CHAPTER 108

IMMUNOGLOBULIN LIGHT-CHAIN AMYLOIDOSIS

Morie A. Gertz, Taimur Sher, Angela Dispenzieri, and Francis K. Buadi

SUMMARY

Amyloidosis should be considered in any patient presenting with nephrotic range proteinuria; infiltrative cardiomyopathy or heart failure with preserved ejection fraction; hepatomegaly without specific imaging findings; or peripheral neuropathy, particularly if a monoclonal protein is present; as well as any patient with atypical multiple myeloma.

When a patient is seen with a relevant syndrome, the patient should have immunofixation of serum and urine proteins and measurement of κ and λ immunoglobulin free light chains. If all of these tests are normal, it is unlikely that the patient has immunoglobulin light-chain (AL) amyloidosis.

If any of the above tests are positive, further investigation for amyloidosis should be undertaken. The diagnostic test of choice is subcutaneous fat aspiration; marrow biopsy is the second best procedure. With these two tests, 83 percent of patients will have a positive result when stained with Congo red under green birefringence.

All patients with biopsy proven amyloidosis should have the deposits analyzed by laser capture microdissection mass spectroscopy to definitively classify the exact protein subunit composing the amyloid. This technique does not distinguish between systemic and localized amyloidosis, however.

The prognosis in AL amyloidosis is determined by three tests: (1) the N-terminal probrain natriuretic peptide, (2) serum troponin, and (3) the difference between the involved and uninvolved immunoglobulin free light chains. These three tests can be combined to stage the patient from stage 1 through stage 4.

Treatment of AL amyloidosis involves either standard systemic chemotherapy or high-dose chemotherapy with autologous stem cell transplantation. Fit patients who are expected to have low morbidity with transplantation should undergo this approach. The majority of patients, however, will not be candidates for transplantation and should be treated with traditional systemic chemotherapy; with the cyclophosphamide, bortezomib, and dexamethasone regimen currently favored by many investigators.

DEFINITION AND HISTORY

Amyloidosis is a heterogeneous group of diseases characterized by tissue infiltration with misfolded protein precursors as amyloid material. For nearly 100 years, amyloid has been defined by its staining properties. Divry and Florin first used Congo red to detect amyloid in the

brain of patients with Alzheimer disease.¹ Amyloid deposits are always extracellular and, under the light microscope, appear amorphous and pink when seen after standard hematoxylin-and-eosin staining. All amyloid deposits bind Congo red dye and demonstrate green birefringence under polarized light,² and this test remains the standard diagnostic procedure required to confirm a diagnosis of amyloidosis. Under the electron microscope, amyloid consists of rigid, linear, nonbranching fibrils of 9.5 nm diameter.³ Historically, amyloid was defined based on whether there was a family history (inherited), whether it was the result of a chronic inflammatory condition (secondary), or whether it was idiopathic (primary). Today, amyloidosis is classified based on the protein subunit composition of the deposits. The term “primary amyloid” is archaic and should not be used. Instead, such cases should be called “immunoglobulin light-chain (AL) amyloidosis,” reflecting the fact that they represent a systemic plasma cell dyscrasia. The subunit classification is important because AA amyloidosis (secondary) can be the consequence of sustained inflammation but can also be inherited, as in familial Mediterranean fever. Inherited forms of amyloidosis are generally composed of mutant transthyretin (TTR) but can also be a consequence of mutations in apolipoprotein, fibrinogen, and gelsolin.⁴ Senile systemic amyloidosis, primarily a cardiac disorder, is being increasingly recognized, and is caused by deposition of wild-type TTR as amyloid material in patients older than age 60 years.⁵ Table 108-1 lists the nomenclature of the various forms of amyloidosis. Practicing hematologists and oncologists are not likely to see patients with forms of amyloidosis other than immunoglobulin light-chain (AL) amyloidosis. This is the only form that is responsive to chemotherapy and is the focus of this chapter; additionally, the term *amyloidosis*, unless specified otherwise, refers to *AL amyloidosis*.

EPIDEMIOLOGY

Amyloidosis is rare, with an incidence of eight per million persons per year with a median age at diagnosis of 67 years.¹¹ This makes it one-sixth as common as myeloma and twice as common as Waldenström macroglobulinemia. Conversely, a practicing oncologist should see approximately one light-chain amyloid patient for every six patients with myeloma in the oncologist's practice. If this is not the case, there is a significant likelihood that the disease is going unrecognized.

ETIOLOGY AND PATHOGENESIS

The fibrils of immunoglobulin light chain amyloid are composed, in most patients, of fragments of immunoglobulin light chains. A normal immunoglobulin light chain has a molecular weight of approximately 25 kDa, but the immunoglobulin light chains found in amyloid deposits usually range from 8 kDa to 15 kDa. The fragment size is important because it usually reflects the deletion of the constant region of the immunoglobulin light chain, making immunohistochemistry a poor technique to identify the fibril type in paraffin-embedded tissues.⁶ A fraction of patients have immunoglobulin heavy chain amyloid deposits where fragments of immunoglobulin G, A, or M heavy chains comprise the basic subunit. Whereas AL amyloidosis represents approximately 62 percent of all amyloid patients, immunoglobulin heavy-chain amyloidosis represents less than 1 percent of all patients.⁷

There is clearly something “amyloidogenic” about the immunoglobulin light chains in patients with AL amyloidosis. Unlike monoclonal gammopathy and myeloma where the $\kappa:\lambda$ ratio is 2:1, in AL amyloidosis, the $\kappa:\lambda$ ratio is 1:3, suggesting an intrinsic propensity of λ light chains to form amyloid. Moreover, the subgroup λ_{VI} is exclusively found in patients with AL amyloidosis.⁸ When the light chains

are extracted from the urine of patients with myeloma and injected into mice, amyloid deposits are not seen. However, when the light chains from patients with amyloidosis are extracted from the urine and injected into mice, they will develop amyloidosis.⁸ The exact structural characteristics that lead to the misfolding of the α helical protein into the amyloid β -pleated sheet configuration are unknown. Patients with amyloidosis are classified into those with myeloma and those without myeloma. The percentage of plasma cells present in the marrow at the time of diagnosis is prognostic and predicts outcome in patients with amyloidosis.⁹ As a result, the percentage of plasma cells in the marrow may dictate alternate therapeutic considerations at diagnosis (see “Therapy” below). Overt myeloma with CRAB criteria (hypercalcemia, renal insufficiency, anemia, or bone disease) is uncommon in AL amyloidosis. However, an elevation in the percentage of plasma cells in the marrow of patients without CRAB criteria confers the same adverse prognosis as observed in patients who have overt symptomatic myeloma, and these groups can be considered as a single cohort of myeloma-associated amyloidosis. Patients who do not have myeloma at presentation have almost no chance of developing myeloma later in the course of their disease.¹⁰ The plasma cells in the marrow of patients with amyloidosis tend to be nonproliferative and frequently lack the karyotypic abnormalities typically seen in myeloma, such as $-17p$, $t(4;14)$, and -13 . A translocation 11;14 is commonly seen in amyloidosis and appears to confer an inferior outcome. Circulating plasma cells detectable by flow cytometry are uncommonly seen relative to their frequency in myeloma¹²

CLINICAL FEATURES

Unfortunately, the symptoms of amyloidosis are vague and often nonspecific. Physical findings, when present, can be highly specific but are only present in a minority of patients. For a disease this rare, it

is important for clinicians to have an operational approach to avoid inappropriate resource utilization. Only 1 percent of patients with AL amyloidosis are younger than age 40 years. Consequently, it would be unlikely for younger patients to have AL amyloidosis, although this age group regularly can be seen with secondary systemic amyloidosis. The majority of patients with AL amyloidosis are males (66 percent), unlike myeloma, where the male-to-female is 52:48.¹⁵

The most common symptoms reported by patients with amyloidosis are fatigue, weight loss, and lower-extremity edema. Unfortunately, these symptoms are too nonspecific to be used as a trigger to screen patients, as the yield for these vague symptoms would be very low. The mechanism underlying fatigue in this disorder is usually amyloid heart disease, which can be an extremely subtle diagnosis and is discussed further under the specific amyloid syndromes. Weight loss accompanying amyloidosis can be impressive, and may exceed 20 kg. This usually results in an investigation for occult malignancy; but even if blind biopsies are performed, the diagnosis may be overlooked if a specific request for amyloid stains is not made to the pathologist. Lower-extremity edema may be attributable to nephrotic range proteinuria, hypoalbuminemia, and transudation of serum into the extracellular space. Edema may also be seen from high filling pressures caused by the restrictive cardiomyopathy, which, again, can easily be overlooked because of the subtle diagnostic testing required. These patients are often treated empirically with diuretics until cardiac dysfunction becomes more evident.

The physical findings of amyloidosis are present in only one patient in six. Periorbital purpura is frequently cited as a diagnostic finding and, when present, is useful but is only seen in 15 percent of patients (Fig. 108-1). Sometimes, the purpura is subtle and can only be seen with the patient's eyes closed. Even when purpura is present, it may lead to an evaluation of a coagulopathy or platelet dysfunction, which would invariably be negative in this setting. Purpura not only is seen on the eyelids but also on the face, neck, and anterior chest above the nipple line. Enlargement of the tongue is seen in approximately one person in eight (Fig. 108-2). Dental indentations on the underside of the tongue are characteristic. Often the patient will have sudden-onset of sleep apnea syndrome as a result of occlusion of the airway by the enlarged tongue when the patient is supine.¹⁶ Even when diagnostic findings are present, their significance is often missed, leading in many cases to tongue biopsy with a preoperative suspicion of tongue cancer. Most patients with enlargement of the tongue will also have palpable submandibular lymphadenopathy, usually caused by displacement of the nodes by the enlarged base of the tongue; although amyloid infiltration of the submandibular gland may also result in a firm palpable mass in the submandibular region. Hepatomegaly is seen in approximately 20 percent

Figure 108-1. Amyloid purpura.

Figure 108-2. Macroglossia as a result of amyloid infiltration.

of patients and may be due to direct infiltration of the liver, which will cause a firm markedly enlarged liver.¹⁷ In some patients, however, the liver enlargement is a reflection of high venous filling pressures in the right-sided cardiac chambers and represents chronic passive congestion. Patients rarely have periarticular infiltration of the shoulders producing the so-called shoulder pad sign, a baseball-shaped enlargement of the anterior soft tissues of the shoulder. A rare patient will develop temporal artery infiltration and develop classic jaw claudication, as well as limb, buttock, and calf claudication.¹⁸ On questioning, many patients will have xerostomia from infiltration of the minor salivary glands; and at some centers, biopsy of the minor salivary glands is a preferred technique for the diagnosis of amyloidosis.¹⁹

● AMYLOID SYNDROMES

Because the symptoms of amyloidosis are highly nonspecific and the physical findings are specific but not very sensitive, an operational approach is required to ascertain which patients need investigation for amyloidosis. We recommend screening for AL amyloidosis when a patient is seen with any of the following clinical syndromes:

- Nephrotic range proteinuria with any serum creatinine level
- Infiltrative cardiomyopathy or heart failure with preserved ejection fraction. A normal ejection fraction does not exclude AL amyloidosis
- Hepatomegaly or alkaline phosphatase elevation without specific imaging abnormalities
- A mixed axonal demyelinating peripheral sensory, motor or autonomic neuropathy, particularly when associated with a monoclonal gammopathy
- A patient with myeloma with symptoms that are not typical of the disease, particularly profound, unexplained fatigue

Table 108-2 gives the frequency of amyloid syndromes seen in patients at the Mayo Clinic. If an oncologist sees a patient with one of these five syndromes, or an internist is faced with an undiagnosed patient, laboratory evaluation is indicated, as outlined below.

LABORATORY FEATURES

The best screening tests for initial evaluation of patients with suspected amyloidosis are immunoelectrophoresis and immunofixation of both serum and urine and a serum immunoglobulin free light-chain assay (both κ and λ). Systemic immunoglobulin AL amyloidosis is a plasma cell dyscrasia, and 99 percent of patients will have a detectable abnormality of one of these three tests, reflecting synthesis by a clonal population of plasma cells in the marrow. If an immunoglobulin protein is detected, further investigation for amyloidosis as described in the next section (“Differential Diagnosis”) should proceed. If a systemic plasma cell dyscrasia and an immunoglobulin light chain cannot be confirmed, three possibilities exist: (1) the patient does not have amyloidosis, (2) the patient does not have systemic amyloidosis, or (3) the amyloidosis is not immunoglobulin light chain in type and reflects a different protein subunit.

The serum free light-chain assay is a critically important test. It not only heightens the suspicion of the presence of immunoglobulin AL amyloidosis, it also is prognostic and vital to staging the patient. The serum immunoglobulin free light chain is part of the response evaluation for this disease. A screening serum protein electrophoresis is insufficient as a screening technique because a visible M-spike is seen in less than half of patients because of the high prevalence of primary light-chain proteinemia.

Finding a monoclonal protein in the serum or in the urine of a patient with heavy albuminuria often obviates the need for a renal biopsy. A patient with free light chains in the serum or urine and proteinuria can have only one of three disorders: (1) myeloma cast nephropathy, (2) AL amyloidosis, or (3) Randall-type immunoglobulin deposition disease (κ).

Screening for a light-chain immunoglobulin is the best noninvasive approach when confronted with a patient with any of the five syndromes listed in Table 108-2. If amyloid is present but the light chains are normal, strong consideration of referral to a specialty center to further clarify the underlying form of amyloidosis should be considered.

DIFFERENTIAL DIAGNOSIS

Once a clinician has begun an evaluation of a patient with a compatible clinical syndrome and an immunoglobulin abnormality has been detected, a biopsy is required to confirm the diagnosis before therapy should commence. Although imaging of amyloid deposits with various

Figure 108-3. Technique and results of subcutaneous fat aspiration. **A.** Procedural technique. **B.** Fat stained with Congo red, note the preserved interstices of the fat cells. **C.** Viewed under polarized light to demonstrate green birefringence.

radionuclides, most notably anti-serum amyloid P component, continue to be explored and used in practice, they are not a substitute for histologic confirmation of the presence of amyloidosis.^{20–22} In a patient with renal, cardiac, hepatic, or peripheral nerve amyloidosis, it is straight forward to establish the diagnosis by kidney, heart, liver, or nerve biopsy, but this is unnecessary in the majority of patients. Subcutaneous fat aspiration is a bedside office procedure done with local anesthesia and does not require an incision (Fig. 108–3). An excellent YouTube video has been produced by the Boston Medical Center on the technique (<https://www.youtube.com/watch?v=tctYTmx9gQ>). Typically, fat aspirations are reviewed at a specialty center unless the pathology department regularly processes fatty tissue. The fat is not paraffin-embedded and, therefore, it is subject to overfixation, trapping of Congo red dye, and the possibility of inadequate controls.²³ Fat aspiration is positive in three-quarters of patients with amyloidosis.

A second tissue easily stained for amyloid is the marrow. Because AL amyloidosis patients will have a plasma cell dyscrasia, a marrow examination is clinically indicated to quantify the number of plasma cells in the marrow. Congo red staining of marrow blood vessels can detect amyloid deposits in half of patients with AL amyloidosis. Combining the two techniques (marrow and fat pad aspiration), establishes a diagnosis in 85 percent of afflicted patients. Minor salivary gland biopsy, endoscopic gastric biopsy, rectal biopsy, and skin biopsy can also be used to establish the diagnosis. If the clinical suspicion of AL amyloidosis is strong and these biopsies are negative, it is appropriate to biopsy the affected organ.

Once tissue containing Congo red has been identified, it becomes imperative that the protein subunit be determined. Historically, immunohistochemistry has been used to identify the type of amyloid, but immunohistochemistry can be challenging because only those protein subunits for which antisera exist can be detected.^{24,25} Second, particularly in AL amyloidosis, the reactive epitope may have been deleted during the process of amyloid fibril formation and, frequently, the background staining is high, particularly in kidney tissues. Third, because the protein in amyloid misfolds, even if the epitopes are present, they may be hidden deep within the deposits and may be inaccessible to commercial antisera. Not only can immunohistochemistry be unreliable, it can be misleading. It is therefore recommended that laser capture of the amyloid deposit be performed routinely followed by mass spectroscopic analysis.^{26–28} The subunit protein can be identified by this approach in the majority of cases. Even in patients who have a false-positive Congo red stain, this technique is useful because it will not identify amyloid-related peptides upon analysis. With this technique, one is able to confirm the presence of AL amyloidosis, which represents slightly

less than two-thirds of patients seen with amyloidosis. A full quarter of patients with amyloid deposits are composed of amyloidogenic transthyretin (ATTR) (inherited) or wild-type amyloid (senile systemic). Less than 4 percent are amyloid A (AA) and approximately 4 percent represent ALect2 amyloidosis, which deposits in the kidney and causes proteinuria. Other forms of amyloid, which are often localized, are seen in less than 1 percent of patients. A particularly important form of localized amyloid occurs at the sites of subcutaneous insulin injections in diabetics. Crystalline insulin can form amyloid, which can cause discolored firm deposits which, when biopsied, will be Congo red–positive, but by mass spectroscopic analysis, can be confirmed to be insulin. Other forms of systemic amyloidosis for which systemic chemotherapy is contraindicated include fibrinogen A- α amyloidosis, and amyloid caused by apolipoprotein-A1, and gelsolin.

One additional advantage, particularly for those patients who have TTR amyloidosis is that mass spectroscopy not only identifies the protein, in most instances, it can confirm whether the protein is wild-type or a mutant. We still recommend that patients who have mutant TTR seen on mass spectroscopy have this confirmed by DNA sequencing of a blood sample, which is a readily available commercial test, to confirm the findings on mass spectroscopy. We have investigated a small number of patients in whom an amyloid syndrome was strongly suspected, a subcutaneous fat aspirate was not definitively positive, yet mass spectroscopic analysis demonstrated peptides in the tissue that are associated with amyloid including apolipoprotein-E and serum amyloid P component. When a pathologist makes a diagnosis of amyloid in tissue sections, the clinicians are required to ask what type of amyloidosis it represents. Although not widely available, mass spectroscopic analysis is the most sensitive and specific technique for identifying the amyloid subunit protein.

DIAGNOSIS AND CLINICAL CHARACTERIZATION OF ORGAN-SPECIFIC SYNDROMES

Kidney

Kidney involvement is seen in 45 percent of patients with immunoglobulin AL amyloidosis. It is conspicuously absent in the majority of patients with TTR amyloidosis until late in the disease. Renal involvement is virtually universal in systemic AA amyloidosis as well as ALect2 amyloidosis and A-fib α amyloidosis. Amyloid is seen in 2.5 percent of all renal biopsies. When limited to nondiabetics older than age 50 years, amyloid deposits will be found in 10 percent of renal biopsies.²⁹

These patients present with the typical four features of the nephrotic syndrome: (1) nephrotic range proteinuria, (2) hypoalbuminemia, (3) hyperlipidemia, and (4) edema. Nearly a third of patients with renal amyloidosis have at least a 1-year history of dramatic elevations of cholesterol and triglycerides. These are often managed with statin-type medication and dietary modification without consideration that a dramatic (>100 mg/dL) rise in cholesterol and triglycerides may be caused by heavy proteinuria. In the majority of patients, the glomerular filtration rate (GFR) is preserved until sustained proteinuria has been present for years. Only a small percentage of patients, usually with interstitial but not glomerular amyloid, present with renal insufficiency in the absence of heavy proteinuria.³⁰

The management of the lower-extremity edema is primarily diuretic therapy. However, excessive diuretic use, particularly in patients with cardiac amyloidosis, can aggravate already reduced intravascular volume. Diuretics can also compromise renal blood flow, increase orthostatic hypotension, and reduce cardiac filling pressures necessary for adequate cardiac output in patients that have “stiff heart syndrome.” The threat of continuous proteinuria in amyloidosis is damage to the tubular system. One-third of patients with renal amyloidosis will ultimately require dialysis or renal transplantation.³¹ The serum creatinine level at the time of presentation is the best predictor of which patients are most likely to require dialysis. Clearly, the best method for prevention of the need for dialysis is effective therapy of the underlying plasma cell dyscrasia. There are no reported differences between outcomes for those patients receiving hemodialysis and those receiving peritoneal dialysis.

In rare instances, patients have profound depression of the serum albumin below 1 g/dL. These patients often will be disabled by anasarca. In situations where intractable edema and anasarca makes management next to impossible, renal ablation has been performed to stop the urinary protein leak, normalize the serum oncotic pressure, and resolve the edema. Multiple techniques have been reported, including nephrectomy, ligation of the renal artery, and bilateral ureteral clips. In some patients, the early initiation of dialysis, even with a normal estimated GFR, can result in anuria and restoration of normal serum albumin levels.³²

The correlation between the amount of amyloid detected and the degree of renal dysfunction is poor. The urinary sediment is nonspecific, shows fat and fatty casts, but generally does not contain red cell casts. The most common cause of death in patients with renal amyloidosis is progressive cardiac dysfunction from infiltrative amyloid cardiomyopathy.

Heart

Unlike most cardiac disorders, which are caused by a loss of systolic function, the restrictive cardiomyopathy caused by amyloid infiltration results in poor relaxation (so-called stiff heart syndrome) and poor filling during diastole so that the ventricular chamber has a low end-diastolic volume, which results in reduced stroke volume and a reduced cardiac output. This constitutes a classic example of heart failure with preserved systolic function. In fact, the majority of patients with amyloidosis have an echocardiographically normal ejection fraction until late in the disease.⁵ Cardiac amyloid is found in 40 to 50 percent of patients at diagnosis and is responsible for nearly 90 percent of deaths. It is the most challenging syndrome to diagnose because of the lack of specificity of its symptoms. Fatigue and dyspnea on exertion are often not associated with cardiac disease in the presence of amyloid (1) because of the lack of radiographic changes of cardiomegaly, pleural effusions, and pulmonary vascular redistribution; (2) because echocardiography will demonstrate preserved ejection fraction; and (3) because coronary angiography is invariably normal.³³ This triad often leads to a diagnosis

Figure 108-4. Amyloid heart disease. Note thickening of heart walls from infiltration. White patches were responsible for the designation “lardaceous change.”

of noncardiac dyspnea. Even when amyloid infiltrates the myocardial wall and causes it to be thickened, it is often misattributed to hypertensive heart disease (hypertrophy) rather than infiltration (Fig. 108-4). Electrocardiographic abnormalities, including pseudoinfarction and low voltage, are quite common but are frequently overlooked, whereas a pseudoinfarction pattern is misattributed to ischemic heart disease.

The supportive care of patients with cardiac amyloidosis can be strikingly different from that of ischemic or valvular heart disease. There is no evidence that afterload reduction with angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers benefits patients with relaxation abnormalities, and dyspnea and reduced exercise tolerance frequently increase in patients treated with these medications. Fatigue and dyspnea on exertion can also be exacerbated when β blockers are used for rate or rhythm control.

In addition to standard echocardiography, accurate diagnosis of cardiac amyloid requires Doppler flow studies to demonstrate the rapid decline in velocity of blood inflow into the ventricular chambers and optimally conducted cardiac strain studies that demonstrate a decline in the rate of fractional shortening of the ventricular chamber. Patients with unexplained fatigue and/or dyspnea on exertion should have immunofixation of the serum and urine and free light-chain testing to assess for possible light-chain amyloid. However, even if light chain-testing is negative, age related amyloidosis may still be present because of the deposition of wild-type TTR in the heart.³⁴ This typically occurs in patients older than age 60 years, predominantly men, half of whom will also have carpal tunnel syndrome.^{35,36} Wild-type TTR amyloidosis will not be detected by screening for serum and urine light chains, and

A

B

Figure 108-5. **A.** Polarized micrograph of Congo red–stained endomyocardial biopsy demonstrates birefringence in the involved area. **B.** Light micrograph of hematoxylin-and-eosin–stained slide of the same specimen demonstrating amyloid as extracellular eosinophilic amorphous material.

subcutaneous fat aspiration has a lower sensitivity than in AL amyloidosis. These patients require recognition by echocardiography, magnetic resonance imaging (MRI), or endomyocardial biopsy to establish a diagnosis (Fig. 108-5).

Early diagnosis of cardiac amyloid is imperative because it is this group that is responsible for the majority of the early deaths with this disorder. In our experience, 40 percent of newly diagnosed patients with AL amyloidosis will succumb to the disease within the first year; and this percentage has not changed over a quarter century.

Echocardiography remains the most useful test for the imaging and diagnosis of amyloid; however, it is not particularly useful for serial monitoring of patients for response or progression after treatment. The technique still suffers from interobserver variability, and the calculations of the septal thickness can vary substantially on serial measurements. Conversely, a septal thickness greater than 15 mm would be rare with hypertensive cardiomyopathy and would be limited to either amyloidosis or hypertrophic cardiomyopathy. Interestingly, the degree of cardiac infiltration in senile systemic and familial amyloid cardiomyopathy is substantially greater than that seen in AL amyloidosis. A patient with AL amyloidosis with a septal thickness greater than 18 mm will generally have significant disability related to cardiac failure. Patients with TTR amyloidosis, both mutant and wild-type, will frequently have septal thicknesses in the range of 25 mm with minimal symptomatology. The old echocardiographic finding of granular sparkling appearance is little used today. Other echocardiographic clues include thickening of the right ventricle and reduction in left ventricular chamber size.³⁷ Late consequences of cardiac involvement include valvular thickening and valvular regurgitation. Repair of the valve will not result in meaningful improvement in the patient's aerobic exercise capacity. The restriction to flow seen in restrictive cardiomyopathy can be confused with restrictive pericardial disease; and occasionally, patients have undergone pericardiectomies without benefit.³⁸ Endomyocardial biopsy is highly sensitive in the diagnosis of cardiac amyloidosis; and if five specimens are taken, recognition of the diagnosis is virtually certain. Patients with cardiac amyloidosis have poor atrial function and a high incidence of atrial standstill. Atrial and atrial appendage thrombi are well recognized and are potential sources of cardiac embolism.³⁹ Rare patients can develop amyloid deposition in the coronary microcirculation resulting in true

ischemic symptomatology and angina with normal epicardial coronary artery anatomy.⁴⁰

Sudden death remains a problem in patients with amyloidosis.⁴¹ The placement of an implantable defibrillator may not reduce the risk of sudden death.⁴² Electromechanical dissociation is a common occurrence and the ability of a fibrillating amyloid heart to be appropriately shocked internally and establish hemodynamic stability has not been established.⁴³

Diuretic therapy remains the mainstay of management for cardiac amyloidosis; but in these patients with noncompliant ventricular chambers, higher than normal filling pressures are often required to open the ventricle and fill it with blood. Aggressive diuretic therapy will often reduce preload, and this can result in drops in systolic blood pressure, reduced renal blood flow, and syncope.⁴⁴

Familial amyloid cardiomyopathy is rare, but one special TTR mutant known as TTRVal122Ile requires awareness. In a prospective study of cord blood samples, this mutation was found in 3 percent of newborns of American parents of African descent. This compared with a prevalence of 0.44 percent in Americans of European descent and 0 percent of Americans of Hispanic descent. The degree of penetrance of this mutation at the clinical level has not been determined; however, in view of the high incidence and prevalence of this genetic abnormality, the diagnosis of cardiac amyloidosis in Americans of African descent warrants early analysis of the DNA for this mutation.^{45,46}

Cardiac biomarkers play an important role in the prognosis of amyloid as well as in its functional assessment.⁴⁷ Both the B-natriuretic peptide and troponin levels predict outcomes in patients with amyloidosis and are important parts of the staging system for this disease.⁴⁸ Staging involves assigning a point for any of the following characteristics: difference between the involved and uninvolved free light chain of greater than 180 mg/L; for a cardiac troponin T level greater than 0.025 ng/mL; and for the N-terminal of the prohormone brain natriuretic peptide (NT-proBNP) level greater than 1800 pg/mL. This creates four stages with median survivals ranging from 6 months (stage 4) to 60 months (stage 1). Serialized measurements of the NT-proBNP also have been used to define response and progression and, in fact, have supplanted the use of serial echocardiography to assess changes over time, both in following the natural history as well as assessing response

TABLE 108-3. Suggested Testing of a Known Amyloid Patient

to therapeutic interventions.⁴⁹⁻⁵¹ All patients who present with amyloidosis, whether or not cardiac disease is suspected, should have cardiac biomarkers performed. Table 108-3 lists the suggested diagnostic tests to perform when a patient with amyloidosis is seen.

Contrast-enhanced cardiac MRI is increasingly being used in the assessment of cardiac amyloid. Cardiac MRI (Fig. 108-6) can measure the thickness of the myocardium accurately and, after gadolinium injection, can demonstrate delayed subendocardial enhancement that can be quite specific for cardiac amyloidosis.^{52,53} Phase-contrast MRI provides information on flow dynamics, diastolic filling parameters, and mitral peak in-flow velocity.⁵⁴ By providing a functional assessment, this technique can help establish an early diagnosis and has the potential to assess response to therapy. MRI cannot be used in the presence of a pacemaker or defibrillator or if there is renal insufficiency, because gadolinium is contraindicated. Radionuclide scanning is being explored for amyloidosis. Technetium pyrophosphate is a sensitive marker for the presence of ATTR amyloidosis, both wild-type and mutant, whereas uptake is not seen in AL amyloidosis.⁵⁵ A recent small study assessing ¹¹C-labeled Pittsburgh Compound-B (¹¹C-PiB)-based positron emission tomography (PET) imaging identified cardiac amyloid deposits in all patients with light chain amyloidosis and ATTR and was negative in controls.⁵⁶ Therefore, nuclear imaging in the future may not only help

confirm cardiac involvement by amyloidosis, but also help differentiate one type versus another.

Liver

Liver infiltration from amyloid can be seen in up to one-quarter of patients with AL amyloidosis.¹⁷ These patients will present with hepatomegaly, elevation of the serum alkaline phosphatase with normal or near-normal transaminases and bilirubin. Half of the patients with hepatic amyloidosis have renal amyloidosis, which dominates the clinical syndrome. When a patient presents with hepatomegaly and imaging shows no filling defects, the presence of proteinuria, a monoclonal protein, or the presence of Howell-Jolly bodies in a blood film indicative of hyposplenism are highly suggestive of amyloidosis. Most patients have symptoms consistent with chronic liver disease, early satiety, anorexia, and unexplained weight loss. It is common to find spider telangiectasias on the upper chest. Portal hypertension and ascites are uncommon, however.⁵⁷ Rare instances of both hepatic and splenic rupture have been reported.⁵⁸ The diagnosis can usually be established with fat aspiration and marrow biopsy, but a liver biopsy is safe and does not have a higher risk of bleeding complications than in other patients with liver disease.

Nervous System

Amyloid, by virtue of its deposition in the vasa nervorum, causes a mixed axonal and demyelinating peripheral neuropathy. The neuropathy is symmetric, tends to ascend beginning in the toes, and eventually involves the upper extremities. It causes paresthesias, often painful dysesthesias, and eventually causes motor loss. Approximately half of the patients have an associated carpal tunnel syndrome, and approximately one-quarter have associated autonomic features including orthostatic hypotension, autonomic dysmotility of the gastrointestinal tract, including vomiting because of pseudoobstruction and alternating constipation with diarrhea, often intractable, and bladder abnormalities, including overflow incontinence and incomplete emptying.^{59,60} The progression of amyloid neuropathy is slow, and it is common to have delays of 2 to 3 years before a diagnosis is established. Electromyography is not particularly useful in the early diagnosis because amyloid preferentially affects the small unmyelinated fibers of the extremities, which are not well assessed with standard electrodiagnostic studies. Patients with an unexplained peripheral neuropathy who are not diabetic should have immunofixation of serum and urine and a free light-chain assay performed. A positive finding requires the consideration of amyloidosis in the differential; although, for patients who have an immunoglobulin (Ig) M monoclonal protein, the possibility that the IgM is directly responsible for neuropathy in the absence of amyloid is significant. Sural nerve biopsies can usually detect the amyloid deposits, but there are reports in the literature of sural nerve biopsies having missed proven amyloidosis.⁶¹ Mass spectroscopic analysis of the amyloid deposits is particularly important because of the high prevalence of neuropathy in patients with non-AL amyloidosis.

● THERAPY

Treatment of amyloidosis has improved significantly with the introduction of novel agents and refinements in autologous stem cell transplantation. For years, the regimen of melphalan and prednisone was the standard of therapy, but the response rate never exceeded 25 percent, and the impact on survival was unimpressive. Melphalan and prednisone therapy has now been supplanted by the use of melphalan and dexamethasone, which has a very low therapy-related mortality and can be administered to patients with cardiac and renal failure as well as frail patients. The 5-year actuarial survival in patients treated with

Figure 108-6. **A.** Magnetic resonance imaging demonstrating thickened interventricular septum from amyloid infiltration. **B.** Delayed gadolinium enhancement on subendocardial tissue is characteristic of amyloid cardiomyopathy.

melphalan and dexamethasone is 50 percent but is highly dependent on the enrolled population. Median responses as short as 10.5 and 17.5 months have been reported and are a function of the proportion of patients with advanced cardiac amyloid enrolled. Retreatment with melphalan and dexamethasone after an initial response also can be successful. It is often difficult to interpret results in phase 2 trials because of patient heterogeneity. Stratification of patients, based on the staging mentioned above, is important in reporting outcomes. Melphalan and dexamethasone should be considered the standard of care in patients that are not eligible for stem cell transplantation.⁶⁶

AUTOLOGOUS STEM CELL TRANSPLANT

Most experts believe that autologous stem cell transplantation is the treatment of choice for patients with amyloidosis who do not have severe end-organ dysfunction, even though this approach has not been proven superior to conventional chemotherapy in prospective randomized trials or meta-analyses. However, it must be recognized that no more than 20 percent of patients with amyloidosis are eligible for stem cell transplantation. Currently, the therapy-related mortality at the Mayo Clinic is 2.5 percent (three out of 120), and the 10-year overall survival is 43 percent. Significant improvements in organ function and quality of life are commonly observed following stem cell transplantation and are strongly correlated with attainment of a very good partial response or better.⁶⁷⁻⁶⁹ To reduce treatment-related mortality, current patient selection for transplantation includes age younger than 70 years, serum creatinine less than 1.8 mg/dL, serum troponin T less than 0.06, and an NT-proBNP less than 5000 pg/mL. The median age at the time of transplantation at the Mayo Clinic is 57 years. The median percent plasma cells in the marrow of transplanted patients is 7 percent, and the median urinary protein loss is just under 4 g/day. Seventy percent of patients who receive autologous stem cell transplantation have predominant renal involvement, 12 percent have peripheral neuropathy, and 14 percent have liver involvement. Patients with advanced cardiac involvement are generally excluded from transplantation, although half of transplanted patients have mild to moderate cardiac involvement as assessed by biomarkers and echocardiogram.

Blood stem cells are generally mobilized using leukocyte growth factors alone without cytotoxic chemotherapy to avoid hemodynamic deterioration during the mobilization process. A median of two aphereses are required to collect adequate stem cells for transplantation. The standard conditioning regimen is melphalan 200 mg/m², although the dose may be reduced for multiorgan involvement, age, and frailty. Induction chemotherapy is not generally administered prior to autologous stem cell transplantation, although this approach is considered in patients with significant marrow plasmacytosis, because of data suggesting an inferior outcome in such patients. In 2013, 40 percent of patients were transplanted at the Mayo Clinic without requiring hospitalization, and of the 60 percent of patients who were hospitalized, the median hospital stay was 6 days. Leukocyte growth factors are not routinely used after transplantation because they increase fluid retention. A partial response or better is seen in 75 percent of patients. Complete hematologic responses are documented in 40 percent of patients. Organ responses are seen in 50 percent of patients transplanted at the Mayo Clinic. Median survival for complete responders has not been reached, whereas patients with partial response or better have a median survival of 107 months. Predictors of outcome following autologous stem cell transplantation include cardiac biomarkers, NT-proBNP, and troponin.⁷⁰

IMMUNOMODULATORY DRUGS

The combination of melphalan, dexamethasone, and lenalidomide has been reported for the treatment of AL amyloidosis. The maximum tolerated dose of lenalidomide was found to be 15 mg. Melphalan doses lower than those recommended for myeloma patients are used (0.18 mg/kg/day for 4 days every 28 days), with a complete response rate of 42 percent, an overall response rate of 58 percent, and a 2-year overall survival of 81 percent. Prophylaxis against deep venous thrombosis is required when lenalidomide is used. A combination of cyclophosphamide, thalidomide, and dexamethasone is safe and effective. In a risk-adapted all-oral therapy, 75 patients (with PS was 0-1) were treated, with a hematologic response in 74 percent, of which 21 percent were complete. The 3-year estimated overall survival was 82 percent, and grade 2 toxicity

was seen in 52 percent. Lenalidomide and dexamethasone have been used in amyloidosis in a fashion identical to that used for multiple myeloma. It is important to remember that lenalidomide can increase the level of NT-proBNP and may actually aggravate heart failure.⁷¹ Additionally, the typical dose of lenalidomide used to treat multiple myeloma is not well tolerated by AL patients and treatment should be initiated at a dose of no more than 15 mg daily. There is a high discontinuation rate of lenalidomide within the first three cycles. Myelosuppression, skin rash, and fatigue are common. In a study of lenalidomide and dexamethasone in patients who had failed melphalan and bortezomib, two patients died prior to first-response evaluation and 50 percent experienced grade 3 or greater toxicity. The hematologic response rate was 41 percent. The median overall survival was 14 months. Cyclophosphamide, lenalidomide, and dexamethasone have been used in the treatment of amyloidosis with lenalidomide at 15 mg per day and cyclophosphamide 100 mg per day. A partial response or greater was observed in 55 percent of patients, with complete responses in 8 percent, organ responses in 40 percent, and a 2-year overall survival of 41 percent. Cyclophosphamide, lenalidomide, and dexamethasone hematologic response rates ranged from 40 to 77 percent in three different studies. Complete responses did not exceed 10 percent. Lenalidomide toxicity was substantial and included fatigue and fluid retention.

Pomalidomide has been used with dexamethasone in relapsed amyloidosis. In a population of 33 evaluable patients, the response rate was 48 percent with a median time to response of 2 months. Organ improvement was found in 15 percent. The progression-free survival was 14 months; overall survival was 28 months.⁷²

Bortezomib is highly active in the treatment of amyloidosis.⁷³ The combination with dexamethasone in untreated patients produces a 47 percent complete response rate, with higher responses seen in patients treated with twice-weekly bortezomib. The cardiac response rate is 29 percent. Hematologic responses are associated with cardiac response as measured by a reduction in NT-proBNP. Bortezomib also has been used with melphalan and dexamethasone, as well as cyclophosphamide with dexamethasone.⁷⁴ The CyBORd (cyclophosphamide, bortezomib, and dexamethasone) regimen was reported by the Mayo Clinic as a retrospective review of 17 patients with responses seen in 94 percent (71 percent complete, 24 percent partial) and a median time to response of 2 months.⁷⁵ In many published trials, patients with severe cardiac involvement were excluded; as a consequence, it is difficult to determine the efficacy of bortezomib in this difficult subgroup.⁷⁶ In one study of 38 patients with advanced cardiac disease using reduced doses of twice-weekly bortezomib and dexamethasone, 18 of 38 patients died during therapy; 21 patients achieved a hematologic response after a median of three cycles. In a series of 35 patients treated with bortezomib-dexamethasone with subsequent addition of cyclophosphamide, 86 percent achieved a rapid response. A second trial of cyclophosphamide-bortezomib-dexamethasone resulted in hematologic responses in 68 percent and a 1-year overall survival of 65 percent. Because bortezomib has been reported to increase the severity of heart failure in myeloma, it is clearly a concern that requires monitoring in patients. The oral proteasome inhibitor MLN9708, ixazomib, is currently under investigation.

Bortezomib and dexamethasone have been used as consolidation therapy following stem cell transplantation.⁷⁷ Forty patients were transplanted with risk-adapted melphalan; patients with less than a complete response received consolidation with bortezomib-dexamethasone. Survivals at 12 and 24 months post treatment were 88 and 82 percent, respectively. Of the original 40 patients, 23 received consolidation, and their response was enhanced in 20 (86 percent). Organ response occurred in 70 percent at 24 months. The use of bortezomib-dexamethasone consolidation following stem cell transplantation can help deepen the response in patients that do not achieve a complete response.

COURSE AND PROGNOSIS

In spite of the introduction of new agents, late diagnosis, particularly of cardiac amyloid, remains a major barrier to improvement in the overall survival of patients; and despite recent improvements in survival, 40 percent of patients succumb to the disease within the first year after diagnosis, and this early mortality has not changed in 30 years. Patients can have a hematologic response and still die of end-organ damage because it is impossible to repair the tissue damage that has occurred prior to diagnosis.^{64,65} The prognosis in amyloidosis is determined by two primary factors. The first is the extent of cardiac involvement, and the second is the plasma cell burden seen in these patients. The former, historically measured by echocardiography, is more reproducibly measured by the use of cardiac biomarkers. The percentage of plasma cells in the marrow has an important impact on prognosis.^{9,62} The best surrogate and the most reproducible way to measure the plasma cell burden is to look at the difference between the involved and uninvolved light chains in the serum (dFLC). A four-stage prognostic model has been developed using measurements of NT-proBNP, troponin, and serum free light chains. One point each is assigned for a troponin T level of 0.025 ng/mL or greater, an NT-proBNP greater than 1800 pg/mL, and a free light chain difference of greater than 180 mg/L. This provides almost four equal-size groups (if you have none of the 3 its stage 1; if you have 1 its stage 2; if you have 2 its stage 3 and if you have all 3 its stage 4) with median overall survivals of 94, 40, 14, and 6 months, respectively. These serum tests are currently the standard for assessing prognosis in amyloidosis. Assessing response in amyloidosis is a twofold process. First, the hematologic response is assessed by determining the reduction of the plasma cell burden and of the production of precursor amyloid light chains achieved by systemic therapy. There are four classes of response: (1) complete remission defined by negative immunofixation of serum and urine and a normal immunoglobulin free light-chain ratio; (2) a very good partial response that requires the difference between involved and uninvolved serum free light chain be less than 40 mg/L; (3) a partial response is defined as a 50 percent decrease from baseline in the dFLC; and (4) failure to respond includes all other patients. Light-chain assessment is not only the ideal method for measuring response because of the rapid decline in levels if therapy is effective, but it is better than the intact immunoglobulin as a measure of response when both are present.⁶³ Although hematologic response is the first goal, the purpose of therapy is preservation of organ function. Therefore, to have a meaningful impact, an organ response should be seen. Current data indicate that organ response rates are directly linked to hematologic response rates; and the deeper the hematologic response, the more likely there will be an organ response. A renal response is defined as a 50 percent decrease in 24-hour urine protein. The decrease must be no less than 0.5 g/day without a change in serum creatinine. A 50 percent increase in urinary protein loss to at least 1 g/day or a 25 percent worsening of creatinine clearance is indicative of progression. Cardiac response is defined primarily by changes in the NT-proBNP. A 30 percent reduction in the NT-proBNP, a minimum of 300 ng/L in patients whose baseline NT-proBNP is greater than 650 ng/L, constitutes a response. However, we have seen patients in whom fluctuations of the NT-proBNP of as much as 30 percent can occur as a result of changes in diuretics or the development of superimposed pulmonary infections that are unrelated to true changes in cardiac function; consequently, some caution is warranted in interpreting the results. An improvement in New York Heart Association class by two stages from 4 to 2 or 3 to 1 also is considered a response. Historically, echocardiography has been used to assess response, but interobserver variability has rendered it less useful and echocardiography is not currently part of response criteria. Cardiac progression constitutes a 30 percent increase in NT-proBNP, a

minimum increase of 300 ng/dL. Finally, liver response is defined as a 50 percent reduction in the abnormal alkaline phosphatase value, with progression defined as a 50 percent increase of alkaline phosphatase above the lowest recorded value. Currently, consensus criteria to define response in soft tissues, the gastrointestinal tract, the tongue, the lung, or the peripheral nerve do not exist for AL amyloidosis.

Giampaolo Merlini

SUMMARY

Waldenström macroglobulinemia (WM) is an indolent B-cell neoplasm manifested by the accumulation of clonal immunoglobulin (Ig) M secreting lymphoplasmacytic cells. MYD88^{L265P} and CXCR4 WHIM (warts, hypogammaglobulinemia, infections, myelokathexis)-like somatic mutations are present in more than 90 percent, and 30 to 35 percent of WM patients, respectively, and impact disease presentation, treatment outcome, and/or overall survival. Familial predisposition is common in WM. Asymptomatic patients should be observed. Patients with disease-related hemoglobin of less than 10g/dL, platelets less than $100 \times 10^9/L$, bulky adenopathy and/or organomegaly, symptomatic hyperviscosity, peripheral neuropathy, amyloidosis, cryoglobulinemia, cold-agglutinin disease, or transformed disease should be considered for therapy. Plasmapheresis should be used for patients with symptomatic hyperviscosity, and prirituximab for those with high serum IgM levels to preempt a symptomatic IgM flare. The treatment choice should take into account specific goals of therapy, necessity for rapid disease control, risk of treatment-related neuropathy, immunosuppression and secondary malignancies, and planning for future autologous stem cell transplantation. Frontline treatments include rituximab alone or combined with alkylating agents (bendamustine, cyclophosphamide), proteasome inhibitors (bortezomib, carfilzomib), or nucleoside analogues (fludarabine, cladribine). In case of relapsed or treatment-resistant patients, an alternative frontline regimen or autologous stem cell transplantation can be considered. Novel targeted agents for the treatment of WM include everolimus and ibrutinib.

DEFINITION AND HISTORY

Waldenström macroglobulinemia (WM) is a lymphoid neoplasm resulting from the accumulation, predominantly in the marrow, of a clonal population of lymphocytes, lymphoplasmacytic cells, and plasma cells, which secrete a monoclonal immunoglobulin (Ig) M.¹ WM corresponds to lymphoplasmacytic lymphoma (LPL) as defined in the Revised European-American Lymphoma (REAL) and World Health Organization (WHO) classification systems.^{2,3} Most cases of LPL are WM; less than 5 percent of cases are IgA-secreting, IgG-secreting, or nonsecreting LPL.

Acronyms and Abbreviations: CD16, FcγRIIIa receptor; CD40L, CD40 ligand; CDR, complement determination region; CHOP, cyclophosphamide, doxorubicin, vincristine, and prednisone; GM₁, ganglioside M₁; HCV, hepatitis C virus; Ig, immunoglobulin; IL, interleukin; κ, kappa light chain; LPL, lymphoplasmacytic lymphoma; MAG, myelin-associated glycoprotein; R-CHOP, cyclophosphamide, doxorubicin, vincristine, prednisone, and rituximab; R-CP, cyclophosphamide, prednisone, and rituximab; R-CVP, cyclophosphamide, vincristine, prednisone, and rituximab; sCD27, soluble CD27; WHO, World Health Organization; WM, Waldenström macroglobulinemia.

In 1944, Jan Waldenström, a Swedish physician-scientist, reported in *Acta Medica Scandinavica* three cases of a disease, he presciently thought was related to myeloma but for the absence of bone involvement and the scarcity of plasma cells in the infiltrate of small lymphocytes. He noted the increase in plasma protein concentration, marked increased serum viscosity, exaggerated bleeding and retinal hemorrhages, and virtually every other feature of the disorder in his case descriptions. In collaboration with a colleague, he showed, using ultracentrifugation and electrophoresis, that the abundant abnormal protein had a molecular weight of approximately 1 million and was not an aggregate of smaller proteins. The disease, which he described with such thoroughness, was later named in his honor.

EPIDEMIOLOGY

The age-adjusted incidence rate of WM is 3.4 per 1 million among males and 1.7 per 1 million among females in the United States. It increases in incidence geometrically with age.^{4,5} The incidence rate is higher among Americans of European descent. Americans of African descent represent approximately 5 percent of all patients.

Genetic factors play a role in the pathogenesis of WM. Approximately 20 percent of WM patients are of Ashkenazi-Jewish ethnic background.⁶ Familial disease has been reported commonly, including multigenerational clustering of WM and other B-cell lymphoproliferative diseases.⁷⁻¹⁰ Approximately 20 percent of 257 sequential patients with WM presenting to a tertiary referral center had a first-degree relative with either WM or another B-cell disorder.⁹ Familial clustering of WM with other immunologic disorders, including hypogammaglobulinemia and hypergammaglobulinemia (particularly polyclonal IgM), autoantibody production (particularly to the thyroid), and manifestation of hyperactive B cells has also been reported in relatives without WM.^{9,10} Increased expression of the *BCL-2* gene with enhanced survival has been observed in B cells from familial patients and their family members.¹⁰

The role of environmental factors is uncertain, but chronic antigenic stimulation from infections and certain drug or chemical exposures have been considered but have not reached a level of scientific certainty. Hepatitis C virus (HCV) infection was implicated in WM causality in some series, but in a study of 100 consecutive WM patients in whom serologic and molecular diagnostic studies for HCV infection were performed, no association was found.¹¹⁻¹³

PATHOGENESIS

NATURE OF THE WALDENSTRÖM MACROGLOBULINEMIA CLONE

Examination of the B-cell clone(s) found in the marrow of WM patients reveals a range of differentiation from small lymphocytes with large focal deposits of surface immunoglobulins, to lymphoplasmacytic cells, to mature plasma cells that contain intracytoplasmic IgM (Fig. 109-1).¹⁴ Circulating clonal B cells are often detectable in patients with WM, although lymphocytosis is uncommon.^{15,16} WM cells express the monoclonal IgM, and some clonal cells also express surface IgD.¹⁷ The characteristic immunophenotypic profile of WM lymphoplasmacytic cells includes the expression of the pan-B-cell markers CD19, CD20 (including FMC7), CD22, and CD79.^{17,18} Expression of CD5, CD10, and CD23 can be present in 10 to 20 percent of cases, and their presence does not exclude the diagnosis of WM.¹⁹ Multiparameter flow cytometric analysis has also identified CD25 and CD27 as being characteristic of the WM clone, and found that a CD22^{dim}/CD25⁺/CD27⁺/IgM⁺ population may be present among clonal B lymphocytes in patients with

Figure 109-1. Waldenström macroglobulinemia. **A.** Blood film displaying the characteristic pathologic rouleaux seen as a result of the red cell aggregating properties of immunoglobulin M. **B.** Marrow film showing characteristic infiltrate of lymphocytes, lymphoplasmacytic cells, and plasma cells. A mast cell is evident lower center. Although not specific for this disease, mast cells are commonly present in the marrow. **C.** Marrow film showing infiltrate of lymphocytes with occasional plasma cells and a mast cell. **D.** Marrow film showing lymphocytic infiltrate with a “cracked” mast cell sometimes seen in this disease. The fraction of plasma cells varies as shown by the somewhat higher proportion in **(B)** as compared to **(C)** and **(D)**. Lymphocytes and lymphoplasmacytic cells predominate. essential monoclonal gammopathy (synonym: monoclonal gammopathy of unknown significance [MGUS]) of the IgM type who ultimately progressed to WM.²⁰

Somatic mutations in immunoglobulin genes are present with an increased frequency of nonsynonymous as compared to silent mutations in complement determining regions, along with somatic hypermutation, thereby supporting a postgerminal center derivation for the WM B-cell clone in most patients.^{21,22} A strong preferential usage of *VH3/JH4* gene families without intraclonal variation, and without evidence for any isotype-switched transcripts is present.^{23,24} These data support an IgM⁺ and/or IgM⁺IgD⁺ memory B-cell origin for most cases of WM.

In contrast to myeloma plasma cells, no recurrent translocations have been described in WM, which can help to distinguish WM from IgM myeloma cases, as IgM myeloma cases often exhibit t(11;14) translocations.^{25,26} Despite the absence of IgH translocations, recurrent chromosomal abnormalities are present in WM cells. These include deletions in chromosome 6q21–23 in 40 to 60 percent of WM patients, with concordant gains in 6p in 41 percent of 6q-deleted patients.^{27–30} In a series of 174 untreated WM patients, 6q deletions, followed by trisomy 18, 13q

deletions, 17p deletions, trisomy 4, and 11q deletions, were observed.³⁰ Deletion of 6q and trisomy 4 were associated with adverse prognostic markers in this series. As 6q deletions represent the most recurrent cytogenetic finding in WM cases, there has been interest in identifying the region of minimal deletion and possible target genes within this region. Two putative gene candidates within this region are *TNFAIP3*, a negative regulator of nuclear factor kappa B signaling (NFκB), and *PRDMI*, a master regulator of B-cell differentiation.^{29,31} The removal of a NFκB-negative regulator is of particular interest as the phosphorylation and translocation of NFκB into the nucleus is a crucial event for WM cell survival.³² The success of proteasome inhibitor therapy in WM may occur because the degradation of negative regulators of NFκB, such as the inhibitor of kappa B (IκB), is blocked^{33,34}.

MUTATION IN MYD88

A highly recurrent somatic mutation (MYD88^{L265P}) was first identified in WM patients by whole-genome sequencing (WGS), and confirmed by multiple studies through Sanger sequencing and/or allele-specific

polymerase chain reaction (PCR) assays.^{35–40} MYD88^{L265P} is expressed in 90 to 95 percent of WM cases when more sensitive allele-specific PCR has been employed, using both CD19-sorted and unsorted marrow cells.^{36–40} By comparison, MYD88^{L265P} was absent in myeloma samples, including IgM myeloma, and was expressed in a small subset (6 to 10 percent) of marginal zone lymphoma patients, who surprisingly have WM-related features.^{36–38,41} By PCR assays, 50 to 80 percent of IgM MGUS patients, also express MYD88^{L265P}, and expression of this mutation was associated with increased risk for malignant progression.^{36–38,42} The presence of MYD88^{L265P} in IgM MGUS patient suggests a role for this mutation as an early oncogenic driver, and other mutations and/or copy number alterations leading to abnormal gene expression are likely to promote disease progression.²⁹

The impact of MYD88^{L265P} to growth and survival signaling in WM cells has been addressed in several studies (Fig. 109–2). Knockdown of MYD88 decreased survival of MYD88^{L265P}-expressing WM cells, whereas survival was enhanced by knock-in of MYD88^{L265P} versus wild-type MYD88.⁴³ The discovery of a mutation in MYD88 is significant given its role as an adaptor molecule in toll-like receptor (TLR) and interleukin-1 receptor (IL-1R) signaling.⁴⁴ All TLRs except for TLR3 use MYD88 to facilitate their signaling. Following TLR or IL-1R stimulation, MYD88 is recruited to the activated receptor complex as a homodimer which then complexes with IRAK4 and activates IRAK1 and IRAK2.^{45–47} Tumor necrosis factor receptor-associated factor 6 is then activated by IRAK1 leading to NF κ B activation via I κ B α phosphorylation.⁴⁸ Use of inhibitors of MYD88 pathway led to decreased IRAK1 and I κ B α phosphorylation, as well as survival of MYD88^{L265P} expressing WM cells. These observations are of particular relevance to WM since NF κ B signaling is important for WM growth and survival.⁴⁹ Bruton tyrosine kinase (BTK) is also activated by MYD88^{L265P}.⁴³ Activated BTK coimmunoprecipitates with MYD88 that could be abrogated by use of a BTK kinase inhibitor, and overexpression of MYD88^{L265P}, but not wild-type(WT) MYD88, triggers BTK activation. Knockdown of MYD88 by lentiviral transfection or use of a MYD88 homodimerization inhibitor also abrogated BTK activation in MYD88^{L265P}-mutated WM cells.

CXCR4^{WHIM} Mutations

The second most common somatic mutation after MYD88^{L265P} revealed by WGS was found in the C-terminus of the CXCR4 receptor. These mutations are present in 30 to 35 percent of WM patients, and impact serine phosphorylation sites that regulate CXCR4 signaling by its only known ligand, stromal cell-derived factor (SDF)-1 α (CXCL12).^{29,50–52} The location of somatic mutations found in the C-terminus of CXCR4 in WM are similar to those observed in the germline of patients with WHIM (warts, hypogammaglobulinemia, infections, and myelokathexis) syndrome, a congenital immunodeficiency disorder characterized by chronic noncyclic neutropenia.⁵³ Patients with WHIM syndrome exhibit impaired CXCR4 receptor internalization following SDF-1 α stimulation, which results in persistent CXCR4 activation and myelokathexis.⁵⁴

In WM patients, two classes of CXCR4 mutations occur in the C-terminus. These include nonsense (CXCR4^{WHIM/NS}) mutations, which truncate the distal 15- to 20-amino-acid region, and frameshift (CXCR4^{WHIM/FS}) mutations, which compromise a region of up to 40 amino acids in the C-terminal domain.^{29,50} Nonsense and frameshift mutations are almost equally divided among WM patients with CXCR4 somatic mutations, and more than 30 different types of CXCR4^{WHIM} mutations have been identified in WM patients.^{29,50} Preclinical studies with WM cells engineered to express nonsense and frameshift CXCR4^{WHIM}-mutated receptors have shown enhanced and sustained AKT and extracellular signal-regulated kinase (ERK) signaling following SDF-1 α relative to CXCR4^{WT} (see Fig. 109–2), as well increased cell migration, adhesion, growth and survival, and drug resistance of WM cells.^{51,55,56}

Other Somatic Events

Many copy number alterations have been revealed in WM patients that impact growth and survival pathways. Frequent loss of *HIVEP2* (80 percent) and *TNFAIP3* (50 percent) genes that are negative regulators of NF κ B expression (Fig. 109–2), as well as *LYN* (70 percent) and *IBTK* (40 percent) that modulate B-cell receptor (BCR) signaling have been

Figure 109–2. MYD88^{L265P} and CXCR4^{WHIM} mutations are highly prevalent in patients with Waldenström macroglobulinemia, and trigger transcriptional factors that include nuclear factor κ B (NF κ B), AKT, and extracellular signal-regulated kinase (ERK) that support the growth and survival of lymphoplasmacytic cells.

revealed by WGS.²⁹ WGS has also revealed common defects in chromatin remodeling with somatic mutations in ARID1A present in 17 percent, and loss of ARID1B in 70 percent of WM patients. Both ARID1A and ARID1B are members of the SWI/SNF family of proteins, and are thought to exert their effects via p53 and CDKN1A regulation. TP53 is mutated in 7 percent of sequenced WM genomes, while PRDM2 and TOP1 that participate in TP53-related signaling are deleted in 80 percent and 60 percent of WM patients, respectively.²⁹ Taken together, somatic events that contribute to impaired DNA damage response are also common in WM.

