyte subsets after both physical and psychological stress.^{96,97} Characteristically, two phases are recognized after catecholamine administration: a quick (<30 minutes) mobilization of lymphocytes, followed by an increase in granulocyte numbers with decreasing lymphocyte numbers.^{98,99}

Hypersensitivity Reactions

Delayed hypersensitivity reactions to insect bites, especially mosquitos, may be associated with a large granular lymphocytic lymphocytosis and adenopathy.¹⁰⁰ These delayed hypersensitivity reactions can be associated with EBV-NK lymphocytosis.¹⁰¹ Idiosyncratic drug reactions also may be associated with subacute lymphocytosis, typically developing 2 to 8 weeks after initiating administration of the responsible drug.¹⁰²⁻¹⁰⁷ An infectious mononucleosis-like syndrome can be induced in some patients by salazosulfapyridine or sulfasalazine (see Fig. 79-2).¹⁰⁸

Persistent Lymphocytosis

Patients may have subacute or chronic lymphocytosis, termed *persistent lymphocytosis*, in association with a variety of clinical conditions (see Table 79-1).

Patients with lymphocytosis may have underlying neoplastic disease. Most notably, patients with malignant thymoma may have a polyclonal T-cell lymphocytosis thought to be secondary to the aberrant release of thymic hormones by the neoplastic epithelium.¹⁰⁹⁻¹¹¹ A reactive lymphocytosis or plasmacytosis may be detected in patients with acute myeloid leukemia or systemic mastocytosis.¹¹²⁻¹¹⁴ Patients with solid tumors also may develop lymphocytosis following cancer chemotherapy.

Patients may develop polyclonal lymphocytosis following splenectomy.^{76,115,116} An absolute lymphocyte count ranging from 4.0 to $8.7 \times 10^9/L$ often is noted 4 to 242 (median: 70) months after splenectomy and can persist for prolonged periods (e.g., longer than 50 months).

Chronic Infections A reactive lymphocytosis commonly is associated with many viral and certain bacterial infections, which, if protracted, can result in subacute or chronic lymphocytosis (see Table 79-1).¹¹⁷

LYMPHOCYTOPENIA

DEFINITION

Chapter 2 presents the methods for determining the absolute lymphocyte count and the normal range for such counts. *Lymphocytopenia* is defined as a total lymphocyte count less than $1.0 \times 10^9/L$, but some consider the lower limit of normal to be $1.5 \times 10^9/L$ ($1500/\mu L$).

Because approximately 80 percent of normal adult blood lymphocytes are T lymphocytes and nearly two-thirds of blood T lymphocytes are CD4+ (helper) T lymphocytes, most patients with lymphocytopenia have reductions in the absolute numbers of T lymphocytes, particularly CD4+ T lymphocytes. The average absolute number of T lymphocytes in normal adult blood is $1.9 \times 10^9/L$, ranging from 1.0 to $2.3 \times 10^9/L$. The average absolute number of CD4+ T lymphocytes is $1.1 \times 10^9/L$, ranging from 7.2 to $14 \times 10^8/L$. The average absolute number of cells of the other major T-cell subgroup, CD8+ T lymphocytes, is $6.5 \times 10^8/L$, ranging from 3.8 to $9.7 \times 10^8/L$.

Table 79-3 summarizes the conditions associated with lymphocytopenia. The mechanism of lymphocytopenia is not established for many of these disorders, and several possible mechanisms exist. Further discussion of lymphocytes and of the diseases associated with lymphocytopenia are presented in the cited reports (see Table 79-3).

The relative incidence of each of these conditions varies, depending upon the patient population. In one New Zealand survey of patients who had significant lymphocytopenia ($<0.6 \times 10^9/L$), the patients fell into several categories with some overlap.¹¹⁸ In order of decreasing frequency, the factors associated with lymphocytopenia were bacterial or fungal sepsis (250 patients), major surgery (228 patients), definite (153 patients) or suspected (53 patients) glucocorticoid therapy, malignancy (180 patients), cytotoxic therapy and/or radiotherapy (90 patients), recent trauma or hemorrhage (86 patients), renal allograft (38 patients), marrow allograft (35 patients), "viral infections" other than HIV (26 patients), or infection with HIV (13 patients). Only one patient was suspected of having idiopathic CD4+ T lymphocytopenia.