Impact of Waldenström Macroglobulinemia Genomics on Clinical Presentation

MYD88 and CXCR4 mutations are important determinants of the clinical presentation of WM patients. Significantly higher marrow disease involvement, serum IgM levels, and symptomatic disease requiring therapy, including hyperviscosity syndrome was observed in those patients with MYD88^{L265P}CXCR4^{WHIM/NS} mutations.⁵⁰ Patients with MYD88^{L265P}CXCR4^{WHIM/FS} or MYD88^{L265P}CXCR4^{WT} had intermediate marrow and serum IgM levels; those with MYD88^{L265P}CXCR4^{WT} showed the lowest marrow disease burden. Fewer patients with MYD88^{L265P} and CXCR4^{WHIM/FS} or CXCR4^{WHIM/NS}, compared to MYD88^{L265P}CXCR4^{WT} presented with adenopathy, further delineating differences in disease tropism based on CXCR4 status. Despite the more-aggressive presentation associated with CXCR4^{WHIM/NS} genotype, risk of death was not impacted by CXCR4 mutation status. Risk of death was found to be 10-fold higher in patients with MYD88^{WT} versus MYD88^{L265P} genotype.⁵⁰

MARROW MICROENVIRONMENT

Increased numbers of mast cells are found in the marrow of WM patients, wherein they are usually admixed with tumor cell aggregates (see Fig. 109–1).^{14,18,57} The role of mast cells in WM was investigated in one study wherein coculture of primary autologous or mast cell lines with WM cells resulted in dose-dependent WM cell proliferation and/or tumor colony formation, through CD40 ligand (CD40L) signaling.⁵⁷ WM cells release soluble CD27 (sCD27), which may be triggered by cleavage of membrane-bound CD27 by matrix metalloproteinase 8 (MMP8).⁵⁸ sCD27 levels are elevated in the serum of WM patients, and follow disease burden in mice engrafted with WM cells, as well as in WM patients.⁶⁰ sCD27 triggers the upregulation of CD40L and a proliferation-inducing ligand (APRIL) on mast cells derived from WM patients, and mast cell lines through its receptor CD70. Modeling in mice engrafted with a CD70-blocking antibody shows inhibition of tumor cell growth, suggesting that WM cells require a microenvironmental support system for their growth and survival.⁵⁹ High levels of CXCR4 and very late antigen-4 (VLA-4) have also been observed in WM cells.⁶⁰ In blocking experiments studies, CXCR4 supported migration of WM cells, while VLA-4 contributed to adhesion of WM cells to marrow stromal cells.⁶⁰

CLINICAL FEATURES

Table 109–1 presents the clinical and laboratory findings at time of diagnosis of WM in one large institutional study.¹⁶ Unlike most indolent lymphomas, splenomegaly and lymphadenopathy are uncommon (≤ 15 percent). Purpura is frequently associated with cryoglobulinemia and in rare circumstances with light-chain (AL) amyloidosis (Chap. 108). Hemorrhagic and neuropathic manifestations are multifactorial (see “Immunoglobulin M–Related Neuropathy” below). The morbidity associated with WM is caused by the concurrence of two main components: tissue infiltration by neoplastic cells and, importantly, the

physicochemical and immunologic properties of the monoclonal IgM. As shown in Table 109–2, the monoclonal IgM can produce clinical manifestations through several different mechanisms related to its physicochemical properties, nonspecific interactions with other proteins, antibody activity, and tendency to deposit in tissues.^{61–63}

MORBIDITY MEDIATED BY THE EFFECTS OF IMMUNOGLOBULIN M

Hyperviscosity Syndrome

The increased plasma IgM levels leads to blood hyperviscosity and its complications.⁶⁴ The mechanisms behind the marked increase in the resistance to blood flow and the resulting impaired transit through the microcirculatory system are complex.^{64–67} The main determinants are (1) a high concentration of monoclonal IgMs, which may form aggregates and may bind water through their carbohydrate component; and (2) their interaction with blood cells. Monoclonal IgM increases red cell aggregation (rouleaux formation; see Fig. 109–1) and red cell internal viscosity while reducing red cell deformability. The presence of cryoglobulins contributes to increasing blood viscosity, as well as to the tendency to induce erythrocyte aggregation. Serum viscosity is proportional to IgM concentration up to 30 g/L, then increases sharply at higher levels. Increased plasma viscosity may also contribute

TABLE 109–2. Physicochemical and Immunological Properties of the Monoclonal Immunoglobulin M Protein in Waldenström’s Macroglobulinemia

Properties of IgM Monoclonal Protein	Diagnostic Condition	Clinical Manifestations
Pentameric structure	Hyperviscosity	Headaches, blurred vision, epistaxis, retinal hemorrhages, leg cramps, impaired mentation, intracranial hemorrhage
Precipitation on cooling	Cryoglobulinemia (type I)	Raynaud phenomenon, acrocyanosis, ulcers, purpura, cold urticaria
Autoantibody activity to myelin-associated glycoprotein, ganglioside M ₁ , sulfatide moieties on peripheral nerve sheaths	Peripheral neuropathies	Sensorimotor neuropathies, painful neuropathies, ataxic gait, bilateral foot drop
Autoantibody activity to IgG	Cryoglobulinemia (type II)	Purpura, arthralgia, renal failure, sensorimotor neuropathies
Autoantibody activity to red blood cell antigens	Cold agglutinins	Hemolytic anemia, Raynaud phenomenon, acrocyanosis, livedo reticularis
Tissue deposition as amorphous aggregates	Organ dysfunction	Skin: bullous skin disease, papules, Schnitzler syndrome Gastrointestinal: diarrhea, malabsorption, bleeding Kidney: proteinuria, renal failure (light-chain component)
Tissue deposition as amyloid fibrils (light-chain component most commonly)	Organ dysfunction	Fatigue, weight loss, edema, hepatomegaly, macroglossia, organ dysfunction of involved organs (heart, kidney, liver, peripheral sensory and autonomic nerves)

Ig, immunoglobulin.

to inappropriately low erythropoietin production, which is the major reason for anemia in these patients.⁶⁷ Renal synthesis of erythropoietin is inversely correlated with plasma viscosity. Clinical manifestations are related to circulatory disturbances that can be best appreciated by ophthalmoscopy, which shows distended and tortuous retinal veins, hemorrhages, and papilledema (Fig. 109–3).⁶⁸ Symptoms usually occur when the monoclonal IgM concentration exceeds 50 g/L or when serum

viscosity is greater than 4.0 centipoises (cp), but there is individual variability, with some patients showing no evidence of hyperviscosity even at 10 cp.⁶⁴ The most common symptoms are oronasal mucosal bleeding, visual disturbances because of retinal bleeding, and dizziness that rarely may lead to stupor or coma. Heart failure can be aggravated, particularly in the elderly, owing to increased blood viscosity, expanded plasma volume, and anemia. Inappropriate red cell transfusion can exacerbate hyperviscosity and may precipitate cardiac failure.

Figure 109–3. Fundusoscopic examination of a patient with Waldenström macroglobulinemia with hyperviscosity-related changes, including dilated retinal vessels, hemorrhages, and “venous sausageing.” The white material at the edge of the veins may be cryoglobulin. (Used with permission of Marvin J. Stone, MD.)

Cryoglobulinemia

The monoclonal IgM can behave as a cryoglobulin in up to 20 percent of patients, and is usually type I and asymptomatic in most cases.^{16,64,70} Cryoprecipitation is mainly dependent on the concentration of monoclonal IgM; for this reason plasmapheresis or plasma exchange are commonly effective in this condition. Symptoms result from impaired blood flow in small vessels and include Raynaud phenomenon, acrocyanosis, and necrosis of the regions most exposed to cold, such as the tip of the nose, ears, fingers, and toes (Fig. 109–4), malleolar ulcers, purpura, and cold urticaria. Renal manifestations are infrequent. Mixed cryoglobulins (type II) consisting of IgM–IgG complexes may be associated with hepatitis C infections.⁷⁰

Autoantibody Activity

Monoclonal IgM may exert its pathogenic effects through specific recognition of autologous antigens, the most notable being nerve constituents, immunoglobulin determinants, and red blood cell antigens.

Immunoglobulin M–Related Neuropathy

IgM-related peripheral neuropathy is common in WM patients, with estimated prevalence rates of 5 to 40 percent.^{71–73} Approximately 8 percent of idiopathic neuropathies are associated with a monoclonal gammopathy, with a preponderance of IgM (60 percent) followed by IgG (30 percent) and IgA (10 percent) (Chap. 106).^{74,75} The nerve damage is mediated by diverse pathogenetic mechanisms: (1) IgM antibody activity toward nerve constituents causing demyelinating polyneuropathies;

Figure 109-4. Cryoglobulinemia manifesting with severe acrocyanosis in a patient with Waldenström macroglobulinemia before (A) and following warming and plasmapheresis (B).

(2) endoneurial granulo-fibrillar deposits of IgM without antibody activity, associated with axonal polyneuropathy; (3) occasionally by tubular deposits in the endoneurium associated with IgM cryoglobulin; and, rarely, (4) by amyloid deposits or by neoplastic cell infiltration of nerve structures.^{73,76} Half of the patients with IgM neuropathy have a distinctive clinical syndrome that is associated with antibodies against a minor 100-kDa glycoprotein component of nerve known as the myelin-associated glycoprotein (MAG). Anti-MAG antibodies are generally monoclonal IgM κ , and usually also exhibit reactivity with other glycoproteins or glycolipids that share antigenic determinants with MAG.⁷⁷⁻⁷⁹ The anti-MAG-related neuropathy is typically distal and symmetrical, affecting both motor and sensory functions; it is slowly progressive with a long period of stability.^{72,80} Most patients present with sensory complaints (paresthesias, aching discomfort, dysesthesias, or lancinating pains), imbalance and gait ataxia, owing to lack proprioception; leg muscles atrophy in advanced stage. Patients with predominantly demyelinating sensory neuropathy in association with monoclonal IgM to gangliosides with disialosyl moieties, such as GD1b, GD3, GD2, GT1b, and GQ1b, have also been reported.^{81,82} Anti-GD1b and anti-GQ1b antibodies were associated with sensory ataxic neuropathy. These antiganglioside monoclonal IgMs present core clinical features of chronic ataxic neuropathy sometimes with present ophthalmoplegia and/or red blood cell cold agglutinating activity. The disialosyl epitope is also present on red blood cell glycoporphins, thereby accounting for the red cell cold agglutinin activity of anti-Pr2 specificity.^{83,84} Monoclonal IgM proteins that bind to gangliosides with a terminal trisaccharide moiety, including ganglioside M₂ (GM₂) and GalNac-GD1A, are associated with chronic demyelinating neuropathy and severe sensory ataxia, unresponsive to glucocorticoids.⁸⁵ Antiganglioside IgM proteins may also cross-react with lipopolysaccharides of *Campylobacter jejuni*, whose infection is known to precipitate the Miller-Fisher syndrome, a variant of the Guillain-Barré syndrome.⁸⁶ Thus, molecular mimicry may play a role in this condition. Antisulfatide monoclonal IgM proteins, associated with sensory-sensorimotor neuropathy, have been detected in 5 percent of

patients with IgM monoclonal gammopathy and neuropathy.⁸⁷ Motor neuron disease has been reported in patients with WM and monoclonal IgM with anti-GM₁ and sulfoglucuronyl paragloboside activity.⁸⁸ Polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes (the POEMS syndrome) are rare in patients with WM.⁸⁹

Cold Agglutinin Hemolytic Anemia

Monoclonal IgM may have cold agglutinin activity, that is, it can recognize specific red cell antigens at temperatures below 37°C, producing chronic hemolytic anemia. This disorder occurs in less than 10 percent of WM patients and is associated with cold agglutinin titers greater than 1:1000 in most cases.⁹⁰ The monoclonal component is usually an IgM κ and reacts most commonly with red cell I/i antigens, resulting in complement fixation and activation.^{91,92} Mild to moderate chronic hemolytic anemia can be exacerbated after cold exposure. Hemoglobin usually remains above 70 g/L. The hemolysis is usually extravascular, mediated by removal of C3b opsonized red cells by the mononuclear phagocyte system, primarily in the liver. Intravascular hemolysis from complement destruction of red blood cell membrane is infrequent. The agglutination of red cells in the skin circulation also causes Raynaud syndrome, acrocyanosis, and livedo reticularis. Macroglobulins with the properties of both cryoglobulins and cold agglutinins with anti-Pr specificity can occur. These properties may have as a common basis the binding of the sialic acid-containing carbohydrate present on red blood cell glycoporphins and on Ig molecules. Several other macroglobulins with antibody activity toward autologous antigens (e.g., phospholipids, tissue and plasma proteins) and foreign ligands have also been described.

Immunoglobulin M Tissue Deposition

The monoclonal protein can deposit in several tissues as amorphous aggregates. Linear deposition of monoclonal IgM along the skin basement membrane is associated with bullous skin disease.⁹³ Amorphous IgM deposits in the dermis result in IgM storage papules on the extensor

surface of the extremities, referred to as macroglobulinemia cutis.⁹⁴ Deposition of monoclonal IgM in the lamina propria and/or submucosa of the intestine may be associated with diarrhea, malabsorption, and gastrointestinal bleeding.^{95,96} Kidney involvement is less common and less severe in WM than in myeloma, probably because the amount of light chain excreted in the urine is generally lower in WM than in myeloma and because of the absence of contributing factors, such as hypercalcemia. Urinary cast nephropathy, however, has occurred in WM.⁹⁷ On the other hand, the IgM macromolecule is more susceptible to being trapped in the glomerular loops where ultrafiltration presumably contributes to its precipitation, forming subendothelial deposits of aggregated IgM proteins that occlude the glomerular capillaries.⁹⁸ Mild and reversible proteinuria may result and most patients are asymptomatic. The deposition of monoclonal light chain as fibrillar amyloid deposits (AL amyloidosis) is uncommon in patients with WM.⁹⁹ Clinical expression and prognosis are similar to those of other AL amyloidosis patients with involvement of heart (44 percent), kidneys (32 percent), liver (14 percent), lungs (10 percent), peripheral or autonomic nerves (38 percent), and soft tissues (18 percent). The incidence of cardiac and pulmonary involvement is higher in patients with monoclonal IgM than with other immunoglobulin isotypes. The association of WM with reactive amyloidosis has been documented rarely.^{100,101} Simultaneous occurrence of fibrillary glomerulopathy, characterized by glomerular deposits of wide nonconglomerular fibrils and amyloid deposits, has been described.¹⁰²

MANIFESTATIONS RELATED TO TISSUE INFILTRATION BY NEOPLASTIC CELLS

Tissue infiltration by neoplastic cells is uncommon but can involve various organs and tissues, including the liver, spleen, lymph nodes, lungs, gastrointestinal tract, kidneys, skin, eyes, and central nervous system.

Lung

Pulmonary involvement in the form of masses, nodules, diffuse infiltrate, or pleural effusions is uncommon; the overall incidence of pulmonary and pleural findings is approximately 4 percent.^{103–105} Cough is the most common presenting symptom, followed by dyspnea and chest pain. Chest radiographic findings include parenchymal infiltrates, confluent masses, and effusions.

Gastrointestinal Tract

Malabsorption, diarrhea, bleeding, or obstruction may indicate involvement of the gastrointestinal tract at the level of the stomach, duodenum, or small intestine.^{106–109}

Renal System

In contrast to myeloma, infiltration of the kidney interstitium with lymphoplasmacytoid cell can occur in WM, and renal or perirenal masses are not uncommon.^{110,111}

Skin

The skin can be the site of dense lymphoplasmacytoid infiltrates, similar to that seen in the liver, spleen, and lymph nodes, forming cutaneous plaques and, rarely, nodules.¹¹² Chronic urticaria and IgM gammopathy are the two cardinal features of the Schnitzler syndrome, which is not usually associated initially with clinical features of WM, although evolution to WM is not uncommon.¹¹³ Thus, close followup of these patients is important.

Joints

Invasion of articular and periarticular structures by WM malignant cells is rarely reported.¹¹⁴

Eye

The neoplastic cells can infiltrate the periorbital structures, lacrimal gland, and retroorbital lymphoid tissues, resulting in ocular nerve palsies.^{115,116}

Central Nervous System

Direct infiltration of the central nervous system by monoclonal lymphoplasmacytoid cells as infiltrates or as tumors constitutes the rarely observed Bing-Neel syndrome, characterized clinically by confusion, memory loss, disorientation, and motor dysfunction (reviewed in Ref. 117).

LABORATORY FINDINGS

BLOOD ABNORMALITIES

Anemia is the most common finding in patients with symptomatic WM and is caused by a combination of factors: decrease in red cell survival, impaired erythropoiesis, moderate plasma volume expansion, hepcidin production leading to iron reutilization defect, and blood loss from the gastrointestinal tract.^{16,118,119} Blood films are usually normocytic and normochromic, and rouleaux formation is often pronounced (see Fig. 109–1). Mean red cell volume may be elevated spuriously owing to erythrocyte aggregation. In addition, the hemoglobin estimate can be inaccurate, that is, falsely high, because of interaction between the monoclonal protein and the diluent used in some automated analyzers.¹²⁰ Leukocyte and platelet counts are usually within the reference range at presentation, although patients may occasionally present with severe thrombocytopenia. Monoclonal B-lymphocytes expressing surface IgM and late-differentiation B-cell markers are uncommonly detected in blood by flow cytometry. A raised erythrocyte sedimentation rate is almost always present and may be the first clue to the presence of the macroglobulinemia. The clotting abnormality detected most frequently is prolongation of thrombin time. AL amyloidosis should be suspected in all patients with nephrotic syndrome, cardiomyopathy, hepatomegaly, or peripheral neuropathy. Diagnosis requires the demonstration of green birefringence under polarized light of amyloid deposits stained with Congo red.

MARROW FINDINGS

Central to the diagnosis of WM is the demonstration, by trephine biopsy, of marrow infiltration by a lymphoplasmacytoid cell population characterized by small lymphocytes with evidence of plasmacytoid and plasma cell maturation (see Fig. 109–1).^{1,14} The pattern of marrow infiltration may be diffuse, interstitial, or nodular, usually with an intertrabecular pattern of infiltration. A solely paratrabecular pattern of infiltration is unusual and should raise the possibility of follicular lymphoma.¹ The marrow cell immunophenotype should be confirmed by flow cytometry and/or immunohistochemistry. The cell immunoprofile: sIgM⁺CD19⁺CD20⁺CD22⁺CD79⁺ is characteristic of WM.^{14,120,121} Up to 20 percent of cases may express either CD5, CD10, or CD23.¹⁹ In these cases, chronic lymphocytic leukemia and mantle cell lymphoma should be excluded. “Intranuclear” periodic acid-Schiff–positive inclusions (Dutcher–Fahey bodies)¹²² consisting of IgM deposits in the perinuclear space, and sometimes in intranuclear vacuoles, may be seen occasionally in lymphoid cells. An increased number of mast cells, usually in association with the lymphoid aggregates is commonly found, and their presence may help in differentiating WM from other B-cell lymphomas (Fig. 109–5).¹⁴ MYD88^{L265P} testing of marrow samples has been incorporated into many clinical laboratories, and may help in clarifying the diagnosis of WM from other IgM-secreting entities.^{35–39} The use of blood B cells may also permit determination of MYD88^{L265P} status by allele-specific PCR assays, particularly in untreated WM patients.

Figure 109-5. Marrow clot section. **A.** Tryptase-staining mast cells surrounding a nodule of lymphoplasmacytic cells in a patient with Waldenström macroglobulinemia. **B.** Mast cells in the same section exhibit strong CD40 ligand signaling, which has been shown to support (at least in part) the growth and survival of lymphoplasmacytic cells.

IMMUNOLOGIC ABNORMALITIES

High-resolution electrophoresis combined with immunofixation of serum and urine is recommended for identification and characterization of the IgM monoclonal protein. The light chain of the monoclonal IgM is κ in 75 to 80 percent of patients. More than one M component may be present. The concentration of the serum monoclonal protein is very variable but in most cases lies within the range of 15 to 45 g/L. Densitometry should be adopted to determine IgM levels for serial evaluations because nephelometry is unreliable and shows large laboratory variation. The presence of cold agglutinins or cryoglobulins may affect determination of IgM levels and, therefore, testing for cold agglutinins and cryoglobulins should be performed at diagnosis. If present, subsequent serum samples should be analyzed at 37°C for determination of serum monoclonal IgM level. Although Bence Jones proteinuria is frequently present, it exceeds 1 g/24 h in only 3 percent of cases. Whereas IgM levels are elevated in WM patients, IgA and IgG levels are most often depressed and do not recover after successful treatment.¹²³

SERUM VISCOSITY

Because of its large size (almost 1,000,000 daltons), most IgM molecules are retained within the intravascular compartment and can exert an undue effect on serum viscosity.⁶⁴ Serum viscosity can be measured if the patient has signs or symptoms of hyperviscosity syndrome, although serum viscosity levels are erratic because of a lack of standardization in most clinical laboratories.¹⁶ As such, inferences derived from serum IgM levels may be more reliable. Patients typically become symptomatic at serum viscosity levels of 4 cp and above, which relates to serum IgM levels above 6000 mg/dL.^{124,125} Patients may be symptomatic at lower serum viscosity and IgM levels, and in these patients cryoglobulins may be present. Recurring nosebleeds, headaches, and visual disturbances are common symptoms in patients with symptomatic hyperviscosity.¹⁶ Funduscopy is an important indicator of clinically relevant hyperviscosity. Among the first clinical signs of hyperviscosity are the appearance of peripheral and midperipheral dot and blot-like hemorrhages in the retina, which are best appreciated with indirect ophthalmoscopy and

scleral depression.⁶⁸ In more severe cases of hyperviscosity, dot, blot, and flame-shaped hemorrhages can appear in the macular area along with markedly dilated and tortuous veins with focal constrictions resulting in “venous sausaging,” as well as papilledema. The effects of hyperviscosity are mediated by the blood viscosity as a result of IgM-red cell interactions but measurement of serum viscosity is much simpler than is blood viscosity and is not shear rate dependent so easier to related to clinical manifestations.

IMAGING

Magnetic resonance imaging (MRI) of the spine in conjunction with computed tomography (CT) of the abdomen and pelvis are useful in evaluating the disease status.¹²⁶ Marrow involvement can be documented by MRI studies of the spine in more than 90 percent of patients; CT of the abdomen and pelvis demonstrates enlarged nodes in approximately 40 percent of WM patients.¹²⁶

LYMPH NODE BIOPSY

Lymph node biopsy may show preserved architecture or replacement by infiltration of neoplastic cells with lymphoplasmacytoid, lymphoplasmacytic, or polymorphous cytologic patterns.

POLYMERASE CHAIN REACTION

The residual disease after high-dose chemotherapy with allogeneic or autologous stem-cell rescue can be monitored by PCR-based methods using primers specific for the monoclonal Ig variable regions.

TREATMENT

DECIDING ON INITIATING TREATMENT

As part of the Second International Workshop on Waldenström Macroglobulinemia, a consensus panel was organized to recommend criteria for the initiation of therapy in patients with WM.¹²⁷ The panel recommended that initiation of therapy should not be based on the IgM level per se, as this may not correlate with the clinical manifestations of WM.

The consensus panel did, however, agree that initiation of therapy is appropriate for patients with constitutional symptoms, such as recurrent fever, night sweats, fatigue as a consequence of anemia, or weight loss. Progressive symptomatic lymphadenopathy and/or splenomegaly provide additional reasons to begin therapy. Anemia with a hemoglobin value of 10 g/dL or less or a platelet count of $100 \times 10^9/L$ or less owing to marrow infiltration, also justifies treatment. Certain complications, such as hyperviscosity syndrome, symptomatic sensorimotor peripheral neuropathy, systemic amyloidosis, renal insufficiency, or symptomatic cryoglobulinemia, may also be indications for therapy.^{16,127}

INITIAL THERAPY

The International Workshops on Waldenström Macroglobulinemia have also formulated consensus recommendations for both initial therapy and therapy for refractory disease based on the best available evidence. The most recent recommendations emerged from the Seventh International Workshop on Waldenström Macroglobulinemia.¹²⁸ Individual patient considerations, including the presence of cytopenias, need for more rapid disease control, age, and candidacy for autologous transplant therapy, should be taken into account in making the choice of the drugs to use. For patients who are candidates for autologous stem cell transplantation, which typically is reserved for those patients younger than 70 years of age, the panel recommended that exposure to alkylating agents or nucleoside analogues should be limited. The use of nucleoside analogues should be approached cautiously in patients with WM as there appears to be an increased risk for the development of disease transformation, as well as myelodysplasia and acute myelogenous leukemia.

Oral Alkylating Agents

Oral alkylating drugs, alone and in combination therapy with glucocorticoids, have been extensively evaluated in the treatment of WM. Chlorambucil has been administered on both a continuous (i.e., daily dose schedule) and an intermittent schedule. Patients receiving chlorambucil on a continuous schedule typically receive 0.1 mg/kg per day, whereas on the intermittent schedule patients typically receive 0.3 mg/kg for 7 days, every 6 weeks. In a prospective randomized study, no significant difference in the overall response rate between these schedules was observed,¹²⁹ although the median response duration was greater for patients receiving intermittent-dose versus continuous-dose chlorambucil (46 vs. 26 months). Despite the favorable median response duration in this study for use of the intermittent schedule, no difference in the median overall survival was observed. Moreover, an increased incidence for development of myelodysplasia and acute myelogenous leukemia with the intermittent (three of 22 patients) versus the continuous (zero of 24 patients) chlorambucil schedule prompted the preference for use of continuous chlorambucil dosing. The use of glucocorticoids in combination with alkylating agent therapy has also been explored. Chlorambucil (8 mg/m²) plus prednisone (40 mg/m²) given orally for 10 days, every 6 weeks, resulted in a major response (i.e., reduction of IgM by more than 50 percent) in 72 percent of patients.¹³⁰ Alkylating agent regimens employing melphalan and cyclophosphamide in combination with glucocorticoids also have been examined.^{131,132} This approach produced slightly higher overall response rates and response durations, although the benefit of these more complex regimens over chlorambucil remains to be demonstrated. Pretreatment factors associated with shorter survival in the entire population of patients receiving single-agent chlorambucil were age older than age 60 years, male sex, hemoglobin less than 10 g/dL, leukocytes less than $4 \times 10^9/L$, and platelets less than $150 \times 10^9/L$. Organomegaly, signs of hyperviscosity, renal failure, monoclonal IgM level, blood lymphocytosis, and percentage of marrow lymphoid cells were not significantly correlated with survival.¹³³ Additional factors to be taken into account in considering alkylating

agent therapy for patients with WM include necessity for more rapid disease control given the slow response, as well as consideration for preserving stem cells in patients who are candidates for autologous stem cell transplantation therapy. A large randomized study showed an inferior response rate and time to progression in WM patients receiving chlorambucil versus fludarabine, as well as a higher incidence of secondary malignancies in the former. Neutropenia was, however, more pronounced in those patients on fludarabine.¹³⁴

Nucleoside Analogue Therapy

Cladribine administered as a single agent by continuous intravenous infusion, by 2-hour daily infusion, or by subcutaneous bolus injections for 5 to 7 days has resulted in major responses in 40 to 90 percent of patients who received primary therapy, whereas in the previously treated patients, responses have ranged from 38 to 54 percent.¹³⁵⁻¹⁴¹ Median time to achievement of response in responding patients following cladribine ranged from 1.2 to 5 months. The overall response rate with daily infusion of fludarabine, administered mainly on 5-day schedules, in previously untreated and treated patients, ranged from 38 to 100 percent and 30 to 40 percent, respectively,¹⁴²⁻¹⁴⁷ similar to the responses to cladribine. Median time to achievement of response for fludarabine (3 to 6 months) was also similar to cladribine. In general, response rates and durations of responses have been greater for patients receiving nucleoside analogues as initial therapy, although in several studies in which both untreated and previously treated patients were enrolled, no difference in the overall response rate was reported.

Myelosuppression commonly occurs following prolonged exposure to either of the nucleoside analogues. A sustained decrease in both CD4+ and CD8+ T lymphocytes, measured 1 year following initiation of therapy, is notable.¹³⁵⁻¹³⁷ Treatment-related mortality as a consequence of myelosuppression and/or opportunistic infections attributable to immunosuppression occurred in up to 5 percent of all treated patients in some series with nucleoside analogues.

Factors predicting for a better response to nucleoside analogues include younger age at start of treatment (<70 years), higher pretreatment hemoglobin (>95 g/L), higher platelet count (> $75 \times 10^9/L$), disease relapsing off therapy, and a long interval between first-line therapy and initiation of a nucleoside analogue in relapsing patients.^{135,140,146} There are limited data on the use of an alternate nucleoside analogue in previously treated patients among whom disease relapsed or who had resistance when not on cladribine or fludarabine therapy.^{148,149} Three of four (75 percent) patients responded to cladribine after progression following an unmaintained remission to fludarabine, whereas only one of 10 (10 percent) with disease resistant to fludarabine responded to cladribine.¹⁴⁸ A response in two of six patients (33 percent) and disease stabilization in the remaining patients to fludarabine, in spite of an inadequate response or progressive disease, following cladribine therapy has been reported.¹⁴⁹

Harvesting autologous blood stem cells succeeded on the first attempt in 14 of 15 patients who did not receive nucleoside analogue therapy as compared to two of six patients who received a nucleoside analogue.¹⁵⁰ A sevenfold increase in transformation to an aggressive lymphoma and a threefold increase in the development of myelodysplasia or acute myelogenous leukemia were observed among patients who received a nucleoside analogue versus other therapies for their WM.¹⁵¹ A meta-analysis of several trials in which patients were treated with nucleoside analogues in WM patients, included patients who had previously received an alkylating agent, and showed a crude incidence of approximately 8 percent for development of disease transformation and of approximately 5 percent for development of myelodysplasia or acute myelogenous leukemia.¹⁵² None of the risk factors—that is, gender, age, family history of WM, or B-cell malignancies, typical markers of tumor burden and prognosis, type of nucleoside analogue therapy (cladribine

vs. fludarabine), time from diagnosis to nucleoside analogue use, nucleoside analogue treatment as primary or salvage therapy, or treatment with an oral alkylator (i.e., chlorambucil)—predicted for the occurrence of transformation or development of myelodysplasia or acute myelogenous leukemia in patients treated with a nucleoside analogue.¹⁵²

CD20-Directed Antibody Therapy

Rituximab is a chimeric monoclonal antibody that targets CD20, a widely expressed antigen on lymphoplasmacytic cells in WM.¹⁵³ Several retrospective and prospective studies indicated that rituximab, when used at standard doses (i.e., 4 weekly intravenous infusions of 375 mg/m²) induced major responses in approximately 30 percent of previously treated and untreated patients.^{154,155} Even patients who achieved minor responses benefited from rituximab by improved hemoglobin and platelet counts, and reduction of lymphadenopathy and/or splenomegaly.¹⁵⁴ The median time to treatment failure in these studies was found to range from 8 to 27+ months. Patients on an extended rituximab schedule consisting of four weekly courses at 375 mg/m² per week, repeated 3 months later by another 4-week course have demonstrated major response rates of approximately 45 percent, with time to progression estimates of 16+ to 29+ months.^{156,157}

In many WM patients, a transient increase or flare of the serum IgM may occur immediately following initiation of rituximab treatment.^{156,158,159} Such an increase does not herald treatment failure and most patients will return to their baseline serum IgM level by 12 weeks. Some patients continue to show a prolonged increase in IgM despite an apparent reduction in their marrow tumor cells. However, patients with baseline serum IgM levels of greater than 50 g/dL or serum viscosity of greater than 3.5 cp may be particularly at risk for a hyperviscosity-related event and plasmapheresis should be considered in these patients in advance of rituximab therapy.¹⁵⁸ Because of the decreased likelihood of response in patients with higher IgM levels, as well as the possibility that serum IgM and blood viscosity levels may abruptly rise, rituximab monotherapy should not be used as sole therapy for the treatment of patients at risk for hyperviscosity signs and symptoms.^{128,156,157}

Time to response after rituximab is slow and exceeds 3 months on the average. The time to best response in one study was 18 months.¹⁵⁷ Patients with baseline serum IgM levels of less than 60 g/dL are more likely to respond, regardless of the underlying marrow involvement by tumor cells.^{156,157} An analysis of 52 patients who were treated with single-agent rituximab found the objective response rate was significantly lower in patients who had either low serum albumin (<35 g/L) or a serum monoclonal protein greater than 40 g/L.¹⁶⁰ The presence of both adverse prognostic factors was associated with a short time to progression (3.6 months). Patients who had normal serum albumin and relatively low serum monoclonal protein levels derived a substantial benefit from rituximab with a time to progression exceeding 40 months.

A correlation between polymorphisms at position 158 in the FcγRIIIa receptor (CD16), an activating Fc receptor on important effector cells that mediate antibody-dependent cell-mediated cytotoxicity, and rituximab response was observed in WM patients.¹⁶¹ Individuals may encode either the amino acid valine or phenylalanine at position 158 in the FcγRIIIa receptor. WM patients who carried the valine amino acid (either in a homozygous or heterozygous pattern) had a fourfold higher major response rate (i.e., 50 percent decline in serum IgM levels) to rituximab versus those patients who expressed phenylalanine in a homozygous pattern.

Proteasome Inhibitors

Both bortezomib and carfilzomib have been evaluated in prospective studies in patients with WM, although the latter only in combination therapy (discussed below). In a retrospective study, 10 patients with refractory or relapsed WM were treated with bortezomib administered intravenously at a dose of 1.3 mg/m² on days 1, 4, 8, and 11 in a 21-day

cycle for a total of four cycles. Most patients had been exposed to all active agents for WM and eight patients had received three or more regimens. Six of these patients achieved a partial response which occurred at a median of 1 month. The median time to progression in the responding patients is expected to exceed 11 months. Peripheral neuropathy occurred in three patients and one patient developed severe paralytic ileus in this series.¹⁶² In a prospective study among 27 relapsed or refractory patients who received up to eight cycles of bortezomib at 1.3 mg/m² on days 1, 4, 8, and 11, median serum IgM levels declined significantly from 4.7 g/dL to 2.1 g/dL.³³ The overall response rate was 85 percent, with 10 and 13 patients achieving a minor (≥25 percent) and major (≥50 percent) decrease in IgM level. Responses occurred at a median of 1.4 months. The median time to progression for all responding patients in this study was 7.9 (range: 3.0 to 21.4+) months, and the most common grades III/IV toxicities were sensory neuropathies (22.2 percent), leukopenia (18.5 percent), neutropenia (14.8 percent), dizziness (11.1 percent), and thrombocytopenia (7.4 percent). Sensory neuropathies resolved or improved in nearly all patients following cessation of therapy. Twenty-seven patients with both untreated (44 percent) and previously treated (56 percent) disease received bortezomib, using the standard schedule until they either demonstrated progressive disease or two cycles beyond a complete response or stable disease.¹⁶³ The overall response rate was 78 percent, with major responses observed in 44 percent of patients. Sensory neuropathy occurred in 20 patients following two to four cycles of therapy. Among the 20 patients developing a neuropathy, 14 showed resolution or improvement 2 to 13 months after therapy.

Combination Therapies

Because rituximab is not myelosuppressive, its combination with chemotherapy has been explored. A regimen of rituximab, cladribine, and cyclophosphamide used in 17 previously untreated patients resulted in a partial response in 94 percent of WM patients, including a complete response in 18 percent.¹⁶⁴ No patient had relapsed with a median followup of 21 months. The combination of rituximab and fludarabine used in 43 patients of whom 32 (75 percent) were previously untreated, led to an overall response rate of 95.3 percent, with 83 percent of patients achieving a major response (i.e., 50 percent reduction in disease burden).¹⁶⁵ The median time to progression was 51.2 months in this series, and was longer for those patients who were previously untreated and for those achieving a very good partial remission (i.e., 90 percent reduction in disease) or better. Hematologic toxicity was common: grade 3 neutropenia and thrombocytopenia observed in 27 and four patients, respectively. Two deaths occurred in this study from pneumonia. Secondary malignancies including transformation to aggressive lymphoma and development of myelodysplasia or acute myelogenous leukemia were observed in six patients in this series. The addition of rituximab to fludarabine and cyclophosphamide has also been explored in previously treated patients, of whom four of five patients had a response.¹⁶⁶ In another combination study, rituximab along with pentostatin and cyclophosphamide given to 13 patients with untreated and previously treated WM or LPL resulted in a major response in 77 percent of patients.¹⁶⁷ The combination of rituximab, dexamethasone, and cyclophosphamide was used as primary therapy to treat 72 patients with WM in whom a major response was observed in 74 percent of patients in this study, and the 2-year progression-free survival was 67 percent.¹⁶⁸ Therapy was well tolerated, although one patient died of interstitial pneumonia.

Two studies examined cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) in combination with rituximab (R-CHOP). In a randomized trial involving 69 patients, most of whom had WM, the addition of rituximab to CHOP resulted in a higher overall response rate (94 percent vs. 67 percent) and median time to progression (63 vs. 22 months) in comparison to patients treated with

CHOP alone.¹⁶⁹ R-CHOP was also used in 13 WM patients, 10 of whom had relapsed or refractory disease.¹⁷⁰ Among 13 evaluable patients, 10 patients achieved a major response (77 percent), including three complete and seven partial remissions. Two other patients achieved a minor response. In a retrospective study of symptomatic WM patients who received either R-CHOP; rituximab, cyclophosphamide, vincristine, and prednisone (R-CVP); or cyclophosphamide, prednisone, and rituximab (R-CP) and were similar in most pretreatment variables, the overall response rates to therapy were comparable among all three treatment groups—R-CHOP (96 percent), R-CVP (88 percent), and R-CP (95 percent)—although there was a trend for more complete remissions among patients treated with R-CVP and R-CHOP.¹⁷¹ Adverse events attributed to therapy showed a higher incidence for neutropenic fever and treatment related neuropathy for R-CHOP and R-CVP versus R-CP. The results of this study suggest that in WM, the use of R-CP may provide analogous treatment responses to more intense cyclophosphamide-based regimens while minimizing treatment-related complications. The extended alkylator bendamustine has also been evaluated in combination with rituximab in both untreated, as well as previously treated WM patients. A randomized study by the German STiL Group examined bendamustine plus rituximab (BR) versus R-CHOP in patients with untreated, indolent B-cell lymphomas including WM.¹⁷² Patients with WM in this study showed similar overall responses (96 percent vs. 94 percent), although progression-free survival was significantly longer (69 vs. 29 months) in patients who received BR versus R-CHOP. Treatment was also better tolerated in patients receiving BR. In the relapsed or refractory setting, an overall response rate of 83 percent was observed with bendamustine in combination with a CD20 monoclonal antibody.¹⁷³ The median time to progression was 13 months in this study. Prolonged myelosuppression was more common in patients who received prior nucleoside analogues.

The use of two cycles of oral cyclophosphamide along with subcutaneous cladribine to 37 patients with previously untreated WM led to a partial response in 84 percent of patients and the median duration of response was 36 months.¹⁶⁴ Fludarabine in combination with intravenous cyclophosphamide resulted in partial responses in six of 11 (55 percent) WM patients with either primary refractory disease or who had relapsed on treatment.¹⁷⁴ The combination of fludarabine plus cyclophosphamide was also evaluated in 49 patients, 35 of whom were previously treated. Seventy-eight percent of the patients achieved a response, and the median time to treatment failure was 27 months.¹⁷⁵ Hematologic toxicity was frequent, and three patients died of treatment-related toxicities. Two important findings in this study were the development of acute leukemia in two patients, histologic transformation to diffuse large B-cell lymphoma in one patient, and two cases of solid malignancies (prostate and melanoma), as well as failure to mobilize stem cells in 4 of 6 patients.

The combination of bortezomib, dexamethasone, and rituximab (BDR) as primary therapy in patients with WM resulted in an overall response rate of 96 percent, and a major response rate of 83 percent.¹⁷⁶ The incidence of grade 3 neuropathy was approximately 30 percent, but was reversible in most patients following discontinuation of therapy. An increased incidence of herpes zoster was also observed prompting the prophylactic use of antiviral therapy. Alternative schedules for administration of bortezomib (i.e., once weekly at higher doses) in combination with rituximab in patients with WM have achieved overall response rates of 80 to 90 percent.^{177,178} The European Myeloma Network (EMN) recently showed that transitioning bortezomib from twice weekly intravenous dosing during the first cycle to weekly administration thereafter reduced grade 3 neuropathy to less than 10 percent in patients treated with BDR.¹⁷⁹ There have been no studies addressing the safety and efficacy of subcutaneous bortezomib use in WM.

Carfilzomib which is associated with a low risk of treatment-related peripheral neuropathy has been evaluated in combination with rituximab and dexamethasone (CaRD) in WM patients.³⁴ Carfilzomib was administered intravenously at 20 mg/m² (cycle one), then 36 mg/m² (cycles two to six), together with dexamethasone (20 mg) on days 1, 2, 8, and 9 as part of a 21-day cycle. As part of this regimen, rituximab 375 mg/m² was given on days 2 and 9 every 21 days. Maintenance therapy was given 8 weeks following induction therapy with intravenous carfilzomib (36 mg/m²) and dexamethasone (20 mg) administered on days 1 and 2 and rituximab 375 mg/m² on day 2 every 8 weeks for up to eight cycles. Overall response rate with this regimen was 87.1 percent (one complete response, 10 very good partial responses, 10 partial responses, and six minimal responses) and was not impacted by MYD88^{L265P} or CXCR4^{WHIM} mutation status. With a median followup of 15.4 months, 20 patients remained progression free. Grade 2 or higher toxicities included asymptomatic hyperlipasemia (41.9 percent), reversible neutropenia (12.9 percent), and cardiomyopathy in one patient (3.2 percent) with multiple risk factors. Treatment-related neuropathy, which was grade 2, occurred in one patient (3.2 percent). Declines in serum IgA and IgG were common, and some patients required intravenous gammaglobulin therapy for recurring sinus and bronchial infections.

Novel Therapeutics

The use of Ibrutinib was recently approved by the FDA for the treatment of symptomatic patients with WM. Ibrutinib targets BTK, a target of ibrutinib that is activated by MYD88^{L265P}.⁴³ In a multicenter study that examined the role of ibrutinib in previously treated (median: two prior therapies, 40 percent refractory) WM patients, the overall response rate was 91 percent.¹⁸⁰ Patients on this study received 420 mg/day of ibrutinib by mouth. Posttherapy, median serum IgM levels declined from 3610 to 915 mg/dL; hemoglobin rose from 10.5 to 13.5 g/dL; and marrow involvement declined from 60 percent to 25 percent. Decreased or resolved adenopathy was observed in 60 percent of patients with extramedullary disease, and five of nine patients with IgM-related peripheral neuropathy had symptomatic improvement. The 24-month estimate for progression-free and overall survival was 70 percent and 95 percent, respectively. Although major response rates were lower in patients with MYD88^{WT} and CXCR4^{WHIM} mutations, it is not recommended that genotyping be used to select which patients should go on ibrutinib until further data is available. Grade 2 or higher treatment-related toxicities included neutropenia (25 percent) and thrombocytopenia (14 percent), which were more common in heavily pretreated patients; atrial fibrillation associated with a prior history of arrhythmia (5 percent); and bleeding associated with procedures and marine oil supplements (3 percent). Serum IgA and IgG levels were unchanged following treatment with ibrutinib, and treatment-related infections were infrequent.

Everolimus is an oral inhibitor of the mammalian target of rapamycin (mTOR) pathway that is active in WM. A multicenter study examined everolimus in 60 previously treated patients that showed an overall response rate (ORR) of 73 percent, with 50 percent of patients attaining a major response.¹⁸¹ The median progression-free survival in this study was 21 months. Grade 3 or higher related toxicities were observed in 67 percent of patients, with cytopenias constituting the most common toxicity. Pulmonary toxicity occurred in 5 percent of patients, and dose reductions as a result of toxicity occurred in 52 percent of patients. A clinical trial examining the activity of everolimus in 33 previously untreated patients with WM has also been reported that included serial marrow biopsies in response assessment.¹⁸² The ORR in this study was 72 percent, including partial or better responses in 60 percent of patients. However, discordance between serum IgM levels upon which consensus criteria for response are based, and marrow disease response were common and complicated response assessment. In a few patients,

discontinuation of everolimus led to rapid increases in serum IgM levels, and symptomatic hyperviscosity. Grade 2 or higher hematologic and nonhematologic toxicities in this study that were related to everolimus were predominately hematologic, including anemia (40 percent), thrombocytopenia (12 percent), and neutropenia (18 percent). Non-hematologic toxicities included oral ulcerations (27 percent), which improved with oral dexamethasone swish and spit solution, and pneumonitis (15 percent), which led to treatment discontinuation.

Maintenance Therapy

A large retrospective study examined the categorical responses outcome of rituximab-naïve patients who were either observed or received maintenance rituximab. ¹⁸³ Categorical responses improved after induction therapy in 42 percent of patients who received maintenance rituximab versus 10 percent in patients on observation. Additionally, both progression-free survival (56.3 vs. 28.6 months) and overall survival (>120 vs. 116 months) were longer in patients who received maintenance rituximab. Improved progression-free survival was evident despite previous treatment status or induction with rituximab, either alone or in combination therapy. Best serum IgM response was also lower and hematocrit higher in those patients who received maintenance rituximab. Among patients who received maintenance rituximab therapy, an increased number of infectious events, predominantly grade 1 or 2 sinusitis and bronchitis were observed, along with lower serum IgA and IgG levels. A prospective study examining the role of maintenance rituximab was also initiated by the German STiL group. ¹⁸⁴ In this study, patients received up to six cycles of bendamustine and rituximab, and responders randomized to either observation or maintenance rituximab every 2 months for 2 years. Enrollment for this study is complete and response outcome for maintenance rituximab therapy is awaited.

HIGH-DOSE THERAPY AND STEM CELL TRANSPLANTATION

The European Bone Marrow Transplant Registry reported the largest experience for both autologous as well as allogeneic stem cell transplantation (SCT) in WM. ^{185,186} Among 158 WM patients receiving an autologous SCT, which included primarily relapsed or refractory patients, the 5-year progression-free and overall survival rate was 39.7 percent and 68.5 percent, respectively. ¹⁸⁵ Nonrelapse mortality at 1 year was 3.8 percent. Chemorefractory disease, and the number of prior lines of therapy at time of the autologous SCT were the most important prognostic factor for progression-free and overall survival. In the allogeneic SCT experience from the European Bone Marrow Transplant, the long-term outcome of 86 WM patients was reported. ¹⁸⁶ A total of 86 patients received allograft by either myeloablative or reduced-intensity conditioning. The median age of patients in this series was 49 years, and 47 patients had three or more previous lines of therapy. Eight patients failed prior autologous SCT. Fifty-nine patients (68.6 percent) had chemotherapy-sensitive disease at the time of allogeneic SCT. Nonrelapse mortality at 3 years was 33 percent for patients receiving a myeloablative transplant, and 23 percent for those who received reduced-intensity conditioning. The overall response rate was 75.6 percent. The relapse rates at 3 years were 11 percent for myeloablative, and 25 percent for reduced-intensity conditioning recipients. Five-year progression-free and overall survival for WM patients who received a myeloablative allogeneic SCT were 56 percent and 62 percent, respectively, and for patients who received reduced intensity conditioning were 49 percent and 64 percent, respectively. The occurrence of chronic graft-versus-host disease was associated with improved progression-free survival, and suggested the existence of a clinically relevant graft-versus-WM effect in this study.

● RESPONSE CRITERIA IN WALDENSTRÖM MACROGLOBULINEMIA

Table 109-3 summarizes the response categories and criteria for progressive disease in WM based on the most recent consensus recommendations. ¹⁸⁷ The term *overall response* is used to characterize all responses, including minor responses. Major responses only include partial, very good partial, and complete responses. The attainment of very good partial or complete responses is associated with improved progression-free survival. ^{155,165,176,179,188} Response assessments in WM rely primarily on serum IgM or IgM paraprotein levels, although complete responses require disappearance of the IgM monoclonal protein, and resolution of marrow and/or extramedullary WM disease. ¹⁸⁷ An important concern with the use of IgM as a surrogate marker of disease is that it can fluctuate, independent

TABLE 109-3. Summary of Consensus Response Criteria for Waldenström's Macroglobulinemia ¹⁸⁷

Complete Response	CR	Absence of serum monoclonal IgM protein by immunofixation. Normal serum IgM level. Complete resolution of extramedullary disease, i.e., lymphadenopathy/splenomegaly if present at baseline. Morphologically normal marrow aspirate and trephine biopsy.
Very Good Partial Response	VGPR	Monoclonal IgM protein is detectable. 90% reduction in serum IgM level from baseline, or normalization of serum IgM level. Complete resolution of extramedullary disease, i.e., lymphadenopathy/splenomegaly if present at baseline. No new signs or symptoms of active disease.
Partial Response	PR	Monoclonal IgM protein is detectable. ≥50% but <90% reduction in serum IgM level from baseline. Reduction in extramedullary disease, i.e., lymphadenopathy/splenomegaly if present at baseline. No new signs or symptoms of active disease.
Minor Response	MR	Monoclonal IgM protein is detectable. ≥25% but <50% reduction in serum IgM level from baseline. No new signs or symptoms of active disease.
Stable Disease	SD	Monoclonal IgM protein is detectable. <25% reduction and <25% increase in serum IgM level from baseline. No progression in extramedullary disease, i.e., lymphadenopathy/splenomegaly. No new signs or symptoms of active disease.
Progressive Disease	PD	>25% increase in serum IgM level from lowest nadir (requires confirmation) and/or progression in clinical features attributable the disease.

of tumor-cell killing with some agents. By way of example, rituximab can induce a flare in serum IgM levels, whereas everolimus, bortezomib, and ibrutinib can suppress IgM levels independent of tumor-cell killing in some patients, a finding referred to as IgM discordance.^{158,159,162,181,183,189} Moreover, with selective B-cell-depleting agents such as rituximab and alemtuzumab, residual IgM-producing plasma cells are spared and continue to persist, thus potentially skewing the relative response and assessment to treatment.¹⁹⁰ sCD27 levels have been investigated as an alternative surrogate marker in WM given their correlation with WM disease burden, and may remain a faithful marker of disease in patients experiencing a rituximab-related IgM flare, as well as after plasmapheresis.^{59,191} The use of quantitative allele-specific PCR assays to assess serial MYD88^{L265P} burden in WM patients is also under investigation.^{36,38}

COURSE AND PROGNOSIS

WM typically presents as an indolent disease. The presence of 6q deletions may have prognostic significance, although this is disputed.^{20,21} Age is an important prognostic factor (>65 years),^{192–194} but is influenced by comorbidities. Anemia that reflects both marrow involvement and the serum level of the IgM monoclonal protein (because of the impact of IgM on intravascular fluid retention) has emerged as a strong adverse prognostic factor with hemoglobin levels of less than 9 to 12 g/dL associated with decreased survival in several series.^{192–194}

Other cytopenias also may be significant predictors of survival.¹⁹³ The precise level of cytopenias with prognostic significance has not been determined. Some series have identified a platelet count of less than 100 to 150 × 10⁹/L and a granulocyte count of less than 1.5 × 10⁹/L as independent prognostic factors.^{193,194} The number of cytopenias in a given patient has been proposed as a prognostic factor.¹⁹³ Serum albumin levels also correlate with survival in WM patients in some studies, using multivariate analyses.^{193,195} Elevated serum β₂-microglobulin levels (>3.0 to 3.5 g/dL) have also shown strong prognostic correlation in WM.^{193–196} Several scoring systems have been proposed based on these analyses (Table 109–4), including the WM International Prognostic Scoring System (WM IPSS) which incorporates five adverse covariates: advanced age (>65 years), hemoglobin less than or equal to 11.5 g/dL, platelet count less than or equal to 100 × 10⁹/L, β₂-microglobulin greater than 3 mg/L, and serum monoclonal protein concentration greater than 7 g/dL.¹⁹⁷ Among 537 WM patients evaluated in the development of WM IPSS, low-risk patients (27 percent) presented with none or one of the adverse characteristics and advanced age, intermediate-risk patients (38 percent) with two adverse characteristics or only advanced age, and high-risk patients (35 percent) with more than two adverse characteristics. Five-year survival rates for these patients were 87 percent, 68 percent, and 36 percent, respectively. Importantly, the WM IPSS retained its prognostic significance in subgroups defined by age, treatment with alkylating agent and nucleoside analogues. Recent data from the

TABLE 109–4. Prognostic Scoring Systems in Waldenström Macroglobulinemia

Study	Adverse Prognostic Factors	Number of Groups	Survival
Gobbi and colleagues ¹⁸⁵	Hgb <9 g/dL	0–1 prognostic factors	Median: 48 months
	Age >70 years	2–4 prognostic factors	Median: 80 months
	Weight loss		
	Cryoglobulinemia		
Morel and colleagues ¹⁸⁶	Age ≥65 years	0–1 prognostic factors	5 year: 87% of patients
	Albumin <4 g/dL	2 prognostic factors	5 year: 62%
	Number of cytopenias:	3–4 prognostic factors	5 year: 25%
	Hgb <12 g/dL		
	Platelets <150 × 10 ⁹ /L		
Dhodapkar and colleagues ¹⁸⁷	β ₂ M ≥3 g/dL	β ₂ M <3 mg/dL + Hgb ≥12 g/dL	5 year: 87% of patients
	Hgb <12 g/dL	β ₂ M <3 mg/dL + Hgb <12 g/dL	5 year: 63%
	IgM <4 g/dL	β ₂ M ≥3 mg/dL + IgM ≥4 g/dL	5 year: 53%
		β ₂ M ≥3 mg/dL + IgM <4 g/dL	5 year: 21%
Application of International Staging System Criteria for Myeloma to WM Dimopoulos and colleagues ¹⁸⁸	Albumin ≤3.5 g/dL	Albumin ≥3.5 g/dL + β ₂ M <3.5 mg/dL	Median: NR
	β ₂ M ≥3.5 mg/L	Albumin ≤3.5 g/dL + β ₂ M <3.5 or	Median: 116 months
		β ₂ M 3.5–5.5 mg/dL	Median: 54 months
		β ₂ M >5.5 mg/dL	
International Prognostic Scoring System for WM Morel and colleagues ¹⁹⁰	Age >65 year	0–1 prognostic factors (excluding age)	5 year: 87% of patients
	Hgb <11.5 g/dL	2 prognostic factors (or age >65 years)	5 year: 68%

	β ₂ M >3 mg/L		
	IgM >7 g/dL		

β₂M, β₂-microglobulin; Hgb, hemoglobin; NR, not reported; WBC, white blood cell count.

Surveillance, Epidemiology, and End Results (SEER) database involving 7744 WM patients showed that the relative survival of WM patients has improved over time. Patients diagnosed during the years 2001 to 2010 had higher 5-year (78 percent vs. 67 percent) and 10-year (66 percent vs. 49 percent) relative survival rates versus patients diagnosed during the years 1980 to 2000.¹⁹⁸ A Greek study that included 345 patients with WM failed to show any overall or cause-specific survival improvement in recent years, although the study might have been too underpowered to detect any expected benefit.¹⁹⁹ A Swedish study of 1555 patients diagnosed with WM between 1980 and 2005 showed that the 5-year relative survival rate improved from 57 percent in 1980 to 1985 to 78 percent in 2001 to 2005.²⁰⁰

CHAPTER 110

HEAVY-CHAIN DISEASE

Dietlind L. Wahner-Roedler and Robert A. Kyle

SUMMARY

The heavy-chain diseases (HCDs) are B-cell lymphoplasmacytic proliferative disorders in which neoplastic cells produce monoclonal immunoglobulins (Ig) consisting of truncated heavy chains (HCs) without attached light chains. The complex abnormalities of HCD proteins and the usual lack of normal light chains are a result of several distinct gene alterations, including somatic mutations, deletions, and insertions. HCDs involving the three main immunoglobulin classes have been described: α -HCD is the most common and has the most uniform presentation; γ - and μ -HCDs have variable clinical presentations and histopathologic features. The diagnosis is established from immunofixation of serum, urine, or secretory fluids in the case of α -HCD or by immunohistologic analysis of the proliferating lymphoplasmacytic cells in nonsecretory disease. Treatment of α -HCD consists of antibiotics. If there is no response to antibiotics or if aggressive lymphoma is diagnosed, chemotherapy is indicated. Treatment of γ - and μ -HCDs depends on the underlying clinicopathologic features rather than on the presence of the abnormal protein. [Table 110–1](#) summarizes the features of the HCDs.

● γ -HEAVY-CHAIN DISEASE DEFINITION AND HISTORY

γ -Heavy-chain disease (HCD) is not a specific cytopathologic process; rather, it is a biochemical expression of a mutant B-cell clone. The disease should be considered a serologically determined entity with a variety of clinical and histopathologic features. It is defined by the recognition of monoclonal deleted gamma (γ) chains devoid of light chains.¹

The first case of γ -HCD was described in 1964 by Franklin and colleagues,² who observed a homogeneous band between γ - and β -globulin in an African American patient with generalized lymphadenopathy. Comparison of the proteins in the urine to those in the serum showed that they were the same, a suggestion of the presence of a low-molecular-weight serum γ -globulin, which then was shown to be a fragment of a γ -heavy chain (HC). Since this first description, more than 130 patients with γ -HCD have been described in the literature.^{3–5}

● EPIDEMIOLOGY

γ -HCD has been described throughout the world. Although initially γ -HCD was reported to occur equally in men and women,⁴ there was a clear predominance of women in a more recent series of 23 patients.⁵ The median age at diagnosis in that series was 68 years (range: 42 to 87 years).

Acronyms and Abbreviations: C_H1 (2, 3, 4), constant region 1 (2, 3, 4); D, diversity; HC, heavy chain; HCD, heavy-chain disease; Ig, immunoglobulin; IPI, immunoproliferative small intestinal disease; J, joining; V, variable.

● ETIOLOGY AND PATHOGENESIS

The etiology of γ -HCD is unknown.

● CLINICAL FEATURES

Originally, γ -HCD was considered to be a lymphomatous illness. However, γ -HCD has various clinical and pathologic features that can be divided into three broad categories, as described below.

DISSEMINATED LYMPHOPROLIFERATIVE DISEASE

Disseminated lymphoproliferative disease is present in most patients at the time of diagnosis, and various series have reported it in 57 percent to 66 percent of patients.^{4–6} In two different series,^{4,5} lymphadenopathy was present in 56 percent and 62 percent of patients, splenomegaly in 38 percent and 52 percent, and hepatomegaly in 8 percent and 37 percent at the time of diagnosis.

LOCALIZED PROLIFERATIVE DISEASE

In approximately 25 percent of patients, the lymphoproliferative process is localized, which may be extramedullary or may involve only the marrow.^{4,5} Cutaneous involvement is the most frequently reported extramedullary presentation.^{4,5} Patients may present with extramedullary plasmacytoma of the thyroid or parotid gland or an oropharyngeal mass⁵ and hypertrophic spinal pachymeningitis.⁷

NO APPARENT PROLIFERATIVE DISEASE

A proliferative lymphoplasmacytic disease is not apparent in 9 percent to 17 percent of patients. In most of these patients, an underlying autoimmune disorder has been reported. Autoimmune disorders with or without underlying lymphoid proliferation include rheumatoid arthritis, autoimmune cytopenias, systemic lupus erythematosus, Sjögren syndrome, myasthenia gravis, thyroiditis, and vasculitis.⁵

● LABORATORY FEATURES

MOLECULAR BIOLOGY AND GENETICS

Most γ -HCD proteins are dimers of truncated HCs devoid of light chains. The molecular weight of the monomeric unit varies from 27,000 to 49,000. The length of the truncated γ chain varies, but usually it is one-half to three-fourths the length of the normal γ chain. Structural analysis of the defective monoclonal γ -HC of 23 patients with γ -HCD showed several characteristic features ([Fig. 110–1](#)). The proteins usually begin with a normal variable region. In most cases, this sequence is short and interrupted by a large deletion encompassing the remainder of the variable region, although four of the HCs shown in [Fig. 110–1](#) appear to have retained most or all of their variable (V), diversity (D), and joining (J) sequences. In all γ -HCD proteins, the entire constant region 1 (C_H1) domain is also deleted, with normal sequence beginning at the hinge or occasionally at the C_H2 domain. C_H1 is responsible for light-chain binding. In the absence of an associated light chain, the C_H1 domain binds to heat shock protein 78 (HC binding protein), and the HC undergoes proteasomal degradation rather than secretion.

In two cases of γ -HCD (OMM and RIV), genomic sequence data are available ([Fig. 110–2](#)). The presence of large deletions in the switch/C_H1 regions of these two γ -HCD genes explains why the corresponding HCD proteins lack C_H1. Because the normal C_H1 acceptor splice site is deleted, the donor splice of the leader, or the J region, is spliced directly

TABLE 110-1. Summary of Features of the Heavy-Chain Diseases

Features	Types of Heavy-Chain Diseases		
	α	γ	μ
Year described	1968	1964	1969
Incidence	Rare	Very rare	Very rare
Age at diagnosis	Young adult (<30 years)	Older adult (60–70 years)	Older adult (50–60 years)
Demographics	Mediterranean region	Worldwide	Worldwide
Structurally abnormal monoclonal protein	IgA	IgG	IgM
MGUS phase	No	Rarely	Rarely
Urine monoclonal light chain	No	No	Yes
Urine abnormal heavy chain	Small amounts	Often present	Infrequent
Sites involved	Small intestine, mesenteric lymph nodes	Lymph nodes, marrow, spleen	Lymph nodes, marrow, liver, spleen
Pathology	Extranodal marginal zone lymphoma (MALT or IPSID)	Lymphoplasmacytoid lymphoma	Small lymphocytic lymphoma, CLL
Associated diseases	Infection, malabsorption	Autoimmune diseases	None
Therapy	Antibiotics, chemotherapy	Chemotherapy	Chemotherapy

CLL, chronic lymphocytic leukemia; Ig, immunoglobulin; IPSID, immunoproliferative small intestinal disease; MALT, mucosa-associated lymphoid tissue; MGUS, monoclonal gammopathy of undetermined significance.

to the next available functional acceptor splice site at the beginning of the hinge or C_{H2} domain.

SERUM AND URINE PROTEIN FINDINGS

The serum protein electrophoretic pattern is extremely variable. A monoclonal peak is detected in 60 percent to 86 percent of patients.^{4,5} When present, it is most commonly in the β_1 or β_2 region. The median value of the monoclonal spike at diagnosis in 19 patients was 1.59 g/dL (range: 0.40 to 3.91 g/dL).⁵ The diagnosis is established by immunofixation of the serum and a concentrated urine specimen. A modified immunoselection technique for the diagnosis of HCD has been described.⁸ In one case of γ -HCD, low concentrations of free HCs in serum were detected by capillary zone electrophoresis coupled with immunosubtraction.⁹ A heavy/light chain assay to identify truncated immunoglobulin (Ig) HCs was used on serum samples from 15 patients with known γ -HCD. By this method, 20 percent of these patients were shown to also have small amounts of monoclonal free light chains.¹⁰ The amount of HCD protein in the urine usually is small (<1 g/24 h) but may reach 20 g/24 h. An occasional patient with Bence Jones proteinuria has been described.⁵

No standard has been established to identify the subclass of the HC fragment. In reported cases in which the HC fragment subclass has been studied, different methods have been used, ranging from Ouchterlony in the earlier cases to indirect immunofluorescence staining, immunoblotting, amino acid sequence, immunoselection, and enzyme-linked immunosorbent assay.¹¹ IgG subclass distribution shows a lower-than-expected incidence of IgG₂. The most common subclass is IgG₁, which occurs in 65 percent of cases. IgG₃ has been identified in 27 percent of patients, IgG₄ in 5 percent, and IgG₂ in 3 percent.⁴ Although biclonal gammopathy has been reported in 1 percent to 8 percent of all patients with serum monoclonal components, the association between

γ -HCD and another monoclonal protein is much higher. In a series of 23 patients with γ -HCD, 7 percent had an IgM- λ intact monoclonal Ig.⁵ No association between γ -HCD and monoclonal IgA has been described, although the IgG-IgA association was the most frequent in several series of biclonal gammopathies. One patient described in the literature was unique in that the serum contained two deleted γ chains of different subclasses (IgG₁ and IgG₂).¹²

HEMATOLOGIC ABNORMALITIES

Anemia is frequent. It is usually normochromic, normocytic, and moderate. Coombs-positive autoimmune hemolytic anemia has been reported in several cases and may be associated with thrombocytopenia (Evans syndrome). The total and differential leukocyte counts are usually normal. Lymphocytosis may occur, and an occasional patient presents with chronic lymphocytic leukemia. In some cases, rare plasmacytoid lymphocytes or plasma cells have been noted in the blood. Plasma cell leukemia has been reported in two patients.^{13,14}

Marrow aspirates and biopsy specimens often show an increase of plasma cells, lymphocytes, or plasmacytoid lymphocytes, similar to the marrow findings in Waldenström macroglobulinemia. The typical marrow features of myeloma or chronic lymphocytic leukemia are rare. An unusual concurrence of T-cell large granular lymphocytic leukemia with γ -HCD has been reported.¹⁵ Marrow changes consistent with a myeloproliferative neoplasm have been noted in a few patients.⁵

OTHER FEATURES

Bone lesions are rare in γ -HCD. Cytogenetic studies have seldom been reported. No unique abnormalities or characteristics of lymphoma have been found.

OMM,⁶⁶ RIV.⁸⁵

HISTOPATHOLOGY

In contrast to α -HCD, γ -HCD has no consistent morphologic pattern and a variety of underlying lymphoproliferative disorders have been described.¹⁶ The most frequent histopathologic finding is a pleomorphic malignant lymphoplasmacytic proliferation in marrow and lymph nodes. These lymphocytoid plasma cells express pan-B-cell markers and cytoplasmic γ -HC without light chains and are negative for CD5 and CD10.¹⁷

Lymphoma without any consistent morphologic type was diagnosed in 18 (38 percent) of 47 patients in whom lymph nodes were examined. A lymphoplasmacytic proliferation was present in 36 percent and hyperplastic nodes and plasmacytoma in 11 percent each; there was one case of Hodgkin lymphoma and one of probable Hodgkin lymphoma.⁶ Plasmacytic infiltration may be found in the salivary glands or thyroid.^{4,5,18}

DIFFERENTIAL DIAGNOSIS

All patients presenting with a lymphoplasmacytic proliferative disorder should be evaluated for γ -HCD.

THERAPY

Because γ -HCD is a heterogeneous condition, the choice of therapy depends on the clinical findings. In an asymptomatic patient with a monoclonal γ -HC, no therapy is indicated. Any associated autoimmune disease should be managed with standard therapy for that specific disease type. In symptomatic patients with a low-grade lymphoplasmacytic malignancy, a trial of chlorambucil may be beneficial. Melphalan and prednisone can be used, if the proliferation is predominantly plasmacytic. A trial of cyclophosphamide, vincristine, and prednisone with or without doxorubicin is reasonable for patients with evidence of a progressive lymphoplasmacytic proliferative process or high-grade lymphoma. One patient achieved a complete response after six courses of fludarabine.¹⁹ Successful treatment of γ -HCD with low-dose etoposide has been reported.²⁰ CD20 expression has been analyzed in only seven cases and was detected in six of the seven, including one in which CD20 expression appeared transient.^{5,21–23} Rituximab monotherapy was given in two cases, resulting in clinical responses in both.^{5,21} In two other cases, a combination of rituximab with chemotherapy had an antitumor effect in lymphoplasmacytic-type γ -HCD.^{22,24} In localized extramedullary plasmacytomas treated with radiation⁴ or surgical removal (or both), complete clinical and serologic remission has been achieved.

COURSE AND PROGNOSIS

The clinical course of γ -HCD is extremely variable and ranges from an asymptomatic, benign, or transient process to a rapidly progressive neoplasm leading to death within a few weeks. Patients with the features of only a monoclonal gammopathy have remained clinically well for 2 to 7 years of followup.^{5,25} Spontaneous disappearance of the γ -HCD protein has been reported.⁴ The median duration of survival in a series of 23 patients was 7.4 years (range: 1 month to more than 21 years).⁵

The amount of serum γ -HCD protein usually parallels the severity of the associated malignant process. Disappearance of the monoclonal component from serum and urine associated with apparent complete response has been induced by chemotherapy,¹⁹ radiotherapy,⁴ or surgical removal of a localized process. In some instances, however,

the γ -HCD protein does not vary in parallel with the associated process, and relapse can occur without the reappearance of the pathologic protein.⁴

α -HEAVY-CHAIN DISEASE DEFINITION AND HISTORY

α -HCD is a proliferative disorder of B-lymphoid cells involving the IgA secretory immune system, especially the gastrointestinal tract. It is defined by the recognition of internally deleted monoclonal α chains devoid of light chains.

In the first case description of α -HCD, in 1968 by Seligman and colleagues,²⁶ an Arab woman had severe malabsorption resulting from a lymphoplasmacytic infiltrate in the small bowel. Since then, more than 400 cases have been reported.

EPIDEMIOLOGY

The majority of reported cases have been from northern Africa, Israel, and surrounding Middle Eastern countries. A common variable for patients with α -HCD is a low socioeconomic status. In a study of the distribution of monoclonal gammopathies in Tunisia published in 1990, 17 percent of 198 cases were attributed to α -HCD.²⁷ In a later study of 270 cases observed between 1992 and 2000 at the university hospital of Sfax in Tunisia, only 2.2 percent were attributed to α -HCD,²⁸ a finding that might be partially explained by improved socioeconomic conditions. Similarly, a persistent decrease in the incidence of immunoproliferative small intestinal disease (IPSID) since 1986 as a result of improving sanitation has been reported from Iran²⁹ and Greece.³⁰ α -HCD has a predilection for young adults. The prevalence of the disease is slightly higher in males than in females.

ETIOLOGY AND PATHOGENESIS

The cause of α -HCD is unknown. The disease might be considered a model showing the complex interactions of the environment with genetic factors and the infection-immunity-cancer interrelationships originating from the same proliferating clone. Although the mechanisms leading to the development of a clonal population synthesizing the structurally abnormal IgA are still speculative, the lymphoplasmacytic infiltration of the intestinal mucosa is likely a response of the alimentary tract immune system to protracted luminal antigenic stimulation. A causal relationship between infection and pathogenesis is supported by the observation that α -HCD can respond to broad-spectrum antibiotics. Using molecular strategies, *Campylobacter jejuni* was detected in five of seven patients with α -HCD.³¹ However, no specific microorganism has been found in other clinical studies. The putative agent may be present only at the onset of the disease and absent at diagnosis.

CLINICAL FEATURES

In most cases, patients who have α -HCD present with the digestive form. The disease is characterized by malabsorption manifested by diarrhea, weight loss, and abdominal pain. Ascites, tetany, edema, and clubbing may be present. Hepatosplenomegaly and peripheral lymphadenopathy are infrequent. Fever is uncommon. Amenorrhea, alopecia, and growth retardation in children and adolescents correlate with the duration and the severity of the malabsorptive

Figure 110-3. Structure of various α -heavy-chain disease (HCD) proteins compared with that of normal chain. *Structures shown are primary synthetic products synthesized by the HCD cells. process. α -HCD may be confined to the respiratory tract, but this is extremely rare, as is a lymphomatous form characterized by generalized lymphadenopathy. α -HCD has been reported in a patient with a goiter from a plasmacytoma of the thyroid³² and in a patient with polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, and skin lesions (POEMS).³³

three genes show striking similarity in their position and extent of the two main deletions, which encompass sequences in the V/J and the switch/C_H1 region.

LABORATORY FEATURES

MOLECULAR BIOLOGY AND GENETICS

Most α -HCD proteins consist of multiple polymers. The molecular weight of the basic monomeric unit varies from 29,000 to 34,000. The length of the basic polypeptide subunit differs from patient to patient and in most instances is between one-half and three-fourths that of a normal α chain. Sequence data are available for several α -HCD proteins (Fig. 110-3). In all cases of α -HCD studied, the α -HCD protein belonged to the α_1 subclass. Common features of the defective α chain include deleted V regions, missing C_H1 domains, and the absence of light chains. Most of the proteins have short, non-Ig-related sequences of unknown origin at the amino terminus. The complete sequences of the genes encoding 3 α -HCD proteins are shown in Fig. 110-4. These

SERUM, URINE, AND INTESTINAL FLUID PROTEIN FINDINGS

In contrast to other monoclonal gammopathies, the characteristic sharp spike of a monoclonal gammopathy is not found on serum protein electrophoresis in α -HCD. In about half of cases, an abnormal broad band is found in the α_2 - or β -globulin region, which is probably related to polymerization of the α chains. In the other half of cases, serum protein electrophoresis shows no evidence of an abnormal protein. Identification of the α -HCD protein depends on immunoselection or immunofixation. The pathologic protein may easily escape detection by immunoelectrophoresis when its serum concentration is low. In most patients, the α -HCD protein can be found in the serum. During the course of the disease, the progressive diminution of mature plasma cells and their replacement by immature immunoblasts likely is followed by a progressive decrease in the serum concentration of α -HCD protein. α -HCD protein hyposecretion also may be found during the early stage of the disease.

Figure 110-4. Structure of three genes coding for different α_1 -heavy-chain disease proteins compared with that of normal α_1 gene. Boxes indicate coding regions; **///**, switch region; **■**, inserted coding sequence; **■**, inserted noncoding sequence; lines, intervening (noncoding) sequences; L, leader region; V, variable region; D, diversity segment; J, joining region; S, switch region; H, hinge region; C_H1, C_H2, C_H3, constant regions of heavy chains; I, inserted sequence; Del, deleted sequence; Memb., membrane exon. YAO,⁸⁷ MAL,⁸⁸ SEC.⁹¹

In most cases, the α -HCD protein also is found in the jejunal secretions.³⁴ α -HCD protein has been found in the intestinal or gastric fluid in a few cases when it was undetectable in serum and urine. The concentration of α -HCD protein in the urine is low. Bence Jones proteinuria has never been documented.

Synthesis of the α -HCD protein by the proliferating cells has been demonstrated by immunohistochemical or immunocytochemical methods and by biosynthesis studies *in vitro*.³⁵ These techniques are helpful in the recognition of nonsecreting forms of α -HCD.

HEMATOLOGIC AND METABOLIC ABNORMALITIES

Mild to moderate anemia is often found. Hypokalemia, hypocalcemia, hypomagnesemia, and hypoalbuminemia are common. The intestinal isoenzyme fraction of the alkaline phosphatase level may be increased. Results of tests to indicate malabsorption are usually positive.

IMAGING PROCEDURES

Abnormal radiographic findings of the small intestine include hypertrophic and pseudopolypoid mucosal folds, occasionally associated with strictures and filling defects. The extent of the disease should be evaluated with computed tomography.

ENDOSCOPY

α -HCD intestinal lesions nearly always affect the duodenum and jejunum, making endoscopy with biopsy a useful tool in the evaluation of patients in whom α -HCD is suspected. Several endoscopic patterns have been defined. The infiltrated pattern is the most specific, followed by the nodular pattern. Other primary lesions (ulcerations, mosaic pattern, and mucosal fold thickening alone) are nonspecific.

HISTOPATHOLOGY

In the digestive form of α -HCD, the proliferation involves at least the proximal half of the small intestine and adjacent mesenteric lymph nodes. The whole length of the small bowel, the gastric, and the colorectal mucosae that belong to the IgA secretory system may be involved.

The disease progresses in three histopathologic stages according to Galian and colleagues.³⁶ In stage A, a mature plasmacytic or lymphoplasmacytic infiltration of the mucosal lamina propria is noted. Villous atrophy is variable. Stage B is characterized by the presence of atypical plasmacytic or lymphoplasmacytic cells and more or less atypical immunoblast-like cells extending at least to the submucosa. Subtotal or total villous atrophy is present. Stage C corresponds to an immunoblastic lymphoma. Similar to the changes described in the small intestine, three histologic stages (A, B, C) have been described in the mesenteric lymph nodes. Involvement of liver, spleen, and peripheral lymph nodes is uncommon. The histologic lesions may progress at any given site from stage A to stage B or from stage B to stage C. However, different stages can be found at the same time in different organs or even at different sites in the same organ. Thus, accurate pathologic staging of α -HCD requires a laparotomy with sampling of multiple sites in all patients with α -HCD in whom no stage C lesions are found on peroral biopsy. This recommendation is based on the observation that mesenteric lymph nodes may harbor malignant lymphoma when the intestinal mucosa reveals only a benign-appearing cellular infiltrate that one might be tempted to treat with antibiotics alone.³⁷ A staging system based on anatomical spread of the

disease, which is complementary to the Galian staging system has been published;³⁸ however, most physicians use the Galian staging system for determining prognosis and therapeutic strategies.

In the past, confusion existed over whether Mediterranean lymphoma and α -HCD were different conditions. In 1976, a consensus panel concluded that α -HCD and Mediterranean lymphoma constitute a spectrum of disease, and the term *immunoproliferative small intestinal disease* (IPSID) came into use. This term is applied to small intestinal lesions whose pathologic features are identical to those of α -HCD, regardless of the type of Ig synthesized.^{34,39} The pattern of α -HCD pathologic lesions often includes clear lymphoepithelial lesions composed of centrocytic-like cells. This indicates that α -HCD can be considered a subtype of lymphoma arising from mucosa-associated lymph node tissue.⁴⁰ The pathologic changes in the few cases of the respiratory form of α -HCD are poorly documented. In a case of the lymph node or lymphomatous form, lymph node biopsy showed diffuse plasmacytic lymphoma.

CYTOGENETICS

Cytogenetic abnormalities have been found in the lymphoid cells of patients with α -HCD. The clonal proliferation in this disease appears to be associated with frequent alterations of chromosome 14 at band q32 resulting from translocations that differ from those observed in the vast majority of other lymphomas. Abnormal karyotypes were reported in three of four patients.⁴¹ Two patients had a rearrangement of 14q32 resulting from a t(9;14)(p11;q32) and a t(2;14)(p12;q32). Cloning and sequencing of the der(14) breakpoint of a chromosome translocation involving the 14q32 Ig locus in 1 of these patients suggested that the translocation originated from a local pairing of the two chromosomes, 9 and 14.⁴² One case showed complex rearrangements, including t(5;9). No abnormalities were found in the intestinal tumor of the fourth case with immunoblastic lymphoma.

DIFFERENTIAL DIAGNOSIS

The digestive form of α -HCD must be differentiated from lymphoma, although this is an uncommon diagnosis in the age range typical of α -HCD. Other causes of malabsorption need to be considered, especially celiac disease. Enteric presentation of γ -HCD, variable immunodeficiency, and acquired immunodeficiency syndrome with clinicopathologic features simulating IPSID should be excluded.

THERAPY

Patients with stage A lesions limited to the bowel and to the mesenteric lymph nodes should be treated initially with oral antibiotics. In the absence of a documented parasite, tetracycline, metronidazole, or ampicillin is appropriate. Patients with stage B or C lesions or stage A lesions without improvement after a 6-month course of antibiotic treatment should be given chemotherapy. The treatment regimens are those commonly used to treat lymphoma. There have been few controlled clinical trials. In a prospective randomized study, a doxorubicin-based regimen (cyclophosphamide, doxorubicin hydrochloride, vincristine, and prednisone) provided a higher response rate than a non-doxorubicin-containing protocol (cyclophosphamide, vincristine, procarbazine, and prednisone) or total abdominal irradiation.⁴³ Similar results were noted in a retrospective study.⁴⁴ Good results have been reported with cyclophosphamide, doxorubicin, teniposide, and prednisone, sometimes alternating with bleomycin, vinblastine, and doxorubicin⁴⁵ and with cyclophosphamide, epidoxorubicin, vincristine, prednisolone,

ifosfamide, methotrexate, etoposide (VP-16), and dexamethasone.⁴⁶ Surgical resection should be considered for focal or bulky transmural lymphomatous tumors and extramedullary plasmacytoma. Autologous hematopoietic stem cell transplantation has been recommended for patients with advanced or refractory disease,³⁴ but to our knowledge there are no reports in the literature demonstrating the usefulness of this approach. Previous trials have not incorporated immunotherapy with rituximab, an anti-CD20 monoclonal antibody, in the management of IPSID. As expected, the centrocyte-like cells are CD20-positive, but the plasma cells are not. In light of the extreme plasma cell differentiation and the plasmacytic nature of large-cell IPSID lymphoma, there is interest in investigating the value of treating patients with IPSID with the novel agents (thalidomide, lenalidomide, bortezomib, pomalidomide, or carfilzomib).

COURSE AND PROGNOSIS

The course of α -HCD is variable but generally progressive in the absence of therapy. Followup should include a periodic search for α -HCD protein in serum and urine and, if negative, in the intestinal secretions. Bowel radiography, ultrasonography, and esophagogastroduodenoscopy should be performed. A second-look laparotomy may be necessary.³⁴ Relapses may occur after treatment at any stage of the disease. The long-term prognosis for patients with α -HCD remains imprecise because of the lack of large series with prolonged followup. In a small prospective Tunisian study,⁴⁵ including eight patients with stage A disease and 15 with stages B and C, the survival of the total group was 90 percent at 2 years. A series from Turkey⁴⁷ reported 5-year treatment results of 23 patients with IPSID, including five with secretion of α chains. In patients with stage A disease, tetracycline yielded a 71 percent complete response. The 5-year overall survival rate for the entire group was 70 percent. However, the median overall survival for 3 patients with immunoblastic lymphoma was only 7 months.

Thirteen patients were studied who had IPSID associated with α -HCD.⁴⁸ Six patients, two with high-grade lymphoma and four with low-grade disease, received chemotherapy or radiotherapy or both. One patient died at 76 months, and five were alive at an average of 92 months. Five patients with low-grade disease received conservative therapy (antibiotics and in some cases prednisone). All five patients were alive at an average of 40 months after presentation. Three of these five patients achieved remission at 5, 6, and 27 months. Two of the five patients had persistent disease at 20 and 25 months. Two patients did not receive treatment and died of high-grade lymphoma.

Another study⁴⁹ described six patients who had α -HCD with lymphoma. All patients responded poorly to chemotherapy; the median duration of survival was 10.5 months.

A subsequent study⁵⁰ described 12 patients with secretory and nonsecretory IPSID. Six patients presented with stage A disease. Four patients responded to antibiotic or glucocorticoid therapy. In two patients, stage A disease evolved into stage C. Three patients presented with stage B disease. Two of these patients responded completely to chemotherapy, and the third refused treatment and died after 16 months. Three patients with stage C disease at diagnosis received aggressive combination chemotherapy and remained in complete remission with a median followup of 2.2 years.

Preliminary results suggest that flow cytometric analysis of S-phase fraction⁵¹ and certain immunomarkers, such as syndecan, Bcl6, and p53,⁵² may be useful prognostic indicators in the clinical management of patients with IPSID. Patients with a poor prognosis have a higher fraction of cells in S phase, lower syndecan-1 expression, and higher Bcl6 expression than those with a good prognosis.

μ -HEAVY-CHAIN DISEASE DEFINITION AND HISTORY

μ -HCD is a proliferative disorder of B lymphocytes defined by the recognition of monoclonal deleted μ -HCs. In the first reported case, in 1969 by Forte and colleagues,⁵³ the patient had chronic lymphocytic leukemia. Since then, approximately 34 additional cases have been reported.^{54–57}

EPIDEMIOLOGY

μ -HCD is extremely rare. In a series of 27 patients, the majority were white (76 percent) and male (55 percent). The median age at diagnosis in 27 patients was 57.5 years (range: 15 to 80 years).⁵⁴

ETIOLOGY AND PATHOGENESIS

The cause of μ -HCD is unknown.

CLINICAL FEATURES

The most common presenting symptoms of patients with μ -HCD are those of a lymphoproliferative malignancy. An associated lymphoplasma-cytic proliferative disorder was noted in 22 of 27 patients at some time during the disease and designated as chronic lymphocytic leukemia, lymphoma, Waldenström macroglobulinemia, or myeloma.⁵⁴ μ -HCD protein has been described in one patient each with systemic lupus erythematosus, hepatic cirrhosis, hepatosplenomegaly with ascites, pulmonary infection, splenomegaly with pancytopenia,⁵⁴ and myelodysplasia.⁵⁵ Three cases of μ -HCD associated with amyloidosis have been reported.⁵⁸

Splenomegaly and hepatomegaly are common in μ -HCD and were noted in 21 of 22 and 15 of 21 patients, respectively.⁵⁴ Peripheral lymphadenopathy was described in 10 of 25 patients.⁵⁴

LABORATORY FEATURES

MOLECULAR BIOLOGY AND GENETICS

The molecular weight of the μ -HCD protein determined in eight patients ranged from 26,500 to 158,000. The higher molecular weights are thought to be the result of polymerization of the μ -chain fragments. The μ -HCD fragments from 6 patients were subjected to detailed chemical analysis. Figure 110–5 depicts the structure of these six μ -HCD proteins compared with that of normal μ -HC. The V_H domain is absent in all cases. The normal sequence began with C_H1 in three cases, C_H2 in two cases, and C_H3 in one case. There are sequence data for only 1 gene coding for a μ -HCD protein (Fig. 110–6).

SERUM AND URINE PROTEIN FINDINGS

A monoclonal spike was found on serum protein electrophoresis in less than half of a series of patients with μ -HCD (eight of 19).⁵⁴ The diagnosis of μ -HCD is made by documentation of the abnormal HC. Immunofixation of both serum and urine should be done. When these procedures yield ambiguous results, two-dimensional gel electrophoresis is a useful additional tool. The combination of capillary immunotyping electrophoresis and high-resolution two-dimensional electrophoresis has been used successfully for the detection of μ -HCD in one patient,⁵⁹

Figure 110-5. Structure of various deleted μ -heavy-chain disease proteins compared with that of normal chain. ■ indicates unusual amino acid sequences; boxes, coding regions; lines, deletions; V, variable region; D, diversity segment; J, joining region; C_{H1} , C_{H2} , C_{H3} , C_{H4} , constant regions of heavy chains. BOT,⁹³ DAG,⁹⁴ GLI,⁹⁵ BW,⁹⁶ ROUL,⁹⁷ BUR.⁹⁸

whereas in another capillary zone electrophoresis failed to detect the μ -HCD protein.⁶⁰ Three of 33 reported patients with μ -HCD had a biclonal gammopathy. Hypogammaglobulinemia was noted in 10 of 22 patients.⁵⁴ Hypergammaglobulinemia with a polyclonal pattern in the γ -globulin fraction was described in one case.⁵⁵ In contrast to γ - and α -HCD in which there usually is no detectable monoclonal light chain in the serum and urine, Bence Jones proteinuria was found in more than half the cases of μ -HCD (14 of 22 patients).⁵⁴ μ -HCD protein was found in the urine of only two patients.⁵⁴ Three cases of nonsecretory μ -HCD have been reported.⁶¹⁻⁶³ μ -HCs were documented by immunofluorescence on the cell surface of proliferating lymphocytes in 1 case and in marrow plasma cells of two others.

HEMATOLOGIC ABNORMALITIES

Anemia is frequent, but lymphocytosis and thrombocytopenia are uncommon. One patient had a positive direct antiglobulin test.⁵⁵ Examination of the marrow usually shows an increase in lymphocytes, plasma cells, or plasmacytoid lymphocytes. Plasmacytosis was noted in 18 of 20 cases; in 13 of these, vacuolated plasma cells were found.⁵⁴ The presence of vacuolated plasma cells in the marrow of a patient with a lymphoplasmacytic proliferative disorder should always suggest the possibility of μ -HCD.

OTHER FEATURES

Lytic bone lesions were described in three of 15 patients⁵⁴ and osteoporosis was mentioned in three others. No cytogenetic studies have been reported.

HISTOPATHOLOGY

In a literature review that included 27 documented cases of μ -HCD, 22 patients (81 percent) had an associated lymphoplasmacytic proliferative disorder designated as chronic lymphocytic leukemia, lymphoma, Waldenström macroglobulinemia, or myeloma.⁵⁴

Figure 110-6. Structure of a gene coding for a μ -heavy-chain disease protein compared with that of normal μ gene. Boxes indicate coding regions; ▨, switch region; ■, inserted noncoding sequence; L, leader region; V, variable region; D, diversity segment; J, joining region; S, switch region; C_{H1} , C_{H2} , C_{H3} , C_{H4} , constant regions of heavy chains; I, inserted sequence. BW.⁹⁶

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of μ -HCD includes all lymphoplasmacytic proliferative disorders. Without a suspicion for the disease, μ -HCD is difficult to diagnose. The finding of Bence Jones proteinuria in a patient with a lymphoproliferative disorder and vacuolated plasma cells in the marrow deserves further investigation for possible μ -HCD.

THERAPY

There is no specific therapy for μ -HCD. The finding of a μ -HCD protein in the serum of an apparently normal patient should be considered to represent monoclonal gammopathy of undetermined significance, and the patient should be followed closely for the development of a symptomatic lymphoplasmacytic proliferative disorder. Once this develops, chemotherapy is indicated. Various agents have been used. Initially, a combination of cyclophosphamide, vincristine, and prednisone with or without doxorubicin is a reasonable choice. The use of fludarabine has been reported in two patients with μ -HCD; one had an "apparent hematologic response,"⁶⁴ and the other had a partial response.⁵⁶ Vincristine, cyclophosphamide, prednisolone, and doxorubicin in combination with rituximab led to complete resolution of tumoral lesions in one patient with μ -HCD.⁶⁵

COURSE AND PROGNOSIS

The course of μ -HCD is variable. Because of the rarity of the disease, no large series of patients treated systematically in a single center has been reported. The median duration of survival from the time of diagnosis is 24 months (range: <1 month to 11 years).⁵⁴ Because several of the reported patients had findings consistent with μ -HCD before recognition of the μ -HCD protein, the course is probably longer than reported in most patients. In one patient, the hematologic abnormalities became normal and the μ -HC disappeared after 2 years without specific treatment.

CHAPTER 111

MEGAKARYOPOIESIS AND THROMBOPOIESIS

Kenneth Kaushansky

SUMMARY

Each day the adult human produces approximately 1×10^{11} platelets, a level of production that can increase 10- to 20-fold in times of increased demand and an additional five- to 10-fold under the stimulation of exogenous thrombopoietin mimetic drugs. Production of platelets depends on the proliferation and differentiation of hematopoietic stem and progenitor cells to cells committed to the megakaryocyte lineage, their maturation to large, polyploid megakaryocytes, and their final fragmentation into platelets. The external influences that impact megakaryopoiesis and thrombopoiesis are a supportive marrow stroma consisting of endothelial and other cells, matrix glycosaminoglycans, and a family of protein hormones and cytokines, including thrombopoietin, stem cell factor, and stromal cell-derived factor-1. The role of the cytokines essential for these processes has been defined, the transcription factors critical for megakaryocyte development identified, the molecular mechanisms that underlie the two most unusual aspects of thrombopoiesis—endomitosis and proplatelet formation—have been studied, and reagents to specifically modify platelet production have been generated. This chapter focuses on the development of megakaryocytes, their precursors and their progeny, and the hematopoietic growth factors and transcriptionally active molecules that control the survival, proliferation, and differentiation of these cells.

KINETICS OF THROMBOPOIESIS

The circulatory life span of a platelet is approximately 10 days in humans with normal platelet counts, but somewhat shorter in patients with moderate (7 days) to severe (5 days) thrombocytopenia, as a higher proportion of the total-body platelet mass is consumed in the day-to-day function of maintaining vascular integrity.¹ Based on a “normal” level of 200,000 platelets/ μL , a blood volume of 5 L, and a half-life of 10 days, 1×10^{11} platelets per day are produced. If 1 megakaryocyte produces approximately 1000 platelets, approximately 1×10^8 megakaryocytes are generated in the marrow each day.

Several independent lines of evidence indicate the transit time from megakaryocyte progenitor cell to release of platelets into the circulation ranges from 4 to 7 days. For example, following platelet apheresis, the platelet count falls, recovers substantially by day 4, and completely

Acronyms and Abbreviations: CAMT, congenital amegakaryocytic thrombocytopenia; FGF, fibroblast growth factor; GP, glycoprotein; HPS, Hermansky-Pudlak syndrome; IFN, interferon; IL, interleukin; ITP, immune thrombocytopenic purpura; MAPK, mitogen-activated protein kinase; P4P, polyphosphate-4-phosphatase; PI3K, phosphoinositol 3'-kinase; SDF, stromal cell-derived factor; TGF, transforming growth factor.

recovers by day 7.² In most physiologic and pathologic states, the platelet count is inversely related to plasma thrombopoietin levels. For example, liver failure is associated with moderate thrombocytopenia as a result of splenomegaly and thrombopoietin deficiency. Within the first week following orthotopic liver transplantation, the platelet count rises substantially, with kinetics matching those of thrombopoietin infusion.^{3,4} These findings indicate expansion of the megakaryocyte mass takes from 3 to 4 days following a thrombopoietin stimulus in humans and, coupled with the approximate 12 hours required for platelet release,⁵ results in a relatively brisk response to thrombocytopenia.

CELLULAR PHYSIOLOGY OF THROMBOPOIESIS

Platelets form by fragmentation of megakaryocyte membrane extensions termed *proplatelets*, in a process that consumes nearly the entire cytoplasmic complement of membranes, organelles, granules, and soluble macromolecules. Although at first controversial, as the process was initially observed only *in vitro*, *in situ* microscopic studies have identified proplatelet formation and fragmentation in living animals.⁶ Each megakaryocyte is estimated to give rise to 1000 to 3000 platelets⁷ before the residual nuclear material is engulfed and eliminated by marrow macrophages. This process has been extensively reviewed.⁸ The continuum of megakaryocyte development is arbitrarily divided into four stages. The major criteria differentiating these stages are the quality of the cytoplasm and the size, lobulation, and chromatin pattern of the nucleus (Table 111-1).

MEGAKARYOBLAST

Stage I megakaryocytes, also termed *megakaryoblasts*, account for approximately 20 percent of all cells destined to form platelets. These cells in human marrow are 8 to 24 μm in spherical diameter (i.e., the actual size *in vivo*, as opposed to the apparent size of a cell on a flattened marrow smear), contain a relatively large, minimally indented nucleus with loosely organized chromatin and multiple nucleoli, and scant basophilic cytoplasm containing a small Golgi complex, a few mitochondria and α granules, and abundant free ribosomes (Fig. 111-1).

Surface Adhesion Molecule Expression

Although elegant experiments clearly demonstrated that the gene for integrin α_{IIb} is expressed as early as the erythroid-megakaryocytic progenitor stage⁹ and possibly in the common myeloid progenitor, the cell-surface protein becomes demonstrable and functionally important only at the early stages of megakaryocyte development. Integrin $\alpha_{\text{IIb}}\beta_3$ is an integral transmembrane protein of two subunits, but only the α subunit is megakaryocyte-lineage specific. Absence of integrin $\alpha_{\text{IIb}}\beta_3$ leads to Glanzmann thrombasthenia resulting from failure of the defective platelets to engage fibrinogen and other adhesive ligands during hemostasis (Chap. 120). Megakaryocytes and platelets contain in their cytoplasmic membranes approximately twice the amount of integrin $\alpha_{\text{IIb}}\beta_3$ as is present on the cell surface. The granule compartment serves as a mobilizable pool that is exteriorized upon platelet activation. During the early and midstages of megakaryocyte development, the granule content of integrin rises. Moreover, as developing megakaryocytes do not synthesize but contain fibrinogen in their α -granules and cells from patients with Glanzmann thrombasthenia do not, integrin $\alpha_{\text{IIb}}\beta_3$ clearly begins to function, at least at the level of fibrinogen binding and uptake, long before platelet formation.

The glycoprotein (GP) Ib-IX complex is expressed only slightly after the appearance of integrin $\alpha_{\text{IIb}}\beta_3$.¹⁰ Although endothelial cells reportedly express GPIb,¹¹ its levels are very low; otherwise, GPIb is the

TABLE 111-1. Maturation Stages of Megakaryocytes

Term	Size (μM)	Morphology
Megakaryoblast (stage I)	>10	Lobed nucleus, basophilic cytoplasm
Basophilic megakaryocyte (stage II)	>20	Horseshoe-shaped nucleus, basophilic cytoplasm, azurophilic granules around centrosome
Granular megakaryocyte (stage III)	>25–50	Large multilobed nucleus, acidophilic cytoplasm, numerous azurophilic granules
Mature megakaryocyte (stage IV)	>25–50	Pyknotic nucleus, groups of 10–12 azurophilic granules

second most abundant megakaryocyte-specific protein. Glycoprotein V also is expressed in complex with GPIb and GPIX, in a ratio of 1:2:2.¹² However, the genetic elimination of GPV has little effect on platelet adhesion,¹³ and unlike GPIb and GPIX, no mutations of GPV are associated with Bernard-Soulier disease (Chap. 120).¹⁴ Therefore, GPV does

not appear to be required for the GPIb-V-IX complex to function as a von Willebrand factor receptor. Rather, GPV is a target of thrombin, potentially playing a role in platelet activation.¹⁵

Demarcation Membranes

Another feature of the megakaryoblast is the initial development of demarcation membranes, which begin as invaginations of the plasma membrane and ultimately develop into a highly branched interconnected system of channels that course through the cytoplasm. The demarcation membrane system is in open communication with the extracellular space, based on studies using electron dense tracers.¹⁶ Biochemical analysis indicates the composition of these membranes is very similar to the plasma membrane at each stage of megakaryocyte development. Over the 72 hours required for stage III/IV cells to develop from megakaryoblasts, the demarcation membrane system grows substantially. The demarcation membrane system provides the material necessary for development of proplatelet processes, structures that form in stage IV megakaryocytes and give rise upon fragmentation to mature platelets.^{8,17}

Endomitosis

One of the most characteristic features of megakaryocyte development is endomitosis, a unique form of mitosis in which the DNA is repeatedly replicated in the absence of nuclear or cytoplasmic division. The resultant cells are highly polyploid. Endomitosis begins in megakaryoblasts (Fig. 111-2) following the many standard cell divisions required

Figure 111-1. Electron micrograph of a normal human megakaryoblast stained for platelet peroxidase. The small cell ($<9 \mu\text{m}$) exhibits dense platelet peroxidase in the perinuclear space and endoplasmic reticulum (arrows) (magnification $\times 12,150$). (Inset) Enlargement of the Golgi zone. The Golgi saccules and vesicles are devoid of platelet peroxidase (open arrows), whereas the endoplasmic reticulum contains platelet peroxidase activity (closed arrow) (magnification $\times 25,000$). (Used with permission of Dr. J. Breton-Gorius.)

Figure 111-2. Origin and development of megakaryocytes. The pluripotential stem cell produces a progenitor committed to megakaryocyte differentiation (colony-forming unit–megakaryocyte [CFU-MK]), which can undergo mitosis. Eventually the CFU-MK stops mitosis and enters endomitosis. During endomitosis, neither cytoplasm nor nucleus divides, but DNA replication proceeds and gives rise to immature polyploid progenitors, which then enlarge and mature into morphologically identifiable, mature megakaryocytes that shed platelets. This figure does not necessarily imply that endomitosis and platelet formation are sequential but they can occur simultaneously. Meg-CFC, megakaryocyte colony-forming cells.

to expand the number of megakaryocytic precursor cells and is completed by the end of stage II megakaryocyte development.¹⁸ During the endomitotic phase, each cycle of DNA synthesis produces an exact doubling of all the chromosomes, resulting in cells containing DNA content from eight to 128 times the normal chromosomal complement in a single, highly lobated nucleus. Although poorly understood for many years, the ability to produce large numbers of normal megakaryocytes in culture has started to shed light on this enigmatic process. Endomitosis is not simply the absence of mitosis but rather consists of recurrent cycles of aborted mitoses.¹⁹ Cell-cycle kinetics in endomitotic cells also are unusual, characterized by a short G_1 phase, a relatively normal DNA synthesis phase, a short G_2 phase, and a very short endomitosis phase.²⁰ During the endomitosis phase, megakaryocytic chromosomes condense, the nuclear membrane breaks down, and multiple (at advanced stages) mitotic spindles form upon which the replicated chromosomes assemble. However, following initial chromosomal separation, individual chromosomes fail to complete their normal migration to opposite poles of the cell, the spindle dissociates, the nuclear membrane reforms around the entire chromosomal complement, and the cell again enters G_1 phase.

Regulation of Gene Expression

The promoters for integrin α_{IIb} , GPIb, GPVI, GPIIX, and platelet factor-4 genes have been the focus of several studies and are active at the megakaryoblast stage of development. Consensus sequences for both GATA-1 and members of the Ets family of transcription factors (e.g., Fli-1) are present in the 5' flanking regions of these genes, deletion of which reduces or eliminates reporter gene expression,^{21–24} at least in mature hematopoietic cells. MafB also enhances GATA-1 and Ets activity during megakaryoblast differentiation,²⁵ induced by activation of ERK1/2, one of the primary downstream events of thrombopoietin stimulation.²⁶

Another target of GATA-1 in megakaryocytes is polyphosphate-4-phosphatase (P4P), which was first identified by subtraction cloning between normal and GATA-1 knockdown megakaryocytes.²⁷ One of the unexplained features of megakaryocytes in GATA-1 knockdown mice is that, rather than massive cell death as seen in GATA-1-deficient erythroid progenitors,²⁸ the aberrantly developing megakaryoblasts in GATA-1 knockdown marrow are highly abundant and proliferate *in vitro* far more than control cells.²⁹ P4P catalyzes hydrolysis of the D-4 position phosphate of $PI_{3,4}P$ and $PI_{3,4,5}P$. These membrane phospholipids are products of phosphoinositol 3'-kinase (PI3K) action on membrane phospholipids, and they play an important role in the proliferative and survival response to megakaryocyte growth factors. When reintroduced into the knockdown mice, P4P diminishes the exuberant growth characteristic of the knockdown cells.²⁷ These findings are similar to the phenotype of cells from PTEN or SHIP knockout mice, enzymes that hydrolyze the D-3 and D-5 positions of $PI_{3,4,5}P$.

Another transcription factor vital for megakaryoblast differentiation is RUNX1 (also termed CBFA2 and AML1), the gene responsible for thrombocytopenia seen in familial platelet disorder/predisposition to acute myelogenous leukemia (Chap. 119).³⁰ In this disorder, haploinsufficiency of RUNX1 is associated with thrombocytopenia. As its genetic elimination in mice leads to significant maturation defects in the megakaryocyte lineage,³¹ the human disorder almost certainly results from this genetic alteration. During normal megakaryoblast differentiation, RUNX1 levels rise and, conversely, fall during erythroid differentiation. In response to phosphorylation by ERK1/2, RUNX1, in complex with CBF β and together with GATA-1, induces integrin α_{IIb} and integrin α_2 expression in megakaryoblast-like cells,³² providing the beginnings of a molecular explanation for megakaryocyte development.

Cytokine Dependency

The cytokines, hormones, and chemokines that affect the survival and proliferation of megakaryoblasts include thrombopoietin, interleukin (IL)-3, stem cell factor (also termed mast cell growth factor, steel factor, and *c-kit* ligand), and the chemokine CXCL12 (previously termed stromal cell-derived factor [SDF]-1). Thrombopoietin is the most critical (for additional details, see the more extensive discussion in "Hormones and Cytokines" below), as genetic elimination of the *TPO* gene in mice leads to circulating platelet levels approximately 10 percent of normal. Homozygous or complex heterozygous mutation of the gene encoding the thrombopoietin receptor cMPL leads to congenital amegakaryocytic thrombocytopenia, in which platelet levels are approximately 10 percent of normal because of a near absence of megakaryocytic progenitors and megakaryoblasts (Chap. 117). The importance of stem cell factor to megakaryoblast development is revealed by experimental findings both *in vitro* and *in vivo*. Genetic reduction in expression of stem cell factor or its receptor *c-kit* leads to a 50 percent reduction in circulating platelet levels.³³ The cytokine acts in synergy with thrombopoietin to enhance megakaryocyte production in semisolid and suspension culture systems.³⁴ Evidence that IL-3 contributes to normal or accelerated megakaryopoiesis *in vivo* is weak. Genetic elimination of the IL-3 gene fails to affect platelet counts, even when combined with thrombopoietin receptor deficiency,³⁵ but the cytokine can induce growth of marrow progenitors into colonies containing immature megakaryocytes *in vitro* in the absence of thrombopoietin.³⁶ The chemokine CXCL12 appears to play a role in megakaryocyte proliferation. *In vitro*, the chemokine acts in synergy with thrombopoietin to support the survival and proliferation of megakaryocyte progenitors.³⁷ The combination of fibroblast growth factor (FGF)-4 and CXCL12 restores megakaryopoiesis in *TPO* and *c-mpl* null mice.³⁸

Signal Transduction

The survival and proliferation of megakaryoblasts depends on at least two thrombopoietin-induced signaling pathways: PI3K and mitogen-activated protein kinase (MAPK; Chap. 17). In the presence of chemical inhibitors of PI3K, the favorable effects of thrombopoietin on megakaryocyte progenitor survival and proliferation are eliminated,³⁹ although constitutively activating this pathway is not sufficient for thrombopoietin-induced growth. MAPK is another important signaling pathway stimulated by thrombopoietin. Using purified marrow megakaryocytic progenitors and model cell lines, several groups showed that inhibition of MAPK blocks megakaryoblast maturation^{26,40–42} because of its effect of activating Ets transcription factors.

STAGE II MEGAKARYOCYTES

Stage II megakaryocytes contain a lobulated nucleus and more abundant, but less intensely basophilic, cytoplasm. Ultrastructurally, the cytoplasm contains more abundant α granules and organelles. The demarcation membrane system begins to expand at this stage of development. Stage II megakaryocytes measure up to 30 μm in diameter, constitute approximately 25 percent of marrow megakaryocytes, and are the stage of development during which endomitosis is most prominent, generating cells displaying ploidy values of 8N to 64N.

Endomitosis

Whereas megakaryoblasts are generally thought to be able to expand by cell division, at an early stage of their maturation, the cells begin to undergo endomitosis, in which cells diverge from the normal cell cycle during mid- to late anaphase. Like normally mitotic cells, endomitotic megakaryocytes condense their chromatin into chromosomes, form a spindle, dissolve the nuclear membrane, and assemble the

chromosomes on a metaphase plate, then the chromosomes begin to separate during early anaphase. However, rather than the dividing chromosomes migrating to opposite poles of the cell to allow the formation of a cleavage furrow, the chromosomes quickly decondense, the nuclear membrane reforms around the entire chromosomal complement, and the endomitotic cells reenter G₁ phase followed by S phase. A number of attempts to understand this process at the biochemical level have involved leukemic cell lines. Alterations in cyclin B, cdc2, cell-cycle kinase inhibitors, and aurora kinases have been claimed to be responsible for endomitosis.^{43,44} Unfortunately, although these hypotheses possibly explain the polyploidy in various leukemic cell lines, the hypotheses have not been substantiated in studies of normal endomitotic megakaryocytes.^{19,45} Endomitosis departs from a normal mitotic cell cycle at the late anaphase stage, when furrow invagination aborts short of cell abscission.⁴⁶ Additional studies indicate that disordered localization of the small G-protein RhoA may be responsible for this property.⁴⁶ Confirmation that a decrease in proper RhoA function is critical for endomitosis comes from the, genetic elimination of RhoA from the megakaryocytic lineage; *RhoA* null megakaryocytes display enhanced polyploidy, although the released platelets are characterized by abnormal membrane rheology, resulting in their rapid clearance from the circulation.⁴⁷ Proper RhoA localization is controlled by its activation by the RhoA guanosine triphosphate (GTP) exchange factor (GEF) ECT2; ECT2 is down-modulated during the switch from mitosis to endomitosis in megakaryocytes, providing a mechanistic explanation for the onset of endomitosis.⁴⁸

Cytoplasmic Development

Early in megakaryocyte development, the cytoplasm acquires a rich network of microfilaments and microtubules. Toward stages III and IV, the proteins accumulate in the cell periphery, creating an organelle poor peripheral zone. Biochemically, the megakaryocyte cytoskeleton is composed of actin, α -actinin, filamin, nonmuscle myosin (including the product of the *MYH9* gene), mutated in several giant platelet thrombocytopenic syndromes⁴⁹ (Chap. 117), β_1 -tubulin, talin, and several other actin-binding proteins. Like platelets, megakaryocytes can respond to external stimuli by changing shape, transporting organelles around the cytoplasm, and secreting granules. These functions are dependent on the microfilament and microtubule systems of the cell. In addition, microtubules play a vital role during the later stages of platelet formation.⁵⁰

Regulation of Gene Expression

As discussed earlier, GATA-1 is vital for committing primitive multipotent progenitors to the erythroid-megakaryocyte pathway. However, the transcription factor also is critical later in megakaryopoiesis, for cytoplasmic development. The first convincing evidence that GATA proteins affect megakaryocyte development came from overexpression studies of *GATA-1* in a leukemic cell line, in which the transcription factor led to partial megakaryocytic differentiation.⁵¹ Reduction in *GATA-1* expression also impairs cytoplasmic development in murine megakaryocytes, reducing demarcation membranes and platelet-specific granules.²⁹ Additional transcription factors expressed during stage II megakaryocyte development include RUNX-1, Tal1, and Fli1, but these transcription factors appear to play far greater a role in megakaryocyte maturation and platelet formation, and are discussed in "Stage III/IV Megakaryocytes" below.

Platelet Granule Formation

Although more prominent in later stages of differentiation (Fig. 111-3), platelet-specific α granules first begin to form adjacent to the Golgi apparatus as 300- to 500-nm round or oval organelles in stage II megakaryocytes. Three distinct compartments are recognized in α granules:

- (1) a central, electron-dense nucleoid, containing fibrinogen, platelet factor-4, β -thromboglobulin, transforming growth factor (TGF)- β_1 , vitronectin, and tissue plasminogen activator-like plasminogen activator;
- (2) a peripheral zone, containing tubules and von Willebrand factor (arranged much like that seen in endothelial cell Weibel-Palade bodies); and
- (3) the granule membrane, containing many of the critical platelet receptors for cell rolling (P-selectin), firm adhesion (GPIb-V-IX), and aggregation (integrin $\alpha_{IIb}\beta_3$). Proteins present in α granules arise from *de novo* megakaryocyte synthesis (e.g., GPIb-V-IX, GPIV, integrin $\alpha_{IIb}\beta_3$, von Willebrand factor, P-selectin, β -thromboglobulin, platelet-derived growth factor), nonspecific pinocytosis of environmental proteins (albumin and immunoglobulin G), or cell surface membrane receptor-mediated uptake from the environment (e.g., fibrinogen, fibronectin, factor V). Insights into platelet granule formation have come from a molecular understanding of Hermansky-Pudlak syndrome (HPS). In this disorder, characterized by oculocutaneous albinism and a qualitative platelet bleeding disorder, a complex of at least eight proteins form in various granule-associated complexes such as the biogenesis of lysosome-related organelles complexes, which affect δ granule formation.⁵² These complexes are thought to be involved in cargo transport of a number of subcellular granules, such as lysosomes, melanosomes, and platelet δ granules.

STAGE III/IV MEGAKARYOCYTES

Continued cytoplasmic maturation characterizes stage III/IV megakaryocyte development (Fig. 111-4). Cells are extremely large (40 to 60 μ m in diameter) and display a low nuclear-to-cytoplasmic ratio. Cytoplasmic basophilia disappears as cells progress from stage III to stage IV. The demarcation membrane system gradually replaces the endoplasmic reticulum and Golgi apparatus during the final stages of maturation. The nucleus usually is eccentrically placed. Although the nucleus sometimes appears as several distinct nuclei in biopsy sections, it remains highly lobulated but single at all stages of megakaryocyte development. In occasional marrow sections (Fig. 111-4C), neutrophils or other marrow cells are seen transiting through the cytoplasm of the mature megakaryocyte, a process termed *emperipolesis*, and is of no pathologic significance.

Proplatelet Formation

Careful microscopic studies have localized marrow megakaryocytes to the abluminal surface of sinusoidal endothelial cells. In specially prepared specimens, the megakaryocytes can be seen issuing long, slender cytoplasmic processes between endothelial cells and into the sinusoidal lumen, structures termed *proplatelet processes* (Fig. 111-5).⁵³ The processes have been reproduced *in vitro* and *in vivo*.⁶ The processes consist of a β -tubulin cytoskeleton and highway, transporting organelles and platelet constituents from the megakaryocyte to the terminal projection, the nascent platelet.¹⁷

Membrane Composition

Most of the specific characteristics of platelet membranes are present at stages III and IV of megakaryocyte development. Megakaryocyte membrane lipid composition progressively changes through development, achieving approximately four times the content of phospholipids and cholesterol as found in immature cells. Megakaryocytes contain approximately the same amounts of membrane neutral and phospholipid as platelets, but contain relatively more phosphatidylinositol and less phosphatidylserine and arachidonic acid.

Regulation of Gene Expression

One transcription factor that plays an important role in the final stages of megakaryocyte maturation is nuclear factor-E2. Initially described as

Figure 111-3. **A.** Ultrastructure of the cytoplasm of a mature megakaryocyte. The majority of the granules are α granules (α Gr) exhibiting dense nucleoid. Demarcation membranes (DM) are slightly dilated. Transverse sections of microtubules (Mt) are dispersed. At the periphery, a longitudinal microtubule runs under the cell membrane (arrows). Dense aggregates of glycogen (Gly), small cisternae of endoplasmic reticulum (ER), and free ribosomes are seen (magnification $\times 30,320$). **B.** Morphology of an α granule. Dense nucleoid is located at the top. In a clear zone at the opposite pole, four transverse sections of tubular structures are adjacent to the granule membrane (magnification $\times 37,200$). **C.** Dense body can be distinguished from α granule by the black deposit when calcium is added to the fixative (magnification $\times 37,200$). **D.** Cytochemical detection of acid phosphatase using β -glycophosphate as substrate and cerium as a trapping agent. Dense cerium-phosphate precipitates are present in lysosomal granules, whereas α granules are unreactive (magnification $\times 37,200$). **E.** Microperoxisome visualized using alkaline diaminobenzidine. Note the small size of a reactive granule compared to the α granule. **F.** Distribution of a dense tracer filling the lumen of the demarcation membrane system in a maturing megakaryocyte (arrows). In contrast to the demarcation membrane system, which is open to the extracellular space, the endoplasmic reticulum (ER) is not labeled (magnification $\times 9700$). (Used with permission of Dr. J. Breton-Gorius.)

Figure 111-4. Megakaryocyte morphology. **A.** Normal human marrow biopsy. Two megakaryocytes are evident. In one case the section is through the cell at the level of the nuclei (*horizontal arrow*), and in the other it is through the cytoplasm above or below the nucleus (*vertical arrow*). **B.** Normal human marrow aspirate. Mature (stage III) megakaryocyte with a multilobated nucleus and abundant cytoplasm. **C.** Normal human marrow aspirate. Mature megakaryocyte with a neutrophil embedded in the cytoplasm. Many ultrastructural studies have confirmed that this appearance represents marrow cells entering the canalicular system of megakaryocyte cytoplasm through its opening to the exterior of the cell (emperipolesis). (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

Figure 111-5. Megakaryocyte proplatelet processes in the marrow sinusoid. Scanning electron micrograph showing the luminal view of the confluence of two marrow sinusoids with two proplatelet processes protruding through the lining endothelial cells. One of the processes has intermittent constrictions (*arrows*), indicating potential sites for platelet formation. Other cells depicted include lymphocytes and erythrocytes (magnification $\times 3000$). (Reproduced with permission from Becker RP, De Bruyn P: The transmural passage of blood cells into myeloid sinusoids and the entry of platelets into sinusoidal circulation; a scanning electron microscope investigation, *Am J Anat* 1976 Feb;145(2):183-205.)

an erythroid-specific, heterodimeric protein belonging to the basic leucine zipper family of transcription factors, NF-E2 is composed of a ubiquitously expressed p18 subunit, and a 45-kDa protein (p45) expressed only in erythroid cells and megakaryocytes.⁵⁴ NF-E2 binds to tandem AP-1-like motifs, such as those seen in the second deoxyribonuclease (DNase) hypersensitive site of the β -globin locus control region, and is required for β -globin expression.⁵⁵ However, genetic elimination of p45 failed to significantly affect erythropoiesis. Rather, p45-deficient mice display prominent alterations in megakaryocyte development and severe thrombocytopenia,⁵⁶ leading to death from widespread hemorrhage soon after birth. Examination of the animals reveals modest expansion of marrow megakaryocytes but failure of the cells to produce platelets because of defects in cytoplasmic maturation, including substantial reductions in platelet granules and demarcation membranes. Thus, the loss of either GATA-1 or NF-E2 results in failure of late aspects of cellular maturation. As p45 NF-E2 is induced by GATA-1/FOG,⁵⁷ the lack of cytoplasmic development in GATA-deficient mice likely is an indirect effect. The role of transcription factors in late megakaryopoiesis has been reviewed.⁵⁸

Nearly all studies of megakaryopoiesis have focused on the marrow. The final stages of megakaryocyte fragmentation also are proposed to occur in the lung, at least for some cells, a theory based on the finding that platelet levels in pulmonary venous blood exceed those found in the pulmonary artery.⁵⁹ Whether this process represents the migration and fragmentation of intact megakaryocytes in the lung or merely the final size reduction of large fragments of megakaryocyte cytoplasm that also are released into the blood is not clear. Some data exist supporting the notion that lung megakaryocytes contribute to blood platelet production.⁶⁰ However, in mice administered high doses of thrombopoietin, with platelet counts as high as 4 million/ μm^3 , neither intact megakaryocytes nor denuded nuclei were found in the lungs of these animals.⁶¹ One study found that canine lungs contain 2.5 megakaryocytes per cm^2 .⁶² Extrapolation of these data suggest human lungs contain approximately 6000 megakaryocytes, only enough to account for a small proportion (<0.1 percent) of daily platelet production.

PLATELET FORMATION

Numerous studies have indicated thrombopoietin is the primary regulator of megakaryocyte maturation.^{36,63} However, despite the importance of the hormone for generation of fully mature megakaryocytes from which platelets arise, elimination of the cytokine during the final stages of platelet formation is not detrimental.⁶⁴ Although proplatelet formation is possible under serum-free conditions,⁶⁵ most investigators

have reported the presence of plasma and/or an integrin ligand-containing substratum (e.g., fibronectin or vitronectin) stimulates the process substantially.^{64,66} These findings suggest external signals probably are required for normal platelet formation. One report suggests the thrombin–antithrombin complex with or without high-density lipoprotein particles mediates the favorable effect of plasma on proplatelet formation,⁶⁷ although other data suggest prothrombin and its conversion to thrombin by megakaryocytes inhibit the process.⁶⁸ Although the cytokine(s) required for this process is not known, activation of protein kinase $C\alpha$ clearly is necessary for the process to occur.⁶⁶

Platelet formation involves massive reorganization of megakaryocyte cytoskeletal components, including actin and tubulin, during a highly active, motile process in which the termini of the process branch and issue platelets.⁵ The size of the individual platelets formed is of interest. Unfortunately, little is known about this aspect of platelet formation except that tubulin is proposed to act as a measuring device for the proper site to pinch off platelets from proplatelet processes. The mechanism of platelet formation clearly must be affected in some way by the transcription factor GATA-1, the GPIb-IX complex, the Wiskott-Aldrich syndrome protein, and platelet myosin, as defects in each of these genes leads to unusually large or small platelets (Chap. 117).^{69,70} Finally, localized cytoplasmic membrane proteolysis, a sublethal form of apoptosis, likely plays a role in initiating the final stages of platelet formation.⁷¹

● EXTRINSIC REGULATION OF MEGAKARYOCYTE PRODUCTION

HORMONES AND CYTOKINES

Several cytokines, first identified using alternate hematopoietic activity assays, affect megakaryocyte development. IL-3, granulocyte-macrophage colony-stimulating factor, and stem cell factor support the proliferation of megakaryocytic progenitors in plasma-containing cultures.⁷²⁻⁷⁴ In 1994, several groups reported the purification and/or cloning of thrombopoietin.⁷⁵ This cytokine clearly is the primary regulator of megakaryopoiesis but cannot explain thrombopoiesis in its entirety.

Interleukin-3

IL-3 is a 25- to 30-kDa protein produced almost exclusively by T lymphocytes.⁷⁶ The mature human protein contains 133 amino acids, but N-linked carbohydrate modification accounts for the larger than expected Mr of the cytokine. Granulocyte-macrophage colony-stimulating factor is an 18- to 30-kDa protein also produced by T lymphocytes. However, endothelial cells, monocytes, and fibroblasts also produce the protein and, like IL-3, granulocyte-macrophage colony-stimulating factor is highly modified with both N-linked and O-linked carbohydrate.⁷⁷ Although the two proteins display essentially no primary sequence homology, their tertiary structures are highly related,⁷⁸ and the receptors for the two cytokines share a common subunit.⁷⁹ However, the physiologic relevance of IL-3 and granulocyte-macrophage colony-stimulating factor for steady-state thrombopoiesis is uncertain. Administration of the cytokines to mice or humans has only minimal effects on thrombopoiesis, and genetic elimination of either has no impact on megakaryopoiesis, even when combined with elimination of other thrombopoietic cytokines.^{80,81}

Interleukin-6 and Related Cytokines

IL-6, cloned by several groups using multiple assays (hepatocyte growth, myeloma cell growth, immunoglobulin secretion, antiviral activity), enhances megakaryocyte maturation. IL-6 is a 26-kDa polypeptide produced by T lymphocytes, fibroblasts, macrophages, and stromal

cells in response to inflammatory stimuli.⁸² The mature protein is composed of 184 amino acids, contains two disulfide bonds, and displays both N-linked and O-linked carbohydrate modification. Although IL-6 alone fails to affect *in vitro* megakaryopoiesis, it augments the number of megakaryocyte colonies obtained in the presence of IL-3 or stem cell factor⁸³ and exerts primarily a differentiating effect.^{84,85} Administration of IL-6 to mice or nonhuman primates or patients results in a modest thrombocytosis.⁸⁶⁻⁸⁸ These findings suggest IL-6 contributes to megakaryopoiesis *in vivo*, a conclusion supported by its production by tumor cells in selected cases of paraneoplastic thrombocytosis.⁸⁹ However, genetic elimination of the cytokine fails to significantly affect basal platelet production.⁹⁰ Evidence suggests the cytokine affects platelet production indirectly⁹¹ by stimulating thrombopoietin production.

IL-6 acts through a heterodimeric receptor, composed of a signaling subunit, termed GP130, and an affinity-converting subunit, termed IL-6 α . GP130 also acts as the signaling subunit for several other cytokines, including IL-11 and leukemia inhibitory factor. Therefore, the finding that these cytokines also stimulate megakaryopoiesis in a manner similar to that of IL-6 is not surprising. IL-11 and leukemia inhibitory factor act in synergy with IL-3 or stem cell factor to augment megakaryocyte formation. IL-11 is a 23-kDa polypeptide, initially cloned from a gibbon marrow stromal cell line, whose activity can support the proliferation of an IL-6–responsive myeloma cell line.^{92,93} Leukemia inhibitory factor displays a wide range of activities,⁹⁴ including (1) inducing the acute phase hepatic response, (2) inducing an adrenergic-to-cholinergic switch in neurons, (3) inhibiting lipoprotein lipase in adipocytes, and (4) maintaining pluripotentiality in embryonic cells.