INHERITED CAUSES

Patients with inherited immunodeficiency diseases may have associated lymphocytopenia (see Table 79-3 and see Chap. 80, Table 80-2). Inherited immunodeficiency disorders may have a quantitative or qualitative stem cell abnormality, resulting in ineffective lymphopoiesis (see references cited in Table 79-3). Moreover, mutations in the genes that are critical for T-cell development can result in severe combined immunodeficiency and lymphocytopenia as a consequence of the inability to generate mature T cells (Chap. 76).¹¹⁹ Other immune deficiencies, such as the Wiskott-Aldrich syndrome, have associated lymphopenia because of premature destruction of T cells secondary to a defect in the lymphocyte cytoskeleton.¹²⁰ Studies have reported that certain ethnic groups have lower CD4+ T-cell counts in the absence of other identified factors, for example, Ethiopians and Chukotka natives.^{121,122}

ACQUIRED LYMPHOCYTOPENIA

Acquired lymphocytopenia defines syndromes associated with depletion of blood lymphocytes that are not secondary to inherited disease.

Infectious Diseases

The most common infectious disease associated with lymphopenia is AIDS caused by HIV (Chap. 81). The lymphocytopenia results in part from destruction and/or clearance of CD4+ T cells infected with HIV-1 or HIV-2.^{123,124}

Other viral and bacterial diseases may be associated with lymphocytopenia (see Table 79-3). Patients presenting with active tuberculosis often have lymphocytopenia, even if they are HIV negative and this usually resolves 2 weeks after initiating appropriate antimicrobial therapy.¹²⁵⁻¹²⁷ Patients with severe acute respiratory syndrome resulting from infection with coronavirus typically have lymphocytopenia that resolves following recovery.^{128,129} Several other common viral diseases, such as measles, typically are associated with transient lymphocytopenia during the acute phases of infection, which in turn is thought to contribute to

--	---

a disease course-related immunodeficiency that can predispose patients to infection with opportunistic infectious agents (see Table 79–3).¹³⁰ The prognostic value of lymphocytopenia as a consequence of sepsis has been evaluated.¹³¹ In a single-center retrospective study, persistent lymphopenia on the fourth day after the diagnosis of sepsis predicted both 28-day and 1-year survival. Lymphopenia is considered a surrogate marker for sepsis-induced immunosuppression. In patients hospitalized with decompensated heart failure, relative lymphocytopenia

(decrease in percent of lymphocytes, not absolute lymphocyte count) was frequently noted.¹³²

Iatrogenic

Radiotherapy, cytotoxic chemotherapy, glucocorticoids, or administration of antilymphocyte globulin or alemtuzumab (Campath-1H) each can lead to lymphocytopenia by destroying circulating lymphocytes (see Table 79–3). Long-term treatment of psoriasis with psoralen and

ultraviolet A irradiation may result in T-lymphocyte lymphopenia, possibly through destruction of cells circulating through the cutaneous vasculature.¹³³ The mechanism by which glucocorticoids cause lymphocytopenia is not clear, but may be secondary to a glucocorticoid-induced redistribution of lymphocytes in addition to induced cell destruction.^{134–136} Redistribution also may be responsible for the lymphocytopenia occurring after surgery.^{137,138} In thoracic duct drainage, the lymphocytes are lost from the body.¹³⁹ Platelet or stem cell apheresis similarly lowers the lymphocyte count because of inadvertent removal of lymphocytes with the platelets.¹⁴⁰