Like IL-6, IL-11 and leukemia inhibitory factor enhance megakaryocytic maturation *in vitro*^{95,96} and augment the effects of IL-3 and stem cell factor on primitive hematopoietic cells. Consistent with the *in vitro* findings, administration of either recombinant IL-11 or leukemia inhibitory factor to rodents, nonhuman primates, or humans produces modest thrombocytosis.⁹⁷⁻¹⁰⁰ Despite the *in vitro* and *in vivo* findings, genetic elimination of either leukemia inhibitory factor or the IL-11 receptor has no effect on thrombopoiesis,¹⁰¹ even when combined with elimination of the thrombopoietin receptor.¹⁰²

Stem Cell Factor

In contrast to the hematopoietic cytokine family, stem cell factor is more closely related to other hematopoietic proteins that utilize protein tyrosine kinase receptors, such as macrophage colony-stimulating factor and the flt-3 ligand.¹⁰³ Nevertheless, stem cell factor stimulates megakaryocyte colony growth when used in combination with other cytokines.¹⁰⁴ Moreover, genetic elimination of its receptor *c-kit* reduces megakaryocyte production¹⁰⁵ and the rebound thrombocytosis that occurs following immunosuppressive therapy.^{106,107}

Stem cell factor was first identified using several different biologic assays (in addition to this term, the cytokine has been dubbed *c-kit* ligand, mast cell growth factor, and steel factor).¹⁰⁸ Later studies indicate the cytokine acts primarily on primitive cells of the hematopoietic, melanogenic, and germ cell lineages. Stem cell factor is a dimeric protein composed of two identical noncovalently linked polypeptides. The soluble form monomer contains 165 residues,¹⁰⁹ derived by proteolytic cleavage of a membrane-bound splice form of the molecule.¹¹⁰ The membrane bound form is more active than the soluble cytokine, as intracellular signaling in response to membrane-bound stem cell factor is prolonged in receptor-bearing cells.¹¹¹ Moreover, a naturally occurring mutant allele of the gene (*Sl^d*), which allows production of the soluble but not the membrane-bound form of the cytokine, results in a phenotype nearly identical to deletion of the entire locus,¹¹² again pointing to the importance of the membrane-bound form present on marrow stromal cells.

Flt-3 Ligand

The flt-3 ligand initially was identified as a ligand for a novel member of the protein tyrosine kinase family of receptors.¹⁰³ This growth factor also affects megakaryocyte formation. Like stem cell factor, to which it is most closely related, flt-3 ligand is found in both soluble and membrane-bound forms, is a noncovalently linked dimer, and affects primarily primitive hematopoietic cells.¹¹³ Although several studies have shown that flt-3 ligand used alone does not support megakaryocyte colony formation, some studies suggest it works in synergy with other megakaryocyte stimulatory agents to augment the proliferation of megakaryocytic progenitor cells in culture.^{114,115} Administration of flt-3 ligand to mice expands the number of marrow and splenic progenitor cells that can give rise to megakaryocytes *in vitro*.¹¹⁶ However, genetic elimination of either flt-3 ligand or its receptor does not produce a platelet phenotype.

Thrombopoietin

The term *thrombopoietin* was first coined in 1958 to describe the primary regulator of platelet production.¹¹⁷ A major impetus to the discovery of thrombopoietin in 1986 was the identification of the myeloproliferative leukemia virus (MPLV), which induces a vast expansion of hematopoietic cells.¹¹⁸ The responsible viral oncogene was characterized in 1990,¹¹⁹ and its cellular homologue *c-Mpl* was cloned in 1992.¹²⁰ Based on the presence of two copies of the hematopoietic cytokine receptor motif¹²¹ and the ability of a fusion of *c-Mpl* and the IL-4 receptor to signal in factor dependent cells,¹²² *c-Mpl* clearly encoded a growth factor receptor, but its ligand was not known. Using three distinct strategies, four separate groups were able to clone complementary DNA for the corresponding hormone and report their results in 1994 (reviewed in Ref. 75). The gene for thrombopoietin encodes a 36-kDa polypeptide,¹²³ which also is predicted to be extensively posttranslationally modified, resulting in an approximately 50- to 70-kDa protein.

Thrombopoietin bears striking homology to erythropoietin, the primary regulator of erythropoiesis, within the aminoterminal half of the predicted polypeptide. The two proteins are more closely related than any other two cytokines within the hematopoietic cytokine family, sharing 20 percent identical amino acids, an additional 25 percent conservative substitutions, and identical positions of three of the four cysteine residues. Unlike any of the other cytokines in the family, thrombopoietin contains a 181-residue carboxyl-terminal extension, which bears homology to no known proteins. Two functions have been assigned to this region: it prolongs the circulatory half-life of the hormone,³ and it aids in its secretion from the cells that normally synthesize the hormone.¹²⁴

The biologic activities of thrombopoietin have been demonstrated *in vitro* and *in vivo*, in mice, rats, dogs, nonhuman primates, and man. Incubation of marrow cells with thrombopoietin stimulates megakaryocyte survival and proliferation, alone and in combination with other cytokines.³⁴ *In vivo*, thrombopoietin stimulates platelet production in a log-linear manner to levels 10-fold higher than baseline^{3,61,125} without affecting the blood red or white cell counts. In addition, because of its effect on hematopoietic stem cells (Chap. 16), the number of erythroid and myeloid progenitors and mixed myeloid progenitors in marrow and spleen also are increased,^{126,127} an effect that is particularly impressive when the hormone is administered following myelosuppressive therapy.^{126,128,129} This effect likely results from the synergy between thrombopoietin and the other hematopoietic cytokines circulating at high levels in this condition.

Based on genetic studies, thrombopoietin clearly is the primary regulator of thrombopoiesis. Elimination of either the *c-Mpl* or *Tpo* gene leads to profound thrombocytopenia in mice as a result of a greatly reduced number of megakaryocyte progenitors, mature megakaryocytes,

and the reduced ploidy of the remaining megakaryocytes.¹³⁰ A similar result occurs in humans. Patients with congenital amegakaryocytic thrombocytopenia (CAMT) display numerous homozygous or compound heterozygous nonsense or severe missense mutations of the thrombopoietin receptor *c-Mpl* (Chap. 117).^{131,132} The effect of thrombopoietin on hematopoietic stem cells is particularly revealed by consideration of children with CAMT. Within 5 years of birth, nearly every patient with CAMT develops aplastic anemia as a result of stem cell exhaustion.

The thrombopoietin gene displays an unusual 5' flanking structure. Unlike the majority of genes that initiate translation of the encoded polypeptide with the first ATG codon present in the mRNA, thrombopoietin translation initiates at the eighth ATG codon located within the third exon of a full-length transcript.¹³³ However, because the eighth ATG of thrombopoietin mRNA is embedded in the short, open reading frame of the seventh ATG, its translation is particularly inefficient because of the mechanism of ribosomal initiation.¹³⁴ As such, little thrombopoietin protein is produced for any given amount of mRNA. Although this molecular arrangement has no known physiologic consequences, it forms the basis for an unusual form of disease, a disorder of translation efficiency. Four cases of autosomal dominant familial thrombocytosis have been linked to mutations in the region surrounding the initiation codon. In two families, a single mutation in different nucleotides of the intron 3 splice donor sequence results in alternate splicing of the primary thrombopoietin transcript, eliminating the seventh and eighth ATG codons, creating a new aminoterminal by fusing of the fifth open reading frame with the thrombopoietin coding sequence. This novel thrombopoietin mRNA is efficiently translated, resulting in supraphysiologic levels of hormone production and nonclonal expansion of thrombopoiesis.^{135,136} In another mutant thrombopoietin allele, deletion of a single nucleotide within the seventh open reading frame leads to its fusion with the thrombopoietin coding sequence and now enhanced translation of thrombopoietin from the seventh ATG codon.¹³⁷ A fourth mutation has been described within the seventh open reading frame, leading to premature termination of that short peptide, preventing its interference with translation initiation from the usual eighth initiation codon,¹³⁸ again enhancing thrombopoietin production (reviewed in Ref. 139). Of note, while reactive thrombocytosis is not thought to lead to hypercoagulability (Chap. 119), several patients in these pedigrees developed thromboses, raising the physiologic question of why should chronic stimulation of platelets with enhanced levels of thrombopoietin lead to hypercoagulability.

The physiologic regulation of thrombopoietin production has received much attention. Experimental induction of immune-mediated thrombocytopenia results in relatively rapid restoration of platelet levels, followed by a brief period of rebound thrombocytosis.¹⁴⁰ In these experimental cases and in most naturally occurring cases of thrombocytopenia, plasma hormone concentrations vary inversely with platelet counts, rising to maximal levels within 24 hours of onset of profound thrombocytopenia.¹⁴¹ Two non-mutually exclusive models have been advanced to explain these findings. In the first model, thrombopoietin production is constitutive, but its consumption, and hence the level remaining in the blood to affect megakaryopoiesis, is determined by the mass of *c-Mpl* receptors present on platelets and megakaryocytes accessible to the plasma.¹⁴² In this way, states of thrombocytosis result in increased thrombopoietin consumption (by the expanded platelet mass of *c-Mpl* receptors), reducing megakaryopoiesis. Conversely, thrombocytopenia reduces blood thrombopoietin destruction, resulting in elevated blood levels of the hormone that drive megakaryopoiesis and platelet recovery. This model is based on one of the mechanisms regulating macrophage colony-stimulating factor levels.¹⁴³ The invariable levels of thrombopoietin-specific mRNA present in the liver and kidney

of experimental animals and patients with thrombocytopenia or thrombocytosis support this model.^{144,145} Moreover, thrombopoietin knock-out mice display a gene dosage effect.¹⁴⁶ Platelet levels in heterozygous mice are intermediate between that seen in wild-type and nullizygous animals, suggesting active regulation of the remaining thrombopoietin allele cannot compensate for the mild (60 percent of normal) thrombocytopenia induced by the loss of one allele.

A second model suggests thrombopoietin expression is a regulated event. Very-low platelet levels can induce thrombopoietin-specific mRNA production. Several studies show that thrombopoietin mRNA levels are modulated in response to moderate to severe thrombocytopenia, at least in the marrow.^{145,147} The signal(s) responsible for this form of thrombopoietin regulation is being uncovered, but is, at least in part, mediated by transcriptional enhancement.¹⁴⁸ CD40 ligand, platelet-derived growth factor, FGF, TGF- β , platelet factor-4, and thrombospondin modulate thrombopoietin production from marrow stromal cells.^{149,150}

The human thrombopoietin gene 5' flanking region lacks a TATA box or CAAT motif and directs transcription initiation at multiple sites over a 50-nucleotide region.¹⁵¹ Reporter gene analysis in a hepatocyte cell line identified an Ets2 transcription factor-binding motif responsible for high-level expression of the gene. The 5' flanking region also includes SP-1, AP-2, and nuclear factor- κ B binding sites,¹⁵² although the contribution of these transcription factors to thrombopoietin gene expression, either under steady-state or inflammatory conditions, has not been studied.

CXCL12 (Stromal Cell-Derived Factor-1)

Chemokines are members of a rapidly growing class of molecules that play multiple roles in blood cell physiology.¹⁵³ Initially defined as substances that induce leukocyte chemotaxis, four classes of the 8- to 12-kDa polypeptides have been recognized, based on the spacing of cysteine residues close to the aminoterminal of the proteins. An equally rapidly growing family of chemokine receptors also has been discovered, classified by the subfamily of chemokines they serve. All chemokine receptors are members of the seven-transmembrane family of receptors that signal through heterotrimeric G proteins.

Most work has been conducted with the CC and CXC subfamilies of chemokines, molecules that display modest inhibitory effects on cell proliferation when used alone and potent effects when used in combination on hematopoietic progenitors at all levels of development.¹⁵⁴ On many levels, the CXC chemokine CXCL12 (previously termed SDF-1) and its receptor CXCR4 are notable exceptions to the many features shared by most members of the chemokine and chemokine receptor families. For example, although all the other genes for the known CXC chemokines reside on the long arm of human chromosome 14, CXCL12 localizes to the long arm of chromosome 10.¹⁵⁵ Moreover, most chemokine receptors can be activated by multiple ligands. For example, the chemokine CCL3 (macrophage inflammatory protein [MIP]-1 α) can bind and activate CCR1 and CCR5, and IL-8 can bind both CXCR1 and CXCR2.¹⁵⁶ In contrast, as the phenotype of genetic elimination of both CXCR4 and CXCL12 are almost identical,^{157,158} CXCR4 appears to be the only receptor for CXCL12, and CXCL12 is the only ligand for CXCR4.

The marrow stroma is the primary source of CXCL12, and most of the cell types known to express CXCR4 are hematopoietic in origin. One of the major phenotypes in CXCL12- or CXCR4-deficient neonatal mice is marrow aplasia, thought to be secondary to failure of perinatal hematopoietic stem cell homing (Chap. 16).¹⁵⁹ In addition, megakaryocytes display CXCR4¹⁶⁰ and migrate in response to an CXCL12 concentration gradient.¹⁶¹ Several groups have shown that CXCL12 augments thrombopoietin-induced megakaryocyte growth in suspension culture.^{37,160} Later studies have shown the synergy between

CXCL12 and other stimuli on megakaryocyte growth extends to cell surface adhesion.³⁸

Transforming Growth Factor- β

In addition to the many positive regulators of megakaryopoiesis, several substances down-modulate their development. Five isoforms of TGF- β have been identified, all disulfide-linked homodimers each containing 112 residues.¹⁶² TGF- β_1 is the predominant type of TGF found in hematopoietic tissues. Platelet α granules are a particularly rich source of the cytokine. In general, transforming growth factors are inhibitors of hematopoiesis,^{163,164} particularly of megakaryocyte development.^{165,166} The best understood TGF- β growth inhibitory effects are exerted on cell-cycle progression. After binding to one of five receptors, two pathways that block cell-cycle progression are activated. pRb is hypophosphorylated,¹⁶⁷ antagonizing the effects of G₁-phase cyclin-dependent kinases, and cell-cycle inhibitors, including p27 and p15^{INK}, are upregulated, affecting cell-cycle progression.^{168,169} In contrast to these negative effects of TGF- β on cell proliferation, the cytokine enhances megakaryocyte differentiation.

Interferon- α

A second class of cytokines that negatively impact thrombopoiesis are the interferons (IFNs), proteins first defined by their ability to induce an antiviral state in mammalian cells.¹⁷⁰ Biochemical fractionation has revealed three classes of IFNs: IFN- α , a family of 17 distinct but highly homologous molecules; IFN- β , a single molecule more distantly related to the various isoforms of IFN- α ; and IFN- γ , a unique molecule that shares functional properties but not structure with the others. IFNs exert profound inhibitory effects on hematopoiesis.¹⁷¹

The genes for the IFN- α/β subfamily cluster on the short arm of chromosome 9 and encode 165- to 172-residue polypeptides, of which 35 percent are invariant across the family of IFN- α molecules. IFNs of the α/β type are produced by transcriptional upregulation in fibroblasts and leukocytes in response to viruses and other infectious agents and to inflammatory cytokines. Once bound to the IFN receptors, a cascade of kinases and intracellular mediators are triggered, initiated by JAKs (Janus family kinases), STAT (signal transducer and activator of transcription) factors, and p38 MAPK (Chap. 17), resulting in changes in gene transcription.

IFN- α inhibits megakaryopoiesis, the clinical use of which is responsible for modest to severe thrombocytopenia in a significant number of patients undergoing therapy for chronic viral hepatitis.^{172,173} The mechanisms responsible for the inhibitory effect of IFN- α are multifactorial. Some studies suggest a direct inhibitory effect of IFN- α on growth factor-induced proliferation pathways. For example, the cytokine augments double-stranded RNA-activated protein kinase activity, inhibiting translation initiation factor-2, implicating reduction of the growth factor-induced protein synthesis necessary for growth factor response.¹⁷⁴ IFN- β induces expression of the cell-cycle inhibitor p27^{Kip1}, arresting cells in G₀/G₁.¹⁷⁵ Other studies have demonstrated IFN- α induces a SOCS (suppressor of cytokine signaling)-1-based feedback mechanism that cross-reacts and depresses thrombopoietin signaling.¹⁷⁶ Thus, in addition to the multiple positive mediators of megakaryopoiesis, several cytokines block the process and can lead to thrombocytopenia.

MEGAKARYOCYTE MICROENVIRONMENT

Chapter 5 details the role of the marrow microenvironment in hematopoiesis. This chapter discusses only aspects particularly vital for megakaryocyte growth. The cellular concentration within the marrow is estimated to be 10⁹/mL. Consequently, cell-cell and cell-matrix

interactions will occur.¹⁷⁷ A particularly important interaction for thrombopoiesis is between the marrow sinusoidal endothelial cell and the mature megakaryocyte. Studies using *in situ* videomicroscopy indicate that proplatelet processes extend through the sinusoids into the vascular lumen, where the shear stress of flowing blood liberates single platelets.⁶ Marrow stromal cells influence hematopoiesis in a number of other ways, perhaps the most prominent through production of several cytokines that positively or negatively affect megakaryocyte growth.^{145,178-180} Stromal cells are the origin of a number of extracellular matrix proteins and glycomucins that either directly affect hematopoietic cells or indirectly affect hematopoietic cells by binding growth factors and presenting them in a functional context.^{181,182} Stromal cells also bear ligands for Notch proteins, cell-surface receptors that are critical mediators of cell fate decisions.¹⁸³ Notch and its ligands Delta and Jagged play important roles as regulators of hematopoietic progenitor cell proliferation¹⁸⁴ and play a potential role in influencing the lineage fate choice between erythropoiesis and megakaryopoiesis.¹⁸⁵ Cell-cell interactions mediated by integrins present on hematopoietic cells and counterreceptors on stromal cells are very important for megakaryopoiesis,¹⁸⁶ both by bringing hematopoietic cells into close proximity to stromal cells producing soluble or cell-bound cytokines and more directly by triggering or augmenting intracellular signaling, promoting entry into the cell cycle, and preventing programmed cell death.

● THERAPEUTIC MANIPULATION OF THROMBOPOIESIS BY NATURALLY OCCURRING CYTOKINES

Thrombocytopenia is a major clinical problem with multiple origins (Chap. 117). Primary marrow diseases, certain infections, and solid tumors with a high propensity for marrow metastases directly affect platelet production. Nearly all leukemias, advanced lymphomas, and myelomas ultimately cause thrombocytopenia by this mechanism. Hypersplenism and thrombopoietin deficiency contribute to platelet sequestration and reduced platelet production in patients with hepatic failure. Consumptive coagulopathies, initiated by infection, tumors, or severe injury, can be responsible for severe thrombocytopenia. In other patients, autoimmune thrombocytopenia arises during the course of disease or is a primary disease. However, the most common cause of significant thrombocytopenia is iatrogenic: the use of potentially curative or palliative chemotherapy or radiation therapy in patients with malignancy. An estimated 300,000+ persons yearly worldwide undergo courses of chemotherapy adequate to produce clinically significant thrombocytopenia. Recovery from the marrow suppressive effects of most chemotherapeutic agents occurs within 1 to 3 weeks following discontinuation of therapy. However, some agents, including mitomycin C or nitrosoureas, can produce prolonged periods of marrow suppression. Moreover, the widespread use of IFN- α for chronic hepatitis C infection adds large numbers of patients who experience thrombocytopenia as a dose-limiting toxicity. Tumor- or treatment-related thrombocytopenia often delays much needed additional therapy, may necessitate potentially complicated platelet transfusions (Chap. 139), and causes significant morbidity and occasional mortality. Given the increased understanding of the humoral basis for megakaryopoiesis and thrombopoiesis, numerous attempts have been made to manipulate these processes for therapeutic benefit.

INTERLEUKIN-11

IL-11 augments the growth of megakaryocytic progenitors in the presence of IL-3^{187,188} and acts to promote megakaryocyte maturation rather

than proliferation.^{189,190} The preclinical effects of IL-11 were evaluated in mice, rats, and subhuman primates and revealed moderate activity in normal animals and following cytoreductive therapy.^{98,191,192}

The first clinical trials of IL-11 were reported in abstract form in 1993 and 1994.^{193,194} Randomized clinical trials were reported a few years later.¹⁹⁵⁻¹⁹⁷ Most studies reported IL-11 ameliorated drug-induced thrombocytopenia. For example, IL-11 administered to patients with advanced stages of breast cancer undergoing multiple courses of anthracycline-based chemotherapy significantly reduced the need for platelet transfusions by 27 percent. However, use of the drug in patients undergoing autologous stem cell transplantation did not enhance platelet recovery or other indices of hematopoiesis. Although chemical evidence of an acute-phase response was noted in many of the patients treated in these studies, the drug was generally well tolerated, even though fluid retention has been a significant side effect, often necessitating concomitant use of diuretics. IL-11 (oprelvekin, Neumega) was approved by the Food and Drug Administration in 1998 for use in patients undergoing chemotherapy who have evidence of previous drug-induced thrombocytopenia (Chap. 119).

INTERFERON- α

As noted in “Hormones and Cytokines” above, IFN suppresses hematopoiesis and thrombopoiesis by multiple mechanisms. As a consequence, IFN- α has been used to reduce platelet counts in patients with many forms of myeloproliferative disease. The first reported clinical trial was performed in patients with a mixture of these disorders. The trial found the mean platelet count decreased significantly from $1050 \times 10^9/L$ to $340 \times 10^9/L$.¹⁹⁸ Long-term therapy with IFN also was shown to be effective and safe.¹⁹⁹ From these and other studies, IFN (2 to 5 million units 3 times per week) clearly effectively reduces the platelet count toward normal in most patients with myeloproliferative disease. More aggressive regimens (2 to 6 million units daily) result in complete hematologic remissions but with no evidence that the clonal disorder responsible has been affected.²⁰⁰ Not surprisingly, reduced energy level, weight loss, myalgia, and depression have been consistently reported, forcing discontinuation of the drug in approximately one-third of patients taking low to moderate doses of various forms of IFN- α .²⁰¹ Of some concern and possibly related to its effects on the immune system, a significant number of patients treated with IFN for thrombocytosis have developed antibodies to the administered drug, with subsequent reduced efficacy.²⁰²

THROMBOPOIETIN

Clinically, the most important activity of thrombopoietin likely is its effects on megakaryopoiesis, potentially ameliorating the thrombocytopenia that occurs in natural and iatrogenic states of marrow failure. In this regard, a number of promising results in preclinical trials of the cytokine were reported.^{126,128,129,203} In general, in rodent, dog, and non-human primates, almost every model of myelosuppression or immune-mediated platelet destruction has responded favorably to parenteral administration of thrombopoietin. In addition to the favorable effects on platelet recovery, many of these studies also reported enhanced recovery or hematopoietic progenitors of all lineages, accelerated recovery of erythrocytes or leukocytes, or both. The only exception to these generally favorable results has been reported in animal models of stem cell transplantation, where negligible to minimal acceleration of blood cell recovery was found, unless the stem cell donor was treated with the hormone.^{204,205}

A number of clinical trials in patients with cancer undergoing cytotoxic therapy have been conducted. Results were varied, with the hormone helpful in many patients,²⁰⁶⁻²⁰⁸ but not in all clinical

situations.^{209,210} In general, the hormone has been useful in patients who were administered moderately aggressive chemotherapeutic regimens that produce clinically important thrombocytopenia. However, the hormone has not been helpful in the setting of high-dose, prolonged cytotoxic therapy, as in the treatment of acute myelogenous leukemia, or in stem cell transplantation, unless, as in the animal studies, it is administered to the stem cell donor.²¹¹ Thrombopoietin also reportedly increases platelet levels in patients with immune-mediated thrombocytopenia.²¹² The timing of drug administration can significantly impact both the total amount of drug required and its efficacy.²¹³ For example, administration of one dose of drug before and once following myelosuppressive therapy was as effective as any other multidose regimen. This regimen resulted in significant reductions in nadir platelet counts and the need for platelet transfusion during chemotherapy cycles supplemented with thrombopoietin. Nevertheless, use of a modified form of recombinant thrombopoietin is associated with antibody formation to the drug, which cross-reacts with and neutralizes the native hormone, resulting in thrombocytopenia.²¹⁴ Although this effect has not been reported with a nonmodified recombinant thrombopoietin, most efforts using thrombopoietin in patients with thrombocytopenia are focusing on small peptide or organic mimics that bind to and activate the thrombopoietin receptor (reviewed in Ref. 218).^{215–217} Both types of thrombopoietin mimetic agents have been tested in clinical trials (Chap. 117). Two lead indications have been tested; primary immune thrombocytopenia (ITP) and IFN-induced thrombocytopenia in patients being treated for chronic hepatitis C infection. The results of these trials have been very promising. For example, in a randomized control phase III clinical trial of a peptidomimetic bearing four copies of a c-Mpl receptor-stimulating peptide on an immunoglobulin scaffold, 84 percent of heavily pretreated patients with ITP responded to treatment, with rates being slightly lower or higher depending on whether they had previously undergone splenectomy.²¹⁹ Likewise, the administration of a small, orally available organic thrombopoietin mimetic to patients with ITP resulted in 81 percent of patients achieving a platelet count above $50 \times 10^9/L$.²²⁰ These studies have led to FDA approval of the two thrombopoietin agonists for use in patients with ITP. The same molecule was administered to patients with modest hepatic insufficiency undergoing IFN/ribavirin therapy for hepatitis C; 75 percent of such patients were able to complete 3 months of therapy without IFN dose reduction, compared to 6 percent of patients given placebo.²²¹

Thrombopoietin mimics have also been tested in combination with other agents for the treatment of chronic ITP. For example, the combination of recombinant human thrombopoietin plus rituximab results in higher response rates and longer duration of response than rituximab alone.²²²

A number of studies have suggested that thrombopoietin mimics could lead to marrow fibrosis, particularly if used for long periods of time. For example, in a series of patients treated with several different thrombopoietin mimics over 60 patients were shown to develop modest degrees of marrow fibrosis, that progressed with time.²²³ Careful study of these patients will be required to assess the true incidence and predictors of such complications of therapy.

CHAPTER 112

PLATELET MORPHOLOGY, BIOCHEMISTRY, AND FUNCTION

Susan S. Smyth, Sidney Whiteheart, Joseph E. Italiano Jr., Paul Bray, and Barry S. Collier

SUMMARY

The approximately 1 trillion platelets that circulate in an adult human are small anucleate cell fragments adapted to adhere to damaged blood vessels, to aggregate with one another, and to facilitate the generation of thrombin. These actions contribute to hemostasis by producing a platelet plug and then reinforcing plug strength by the action of thrombin converting fibrinogen to fibrin strands. To accomplish these tasks, platelets have surface receptors that can bind adhesive glycoproteins; these include the GPIIb/IX/V complex, which supports platelet adhesion by binding von Willebrand factor, especially under conditions of high shear, and the $\alpha_{IIb}\beta_3$ (GPIIb/IIIa) receptor, which is platelet-specific and mediates platelet aggregation by binding fibrinogen and/or von Willebrand factor. Other receptors for adhesive glycoproteins (integrin $\alpha_2\beta_1$ [GPIa/IIa], GPVI, and perhaps others for collagen; integrin $\alpha_5\beta_1$ [GPIc*/IIa] for fibronectin; integrin $\alpha_6\beta_1$ [GPIIc/IIa] for laminin; and CLEC-2 for podoplanin) also contribute to platelet adhesion, but their precise contributions are less-well defined. Activated platelets express both surface P-selectin, which mediates interactions with leukocytes, and CD40 ligand, which activates a

number of proinflammatory cells, and release chemokines and a soluble form of CD40 ligand, thus initiating an inflammatory reaction. Platelet coagulant activity results from the exposure of negatively charged phospholipids on the surface of platelets and the generation of platelet microparticles, along with release and activation of platelet factor V and perhaps exposure of specific receptors for activated coagulation factor. Platelets change shape with activation as a result of a complex reorganization of the platelet membrane skeleton and cytoskeleton. With activation, platelets undergo release of α granules, dense bodies, and lysosomes, the contents of which work to restore vascular integrity. The activation process involves a number of receptors for agonists such as adenosine diphosphate, epinephrine, thrombin, collagen, thromboxane (TX) A_2 , vasopressin, serotonin, platelet activating factor, lysophosphatidic acid, sphingosine-1-phosphate, and thrombospondin, as well as several signal transduction pathways, including phosphoinositide metabolism, arachidonic acid release and conversion into TXA₂, and phosphorylation of a number of different target proteins. Increases in intracellular calcium result from, and further contribute to, platelet activation. Platelet activation results in a change in the conformation of the integrin $\alpha_{IIb}\beta_3$ receptor, leading to high affinity ligand binding and platelet aggregation.

Platelets also act as storehouses for a variety of molecules that affect platelet function, inflammation, innate immunity, cell proliferation, vascular tone, fibrinolysis, and wound healing; these agents are actively released upon platelet activation. Other vasoactive and platelet activating substances are newly synthesized when platelets are activated. Through cooperative biochemical interactions, platelets can communicate with, and are affected by, other blood cells and endothelial cells.

Quantitative and qualitative disorders of platelets produce hemorrhagic diatheses (Chaps. 119 to 122). In pathologic states, uncontrolled platelet thrombus formation can lead to vasoocclusion and ischemic tissue necrosis, as, for example, in myocardial infarction and stroke (Chap. 135). Platelets may also facilitate tumor cell growth and metastasis.

Acronyms and Abbreviations: AA, arachidonic acid; ADAM, a disintegrin and metalloprotease; ADMIDAS, adjacent to metal ion-dependent adhesion site; AngII, angiotensin II; APP, amyloid precursor protein; AP3, activator protein 3; BTK, Bruton tyrosine kinase; CLB, calcium and integrin binding protein; CLEC, C-type lectin-like receptor; COX, cyclooxygenase; DAG, diacylglycerol; DTS, dense tubular system; EDTA, ethylenediaminetetraacetic acid; EGF, epidermal growth factor; EMMPRIN, matrix metalloproteinase inducer; ERK, extracellular signal-regulated kinase; FAK, focal adhesion kinase; FOG, friend of GATA; FERM, four point one, ezrin, radixin, and moesin; Gas, growth arrest-specific gene; GP, glycoprotein; GPCR, G-protein-coupled receptor; GPI, glycosylphosphatidylinositol; GSK, glycogen synthase kinase; HDL, high-density lipoprotein; HPETE, hydroxyeicosate-traenoic acid; hTRPC, human canonical transient receptor potential; ICAM, intercellular adhesion molecule; IL, interleukin; IP₃, inositol-1,4,5-trisphosphate; ITAM, immunoreceptor tyrosine-based activation motif; ITIM, immunoreceptor tyrosine-based inhibitory motif; ITSM, immunoreceptor tyrosine-based switch motif; JAM, junctional adhesion molecule; LAMP, lysosome-associated membrane protein; LDL, low-density lipoprotein; LIBS, ligand-induced binding site; LIMBS, ligand-associated metal binding site; LOX, lipoxygenase; LPA, lysophosphatidic acid; LPC, lysophosphatidyl choline; LPS, lipopolysaccharide; LT, leukotriene; LX, lipoxin; MAPK, mitogen-activated protein kinase; MIDAS, metal ion-dependent adhesion site; miRNA, microRNA; MLC, myosin light chain; MMP,

matrix metalloproteinase; MRP, myeloid-related protein; MVB, multivesicular body; NAP, neutrophil-activating peptide; NET, neutrophil extracellular trap; NMR, nuclear magnetic resonance; NO, nitric oxide; PAF, platelet-activating factor; PAR, protease-activated receptor; PDGF, platelet-derived growth factor; PDI, protein disulfide isomerase; PDZ, postsynaptic density protein (PSD95), *Drosophila* disk large tumor suppressor (Dlg1), and zonula occludens-1 protein (zo-1); PECAM, platelet-endothelial cell adhesion molecule; PG, prostaglandin; PH, pleckstrin homology; PI, phosphoinositol; PIPK, phosphoinositol phosphate kinase; PIP₂, phosphoinositol 4,5-bisphosphate; PKC, protein kinase C; PL, phospholipase; PNH, paroxysmal nocturnal hemoglobinuria; PPAR, peroxisome proliferator-activated receptors; PSGL, P-selectin glycoprotein ligand; PTB, phosphotyrosine binding; RIAM, Rap1GTP-interacting adapter molecule; SERT, serotonin transporter; SNP, single nucleotide polymorphism; S1P, sphingosine-1-phosphate; SR, scavenger receptor; STIM, stromal interaction molecule; SyMBS, synergy metal binding site; TFPI, tissue factor pathway inhibitor; TGF, transforming growth factor; TLR, toll-like receptor; TLT, TREM-like transcript; TNF, tumor necrosis factor; TP, thromboxane prostanoid receptor; TRAIL, TNF-related apoptosis-inducing ligand; TREM, triggering receptors expressed on myeloid cells; TSP, thrombospondin; TX, thromboxane; VASP, vasodilator-stimulated protein; VEGF, vascular endothelial growth factor; VWF, von Willebrand factor; WASP, Wiskott-Aldrich syndrome protein.

OVERVIEW OF PLATELET ADHESION, AGGREGATION, AND PLATELET THROMBUS FORMATION

The hemostatic system is under elaborate control mechanisms lest the response be either inadequate to meet the hemorrhagic challenge or result in inappropriate thrombosis in response to trivial provocation. Evolutionary pressures have probably favored a more active hemostatic system as individuals with more active hemostatic systems were more likely to avoid death from hemorrhage prior to attaining sexual maturity or in association with childbirth. Our active hemostatic system may be less-well adapted to our modern age, which is characterized by long life spans and progressive vascular disease, given that the deposition of a platelet-fibrin thrombus on a damaged atherosclerotic plaque is the cause of most myocardial infarctions and many strokes.

The platelet's major function is to seal openings in the vascular tree. It is appropriate, therefore, that the initiating signal for platelet deposition and activation is exposure of underlying portions of the blood vessel wall that are normally concealed from circulating platelets by an intact endothelial lining (Fig. 112-1).¹ Additional parameters that probably control the platelet response are: (1) the depth of injury, with deeper damage exposing more platelet-reactive materials and tissue factor (Chap. 115); (2) the vascular bed, with the blood vessels serving mucocutaneous tissues especially dependent on platelets for hemostasis, in contrast to the vascular beds in muscles and joints, which rely more on the coagulation mechanism; (3) the age of the individual, because the composition of the blood vessel wall probably changes with age; (4) the hematocrit, because increased numbers of erythrocytes enhance

platelet interactions with the blood vessel wall by forcing platelets to the periphery of the bloodstream (as the erythrocytes disproportionately occupy the axial region), by imparting radially directed energy to platelets as the erythrocytes engage in flip-flop motions, and perhaps by releasing the platelet activator adenosine diphosphate (ADP) at sites of vascular injury²⁻⁴; and (5) the speed of blood flow and the size of the blood vessel, which will determine the number of platelets passing by a single point in a given time interval, the amount of time a platelet has to interact with the blood vessel wall or other platelets, the rate of dilution of platelet activating agents, and the forces tending to pull a platelet from the vessel wall or another platelet (shear rate).^{2,4-6} The vasospastic response that accompanies vascular injury, to which platelets contribute by release of thromboxane (TX) A₂ and serotonin, probably plays a key role in decreasing hemorrhage and facilitating platelet and fibrin deposition via its effect on blood flow.

The initial adhesion of platelets occurs to the adhesive proteins within the subendothelial layer immediately subjacent to the endothelium^{1,5} or to activated endothelium. The platelet expresses many receptors that participate in adhesive interactions (Table 112-1). Intravital microscopy and *ex vivo* flow chamber studies indicate that discoid platelets that show minimal or no evidence of activation can form the initial layers of platelet aggregates when laminar flow is disrupted by a stenotic lesion, but that stable thrombus development requires the generation and/or release of soluble activators.⁶ Membrane tethers, which can undergo restructuring and stabilization, are important in achieving interactions with matrix proteins and other platelets.

The shear rate differentially affects platelet adhesion to surfaces.^{3,4,7-12} Shear rates, which reflect the differences in flow velocity

A

Figure 112-1. Platelet adhesion, activation, aggregation, and platelet-leukocyte interactions. **A.** Endothelial cells limit platelet deposition because they separate platelets from the adhesive proteins in the subendothelial area, produce two inhibitors of platelet function (nitric oxide [NO] and prostacyclin [PGI₂]), and contain a potent enzyme (CD39) that can digest adenosine diphosphate (ADP) released from platelets. Platelet adhesion is initiated by loss of endothelial cells (or, in the case of an atherosclerotic lesion, rupture or erosion of the plaque), which exposes adhesive glycoproteins such as collagen and von Willebrand factor (VWF) in the subendothelium. In addition, VWF and perhaps other adhesive glycoproteins in plasma deposit in the damaged area, in part by binding to collagen. Platelets adhere to the subendothelium via receptors that bind to the adhesive glycoproteins. Glycoprotein (GP) Ib binding to VWF plays a prominent role, but integrin $\alpha_2\beta_1$ (GPIa/IIa) and GPVI binding to collagen and other platelet receptors (see Table 112-4) probably also play a role. After platelets adhere, they undergo an activation process that leads to a conformational change in integrin $\alpha_{1b}\beta_3$ receptors involving headpiece extension and leg separation (see Fig. 112-5), resulting in their ability to bind with high-affinity select multivalent adhesive proteins, most prominently fibrinogen and VWF, including the VWF that binds to collagen in the subendothelial area.

B

C

Figure 112-1. B. Platelet aggregation occurs when the multivalent adhesive glycoproteins bind simultaneously to integrin $\alpha_{IIb}\beta_3$ receptors on two different platelets, resulting in receptor crosslinking. Clustering of the receptors probably also contributes to the stability of the aggregates (not shown). **C.** After platelets adhere and aggregate, they help to initiate coagulation by binding tissue factor-containing vesicles circulating in the plasma, exposing negatively charged phospholipids on their surface (not shown), releasing platelet factor V (not shown), and releasing procoagulant microparticles. Activated platelets also express P-selectin on their surface, which leads to recruitment of leukocytes via interactions between platelet P-selectin and P-selectin glycoprotein ligand-1 (PSGL-1) expressed on the surface of leukocytes. Other interactions between platelets and leukocytes are detailed in Fig. 112-9. Thrombus formation is a dynamic cyclical process, with platelets repeatedly adhering, aggregating, and then breaking off and embolizing downstream. Platelet-leukocyte aggregates, platelet aggregates, platelet microparticles, thrombin, thromboxane A_2 (TXA_2), leukotrienes (LTs), and serotonin probably all go downstream and affect the microvasculature. Ultimately, the vessel either becomes fully occluded or loses its thrombogenic reactivity; that is, it becomes passivated.

as a function of distance from the blood vessel wall, vary considerably throughout the vasculature, being highest in small arterioles and lowest in large arteries and veins; very high rates are observed at the tips of severely stenotic atherosclerotic arteries.^{6,11,12} Very high shear rates can cause platelets to aggregate via a mechanism that involves von

Willebrand factor (VWF) binding to glycoprotein (GP) Ib/IX followed by intracellular signaling, leading to activation of integrin $\alpha_{IIb}\beta_3$.¹³⁻¹⁶ Platelets contribute more significantly to arterial thrombi than to venous thrombi, perhaps as a result of differences in the shear rates in the different beds.⁵

TABLE 112-1. Platelet Cytoskeletal Proteins*

Protein	Properties
Actin ¹⁸¹¹	<p>Mr = 42,000</p> <p>20–30% of total platelet protein (0.55 M; 2×10^6 per platelet)</p> <p>β and γ forms present at a ratio of 5:1</p> <p>Monomeric actin (G-actin) bound to calcium-ATP (or adenosine diphosphate [ADP])</p> <p>Polymerization requires energy (ATP→ADP) and produces F-actin</p> <p>F-actin filaments: two strands of intertwined helices with polarity based on ability to interact with myosin fragment (“pointed” and “barbed” ends)</p> <p>Steady-state polymerization: monomers lost from pointed end while others join barbed end (“treadmilling”)</p>
Profilin ¹⁸¹²	<p>Mr = 15,200</p> <p>Forms 1:1 reversible complex with actin monomer</p> <p>Prevents actin polymerization</p> <p>May help “recharge” actin monomers with ATP</p>
Gelsolin ¹⁸¹³	<p>Mr = 81,000 (5 μM; 2×10^4 per platelet)</p> <p>Binds to barbed end of F-actin filaments</p> <p>Severs actin filaments</p> <p>Facilitates nucleation</p> <p>Produces shorter filaments with gel→sol transformation</p>
Thymosin β_4 ^{267,268}	<p>Mr = 5000 (0.55 M; 2×10^6 per platelet)</p> <p>Binds actin monomer</p> <p>Inhibits actin polymerization</p>
Tropomyosin ¹⁸¹⁴	<p>Mr = 28,000; rod-shaped dimer of 35-nm length</p> <p>Binds to groove on actin filaments (6 actins:1 tropomyosin)</p> <p>Not all actin filaments have bound tropomyosin</p>
Caldesmon ¹⁸¹⁵	<p>Mr = 80,000; asymmetric</p> <p>Binds to actin, tropomyosin, myosin, and calmodulin</p> <p>May control actin filament bundling and actomyosin adenosine triphosphatase (ATPase)</p>
Filamin A (X) and B (3) (actin-binding protein) ^{133,154,216,249,1816,1817}	<p>Filamin A-to-B = 10:1</p> <p>Mr = 260,000 subunit; tail-to-tail dimer; elongated 162-nm flexible rod composed of 24 immunoglobulin-like domains; phosphorylated</p> <p>2–3% of platelet protein</p> <p>Binds actin with 1 actin binding protein molecule per 14 actin molecules</p> <p>Binds glycoprotein (GP) Iba and integrin β subunit cytoplasmic domains and links GPIb/IX to actin</p> <p>Binds small guanosine triphosphatases (GTPases) RaA, ras, rho, Cdc-42, as well as kinases and phosphatases, and exchange factors</p> <p>Trio and Toll</p> <p>Crosslinks actin filaments to form a gel</p> <p>Dephosphorylation leads to loss of activity</p>
Migfilin ^{142,1818}	<p>Mr = 50,000; binds kindling-2 and vasodilator-stimulated protein (VASP)</p> <p>Can displace filamin from β_3 cytoplasmic domain, facilitating binding of talin</p>
Talin ^{142,245,1818–1820}	<p>Mr = 235,000</p> <p>3% of platelet protein</p> <p>Binds to β_3 integrin cytoplasmic tail to activate $\alpha_{IIb}\beta_3$; also binds vinculin and α-actinin; cleaved and activated by calpain</p>
α -Actinin ¹⁸¹²	<p>Mr = 100,000 and 102,000; dimer</p> <p>Binds actin at 1:10 stoichiometry; binds Ca^{2+}</p> <p>Forms gel with F-actin; cooperates with actin-binding protein; promotes actin polymerization</p>
Vinculin ^{269,1821,1822}	<p>Mr = 130,000</p> <p>Binds to talin; may link actin to membrane proteins at adhesion sites</p>

(Continued)

TABLE 112-1. Platelet Cytoskeletal Proteins* (Continued)

Protein	Properties
Myosin II ^{1823,1824}	Mr = 480,000 (2 × 200,000; 2 × 20,000; 2 × 16,000) 2–5% of platelet protein; 325 × 111-nm filaments Myosin light chain ($M_r = 20,000$); phosphorylated; required for ATPase activity
Myosin light-chain kinase ¹⁸²⁵	Mr = 105,000 Phosphorylates myosin light chain and activates actomyosin ATPase leading to contraction
Calmodulin ¹⁸²⁶	Mr = 17,000 Binds four calciums and activates myosin light-chain kinase
CapZ ^{154,216}	Mr = 36,000 and 32,000 (5 μM; 2 × 10 ⁴ per platelet) Heterodimer Binds barbed ends of actin filaments
Cofilin ^{154,216}	Mr = 20,000 Accelerates depolymerization of actin filaments
Fimbrin (L-plastin)	Mr = 68,000 Bundles actin filaments Found in microvilli
VASP ^{154,216}	Mr = 50,000 Tetrameric Binds profilin, vinculin, zyxin
GTPases ^{154,229,249}	Cdc42–filopodia Rho–stress fibers Rac–lamellipods and ruffles Rap1b– $\alpha_{IIb}\beta_3$ control
Tyrosine kinases	pp60 ^{src} pp125 ^{Fak} – $\alpha_{IIb}\beta_3$ signaling pp72 ^{syk} –GPVI signaling
Adaptor proteins	14–3–3 ζ –binds to GPIIb Pleckstrin–phosphorylated on activation
PI kinases	PI-3 kinase PI ₄ P-5 kinase
Spectrin	α,β heterodimers form head to head tetramers Bind to actin filaments
α,γ Adducins	Cap barbed ends of actin filaments and bind to spectrin Phosphorylated with platelet activation and cleaved by calpain

*See Refs. 216, 249, 261, 266, and 1827.

Platelets also interact directly with exposed collagen, including types I, III, and VI, via GPVI and integrin $\alpha_2\beta_1$ (GPIa/IIa), or perhaps one or more of the many other receptors implicated in platelet-collagen interactions (e.g., CD36 [GPIV], p65).^{17–29} The interaction of platelets with collagen is most evident at relatively low shear rates. Depending on the vascular bed, available adhesive glycoproteins, and shear conditions, it is likely that various combinations of platelet receptors, including GPIIb α , integrin $\alpha_2\beta_1$ (GPIa/IIa), GPVI, and integrin $\alpha_{IIb}\beta_3$, act in concert to transform the tethering and slow translocation of platelets initiated by GPIIb α interacting with VWF into stable platelet adhesion.^{1,3,4,8,10,16,25,28}

For platelet plug formation to occur, platelets must undergo activation as well as adhesion. Adhesion of platelets to subendothelial structures, in particular VWF at high shear, may itself lead to platelet activation, including the generation of TXA₂, release of ADP and serotonin, and activation of the integrin $\alpha_{IIb}\beta_3$ receptors on the

luminal side of the platelet so that they adopt their high-affinity ligand-binding conformation(s).¹⁰ These positive feedback mechanisms insure an adequate hemostatic response. Depending on the nature of the surface to which they adhere, platelets also undergo variable spreading reactions and become anchored by a process that at least partially involves integrin $\alpha_{IIb}\beta_3$ ligation and clustering, leading to “outside-in” signaling, cytoskeletal reorganization, and tyrosine phosphorylation; these reactions also contribute to initiating the release reaction.^{30–36} In addition, platelet activators, such as ADP, are released or synthesized at the site of vascular injury, resulting in a local response. Cooperative biochemical interactions between erythrocytes and platelets may enhance platelet activation.³⁷

Activated luminal integrin $\alpha_{IIb}\beta_3$ receptors on adherent platelets bind VWF, fibrinogen, and other adhesive glycoproteins, and await the interaction with another platelet, which itself may have undergone activation of its integrin $\alpha_{IIb}\beta_3$ receptors as a result of exposure to released

ADP and TXA₂. Alternatively, a platelet may become activated and bind VWF or fibrinogen while still circulating, in which case the platelet-ligand complex may bind directly to an activated integrin $\alpha_{IIb}\beta_3$ receptor on the luminal surface. The binding of adhesive ligands to platelet receptors then repeats itself, resulting in the recruitment of additional layers of platelets, and ultimately the formation of a hemostatic plug. Intravital videomicroscopy of the mesenteric and cremasteric circulations of mice after endothelial cell damage demonstrates that, at least in these vascular beds, platelet thrombus formation is initially a very dynamic process, with many platelets depositing but then embolizing.³⁸ The thrombus grows relatively slowly compared to what its growth would be if all of the platelets that deposited remained attached to the surface.^{39–41}

The integrin $\alpha_{IIb}\beta_3$ receptor occupies a central role in determining the extent of platelet aggregation, in part because it is present at an extraordinarily high density on the platelet surface (approximately 50,000 receptors per platelet, such that receptors are probably less than 20 nm apart).^{30,42–45} This permits it to rapidly initiate platelet aggregation. On the other hand, the receptor is not in its high-affinity ligand-binding state on resting platelets but rather needs to be activated by agonists, including ADP, serotonin, thrombin, collagen, and TXA₂, that are localized to sites of vascular injury.^{34,44,46} As a result, platelets can circulate in plasma containing high concentrations of the integrin $\alpha_{IIb}\beta_3$ ligands fibrinogen and VWF without ongoing platelet thrombus formation. The agonists that activate the integrin $\alpha_{IIb}\beta_3$ receptor are likely to work in combination *in vivo*. In fact, the mixture of agonists present is likely to change as the process unfolds, with collagen perhaps more important at the beginning, thrombin more important later on, and the other agonists in varying mixtures throughout. The platelet activation effects of multiple agonists may be additive or synergistic, depending on the mechanism(s) involved.^{47,48}

A number of mechanisms stabilize platelet aggregates. These include absence of fibrinogen (presumably limiting fibrin formation),⁴¹ leptin,^{49–51} CD40 ligand,⁵² growth arrest-specific gene 6 product (Gas6) and its receptors (Axl, Sky, and Mer),^{53–57} Eph kinases and ephrins,⁵⁸ factor XII,⁵⁹ plasminogen activator inhibitor-1 and vitronectin,⁵⁰ or inhibition of select regions of fibrinogen.⁶⁰

Activated platelets can facilitate thrombin generation by one or more different mechanisms, including recruitment of bloodborne tissue factor, synthesis or activation of tissue factor, formation of procoagulant microvesicles, exposure of activated factor V, exposure of negatively charged phospholipids, and perhaps activation of the contact system. The thrombin thus generated further activates platelets, leading to more extensive degranulation; it also further activates coagulation and initiates the deposition of fibrin strands that reinforce the platelet thrombus and serve as sites for additional VWF deposition.⁶¹ Thrombin also helps to consolidate the plug by initiating platelet-mediated clot retraction (see section “Platelet Shape Change, Spreading, Contraction and Clot Retraction” below). Finally, thrombin affects the surface membrane receptors, down-regulating GPIb/IX and upregulating integrin $\alpha_{IIb}\beta_3$, perhaps facilitating the transition from platelet adhesion to platelet aggregation.^{62–65}

Release of vasoactive and mitogenic agents, as well as chemokines, from platelets contributes to the inflammatory response, as does the appearance of P-selectin on the surface of activated platelets and endothelial cells, because P-selectin and other platelet receptors recruit leukocytes to the damaged region.^{66–68} Finally, after contributing to hemostasis and initiating an inflammatory response, platelet-fibrin thrombi eventually resolve, most likely by a combination of embolization, fibrinolysis, and macrophage removal of debris.

Several inhibitory factors serve to balance platelet activation and thus prevent excessive platelet deposition. The dilutional effects of flowing blood are probably most important; thus, alterations in the surface of the blood vessel that produce local areas of stasis in which platelets

and coagulation factors may concentrate are prothrombogenic.^{2,5} Endothelial cells can synthesize two potent inhibitors of platelet activation, prostacyclin and nitric oxide (Chap. 115).^{69–72} Generation of prostacyclin at sites of vascular injury or inflammation may provide a mechanism to limit platelet accumulation. Nitric oxide, which is synthesized by endothelial cells, is a potent inhibitor of *ex vivo* platelet adhesion and aggregation. Endothelial cells and lymphocytes also have CD39, an ecto-ATP diphosphohydrolase (ecto-ADPase) that can digest ATP and ADP to adenosine monophosphate (AMP), and thus limit the effects of released ADP.^{73,74} They also have CD73, which can convert AMP into the platelet inhibitor adenosine.

● PLATELET MORPHOLOGY AND BIOCHEMISTRY

MICROSCOPIC APPEARANCE

On films made from blood anticoagulated with the strong calcium chelating agent ethylenediaminetetraacetic acid (EDTA) and treated with Wright stain, platelets appear as small bluish-gray, oval-to-round shaped cell fragments with several purple-red granules. The mean diameter of platelets varies in different individuals, ranging from approximately 1.5 to 3.0 μm , approximately one-third to one-fourth that of erythrocytes. There is also considerable variability in the size of platelets in a single individual, with occasional platelets in normal blood samples having diameters greater than half the diameter of erythrocytes. Overall, platelet size appears to follow a log normal distribution with an average volume of approximately 7 fL.⁷⁵ When unanticoagulated blood is used to prepare blood films, platelets undergo variable activation and spreading, and thus platelet aggregates are commonly seen; platelets from such specimens may demonstrate three or four very long finger-like processes extending out from the body of the platelet (filopodia), and some platelets may be devoid of granules.

Electron microscopy reveals a fuzzy coat (glycocalyx) extending 14 to 20 nm from the platelet surface, which is thought to be composed of membrane GPs, glycolipids, mucopolysaccharides, and adsorbed plasma proteins (Fig. 112–2).⁷⁶ Platelets move in an electric field as if they have a net negative surface charge; sialic acid residues attached to proteins and lipids are major contributors to this negative charge.⁷⁷ The electrostatic repulsion created by the negative surface charge may help prevent resting platelets from attaching to each other or to negatively charged endothelial cells.

Indentations on the platelet surface are thought to be the openings of the open canalicular system, which is an elaborate channel system composed of invaginations of the plasma membrane that extend throughout the platelet (see Fig. 112–2 and “Membrane Systems” below). The contents of platelet granules can gain access to the outside when the granules fuse with either the plasma membrane or any region of the open canalicular system. Similarly, glycoproteins contained within granule membranes can join the plasma membrane after granule fusion with either the plasma membrane or the open canalicular system.

MEMBRANE SYSTEMS

The Plasma Membrane

The plasma membrane is a trilaminar unit composed of a bilayer of phospholipids embedded with cholesterol, glycolipids, and glycoproteins.^{76,78} Platelets prepared by the freeze–fracture technique demonstrate more intramembranous particles embedded in the outer platelet membrane leaflet than in the inner leaflet, which is the reverse of findings in erythrocytes; this observation presumably reflects the many external receptors that mediate platelet interactions. The plasma membrane is

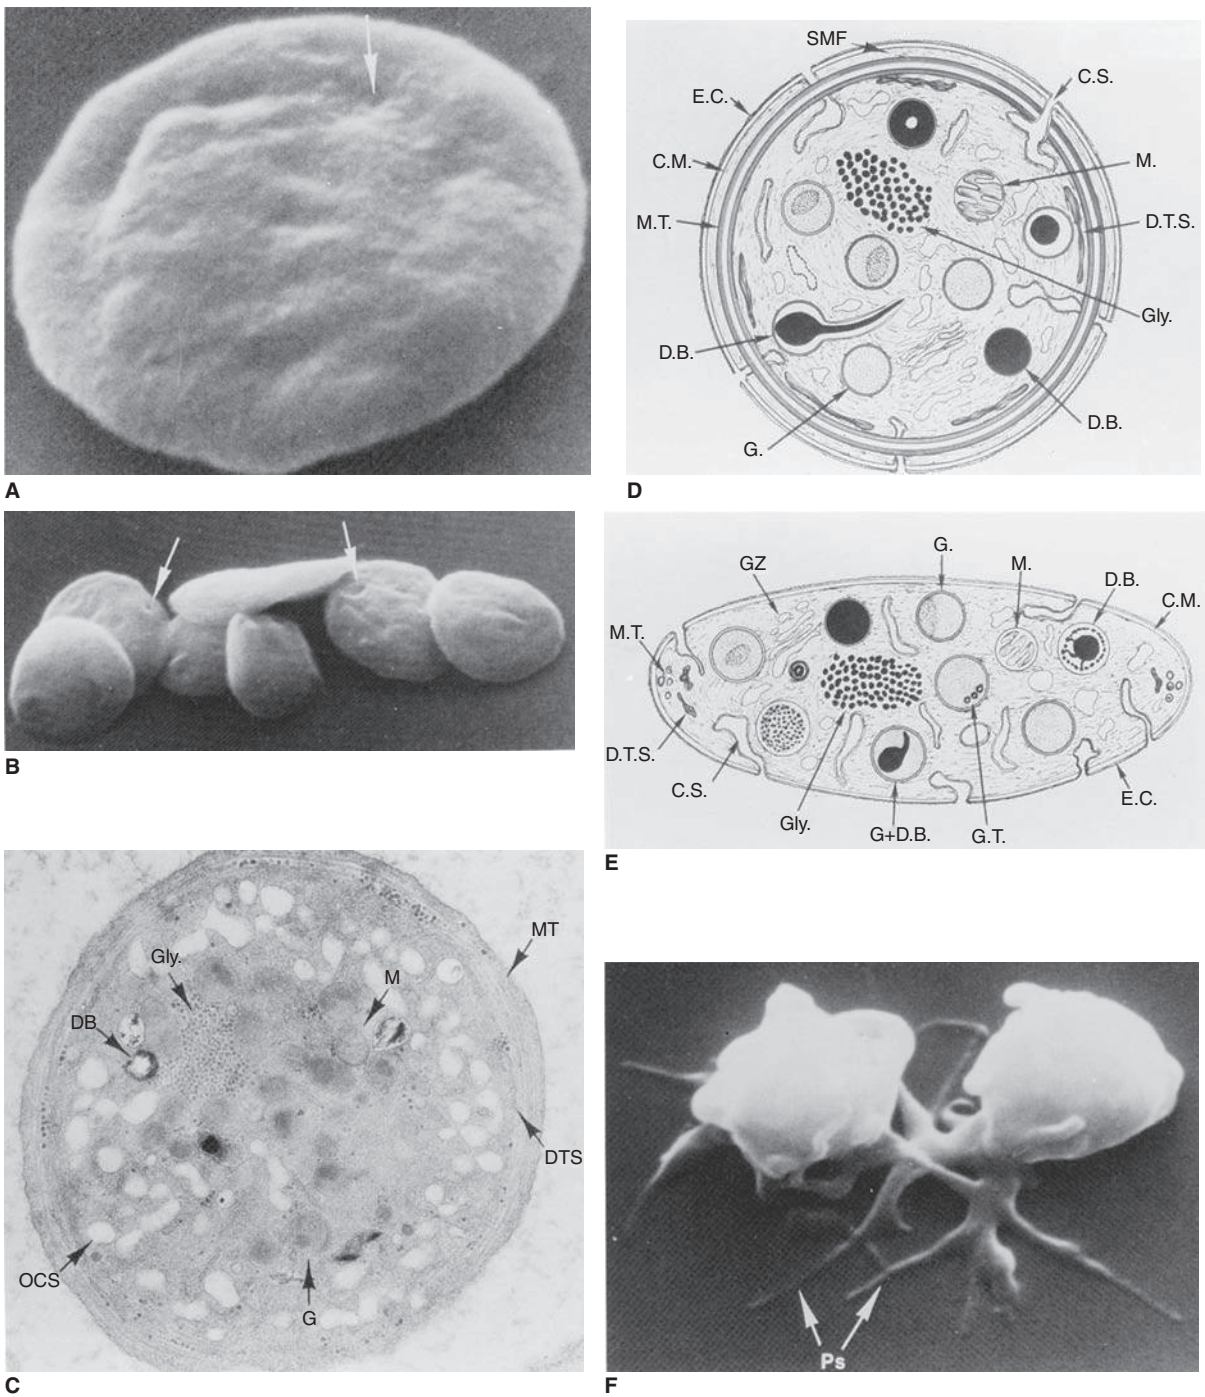

Figure 112-2. **A** and **B.** Discoid platelets. The lentiform shape of blood platelets is well preserved in samples fixed in glutaraldehyde and critical point dried for study in the scanning electron microscope. The indentations apparent on the otherwise smooth surfaces of the platelets (*arrows*) indicate sites where channels of the open canalicular system (OCS) communicate with the cell exterior. (Magnification: **A**, $\times 13,200$; **B**, $\times 35,000$.) **C**, **D**, and **E.** Ultrastructural features observed in thin sections of discoid platelets cut in the equatorial plane (**C** and **D**) or cross-section (**E**). Components include the exterior coat (E.C.), trilaminar unit membrane (C.M.), and submembrane area containing the specialized filaments of the membrane skeleton (SMF). The plasma membrane indentations form the walls of the channels of the surface-connected open canalicular system (C.S. and OCS). The circumferential band of microtubules (M.T.) is seen as a continuous band beneath the plasma membrane on the equatorial section and as small open cylinders at the ends of the platelet on the cross-section. Glycogen granules (Gly) are prominent punctate structures in the cytoplasm, and residual Golgi zones (GZ) can also be identified. Organelles include mitochondria (M.), dense bodies (D.B.), and α granules (G.), many of which have regions of electron density (nucleoids). The dense tubular system (D.T.S.), the platelet equivalent of the sarcoplasmic reticulum sequesters calcium. (Magnification: **C**, $\times 30,000$.) **F.** Platelet shape change. Platelets exposed to adenosine diphosphate and then fixed and examined by scanning electron microscopy. The platelets lose their discoid shape and become spiny spheres with long extensions, variably referred to as *filopodia* or *pseudopodia*. (Magnification: $\times 17,000$.) (Reproduced with permission from Bloom AL, et al: Hemostasis and Thrombosis, Edinburgh: Churchill Livingstone; 1994.)

thought to contain the sodium- and calcium-adenosine triphosphatase (ATPase) pumps that control the intracellular ionic environment of the platelet. Approximately 60 percent of platelet phospholipids are contained in the plasma membrane. The phospholipids are asymmetrically organized in the plasma membrane; the negatively charged phospholipids are almost exclusively present in the inner leaflet, whereas the others are more evenly distributed.⁷⁹ The negatively charged phospholipids, especially phosphatidylserine, are able to accelerate several steps in the coagulation sequence and so their presence in the inner leaflet of resting platelets, separated from the plasma coagulation factors, is thought to be a control mechanism for preventing inappropriate activation of the coagulation system.^{80,81} During platelet activation induced by select agonists, the aminophospholipids may become exposed on the platelet surface or on the surface of microparticles (see “Platelet Coagulant Activity” below).^{80–83}

The phospholipid asymmetry in resting platelets may be maintained by an ATP-dependent aminophospholipid translocase that actively moves phosphatidylserine and phosphatidylethanolamine from the outer to the inner leaflet.^{80,84} Interactions of negatively charged phospholipids with cytoskeletal or other cytoplasmic elements may also contribute to the asymmetry.^{80,81,85,86}

Lipid rafts are dynamic, cholesterol- and sphingolipid-rich membrane microdomains that are important in signaling and intracellular trafficking. In platelets the cholesterol-to-phospholipid molar ratio is twofold higher in rafts than in bulk membranes, with sphingomyelin accounting for the majority of total raft lipids.⁸⁷ Platelet lipid rafts contain the marker proteins flotillin 1, flotillin 2, stomatin, and the ganglioside GM₁; the rafts are also notable for being devoid of caveolin. Other proteins, such as CD36, CD63, CD9, integrin $\alpha_{IIb}\beta_3$, and glucose transporter (GLUT)-3, are present in rafts prepared from resting platelets.⁸⁷ Upon activation of GPVI, Fc gamma chain, Fc γ RIIa, and GPIb/IX/V partition into the lipid rafts,^{88,89} as do c-Src,⁹⁰ phosphatidic acid, and phosphoinositol (PI) 3'-kinase (PI3K) products.^{87,91} Factor XI binds to extracellularly-oriented lipid rafts and undergoes activation.⁹² The calcium entry channel hTRPC1 is associated with lipid rafts in platelets and, upon platelet activation, contributes to calcium entry that is regulated by the state of intracellular calcium stores (store-mediated calcium entry).⁹³ The functionally detrimental effects of chilling platelets are thought to be mediated, at least in part, by the temperature-dependent coalescence of platelet lipid rafts.⁹⁴

Open Canalicular System The surface-connected open canalicular system is an elaborate series of conduits that begin as indentations of the plasma membrane and tunnel throughout the interior of the platelet.^{76,95,96} Tracer studies demonstrate that the open canalicular system is contiguous with the exterior of the platelet, even though elements of the open canalicular system may appear as closed vesicles or vacuoles by electron microscopy of sectioned platelets.^{76,95–97}

The open canalicular system may serve several functions. It provides a mechanism for entry of external elements into the interior of the platelet. It also provides a potential route for the release of granule contents to the outside, eliminating the need for granule fusion with the plasma membrane itself.^{97,98} This latter function is especially important because, under most circumstances, platelet granules appear to move to the center of the platelet upon platelet activation rather than to the periphery.^{76,95,99} Controversy remains, however, regarding the relative frequency with which secretion occurs via the open canalicular system versus direct fusion with the plasma membrane.^{76,95,100}

The open canalicular system also represents an extensive internal store of membrane. Both filopodia formation and platelet spreading after adhesion require a dramatic increase in surface plasma membrane compared to the plasma membrane of resting platelets, and it is not possible for new membrane to be synthesized during the short time-course

of these phenomena. Thus, the membrane of the open canalicular system most likely contributes to the increase in plasma membrane under these conditions; the membranes of α granules, dense bodies, and, to a lesser extent, lysosomes may also contribute, but only if the stimulus is sufficient to induce the fusion of these organelles with the plasma membrane (release reaction). Finally, the membrane of the open canalicular system may serve as a storage site for plasma membrane glycoproteins. For example, under certain conditions, platelet activation by thrombin leads to a consistent, selective loss of GPIb/IX from the platelet surface and data from electron microscopy indicate that the GPIb/IX becomes sequestered in the open canalicular system.^{63,64,101} Plasmin may produce a similar phenomenon.^{101,102} Platelet activation leads to an increase in surface integrin $\alpha_{IIb}\beta_3$, and although much of this receptor is thought to derive from α -granule membranes, at least some may come from integrin $\alpha_{IIb}\beta_3$ in the membranes of dense bodies and the open canalicular system.^{101,103} Similarly, GPVI, the P2Y₁ ADP receptor, and the TXA₂ receptor, and perhaps other receptors are present in the open canalicular system and can be recruited to the platelet surface with activation.^{104,105}

Dense Tubular System/Sarcoplasmic Reticulum The dense tubular system (DTS) is a closed-channel network of residual endoplasmic reticulum characterized histochemically by the presence of peroxidase activity.^{76,106–108} The channels of the DTS are less extensive than those of the open canalicular system and tend to cluster in regions in close approximation to the open canalicular system.⁷⁶ The DTS is analogous to the sarcoplasmic reticulum of muscle because it can sequester Ca²⁺ and release it when platelets are activated, leading to shape change, granule centralization, and secretion.^{109,110} Calreticulin, a calcium binding protein found in the DTS/sarcoplasmic reticulum, probably helps to sequester ionized calcium.^{111,112} Release of Ca²⁺ from the DTS/sarcoplasmic reticulum involves the binding of inositol-1,4,5-trisphosphate (IP₃), a messenger molecule formed during signal transduction, to IP₃ type II receptors on the DTS/sarcoplasmic reticulum membrane (Fig. 112–3).^{113,114} Cyclic AMP inhibits Ca²⁺ release from the DTS/sarcoplasmic reticulum, either by enhancing the calcium pumping mechanism¹¹⁵ or by inhibiting release induced by IP₃.¹¹⁶ NO inhibits Ca²⁺ uptake by the DTS/sarcoplasmic reticulum at high concentrations and stimulates uptake at low concentrations by effects on the calcium ATPase(s) SERCA26 and SERCA3.^{117,118} Depletion of intracellular calcium stores activates store-operated calcium entry (SOCE) into platelets (reviewed in Ref. 119). The depletion of Ca²⁺ from the DTS/sarcoplasmic reticulum is sensed by stromal interaction molecule 1 (STIM1), a transmembrane protein with a Ca²⁺ binding motif (EF hand) in the DTS/sarcoplasmic reticulum.^{120–122} Loss of Ca²⁺ binding to STIM1 results in translocation and activation of Orai1, a calcium release activated calcium (CRAC) channel in the plasma membrane,^{123,124} that allows Ca²⁺ entry into the platelet. Although mice with defects in STIM1 and Orai1 have demonstrated abnormalities in platelet function,^{120–122} humans with mutations in these proteins have had immune dysfunction, but no overt hemostatic or thrombotic abnormalities.^{125–127} The human canonical transient receptor potential 1 (hTRPC1) has also been implicated in regulating platelet SOCE, but mice deficient in this protein do not have a defect in platelet Ca²⁺ entry.^{128–130}

The DTS membrane is also probably a major site of prostaglandin and TX synthesis^{109,131}; in fact, the peroxidase activity used to identify the DTS is an enzymatic component of prostaglandin synthesis.^{131,132}

Cytoskeletal Elements

The discoid shape of the resting platelet is maintained by a well-defined and highly specialized cytoskeleton. This system of molecular struts and girders preserves the shape and integrity of the platelet as it encounters high shear forces in the circulation. The platelet cytoskeleton is operationally defined as proteins that are insoluble in the presence of the

Figure 112-3. Platelet calcium homeostasis. Upon receptor activation different phospholipase (PL) C isoforms hydrolyze phosphatidylinositol-4,5-bisphosphate (PIP_2) to inositol-1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). IP_3 releases Ca^{2+} from the intracellular stores in the dense tubular system (DTS)/sarcoplasmic reticulum. The transmembrane protein stromal interaction molecule 1 (STIM1) senses the reduction in Ca^{2+} through a decrease in Ca^{2+} occupancy of its EF hand domain, and then opens Orai1 Ca^{2+} channels in the plasma membrane, a process called store-operated calcium entry, whereas DAG mediates calcium entry through canonical transient receptor potential channel 6 (TRPC6). Additionally, a direct receptor-operated calcium (ROC) channel, P2X_1 , and a $\text{Na}^+/\text{Ca}^{2+}$ exchanger (NCX) contribute to the elevation in Ca^{2+} in the platelet cytoplasm. The counteracting mechanisms to replenish DTS/sarcoplasmic reticulum Ca^{2+} stores involve Ca^{2+} adenosine triphosphatases (ATPases) (SERCA). Plasma membrane Ca^{2+} ATPases (PMCAs) pump Ca^{2+} through the plasma membrane out of the cell. ADP, adenosine diphosphate; CLEC-2, C-type lectin-like receptor 2; FcR γ , Fc receptor γ chain; Fc γ RIIa, Fc γ receptor IIa; GPVI, glycoprotein VI; IP_3 R, IP_3 -receptor; PI_3 -K, phosphatidylinositol 3-kinase; Syk, spleen tyrosine kinase. Because of controversies about the localization and role of TRPC1 in the literature, this protein is not depicted in the figure. (Adapted with permission from Varga-Szabo D, Braun A, Nieswandt B: Calcium signaling in platelets. *J Thromb Haemost* 7(7):1057–1066, 2009.)

nonionic detergent Triton X-100 under defined ionic conditions. The three major cytoskeletal elements are the spectrin membrane skeleton, the marginal microtubule coil, and the actin cytoskeleton.

Membrane Skeleton The plasma membrane and open canalicular system of the resting platelet are supported by a highly structured cytoskeletal system (see Figs. 112-2 and 112-4). This two-dimensional network, located just beneath the plasma membrane, has remarkable structural resemblance to its red blood cell counterpart. Thus, both involve the self-assembly of elongated spectrin strands that interconnect through their binding to actin filaments, generating triangular pores. Platelets contain approximately 2000 molecules of spectrin.^{133–136} The spectrin network coats the cytoplasmic surfaces of both the plasma membrane and the open canalicular system. In contrast to the erythrocyte membrane skeleton, however, in which spectrin molecules connect on short actin filaments, in platelets, spectrin joins into a network by binding to the ends of actin filaments in close apposition to the plasma membrane. As a result, the spectrin lattice is assembled into a continuous network by its association with actin filaments. Moreover, tropomodulins, which are abundant in erythrocytes, are not expressed at significant levels in platelets and thus are unlikely to play a role in capping the pointed ends of actin filaments. Instead, these ends appear to be free in resting platelets. Finally, the protein adducin is abundantly expressed in platelets and appears to cap the majority of the barbed ends of the filaments making up the resting platelet cytoskeleton.¹³⁷ This serves to target them to the spectrin-based membrane skeleton, as the affinity of spectrin for adducin-actin complexes is greater than for either adducin or actin alone.^{138–140}

The platelet spectrin-actin filament network is fortified by interactions with filamin A (actin binding protein), a noncovalent dimer of two identical Mr 280,000 protein subunits that fastens GPIb/IX/V complexes to the sides of actin filaments. By interacting with both the

transmembrane glycoprotein GPIb α and the actin immediately below the membrane, filamin A connects these components to the spectrin network and the resulting membrane cytoskeleton, probably contributing to the platelet's discoid shape. In addition, the association of GPIb α with the membrane skeleton restricts the expansion of the spectrin network and probably helps to organize receptors into linear arrays on the platelet surface, thus enhancing receptor cooperation (see Fig. 112-4).¹³³ Filamin also binds to the cytoplasmic domains of the β_3 subunits of integrin receptors and this keeps the receptor in a low affinity state.^{141–143} Other proteins that have been found in the membrane skeleton include talin, vinculin, dystrophin-related protein, molecules implicated in signal transduction, and several isoenzymes of protein kinase C.¹³³

Talin has been implicated in controlling integrin $\alpha_{\text{IIb}}\beta_3$ activation, by binding to the cytoplasmic domain of integrin β_3 when phosphorylated and/or cleaved by calpain (see "Integrin $\alpha_{\text{IIb}}\beta_3$ " below and Fig. 112-4).^{144–148} Migfilin (filamin-binding LIM protein-1) is a 373-amino-acid protein of Mr 50,000 that can displace filamin from the integrin β_3 cytoplasmic domain, thus facilitating talin binding and activation. Moreover, joining integrin $\alpha_{\text{IIb}}\beta_3$ to the membrane skeleton via an integrin β_3 linkage creates the possibility for an actin-myosin contraction process to supply sufficient force to integrin $\alpha_{\text{IIb}}\beta_3$ to induce conformational changes in the receptor that result in high affinity ligand binding.¹⁴⁹ The protein vimentin (Mr 58,000), which is an important component of intermediate filaments, is present in platelets and contributes to the membrane cytoskeleton. When platelets are activated, vitronectin-plasminogen activator inhibitor-1 (PAI-1) complexes bind to surface vimentin where they are strategically located to inhibit fibrinolysis.¹⁵⁰ With platelet activation, integrins $\alpha_{\text{IIb}}\beta_3$ and $\alpha_2\beta_1$ join the cytoskeleton. Thus, the cytoskeleton may affect whether receptors are free to move in the plane of the membrane; it may also have a role in moving certain receptors from the surface to the interior of platelets and

Figure 112-4. Diagrammatic depiction of established and hypothetical connections between select platelet transmembrane glycoproteins and the underlying membrane skeleton. Although evidence exists for direct interactions between IIb 3 with talin and Src and between GPIb with 14-3-3 and filamin, the remainder of the interactions are only hypothetical and are based on the recovery of proteins in the membrane skeleton fraction of solubilized platelets. (Adapted with permission from Colman RW: Hemostasis and Thrombosis: Basic Principles and Clinical Practice, 4th edition. Philadelphia, PA: Williams & Wilkins; 2001.)

vice versa via the open canalicular system.^{101,133} The membrane skeleton may also be important in platelet spreading after adhesion.

Microtubules One of the most distinguishing features of the resting platelet is its marginal microtubule coil (see Fig. 112-2). Located below the plasma membrane, it plays an important role in platelet formation from megakaryocytes and maintaining the platelet's discoid shape.^{76,151-153} Microtubules are the largest cytoskeletal filaments (25 nm) and are comprised of hollow polarized polymers composed of 13 protofilaments made up of $\alpha\beta$ tubulin dimers (each of Mr 110,000) that associate with several high-molecular-weight proteins (microtubule-associated proteins).¹⁵³⁻¹⁵⁵ Motor proteins of the dynein and kinesin families are also associated with microtubules.¹⁵⁶⁻¹⁵⁸ In cells, $\alpha\beta$ tubulin subunits are in dynamic equilibrium with assembled microtubules such that reversible cycles of assembly and disassembly of microtubules are frequently observed.¹⁵⁹ The critical concentration for tubulin polymerization is 5 μM , which is well below the tubulin concentration in platelets (70 μM) and thus 60 percent of platelet tubulin is present as polymer.^{154,160} On cross-section, approximately eight to 12 separate hollow structures are observed at the tapered ends of the platelet (see Fig. 112-2). Direct visualization of microtubule assembly in resting mouse platelets indicates that the circumferential coil in platelets is composed of at least 8 actively polymerizing microtubules.¹⁵⁹ Microtubule dynamics allows for necessary changes in platelet shape that occur during the platelet life span and with activation. Tubulin is acetylated in resting platelets and undergoes deacetylation by histone deacetylase (HDAC) 6 with activation in association with the dissolution of the marginal band.^{161,162}

Platelets contain four different tubulin isoforms ($\beta_1, \beta_2, \beta_4, \beta_5$), but β_1 is dominant and is specific for megakaryocytes and platelets. Targeted gene deletion of β_1 tubulin in mice results in thrombocytopenia and abnormal platelet and microtubule morphology.¹⁵³ β_1 -Tubulin-deficient platelets are spherical in shape, probably as a result of having defective

marginal bands with fewer (approximately two to three) than normal (approximately eight) microtubule coils.¹⁶³ A heterozygous polymorphism of human β_1 -tubulin (Q43P) has been described in association with macrothrombocytopenia,¹⁶⁴ but it is probably not causal,¹⁶⁵ and individuals homozygous for the Q43P variant have low platelet counts, abnormal platelet ultrastructure, and decreased tubulin, but normal platelet length, width, and area.¹⁶⁶ A heterozygous β_1 -tubulin mutation (R207H) in a strategically located region of the molecule has been reported in association with macrothrombocytopenia as has an F260S¹⁶⁷ mutation and an R318W mutation¹⁶⁵ (Chap. 120).¹⁶⁸

Actin Filaments Actin is the most abundant of all platelet proteins, with 2 million molecules expressed per platelet (0.5 mM).¹⁶⁹ Like tubulin, actin is in dynamic monomer-polymer equilibrium, with 40 percent of the actin subunits polymerized to form 2000 to 5000 linear actin filaments in resting platelets (Fig. 112-5). The rest of the actin in the platelet cytoplasm is maintained in storage as a 1:1 complex with β_4 -thymosin; this stored actin is converted to filaments during platelet activation to drive cell spreading.¹⁷⁰ Thus, actin filaments crisscross the interior of the cell, interconnected at various points into a rigid cytoplasmic network by abundantly expressed actin crosslinking proteins, including filamin and α -actinin.¹⁷¹⁻¹⁷³ Filamin exists in solution as homodimers of subunits that themselves are elongated strands composed primarily of 24 repeats, each approximately 100 amino acids in length, that are folded into immunoglobulin (Ig) G-like β barrels.^{174,175} There are three filamin genes and they are located on the X chromosome, chromosome 3, and chromosome 7.^{176,177} Filamin A and filamin B are expressed in platelets, with filamin A accounting for approximately 90 percent of total filamin.

Filamin is a prototypical scaffolding protein that attracts binding partners, including the small guanosine triphosphatase (GTPase), RalA, Rac, Rho, and Cdc42,¹⁷⁸ and positions them adjacent to the plasma membrane.¹⁷⁹ Approximately 90 percent of the filamin in resting

Figure 112-5. Control of platelet actin assembly. (*Rest*) Forty percent of the actin in the resting cell is filamentous. The rest of the actin is soluble (60 percent) and is in a 1:1 complex with β_4 -thymosin. Filaments are stable because they are capped on their barbed ends by capZ. (*Active*) Shape change begins when calcium rises into the micromolar level and gelsolin becomes active. Gelsolin binds to actin filaments, interdigitates, and causes filaments to fragment. After fragmentation, gelsolin remains bound to the barbed filament end. Assembly of actin begins when capping proteins are dissociated from the barbed ends of the filament fragments formed in the rounding step by polyphosphoinositides (ppls) and when the actin-related protein (ARP2/3) complex in platelets is activated to nucleate de novo filaments. Actin monomers, stored in complex with β_4 -thymosin, are the source of the actin for this polymerization event. Transfer of actin from β_4 -thymosin to the barbed ends of actin filaments is facilitated by profilin. Once assembly is complete, capZ recaps the barbed filament ends. (Adapted with permission from Michelson A: Platelets. 2nd edition. Boston, MA: Academic Press/Elsevier; 2007.)

platelets interacts with the cytoplasmic tail of the GPIIb α subunit of the GPIIb-IX-V complex via a binding site in filamin's second rod domain (repeats 17 to 20).^{180,181} This interaction has three consequences. First, it positions filamin's self-association domain and associated partner proteins at the plasma membrane while presenting filamin's actin-binding sites into the cytoplasm. Second, because a large fraction of filamin is also bound to actin, it aligns the GPIIb-IX-V complexes into rows on the plasma membrane surface of the platelet over the underlying actin filaments. Third, because the filamin linkages between actin filaments and the GPIIb-IX-V complex pass through the pores of the spectrin lattice, it restrains the molecular movement of the spectrin strands in this lattice and holds the lattice in compression. The filamin-GPIIb α connection is essential for the formation and release of discoid platelets by megakaryocytes, as platelets lacking this connection are produced in lower numbers and the ones that are produced are abnormally large and fragile. Platelets deficient in GPIIb (Bernard-Soulier syndrome; Chap. 120) are very large, perhaps as a result of abnormalities in organizing the cytoskeleton.

● PLATELET ENERGY METABOLISM

Platelets have sizable stores of glycogen that can often be seen on electron microscopy (see Fig. 112-2). Glycogen can be broken down into glucose 1-phosphate, and platelets can also take up glucose from their surrounding medium. Platelet glycolysis rates significantly exceed those of erythrocytes and skeletal muscle.¹⁸² Oxidative metabolism probably contributes to energy production in resting platelets, but it has been estimated that less than 1 percent of the pyruvate produced by glycolysis actually enters the citric acid cycle. The remainder is either converted to lactate or remains as pyruvate; both leave the platelet.¹⁸³ Platelet mitochondria are capable of oxidation of fatty acids, but its importance to energy production is unclear.¹⁸⁴⁻¹⁸⁷ Platelets can actively metabolize acetate, which has been exploited to improve platelet storage conditions.^{185,188} Amino acids may also serve as energy sources and feed into the citric acid cycle, but their contributions are uncertain.

As in all cells, ATP consumption by platelets is partially devoted to maintaining ionic and osmotic homeostasis.^{189,190} In addition, the

continuous polymerization and depolymerization of actin involves conversion of ATP to ADP, and this may account for as much as 40 percent of the ATP consumption in resting platelets.¹⁹¹ The continuous polymerization and depolymerization of tubulin that occurs in the coil of resting platelet involves conversion of guanosine triphosphate (GTP) to guanosine diphosphate (GDP), and thus consumes energy.¹⁵⁹ Continuing dephosphorylation and rephosphorylation of phosphatidylinositols, which are important in signal transduction, has been estimated to consume as much as 7 percent of the total ATP produced.¹⁹² Protein phosphorylation also occurs as an ongoing process, but its fractional use of ATP is not clear in resting cells. Platelet stimulation leads to a marked increase in both glycolytic activity and oxidative ATP production, perhaps as a result of the abrupt decrease in ATP that occurs with platelet activation or the increase in cytoplasmic pH.¹⁸⁷ The increased ATP appears to be used, at least in part, for phosphatidylinositide and protein phosphorylation.

Platelet stimulation is accompanied by a marked increase in both glycolytic activity and oxidative ATP production, perhaps through a feedback mechanism in response to the abrupt decrease in ATP that occurs with platelet activation or as a result of the increase in cytoplasmic pH.¹⁹³ The increased ATP appears to be utilized, at least in part, in phosphoinositide phosphorylation and protein phosphorylation.

Organelles

Peroxisomes In platelets, some of the main metabolic functions of peroxisomes include fatty acid β -oxidation, plasmalogen (a phospholipid) synthesis, and synthesis of platelet-activating factor (PAF).¹⁹⁴ They contain acyl-CoA:dihydroxyacetone phosphate acyltransferase, which catalyzes the first step in the synthesis of ether-containing phospholipids. Deficiencies of this enzymatic activity have been identified in the cerebrorenal Zellweger syndrome, and the platelet activity can be used to diagnose the disorder.^{195,196}

Mitochondria Platelets contain approximately four to seven mitochondria of relatively small size, often located near the plasma membrane; they are involved in oxidative energy metabolism.^{197–199} Control of mitochondrial Bcl-2 family proteins, including Bcl-x1 and Bak, directly affects a platelet's life span and alterations in these proteins can produce thrombocytopenia (Chaps. 111 and 117).²⁰⁰ Release of mitochondria upon platelet activation, either in microparticles or free in the circulation, may contribute to inflammation and nonhemolytic transfusion reactions.¹⁹⁹ Abnormalities of mitochondrial enzymes, including the reduced form of nicotinamide adenine dinucleotide (NADH) coenzyme Q reductase (complex I), have been implicated in the pathophysiology of aging and several neurodegenerative disorders, including Alzheimer disease, schizophrenia, and some forms of Parkinson disease. Assays of platelet mitochondrial enzyme levels have been used in these studies.^{201–206} In addition, hyperglycemia-induced mitochondrial superoxide generation may contribute to the enhanced platelet aggregation observed in diabetes.²⁰⁷ Loss of the mitochondrial inner leaflet potential has been associated with surface expression of platelet procoagulant activity and coated platelet formation (see "Platelet Coagulant Activity" below).^{208–211}

● PLATELET SHAPE CHANGE, SPREADING, CONTRACTION, AND CLOT RETRACTION

OVERVIEW

The cytoskeleton establishes the platelets native structure and its ability to respond to stimuli through changes in shape and force generation; as such, the cytoskeleton can be considered analogous to an animal's

bones and muscles. Table 112–1 lists the major components of the platelet contractile system. These elements are thought to contribute to platelet shape change, secretion, and clot retraction after platelet activation.

When exposed to a variety of agonists, platelets undergo dramatic changes in shape within seconds. Shape change follows a reproducible sequence of events during which the resting platelet cytoskeleton is dismantled and reorganized. The first noticeable change following activation is the dismantling of the microtubule coil and conversion from discs to spheres. Filopodia and lamellipodia, generated by new actin filament assembly, then extend from the plasma membrane. At the same time, intracellular organelles and granules, and the dismantled microtubule coil, are compressed into the center of the platelet. Once shape change is finished, the actin cytoskeleton is used as a platform for contraction, and contractile tension is exerted between platelets and between platelets and the adjacent fibrin strands.

PLATELET SHAPE CHANGE

Platelet shape change occurs in response to many different agonists. It involves loss of the platelet's normal discoid shape (approximately 1.5 to 2.5 μm diameter and approximately 0.5 to 0.9 μm width) and transformation to a spiny sphere with long, thin filopodia extending several micrometers out from the platelet and ending in points that are as small as 0.1 μm in diameter (see Fig. 112–2).^{95,212} In the aggregometer, it has been generally assumed that the initial decrease in light transmission immediately after adding certain agonists is a reflection of platelets undergoing shape change,²¹³ but this interpretation has been challenged by the suggestion that microaggregation rather than shape change accounts for this phenomenon.²¹⁴ Although the reason platelets undergo shape change is unclear, one possibility is that it reduces electrostatic repulsion between two negatively charged platelets or between a platelet and a negatively charged surface or cell without the need to reduce surface charge density. Thus, after changing shape, the tip of a platelet filopodium can more easily approach and make contact with a surface or a cell because the great bulk of the repulsive surface charge is now at a distance from the tip.²¹⁵

A change in platelet shape from disk to sphere is the first event that is observed as the platelet is activated. Agonist binding to select receptors activates phospholipase (PL) $C\beta$, which hydrolyzes membrane-bound PI-4,5-bisphosphate to inositol-1,4,5-triphosphate (IP_3) and diacylglycerol. IP_3 then binds to receptors on the DTS/sarcoplasmic reticulum, generating a rise in cytosolic calcium concentrations to 5 to 10 μM . While calcium can influence the activity of many actin-binding proteins, one of the major proteins that is activated is gelsolin, which is present in platelets at a concentration of approximately 5 μM . Actin filaments in resting platelets are relatively stable because their barbed ends (the end from which they can grow by adding additional actin monomers), are capped with the protein CapZ and α,γ -adducins (see Fig. 112–5). Calcium-activated gelsolin both severs existing actin filaments and caps the newly created barbed ends. This increases the number of actin filaments by an estimated 10-fold, and substitutes gelsolin for CapZ and α,γ -adducins as the actin filament capping protein.²¹⁶ Severe severing of actin filaments that interact with the planar lattice composed of filamin A (actin binding protein), GPIb/IX, and spectrin in the membrane cytoskeleton releases the constraints on the spectrin network. This allows the membrane skeleton to swell (but not produce filopodia) (see Fig. 112–5) by incorporating into the plasma membrane the membranes from the open canalicular system, and later the membranes from the granules that release their contents.

The protrusive force for lamellipodia and filopodia formation comes from new actin polymerization, such that there is a doubling of actin filament content. This burst of actin filament assembly is powered

by the generation of barbed-end nucleation sites after receptor activation. These nucleation sites are generated *de novo* by the activation of the Arp2/3 complex or by the exposure of the barbed ends of preexisting filaments.²¹⁷ Because barbed ends have a higher affinity for actin molecules than do the actin sequestering proteins, they have the capacity to initiate actin filament polymerization.

Platelets contain two proteins whose main function is to bind and sequester actin monomers. The first is profilin, which is present at a concentration of 50 μ M. Profilin can sequester actin monomers from the pointed ends of actin filaments, but not the barbed ends. Profilin also functions as a major transfer factor in actin filament polymerization. The second and more abundant protein involved in sequestration of actin monomers and stimulation of the polymerization of actin is thymosin- β_4 . With a platelet concentration of 55 mM, it is equimolar to actin. Thymosin- β_4 binds actin molecules with an affinity that is greater than that of the pointed end of the actin filament, allowing it to compete effectively for molecules from the pointed end. Thymosin- β_4 has a lower affinity for actin monomer than actin has for the barbed end of the filament, resulting in filament assembly when barbed ends are free. Thymosin- β_4 maintains a large pool of unpolymerized actin, and 60 percent of the total actin in the platelet is bound to thymosin- β_4 . The affinity of thymosin- β_4 for actin monomer is regulated by the nucleotide that is bound to actin.²¹⁸

The platelet actin assembly reaction that follows the addition of agonists starts when free barbed ends are formed (see Fig. 112–5). Barbed ends are generated by the uncapping of filament ends and the *de novo* assembly of filaments by the Arp 2/3 complex. Platelets contain high concentrations of barbed-end capping proteins that regulate the accessibility of these ends to regulate actin dynamics. Platelets contain 5 μ M each of gelsolin²¹⁹ and capZ,²²⁰ and 3 mM of adducin.²²¹ Uncapping of the actin filaments appears to be accomplished by the inactivation of capping proteins by phosphoinositides that are produced during platelet activation, including PI-3,4-bisphosphate (PI_{3,4}P₂), PI_{4,5}P₂, and PI_{3,4,5}P₃.²¹⁶ The uncapped actin filaments act as nuclei onto which actin monomers (which are maintained in an available pool by association with thymosin- β_4) can assemble on the barbed ends of the filaments. Profilin accelerates actin polymerization by facilitating the transfer of actin from the actin-thymosin- β_4 complex to the barbed ends of the actin filaments. In addition to exposing new filament ends as a source of nuclei, new nucleation sites are generated by activation by the Arp 2/3 complex. The Arp 2/3 complex mimics the pointed ends of actin filaments and stimulates barbed-end assembly of actin filaments. The Arp 2/3 complex is made up of seven polypeptides, two of which have actin-related sequences, Arp2 and Arp3.^{222,223} Platelets contain high concentrations of the Arp2/3 complex (2 to 10 μ M). Approximately 30 percent of the Arp2/3 complex is bound to the resting platelet cytoskeleton. Once platelets are activated, the Arp2/3 complex redistributes to the cytoskeleton, increasing three-fold and concentrating in the lamellipodial zone of actin filament assembly. Several signaling pathways regulate the activity of the Arp2/3 complex, including Wiskott-Aldrich syndrome protein (WASP) family members. Mutations in the WASP gene result in Wiskott-Aldrich syndrome, an inherited X-linked recessive disorder characterized by thrombocytopenia and T-cell immunodeficiency (see Chap.121).

Simultaneous with these changes, the peripheral microtubule coil becomes constricted and fragmented, and is ultimately compressed into the center of the cell. As the filopodia form, the platelet's granules and organelles move to the center, surrounded by the microtubule coil, resulting in an increase in electron density. Activation of myosin II via phosphorylation of myosin light chain kinase, contributes to the inward contractile force by its interaction with the actin fibers.

PLATELET SPREADING AND SURFACE-INDUCED ACTIVATION

After platelets adhere to surfaces, they undergo variable degrees of spreading and activation. The patterns of spreading and activation depend primarily on the protein surface on which they spread, with collagen consistently inducing the most activation.^{224,225} In addition to the nature of the surface, the protein density, especially in the case of fibrinogen, can dramatically affect the signaling systems that are activated in the adherent platelets.²²⁶ Activation can result in release of granule contents and exposure of activated integrin $\alpha_{IIb}\beta_3$ receptors on the luminal surface of the platelets, where they are strategically located to bind adhesive glycoprotein ligands that can recruit additional platelets.²²⁷ If the surface density of platelets is sufficient, the platelets can also enter into lateral associations, which appear to depend on integrin $\alpha_{IIb}\beta_3$.²²⁸ In general, platelet spreading results in the development of broad lamellipodia rather than spike-like filopodia (see Fig. 112–2).^{216,229} The different morphologies of platelet spreading reflect differences in the organization of the network of actin filaments. Ultrastructural examination of lamellipodia reveals them to be replete with actin filaments that are organized into orthogonal networks. This organization is established by the actin filament crosslinking protein filamin A. In contrast, filopodia contain long actin filaments that are organized as tight bundles. These structural differences reflect the different signals initiated by the adhesion process, and both PIs and the small GTPase molecules Rac and Cdc42 appear to be particularly important in this process.¹⁵⁴ In platelets, Rac is activated by thrombin receptor ligation and it stimulates actin filament uncapping.²³⁰ Proteins that have been implicated in organizing the tips of the filopodia where the actin bundles attach to the plasma membrane are the small GTPase Cdc42, the exchange protein WASP, vinculin, vasodilator-stimulated protein (VASP), zyxin, and profilin.¹¹¹ Pleckstrin, a platelet protein that is phosphorylated during platelet activation, appears to participate in this process by binding to PIs and affecting Rac via an exchange factor.^{231,232} Platelets from mice deficient in pleckstrin have a defect in granule secretion, integrin $\alpha_{IIb}\beta_3$ activation, and aggregation mediated by protein kinase C. Thrombin can overcome this abnormality via a pathway involving PI3K.²³³ Signaling after adhesion results from the assembly of protein complexes on the cytoplasmic surfaces of the receptor(s) involved in the adhesion process, including focal adhesion kinase (FAK), which is activated by integrin ligation and colocalizes with a number of cytoskeletal proteins. Deletion of FAK in megakaryocytes and platelets results in defects in platelet spreading.²³⁴ These complexes then initiate local cytoskeletal rearrangements as well as the generation of signaling molecules that act throughout the platelet to produce a variety of effects, including the translation of new proteins.^{235–238} The nature and extent of the signaling may determine whether the adherent platelets recruit additional platelets or white blood cells. In particular, the conversion of spread platelets to a microvesiculated procoagulant form has been associated with the recruitment of neutrophils.²³⁹ Additionally, spread platelets can assemble fibronectin matrix on their surface, which may be important in stabilizing platelet-platelet interactions.²⁴⁰

Membrane glycoproteins are affected by cytoskeletal rearrangements associated with platelet shape change and spreading. Activation of platelets in suspension under certain conditions results in movement of GPIb/IX receptors from the surface of platelets to the open canalicular system.^{241,242} With adherent platelets, the GPIb internalization is much slower.¹¹¹ The initial effect of activation on integrin $\alpha_{IIb}\beta_3$ is an approximate doubling of these receptors on the plasma membranes, as preassembled receptors in α granules, and perhaps dense bodies and the open canalicular system, join the plasma membrane. Inside-out activation of integrin $\alpha_{IIb}\beta_3$ has been associated with cytoskeletal

changes, in particular, the binding of talin to the integrin β_3 cytoplasmic domain.^{243–246} Tyrosine kinases, including FAK,^{33,247} and Src,²⁴⁷ may play a role in this process, along with cortactin, a protein of Mr 85 kDa that is phosphorylated on tyrosine, and small GTP binding proteins such as Rho, Rac, and Cdc42.^{216,229,248,249} When the attachment of integrin $\alpha_{IIb}\beta_3$ to the cytoskeleton includes actin and myosin, the force produced by the cytoskeleton on the integrin may supply the energy to produce the conformational changes that lead to higher ligand binding affinity.²⁵⁰ After activation, more integrin $\alpha_{IIb}\beta_3$ molecules become associated with the cytoskeleton, and this presumably reflects the interaction with talin and other cytoskeletal proteins and ligand-induced integrin clustering, resulting in the development of protein complexes, including cytoskeletal proteins, on the cytoplasmic surface of the receptor.^{237,245,251} When ligand-coated beads are added to adherent platelets and bind to integrin $\alpha_{IIb}\beta_3$ receptors, the beads are transported to the center of the platelets, indicating that the cytoskeleton can move integrin receptors that have bound ligand.^{252,253}

Platelets contain calpains, which are calcium-dependent, sulfhydryl-containing, neutral proteases composed of two subunits that preferentially cleave cytoskeletal proteins, in particular filamins and talin,^{229,254} but have also been reported to cleave the cytoplasmic domain of integrin β_3 , and a number of molecules involved in signaling, including kinases and phosphatases (see “Calcium-Dependent Proteases [Calpains]” below). μ -Calpain requires micromolar calcium and m-calpain requires millimolar calcium for activation. It has been proposed that calpains are involved in cytoskeletal reorganization upon platelet activation, specifically via cleavage of the integrin β_3 cytoplasmic tail and talin upon ligand engagement.^{245,255–257} Calpain cleavage of the integrin β_3 cytoplasmic tail may switch the function of the integrin from promoting platelet spreading to mediating clot retraction.²⁵⁸ Calpains have also been implicated in platelet spreading, microparticle formation, and the generation of platelet coagulant activity.^{229,256,259} Mice lacking μ -calpain have reduced platelet aggregation and clot retraction, but normal bleeding time.²⁶⁰

PLATELET CONTRACTION AND CLOT RETRACTION

The contractile mechanism involving actin and myosin is thought to facilitate granule secretion, but the details remain obscure.^{261,262} In fact, mice with nearly complete disruption of the platelet heavy-chain myosin gene, *Myh9*, have a defect in secretion, but only in response to low concentrations of select agonists.²⁶³ The cytoskeleton of resting platelets consists of the membrane skeleton described above, which lies just beneath the membrane, and a lacy cytoplasmic actin filament network composed of 2000 to 5000 linear actin polymers, which also contains α -actinin, filamins (actin binding proteins) A and B, tropomyosin, vinculin, and caldesmon.^{176,177,248,249,264–268} The contractile response is also thought to be initiated by an increase in cytosolic calcium, which results in the formation of a calcium-calmodulin complex that then activates myosin light-chain kinase; phosphatases and cyclic adenosine monophosphate (cAMP) kinase can modulate this response. After the initial platelet shape change, actin becomes organized centrally into thick filamentous masses, where it probably associates with phosphorylated myosin filaments.^{269,270} The centralization of organelles within a contractile ring correlates with secretion.⁹⁵ There is controversy, however, as to whether platelets secrete their granular contents by fusion with the open canalicular system in the center of the platelet or by direct fusion with the plasma membrane, or both.^{95,100}

When blood initially clots *in vitro*, the fibrin mesh extends throughout, trapping virtually all of the serum in a gel-like state. If platelets are present, within minutes to hours, the clot retracts,

extruding a very large fraction of the serum.²⁷¹ This process is thought to mimic *in vivo* phenomena that result in consolidation of thrombi and perhaps enhancement of wound healing. Clot retraction has also been implicated in decreasing porosity and solute transport so as to concentrate intrathrombus thrombin,²⁷² as well as decreasing the efficiency of thrombolysis, which may partially account for the resistance of platelet-rich thrombi to fibrinolytic agents.²⁷³ The platelet requirement for clot retraction is indisputable as is a requirement for integrin $\alpha_{IIb}\beta_3$ and a contractile mechanism involving actin and myosin.^{274,275} In fact, nearly complete selective disruption of the myosin *Myh9* gene in murine megakaryocytes gives rise to a phenotype characterized by macrothrombocytopenia; absence of clot retraction; reduced secretion in response to low concentrations of agonists, but not high concentrations; prolonged bleeding time; and protection from thrombus formation.²⁶³ The mice do not, however, spontaneously bleed.²⁶³ Myosin activation involves phosphorylation of the myosin light chain, a process that is governed by calcium-regulated myosin light-chain kinase activity and Rho kinase-regulated myosin phosphatase activity. Calpain-cleavage of the cytoplasmic tail of integrin β_3 may promote RhoA activity and serve a molecular switch to convert platelet spreading to clot retraction.²⁵⁸ Other signaling molecules appear to contribute to clot retraction, including the Eph kinase EphB2,²⁷⁶ protein phosphatase 2B,²⁷⁷ and PI3K.²⁷⁸ Despite these data, no model describing the details of the clot retraction process has gained acceptance.²⁷⁹ Proposed mechanisms include movement of platelet filopodia along fibrin strands, tugging of fibrin strands by filopodia, and internalization of fibrin by the action of the membrane skeleton.^{274,275,279–282}

Platelet integrin $\alpha_{IIb}\beta_3$ is required for clot retraction, as demonstrated by studies of patients with Glanzmann thrombasthenia (Chap. 121) and studies of normal platelets in the presence of agents that block either the integrin $\alpha_{IIb}\beta_3$ receptor^{280,283–288} or the fibrinogen γ -chain C-terminal sequence that mediates interactions with the integrin.²⁸⁹ It also requires disulfide bond exchange²⁹⁰ and the tyrosine residues on the integrin β_3 subunit that are phosphorylated upon platelet activation and contribute to outside-in signaling.²⁹¹ Clot retraction correlates temporally with an integrin $\alpha_{IIb}\beta_3$ -dependent decrease in protein tyrosine phosphorylation, presumably via activation of one or more phosphatases,²⁹² and may require both integrin-mediated mitogen-activated protein kinase (MAPK) activation²⁹³ and translation of proteins such as Bcl-3, with the latter facilitated by ligand binding to integrin $\alpha_{IIb}\beta_3$.²⁹⁴ Results with integrin $\alpha_{IIb}\beta_3$ antagonists demonstrate, however, differences in their ability to inhibit clot retraction that do not correlate with their ability to block fibrinogen binding to platelets,^{280,287} and patients with Glanzmann thrombasthenia differ in the extent of their defect in clot retraction. Some integrin $\alpha_{IIb}\beta_3$ mutations, such as integrin β_3 L262P, interfere with interactions with fibrinogen but do not prevent interactions with fibrin and clot retraction.²⁹⁵ Of particular note, fibrinogen lacking the γ -chain C-terminal sequence (amino acids 400 to 411) that mediates binding to platelet integrin $\alpha_{IIb}\beta_3$, as well as the two Arg-Gly-Asp (RGD)-containing regions in fibrinogen, is still capable of supporting clot retraction.^{296,297} It is well established that when fibrinogen converts to fibrin, new sites become exposed on the surface of the molecule. Therefore, one possible explanation for this paradox is that additional or alternative integrin binding sequences in the fibrinogen γ -chain (e.g., 316 to 322, 370 to 383, or other regions) may be able to mediate clot retraction.^{298,299} Potential binding sites for the γ 370 to 381 sequence, which is better expressed on fibrin than fibrinogen, on the integrin $\alpha_{IIb}\beta_3$ propeller region, were identified and peptides from these regions inhibit clot retraction.³⁰⁰ Factor XIII also plays an important role in clot retraction; it has been proposed to mediate the translocation of the fibrinogen/fibrin-integrin $\alpha_{IIb}\beta_3$ complex to sphingomyelin-rich lipid rafts in the platelet membrane as well as crosslink the complex to

cytoskeletal and contractile elements.^{301,302} It is also possible that GPIb/IX contributes to clot retraction by virtue of the binding of GPIb α to the thrombin and/or VWF bound to the fibrin.^{303,304} Thus, while integrin $\alpha_{IIb}\beta_3$ is required for clot retraction, the process is not a simple reflection of fibrinogen binding to integrin $\alpha_{IIb}\beta_3$.

● PLATELET SECRETORY MACHINERY AND SECRETION

Platelets possess secretory granules and mechanisms for cargo release to amplify responses to stimuli and influence the surrounding environment. Platelet granule structures include α - and dense granules, lysosomes, and peroxisomes.

SECRETORY ORGANELLES

Lysosomes

Lysosomes are produced from the endosomal membrane system through a complex mechanism involving membrane and protein sorting and trafficking.³⁰⁵ Platelet lysosomes contain acid hydrolases typical of these organelles (e.g., β -glucuronidase, cathepsins, aryl sulfatase, β -hexosaminidase, β -galactosidase, endoglucosidase [heparitinase], β -glycerophosphatase, elastase, and collagenase).¹⁹⁷ With activation, platelets secrete some of these enzymes; however, lysosomal contents are more slowly and less completely released than are those from α granules and dense bodies.³⁰⁶⁻³⁰⁸ Thus, stronger agonists are required to induce lysosomal enzyme release than release from the other granules, and their appearance on the platelet plasma membrane serves as a marker of high-level platelet activation.^{309,310} The elastase and collagenase activities released from platelet lysosomes may contribute to vascular damage at sites of platelet thrombus formation.³¹¹ The heparitinase may be able to cleave heparin-like molecules from the surface of endothelial cells, and the resulting soluble molecules appear to inhibit growth of smooth muscle cells.³¹²

Dense Bodies

Platelets contain approximately three to eight electron-dense organelles, 20 to 30 nm in diameter (see Fig. 112-2).^{76,262} The intrinsic electron density of dense bodies when viewed as unstained whole mounts derives from their high content of calcium^{76,197}; the granules are also dense when viewed by transmission electron microscopy because they are highly osmophilic.²⁶² Dense granules contain high concentrations of serotonin, which is taken up from plasma by a plasma membrane carrier and then trapped in the dense bodies.²⁶² Trapping of serotonin may occur as a result of the lower pH (approximately 6.1) maintained in dense granules as a result of the action of a proton pumping ATPase on the dense-body membrane.²⁶² ADP and ATP are also highly concentrated in dense bodies.¹⁹⁷ There is more ADP than ATP in the dense bodies (ATP to ADP ratio = 2:3), which is the reverse of their relative concentrations in the cytoplasm (ATP to ADP ratio = 8:1). As there is little connection between the pools of adenine nucleotides in the cytoplasm and the dense bodies, they have been respectively designated as the *metabolic* and *storage pools* of adenine nucleotides.¹⁹⁷ Storage of adenine nucleotides at such a high concentration in dense bodies appears to be achieved by stacking the ATP and ADP purine rings vertically in aggregates that are stabilized by the interactions of calcium ions with the polyphosphate groups.^{313,314} The planar hydroxyindole rings of serotonin may also enter these stacks, providing a molecular basis for the trapping mechanism. Trapping of serotonin must differ from that of adenine nucleotides, however, because dense granule serotonin exchanges readily with external serotonin.¹⁹⁷ Transport and delivery of platelet-derived serotonin may play an important role in a variety of

biologic phenomena including vasospasm, platelet coagulant activity, and liver regeneration.³¹⁵

The membrane of dense granules contains glycoproteins that are also found on the plasma membrane and the membranes of α granules and lysosomes, including CD36, LAMP-2, CD63, P-selectin, $\alpha_{IIb}\beta_3$, and GPIb/IX. Abnormalities of eight different genes have been implicated in the Hermansky Pudlak syndrome (HPS) (Chap. 121), an autosomal disorder characterized by a deficiency of dense bodies, and so these genes are presumed to participate in dense body formation. As with lysosomes, dense bodies are thought to derive from endosomes, via different types of multivesicular bodies (MVBs). The eight genes associated with HPS are thought to affect sorting and/or trafficking of membrane structures through participation in protein complexes that mediate these phenomena.^{316,317} These complexes include three biogenesis of lysosome-related organelles complexes (BLOCs) and the activator protein 3 (AP3) complex.³⁰⁵ Similarly, the product of the *LYST* gene, which is abnormal in some patients with Chediak-Higashi syndrome (who also have abnormal dense bodies), has been proposed to associate with the dense granule membrane (Chap. 121).³¹⁸ The *LYST* gene product may associate with the AP3 complex.³⁰⁵

The abnormalities of *in vitro* platelet function in patients with HPS suggest that released dense granule contents contribute to platelet activation through a positive feedback mechanism. Release of ADP, which is a potent platelet activator, and serotonin, a weaker agonist (see section "Signaling Pathways in Platelets" below), probably account for most of the positive feedback effects on platelet aggregation. ATP is a partial antagonist of ADP-induced activation, but as ATP is rapidly catabolized to ADP in plasma ($T_{1/2} = 1.5$ min), and ADP is rapidly catabolized to AMP ($T_{1/2} = 4$ min) and then to adenosine,¹⁹⁷ a platelet inhibitor,³¹⁹ it is difficult to predict the overall effect of ATP release. Adding to the complexity *in vivo* is the presence of an ecto-ADPase (CD39; ecto-ADPase) present on endothelial and lymphoid cells, which can metabolize ATP and ADP to AMP and thus probably limits the amount of ADP present.⁷⁴ ATP released from platelets may also serve as a high energy phosphate source for platelet ecto-protein kinases, which can phosphorylate several proteins, including CD36 (GPIV).³²⁰⁻³²²

α Granules

An important platelet function is storage and release of a variety of bioactive substances packaged in α granules. α Granules are the most abundant granule type of platelets, numbering approximately 50 to 80 per platelet.^{323,324} They are approximately 200 nm in diameter on cross-section and demonstrate internal variation in electron density, often with an eccentric area of accentuated electron density, termed a *nucleoid*, in which β -thromboglobulin, platelet factor 4 (PF4), and proteoglycans are concentrated (see Fig. 112-2).³²⁵ The more electron-lucent areas contain tubular elements in which VWF, multimerin, and factor V are preferentially localized.⁷⁶ Proteomic analysis of the releasate of activated human platelets has identified more than 300 proteins, most of which are stored within α granules.³²⁶⁻³²⁸ The list of α -granule proteins includes adhesive proteins, coagulation factors, protease inhibitors, chemokines, and angiogenesis regulatory proteins. Some of the most important proteins present in α granules are described in detail below. Platelets contain distinct subpopulations of α granules that undergo differential release of α -granule cargo during activation. For example, some α granules contain proangiogenic proteins, such as vascular endothelial growth factor (VEGF), whereas others contain antiangiogenic factors, such as endostatin (Fig. 112-6).³²⁹ These two subclasses of α granules can be differentially induced to undergo degranulation by exposure of human platelets to agonists specific for either protease-activated receptor (PAR)-1 or PAR-4. Fibrinogen and VWF are localized

Figure 112-6. Platelets contain separate and distinct α -granule populations. **A, B,** and **C.** Specific pro- and antiangiogenic regulators organize into separate, distinct α granules in resting platelets. Double immunofluorescence microscopy of resting platelets using antibodies against vascular endothelial growth factor (VEGF) (**A**) and endostatin (**B**) and an overlay (**C**). **D.** Localization of proteins in resting, human platelets using immunoelectron microscopy of ultrathin cryosections. Double immunogold labeling on platelet sections was performed with the use of anti-VEGF antibody and antiendostatin antibodies. Large gold particles representing anti-VEGF staining (15 nm, *arrows*) are evident on one population of α granules and small gold particles (5 nm) representing endostatin staining are abundantly present on a different population of α granules (*arrowheads*). **E, F,** and **G.** Pro- and antiangiogenic regulatory proteins are also segregated into separate, distinct α granules in megakaryocyte proplatelets. Megakaryocytes generate platelets by remodeling their cytoplasm into long proplatelet extensions, which serve as assembly lines for platelet production. Distinct α granules are visualized along proplatelets. Shown is a double immunofluorescence microscopy experiment of proplatelets using antibodies against VEGF (**E**) and endostatin (**F**), and an overlay (**G**). (Reproduced with permission from Italiano, J.E., Jr., et al., *Angiogenesis is regulated by a novel mechanism: pro- and antiangiogenic proteins are organized into separate platelet α granules and differentially released*, *Blood* 1;111(3):1227–1233, 2008.)

in separate α granules,³³⁰ and glass activation of platelets results in the selective release of the fibrinogen-containing granules.

The α granule acquires its protein content by both biosynthesis (predominantly at the megakaryocyte level) and endocytosis (at both the megakaryocyte and circulating platelet levels). Small amounts of virtually all plasma proteins are nonspecifically taken up into α granules, and thus the plasma levels of these proteins determines their platelet levels.^{331,332} For example, the α -granule pool of immunoglobulins contains most of the platelet immunoglobulin; therefore, total platelet immunoglobulin is more affected by changes in plasma immunoglobulin levels than by changes in surface immunoglobulin.^{331,332}

The cell biologic pathways that regulate α -granule assembly are not fully understood, but several studies suggest MVBs play a crucial intermediary role in α -granule biogenesis.^{316,333} These membranous sacs, containing numerous small vesicles, develop from budding vesicles in the Golgi complex within megakaryocytes and can interact with endocytic vesicles. They are abundant in immature megakaryocytes and decrease in number with cellular maturation, suggesting that they are the precursors of α granules and/or dense bodies. MVBs may also function as a sorting hub to rout proteins into distinct classes of α granules.

The platelet-specific proteins (PF4 and the β -thromboglobulin family) are present in α granules at concentrations that are approximately 20,000 times higher than their plasma concentrations (when each is expressed as a fraction of total protein in platelets or plasma, respectively).^{334,335} These Mr 7000 to 11,000 proteins all bind to heparin, but with varying affinities. They also share amino acid sequence homology with each other and with other members of the “intercrine-cytokine” family of molecules, such as interleukin (IL)-8 (neutrophil-activating peptide 1 [NAP1]), which are active in inflammation, cell growth, and malignant transformation.^{336–338}

PF4 is a CXC chemokine (CXCL4) that does not contain the Glu-Leu-Arg (ELR) conserved sequence.^{339,340} It binds to heparin with high affinity and can neutralize heparin’s anticoagulant activity.^{335,341–343}

PF4 tetramers complex with a proteoglycan carrier.^{344,345} Specific PF4 lysine residues (amino acids 61, 62, 65, and 66) are implicated in its binding to heparin, and X-ray crystallography indicates that these lysines are on the surface of the PF4 tetramer and interact with negatively charged heparin molecules that wind around this core.^{346–348}

After PF4 is released from platelets, it binds to heparin-like molecules on the surface of endothelial cells.³⁴⁶ Heparin administration can mobilize this endothelial-bound pool of PF4 into the circulation.³⁴⁶ PF4-heparin complexes and PF4-heparin-like molecule complexes on endothelial cells have been implicated as the target antigens in heparin-induced thrombocytopenia with thrombosis.^{349,350} PF4 also binds to hepatocytes, which take it up and catabolize it.³⁵¹ PF4 is a weak neutrophil and fibroblast attractant.^{340,352} It inhibits angiogenesis, perhaps through inhibition of endothelial cell proliferation.³⁵³ A large number of other activities have been ascribed to PF4, including histamine release from basophils³⁵⁴; inhibition of both tumor growth³⁵⁵ and megakaryocyte maturation^{355–357}; reversal of immunosuppression^{352,358}; enhancement of fibroblast attachment to substrata³⁵⁹; potentiation of platelet aggregation³⁶⁰; inhibition of contact activation³⁶¹; and enhancement of both polymorphonuclear leukocyte responsiveness to the activating peptide f-Met-Leu-Phe and monocyte responsiveness to lipopolysaccharide.^{362,363}

The β -thromboglobulin family of proteins are CXC chemokines that contain the conserved Glu-Leu-Arg (ELR) sequence.³⁴⁰ They include platelet basic protein, low-affinity PF4 (connective tissue-activating peptide III [CTAP-III]), β -thromboglobulin, and β -thromboglobulin-F (NAP2, CXCL7).^{334,364–366} All of these proteins share the same carboxy terminus but differ in the length of their amino termini, presumably as a result of proteolytic digestion of the parent molecule, platelet basic protein. These proteins bind to heparin but with lower affinity than PF4, and thus neutralize heparin less well. Unlike PF4, they are cleared from the circulation by the kidney rather than the liver.³⁶⁷ CTAP-III is a weak fibroblast mitogen, and β -thromboglobulin is a chemoattractant

for fibroblasts.³⁴⁰ β -thromboglobulin-F NAP2 (CXCL7) binds to CXCR2 and is chemotactic for granulocytes and activates them to undergo endocytosis.^{339,340,366} Platelet α granules also contain additional chemokines that can variably activate leukocytes and platelets.³³⁹

The biochemistry of the adhesive glycoproteins contained in α granules and others variably present in plasma and extracellular matrix is described in Table 112-2 and in other chapters (e.g., Chaps. 113 and 125 for fibrinogen and Chap. 126 for VWF). Their relative concentrations in α granules varies significantly. Their localization in platelet α granules allows them to achieve high local concentrations when released from platelets at the site of vascular injury.

Multimerin comprises a family of disulfide-linked homomultimers, ranging in molecular weight from 450,000 to many millions.³⁶⁸ The Mr 450,000 multimer is thought to be a trimer of a single subunit of either Mr 167,000³⁶⁹ or Mr 155,000³⁶⁸ that is synthesized in megakaryocytes and endothelial cells and stored in the electron-lucent region of α granules in platelets and dense-core granules in endothelial cells.³⁷⁰ It colocalizes with VWF in platelets, but not endothelial cells. Although multimerin's multimeric structure is similar to that of VWF, the deduced amino acid sequence of its subunit is not homologous to that of VWF.³⁶⁸ The prepromultimerin subunit contains 1228 amino acids. It undergoes glycosylation and proteolysis during synthesis. It is composed of a number of domains, including an aminoterminal region that includes an RGD sequence, coiled coil sequences, epidermal growth factor (EGF)-like domains, and a carboxyterminal globular head similar to that found in the complement protein C1q. Multimerin binds both factor V and factor Va, and all of the biologically active factor V in platelets is bound to multimerin.³²⁵ With thrombin activation of platelets, factor V separates from multimerin, and the higher molecular weight multimerin multimers bind to platelets. Multimerin does not circulate in plasma at an appreciable concentration, but it may act as an adhesive extracellular matrix protein.

Fibrinogen is concentrated in α granules as judged by the ratio of platelet-to-plasma fibrinogen. Megakaryocytes do not appear to synthesize fibrinogen; instead, it is taken up from plasma by a process that involves the $\alpha_{IIb}\beta_3$ receptor.³⁷¹ Because fibrinogen molecules that contain altered sequences in the γ chain are not stored in α granules, even when the molecules are heterodimeric (i.e., contain one normal and one abnormal γ chain), it is possible that uptake requires simultaneous binding of a single fibrinogen molecule to two different $\alpha_{IIb}\beta_3$ receptors via the γ -chain carboxyterminal sequence (see $\alpha_{IIb}\beta_3$ in the section "Platelet Membrane Glycoproteins" below and Chap. 121).^{371,372}

The VWF stored in platelet α granules appears to contribute to hemostasis because in certain pathologic states it correlates better with bleeding symptoms than does plasma VWF concentration (Chap. 126). VWF is synthesized in megakaryocytes and endothelial cells. The multimeric structure of platelet VWF is thought to reflect endothelial VWF more nearly than plasma VWF, as higher Mr multimers are present.

Fibronectin is present in α granules, but no clear role in platelet function under normal conditions has been identified for this adhesive protein. Paradoxically, in murine models fibronectin has been reported to both support platelet thrombus formation and inhibit platelet aggregation and thrombus formation^{413,373}; the former effect may be mediated by insoluble fibronectin fibrils whereas the latter may be mediated by soluble fibronectin.³⁷⁴

Vitronectin, which gets its name from its propensity to bind to glass, also binds to PAI-1, the urokinase receptor (uPAR), collagen, and heparin; it also forms ternary complexes with serine proteases and serpins in the coagulation and complement systems. It is present in platelets at levels that suggest it is concentrated,³⁷⁵ but it does not appear to be synthesized in megakaryocytes. The binding of PAI-1 with vitronectin stabilizes PAI-1 in its active conformation, and it has been proposed that

only the approximately 5 percent of PAI-1 complexed with vitronectin in platelet α granules is active.¹⁵⁰ Mice deficient in vitronectin have been reported to be protected from, or have a predisposition to develop, thrombosis, depending on the method of inducing thrombosis.³⁷⁶⁻³⁷⁸

Thrombospondin-1 is unique among the adhesive glycoproteins in blood in that it is present almost exclusively inside the platelet.³⁷⁹⁻³⁸¹ It constitutes approximately 20 percent of the released platelet proteins. Thrombospondin-1 is synthesized by megakaryocytes, cultured endothelial cells, and other cultured cells.^{382,383} Although integrin $\alpha_{III}\beta_3$, GPIb/IX, integrin $\alpha_v\beta_3$, proteoglycans, integrin-associated protein (CD47 or IAP), and CD36 (GPIV) have all been implicated as receptors for thrombospondin,³⁸⁴⁻³⁹⁰ CD47 appears to be most important in initiating platelet activation by thrombospondin (see "Signaling Pathways in Platelet Activation and Aggregation" below).^{386,387,391} The phosphorylation state of CD36 (GPIV) may affect its ability to bind thrombospondin.³⁸⁵ Thrombospondin contains an RGD (RGD) sequence, which may contribute to its binding to platelets, but other regions are probably also involved.^{381,392} The conformation of thrombospondin varies with the calcium concentration of the surrounding environment. Thrombospondin can interact with many other adhesive glycoproteins, including fibronectin and fibrinogen,^{210,393,394} and it is a component of the extracellular matrix.³⁹⁵ Thrombospondin appears to stabilize platelet aggregates that are formed³⁹⁶; it may also act as a negative regulator of angiogenesis, modulate fibrinolysis, and contribute to activation of latent transforming growth factor (TGF)- β_1 released from platelets (see below in this section).^{397,398}

Platelets contribute approximately 20 percent of the factor V present in whole blood, with nearly all of it in α granules.³⁹⁹⁻⁴⁰¹ Human platelet factor V appears to be taken up from plasma rather than being synthesized in megakaryocytes, which is in stark contrast to the situation in mice. When stored in α granules, factor V associates with multimerin.^{402,403} Platelet-derived factor V appears to undergo unique posttranslational modifications and proteolytic activation, resulting in resistance to protein C-catalyzed inactivation.⁴⁰⁴⁻⁴⁰⁶ Evidence from patients with inhibitors and deficiencies of plasma and platelet factor V indicate that platelet-derived factor V has an important role in hemostasis.^{399,407,408} Platelets undergo microvesiculation when activated, and the microvesicles, which are rich in factor V, are potent promoters of coagulation.⁴⁰⁹

Protein S (Chap. 114), plasminogen activator-1 (Chap. 135), and α_2 -plasmin inhibitor (Chap. 135) are also contained in α granules and can be released from platelets. Similarly, tissue factor pathway inhibitor (TFPI; Chap. 114), α_1 -protease inhibitor, and C-1 inhibitor (Chap. 114) have also been identified in α granules.