Systemic Disease Associated with Lymphocytopenia

Patients with systemic autoimmune disease can have lymphocytopenia, secondary to either the underlying disease or therapy. Patients who present with systemic lupus erythematosus may have autoantibody-mediated lymphocytopenia prior to therapy and the presence of antilymphocyte antibodies was independently associated with disease activity and lupus nephritis.¹⁴¹ Similarly, patients with primary Sjögren syndrome sometimes have lymphocytopenia even prior to therapy and an association between lymphocytopenia and risk of developing lymphoma has been observed.^{142,143} In conditions such as protein-losing enteropathy, lymphocytes may be lost from the body. Severe thermal injury may result in profound T-cell lymphopenia secondary to redistribution of blood T cells to the tissues.¹⁴⁴ Lymphopenia has also been noted to be an independent predictor of poor outcomes in heart failure patients requiring hospitalization. Patients with low lymphocyte counts tend to be older with higher rates of comorbid diseases such as diabetes, renal disease, atrial fibrillation and have high levels of brain natriuretic peptides (BNPs) and wide QRS intervals on electrocardiography. After adjusting for multiple known clinical risk factors, lymphocytopenia remains a strong predictor of all-cause or cardiovascular mortality.¹⁴⁵

Nutritional or Dietary

Zinc is essential for normal T-cell development and function.^{146,147} Low zinc levels have been observed in critically ill children within 72 hours of admission to an intensive care unit.¹⁴⁸ Zinc therapy corrects the lymphocytopenia of zinc deficiency, and lymphocytic function is restored. Excessive intake of ethanol and/or chronic ethanol use may result in impaired lymphocyte proliferative responses and lymphopenia, which may resolve with abstinence from alcohol.¹⁴⁹ Concerns over whether the soy isoflavones found in soy protein can factor in the development of lymphocytopenia appear unjustified.¹⁵⁰

IDIOPATHIC CD4+ T LYMPHOCYTOPENIA

The advent of immunophenotyping and HIV serologic testing has identified a syndrome of isolated CD4+ T-cell depletion in the absence of evidence for retroviral infection.¹⁵¹ The syndrome, termed *idiopathic CD4+ T lymphocytopenia* by the Centers for Disease Control and Prevention in 1993, is defined by the WHO as a CD4+ T-lymphocyte count less than $0.3 \times 10^9/L$ on two separate occasions in patients without serologic or virologic evidence of HIV-1 or HIV-2 infection.¹⁵² Unlike HIV infection, the decrease in the CD4 cell counts of patients with idiopathic CD4+ T lymphocytopenia is generally slow.¹⁵³ It is important to exclude congenital immunodeficiency diseases, such as common variable immunodeficiency, which may lead to altered CD4+ T-cell counts that are recognized in later life (Chap. 80).^{123,154}

Although some patients with idiopathic CD4+ T lymphocytopenia do not have any clinical manifestations, more than half of all reported cases had prior opportunistic infections indicative of a cellular immunodeficiency (e.g., recurrent herpes zoster, pulmonary *Mycobacterium avium*, *Mycobacterium tuberculosis*, *Pneumocystis carinii* pneumonia,

toxoplasmosis, neuroinvasive West Nile disease, progressive multifocal leukoencephalopathy, or cryptococcal infections).^{155–159} The WHO classifies such patients as having idiopathic CD4+ T lymphocytopenia and severe unexplained HIV-seronegative immune suppression.¹²³

Several observations have helped understand the pathogenesis of idiopathic lymphocytopenia. Lymphocyte-specific kinases (LCKs) play a key role in initiation of signaling from the T-cell receptor (TCR). TCR activates LCK through the adaptor protein, uncoordinated 119 (UNC119).¹⁶⁰ Consequently a mutation of human UNC119 impairs LCK activation resulting in diminished T-cell responses to TCR stimulation and clinically manifests as lymphopenia and opportunistic infections. A heterozygous mutation of UNC119 has been noted in patients with Idiopathic CD4+ T-lymphocytopenia.¹⁶¹ IL-7 and IL-2 signaling have been shown to be impaired in this condition, which may explain for the loss of CD4+ T-lymphocyte homeostasis.¹⁶² The exact proportion of patients with this disorder is unknown because patients who are not affected clinically by the isolated CD4+ T-cell depletion may not come to medical attention. In conclusion, idiopathic CD4+ T lymphocytopenia is a heterogeneous condition diagnosed typically in middle age and is associated with multiple opportunistic infections and autoimmune diseases. Experimental cytokine therapies with IL-2 have been evaluated in these patients.¹⁶³