Gas6 is a 75-kDa vitamin K-dependent protein that contains γ -carboxyglutamic acids and is similar in structure to protein S.^{410,411} Gas6 was originally isolated as a growth arrest-specific gene from quiescent fibroblasts, but subsequently was found to enhance platelet aggregation and secretion in response to several agonists.⁴¹² Mice deficient in Gas6 have abnormalities in platelet aggregation and are protected from experimental thrombosis.⁴¹² Gas6 is present in α granules and secreted with platelet activation. Platelets also express Mer, a tyrosine kinase receptor for Gas6, and mice deficient in Mer demonstrate both abnormalities in platelet aggregation and protection from thrombosis, but not to the same extent as mice deficient in Gas6.^{413,414} Other Gas6 receptors in the same family as Mer also appear to contribute to platelet thrombus stability.⁴¹³⁻⁴¹⁷

Platelet-derived growth factor (PDGF) is a disulfide-linked dimeric molecule of approximately Mr 30,000 that is mitogenic for smooth muscle cells.⁴¹⁸ Platelet α granules contain a mixture of the homodimer PDGF-BB (30 percent) and the heterodimer PDGF-AB (70 percent); the different forms appear to have different functional activities.⁴¹⁹ PDGF may play a role in normal cell proliferation, as well

TABLE 112-2. Adhesive Glycoproteins

Protein	Subunit, κ Da	Unusual 1° Structural Features & Modifications	Domain Homologies & Binding Regions	Mature Protein Composition	Mature Protein M_r	Known Interactions
Collagens	95–180	Gly-Pro-X repeating sequence Hydroxylysine Hydroxyproline	RGD Right-handed triple helix	Tropocollagen = 3 chains		Variable Thrombospondin
Type I	$\alpha_1(I)$ $\alpha_2(I)$		DGEA [†] VWFC	$[\alpha_1(I)]_2\alpha_2(I)$ (major component)		Fibronectin von Willebrand factor

*Assumes 10¹¹ platelets per mL of packed platelets.

†DGEEA, VTCG, and YIGSR are other amino acid sequences involved in function.

as in the development of atherosclerosis, tumor growth, wound repair, and fibroproliferative responses.⁴²⁰⁻⁴²² After it was discovered in platelets and termed PDGF, other tissues were found to produce the same factor; thus, despite its name, PDGF is not exclusively derived from platelets. PDGF is structurally related to the transforming protein p28^{sis} of simian sarcoma virus,^{423,424} and its receptor is in the tyrosine kinase family.⁴²⁵ Recombinant human PDGF-BB (becaplermin) is approved as adjunctive therapy to improve healing of foot ulcerations in diabetics.⁴²⁶

Platelets contain high concentrations of VEGF, an important stimulator of angiogenesis, and can release VEGF after stimulation *in vitro* and during the hemostatic response to a bleeding time wound.⁴²⁷⁻⁴²⁹ Megakaryocytes express mRNA of the three VEGF isoforms (121, 165, and 189 amino acids),⁴³⁰ and by immunoblot VEGF protein bands of apparent molecular weights 34,000 and 44,000 are identifiable in platelets.⁴³¹ Platelets and megakaryocytes also express the gene transcript for the VEGF receptor termed KDR.⁴³² Another endothelial growth factor structurally related to VEGF, VEGF-C, has also been identified in platelets.⁴³³ Platelet levels of VEGF have been reported to be increased in malignancies, and so elevated levels of platelet VEGF may be a cancer biomarker.^{434,435} Platelet VEGF has also been postulated to play in role in tumor growth⁴³⁶ and proliferative retinopathy in sickle cell disease.^{437,438}

EGF has also been identified in platelets, but the kinetics of its release upon thrombin or collagen stimulation differs from that of other granule proteins.⁴³⁹

Platelets contain the highest levels of all peripheral tissues of amyloid precursor protein (APP), which contains the sequence for the self-aggregating 40- to 43-amino-acid-residue peptide, A β , that has been strongly implicated in the pathogenesis of Alzheimer disease.^{440,441} The isoforms containing the Kunitz protease inhibitor domain (APP 770 and APP 751) predominate in platelets. Although synthesized as a membrane protein, platelet APP is cleaved by α -, β -, and γ -secretase activities, producing all of the fragments produced by neurons, as well as the soluble sAPP α , sAPP β , and A β peptides, and the corresponding remaining C-terminal membrane-associated fragments.^{440,442,443} Calpain, which is present in platelets, can also cleave platelet APP.⁴⁴⁴ Approximately 90 percent of platelet APP is soluble and stored in α granules, but full-length APP surface expression is increased threefold by thrombin stimulation.⁴⁴⁵ Platelets are the major source of plasma sAPPs and A β .^{443,446} APPs released by platelets are potent inhibitors of factor XIa⁴⁴⁷ and IXa,^{448,449} and also can inhibit platelet aggregation induced by ADP or epinephrine. In contrast, A β appears to enhance ADP-induced platelet aggregation and support platelet adhesion. It is possible, but not certain, that plasma A β contributes to brain A β in Alzheimer disease.⁴⁴¹ Patients with Alzheimer disease have been reported to display altered platelet APP metabolism.⁴⁵⁰⁻⁴⁵⁵

Factor XIII is present in the cytoplasm of platelets; it differs from plasma factor XIII in having only the "a" subunits (Chap. 113).⁴⁵⁶⁻⁴⁵⁹ Platelet factor XIII accounts for approximately 50 percent of total blood factor XIII,^{456,457} and platelet factor XIII may contribute to the plasma pool.⁴⁶⁰ Upon platelet activation, factor XIII redistributes to the platelet periphery where it associates with the cytoskeleton and crosslinks filamin and vinculin.⁴⁶¹ It may also crosslink thymosin β_4 to fibrin after thrombin stimulation⁴⁶² and, in concert with calpain, decrease integrin $\alpha_{IIb}\beta_3$ adhesive function in thrombus formation on collagen.⁴⁶³ Transglutaminase-mediated conjugation of serotonin to α -granule proteins after platelet stimulation with collagen and thrombin results in the generation of a subpopulation of platelets that are coated with fibrinogen, thrombospondin, factor V, VWF, and fibronectin, either directly through ligand-receptor interactions or through interactions between the serotonin conjugates and platelet surface fibrinogen or thrombospondin (COAT platelets).^{464,465}

Platelet α granules contain a high concentration of TGF- β_1 , an Mr 25,000 homodimeric protein that promotes the growth of certain cells and inhibits the growth of others.⁴⁶⁶⁻⁴⁶⁹ For example, TGF- β can increase thrombopoietin production by marrow stromal cells. In turn, thrombopoietin induces both increased megakaryocyte production and megakaryocyte expression of TGF- β receptors. The interaction of TGF- β with these receptors then results in inhibition of megakaryocyte maturation.⁴⁷⁰ TGF- β_1 also induces synthesis of extracellular matrix proteins, PAI-1, and metalloproteinases. It has been implicated in wound healing, malignancy, and tissue fibrosis.⁴⁷¹ In addition, TGF- β_1 has been reported to enhance platelet aggregation through a nontranscriptional effect.⁴⁷² Migration of endothelial cells is inhibited by TGF- β_1 , but it acts as a chemoattractant for monocytes and fibroblasts. TGF- β exists in three isoforms (TGF- β_1 , TGF- β_2 , and TGF- β_3), but platelets contain only TGF- β_1 . TGF- β_1 released from platelets can stimulate smooth muscle cells to express and release VEGF, thus perhaps supporting reendothelialization after vascular injury.⁴⁷³

TGF- β_1 released from platelets is inactive (latent) because it is complexed with the remaining portion of its precursor protein (latency-associated peptide [LAP]).⁴⁷⁴ LAP, in turn, is covalently coupled to another protein, the latent TGF- β -binding protein-1 (LTBP-1), which localizes the complex to the extracellular matrix.⁴⁷⁵ Activation of latent TGF- β_1 is a complex process that is thought to involve a conformational change in LAP that results in altering its ability to shield the active site in TGF- β_1 .⁴⁷⁵ Activation of latent TGF- β_1 can be achieved by several different mechanisms, including acidification; proteolysis by plasmin, a furin-like enzyme, or other enzymes; traction produced by LTBP-1 binding to extracellular matrix and LAP interaction with integrin $\alpha_v\beta_6$ or $\alpha_v\beta_8$; interaction with thrombospondin-1 or a small peptide derived from thrombospondin-1; or exposure to stirring or shear.⁴⁷⁵⁻⁴⁷⁹ The interaction of LAP with integrin receptors via its RGD sequence probably plays a dominant role as mice with a mutation in this sequence have a phenotype like that of TGF- β_1 null mice.⁴⁸⁰ The ability of thrombospondin-1 to activate TGF- β_1 is of special interest because both TGF- β_1 and thrombospondin-1 are present in α granules. However, data from mice suggest a minor role for platelet thrombospondin in either TGF- β_1 packaging or activation.⁴⁸¹⁻⁴⁸³ Only a very small percentage of the TGF- β_1 released from platelets with thrombin stimulation becomes activated, but this amount is sufficient to activate synthesis of PAI-1.^{479,481,482,484} Based on animal models, TGF- β_1 released from platelets has been implicated in promoting tumor metastases and cardiac fibrosis in response to constriction of the aorta or aortic valve stenosis.⁴⁸⁵⁻⁴⁸⁷ Active TGF- β can bind to three different cell surface proteins, a proteoglycan (β -glycan), and two serine/threonine kinases.^{471,485-488}

Platelets may also release proteins that affect the uptake of oxidized low-density lipoproteins by macrophages, furnishing another potential link between platelet activation and atherosclerosis.⁴⁸⁹

Exosomes

In addition to the contents of α granules, activated platelets release both microparticles (see "Platelet Coagulant Activity" below), which are derived from the plasma membrane, and exosomes, which are internal membrane MVBs.⁴⁹⁰ Exosomes are smaller than microparticles (40 to 100 nm vs. 100 to 1000 nm), enriched in CD63 and tetraspanins (see section "Platelet Membrane Glycoproteins" below), and relatively deficient in membrane proteins such as GPIb/IX and platelet-endothelial cell adhesion molecule (PECAM)-1. Unlike microparticles, exosomes are not highly procoagulant as judged by their inability to bind prothrombin or factor X, or to present negatively charged phospholipids on their surface. They may, however, contain NAD(P)H oxidase activity, which has the potential to generate reactive oxygen species that contribute to endothelial cell apoptosis in sepsis.⁴⁹¹

PLATELET SECRETION

An intricate pathway of protein–protein interactions has been proposed for platelet secretion in which granules tether and dock to the inner leaflet of the plasma membrane, after which fusion of the two opposing lipid bilayers mediates cargo release.⁴⁹² Docking and tethering are thought to be, in part, mediated by small GTP-binding proteins of the Rab family. Platelets have been reported to contain at least 11 Rabs, although only a few have been shown to be functionally relevant. Rab27a and b are important for both granule biogenesis and secretion,⁴⁹³ while Rab 4 appears to have a role in secretion.⁴⁹⁴ The α -granule–associated Rab6 was shown to be phosphorylated upon thrombin stimulation in a protein kinase C (PKC)-dependent manner and phosphorylation seems to increase its GTP-loading.⁴⁹⁵

Platelet granule–plasma membrane fusion is analogous to exocytosis in neurons, where detailed studies have shown the importance of a core set of integral membrane proteins called soluble N-ethylmaleimide-sensitive factor (NSF) attachment protein receptors (SNAREs).⁴⁹⁶ It is generally accepted that vesicle/granule–target membrane fusion is governed by the binding of a SNARE from the cargo-containing granule or vesicle (v-SNARE), with a heteromeric protein complex in the target membrane (t-SNAREs). The resulting, *trans*-bilayer complex is minimally sufficient for membrane fusion.⁴⁹⁷ In human platelets, the v-SNAREs are vesicle-associated membrane protein (VAMP)-2/synaptobrevin, VAMP-3/cellubrevin, VAMP-7/TI-VAMP, and VAMP-8/endobrevin, with the latter being most abundant.^{498–502} There are two classes of t-SNAREs: the synaptosome-associated protein (SNAP)-23/25/29 type and the syntaxin type. Human platelets contain syntaxins 2, 4, 7, and 11^{498–502} as well as SNAP-23, -25, and -29.^{503,504} Functional studies using *in vitro* assays and genetically engineered mice, have established that VAMP-8 is the primary v-SNARE required for secretion from all three classes of platelet granules.^{501,502} VAMP-2 or VAMP-3 can also play a role at higher levels of stimulation. As for t-SNAREs, SNAP-23 and syntaxin 2 are required for each secretion event. Syntaxin 4 appears to also play a role, but only in α granule and lysosome release.^{505–508}

Although the SNARE proteins are sufficient to mediate membrane fusion, they do so inefficiently and thus require accessory proteins to control where and when they interact. Many of these regulators may be sensitive to second messengers such as diacylglycerol (DAG) and Ca^{2+} , while others are substrates for kinases, such as PKC. The Munc18 family (a, b, and c) control syntaxins and are critical for platelet secretion.^{509–511} Studies show that Munc18a and c are phosphorylated by PKC upon platelet activation and that this affects Munc18/syntaxin binding affinity.^{510,511} At least two members of the Munc13 family are present in platelets (Munc13–1 and Munc13–4) (Schraw TD, Ren Q, and Whiteheart SW, unpublished data).⁵¹² Munc13–4 appears to be important for dense granule release and functions through its interactions with Rab27.^{513,514} Munc13s have Ca^{2+} and DAG binding sites and thus may be regulated by the secondary messengers generated during platelet activation.

Munc13–4 has drawn particular attention based on its involvement in familial hemophagocytic lymphohistiocytosis (FHL) and Griscelli syndrome. Munc13–4 is mutated in type 3 FHL⁵¹⁵ and interacts with the protein mutated in type 2 Griscelli syndrome, namely Rab27a.⁵¹⁶ One feature common to both diseases is the inability of T-cells to properly organize the cytotoxic synapse required for toxin secretion and target cell killing.⁵¹⁵ For FHL patients, it is not clear whether they have bleeding-time defects as they generally receive marrow transplants very early in life.

PLATELET EXOCYTOSIS

Platelet granule–plasma membrane fusion is mechanistically analogous to exocytosis in neurons and other secretory cell types, where detailed

studies have demonstrated the importance of a core set of integral membrane proteins called SNAREs.^{517,518} It is generally accepted that vesicle/granule–target membrane fusion, and thus granule content release, require the binding of a SNARE from the cargo-containing granule or v-SNARE, with a heteromeric protein complex in the t-SNAREs. The resulting, *trans*-bilayer complex is minimally sufficient for membrane fusion.⁵¹⁹ In human platelets, the detectable v-SNAREs are VAMP-2/synaptobrevin, VAMP-3/cellubrevin, VAMP-4, VAMP-5, VAMP-7/TI-VAMP, and VAMP-8/endobrevin, with VAMP-8 being most abundant.^{501,502,520–523} There are two classes of t-SNAREs: the SNAP-23/25/29 type and the syntaxin type. Human platelets contain syntaxins 2, 4, 6, 7, 8, 11, 12, 16, 17, and 18.^{501,502,520–524} SNAP-23, -25, and -29 are all detectable, but SNAP-23 is the most abundant.^{521,525,526} Functional studies, using *in vitro* assays and genetically altered mice, established that VAMP-8 is the primary v-SNARE required for secretion from all three classes of platelet granules; however, platelets lacking VAMP-8 do release their contents at attenuated rates, suggesting roles for other VAMPs.⁵⁰² Differential usage of the VAMPs may allow platelets to fine tune their release of cargo. For t-SNAREs, patients with FHL4, who are deficient in syntaxin 11, show robust platelet secretion defects from all three granule types.⁵²⁷ Studies of mouse platelets suggest a minor role for syntaxin 8⁵²⁴ but loss of syntaxin 2 and/or syntaxin 4 had no effect.⁵²⁷ Syntaxins form a heterodimeric complex with SNAP-23/25–like t-SNAREs. In platelets, SNAP-23 is the critical family member, based on its abundance and results from *in vitro* assays.^{505,506,528} SNAP-23 phosphorylation, by I κ B kinase (IKK), is important for SNARE complex assembly, membrane fusion, and secretion. Platelet-specific loss of IKK or its pharmacological inhibition leads to bleeding.⁵²⁹

Although the SNARE proteins mediate membrane fusion, they do so inefficiently and thus require accessory proteins to control where, when, and how they interact. Many of these regulators are sensitive to second messengers (e.g., calcium). The Sec1/Munc18 (SM) proteins are syntaxin chaperones that control how the t-SNAREs interact with other SNAREs.^{510,530–533} Although several isoforms are present, only Munc18b is important for platelet exocytosis.^{530,532,534} It chaperones syntaxin 11 and is defective in FHL5 patients. Other SM proteins (e.g. Vps33a/b) are important for granule biogenesis.^{535,536} Another syntaxin regulator, tomosyn1/syntaxin binding protein 5 (STXBP5), binds to syntaxin/SNAP-23 heterodimers and affects access to v-SNAREs.⁵³⁷ Genome-wide association studies (GWAS) suggest that alterations in STXBP5 are linked to venous thrombosis risk resulting from increased plasma VWF.^{537–539} Surprisingly, mice lacking STXBP5 have a severe arterial bleeding diathesis as a result of their defective platelet secretion.^{537,539}

Munc13 family members contain binding sites for calcium, phosphatidylserine, DAG, and calmodulin.⁵⁴⁰ Two major family members, Munc13–2 and Munc13–4, are detectable in platelets, although only Munc13–4 is functionally relevant.^{521,541} Munc13s are generally thought to be docking factors that localize granules for membrane fusion. Both FHL3 patients and the Unc13d^{flx} mouse strain lack Munc13–4 and have robust granule-release defects and bleeding diatheses.^{541,542} Munc13–4 binds to a small GTP-binding protein called Rab27, which is also important for platelet exocytosis and is defective in Griscelli syndrome.⁵⁴³ Another Rab27-binding protein, called synaptotagmin-like protein 4/granuphilin, is also reported to be important for platelet exocytosis.⁵⁴⁴

Three types of FHL are caused by defects in genes encoding proteins that are important in platelet secretion: Munc13–4/FHL3, syntaxin 11/FHL4, and Munc18b/FHL5. Rab27a is defective in a related disease, Griscelli syndrome. One feature common to both diseases is the inability of T cells to properly organize the cytotoxic synapse required for toxin secretion and target cell killing. This suggests that these T-cell populations and platelets share common secretory machinery elements. For FHL patients, it is unclear whether bleeding or defective platelet

function can be used as diagnostic criteria, but they have been reported as symptoms.⁵⁴⁵

● PLATELET GENOMICS, THE PLATELET TRANSCRIPTOME, AND PLATELET PROTEOMICS

PLATELET GENOMICS

The *Homo sapiens* genome is comprised of approximately 3.2 billion base pairs and has approximately 3.5 million single nucleotide polymorphisms (SNPs) that occur at frequencies of 1 percent or greater, but continued sequencing of more genomes indicates there are at least an additional 43 million rare or “private” SNPs. dbSNP (www.ncbi.nlm.nih.gov/projects/SNP) maintains information about sequence variation, allele frequencies, differences in frequencies between populations of different ethnicity and their functional consequences. New technologies, such as next-generation sequencing, and new analytic methodologies have driven and continue to drive expansion of genomics at a very rapid pace. Both epidemiologic and experimental approaches have been and are used to assess significance and functionality of platelet gene variants and gene expression, including genetic epidemiology, biochemistry, cell biology, physiology, and animal studies.

GENE VARIANTS ASSOCIATED WITH DISEASE

Candidate Genes

Because platelets play a central role in acute ischemic syndromes, anti-platelet therapy is a mainstay of therapy. Platelets may also contribute to the pathophysiology of the chronic process of atherosclerosis,⁵⁴⁶ although the data are less consistent than with thrombosis. The earliest platelet genetic association studies considered associations between atherothrombotic disease outcomes and candidate platelet gene variants that altered amino acids in platelet membrane adhesion receptors. Numerous studies reported associations between myocardial infarction and stroke with SNPs in integrin β_3 (*ITGB3*), integrin α_2 (*ITGA2*), and GPIIb (*GP1BA*) and GPVI (*GP6*).⁵⁴⁷ In these relatively small studies, positive associations were more likely to be observed in patients with acute thrombosis and less likely in patients with stable atherosclerosis.

However, there were inconsistent and conflicting results in these candidate studies.

Genome-Wide Associations Studies

No unbiased GWAS has been performed using documented arterial thrombosis as the clinical phenotype, but many have been performed with coronary artery disease (CAD). Multiple studies have demonstrated that the Chr9p21.3 locus is associated with both myocardial infarction (MI) and CAD. A meta-analysis of all CAD GWAS studies that included 63,746 patients with acute and chronic CAD and 130,681 controls identified 46 loci meeting genome-wide significance.⁵⁴⁸ These loci explain less than 11 percent of CAD heritability and although a substantial proportion of the identified genes regulate lipid metabolism and inflammation, most loci are not located in previously well-known or well-characterized platelet genes. Few of these loci have been tested for functional effects in platelets. There are numerous possible explanations for the non-association with well-studied platelet candidate genes, including small platelet gene effect sizes in under-powered heterogeneous clinical phenotypes.⁵⁴⁹

Whole-Exome Sequencing

Whole exome-sequencing is well-suited to identify variants in protein-coding genes and was used to identify *NBEAL2* as the causative gene in the gray platelet syndrome.^{550,551}

Pharmacogenetics

The *CYP2C19**2 allele (681G>A; rs4244285) causes a loss of function of the *CYP2C19* enzyme and reduced platelet inhibition by clopidogrel as a result of decreased conversion to the active metabolite.⁵⁵² It could account for approximately 12 percent of the variation in platelet inhibition in response to clopidogrel.⁵⁵³ Several large meta-analyses have shown the loss-of-function *CYP2C19**2 allele is associated with both stent thrombosis and cardiovascular ischemic events or death in patients undergoing percutaneous coronary interventions.^{554,555}

GENE VARIANTS ASSOCIATED WITH PLATELET TRAITS

Many cellular pathways in multiple tissues contribute to the pathogenic processes resulting in an atherothrombotic event (Fig. 112–7),

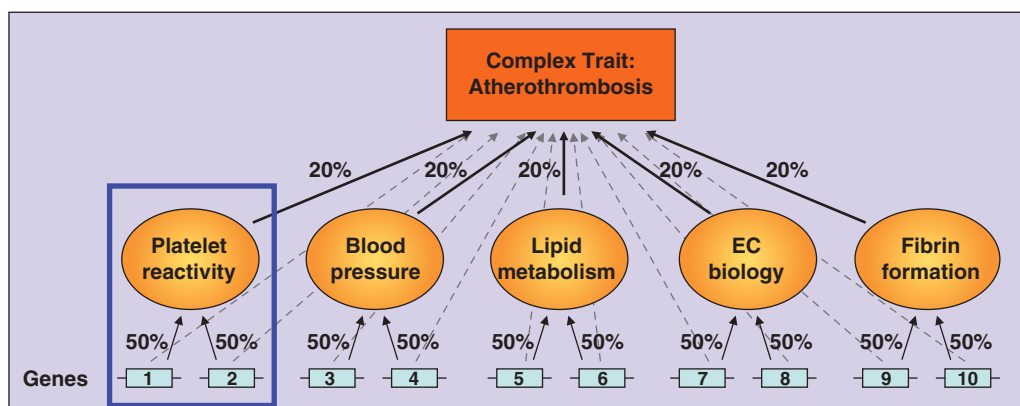

Figure 112–7. Intermediate phenotypes in association studies. Atherothrombosis is a complex phenotype that is regulated by many intermediate traits, of which platelet reactivity is only one. Because a large number of genes contribute to multiple traits, the effect of any one gene on atherothrombotic events, such as myocardial infarction, is small. This highly simplified diagram assumes five traits each contribute 20 percent to the complex trait (*heavy solid arrows*) and two different genes equally regulate each intermediate trait. Thus, each gene contributes 50 percent to the intermediate trait (*thin arrows*), but only 10 percent to the clinical end point (*faint dashed arrows*). Thus, for any given sample size, there is more power to detect genetic associations with intermediate phenotypes than with complex traits. (Reproduced with permission from Bray PF: Platelet genomics beats the catch-22. *Blood* 13;114(7):1286–1287, 2009.)

increasing the “noise” in genetic epidemiology studies testing for associations with complex phenotypes. The use of intermediate phenotypes as outcomes in genetic association studies has enhanced power to detect gene associations because the number of genes potentially responsible for the phenotype is reduced, thereby increasing the fraction of the variance explained by any single factor or gene. Despite large interindividual variability in platelet reactivity, light transmission aggregometry has been shown to be reproducible and heritable, with the reproducibility persisting for years.^{556,557}

Candidate Functional Platelet Genes

The Leu33Pro variant of integrin β_3 (rs5918 of *ITGB3*) is responsible for human platelet alloantigen 1a/b (PI^{A1}/PI^{A2}).⁵⁵⁸ Fibrinogen and prothrombin binding is enhanced to the Pro³³ isoform of purified integrin $\alpha_{IIb}\beta_3$.⁵⁵⁹ Compared to cell lines expressing Leu33 variant of integrin, Pro33 cells have increased adhesion, spreading, actin cytoskeletal reorganization and migration under static^{560,561} and shear conditions.⁵⁶² This prothrombotic phenotype of Pro33 is mediated by *enhanced outside-in platelet signaling* through integrin $\alpha_{IIb}\beta_3$.^{563,564} Notably, this variant does *not* affect inside-out signaling, as assessed by standard platelet light transmission aggregometry of human platelets.⁵⁶⁵ Additional support for the prothrombotic nature of the Pro33 variant of integrin β_3 comes from mice made homozygous for Pro33. These animals have reduced bleeding, increased *in vivo* thrombosis and enhanced outside-in integrin $\alpha_{IIb}\beta_3$ signaling, but normal inside-out signaling.⁵⁶⁶

Laboratory evidence for functional effects of genetic variants in the gene encoding GPIIb has been inconsistent. Variants in the two platelet collagen receptors, GPVI and integrin α_2 subunit (of integrin $\alpha_2\beta_1$) alter receptor expression and adhesion to collagen using *in vitro* perfusion assays.^{567–569} Functional variants in the genes encoding Fc γ RIIA (*FCGR2A*), P2Y₁₂ (*P2RY12*), GPIV (*CD36*), and PAR-1 (*F2R*) have also been reported.

Associations between SNPs in 97 hematopoietic cell genes were tested and 17 novel associations with platelet responses to crosslinked collagen-related peptide (CRP) and ADP were identified, including genes encoding cell surface receptors (*CD36*, *GP6*, *ITGA2*, *PEAR1*, and *P2Y12*), kinases (*JAK2*, *MAP2K2*, *MAP2K4*, and *MAPK14*), and other signaling molecules (*GNAZ*, *VAV3*, *ITPR1*, and *FCERG1*).⁵⁷⁰ Variants at the Chr9p21.3 locus are associated with the platelet aggregation response to low (0.5 mcg/mL) but not higher concentrations of collagen in a large cohort with two replication studies.⁵⁷¹

Genome-Wide Association Studies

The first GWAS reported for platelet reactivity tested association of 2.5 million SNPs with platelet aggregation responses to ADP, collagen, and epinephrine.⁵⁶⁵ The primary cohorts were generally healthy, European-ancestry populations from the Framingham Heart Study (FHS) (n = 2753) and the GeneSTAR cohorts (n = 1238). SNPs at seven loci (*PEAR1*, *MRV11*, *SHH*, *ADRA2A*, *PIK3CG*, *JMJD1C*, and *GP6*) met genome-wide statistical significance and were replicated in an African-ancestry cohort (n = 840). A second platelet function GWAS identified SNPs in *SVIL* (encodes supervillin) as associated with closure time in the *in vitro* platelet function analyzer PFA-100.⁵⁷² Human platelet gene expression studies and data with *Svil* $-/-$ mice demonstrated an inhibitory role for supervillin in platelet adhesion and thrombus formation under high-shear but not low-shear conditions. A meta-analysis by the HaemGen consortium of 66,867 individuals identified 43 and 25 loci associated with platelet number and mean platelet volume (MPV), respectively.⁵⁷³ These loci accounted for 4.8 percent of the phenotypic variance in platelet number and 9.9 percent in MPV and included well-known platelet regulators (*ITGA2B*, *GP1BA*, and *F2R*). These investigators identified

11 of the genes as novel regulators of blood cell formation using gene silencing in *Danio rerio* and *Drosophila melanogaster*.

PLATELET GENE EXPRESSION

TRANSCRIPTOMICS

The *Homo sapiens* genome includes approximately 21,000 protein-coding genes (genome build GRCh38). To date, more than 10 times this number of protein-coding transcripts have been identified, primarily as a result of alternate exon splicing, and more are being continually discovered. Platelets from healthy subjects contain approximately 2.20 femtograms (fg) of total RNA per cell, which is approximately 1000-fold less than nucleated blood cells. Platelets can splice pre-mRNA into mature mRNA, which is translated into proteins.^{574,575} Characterization of the transcriptome enables quantitative assessment of gene expression in the tissue of interest and identification of alternately spliced transcripts. Genome-wide transcriptome studies have enabled dissection of the molecular basis of inherited platelet disorders and a better understanding of the relationship between gene expression and megakaryocyte and platelet differentiation. In addition, platelet RNA profiles may have utility as biomarkers.⁵⁷⁶

Technologic advances have greatly facilitated understanding the platelet transcriptome. Early studies using serial analysis of gene expression and microarrays estimated approximately 6000 mRNAs in the human platelet.^{577,578} Platelet RNA-sequencing (RNA-seq) has demonstrated an unexpected complexity to the transcriptome and substantive differences between the human and mouse platelet transcriptome.⁵⁷⁹ The exquisite sensitivity of RNA-seq provided estimates of approximately 9,000 protein-coding genes in platelets (Fig. 112–8),^{580,581} although only approximately 7800 are commonly expressed⁵⁸² in human platelets. Approximately half of the transcripts in platelets encode mitochondrial genes.⁵⁸¹ Platelet mitochondrial mRNAs are inversely correlated with subject age,⁵⁸² and mitochondrial function may regulate platelet apoptosis⁵⁸³ and support optimal platelet function during storage,⁵⁸⁴ but platelet mitochondrial diseases have not been described. The S-shaped curves in Fig. 112–8 illustrate several features of the human platelet transcriptome: (1) estimates of expressed protein-coding genes are more similar amongst different subjects for high abundance genes (leftwards in Fig. 112–8) and (2) there is substantial interindividual variation in total transcript estimates when considering the less abundant genes (rightward in Fig. 112–9). Furthermore, it is not known what is the biologically relevant copy number of transcripts in any cell, and the arbitrary choice of “threshold” could dramatically affect the number of reported genes expressed in platelets. Transcriptomes of *primary* megakaryocytes have not been determined, but RNA profiling of megakaryocytes derived from cultured CD34+ hematopoietic stem cells has identified transcripts that are differentially expressed upon differentiation and between normal subjects and patients with essential thrombocytosis (ET).^{585,586}

Platelet mRNAs Associated with Disease

Platelet mRNA profiling in patients with acute ST-segment-elevation MI and stable CAD demonstrated that *S100A9* (myeloid-related protein-14 [MRP-14]) was expressed at higher levels in patients than controls.⁵⁸⁷ This discovery was validated in the Women’s Health Study and PROVE IT-TIMI 22 trials.^{587,588} Platelet mRNA expression profiling can distinguish essential thrombocytosis (ET) patients from healthy subjects⁵⁸⁹ and levels of *HIST1H1A*, *SRP72*, *C20orf103*, and *CRYM* can predict JAK2 V617F–negative ET in 87 percent of patients.⁵⁹⁰ mRNA expression profiling identified reduced *MYL9* transcripts in platelets of

Figure 112-8. Estimates of platelet expressed mRNAs. Platelet total RNA was extracted from four normal donors, depleted of ribosomal RNA (rRNA) and subjected to RNA-seq. The number of platelet-expressed mRNAs (*y* axis) was plotted against RNA-seq read number in log₂ ratios normalized to β -actin. (Reproduced with permission from Bray, P.F., et al: *The complex transcriptional landscape of the anucleate human platelet*. BMC Genomics 16;14:1, 2013.)

Figure 112-9. Platelet-leukocyte interactions. A number of interactions can occur between platelets and leukocytes, including neutrophils and monocytes. The interaction between platelet P-selectin and leukocyte P-selectin glycoprotein ligand-1 (PSGL-1) probably is the most important initial interaction (and can lead to tissue factor synthesis by monocytes), but fibrinogen binding simultaneously to activated $\alpha_M\beta_2$ on leukocytes and either $\alpha_{IIb}\beta_3$ or $\alpha_V\beta_3$ on platelets may play a role under certain circumstances. Platelets can release platelet-activating factor (PAF), which can interact with a PAF receptor (PAFR) on leukocytes, leading to $\alpha_M\beta_2$ activation and binding of fibrinogen and factor X. Leukocyte $\alpha_M\beta_2$ can also interact with platelet junctional adhesion molecule-3 (JAM-3) or GPIIb. Platelets can release chemokines (e.g., ENA-78, GRO- α , and RANTES [regulated upon activation, normal T-cell expressed and secreted]), and β -thromboglobulin (β TG) released by platelets can be converted by leukocyte cathepsin G (CG) into the potent chemotactic CXC chemokine NAP-2. Some of the chemokines, in turn, activate leukocytes by binding to the chemokine receptor CXCR2. Platelets also contain the potent immune-stimulating molecule CD40 ligand (CD40L), and both express it on the platelet surface and release it into the circulation upon platelet activation. The interaction between thrombospondin and CD36 molecules on both platelets and some leukocytes and the presence of CD40 on platelets are not shown. VWF, von Willebrand factor.

a patient with an inherited platelet defect.⁵⁹¹ Platelet RNA-seq was also used to identify *NBEAL2* as causing the gray platelet syndrome.⁵⁹²

Platelet mRNAs Associated with Platelet Traits

An unbiased genome-wide platelet RNA expression study identified an association between expression of *PEAR1* with and platelet activation.⁵⁹³ A similar approach identified 290 differentially expressed transcripts between hyperreactive versus hyporeactive platelets.⁵⁹⁴ mRNA and protein levels of VAMP-8, a critical v-SNARE involved in platelet granule secretion, were significantly higher in hyperreactive platelets. Another study identified 63 genes differentially expressed according to platelet activation by ADP and/or CRP.⁵⁹⁵ Two of these genes, *COMMD7* and *LRRFIP1*, were associated with early-onset MI.⁵⁹⁵ The Platelet RNA and Expression-1 (PRAX1) study phenotyped platelet function and performed genome-wide platelet RNA expression profiling on 70 black and 84 white subjects.⁵⁹⁶ PAR4-mediated platelet aggregation and calcium mobilization were greater in black subjects than white subjects. A novel platelet gene encoding phosphatidylcholine transfer protein (PC-TP) showed a strong correlation with race and with PAR-4 reactivity and a PC-TP-specific inhibitor blocked PAR-4- but not PAR-1-mediated platelet aggregation. This finding underscores the genetic basis for interindividual variation in platelet function and the potential need to consider race and genetic factors when treating patients with anti-platelet therapies.

Platelet Noncoding RNAs

The best studied of the noncoding RNAs are microRNAs (miRNAs), which regulate expression of more than 60 percent of protein coding genes.^{597,598} Human platelets express approximately 200 annotated miRNAs, some of which are differentially expressed according to platelet reactivity and may predict platelet responsiveness to activation,⁵⁹⁹ and some of which are differentially expressed by age, gender, and race.^{582,596} Indirect evidence indicates strong correlations between megakaryocyte and platelet miRNA levels.⁶⁰⁰ *miR-155* maintains megakaryocyte progenitors in an undifferentiated state,⁶⁰¹ whereas *miR-150* and *miR-125b-2* drive megakaryocyte differentiation.^{602,603} Loss of expression of *miR-145* in the 5q- syndrome leads to an increase in the megakaryocyte Fli-1 transcription factor, thus enhancing megakaryocyte production.⁶⁰⁴

Platelet miRNA profiles are more stable than mRNA profiles and are useful as biomarkers.⁵⁷⁶ Levels of *miR-26b* and *miR-28* are associated with myeloproliferative neoplasms,^{605,606} whereas levels of *miR-10a*, *miR-148a*, and *miR-490-5p* discriminate ET from secondary thrombocytosis.⁶⁰⁷ Specific sets of platelet miRNAs have associated with MI.^{608,609} Antiplatelet therapies alter platelet miRNA levels.^{610,611} Relationships between platelet miRNAs, mRNAs, and physiology in the same subjects permit prediction of miRNA function and discovery of novel platelet genes.⁵⁹⁹ This approach identified *PRKAR2B* as associated with platelet reactivity, and a functional effect was confirmed in murine platelets lacking *Prkar2b*.⁵⁹⁹ A similar approach was used to demonstrate platelet *miR-376c* levels were higher in white subjects compared to black subjects and these levels correlated with *PCTP* mRNA, PC-TP protein and platelet PAR-4 reactivity.⁵⁹⁶ *miR-376c* directly targets the *PCTP* 3'UTR and represses its expression.⁵⁹⁶

PROTEOMICS

Disease pathophysiology is dictated by the effects of proteins, including their levels, structures and posttranslational modifications. Cataloging platelet proteomes in health and disease and under different activation states provides information not achievable from genomics or transcriptomics, including protein isoforms, localization, stoichiometry, and posttranslational modifications. Early proteome-wide studies of platelet

lysates utilized two-dimensional gel electrophoresis (2D-GE).⁶¹² However, technologic advances using nongel approaches with proteolytic peptide analyses have largely replaced 2D-GE, and include surface-enhanced laser desorption/ionization (SELDI), isotope-coded affinity tags (iCAT), and isotope tags for relative and absolute quantification (iTRAQ).^{613,614} These improved technologies have provided an estimate of approximately 20 million protein molecules per platelet and have updated estimates of the number of detectable different proteins in the platelet proteome to nearly 5000.⁶¹⁵ Pathway and gene ontology analyses reveal most highly expressed platelet proteins localize to the cytoplasm, with substantial percentages in the membrane or secretome,⁶¹⁶ and fall into expected functional categories of cytoskeletal rearrangement, membrane trafficking, and intracellular signal transduction.⁶¹⁵

Platelet protein levels are regulated by mRNA translation in megakaryocytes and platelets, uptake of plasma proteins, and protein degradation,^{574,617} although the relative contribution of each mechanism to the platelet proteome in health and disease is unknown. The dynamic nature of the platelet proteome is illustrated by alterations with disease, aging, gender, and other environmental factors,⁶¹⁶ as well as differential sorting of proteins between megakaryocytes and platelets.⁶¹⁸ Infectious agents, such as dengue virus, stimulate blood platelet mRNA translation into protein.⁶¹⁹ Posttranslational modifications of platelet proteins, such as phosphorylation, have critical effects on platelet activation. Platelets from healthy individuals exhibit marked interindividual variation in function,⁵⁵⁶ and unbiased genome-wide approaches have identified variation in proteins regulating the corresponding function.⁵⁹⁴ Components of protein ubiquitination and degradation have been identified in platelets, but their function is poorly understood.

Cataloging the Platelet Proteome

Most platelet proteomic analyses to date have studied platelets from small numbers of healthy donors. Analyses of resting whole platelets have provided global protein profiles.^{612,620} Fractionation of platelet lysates has been used to assess the α granule,⁶²¹ dense granule,⁶²² and membrane proteomes.^{623,624} Proteins with posttranslational modifications have been identified for phosphorylation,^{625,626} palmitoylation,⁶²⁷ and glycosylation.⁶²⁸ After platelet activation, hundreds of proteins have been identified in releasates (secretomes)^{629,630} and microparticles.^{631,632}

Platelet Proteome Association Studies

Platelet proteome-wide analyses were used to identify *NBEAL2* as the gene responsible for the gray platelet syndrome⁵⁵¹ and to unravel the molecular basis of the Quebec platelet disorder.⁶³³ Differentially expressed platelet proteins involved in integrin $\alpha_{IIb}\beta_3$ signaling were observed in the myelodysplastic syndrome.⁶³⁴ Proteomic approaches have consistently identified platelet septin and actin as increasing over time in storage.⁶³⁵⁻⁶³⁷ A small study suggested platelet protein post-translational modifications may be associated with acute coronary syndromes.⁶³⁸

Relationship Between Platelet Proteome and Transcriptome

Transcriptomic approaches have identified about twice as many genes expressed in platelets as have proteomic approaches, primarily because the former has greater sensitivity. Correlations between 10 platelet RNA-seqs and the most quantitatively robust proteomic analyses to date has been reported.⁶³⁹ Most (87.8 percent) proteins had a detectable corresponding mRNA and the relative abundances showed a significantly positive, albeit weak, correlation. Platelet proteins that lack a corresponding mRNA are likely to be taken up from plasma rather than being synthesized in megakaryocytes, and include fibrinogen, albumin, and immunoglobulins, all of which were suspected to fall into this category based on other studies.⁶⁴⁰ Platelet mRNAs that lack a corresponding

protein may be vestigial from the megakaryocyte. Some of these could be translated subsequently by the platelet under physiologic demands. Combining “multiomic” data with phenotyping can provide important insights as demonstrated by a study in which transcriptomic and proteomic analysis identified six platelet transcripts associated with aspirin resistance.⁶⁴¹ The expression of these genes was associated with death or MI. In addition, platelet phenotyping and genome-wide genotyping and platelet mRNA and miRNA profiling led to the identification of novel protein-coding and noncoding transcripts associated with platelet activation.⁵⁹⁶

● PLATELET COAGULANT ACTIVITY

In resting platelets, negatively charged phospholipids, including phosphatidyl serine (PS) and phosphatidylethanolamine (PE), are almost exclusively present in the inner leaflet of the cell membrane and phosphatidylcholine predominates in the outer leaflet. This asymmetry is maintained by ATP-dependent “flippase” transporters, which restrict PS to the inner membrane surface and “floppases,” which promote outward-directed lipid transport.^{84,85,642,643} When platelets are activated by strong agonists, negatively charged phospholipids redistribute to the outer leaflet of the platelet plasma membrane. This involves a putative calcium-dependent “scramblase” that transports lipids bidirectionally and, when active, collapses membrane asymmetry and results in PS exposure on the outer leaflet. The eight transmembrane domain containing protein TMEM16F serves as a Ca^{2+} -activated, nonselective cation channel that is crucial for Ca^{2+} -dependent phospholipid scrambling and PS exposure on activated platelets.⁶⁴⁴

Platelet activation with strong agonists also results in the formation of microparticles, which are particularly rich in surface-exposed negatively charged phospholipids. Microparticles also are rich in factor Va and thus actively support thrombin generation.^{82,645,646} Microparticle formation can be induced *in vitro* by activation of platelets with ionophore A23187, complement C5b-9, or the combination of thrombin and collagen; by adding tissue factor to recalcified platelet-rich plasma; or by high shear stress.^{645,647–652} Elevations of cytosolic Ca^{2+} , calpain activation, cytoskeletal reorganization, protein phosphorylation, and phospholipid translocation have all been implicated in microparticle formation.

The biologic relevance of platelet microparticles is supported by the finding of increased circulating levels of platelet microparticles in patients with activated coagulation and fibrinolysis, diabetes mellitus, sickle cell anemia, human immunodeficiency virus infection, unstable angina, heparin-induced thrombocytopenia with thrombosis, and respiratory distress syndrome.^{645,653} Microparticles can bind to fibrin thrombi via one or more of the receptors present on their surface, including integrin $\alpha_{\text{IIb}}\beta_3$, GPIb/IX, P-selectin, and possibly P-selectin glycoprotein ligand (PSGL)-1.⁶⁵⁴

Microparticles bind factors VIII, Va, and Xa, allowing them to form both the factor Xase and prothrombinase complexes on their surface.⁶⁴⁵ They can also bind protein S and facilitate inactivation of factors Va and VIIIa which could serve an anticoagulant function.^{655,656} In addition, microparticles can activate platelets by supplying arachidonic acid.

Evidence supporting the importance of platelet microparticle formation to platelet coagulant activity has been gathered from observations of patients who have significant bleeding diatheses in association with defects in platelet microparticle formation (Scott syndrome; Chap. 121).^{657–659} Platelets from the most intensively studied patient had an impaired ability to accelerate the activation of both factor X and prothrombin. In addition, this patient's platelets exhibited both abnormal factor V binding and abnormal exposure of negatively charged phospholipids.

Activated platelets synthesize tissue factor by splicing pre-mRNA into mature mRNA and then translating the tissue factor protein.^{660,661} Additionally, platelet thrombi can recruit tissue factor from blood by binding leukocyte-derived, tissue factor-containing microparticles or by binding an alternatively spliced, soluble form of tissue factor.^{466,472,662–665} The interaction between PSGL-1 on the surface of leukocyte-derived microparticles and P-selectin on the surface of activated platelets appears to play an important role in the binding of microparticles to platelet thrombi.⁶⁶⁴ Interactions between platelets and leukocytes, and perhaps leukocyte-derived microparticles, reportedly enhance (“de-encrypt” or decrypt) tissue factor activity, probably by supplying negatively charged phospholipids⁶⁶⁶ and/or the oxidoreductase enzyme protein disulfide isomerase (PDI).⁶⁶⁷

Platelet dense granules contain polyphosphate, a linear polymer of inorganic phosphate synthesized by inositol hexakisphosphate 6 kinase. Polyphosphates are released during platelet activation and promote clot formation. Polyphosphates affect many steps in coagulation. Polyphosphates accelerate factor V and factor XII⁶⁶⁸ and alter the structure of fibrin clots. In the presence of polyphosphates, fibrin clots have thicker fibers and are more resistant to fibrinolysis.⁶⁶⁹ In contrast to bacterial polyphosphates, which are long-chain structures, platelet polyphosphates have shorter chain length and are more effective in increasing factor V and TFPI activity.

Incontrovertible evidence exists that platelets accelerate thrombin formation.^{658,659,670–672} Platelets accelerate the activation of factor X by factors IXa and VIIIa and the activation of prothrombin by factors Xa and Va.^{659,670} However, only a subpopulation of platelets develops a procoagulant phenotype with activation, as only a fraction of activated platelets display high levels of factors Va and Xa, termed “coat” platelets.^{464,465,670,673} The assembly of the factor IXa/factor VIIIa/platelet complex increases the catalytic efficiency of factor X activation (k_{cat}/K_m [turnover number/Michaelis-Menten dissociation constant]) by a factor of 2.4×10^6 .⁶⁷⁰ Prothrombin binds to approximately 20,000 sites on activated platelets with a K_D equal to its plasma concentration (approximately $0.15 \mu\text{M}$).⁶⁷⁴ Integrin $\alpha_{\text{IIb}}\beta_3$ binds prothrombin through its RGD domain, and may contribute to the localization of prothrombin to the surface of unactivated and activated platelets.⁶⁷⁵

In addition to accelerating coagulation, the binding of activated coagulation factors to the surface of platelets appears to protect them from inactivation by inhibitors in plasma and platelets.³⁹⁹ The bleeding diathesis in patients with Quebec platelet syndrome, who have proteolysis of their platelet α -granule factor V, supports the potential importance of platelet factor V in normal hemostasis (Chap. 121), as do the studies of another patient with abnormal platelet factor V.⁶⁵⁹

Other connections between platelets and the coagulation system include: (1) the presence of fibrinogen in platelet α granules and perhaps on the surface of platelets, where it is strategically located for interactions with locally generated thrombin^{371,399}; (2) the presence of intracellular VWF and the binding of extracellular VWF to platelets (via GPIb/X and integrin $\alpha_{\text{IIb}}\beta_3$), with the potential colocalization of factor VIII attached to the VWF (Chap. 126); (3) activation of factor XI by thrombin on the platelet surface,^{676,677} with the dimeric structure of factor XI allowing it to interact both with the platelet and factor IX simultaneously⁶⁷⁸; (4) a factor XI-like protein associated with platelet membranes, which may be an alternatively spliced form of factor XI lacking exon V; the level of this factor appears to correlate better with hemorrhagic symptoms than does the level of plasma factor XI^{399,679}; (5) the presence of cytoplasmic factor XIII (Chap. 113); (6) the presence of inhibitors of coagulation (α_1 -protease inhibitor, C-1 inhibitor, TFPI, the thrombin inhibitor protease nexin I, and the factors IXa and XIa inhibitor protease nexin II or β -APP)^{399,448}; and (7) promotion of factor XII activation by ADP-treated platelets.³⁹⁹

● PLATELETS AND THROMBOLYSIS

The interactions between platelets and the fibrinolytic system are complex; Table 112-3 contains a partial listing of reported findings.⁶⁸⁰⁻⁶⁸⁴ Both profibrinolytic^{398,685-692} and antifibrinolytic⁶⁹³⁻⁷⁰¹ effects of platelets have been described, and so it is difficult to predict the net effect. Since platelet-rich thrombi are known to resist thrombolysis in animal models, the antifibrinolytic effects of platelets appear to predominate *in vivo*.⁷⁰²

TABLE 112-3. Platelets and Thrombolysis

Profibrinolytic effects of platelets

Tissue plasminogen activator (t-PA) and single-chain urokinase-type t-PA identified on or in platelets.

Unactivated platelets bind plasminogen, and binding is enhanced by thrombin.

Thrombospondin, a plasminogen-binding protein, is expressed on the surface of platelets after activation.

Activation of plasminogen by t-PA is enhanced by platelets.

Clot lysis is enhanced by platelets in some model systems.

Antifibrinolytic effects of platelets

Plasminogen activator inhibitor-1 and α_2 -antiplasmin are present in platelet granules.

Platelets contain protease nexin-1, a serpin that inhibits plasminogen activators and plasmin.

Platelets contain factor XIII, which can crosslink fibrin, making it resist fibrinolysis, and can crosslink α_2 -antiplasmin to fibrin, enhancing its antifibrinolytic effects.

Platelets contain tissue factor pathway inhibitor-2, which inhibits tissue plasminogen activator.

Platelet $\alpha_{IIb}\beta_3$ can bind plasma factor XIIIa directly or indirectly, localizing it to the site of thrombus formation.

Platelets facilitate clot retraction, which diminishes the efficiency of fibrinolysis.

Platelet-activating effects of thrombolytic agents

Streptokinase and t-PA activate platelets *in vivo* and *in vitro*.

Plasmin, at high doses, can aggregate platelets.

Thrombolytic agents may paradoxically generate the potent platelet agonist thrombin or release it from thrombi.

Thrombolytic agents may blunt the prostacyclin increase that accompanies acute thrombosis.

Platelet-inhibiting effects of thrombolytic agents

Plasmin, at low doses, can inhibit platelet activation and aggregation.

Platelets can be disaggregated by t-PA by selective lysis of platelet-bound fibrinogen.

Plasmin can cause redistribution and/or cleavage of platelet glycoprotein Ib.

Inhibition of platelet aggregation by the depletion of plasma fibrinogen, if severe, and generation of fibrin (ogen) degradation products.

Proteolysis of plasma von Willebrand factor.

Prolongation of the bleeding time.

Adapted with permission from Fozzard HA, et al: *The Heart and Cardiovascular System*. New York, NY: Raven Press; 1991.

The effects of fibrinolytic agents on platelets are similarly complex. For example, there is considerable evidence that fibrinolytic agents can activate platelets soon after administration,⁷⁰³⁻⁷⁰⁹ via either a direct effect of plasmin,⁷¹⁰⁻⁷¹³ perhaps acting on PAR-4⁷¹⁴ or an indirect effect through the paradoxical generation of thrombin.^{683,715-718} Interpretation of the latter studies are complicated by the ability of tissue plasminogen activator to release fibrinopeptides from fibrinogen, one of the biomarkers used to assess thrombin activation.⁷¹⁹

Stimulation of platelets by thrombolytic agents may prolong the time required for reperfusion of thrombosed blood vessels and may contribute to reocclusion after successful reperfusion.^{680,720} In animal models and in humans, potent antiplatelet agents can, in fact, speed reperfusion, abolish reocclusion, and diminish the size of myocardial infarcts.⁷²¹⁻⁷²³ In human studies, the benefits of combining integrin $\alpha_{IIb}\beta_3$ antagonists with fibrinolytic agents in enhancing coronary thrombolysis have been counterbalanced by an increase in major hemorrhage.⁷²⁴ Combining a potent integrin $\alpha_{IIb}\beta_3$ antagonist with a reduced dose of a fibrinolytic agent in acute ST-elevation MI when patients are rapidly treated with percutaneous coronary intervention has demonstrated evidence for more rapid reperfusion, but clinical benefit has been variable and bleeding has been increased.^{725,726} In experimental models of stroke, paradoxically, early treatment with integrin $\alpha_{IIb}\beta_3$ antagonists reduces the hemorrhage associated with thrombolytic therapy, perhaps by preventing platelet aggregation in the microcirculation and the release of agents that can damage the vasculature and diminish its integrity.⁷²⁷⁻⁷²⁹ In human studies, however, a potent integrin $\alpha_{IIb}\beta_3$ antagonist given alone did not improve clinical outcomes.^{730,731}

With prolonged use of thrombolytic agents, inhibition of platelet function can occur via a variety of mechanisms.^{102,707,708,732-744} These effects may contribute to some of the hemorrhagic phenomena observed with this therapy. One proposed mechanism is that the thrombolytic agents make platelets refractory to further stimulation by agonists.

● PLATELETS IN INFLAMMATION AND INFECTION

Leukocytes can bind to activated platelets and in model systems transmigrate through a platelet monolayer (reviewed in Ref. 745; see Fig. 112-9). Animal models and studies of human tissue demonstrate that within hours after vascular injury, leukocytes become enmeshed in platelet thrombi and/or transiently form a monolayer on top of adherent or aggregated platelets.^{746,747} These interactions may be important at sites of vascular injury or inflammation where leukocytes have been shown to deposit on adherent and aggregated platelets. Platelet recruitment of leukocytes has been associated with a number of systemic and inflammatory processes in animal models, including the development of intimal hyperplasia after vascular injury,⁷⁴⁸ ischemia-reperfusion injury, alloimmunity-mediated transplant rejection,⁷⁴⁹ obesity,⁷⁵⁰ and acute lung injury.⁷⁵¹ By depositing chemokines such as CCL5 (also termed RANTES [regulated upon activation, normal T-cell expressed and secreted]) on activated endothelium^{752,753} or by direct interactions with leukocytes,⁷⁵⁴ platelets may also enhance leukocyte recruitment to inflamed or atherosclerotic endothelium and thereby promote the development and progression of atherosclerosis.

Many mechanisms of platelet-leukocyte interactions have been defined, but the initial interaction appears to be mediated primarily by the interaction between P-selectin (CD62P) expressed on the surface of activated platelets and PSGL-1 on the surface of neutrophils and monocytes.⁷⁵⁵⁻⁷⁶¹ P-selectin-PSGL-1 interactions are characterized by rapid on-and-off rates that promote tethering and rolling of leukocytes along

adherent platelets. In addition to PSGL-1, leukocyte CD24 may also bind P-selectin. The transient P-selectin-mediated interactions are stabilized by subsequent contacts mediated, in large part, by activation of leukocyte β_2 integrins. Platelet surface-immobilized and released chemokines promote firm leukocyte adhesion and arrest by acting through G-protein-coupled receptors to activate leukocyte β_2 integrins. Platelets can synthesize and release PAF, which can activate leukocyte $\alpha_M\beta_2$, CCL5 and the CXC chemokines ENA-78 and GRO- α , released by activated platelets, can also activate leukocytes. The chemokine neutrophil-activating peptide-2 (NAP-2) can be produced by the action of leukocyte cathepsin G on β -thromboglobulin secreted by platelets.^{762,763} Activated $\alpha_M\beta_2$ on leukocytes can interact with platelet GPIb α ⁷⁶⁴ as well as with platelet-bound fibrinogen via a region(s) on the γ chain (amino acids 190 to 202,⁷⁶⁵ and 377 to 395). Thrombospondin may serve as a bridging molecule between CD36 (GPIV) receptors, which are expressed on both platelets and mononuclear cells.⁷⁶⁶ Platelets also have intercellular adhesion molecule (ICAM)-2 on their surface, which is a ligand for the leukocyte integrin receptor $\alpha_L\beta_2$; although this ligand-receptor interaction appears to have only a minor role in platelet-leukocyte adhesion, it may be more important in leukocyte tethering.⁷⁶³ Platelet junctional adhesion molecule (JAM)3 has also been suggested as a counterreceptor for leukocyte $\alpha_M\beta_2$.⁷⁶⁷ The immunoreceptor tyrosine-based activation motif (ITAM)-associated receptors GPVI and C-type lectin-like receptor-2 (CLEC-2) also promote platelet-leukocyte interactions during inflammation via their respective counterreceptors matrix metalloproteinase inducer (EMMPRIN) on neutrophils and macrophages and podoplanin on inflammatory macrophages.

Transcellular metabolism of eicosanoids can result in production of unique products (Fig. 112–10) and leukocytes can modify platelet activation.⁷⁶⁸ In a complementary fashion, the intimate relationship between leukocytes and platelets allows the latter to contribute to the inflammatory response, including the release of chemokines that can activate leukocytes; PDGF can affect fibroblast and smooth muscle cells; TGF- β_1 both stimulates and inhibits cellular growth; and PF4 primes neutrophils and has antiangiogenic activity. Platelets synthesize the cytokine IL-1 β , an important mediator of the inflammatory response.⁷⁶⁹ Platelets contain Fc γ IIA receptors that can localize IgG and immune complexes, resulting in complement activation. Platelets express CD40L on their surface after activation, and this molecule can interact with CD40, a member of the tumor necrosis factor (TNF) receptor family, on leukocytes and endothelial cells, leading to their activation and their elaboration of a number of proinflammatory molecules^{770–772} (see “CD40 Ligand (CD40L, CD154) and CD40”). Platelet CD40L also promotes procoagulant activity in endothelial cells.⁷⁷³ Finally, platelet-leukocyte interactions can promote the generation of reactive oxygen species, but platelets can also generate signals to stop their production.⁷⁷⁴

Platelet-leukocyte interactions may be important in the initiation of coagulation and fibrin formation through a P-selectin-dependent pathway. In fact, platelet-leukocyte aggregates facilitate thrombin generation to a greater extent than either platelets or leukocytes alone.^{775,776} Coincubation of platelets and leukocytes generates tissue factor activity, in part, through P-selectin-PSGL-1 interactions. The induction of tissue factor activity involves both *de novo* protein synthesis and exposure (“decryption”) of latent tissue factor. The latter may occur by P-selectin-mediated production of tissue factor containing microparticles from leukocytes. Real-time imaging of platelet thrombus formation *in vivo* indicates that tissue factor accumulates in growing thrombi before leukocytes become associated with the thrombus. The accumulation of tissue factor and fibrin formation in thrombi depend on both platelet P-selectin and PSGL-1. These observations, coupled with the finding of bloodborne tissue factor antigen in the circulation,⁷⁷⁷ has led

to a model in which platelet P-selectin recruits tissue factor-containing leukocyte microparticles to platelet-rich thrombi.⁷⁷⁸ Neutrophil-derived microparticles express active integrin $\alpha_M\beta_2$, which can interact with platelets by binding to GPIb α . This, in turn, can initiate platelet P-selectin expression, which will enhance the interactions with neutrophil microparticles containing the counterreceptor PSGL-1.⁷⁷⁹ In mice, increases in soluble P-selectin levels promote a procoagulant state associated with elevated levels of leukocyte-derived microparticles,⁷⁸⁰ and a P-selectin-immunoglobulin chimeric molecule can increase levels of leukocyte-derived microparticles *in vitro* and normalize the bleeding time in hemophilia A mice.⁷⁸¹

Several clinical observations support a potential role for platelet-leukocyte interactions in vascular disease, including the presence of circulating platelet-leukocyte aggregates in patients with unstable angina⁷⁸² and after coronary artery angioplasty⁷⁸³; in the latter situation, the presence of such aggregates appears to confer a worse prognosis for ischemic vascular complications.⁷⁸³ Circulating platelet-leukocyte aggregates are perhaps the most sensitive indicator of systemic platelet activation, reflecting the expression of P-selectin on the surface of platelets.⁷⁸⁴ Analysis of polymorphisms of PSGL-1 involving variable numbers of tandem repeats indicates that the longer PSGL-1 molecules are better able to form platelet-leukocyte aggregates; in some, but not all, studies, the longer molecules were associated with increased risk of some forms of thrombotic vascular disease.^{785–790} The S100 calcium-modulated protein family member MRP-14 (also known as S100A9), which is abundant in neutrophils and released by activated platelets, promotes platelet thrombus, at least in part through CD36.⁷⁹¹

Platelets can contribute to both innate and adaptive immunity in several ways. Bacterial endotoxin binding to toll-like receptors can activate platelets (see “Toll-Like Receptors^{1,2,4,6,99}”), enhance platelet-neutrophil interactions, and promote bacterial trapping by stimulating the production of neutrophil extracellular traps (NETs) composed of DNA, histones, and enzymes that degrade pathogens.^{792–794} The production of NETs confers resistance to a variety of pathogens, including Gram-positive (*Staphylococcus aureus*, *Streptococcus pneumoniae*, and Group A streptococci) and Gram-negative (*Salmonella typhimurium*, *Shigella flexneri*, and *Escherichia coli*) bacteria. A number of Gram-positive bacteria can activate and aggregate platelets and the platelet immune receptor RcyRIIA, integrin $\alpha_{IIb}\beta_3$, Src, and Syk, along with PF4, ADP, and TXA₂ all play a role in the process.⁷⁹⁵ Platelets release mitochondria, which are related to bacteria in composition, when activated either in microparticles or free into plasma, where they associate with neutrophils and the platelet enzyme PLA2 IIA, which hydrolyzes mitochondrial and bacterial membranes, releasing a variety of proinflammatory molecules, including mitochondrial DNA, arachidonic acid, and lysophospholipids that are themselves capable of initiating NET formation.⁷⁹⁶ Release of platelet mitochondria during storage for transfusion has been suggested as being a contributor to platelet-associated nonhemolytic transfusion reactions.⁷⁹⁶

Thrombocytopenia is often present in association with bloodborne bacterial infections (sepsis) and the severity of the thrombocytopenia mirrors the severity of the infection and prognosis. Platelet factor V contributes to resistance to Group A streptococcal infection⁷⁹⁷ by promoting thrombin generation and fibrin deposition, which may help to wall off the bacteria.⁷⁹⁷ Platelets also influence the function of lymphocytes.⁷⁹⁸ They enhance cytolytic T-cell proliferation and antibody production by B cells. Platelets can inhibit the responses of helper T-cells, and via release of TGF- β_1 , increase regulatory T (Treg) cells. Finally, platelets can bind to malarial-infected erythrocytes and both suppress the growth of the parasites and destroy the intraerythrocytic malarial parasites.⁷⁹⁹

Figure 112–10. Select aspects of transcellular eicosanoid metabolism. At sites of platelet-white blood cell (WBC) interactions, free arachidonic acid (AA) can be generated by both activated platelets and leukocytes and exchanged between the cells. In the platelet, cyclooxygenase 1 (COX-1), the target for aspirin, generates the major AA-metabolite prostaglandin (PG) G_2 , the precursor for PGH_2 that, in turn, is converted by thromboxane (TX) synthase to TXA_2 . TXA_2 and PGH_2 promote platelet activation and inflammation through binding to thromboprostanoïd (TP) receptors. TXA_2 is rapidly converted to TXB_2 . Platelets also express platelet-type 12-lipoxygenase (LOX) that converts AA to the relatively unstable intermediate 12-hydroperoxy-5,8,10,14-eicosatetraenoic acid (12-HPETE), which is subsequently converted to 12-hydroxyeicosatetraenoic acid (12-HETE). Platelets from most mammalian species do not possess 5-LOX and, therefore, cannot generate leukotriene A_4 (LTA_4) from AA. However, LTA_4 produced by leukocytes can be transferred to interacting platelets, where it can be metabolized by glutathione-S-transferase to LTC_4 , or by platelet 12-LOX to the antiinflammatory mediator lipoxin (LXA_4). In endothelial cells, AA can also be released from membrane phospholipids, but unlike in the platelet, it is sequentially metabolized by COX-1 or COX-2 and prostacyclin synthase to PGI_2 , which inhibits platelet activation by effects on the platelet inhibitory prostanoid (IP) receptor. Endothelial cells can also serve as a source of PGH_2 that is metabolized by PGE synthase to PGE_2 . At high concentrations, PGE_2 inhibits platelet activation, and at lower concentrations ($<10^{-6}$ M), it activates platelets through the EP3 receptor. (Used with permission of Matt Hazard, Teaching and Academic Support Center, The University of Kentucky.)

● PLATELETS IN VESSEL INTEGRITY AND DEVELOPMENT

Platelets are essential to maintain the integrity of the vasculature, especially in inflammatory sites, although the mechanisms are not fully understood. Platelets store a number of barrier-stabilizing cytokines and growth factors that may be released constitutively or in a stimulus-dependent manner, including sphingosine-1-phosphate (S1P), which is essential for barrier function, ADP, serotonin, VEGF, and thrombospondin. While platelet G-protein-coupled signaling is essential for hemostasis and thrombosis after vascular injury, these pathways do not appear to be required for hemostasis during inflammation. And functional platelet ITAM motif receptors, CLEC-2 and GPVI, are required to maintain vascular integrity during inflammation, likely by triggering a unique response in the setting of inflammation.⁸⁰⁰

The partitioning between lymphatic and blood vessels during development requires normal platelet function. Platelets regulate lymphangiogenesis, at least in part, through interactions between platelet CLEC-2 and podoplanin on lymphatic endothelial cells. In addition, downstream ITAM signaling, mediated by Syk, SLP-76, and $PLC\gamma_2$, is also required.

Platelet activation along lymphatic endothelium may result in secretion of angiogenic factors. Importantly, platelet adhesion may result in intravascular hemostasis that promotes the lymphovenous junction, in that mouse embryos lacking CLEC-2, podoplanin, Syk, or SLP-76 display blood-filled lymphatic vessels. The requirement for platelets in maintaining blood-lymphatic separation extends beyond embryogenesis into adulthood. Importantly, the requirement for lymphovenous hemostasis are different from arterial and venous hemostasis, likely because of the low-flow, low-shear environment and intact lymphatic endothelium.

● PLATELET MEMBRANE GLYCOPROTEINS

Platelet membrane glycoproteins mediate most of the interactions between platelets and their external environment. Receptors can receive signals from outside the platelet and transmit signals inside. In addition, glycoprotein receptors receive signals from inside the platelet that affect their external domain functions. Platelet glycoprotein receptors are grouped into several different receptor families (integrins, leucine-rich glycoproteins, immunoglobulin cell adhesion molecules, selectins, tetraspansins, and seven-transmembrane domain receptors; see Table 112–4).

Figure 112-11. $\alpha_{IIb}\beta_3$ Integrin structure and activation. **A.** Model for $\alpha_{IIb}\beta_3$ integrin inside-out activation and outside-in signaling. The α subunit is in blue and the β subunit is in red. The bent, inactive receptor is depicted in (A). Under resting condition, the integrin β_3 cytoplasmic domain appears to interact with filamin. Cellular stimulation induces filamin to displace filamin from the integrin β_3 cytoplasmic domain as well as a conformational change in talin that alters the interactions between the talin head and rod domains and exposes the talin head domain. The FERM F3 domain in the head then binds to the integrin β_3 cytoplasmic domain, which unclamps the inter-subunit cytoplasmic and transmembrane domains from their complex with the integrin β_3 cytoplasmic and transmembrane domains. Kindlin-3 binding to the integrin β_3 cytoplasmic domain may facilitate talin binding and appears to be required for the conversion to the high-affinity state. The binding of talin then leads to separation of the ectodomain subunit tails and may diminish the interaction of the integrin headpiece with the tails. Although small ligands can bind to the receptor without headpiece extension, the large glycoprotein ligands may require extension to facilitate access to the ligand binding site. Extension (B) may occur spontaneously after leg separation, or may result from traction force exerted on the integrin β_3 cytoplasmic domain via talin's association with the cytoskeleton

One member of the integrin family, integrin $\alpha_{IIb}\beta_3$, is virtually unique to platelets (and their precursors, megakaryocytes), whereas the leucine-rich glycoproteins GPIb/IX and GPV appear to have highly restricted but not uniquely platelet expression patterns, including cytokine-activated endothelial cells.^{801,802} All of the other receptors are expressed more widely on other cell types.

INTEGRINS

Integrin receptors are heterodimeric complexes composed of an α subunit containing three or four divalent cation binding domains and a β subunit rich in disulfide bonds. Both subunits are transmembrane glycoproteins and are coded by different genes. There are at least 18 α subunits and eight β subunits.^{43,803,804} Three major families of integrin receptors are recognized based on the β subunit: β_1 , β_2 , and β_3 . Integrins are widely distributed on different cell types, and each integrin demonstrates unique ligand-binding properties. Integrin receptors mediate interactions between cells and proteins or proteins on cells; they are also involved in protein trafficking in cells. Integrin receptors can also transduce messages from outside the cell to inside the cell, and from inside the cell to outside the cell.

Integrin $\alpha_{IIb}\beta_3$ (Also Termed GPIIb/IIIa, Fibrinogen Receptor, and CD41/CD61)

The integrin $\alpha_{IIb}\beta_3$ complex, a member of the β_3 integrin receptor family, is the dominant platelet receptor, with 80,000 to 100,000 receptors present on the surface of a resting platelet (Fig. 112–11).^{805–812} Another 20,000 to 40,000 receptors are present inside platelets, primarily in α -granule membranes, but also in dense bodies and membranes lining the open canalicular system; these receptors are able to join the plasma membrane when platelets are activated and undergo the release reaction.^{813–815} On average, integrin $\alpha_{IIb}\beta_3$ receptors are less than 20 nm apart on the platelet surface and thus are among the most densely expressed adhesion/aggregation receptors present on any cell type.

On resting platelets, integrin $\alpha_{IIb}\beta_3$ has low affinity for fibrinogen in solution, but when platelets are activated with ADP, epinephrine, thrombin, or other agonists, integrin $\alpha_{IIb}\beta_3$ binds fibrinogen relatively strongly.^{808,816} Activation induces changes in the integrin $\alpha_{IIb}\beta_3$ receptor itself that are responsible for the change in fibrinogen-binding affinity, but changes in the microenvironment surrounding integrin $\alpha_{IIb}\beta_3$ may also be involved. The integrin $\alpha_{IIb}\beta_3$ receptors in α granules appear to cycle to and from the plasma membrane.⁸¹⁷ This recycling helps to explain the ability of the integrin to take up fibrinogen from plasma and transport it to α granules, where it is concentrated.^{375,818}

Data from other integrin receptors identified a cell recognition sequence composed of RGD in the ligand fibronectin,^{819,820} and this same sequence is important in ligand binding to integrins $\alpha_V\beta_3$ and $\alpha_{IIb}\beta_3$. Fibrinogen contains one RGD sequence near the carboxy terminus of each of the two A α chains (amino acids 572 to 574) and another at amino acids 95 to 97.⁸²¹ In addition, the carboxyterminal 12 amino acid region of each of the two γ chains (amino acids 400 to 411) contains a sequence that includes Lys-Gln-Ala-Gly-Asp-Val, which is the most important in the binding of fibrinogen to platelets.^{822–826} VWF contains an RGD sequence in its carboxyterminal domain and that region mediates the binding to integrin $\alpha_{IIb}\beta_3$.^{809,810,812} Small, synthetic peptides containing the RGD or γ -chain sequence inhibit the binding of fibrinogen to platelets, and these observations have been exploited to produce therapeutic agents (tirofiban and eptifibatid) to inhibit platelet thrombus formation⁸²⁷ (Chap. 134). Similarly, monoclonal antibodies that inhibit binding of ligands to integrin $\alpha_{IIb}\beta_3$ have been developed and a mouse/human chimeric Fab fragment of one of them has been developed into a drug (abciximab) that is an effective antiplatelet agent.

The binding of fibrinogen to integrin $\alpha_{IIb}\beta_3$ appears to be a multistep process^{808,828–833}: (1) the initial interaction is most likely via the γ -chain carboxyterminal region(s) and divalent cation-dependent^{823–826}; (2) subsequent interactions enhance the binding and internalization of the fibrinogen⁸³⁴ and render it irreversible, even when divalent cations are removed⁸³⁵; (3) binding of fibrinogen induces changes in the receptor that can be recognized by antibodies (ligand-induced binding sites [LIBSs])^{442,826}; (4) binding of fibrinogen to integrin $\alpha_{IIb}\beta_3$ induces changes in fibrinogen (receptor-induced binding sites) that can be recognized by antibodies and may involve exposure of the A α chain Arg-Gly-Asp-Phe sequence at amino acids 95 to 98^{836,837}; and (5) fibrinogen binding induces receptor clustering.^{251,838}

By electron microscopy, the receptors have a globular head of 8×12 nm and two 18-nm long tails representing the carboxyterminal regions of each subunit, including their hydrophobic transmembrane domains.^{839,840} Crystallographic, electron microscopic, electron and neutron scattering, and biochemical data from integrin $\alpha_{IIb}\beta_3$ and the related integrin $\alpha_V\beta_3$ receptor indicate that the unactivated receptors are in a bent conformation and that activation involves both extension of the receptor head and a swing out motion in the β_3 subunit.^{149,827,841–853} A three-dimensional reconstruction of integrin $\alpha_{IIb}\beta_3$ in a lipid bilayer nano disc from negative-stain electron microscopy images supports a compact conformation of the inactive receptor, but unlike the crystal structure of the ectodomain, the legs are not parallel and straight.⁸⁴⁸

Integrin $\alpha_{IIb}\beta_3$ shares the same basic structural features of all integrin receptors (Table 112–4).^{30,848} The α subunit, α_{IIb} , is a transmembrane

and actin-myosin contractile force. Ligand binding to the integrin is associated with a swing out motion of the integrin β_3 hybrid domain from the $\beta A(I)$ domain (C), which results in both increased ligand affinity via alterations in the ADMIDAS (adjacent to metal ion-dependent adhesion site) and MIDAS (metal ion-dependent adhesion site) regions of integrin β_3 and greater leg separation. This conformational change may initiate outside-in signaling. The ligated integrins may then cluster (not shown). The structure in panel (A) is based on the crystal structure of the ectodomain (PDB 3FCS)²⁵⁰ and the nuclear magnetic resonance (NMR) structure of the transmembrane and cytoplasmic domains (PDB 2K9J).⁸⁹⁴ The structure in (B) is based on the same ectodomain crystal structure, but with extension at the genus of the subunits (PDB 3FCS),²⁵⁰ the NMR structures of the separated transmembrane and cytoplasmic domains,⁸⁹⁴ and the structure of the complex between the β_3 cytoplasmic domain and the talin F3 domain (PDB 2H7E).⁸⁹⁶ The structure in (C) is based on crystal structure of the liganded receptor (PDB 2VDN) headpiece,⁸²⁷ the extended structure of ectodomain (PDB3FCS),²⁵⁰ and the monomeric transmembrane structures connected to unstructured cytosolic tails. **B.** Domain structure of structure of integrin $\alpha_{IIb}\beta_3$. The individual domains and the ligand binding pocket are identified in the model of the extended integrin. I-EGF, Integrin epidermal growth factor; PSI, plexins, semaphorins, integrins. **C.** The integrin transmembrane complex. Selected views of the NMR structure of the α_{IIb} (red) and β_3 (blue) transmembrane complex. The left panel depicts contacts involved in the outer membrane clasp and the right panel depicts the contacts involved in the inner membrane clasp. Note that after the integrin α_{IIb} helical region ends at V990, the next 5 residues (GFFKR) reenter the membrane; the two aromatic F residues make hydrophobic contacts with β_3 and α_{IIb} R995 makes a salt bridge with integrin β_3 D723. (A, reproduced with permission from Lau TL, Kim C, Ginsberg MH, et al: The structure of the integrin $\alpha_{IIb}\beta_3$ transmembrane complex explains integrin transmembrane signalling. protein with four characteristic divalent cation-binding sites (see Fig. 112–11). The mature protein contains 1008 amino acids^{43,854} with one transmembrane domain; during processing, it is cleaved into a heavy chain and a light chain connected by a disulfide bond. The β subunit, β_3 , contains 762 amino acids and is rich in cysteine residues, with a characteristic cysteine-rich region near its transmembrane domain.^{43,855} The integrin α_{11b} and β_3 cytoplasmic tails consist of 20 and 47 amino acids, respectively. The genes coding for α_{11b} and β_3 are very close to each other on chromosome 17 at q21.32, but are not so close as to share common regulatory domains.^{856,857} Both proteins are synthesized in megakaryocytes and join to form a calcium-dependent, noncovalent complex in the rough endoplasmic reticulum.⁸⁵⁸ Calnexin probably serves as a chaperone for integrin α_{11b} ,⁸⁵⁹ but it is unclear which chaperone(s) are involved in integrin β_3 folding and/or integrin $\alpha_{11b}\beta_3$ complex formation. The integrin $\alpha_{11b}\beta_3$ complex subsequently undergoes further processing in the Golgi apparatus, where the carbohydrate structures undergo maturation and the pro-GPIIb molecule is cleaved into its heavy and light chains by furin or a similar enzyme.^{860,861} Approximately 15 percent of the mass of both integrins α_{11b} and β_3 are composed of carbohydrate.⁸⁶² The mature integrin $\alpha_{11b}\beta_3$ complex is then transported to the plasma membrane or the membranes of α granules or dense bodies. If integrins α_{11b} and β_3 do not form a proper complex, either because of a structural abnormality in either subunit or the failure to synthesize one of the subunits, the subunit(s) that are synthesized are rapidly degraded and so are not expressed on the membrane surface (Chap. 121). Degradation of integrin α_{11b} appears to involve retro-translocation from the endoplasmic reticulum into the cytoplasm, ubiquitination, and proteolysis by the megakaryocyte proteasome.⁸⁵⁹

Both integrins α_{11b} and β_3 are composed of a series of domains (see Fig. 112–11). The aminoterminal region of integrin α_{11b} contains a seven-blade β -propeller domain, and each blade is composed of four β strands connected by loops. The propeller interacts with the βA (I-like) domain of integrin β_3 , forming the globular head region observed in electron micrographs. The four calcium ions bound by the propeller domain interact with β hairpin loops in blades four to seven that extend away from the interface with integrin β_3 . In addition, there is a unique integrin α_{11b} cap subdomain made up of four loops from blades one to three that are unique to α_{11b} and contribute to its ligand binding specificity. The remainder of the extracellular components of integrin α_{11b} are made up of a thigh, genu (knee-like), and two calf domains,²⁵⁰ much like the structure of the related integrin α_v subunit.^{841,844} The cytoplasmic domain of integrin α_{11b} interacts with the cytoplasmic domain of integrin β_3 and the interaction is important in controlling activation of the holoreceptor.^{863–866} The cytoplasmic domain of integrin α_{11b} has a GFFKR sequence near the membrane that is thought to control inside-out activation of the integrin receptors because mutations or deletions in this region result in the receptor adopting a conformation with high affinity for fibrinogen.^{867–871} A number of studies using mutagenesis and nuclear magnetic resonance (NMR) identified different structures for the transmembrane and cytoplasmic domains, and differences in the relative roles of heterodimeric and homodimeric associations.^{864,872–875} Disrupting the conformation of this region also results in a constitutively high-affinity receptor,^{876,877} which has led to the conclusion that inside-out activation of integrin $\alpha_{11b}\beta_3$ requires separation of the transmembrane and cytoplasmic domains, but it remains possible that more subtle changes in the cytoplasmic and transmembrane domains may be sufficient.⁸⁴⁸

The integrin β_3 subunit domains are not linearly arranged because the first domain (PSI [plexins, semaphorins, and integrins]) was subjected to the insertion of a hybrid domain, which itself was subjected to the insertion of a βA (I-like) domain; the latter domain is homologous to the VWF A domain and integrin I domains, both of which bind ligands (see Fig. 112–11).^{827,878} The double insertion in the PSI

domain explains why there is a “long range” disulfide bond extending from C13 to C435; thus, even though the βA domain makes contact with the integrin α_{11b} propeller (via Arg261 and other residues that interact with two rings of hydrophobic residues in the integrin α_{11b} “cage”), it is not the aminoterminal of the molecule. The PSI domain contains Leu33, which defines the PI^{A1} (HPA-1a) specificity, as opposed to the alloantigen PI^{A2} (HPA-1b), which is produced by a Pro33 polymorphism (Chap. 137). The integrin β_3 leg is composed of four integrin EGF domains that are rich in disulfide bonds. In the crystal structure, this region interacts with the integrin α_{11b} stalk region and the globular head in the bent, unactivated receptor, but these interactions are less prominent in the three-dimensional reconstruction of the inactive receptor not in the activated receptor.^{250,827,848} Mutations in the integrin EGF domains, including cysteine residues, can activate the receptor as can the binding of monoclonal antibodies.^{879–882} The importance of the normal disulfide bond pairings in integrin β_3 is further supported by data demonstrating that certain reducing agents can cause activation of integrin $\alpha_{11b}\beta_3$, fibrinogen binding, and platelet aggregation,^{883,884} and an enzyme capable of catalyzing the exchange of thiol groups and disulfide in proteins (PDI) has been identified on the surface of platelets and in platelet releasates.^{883,885–887} Thiol-disulfide exchange in integrins $\alpha_{11b}\beta_3$ and $\alpha_v\beta_3$ is implicated as a contributor to clot retraction.⁸⁸⁸ Moreover, regions in integrin β_3 itself have the same consensus sequence (CGXC) present in PDI that is thought to mediate the catalysis.⁸⁸⁹ One model suggests that integrin $\alpha_{11b}\beta_3$ can achieve a low level of activation without alterations in disulfide bonds, but that maximal activation requires PDI or similar activity along with a source of thiols such as plasma glutathione or a membrane NAD(P)H oxidoreductase system.⁸⁸³ Inhibition of PDI and other enzymes that mediate thiol-disulfide exchange (ERp57, ERp5) reduces platelet thrombus formation.^{890,891} It is still unclear, however, whether disulfide bond alterations contribute to activation *in vivo* under physiologic or pathologic conditions.

Transmembrane domain structures of integrin α_{11b} and integrin β_3 have been proposed based on NMR and structural modeling studies.^{871,873,874,892–896} Because the integrin α_{11b} transmembrane helix is shorter than the integrin β_3 helix, they traverse the membrane at an angle of approximately 25 degrees. The association of the integrin α_{11b} and integrin β_3 ectodomains near the site of entry into the membrane results in the transmembrane helices being directly juxtaposed in the region of the membrane closest to the ectodomain (outer membrane clasp). Near the cytoplasmic end of the membrane the helices are held together by an inner membrane clasp composed of the integrin α_{11b} residues immediately after the end of the helix (GFFKR), with the membrane reimmersion of F992 and F993 filling the gap and interacting with integrin β_3 W715 and I719, with integrin α_{11b} R995 creating a salt bridge with integrin β_3 723 and perhaps residue 726.^{897,898} Of note, these regions are conserved in many other integrins receptors and so the basic mechanism may be common to many of the receptors.

Inside-out signaling is accomplished by the talin F3 domain binding to the integrin β_3 cytoplasmic domain, which is proposed to disrupt the inner membrane clasp.^{34,244,245,863,865,866,869,870,872,876,892,899,900} This may be facilitated by migfilin displacing filamin from the integrin β_3 cytoplasmic domain as the latter interaction may prevent talin binding.⁹⁰¹ Talin binding results in dissociation of the transmembrane helices and reorganization of the cytoplasmic region of integrin β_3 into a more extended helix. Integrin $\alpha_{11b}\beta_3$ ectodomain chain separation, headpiece extension, and integrin β_3 swing out then follow, either spontaneously or as a result of the traction force generated by the cytoskeleton on integrin β_3 through talin.¹⁴⁹ Outside-in signaling is presumed to be initiated by loss of ectodomain interactions between the membrane-proximal regions of integrins α_{11b} and β_3 , perhaps as a result of ligand binding producing even greater integrin β_3 swing out, resulting in disruption of the outer

membrane clasp and subsequent dissociation of the transmembrane helices. This potentially may facilitate the interaction of the cytoplasmic domains with cytoskeletal elements and signaling molecules.

The integrin β_3 tail also contains two NXXY motifs and Y747 and Y759 within one of these motifs are phosphorylated upon platelet aggregation, thus producing docking sites for signaling molecules.²³⁵ Studies in mice and in recombinant systems demonstrate a role for the sites in clot retraction and platelet aggregate stability.^{291,902}

A number of proteins have been shown to bind to the cytoplasmic domains of integrin α_{IIb} and/or β_3 , either directly or through interactions with other proteins, including signaling molecules (Src, Shc, FAK, paxillin, and ILK, all of which bind to integrin β_3), cytoskeletal proteins (kindlin-3, skelemin, α -actin, and myosin, which bind to integrin β_3 , and filamin and talin, which bind to integrins α_{IIb} and/or β_3), and other proteins (β_3 -endoneixin and CD98, which bind to integrin β_3 , and CIB and calreticulin, which bind to α_{IIb}) (Fig. 112–12).^{244,866,903–919} These interactions are important in mediating inside-out signaling and outside-in activation by integrin $\alpha_{IIb}\beta_3$ that acts by regulating activation of Src.⁹²⁰ Similarly, PECAM-1 serves as an inhibitor of integrin $\alpha_{IIb}\beta_3$ activation through a sequential phosphorylation mechanism.^{921,922} Force on the integrin β_3 cytoplasmic domain by actin–myosin action may supply the energy for the conformational change in integrin $\alpha_{IIb}\beta_3$ from bent to extended.²⁵⁰

The junction between the integrin α_{IIb} propeller and the β_3 βA (I-like) domain is the site of ligand binding to integrin $\alpha_{IIb}\beta_3$ (see Fig. 112–11). This region of integrin β_3 contains three divalent cation binding sites: MIDAS (metal ion-dependent adhesion site), ADMIDAS (adjacent to MIDAS), and SyMBS (synergy metal binding site).²⁵⁰ The latter was previously termed the ligand-associated metal binding site (LIMBS) based on the crystal structure of integrin $\alpha_V\beta_3$.^{844,845}

The crystal structure of integrin $\alpha_V\beta_3$ demonstrated that an RGD peptide bound primarily via interactions between the Arg in the peptide and two Asp residues (D150 and D218) in integrin α_V and between the Asp in the peptide and the MIDAS cation.⁸⁴⁵ The binding pocket in integrin $\alpha_{IIb}\beta_3$ is similar but differs in that only one Asp in integrin α_{IIb} (D224) is available to interact with an Arg (or Lys as in the fibrinogen γ -chain peptide), the distance between D224 in integrin α_{IIb} and the MIDAS cation is longer, and a cap subdomain of the integrin α_{IIb} propeller contributes Phe160 to a hydrophobic exosite in combination with Tyr190.^{149,827} As a result, the pocket is able to accommodate the longer

fibrinogen γ -chain C-terminal peptide better, with the peptide's Asp and C-terminal Val carboxyls interacting with the MIDAS and ADMIDAS cations, respectively.⁸²⁶ It also explains why integrin $\alpha_{IIb}\beta_3$ can bind peptides containing the longer Lys residue (KGD peptides).⁹²³ Crystal structures are also available for the integrin $\alpha_{IIb}\beta_3$ receptor with the drugs eptifibatid and tirofiban, which are effective antithrombotic agents because of their ability to block ligand binding to integrin $\alpha_{IIb}\beta_3$, and demonstrate specificity for integrin $\alpha_{IIb}\beta_3$ compared to integrin $\alpha_V\beta_3$.⁸²⁷ The basis of the specificity of these agents involves in part their interaction with the integrin α_{IIb} -specific exosite and the greater length between their positive and negative charges.⁸²⁷ The third integrin $\alpha_{IIb}\beta_3$ antagonist drug, abciximab, is a chimeric murine monoclonal antibody Fab fragment. Its epitope has been localized to a region on integrin β_3 very close to the MIDAS, suggesting that it works by steric interference with ligand binding, disruption of the binding pocket, or both mechanisms.

Two major conformational changes in integrin $\alpha_{IIb}\beta_3$ have been described in association with activation: headpiece extension and integrin β_3 hybrid and PSI domain swing-out (see Fig. 112–11).^{250,827,853} Headpiece extension can contribute to ligand binding by enhancing access to the binding site; it can also contribute to platelet aggregation by extending the receptor further from the platelet surface,⁹²⁴ thus facilitating the ability of fibrinogen to bridge between platelets.⁸⁴⁶ The integrin β_3 hybrid and PSI domain swing-out motion appears to enhance ligand binding, but the precise mechanism is unclear.^{826,847,850} Swing-out is associated with movement of the ADMIDAS metal ion and the α_1 - β_1 loop toward the MIDAS with the latter movement stabilized by the interaction of two backbone nitrogens in the α_1 - β_1 loop with the ligand carboxyl oxygen, thus reinforcing the binding to the MIDAS metal ion.^{149,826} Mutations that produce swing-out of the hybrid and PSI domains result in constitutive ligand binding to integrin $\alpha_{IIb}\beta_3$.⁹²⁵

Binding of fibrinogen to platelet integrin $\alpha_{IIb}\beta_3$ leads to platelet aggregation, presumably via crosslinking of integrin molecules on two different platelets by fibrinogen.⁸⁴⁰ The dimeric and relatively rigid structure of fibrinogen, and the location of the binding sites at the ends of the γ chains are all consistent with such a model as the two binding sites on a single fibrinogen molecule are probably more than 45 nm apart. Soon after fibrinogen binds, it can be dissociated from the platelet by chelating the divalent cations, but the binding becomes irreversible within an hour.⁸³⁵ Fibrinogen binding alone is not sufficient for platelet aggregation, but the events necessary after fibrinogen binding, which

Figure 112–12. Protein interactions with the cytoplasmic domains of $\alpha_{IIb}\beta_3$ regulate inside-out and outside-in signaling. Shown are some, but not all, of the proteins reported to associate with the $\alpha_{IIb}\beta_3$ cytoplasmic domains, many in a dynamic fashion. Some are associated with resting platelets, while others are recruited to, or dissociate from, the integrin during inside-out or outside-in signaling, leading to F-actin assembly. In addition, several proteins with enzymatic function become activated (*asterisks*) after fibrinogen binding to $\alpha_{IIb}\beta_3$. Not shown are the many additional adapter molecules, enzymes, and substrates that may become recruited through more indirect interactions. CIB, calcium and integrin-binding 1; Csk, c-Src tyrosine kinase; ILK, integrin-linked kinase; ITAM, a yet-to-be identified protein with one or more immunoreceptor tyrosine activation motifs; PKC β , protein kinase C β ; PP1c, protein phosphatase 1c; RACK1, receptor for activated C kinase 1; Syk, spleen tyrosine kinase. (Reproduced with permission from Collier, B.S. and S.J. Shattil, *The GPIIb/IIIa (integrin $\alpha_{IIb}\beta_3$) odyssey: A technology-driven saga of a receptor with twists, turns, and even a bend.* *Blood* 112(8):3011–3025, 2008.)

probably include ligand- and/or cytoskeletal-mediated receptor clustering, are not well understood.^{95,835,926,927} After ligands bind to integrin $\alpha_{IIb}\beta_3$, “outside-in” signaling through the integrin can occur, resulting in a number of phosphorylation events, changes in the platelet cytoskeleton, platelet spreading, and even initiation of protein translation.^{236,237,928}

In addition to fibrinogen, several other proteins can bind to integrin $\alpha_{IIb}\beta_3$ on activated platelets, including VWF, fibronectin, vitronectin, thrombospondin, and prothrombin^{390,675,929}; each of these contains an RGD sequence in the region implicated in the initial interaction with platelets. There are subtle differences in the binding of each of these ligands, however, with regard to divalent cation preference and competent activating agents. The binding of all of these other ligands can also be inhibited by RGD-containing peptides, indicating a common requirement for the interaction between the RGD sequence in the protein and the RGD-binding site in integrin $\alpha_{IIb}\beta_3$.^{930,931}

Platelet aggregation measured in the aggregometer *ex vivo* depends upon fibrinogen binding to integrin $\alpha_{IIb}\beta_3$. It is less clear whether fibrinogen is the most important ligand supporting platelet aggregation *in vivo* since studies performed in model systems under flowing conditions indicate that VWF is the major ligand at higher shear rates.⁹³² Even in the aggregometer, VWF can partially substitute for fibrinogen if the fibrinogen concentration is very low.⁹³³ *In vivo*, mice deficient in both VWF and fibrinogen still make platelet thrombi in response to vascular injury.^{934–936} Although fibronectin was initially implicated in supporting the development of such thrombi, mice deficient in fibrinogen, VWF, and fibronectin have paradoxically increased platelet aggregation and thrombus formation, suggesting that fibronectin may play an inhibiting role in thrombus formation under certain circumstances.³⁷³

Although resting platelets do not bind soluble fibrinogen (or other adhesive glycoproteins) to an appreciable extent, they can adhere to fibrinogen immobilized on a surface.^{825,937} This activation-independent adhesion may be from alterations in the structure of fibrinogen when it is immobilized on a surface.^{836,938} Alternatively, there may always be a few integrin $\alpha_{IIb}\beta_3$ receptors that are transiently in the proper conformation to bind fibrinogen, and immobilization may result in high local density of fibrinogen and favorable kinetics for adhesion. Finally, it is possible that even low-affinity fibrinogen interactions with integrin $\alpha_{IIb}\beta_3$ are sufficient to initiate integrin interactions with the cytoskeleton such that actin-myosin-induced contraction provides the energy required for the conformational changes needed to achieve higher affinity binding.²⁵⁰

Fibrinogen and/or fibrin have been identified on the surface of damaged blood vessels; thus it is possible that integrin $\alpha_{IIb}\beta_3$ mediates platelet adhesion under those circumstances.⁹³⁹ In contrast, integrin $\alpha_{IIb}\beta_3$ on resting platelets does not appear to be able to mediate adhesion to VWF or fibronectin⁹⁴⁰; if platelets are activated, however, integrin $\alpha_{IIb}\beta_3$ can support adhesion to these glycoproteins.⁹³⁰ In models of platelet accumulation under flowing conditions, $\alpha_{IIb}\beta_3$ acts in synergy with GPIIb/IX, VWF, and fibrinogen at the apex of thrombi, where shear forces are greatest.^{28,941,942} The integrin $\alpha_{IIb}\beta_3$ has also been implicated in platelet spreading after adhesion,^{227,228,943} and it is necessary for clot retraction (see above) and the uptake of plasma fibrinogen into platelet α granules.^{818,944}

Less-well-defined roles for integrin $\alpha_{IIb}\beta_3$ have been suggested in the binding of plasminogen,⁶⁸⁸ calcium transport across the platelet membrane,^{945–947} IgE binding to platelets leading to parasite cytotoxicity,⁹⁴⁸ and interactions with the *Borrelia* species spirochetes that cause Lyme disease⁹⁴⁹ and hantavirus.⁹⁵⁰ Integrin $\alpha_{IIb}\beta_3$ also mediates factor XIIIa binding to platelets, but this is primarily as a result of factor XIII's association with fibrinogen.⁴⁵⁶ Factor XIIIa and calpain have also been implicated in limiting platelet–platelet interactions after activation by adhesion to collagen.⁹⁵¹

Integrin $\alpha_2\beta_1$ (Also Termed GPIIb/IIIa, Collagen Receptor, VLA-2 and CD49b/CD29)

Integrin $\alpha_2\beta_1$ (GPIIb/IIIa) is widely distributed on different cell types and can mediate adhesion to collagen.^{19,20,952–957} The integrin α_2 subunit (GPIIb) contains a region of 220 amino acids inserted in the aminoterminal β -propeller region (I domain) that is homologous to similar regions in other proteins that are known to interact with collagen, including VWF and cartilage matrix protein.⁹⁵⁸ This region has a MIDAS and crystallographic data of the α_2 I domain in complex with a CRP containing the type I collagen sequence GFOGER (where O indicates hydroxyproline) demonstrated that the glutamic acid in the peptide coordinates Mg^{2+} binding in the MIDAS.^{959–961} The integrin $\alpha_2\beta_1$ I domain can assume a variety of conformations, going from inactive (closed), through intermediate or low affinity, to active high affinity.^{952,962}

Both integrin $\alpha_2\beta_1$ and GPVI appear to participate in platelet interactions with collagen.^{963–965} Bleeding defects have been described in patients with decreased levels of integrin $\alpha_2\beta_1$ and GPVI, but the precise contributions of the decreases in these receptors is uncertain (Chap. 121). Although integrin $\alpha_2\beta_1$ is capable of supporting adhesion to collagen without exogenous activators, like integrin $\alpha_{IIb}\beta_3$, it appears to be able to increase its affinity for ligand in response to inside-out activation.^{966,967} Potential initiators of integrin $\alpha_2\beta_1$ activation include signaling after GPVI interaction with collagen and GPIIb-mediated adhesion to VWF, perhaps acting via actin polymerization.^{959,968–970} Thus, one possible scenario is that following GPIIb-mediated adhesion to VWF and collagen adhesion and activation mediated by GPVI, integrin $\alpha_2\beta_1$ may promote firm adhesion to collagen, stabilize thrombus growth on collagen, and promote procoagulant activity.^{971,972} In addition, the affinity of integrin $\alpha_2\beta_1$ may also be modulated by alterations in disulfide bonds since inhibition of platelet PDI and sulfhydryl blocking agents inhibit integrin $\alpha_2\beta_1$ -mediated platelet adhesion to type I collagen and to the related peptide GFOGER.^{883,973} The state of the collagen may also influence whether integrin $\alpha_2\beta_1$ or GPVI mediates the interaction with collagen, because GPVI appears to mediate adhesion to fibrillar collagen whereas integrin $\alpha_2\beta_1$ preferentially adheres to collagen that has been treated with partial protease digestion.^{28,974}

Ligand binding to integrin $\alpha_2\beta_1$ is enhanced in the presence of magnesium or manganese and is inhibited by calcium, and thus the conditions in human blood, where calcium concentrations are higher than those of magnesium, do not provide optimal cation concentrations for the receptor's function.⁹⁷⁵ Integrin $\alpha_2\beta_1$ can, however, mediate platelet adhesion to collagen in heparinized blood^{956,975} and inhibitors of integrin $\alpha_2\beta_1$ inhibit thrombus formation in animal models.^{976–978} Regions of collagen type I have been implicated as potential binding sites for integrin $\alpha_2\beta_1$ ⁹⁷⁹; the peptide sequence 502 to 516 of collagen type I α_1 chain, which contains a Gly-Glu-Arg (GER) sequence, may be of particular importance,⁹⁸⁰ but other regions of the collagen molecule may also be important.⁹⁸¹ In type III collagen, amino acids 522 to 528 of fragment α_1 (III) CB4 contains a binding region for $\alpha_2\beta_1$.⁹⁸²

Three different alleles for the integrin α_2 gene, which differ at nucleotides 807 (T or C) and 1648 (G or A), have been described.⁹⁸³ The 807 substitution does not affect the amino acid sequence, but the 1648 substitution causes a change from Glu to Lys, resulting in the Br^b and Br^r alloantigens (HPA-5a and HPA-5b) (Chap. 137). Allele 1 (T-G) is present in 39 percent of individuals, allele 2 (C-G) in 53 percent, and allele 3 (C-A) in 7 percent.^{984,985} Individuals with allele 1 have higher integrin $\alpha_2\beta_1$ platelet density than individuals with allele 2, and individuals with allele 3 have the lowest density; the density of integrin $\alpha_2\beta_1$ correlates with platelet deposition on collagen under flow. The association of these polymorphisms with cardiovascular disease morbidity and mortality, including the risk of developing MI^{986,987} and stroke,⁹⁸⁸ has

been extensively studied without firm conclusions, although there is some suggestion that they may be associated with cardiovascular risk.^{983,989–992}

Integrin $\alpha_2\beta_1$ is probably linked to the membrane skeleton.⁹⁹³ Its ligand specificity appears to be determined by the cell on which it is expressed, since on endothelial cells it functions as a laminin receptor as well as a collagen receptor.^{994,995} Engagement of integrin $\alpha_2\beta_1$ is capable of initiating platelet protein synthesis.²³⁶ Integrin $\alpha_2\beta_1$ has been implicated in megakaryocyte development and platelet formation. In particular, loss of activated integrin $\alpha_2\beta_1$ receptors on the surface of megakaryocytes, as a result of interacting with collagen, has been implicated in the transition from the marrow to the peripheral circulation,⁹⁶⁷ and conditional targeting of megakaryocyte and platelet integrin $\alpha_2\beta_1$ in mice is associated with reduced MPV.⁹⁹⁶

Integrin $\alpha_5\beta_1$ (Also Termed GPIc*/IIa, Fibronectin Receptor, VLA-5 and CD49e/CD29)

Integrin $\alpha_5\beta_1$ is a receptor that is expressed on a wide variety of different cells and mediates adhesion to fibronectin.^{804,819,820} It is important for interactions with extracellular matrix, and data from cells other than platelets indicate a role for this receptor in developmental biology and metastasis formation. The RGD sequence in fibronectin is crucial for cell adhesion, but other regions in fibronectin probably also contribute. RGD-containing peptides can inhibit cell adhesion mediated by integrin $\alpha_5\beta_1$. As with other integrin receptors, adhesion depends on the presence of divalent cations. Integrin $\alpha_5\beta_1$ is competent to mediate adhesion of resting platelets to fibronectin,^{997,998} but its affinity may be modulated by activation.⁹⁹⁹ The biologic role of this receptor on platelets is not clear. Although it may be involved in hemostasis and/or thrombosis, it is also possible that its function is primarily related to megakaryocyte binding to marrow matrix and proplatelet formation.¹⁰⁰⁰ Integrin $\alpha_5\beta_1$ is not the only fibronectin receptor on platelets, since with appropriate activation, integrin $\alpha_{IIb}\beta_3$ can also bind fibronectin.^{804,1001}

Integrin $\alpha_6\beta_1$ (Also Termed GPIc/IIa, Laminin Receptor, VLA-6 and CD49f/CD29)

Platelet adhesion to select laminins, which are variably found in basement membranes and extracellular matrix, can be mediated by integrin $\alpha_6\beta_1$.^{804,1002–1004} Because VWF can bind to some laminins, GPIb can also contribute to platelet adhesion to laminin.¹⁰⁰² This adhesion is best demonstrated with magnesium and manganese; calcium does not support adhesion. This receptor is competent on resting platelets, but its role in platelet physiology is not clear. Mice deficient in integrin $\alpha_6\beta_1$ do not bleed pathologically but are protected against thrombosis.¹⁰⁰² The integrin appears to be able to signal in platelets via PI3 kinase to induce morphological changes.¹⁰⁰⁵ An approximate Mr 67,000 laminin receptor has also been identified on platelets; this receptor is present on other cells as well.¹⁰⁰⁶

Integrin $\alpha_v\beta_3$ (Also Termed Vitronectin Receptor and CD51/CD61)

Integrin $\alpha_v\beta_3$ receptor shares the same β subunit as integrin $\alpha_{IIb}\beta_3$ (GPIIb/IIIa) (see Fig. 112–11).^{804,855,1007–1009} The integrin α_v and α_{IIb} subunits display 36 percent sequence identity.¹⁰¹⁰ Integrin $\alpha_v\beta_3$ differs dramatically, however, from integrin $\alpha_{IIb}\beta_3$ in its platelet surface density, because there are only approximately 50 to 100 integrin $\alpha_v\beta_3$ receptors per platelet.¹⁰¹¹ The crystal structure of the external domains of integrin $\alpha_v\beta_3$ alone and in complex with a peptide containing the RGD cell recognition sequence found in a number of ligands have been solved at high resolution.^{844,845} Such RGD peptides inhibit ligand binding to integrin $\alpha_v\beta_3$. The most important findings were: (1) the receptor adopts a bent conformation in which the globular headpiece composed of the

N-terminal β -propeller region of α_v and the βA (I-like) domain of integrin β_3 , lies near the legs of the integrin α_v and β_3 subunits, and (2) the RGD peptide binds to the headpiece with the Arg (R) making contact with integrin α_v and the Asp (D) making contact with the MIDAS domain in β_3 . Current evidence suggests that the bent conformation is the inactive one and that activation results in extension of the headpiece and pivoting between the integrin β_3 βA and hybrid domains in association with leg separation.^{827,843,1007,1009} Integrin $\alpha_v\beta_3$ can mediate adhesion to vitronectin, but only in the presence of magnesium or manganese, not calcium.¹⁰¹¹ It can also mediate interactions with fibrinogen, VWF, prothrombin, and thrombospondin.^{389,1012–1015} Platelet stimulation can activate integrin $\alpha_v\beta_3$, analogous to activation of integrins $\alpha_{IIb}\beta_3$ and $\alpha_2\beta_1$. Activated integrin $\alpha_v\beta_3$ may uniquely mediate adhesion to osteopontin, a protein found in high concentrations in atherosclerotic plaque.¹⁰¹⁶ The receptor's role in platelet physiology is not defined, but it may contribute to the development of platelet coagulant activity.¹⁰¹⁷

The integrin $\alpha_v\beta_3$ receptor is also present on endothelial cells,^{822,1013} osteoclasts,¹⁰¹⁸ smooth muscle cells and other cells; it has been implicated in bone resorption,^{1019–1021} endothelial–matrix interactions,^{822,1013} lymphoid cell apoptosis,¹⁰²² neovascularization,¹⁰²³ tumor angiogenesis,^{1023–1025} intimal hyperplasia after vascular injury,^{1026–1028} sickle cell disease,^{1029–1031} focal segmental glomerulosclerosis^{1032,1033} and scleroderma.¹⁰³⁴

The presence or absence of integrin $\alpha_v\beta_3$ on the platelets of patients with Glanzmann thrombasthenia can help localize the abnormality to either integrin α_{IIb} (if integrin $\alpha_v\beta_3$ is present in normal or increased amounts) or integrin β_3 (if integrin $\alpha_v\beta_3$ is reduced or absent) (Chap. 121).

LEUCINE-RICH REPEAT GLYCOPROTEIN RECEPTORS

GPIb/GPIX/V (CD42)

GPIb is composed of GPIb α (CD42b) (610 amino acids) disulfide-bonded to two GPIb β subunits (CD42c) (122 amino acids).^{801,1035–1043} GPIb appears to exist on the surface of platelets in a 1:1 complex with GPIX (160 amino acids) and a 2:1 complex with GPV (Fig. 112–13). The GPIb α gene is on the short arm of chromosome 17 and the GPIb β gene is on the long arm of chromosome 22. The GPIX gene is on the long arm of chromosome 3.^{1044–1046} GPIX is required for efficient surface expression of GPIb,¹⁰⁴⁷ but beyond that, its function is unknown. GPIb/IX is expressed on megakaryocytes and platelets; there is controversy as to whether GPIb/IX is expressed on endothelial cells, either constitutively or after cytokine activation.⁸⁰² The promoters for GPIb/IX lack TATA or CAAT boxes, but contain binding sites for the GATA and ETS families of transcription factors, which, along with the expression of the cofactor FOG (friend of GATA-1), may account for the limited expression of GPIb/IX.^{1048–1056}

A genetic polymorphism in GPIb α affects the number of repeating 13-amino-acid units (1, 2, 3, or 4) and produces changes in the molecular weight of GPIb α .¹⁰⁵⁷ The 2 repeat variant is most common, but there is considerable ethnic variation in the frequency of the different numbers of repeats. This molecular weight polymorphism has been linked to the Sib and Ko alloantigens, which have been localized to a T→M variation at amino acid 145 of GPIb α , with M associated with either 3 or 4 repeats and T associated with either 1 or 2 repeats.⁹⁸⁴ Some, but not all reports suggest an association between the alleles with the larger number of repeats and vascular disease.^{983,991,1058,1059} Two other GPIb α polymorphisms have been described: (1) C or T at position –5 from the ATG start codon (RS system), and (2) a nucleotide dimorphism at the third bases of the codon for Arg 358.^{1038,1060,1061} A C at position –5 is

Figure 112-13. The organization of GPIb/IX complex. GPIb α (green), GPIb β (blue), and GPIX (purple) subunits are colored differently. *Left:* A cartoon illustration of the GPIb/IX complex largely drawn in ribbon diagrams. Various parts of GPIb α are labeled on the left. *Right:* The top view of the membrane-proximal portion of GPIb/IX that contains the stalk region of GPIb α , the extra cellular domains of GPIb β and GPIX, and a portion of the transmembrane (TM) helical bundle. The disulfide bonds between GPIb α and GPIb β are highlighted in red. Side chains of Tyr106 in GPIb β are shown in blue spheres, one of which is located at the interface 1 between GPIb β and GPIX. Residue Pro74 in GPIb β are shown in orange spheres, one of which is located at or close to the interface 2. (Reproduced with permission from Li R and Emsley J: *The organizing principle of the platelet glycoprotein Ib-IX-V complex*, *J Thromb Haemost* 2013 Apr;11(4):605-614.)

present in only 8 to 17 percent of individuals, and more closely resembles the sequence surrounding the ATG start codon (Kozak sequence) considered optimal for translation. In fact, this polymorphism is associated with higher levels of platelet surface GPIb, and may be a risk factor for ischemic vascular disease.¹⁰⁶²⁻¹⁰⁷⁰ GPIb has been implicated as a target antigen in autoimmune thrombocytopenia and in quinine and quinidine-induced thrombocytopenia (Chap. 117).

GPIb α has a large number of O-linked carbohydrate chains terminating in sialic acid residues,¹⁰⁷¹ and the latter contribute significantly to the negative charge of the platelet membrane.²¹⁵ Electron micrographic analysis indicates that GPIb exists as a long flexible rod (approximately 60 nm) with two globular domains of approximately 9 and 16 nm.¹⁰⁷² Thus, GPIb probably extends much further out from the platelet's surface than does integrin $\alpha_{IIb}\beta_3$, which may account for its primacy in platelet adhesion, as well as the increased risk of cardiovascular disease in individuals with longer GPIb molecules because of an increased number of 13-amino-acid repeats. The long extension may also make it susceptible to conformational changes induced by shear forces.⁸⁰¹ The extracellular region of GPIb α is readily cleaved by a variety of proteases, including platelet calpains,¹⁰⁷³ yielding a soluble fragment named *glycocalicin* that circulates in normal plasma at 1 to 3 mg/L.¹⁰⁷⁴ *In vivo*, platelet shedding of glycocalicin from GPIb α is mediated by a disintegrin and metalloprotease (ADAM)-17 (also termed TACE) cleaving a juxtamembrane sequence^{1075,1076}, shedding is controlled by GPIb β interactions with an unidentified protein, calpain, and reactive oxygen species.¹⁰⁷⁷⁻¹⁰⁷⁹ Levels of plasma glycocalicin correlate with platelet production and thus can be used to differentiate thrombocytopenia based on decreased platelet production from thrombocytopenia as a result of increased platelet destruction.¹⁰⁸⁰⁻¹⁰⁸⁵

GPIb β and GPIX have free sulfhydryl groups in their cytoplasmic domains that undergo palmitoylation, at least in part, further anchoring the protein to the membrane.^{1086,1087} The penultimate serine residue at the C-terminus of GPIb α is phosphorylated, providing an attachment site for the signal-complex protein 14-3-3 ζ .¹⁰⁸⁸ Similarly, GPIb β can

undergo phosphorylation of Ser 166 in its cytoplasmic domain as a result of protein kinase A activation via cAMP, providing another binding site for 14-3-3 ζ (see Fig. 112-13).¹⁰⁸⁹⁻¹⁰⁹¹ The cytoplasmic domain of GPIb α connects GPIb to filamin A (actin-binding protein), thus connecting GPIb to the platelet cytoskeleton.^{993,1092,1093} Coordinated expression of GPIb α and filamin is required for efficient expression of both proteins and imbalances result in abnormalities in platelet size.^{1094,1095} Alterations in the cytoskeleton can affect GPIb functional activity.¹⁰⁹⁶⁻¹⁰⁹⁸ 14-3-3 ζ can bind PI3 kinase and has been implicated in GPIb-mediated intracellular signaling that results in integrin $\alpha_{IIb}\beta_3$ activation; Lyn; Vav, Rac1, Alet, and Lim kinase-1 also have been implicated in GPIb/IX-mediated signaling.^{9,1099-1101} GPIb also appears to be in close proximity to Fc γ RIIA and the Fc receptor γ -chain, two receptors that can initiate signaling via tyrosine phosphorylation of their cytoplasmic ITAM sequences by Src family kinases and recruitment of the tyrosine kinase syk.¹¹⁰²⁻¹¹⁰⁵ Engagement of GPIb by VWF may lead to clustering of GPIb-IX-V complexes in glycolipid-enriched microdomains or lipid rafts, which may serve to concentrate signaling molecules; clustering also increases ligand avidity.¹¹⁰⁶

GPIb α has eight leucine-rich repeats in the aminoterminal region of its extracellular domain, whereas GPIb β and GPIX have one each.^{1039,1042,1045} These repeats are consensus sequences of 24 amino acids with seven regularly spaced leucines; well-defined disulfide loop sequences flank the repeats.⁸⁰¹ Similar leucine-rich repeats are present in a variety of other proteins.

Crystal structures of the N-terminus of GPIb α (amino acid residue 1-305) alone, and in complex with native and mutated A1 domains of VWF provide important information on the interactions between these proteins (Fig. 112-14).^{1107,1108} This region of GPIb α adopts a curved shape made up of an N-terminal β -hairpin flanking sequence (finger) containing a C4-C17 disulfide loop (H1-D18), eight leucine-rich repeats (K19-W204), a β -switch region (V227-S241), and a C-terminal sulfated anionic region (D269-D287), with Y276, Y278, and Y279 undergoing posttranslational sulfation.¹¹⁰⁸⁻¹¹¹⁰ The VWF-A1 domain,

Figure 112-14. Structural, binding, and mutational features of the A1 domain (cyan) bound to GPIIb/IIIa (magenta). Disulfides are in yellow stick. The A1-GPIIb/IIIa complex forms a super β -sheet at the interface between the A1 β_3 and GPIIb/IIIa β_{14} strands. Platelet-type von Willebrand disease (VWD) mutations (green Ca atom spheres) stabilize the β -switch in its bound over its unbound conformation. VWD type 2B mutations (red Ca spheres) locate distal from the GPIIb/IIIa interface, near to the A2 termini where elongational force is applied. VWD type 2B mutations are hypothesized to stabilize an alternative, high-affinity conformation. A region of GPIIb/IIIa that is important for interaction with A1 in high shear [leucine-rich repeats (LRR) 3-5] and with ristocetin is shown in gray. (Adapted with permission from Li R and Emsley J: *The organizing principle of the platelet glycoprotein Ib-IX-V complex*, *J Thromb Haemost* 2013 Apr;11(4):605-614.)

which has alternating β strands and α helices organized into a central β -sheet surrounded by amphiphatic α helices, interacts with the concave face of GPIIb/IIIa with two areas of tight interactions, at the N-terminal β -hairpin + first leucine-rich repeat (with VWF A1 domain loops $\alpha_1\beta_2$, $\beta_3\alpha_2$, and $\alpha_3\beta_4$), and a more extensive interaction at leucine-rich repeats 5 to 8 + the β switch region (with VWF A1 domain helix α_3 , loop $\alpha_3\beta_4$, and strand β_3). The structure of the VWF A1 domain when not bound to GPIIb/IIIa differs from that of the bound VWF A1 in that the $\alpha_1\beta_2$ loop protrudes in a way that would prevent interaction with GPIIb/IIIa.¹¹⁰⁸ This observation and others related to differences in the ability of different-sized fragments of VWF and GPIIb/IIIa to interact indicate that other regions of both proteins probably contribute to both the binding and activation of the receptor. The crystal structure of GPIIb/IIIa with the naturally occurring mutation M239V in the β -hairpin region that results in platelet-type (pseudo-) von Willebrand disease (Chap. 126) has also been obtained,¹¹⁰⁹ and demonstrates a more stable β -hairpin conformation, which probably accounts for the approximately sixfold increase in binding affinity, primarily through an increase in the association rate. Leucine-rich repeats 3 to 5 do not demonstrate interaction with the normal VWF A domain in the crystal structure, but they are important in ristocetin-induced platelet agglutination, and platelet adhesion at high shear; they do participate to some extent in crystal structures with gain of function mutations in VWF A1.^{1107,1111,1112} It has been proposed that hydrodynamic forces produced at high shear alter the A1 domain and expose regions that interact with these repeats in GPIIb/IIIa.¹¹¹³ Other natural and site-directed mutations causing the platelet-type von Willebrand disease pattern of enhanced VWF binding (G233V, V234G, D235V, K237V) also affect the β -hairpin region. A number of Bernard-Soulier syndrome mutations that cause loss of VWF binding to GPIIb/IIIa localize to the concave face of leucine-rich repeats 5, 6, and 7 (L129P, A156V, and L179del) and to the sides of leucine-rich repeat 2 (C65R and L57P).¹¹¹⁰

The GPIIb/IIIa ectodomain crystal structure has been determined, confirming the four predicted conserved disulfide bonds (C1-C7, C5-C14,

C68-C93, and C70-C116), along with the unpaired C122, which cross-links to GPIIb/IIIa.¹¹¹⁴ The two former disulfides are in the N-capping region and the two latter are in the C-capping region flanking the single leucine-rich repeat.¹⁰⁴⁰ Using a chimeric GPIIb/IIIa/GPIX ectodomain protein, the likely contacts between GPIIb/IIIa and GPIX were identified. The structure proposed is a tetramer of one GPIIb/IIIa, two GPIIb/IIIa β s, and one GPIX in which GPIX interacts with one of the GPIIb/IIIa β molecules.^{1037,1040,1043}

Plasma VWF will not bind to GPIIb/IIIa under static conditions unless the antibiotic ristocetin or the snake venom botrocetin is added. The mechanism by which ristocetin induces VWF binding to GPIIb/IIIa is unclear, but effects on VWF as well as on platelet surface charge have been described, and dimerization of ristocetin molecules and multimerization of VWF, as well as stabilization of an A1 domain conformation with high affinity for GPIIb/IIIa have also been implicated.^{801,1113,1115-1118} Botrocetin binds to VWF, exposing the site that binds to GPIIb/IIIa.¹¹¹⁹ Peptide studies implicate the anionic, sulfated tyrosine region of GPIIb/IIIa as the binding site for botrocetin-treated VWF.⁸⁰¹

Unlike integrin $\alpha_{IIb}\beta_3$, which requires intact, activated platelets to bind to VWF, GPIIb/IIIa-mediated VWF binding does not require platelet activation or even platelet metabolic integrity, because fixed platelets are readily agglutinated in the presence of VWF and either ristocetin or botrocetin.¹¹¹⁶ This observation forms the basis of the assay of plasma VWF activity.

Platelets will adhere to VWF when the latter is immobilized on a surface, even in the absence of ristocetin or botrocetin.^{1116,1120-1122} Under these circumstances, the VWF is believed to undergo a conformational change that allows for direct interactions. It may not, however, be necessary to propose a change in VWF conformation as the interaction between VWF and GPIIb/IIIa appears to have both high association and dissociation rates, permitting tethering and translocation on a surface coated with a high density of VWF, but minimal interaction in fluid phase.⁸⁰⁹ Similarly, VWF associated with fibrin can interact with platelet GPIIb/IIIa without ristocetin or botrocetin.^{61,1123} The C1C2 domains of VWF appears to contain a fibrin binding site.³⁰⁴

Shear stress is an important factor in GPIb-mediated adhesion of platelets to immobilized VWF and subendothelial surfaces.^{1042,1113,1120–1122,1124,1125} Platelets deficient in GPIb or platelets in which GPIb has been blocked with monoclonal antibodies^{1122,1124} adhere poorly to subendothelial surfaces at all shear rates, but the defect in blood from patients with von Willebrand disease is manifest primarily at higher shear rates.^{10,11,1122} In what may be a related phenomenon, subjecting platelets to high shear stresses can induce platelet aggregation, which is mediated by VWF binding to GPIb, followed by platelet activation and integrin $\alpha_{IIb}\beta_3$ -dependent platelet aggregation.^{13,15,1126} Whether the shear rates generated *in vivo* in stenotic blood vessels are of sufficient magnitude and duration to produce a similar degree of platelet activation is unknown. It is also uncertain as to whether the effect of shear is acting on GPIb, on VWF, or on both,^{15,801,809,1042} but shear-induced changes in the structure of VWF, leading to a more extended conformation and conformational changes in the A1 domain, have been defined.^{1113,1127} GPIb forms catch bonds with VWF, meaning that increasing force first prolongs and then shortens bond lifetimes.^{1113,1128}

GPIb also functions as a platelet binding site for thrombin.^{801,1129,1130} The regions between amino acids 216 and 240 and amino acids 269 and 287 were proposed as thrombin binding sites based on biochemical data, with the latter region demonstrating similarity to hirudin, a thrombin-binding protein.^{801,1131} Sulfation of the three tyrosine residues in the latter region is particularly important for thrombin binding.¹⁰⁹³

Two somewhat different crystal structures of the interactions between thrombin and the negatively charged tail region of GPIb have been reported, but in both cases two molecules of thrombin bind to each GPIb molecule using different regions on thrombin (exosites I and II). This raises the possibility that free thrombin or thrombin adherent to fibrin can cluster GPIb/IX/V complexes.¹¹³²

Binding of thrombin to platelet GPIb appears to contribute to thrombin-induced activation of platelets, even when PAR-1 and PAR-4 are desensitized, and platelets lacking GPIb (Bernard-Soulier syndrome) do, in fact, have blunted responses to thrombin. GPIb has been proposed as the high-affinity binding site for thrombin,^{1129,1133} but there are only approximately 50 high-affinity thrombin-binding sites and approximately 25,000 GPIb molecules per platelet,^{1129,1130} raising the possibility that only the subpopulation of GPIb molecules in lipid rafts are able to function in activating platelets.¹¹³⁴ Binding of thrombin to GPIb may also facilitate its effect on one or more of the other thrombin receptors, and there is experimental support for this hypothesis.^{1135,1136}

GPIb has also been demonstrated to interact with P-selectin in a cation-independent manner.^{764,1035,1093} Although GPIb shares a number of features with the P-selectin ligand, PSGL-1 (both are sialomucins and have analogous anionic/sulfated tyrosine sequences), the interaction between GPIb and P-selectin appears to be more like the interaction between P-selectin and heparin.^{1035,1093} In inflamed mesenteric venules in animals, platelets are observed to roll on the activated endothelium¹¹³⁷ and so it is possible that platelet GPIb interacts with endothelial P-selectin in this interaction.¹⁰⁹³ PSGL-1, a well-documented ligand for P-selectin on leukocytes, has also been identified on the surface of platelets,¹¹³⁸ and so may also contribute to this interaction.

GPIb α also binds to high molecular weight kininogen and factor XII, and both of these interactions interfere with thrombin-induced platelet activation.^{1139,1140} Factor XI also binds to GPIb α , where it undergoes activation by thrombin.¹¹⁴¹ Activated leukocyte integrin $\alpha_{M}\beta_2$, also can bind to GPIb α via the I-domain of the integrin,¹¹⁴² and this interaction has been proposed to play an important role in transmigration of leukocytes through platelet thrombi at sites of vascular injury. GPIb plays complex roles in inflammation and endotoxemia in murine models, demonstrating both proinflammatory and antiinflammatory

effects.^{1143,1144} GPIb has also been implicated in supporting metastases in murine models.¹¹⁴⁵

GPV, the third member of the GPIb/IX/V complex, has a Mr 82,000 and is composed of 544 amino acids, including 15 leucine-rich repeats. GPV appears to form a noncovalent complex with GPIb, mediated through association of their transmembrane domains,¹¹⁴⁶ but because the number of GPV molecules on the surface of platelets is approximately 50 percent of the number of GPIb and GPIX molecules,¹¹⁴⁷ it has been suggested that the basic unit consists of two GPIb molecules, two GPIX molecules, and one GPV molecule.^{801,1035,1038} GPV is deficient in platelets from patients with Bernard-Soulier syndrome (Chap. 121), but GPV is not required for surface expression of the GPIb/IX complex.¹¹⁴⁸ A soluble fragment of Mr 69,000 is cleaved from GPV by thrombin, but cleavage does not correlate with thrombin-induced platelet activation.¹¹⁴⁹ Platelets from mice lacking GPV appear to respond more actively to thrombin and ADP than wild-type mice, raising the possibility that GPV inhibits platelet activation.¹¹⁵⁰ The platelets from these mice also adhere to immobilized VWF and can bind VWF in the presence of botrocetin, indicating that GPV is not required for the interaction between VWF and the GPIb/IX/V complex.¹¹⁵⁰ It has been proposed that removing a portion of GPV by thrombin proteolysis allows thrombin access to GPIb α , thus facilitating its ability to activate platelets. In support of this model, thrombin's ability to activate platelets does not require proteolytic activity if GPV is absent, suggesting a direct nonproteolytic effect mediated via GPIb α .¹¹⁵¹

IMMUNOGLOBULIN FAMILY OF CELL-SURFACE ADHESION RECEPTORS AND THEIR ASSOCIATED MEMBRANE PROTEINS

Platelet-Endothelial Cell Adhesion Molecule-1 (Also Termed CD31)

PECAM-1 is a transmembrane glycoprotein of the immunoglobulin gene family with six immunoglobulin-like domains of the C2 group and a Mr 130,000.^{1152–1155} In addition to platelets and endothelial cells, PECAM-1 is expressed on monocytes, myeloid cells, and some lymphocyte subsets. There are approximately 8000 PECAM-1 molecules on the surface of platelets.¹¹⁵⁶ PECAM promotes homophilic interactions via a homophilic binding domain in the immunoglobulin-like repeats. The cytoplasmic tail of PECAM is 118 amino acids in length and contains a palmitoylation site (C595), an immunoreceptor tyrosine-based inhibitory motif (ITIM) including Y663, an immunoreceptor tyrosine-based switch motif (ITSM) including Y686, and a lipid-interacting α helix that contains Y686 and S702, which undergoes inducible phosphorylation.^{1152,1157} Upon phosphorylation, the ITIMs recruit and activate phosphatases, such as SHP-2 and to a lesser extent SHP-1, SHIP, and PP2A,¹¹⁵⁸ via their SH2 domains.¹¹⁵² PECAM-1 undergoes homotypic interactions that lead to signaling and crosslinking.¹¹⁵⁹ PECAM-1 activation overall thus induces inhibitory activity as the phosphatases counteract the effects of stimulating kinases, but are complex and agonist specific. PECAM-1 activation decreases platelet responses to ADP and thrombin and PECAM-1 platelet expression correlates inversely with platelet sensitivity to these agonists.¹¹⁶⁰ PECAM-1 also negatively regulates collagen-induced platelet activation mediated by the ITAM-bearing GPVI/FcR γ -chain complex, GPIb/IX/V signaling, and laminin-induced activation.¹¹⁵⁹ Platelets from mice lacking PECAM-1 are hyperresponsive to subthreshold doses of collagen, and when compared to wild-type mice, form larger platelet thrombi on VWF and in experimental settings *in vivo*.

Crosslinking PECAM-1 molecules on the platelet surface with antibodies enhances platelet adhesion and aggregate formation, suggesting

that under certain circumstances PECAM-1 might be a costimulatory agonist, working in concert with platelet integrin $\alpha_{IIb}\beta_3$.¹¹⁶¹ Moreover, mice lacking PECAM-1 can undergo normal inside-out activation of integrin $\alpha_{IIb}\beta_3$, but have a partial defect in integrin $\alpha_{IIb}\beta_3$ -mediated outside-in signaling.¹¹⁶² PECAM-1 crosslinking may also lead to GPIb internalization, resulting in decreased platelet adhesion.¹¹⁶³

In endothelial cells, PECAM-1 is localized to the contact areas between endothelial cells, in the lateral border recycling compartment, where it is involved in controlling stimulus-specific transmigration of leukocytes.^{1155,1164} It appears to be capable of both homotypic and heterotypic interactions, with the latter mediated by CD177 on neutrophils (and perhaps glycosaminoglycans, integrin $\alpha_v\beta_3$, or CD38) interacting with the fifth or sixth PECAM-1 immunoglobulin domain.^{1155,1165} PECAM-1 engagement triggers signaling and leukocyte integrin receptor activation that facilitates transmigration, with activation of the laminin receptor, integrin $\alpha_6\beta_1$, of particular importance. Endothelial PECAM-1 is also important in maintaining vascular integrity and endothelial and leukocyte PECAM-1 mediate both proinflammatory and antiinflammatory phenomena in model systems.¹¹⁵⁵

Triggering Receptors Expressed on Myeloid Cells–Like Transcript-1

Triggering receptors expressed on myeloid cells (TREM)-like transcript-1 (TLT-1) is a receptor whose external domain is homologous to those in the family termed TREM. Like those receptors, it contains a single V-set immunoglobulin domain, but its cytoplasmic domain is much longer, is palmitoylated and carries a canonical ITIM capable of becoming phosphorylated and binding the Src homology-containing protein, tyrosine phosphatase-1 (SHP-1).^{627,1166} The phosphatase can then dephosphorylate signaling molecules, leading to inhibition of platelet activation. PECAM-1 has a similar ability to bind SHP-1. TLT appears to be restricted in expression to platelets and megakaryocytes. It is primarily in α -granule membranes in resting platelets and joins the plasma membrane when platelets are activated.

GPVI

GPVI is a Mr 62,000 transmembrane glycoprotein of 316 amino acids.^{18,804,1167,1168} It belongs to the immunoglobulin superfamily, and is the major platelet signaling receptor for collagen. It may also mediate platelet interactions with monocytes by binding the ligand EMMPRIN.¹¹⁶⁹ GPVI on the platelet surface exists in a complex with Fc receptor (FcR) γ -chain. Because the latter is a dimer, two GPVI molecules associate with one FcR γ -chain, forming a high-affinity complex.¹¹⁶⁸ The GPVI extracellular region contains two immunoglobulin C2-like domains and its transmembrane domain contains an Arg residue that is essential for association with the FcR γ -chain. The 51-amino-acid cytoplasmic domain contains a proline-rich sequence that binds SH3 (Src homology 3) domains of Src family tyrosine kinases. GPVI signals through the FcR γ -chain, which contains an ITAM. An unpaired thiol in the cytoplasmic tail of GPVI can undergo oxidation, resulting in homodimer formation,¹¹⁷⁰ required for high-affinity interactions with collagen peptides and GPVI-mediated signaling.^{1171,1172} Resting platelets have approximately 29 percent of their GPVI molecules in dimers and interactions with CRPs or thrombin activation increase the percentage of GPVI in dimers.¹¹⁷¹ When GPVI binds collagen, the ITAM domain of the FcR γ -chain becomes phosphorylated by the Src kinases Fyn and/or Lyn, resulting in the formation of large complex of signal-transducing proteins (for a discussion of the role of GPVI as a receptor for collagen, see “Signaling Pathways in Platelets” below).^{1041,1104} GPVI is required for stable platelet thrombus formation on collagen surfaces *in vitro*. Mice lacking GPVI have a relatively mild phenotype and are protected from

thrombosis in some but not all experimental models. GPVI and FcR γ -chain appear to play important roles in ferric chloride-mediated arterial thrombosis in mice, but not in laser-induced thrombosis, perhaps because the former, but not the latter, injury elicits collagen exposure along the damaged vessel. Inherited and acquired defects in human platelet GPVI have been reported (Chap. 121) and the associated bleeding disorders have been variably described as mild to severe.^{1172–1176} Two alternatively spliced forms and several polymorphisms have been identified for GPVI and variably linked to alterations in platelet function or risk of thrombotic disease.^{1177,1178}

Fc Receptor γ -Chain

The FcR γ -chain¹¹⁷⁹ exists as a homodimer of Mr 20,000 that physically and functionally associates with GPVI¹¹⁸⁰ and GPIb/IX.¹¹⁰² In mouse platelets, the absence of FcR γ -chain results in lack of surface expression of GPVI. The FcR γ -chain, along with Fc γ RIIA, are the only known platelet proteins with ITAMs.¹¹⁰⁴ Phosphorylation of the ITAM domain serves to recruit proteins with Src homology 2 (SH2) domains, which are essential for collagen-mediated signaling through the GPVI/FcR γ -chain pathway.^{1041,1104,1181} The FcR γ -chain may also contribute to GPIb/IX-mediated intracellular signaling after VWF binding.^{1035,1102,1105}

Fc γ Receptor IIA (Fc γ RIIA, Also Termed CD32)

The Fc γ RIIA is a low affinity immunoglobulin receptor of Mr 40,000 that is widely distributed on hematopoietic cells.⁸⁰⁴ Three different mRNA transcripts (A, B, and C) make similar Fc γ RIIA molecules¹¹⁸² and these are preferentially expressed on different cells. Fc γ RIIA contains an ITAM domain and thus may be important for signaling by its associated proteins, including GPIb and select integrins, as well as through direct stimulation by immune complexes. Crosslinking of Fc γ RIIA initiates tyrosine phosphorylation, PI metabolism, activation of PLC γ_2 , calcium signaling, and cytoskeletal rearrangements.^{960,961} Fc γ RIIA appears to be in close proximity to the GPIb/IX/V complex in lipid rafts,²¹² and signal transduction that accompanies VWF binding to GPIb may be mediated at least in part through Fc γ RIIA.^{885,971} Fc γ RIIA is also important in mediating integrin $\alpha_{IIb}\beta_3$ outside-in signaling, including effects on platelet spreading, clot retraction, and thrombus formation.^{1183,1184} Platelet 12(S)-lipoxygenase (LOX) is required for platelet activation mediated by Fc γ RIIA.¹¹⁸⁵

The Fc γ RIIA on platelets may bind immune complexes generated in certain diseases, and by engaging these complexes the platelets may become sensitized to other stimuli.^{1186–1188} It may also provide a second binding site for antibodies that bind to platelets via their antibody-binding site (see “CD9” below). This second interaction can potentially lead to bridging between platelets, with the antibody binding to an antigen on one platelet and an Fc γ RIIA receptor on another platelet.¹¹⁸⁹ It is also possible that antibodies can bind to both an antigen and an Fc γ RIIA on a single platelet. These interactions can lead to platelet activation through engagement of Fc γ RIIA, followed by crosslinking of Fc γ RIIA receptors, which can lead to tyrosine phosphorylation, PI metabolism, activation of PLC γ_2 , calcium signaling, and cytoskeletal rearrangements.^{1190,1191} This type of interaction appears to play an important role in heparin-induced thrombocytopenia (Chap. 117). Fc γ RIIA undergoes proteolysis when platelets are activated and Fc γ RIIA proteolysis has been proposed as an assay for heparin-induced thrombocytopenia.^{1192,1193} Cooperation between Fc γ RIIA and C1q receptor has been reported.¹¹⁹⁴ A variety of viruses and bacteria can interact with, and activate platelets and this is variably mediated by Fc γ RIIA, with or without immunoglobulin.^{795,1195,1196} Fc γ RIIA may also contribute to cancer cell activation in platelets.¹¹⁹⁷

FcγRIIA expression on platelets shows considerable variation among individuals (approximately 600 to 1500 molecules per platelet), and this variation correlates with FcγRIIA-mediated function.¹¹⁸⁸ This variation in receptor density may explain individual differences in immune-mediated disorders such as heparin-induced thrombocytopenia with thrombosis.¹¹⁹⁸ An H131R polymorphism within FcγRIIA affects the binding of different IgG subclasses.^{1199,1200} The H131R polymorphism may also have clinical significance because the R131 allele is associated with increased binding of activation-dependent antibodies to platelets.¹²⁰¹ A variety of associations have been identified between the H131ER polymorphism and different aspects of heparin-induced thrombocytopenia and immune thrombocytopenia, but the data differ from study to study and no consensus has yet emerged.^{1202–1207}

Intercellular Adhesion Molecule-2 (CD102)

ICAM-2, a member of the immunoglobulin family of receptors, is an endothelial cell ligand for the β₂-integrin α₁β₂ (LFA-1) on lymphocytes and myeloid cells.¹²⁰⁸ Approximately 2600 ICAM-2 molecules are present on platelets, distributed on the membrane surface and open canalicular system.¹²⁰⁸ Platelet ICAM-2 may contribute to platelet-leukocyte interactions (see “Platelet–Leukocyte Interactions” below).

FcεRI

Platelets express the high affinity IgE receptor FcεRI and appear to participate in both defense against parasitic diseases, including malaria, and allergic phenomena.^{799,1209–1211}

Junctional Adhesion Molecule-A (A Also Termed F11)

JAM-A was identified on platelets by the ability of a monoclonal antibody directed against the receptor to initiate platelet activation via crosslinking to FcγRIIA.^{1212–1216} It is phosphorylated during platelet activation and loss of JAM-A in a mouse model results in a prothrombotic phenotype.¹²¹⁷ JAM-A appears to inhibit outside-in signaling via integrin α_{IIb}β₃ by recruiting Csk, which, in turn, phosphorylates Src at Y529.^{1217,1218} It is also able to interact with the integrin α_Iβ₁ receptor on leukocytes, and in endothelial cells it participates in tight junction formation and leukocyte recruitment and transmigration.⁹²⁰

Junctional Adhesion Molecule-C

The JAM-C transmembrane protein has an Mr of 43,000 and 279 amino acids. It contains two C2-type immunoglobulin domains in its extracellular domain and three potential tyrosine phosphorylation sites in its cytoplasmic domain.^{767,920} JAM-C is expressed on platelets but not granulocytes, monocytes, lymphocytes, or erythrocytes. It shares 32 percent homology with JAM-A. Based on monoclonal antibody binding studies, platelets contain approximately 1600 copies of JAM-C. Platelet JAM-C acts as a counterreceptor for leukocyte integrins α_Mβ₂ and α_Xβ₂ and contributes to platelet–leukocyte interactions under some conditions.⁷⁶⁷ Its precise role in platelet physiology is uncertain, but it has been implicated in binding CD34 stem cells.¹²¹⁹

LECTIN-CONTAINING RECEPTORS

P-Selectin (Also Termed GMP140, PADGEM, and CD62P)

P-selectin, which has a Mr of 140,000, is a glycoprotein present in α-granule membranes in resting platelets that joins the plasma membrane when platelets are activated.^{759,1220–1222} Approximately 13,000 P-selectin molecules are detected by antibodies on the surface of activated platelets. The expression of P-selectin on circulating platelets has, therefore, been used as an indicator of their *in vivo* activation.^{1223,1224} It is also present in the Weibel-Palade body membranes of endothelial cells; as in platelets, it joins the plasma membrane when endothelial cells are activated.^{759,1222}

P-selectin has a modular structure in which the aminoterminal region has a calcium-dependent lectin domain that binds carbohydrates. Adjacent to the lectin domain is an EGF domain, followed by nine repeats that are homologous to complement regulatory proteins (“sushi” domains), a transmembrane domain, and a cytoplasmic domain.^{759,1220} The cytoplasmic domain contains Ser, Thr, Tyr, and His residues that can be phosphorylated. In addition, a Cys residue becomes acylated with stearic or palmitic acid. Alternatively spliced forms of P-selectin may be produced in which sushi domains are omitted. The selectin family also includes E-selectin (ELAM-1; CD62E), which is expressed on the surface of activated endothelial cells, and L-selectin (LAM-1; CD62L), which is expressed on the surface of myeloid and lymphoid cells.¹²²⁵

Soluble P-selectin is present in plasma from humans and mice. Alternative splicing generates a soluble form of human P-selectin that lacks the transmembrane domain.¹²²⁶ In mice, at least a portion of soluble P-selectin is derived from proteolytic cleavage of surface P-selectin by an unidentified protease.¹²²⁷

Recognition of ligand by P-selectin requires specific carbohydrate and protein structures. Fucose and sialic acid are important carbohydrate components, with sialyl-3-fucosyl-*N*-acetyllactosamine (SLe^x; CD15S) a preferred ligand structure.^{756,1228–1230} Myeloid and tumor cell sulfatides may also act as ligands for P-selectin.^{1231,1232} PSGL-1, a mucin-like transmembrane glycoprotein homodimer (Mr 220,000) expressed on neutrophils, monocytes, lymphocytes, and to a small extent on platelets, is an important ligand for P-selectin.^{1138,1233–1235} Both sulfation of tyrosine residues contained in an anionic region and branched fucosylation of O-linked carbohydrates are required for optimal binding to P-selectin.

P-selectin can mediate the attachment of neutrophils and monocytes to platelets and endothelial cells. Thus, neutrophils and monocytes may be recruited to sites of vascular injury where platelets deposit and become activated (see “Platelet–Leukocyte Interactions” below). Platelet P-selectin can also recruit procoagulant monocyte-derived microparticles containing both PSGL-1 and tissue factor to growing thrombi *in vivo*.¹²³⁶ Binding of P-selectin to PSGL-1 on monocytes can trigger tissue factor synthesis¹²³⁷ and infusing a P-selectin chimeric molecule into mice results in the generation of procoagulant microparticles.⁷⁸¹ In a reciprocal fashion, P-selectin engagement of PSGL-1 may lead to platelet activation.¹²³⁸ Soluble P-selectin may also promote a prothrombotic state in humans by increasing tissue factor–expressing microparticles in plasma. Indeed, the risk of future cardiovascular events is elevated in apparently healthy women with the highest levels of soluble P-selectin.¹²³⁹

In intact blood vessels, the rapid on and off rates of the interactions between PSGL-1 on neutrophils and P-selectin on endothelial cells allows leukocytes to roll on the endothelium, the first step in leukocyte transmigration (Chap. 66).¹²⁴⁰ The rapid upregulation of P-selectin after endothelial cell activation allows for a quick response. Platelets have been reported to roll on activated endothelium, and this appears to result from an interaction between endothelial P-selectin and perhaps either platelet GPIbα^{1093,1137} or platelet PSGL-1.^{1138,1241} Upon their corelease from endothelial Weibel-Palade bodies, P-selectin may tether ultralarge VWF to the surface of activated endothelium, and thereby promote platelet GPIbα-mediated platelet rolling.¹²⁴²

Genetic and pharmacologic targeting of P-selectin or PSGL-1 in experimental animal models suggests that these receptors may modulate thrombolysis, sickle cell vasoocclusion, restenosis, deep venous thrombosis, cerebral ischemia and infarction, atherosclerosis, metastasis, and thrombotic glomerulonephritis (reviewed in Refs. 1243 to 1246).

C-Type Lectin-Like Receptor-2

Podoplanin is a sialoglycoprotein present on a variety of tumor cells, lymphatic endothelial cells, kidney podocytes, lung epithelial cells,

lymph node stromal cells, and the choroid plexus epithelium that can aggregate platelets.^{1247–1250} Its receptor on platelets is CLEC-2, a C-type lectin-like receptor selectively expressed on megakaryocytes and platelets (approximately 2,000 copies per platelet) that binds podoplanin and the snake venom platelet-activating protein rhodocytin.^{1251–1253} The cytoplasmic tail of CLEC-2 contains an atypical ITAM (hemITAM) with a single YITL sequence that can be tyrosine phosphorylated by Src kinases when platelets are activated. Because CLEC-2 exists as a dimer, it can supply two ITAMS and lead to activation of Syk and, ultimately, PLC γ_2 .¹²⁵⁴ This signaling system is similar to that of GPVI in combination with the Fc γ -chain. Activation of CLEC-2 leads to proteolytic cleavage of GPVI and Fc γ RIIA.¹²⁵⁵ In experimental tumor models, inhibiting the podoplanin/CLEC-2 system reduces metastases.¹²⁵⁶ CLEC-2 interaction with podoplanin on lymphatic endothelial cells, followed by platelet activation and CLEC-2-podoplanin clustering, is required for the separation of blood and lymph vessels during development.^{1257–1259} CLEC-2 also plays a role in lymph node development and maintenance.¹²⁶⁰ HIV-1 can also bind to CLEC-2.

TETRASPANINS

Tetraspanins are a family of four-transmembrane-domain-containing proteins that have conserved Cys residues that form crucial disulfide bonds. The extracellular and intracellular loops in these proteins contain many motifs that mediate interactions with other proteins.¹²⁶¹ While the specific function(s) of tetraspanins is not yet clear, these proteins are able to associate with several membrane proteins and have been reported to modulate integrin function, perhaps in part by organizing membrane and intercellular signaling molecules in cholesterol-associated microdomains distinct from lipid rafts.¹²⁶² CD9, CD63, and CD151 have juxtamembrane Cys residues that can be palmitoylated and this modification may contribute to assembly of complexes with other proteins and localization to lipid microdomains.¹²⁶³ Studies in mice implicate CD151 and TSSC6 in outside-in signaling of integrin $\alpha_{IIb}\beta_3$.¹²⁶⁴ Oligomers of tetraspanins are known to facilitate the formation of larger complexes of membrane proteins that could serve as scaffolds for several platelet signaling events.¹²⁶⁵ CD9 is the most abundant platelet tetraspanin (approximately 40,000 molecules per platelet), followed by CD151, Tspan9, and CD63.¹²⁶⁶ The levels of TSSC6 are not known.

CD9 (5H9; BA2; P24; GIG2; MIC3; MRP-1; BTCC-1; DRAP-27; TSPAN29)

CD9 is a 228-amino-acid tetraspanin that is present on platelets, endothelial cells, smooth muscle cells, cultured fibroblasts, some lymphoblasts, eosinophils, basophils, and other cells.^{1267–1269} It colocalizes with integrin $\alpha_{IIb}\beta_3$ on the inner surface of α granules in resting platelets and on pseudopods of activated platelets.¹²⁷⁰ Binding of monoclonal antibodies specific for CD9 to platelets results in platelet aggregation by triggering phosphatidylinositol metabolism via a mechanism that also requires binding to the platelet Fc γ RIIA receptor.^{1271–1273} The platelet activation induced by the binding of such antibodies requires external calcium and results in an association between CD9 and integrin $\alpha_{IIb}\beta_3$.¹²⁷⁴ CD9 has been proposed to play a role in microparticle release from platelets.¹²⁷⁵ Studies in mice lacking CD9 suggest that CD9 is a negative regulator of integrin $\alpha_{IIb}\beta_3$ signaling, as the mice have enhanced platelet aggregation, fibrinogen binding, and thrombus formation.¹²⁷⁶

CD63 (Also Termed Granulophysin and LAMP-3)

CD63 (Mr 53,000) appears to be present in both lysosomal and dense granule membranes in platelets.^{310,1263,1277} CD63 is also present in Weibel-Palade bodies in endothelial cells, the lysosomal membranes of a variety of other cells, as well as the membranes of melanosomes.

It appears on the surface membrane when platelets are activated, making it a useful marker for platelet activation.^{310,1224} CD63 colocalizes with integrin $\alpha_{IIb}\beta_3$ and CD9 on the surface of activated platelets in a process that appears to require CD63 palmitoylation.¹²⁶³ CD63 is markedly reduced or absent from the dense bodies of patients with Hermansky-Pudlak syndrome,¹²⁷⁷ who have oculocutaneous albinism and a defect in platelet dense bodies (Chap. 121). The amino acid sequence of CD63 has been deduced from complementary DNA (cDNA) cloning.¹²⁷⁸

CD151 (Also Termed GP27, MER2, RAPH, SFA1, PETA-3, and TSPAN24)

CD151, a glycoprotein of Mr 27,000 is present on platelets, endothelial cells, and many other cells.^{1279–1281} Antibodies to CD151, like those to CD9, can initiate platelet aggregation by binding to both CD151 and Fc γ RIIA.¹²⁸⁰ The role of CD151 in platelet physiology remains to be firmly established but it may participate with Fc γ RIIA as a signal transduction complex.¹²⁸⁰ CD151 appears to functionally associate with integrin $\alpha_{IIb}\beta_3$ and, in mice, loss of CD151 impairs platelet aggregation, clot retraction,¹²⁸² and thrombus formation.¹²⁸³

TSSC6 (PHMX, PHEMX FLJ17158, FLJ97586, MGC22455, TSPAN32)

TSSC6 is a 340-amino-acid tetraspanin that is expressed in marrow, spleen, thymus, and several hematopoietic cell types.⁸⁹⁸ It is present in platelets and has been reported to interact with integrin $\alpha_{IIb}\beta_3$. Mice deficient in TSSC6 display a slightly prolonged bleeding time and a significantly increased rebleeding.¹²⁶⁵ Platelets lacking TSSC6 show impaired aggregation and clot retraction.

GLYCOSYLPHOSPHATIDYLINOSITOL-ANCHORED PROTEINS (CD55, CD59, CD109, PRION PROTEIN)

At least five separate platelet proteins are attached to the membrane through a GPI link. These include proteins involved in complement regulation (CD55, decay accelerating factor, and CD59, membrane inhibitor of reactive lysis)¹²⁸⁴; CD109, a Mr 170,000 protein present on platelets, endothelial cells, hematopoietic cells, and fibroblasts that carries both ABO oligosaccharides and an alloantigen (HPA-15, Gov) involved in neonatal isoimmune thrombocytopenia^{1285,1286}; and a Mr 500,000 protein of unknown identity. Patients with paroxysmal nocturnal hemoglobinuria (PNH) have abnormalities in the GPI anchor and thus variably lack all of the GPI-linked proteins. The diagnosis of PNH can be established by assessing platelet expression of these proteins.^{897,1287,1288} Patients with PNH have been reported to have platelet function abnormalities,¹²⁸⁷ raising the possibility that one or more of these proteins has a role in platelet function, but no specific platelet function roles have yet been assigned to the proteins. Of particular interest is the presence of the normal prion protein, which is a Mr 27,000 to 30,000 GPI-linked protein that is both upregulated and shed from the platelet surface with platelet activation.^{1289–1292} In fact, platelets contain the majority of the prion protein present in normal blood.

TYROSINE KINASE RECEPTORS

Eph Kinases and Ephrin Ligands

Eph kinase receptors comprise the largest family of cell surface-associated tyrosine kinases with 14 members identified in mammals. Eph kinases have a conserved structure consisting of an N-terminal extracellular ephrin-binding domain, two fibronectin type II repeats, and intracellular kinase, sterile α motif (SAM), and PDZ binding domains [defined by the first three proteins to display this protein-protein

domain, post synaptic density protein (PSD95), *Drosophila* disk large tumor suppressor (Dlg1), and zonula occludens-1 protein (zo-1)]. A total of eight ephrins have been identified that serve as cell-surface ligands for the Eph kinases. In general, Eph A kinases recognize ephrins that contain a GPI anchor (ephrin A family), while Eph B kinases bind to ligands with a transmembrane domain (ephrin B family). The Eph receptors and the ephrins appear to signal bidirectionally at sites of cell-to-cell contact. Platelets contain Eph kinases EphA4 and EphB1, and their ligand ephrin B1, as well as EphB2.^{276,1293} Messenger RNA for ephrinA3 has also been detected in platelets, but confirmation of the presence of ephrinA3 protein in platelets is lacking. Forced clustering of either Eph kinases or ephrins in platelets promotes cytoskeletal reorganization, adhesion, granule secretion, and Rap1b activation in concert with other platelet stimuli.^{1293,1294} Eph kinase-ephrin interactions may stabilize platelet aggregates and thrombus formation after platelet-platelet contact has occurred.^{276,1295}

Thrombopoietin Receptor (c-mpl, CD110)

The thrombopoietin receptor (c-mpl; Mr 80 to 85,000) is expressed at low levels on platelets (approximately 25 to 224 per platelet) and binds thrombopoietin with high affinity. (K_D approximately 0.50 nM).¹²⁹⁶⁻¹²⁹⁹ Steady-state plasma levels of thrombopoietin are maintained, in part, by platelets and megakaryocytes, which bind thrombopoietin via the thrombopoietin receptor and then internalize and degrade the growth factor. Additional mechanisms for regulation of thrombopoietin levels have been described (Chap. 111). Although its major function is to stimulate megakaryocyte growth and maturation (Chap. 111), thrombopoietin also is able to sensitize platelets to activation by agonists.¹³⁰⁰⁻¹³⁰⁵ Mutations of the receptor have been associated with inherited thrombocytopenia (Chap. 117) and myeloproliferative neoplasms (Chaps. 83 to 85).^{1306,1307} It can also contribute to hematopoiesis through effects on hematopoietic stem cells and other progenitors.

SCAVENGER RECEPTORS

CD36 (GPIV)

CD36 (GPIV) is a Mr 88,000 glycoprotein that is highly, but variably, expressed on platelets (approximately 20,000 copies per platelet).¹³⁰⁸⁻¹³¹³ The nucleotide sequence of CD36 (GPIV) cDNA encodes a protein of 471 residues with a predicted Mr of 53,000 and 10 potential N-linked glycosylation sites,¹³¹⁴ accounting for the difference between predicted and experimentally determined Mr. It is unusual in having two putative transmembrane domains and two short cytoplasmic tails. The cytoplasmic regions may associate with intracellular tyrosine kinases of the Src family and undergo phosphorylation.¹³¹⁵ Antibodies to CD36 (GPIV) have been reported to produce neonatal alloimmune thrombocytopenia (Chap. 117).¹³¹⁶ Biochemical data suggest that it may form dimers and multimers.¹³¹⁷ Increased platelet surface expression of CD36 (GPIV) has been described in patients with myeloproliferative neoplasms.¹³¹⁸ CD36 (GPIV) is also expressed on phagocytic cells (with the exception of neutrophils), fat and muscle cells, cardiac myocytes, and microvascular endothelial cells. The phosphorylation status of the extracellular region of the protein may control its ligand-binding properties,¹³¹⁹ offering a potential explanation for some of the variable results obtained under different conditions.^{1308,1319,1320}

CD36 (GPIV) plays an important role in long-chain fatty acid transport in the heart, fat, and muscle, and may contribute to atherosclerosis and insulin sensitivity.^{1321,1322} Oxidized low-density lipoproteins (LDL), which can be produced by the effects of endothelial cell or platelet nitric oxide (NO) on LDL, bind to CD36 and, perhaps in concert with scavenger receptor (SR)-A, can increase platelet reactivity

to agonists via signal transduction mediated in part by Src kinases and a MAPK.¹³²³⁻¹³²⁵ The variability in platelet CD36 expression may account for the variability in platelet hyperreactivity in response to elevated levels of oxidized LDL.¹³²⁶ CD36 can also mediate microparticle binding to platelets, which augments platelet-mediated thrombosis in animal systems.¹³²⁷ Thus, CD36 has been reported to contribute to atherogenesis, diabetes, the metabolic syndrome, angiogenesis, and inflammation.¹³²⁸⁻¹³³¹ CD36 also interacts with the S100 calcium-modulated protein family member myeloid-related protein (MRP)-14 (also known as S100A9), which can be released from activated neutrophils and platelets. It has been proposed as a platelet receptor for thrombospondin¹³³² and collagen,^{1333,1334} but the functional significance of these interactions remains unclear because individuals who lack CD36 on an inherited basis (Nak^a-negative) do not have a bleeding disorder.¹³³⁵ (Chap. 121). CD36 may play a role in the thrombospondin-mediated interaction reported between platelets and sickle erythrocytes,¹³³⁶ apoptosis, innate immunity, and in the binding of *Plasmodium falciparum*-infected erythrocytes to endothelial cells and monocytes.^{1310,1314}

Scavenger Receptor-BI (SCARB1; CLA-I)

The class B SR-BI (CLA-I) is related to CD36 and is expressed on platelets, endothelial cells, and hepatocytes.¹³¹³ It transports the cholesteryl esters from high-density lipoprotein (HDL) cholesterol and facilitates bidirectional flux of free cholesterol between cells and lipoproteins. Oxidized, but not unoxidized, HDL can inhibit platelet aggregation via binding to SR-BI.¹³³⁷ SR-BI has many other lipid ligands, however, and it is uncertain how these interact under physiologic conditions. A number of mutations are associated with elevated HDL levels.¹³³⁸ A heterozygous missense mutation has been associated with increased platelet unesterified cholesterol and both increased and decreased platelet function.¹³³⁸ Mouse studies indicate that disrupting the SR in nonhematopoietic tissues can affect platelet function via alterations in plasma lipids and alterations in the platelet SR can protect against hyperactivity induced by increased platelet cholesterol content.¹³²⁶

MISCELLANEOUS

CD40 Ligand (CD40L, CD154) and CD40

CD40 ligand (CD40L, CD154) is a trimeric transmembrane protein (Mr 33,000) of the tumor-necrosis family that localizes to α granules in resting platelets and rapidly appears on the surface of platelets upon activation. Within minutes to hours of platelet activation, an Mr 18,000 fragment of CD40L is released from the platelet surface, perhaps mediated in part by matrix metalloproteinase (MMP-2) bound to integrin $\alpha_{IIb}\beta_3$.¹³³⁹ This soluble form of CD40L circulates as a trimer. The bulk of soluble CD40L in plasma is derived from activated platelets and, hence, can serve as a marker for platelet activation *in vivo*. Elevated levels of soluble CD40L are observed in acute coronary syndromes, following percutaneous coronary intervention, in the setting of coronary artery bypass surgery, and in peripheral vascular disease¹³⁴⁰ (reviewed in Refs. 1341 and 1342). Soluble CD40L activates neutrophil integrin $\alpha_M\beta_2$, enhances neutrophil adhesion, and induces the neutrophil oxidative burst.¹³⁴³ Moreover, elevated levels of soluble CD40L are associated with recurrent cardiovascular events in the setting of acute coronary syndromes^{1340,1344} and restenosis following percutaneous coronary intervention.¹³⁴⁵ CD40L and, to a lesser extent, its counterreceptor CD40 have been implicated in the progression of atherosclerosis in animal models.^{1346,1347}

The extracellular portion of CD40L binds to CD40, a Mr 48,000 transmembrane receptor. Approximately 600 to 1000 copies of CD40 are present on both resting and activated platelets,¹³⁴⁸ and while CD40L

has been reported to initiate platelet activation via binding to CD40,¹³⁴⁹ the functional significance of CD40–CD40L interactions in platelet physiology remains to be determined. CD40L also contains a KGD sequence (RGD in mice) that has been implicated in binding to integrin $\alpha_{IIb}\beta_3$. In mice, CD40L– $\alpha_{IIb}\beta_3$ interactions appear to stabilize thrombus growth,¹³⁴⁸ perhaps by activating receptor mediated signaling.¹³⁵⁰ Additionally, integrin $\alpha_{IIb}\beta_3$ antagonists block the release of soluble CD40L from activated platelets. Both platelet-associated and soluble CD40L may stimulate leukocytes to release proinflammatory cytokines; CD40L may also inhibit endothelial cell migration after vascular injury.¹³⁵¹ The inhibitory effects of CD40L on reendothelialization may partially explain why elevated levels of soluble CD40L are associated with higher rates of clinical restenosis.¹³⁴⁵ Finally, platelet CD40L may modulate adaptive immunity by serving as a costimulatory signal for antigen presenting cells.^{1352,1353}

Fas Ligand, LIGHT and TRAIL

Fas ligand (FasL), LIGHT (also termed TNF superfamily member 14), and TNF-related apoptosis-inducing ligand (TRAIL), along with CD40L, belong to the TNF family of cytokines.¹³⁵⁴ With activation, platelets express FasL, LIGHT, and TRAIL on their surface and release soluble forms of these receptors,^{1354–1356} analogous to activation-dependent CD40L platelet expression and release. The receptor Fas (Apo-1, CD95), is expressed on a wide variety of normal and malignant cells. Engagement of Fas by FasL initiates signaling that results in apoptosis, and this process is important in embryonic development, cellular hemostasis, and immune regulation.¹³⁵⁴ The surface-expressed FasL on platelets is biologically active and can initiate apoptosis. The soluble form of FasL may act as an inhibitor of apoptosis induced by surface-expressed FasL.¹³⁵⁴ Similarly, platelet-derived LIGHT is biologically active and can initiate inflammatory responses in monocytes and endothelial cells.¹³⁵⁶

Lysosome-Associated Membrane Proteins 1 and 2 (CD107a, CD107b)

LAMP-1 and LAMP-2 are lysosome-associated membrane proteins that are approximately 30 percent homologous and constitute approximately 50 percent of lysosomal membrane proteins.¹³⁵⁷ They are integral membrane glycoproteins of Mr 110,000 and 120,000, respectively, that are contained within lysosomal membranes.¹³⁵⁸ When platelets undergo the release reaction, they join the plasma membrane. Each protein has two extracellular disulfide-bonded loops containing 36 to 38 amino acids. The loops are separated by a region rich in Pro and Ser that shares homology with the hinge region of IgA. There are multiple N-linked glycosylation sites on each glycoprotein and they contain more than 60 percent carbohydrate. Among the carbohydrate residues are poly-lactosaminoglycans that may possess sialylated Lewis^x structures, which are thought to interact with selectins. LAMP-1 and LAMP-2 play roles in control of lysosome fusion in autophagosomes and phagosomes.¹³⁵⁷

C1q Receptors

Platelets have several receptors for C1q, a Mr 460,000 glycoprotein composed of six globular domains attached to a short collagen-like triple helix.^{1359–1361} One is for the collagen-like domain (cC1qR, Mr 60,000 to 67,000 nonreduced and 72,000 to 75,000 reduced), and another is for the globular domain (gC1qR, Mr 28,000 to 33,000).^{1362,1363} A third receptor of Mr 126,000 enhances phagocytosis.¹³⁶⁴ C1q circulates with C1r and C1s as a calcium-dependent complex, but interaction with immune complexes leads ultimately to dissociation of the complex and release of free C1q, with its collagen-like domain exposed. cC1qR has sequence homology to calreticulin and can modulate platelet–collagen interactions at low collagen concentrations. It may also localize

immune complexes, and when crosslinked by aggregated C1q, it can initiate platelet activation, aggregation, secretion, and expression of platelet coagulant activity.^{1365,1366} Thus, the binding of C1q monomers to platelets inhibits collagen-induced platelet aggregation but has little effect on platelet adhesion to collagen.¹³⁶⁷ C1q multimers support platelet adhesion and can induce aggregation via activation of integrin $\alpha_{IIb}\beta_3$.¹³⁶⁸ C1q can also augment platelet aggregation induced by aggregated IgG.¹¹⁹⁴ The gC1qR may self-associate to form a doughnut-shaped ternary complex.¹³⁶⁹ In addition to binding C1q, this receptor can bind *S. aureus* protein A on endothelial cells, where it functions as a receptor for high-molecular-weight kinogen.¹³⁶³ It may, therefore, participate in contact activation.

GMP-33 (Thrombospondin N-Terminal Fragment)

A Mr 33,000 α -granule membrane protein was initially identified as an activation-dependent protein that joins the plasma membrane when platelets undergo the release reaction. Approximately 4000 antibody molecules directed against GMP-33 bind to resting platelets, and 19,000 bind to activated platelets.¹³⁷⁰ Subsequent studies identified this antigen as a membrane-associated fragment from the N-terminal of thrombospondin.¹³⁷¹

Leukosialin, Sialophorin (CD43)

Leukosialin, a glycoprotein of Mr 90,000, may act as a ligand for ICAM-1.¹³⁷² It is expressed on myeloid and some lymphoid cells. Abnormalities in leukosialin have been described in Wiskott–Aldrich syndrome (Chap. 121).

Toll-Like Receptors 1, 2, 4, 6, 9

Toll-like receptors (TLRs) are involved in innate immunity by virtue of their ability to sense products of protozoa, fungi, viruses, and bacteria, including endotoxin (lipopolysaccharide [LPS]), and then activate intracellular signaling pathways to initiate the inflammatory response.¹³⁷³ TLRs 1, 2, 4, 6, and 9 have been identified in platelets.^{1373,1374} Activation of TLR-1 and TLR-2 can lead to platelet activation via a GPVI-like mechanism with TLR-4 through the nuclear factor (NF)- κ B pathway.¹³⁷⁵ All of the components of the LPS signaling complex, including relatively high levels of TLR-4¹³⁷⁶ and CD14, MD2, and MyD88, have been identified in platelets. LPS binding to platelets stimulates secretion and potentiates agonist-activation by signaling thru the TLR-4 complex.¹³⁷⁷ LPS binding to platelet TLR-4 causes release of CD40L¹³⁷⁸ and modulates the release of cytokines by platelets.^{1379,1380} In experimental animal models, TLR-4 may mediate LPS-induced microvascular thrombosis and thrombocytopenia.^{1376,1381} TLR-4–null mice have prolonged times to vasoocclusion after vascular injury, but endothelial TLR-4 rather than platelet TLR-4 seems to be more important in supporting platelet thrombus formation.¹³⁸² The interactions of LPS, produced by toxigenic *E. coli*, with platelet TLR-4 has been proposed to contribute to the pathophysiology of hemolytic uremic syndrome.¹³⁷⁸ Ligand binding to platelet TLR-4 also promotes platelet–neutrophil interactions, neutrophil activation, and along with TLR-2, the formation of NETs, which capture and sequester bacteria from the circulation.^{792,1383} Activation of TLR-9 with protein adducts leads to Src-dependent platelet activation.¹³⁷⁴

Peroxisome Proliferator-Activated Receptors

Peroxisome proliferator-activated receptors (PPARs) belong to a nuclear hormone receptor family of ligand-activated transcription factors.¹³⁸⁴ PPAR γ is one of the three PPAR family members and is widely expressed in white adipose tissue, macrophages, B and T lymphocytes, smooth muscle cells, fibroblasts, and endothelial cells. It has been implicated in metabolism, insulin responsiveness, adipocyte differentiation, immune function, and inflammation. The thiazolidinedione class of insulin-sensitizing drugs used to treat type 2 diabetic patients act by

binding PPAR γ . Both PPAR β/δ and PPAR γ are present in platelets. PPAR γ agonists decrease thrombin-induced platelet aggregation and release of ATP, TX, and CD40L.¹³⁸⁴ Thus, PPAR γ appears to downregulate platelet activation. Activated platelets release PPAR γ complexed with the retinoid X receptor.¹³⁸⁵ Treatment with select thiazolidinediones has been associated with reductions in markers of platelet activation, including aggregation and P-selectin expression. PPAR β ligands synergize with NO to inhibit platelet function.^{1386,1387} The antiplatelet effects of the calcium channel blocker nifedipine may be mediated through PPAR receptors.³⁴⁸

Matrix Metalloproteinases

Platelets contain a number of MMPs, as well as MMP activators and inhibitors.^{1388,1389} MMP-1 can be activated by collagen and, in turn, cleave PAR-1 at a site two amino acids N-terminal to the site of thrombin cleavage.¹³⁹⁰ This cleavage, like thrombin's, activates PAR-1 by activating a tethered ligand. Thus, MMP-1 can augment collagen-induced platelet activation mediated by GPVI and integrin $\alpha_2\beta_1$. MMP-2 cleavage has been implicated in enhancing platelet aggregation via cleavage of talin and activation of integrin $\alpha_{IIb}\beta_3$.¹³⁸⁹ It exists in an inactive form in resting platelets and it is cleaved into its active form when platelets are activated, probably by platelet-type von Willebrand disease (MT1-MMP).¹³⁹¹ It then moves to the surface via binding to integrin $\alpha_{IIb}\beta_3$ and may then go on to cleave CD40 ligand.¹³⁸⁹ MMP-2 is released into the coronary circulation of patients with acute coronary syndromes.¹³⁹² ADAM-17 (TACE) is important in the cleavage of GPIb and the release glyco-calcin.¹⁰⁷⁶ MMP-9, which is increased in plasma in models of sepsis, can also cleave platelet CD40L.¹³⁹³ Other related proteins in platelets include MMP-9 and -14, ADAM-10, and tissue inhibitor of metalloproteinase (TIMP)- 1, -2, and -3. Platelets also contain ADAMTS-13, which cleaves VWF, thus controlling hemostasis and thrombosis (Chap. 126).

SIGNALING PATHWAYS IN PLATELETS

OVERVIEW

Platelets generally circulate in a quiescent state, but are poised to be activated in response to a variety of agonists that become available at sites of vascular injury or ruptured atherosclerotic plaques. Agonists differ in their intrinsic ability to produce these phenomena, and added complexity derives from differences in dose responses to each agonist and the synergistic effects of agonists used in combination. Agonists are diverse and include small and large soluble molecules, enzymes, and immobilized adhesive glycoproteins. They can be classified as either "strong" or "weak," depending on whether full activation, including the release reaction, can be initiated without the augmenting effect of platelet aggregation itself. Low doses of strong agonists behave like weak agonists. Most agonists are released, synthesized, or formed at the site of vascular injury, and this undoubtedly serves to localize the response.

Agonists bind to receptors of two general categories: seven-transmembrane G-protein-coupled receptors and receptors that can initiate phosphorylation of target proteins (Fig. 112–15). In both cases, a sequence of signaling events ultimately leads to platelet activation. Physiologic responses of platelets to agonists lead to the activation of the integrin $\alpha_{IIb}\beta_3$ receptor to a high-affinity ligand binding state and subsequent platelet aggregation. Moreover, binding of ligands to platelets and platelet aggregation itself further propagates signals that are required for stabilization of the platelet aggregates and clot retraction. In this section, the major agonists, receptors, and signaling pathways involved in early stages of platelet activation that lead to shape change, granule secretion, and platelet aggregation, as well as postaggregation signaling events are described.

AGONIST-INDUCED PLATELET ACTIVATION

Many platelet agonists initiate platelet activation by binding to seven-transmembrane heterotrimeric G-protein-coupled receptors (see Fig. 112–15).¹³⁹⁴ When such receptors are activated, the $G\alpha$ subunit exchanges GDP for GTP and dissociates from the β/γ complex. The free $G\alpha$ subunit, and in some cases, the β/γ complex can activate some relatively common downstream pathways and initiate positive feedback loops. Activation of these pathways is usually intertwined. One common pathway involves the activation of one or more isozymes of PLC, leading to phosphoinositide hydrolysis. Three classes of PLC (β , γ , and δ), have been described, and multiple isozymes exist within each class.¹³⁹⁵ The best-studied PLCs in platelets include PLC β and PLC γ_2 . PLC β is often activated downstream of the seven-transmembrane, G-protein-coupled, receptor family, whereas PLC γ_2 can be activated by phosphorylation on tyrosine, which is a downstream signal from other types of agonist receptors. PLC of either type hydrolyzes phospholipids between the glycerol backbone and the phosphate moiety; the PLC β class is relatively specific for phosphoinositides, whereas PLC γ can cleave other types of phospholipids as well. The hydrolysis of one particular phosphoinositide, PI 4,5-bisphosphate (PIP $_2$), by either class of PLC is critical in platelet function, since it results in the formation of two important products, IP $_3$ and DAG. IP $_3$ binds to specific receptors on the DTS/sarcoplasmic reticulum, causing a release of intracellular Ca $^{2+}$. Increases in intracellular Ca $^{2+}$ are important for activation of a number of signaling enzymes and proteins involved in cytoskeletal reorganization. Increases in calcium are also important in granule fusion and the release reaction. DAG binds to PKC and participates in its conversion to an active enzyme. For many agonists, activation of one or more of the multiple isozymes of PKC is an obligatory step in the conversion of integrin $\alpha_{IIb}\beta_3$ to a high affinity fibrinogen receptor and subsequent platelet aggregation.^{918,1396,1397} One consequence of PKC activation is to cause the release of ADP from dense granules. Released ADP acts at its own seven-transmembrane G-protein-coupled receptor(s) to potentiate the action of numerous agonists. The precise mechanism(s) by which PKC causes integrin $\alpha_{IIb}\beta_3$ activation, however, remains unclear.

Activation of a number of receptors also leads to the activation of PLA $_2$, which releases arachidonic acid from membrane lipid stores. Arachidonic acid is rapidly converted to prostaglandin (PG) products, PGH $_2$ and TXA $_2$, which are themselves potent activators of platelet aggregation.

Adenosine Diphosphate: P2Y $_1$, P2Y $_{12}$, P2X $_1$

Platelets express receptors for both ADP and ATP. Both nucleotides are present in platelet dense granules and are secreted when platelets are activated by adequate concentrations of most, if not all, agonists. Another source of these nucleotides is the red blood cell (RBC); damaged RBCs or those subjected to high shear stress, may release ADP and ATP, increasing their local concentrations. ADP is an especially important physiologic agonist, not only because it can induce platelet aggregation independent of other agonists, but because secreted ADP contributes significantly to the full aggregation response induced by many other agonists. This has been convincingly demonstrated in experimental systems in which secreted ADP is rapidly degraded or inhibited. Moreover, submaximal concentrations of ADP synergize with other agonists, and this has been best studied with epinephrine. ADP induces or contributes to a variety of responses in platelets: shape change, granule release, TXA $_2$ production, activation of integrin $\alpha_{IIb}\beta_3$, and platelet aggregation.^{1398,1399} Recent pharmacologic and cloning and sequencing studies suggest that ADP exerts its full effect on platelets through at least two different receptors. These receptors, P2Y $_1$ and P2Y $_{12}$, are G-protein-coupled, and are responsible for most of the physiologic effects of ADP.¹⁴⁰⁰

Figure 112-15. Role of G-protein–coupled receptors in platelet activation. Under basal conditions, prostacyclin produced by endothelial cells inhibits platelet activation by binding to its platelet receptor IP and increasing cyclic adenosine monophosphate (cAMP). When the endothelium is denuded, collagen interaction with GPVI can initiate signaling via the FcR γ -chain. In addition, the GPIIb/V/IX complex can mediate adhesion of platelets to the newly exposed or deposited von Willebrand factor. This, in turn, can lead to platelet activation directly by a pathway not shown. GPIIb/V/IX can also contribute to platelet activation by thrombin by facilitating the cleavage of protease-activated receptor (PAR)-1. Not shown is another pathway to PAR-1 cleavage and activation via collagen-induced release of matrix metalloproteinase (MMP)-1. In concert with PAR-4, cleaved PAR-1 initiates intracellular signaling pathways through molecular switches from the G $_q$, G $_{12}$, and G $_i$ protein families. This results in adenosine diphosphate (ADP) secretion and subsequent activation of both P2Y $_{12}$ and P2Y $_1$. A number of signals can also initiate the synthesis of thromboxane (TX) A $_2$, which can exit from the platelet and activate the same or other platelets by binding to its own receptor, TP. Ultimately, activation of phospholipase C (PLC) β and γ , and released calcium (Ca $^{2+}$) initiate a series of steps that terminate in talin and kindlin binding to the cytoplasmic domain of β_3 and activation of the glycoprotein (GP) $\alpha_{IIb}\beta_3$ receptor to its high affinity ligand binding state. CalDAG-GEF1, calcium and diacylglycerol-regulated guanine-nucleotide exchange factor 1; PKC, protein kinase C; RIAM, Rap1-guanosine triphosphate (GTP)-interacting adapter molecule. (Reproduced with permission from Smyth SS, Woulfe DS, Weitz JI, et al: G-protein-coupled receptors as signaling targets for antiplatelet therapy. *Arterioscler Thromb Vasc Biol* 29(4):449–457, 2009.)

The platelet P2Y $_{12}$ receptor, which is the target of the thienopyridine class of drugs (ticlopidine, clopidogrel, prasugrel, and ticagrelor) that are used in the treatment of acute coronary syndromes and peripheral vascular disease, as well as to prevent thrombosis following percutaneous vascular interventions, has been cloned and sequenced.¹⁴⁰¹ It couples to G α_i ^{1402–1404} to inhibit adenylyl cyclases, a class of enzymes that produce cAMP, which, in turn, activates type A protein kinases that inhibit platelet activation by a variety of effects. VASP is phosphorylated in response to P2Y $_{12}$ -mediated activation of protein kinase A and so the extent of VASP phosphorylation in response to a combination of ADP and an agent that stimulates cAMP formation can be used as a marker for receptor blockade (see “Nitric Oxide” below). Decreases in cAMP level alone are likely insufficient to activate platelets,^{1405,1406} and ADP-activation of platelets requires synergistic effects between the signaling pathways of the P2Y $_1$ and P2Y $_{12}$ receptors (and perhaps the P2X $_1$ ATP receptor.) Regulation of P2Y $_{12}$ is complex and involves homologous desensitization, internalization, and recycling.¹⁴⁰⁷ Studies of P2Y $_{12}$ knockout mice demonstrate that P2Y $_{12}$ contributes to multiple

steps during thrombosis, including platelet adhesion and activation, thrombus growth, and thrombus stability.¹⁴⁰⁸ Platelets obtained from P2Y $_{12}$ -deficient mice respond only weakly to ADP and less vigorously than normal to other agonists such as collagen and thrombin.¹⁴⁰⁹ A minor P2Y $_{12}$ haplotype (H2) has been associated with enhanced ADP-induced platelet aggregation, as well as resistance to the antiplatelet effects of clopidogrel.^{1410,1411}

The platelet P2Y $_1$ receptor, the other G-protein–coupled ADP receptor on platelets, has been cloned and sequenced and a high-resolution crystal structure demonstrating two disparate ligand binding sites is available.¹⁴¹² Data from experiments with inhibitors of P2Y $_1$ and mice lacking P2Y $_1$ suggest that stimulation of this receptor is necessary, but not sufficient, to induce platelet aggregation. Thus, platelets from P2Y $_1$ -null mice are unable to change shape or aggregate in response to ADP; however, ADP activation does cause a decrease in cAMP via its effects on P2Y $_{12}$.^{1413,1414} P2Y $_1$ couples to heterotrimeric G-proteins containing G α_q . The importance of G α_q can be inferred from the observation that platelets from mice that do not express G α_q do not aggregate

in response to ADP and that patients with abnormalities in $G_{\alpha q}$ have a bleeding disorder and abnormal platelet function (Chap. 121).¹⁴¹⁵ Activation of PLC β and subsequent phosphoinositide hydrolysis has been linked to both shape change and platelet activation.

P2X₁, the third purine nucleotide receptor on platelets is P2X₁, a member of the P2X family of ligand-gated ion channels rather than a G-protein-coupled receptor.¹⁴¹⁶ This receptor is predicted to span the plasma membrane twice and is largely extracellular.¹⁴¹⁷ While P2X₁ has been described as both an ATP and an ADP receptor, the bulk of current evidence suggests that it is an ATP receptor that is antagonized by ADP.^{1418,1419} Because ATP antagonizes the P2Y₁₂ receptor, the overall contribution of P2X₁, which is stimulated by ATP, to platelet activation, is not clear. Nonetheless, ATP is released from platelets upon stimulation with agonists such as collagen¹⁴²⁰ and ATP binding to P2X₁ causes a rapid Ca²⁺ influx.¹⁴²¹ However, Ca²⁺ influx induced by stimulation of this receptor alone appears to be insufficient to induce platelet shape change or aggregation.¹⁴⁰⁵ It does, however, synergize with the P2Y platelet ADP receptors.¹⁴²¹ This synergy is likely caused by the specific downstream signaling events evoked by ATP stimulation of this receptor, which include Ca²⁺ influx and MAPK activation.¹⁴²⁰ Support for a biologically important role for this receptor comes from data in both mice with targeted deletions of P2X₁, which have impaired *in vivo* thrombus formation,¹⁴²² and mice that overexpress P2X₁, which have a prothrombotic phenotype.¹⁴²³ A variant of P2X₁ P(2X1del), which lacks 17 amino acids, has been described in megakaryocyte-like cell lines,¹⁴²⁴ but its functional role is uncertain.^{1418,1419}

Several antiplatelet agents inhibit ADP-induced platelet activation. Thus, metabolites of ticlopidine, clopidogrel, and prasugrel inhibit the P2Y₁₂ receptor¹⁴²⁵ (Chap. 134), whereas soluble CD39 catabolizes ADP and ATP.¹⁴²⁶

Epinephrine: α_2A Adrenergic Receptors

When added to platelet-rich plasma, epinephrine uniquely-initiates a first phase of aggregation without first inducing shape-change; after a plateau period, a second wave of aggregation occurs. The ability of epinephrine to synergize with other agonists, such as ADP, is well documented, but there is controversy as to whether epinephrine, in the absence of released ADP or TXA₂, is sufficient to initiate platelet aggregation.^{1427–1429} Epinephrine can cause an elevation in intracellular Ca²⁺, even in aspirin-treated platelets,¹⁴²⁷ possibly by opening an external channel or causing release of calcium from membrane sources^{1428,1429}; it does not appear to mobilize intracellular Ca²⁺ or generate measurable amounts of IP₃. Analysis of the purified epinephrine receptor and its nucleotide sequence identified it as a seven-transmembrane, G-protein-coupled, α_2A adrenergic receptor of Mr 64,000.^{1430,1431} It couples to G α_i family members, primarily G α_z , to inhibit adenylyl cyclase and thus prevent formation of cAMP.¹⁴³² The reduction in cAMP caused by epinephrine is probably not sufficient, however, to initiate platelet aggregation, and it is likely that other effectors are required for platelet activation.^{1433–1436} Platelets from a patient with a chronic bleeding disorder contained reduced amounts of G α_i1 and displayed impaired epinephrine-induced aggregation, suggesting that G α_i1 may also contribute to epinephrine-mediated responses.¹⁴³⁷ Polymorphisms of the α_2A adrenergic receptor have been associated with enhanced platelet reactivity and signaling.^{1438,1439}

The physiologic and pathologic significance of epinephrine-induced platelet activation remain unclear, but there is a possibility that sympathetic stimulation may contribute to enhanced platelet activation.¹⁴⁴⁰ In particular, in animal models, infusion of epinephrine can enhance platelet thrombus formation and can overcome the inhibition produced by aspirin.^{1441,1442} Increased sympathetic tone may thus account for the resistance to antiplatelet agents during acute coronary syndromes.¹⁴⁴³

Thromboxane A₂ and Other Arachidonic Acid Metabolites: Thromboxane Prostanoid Receptor

The metabolism of arachidonic acid (AA) to TXA₂ is a fundamental pathway contributing to agonist-induced platelet activation and aggregation. Many agonists stimulate the release of AA from phosphatidylcholine (PC) and PE in the plasma membrane.¹⁴⁴⁴ Most AA is released by the action of PLA₂, but some is also released by the concerted actions of PLC and DAG kinase, followed by PLA₂ and perhaps by the action of PLC followed by the action of DAG lipase. PLA₂ is a cytosolic enzyme, with multiple isoforms in platelets.¹⁴⁴⁵ PLA₂ acts on the C2 position of triacylglycerols such as PC and PE to form free AA and the resulting lysophospholipid. PLA₂ also converts phosphatidic acid into lysophosphatidic acid, which is also a platelet agonist. Some PLA₂ isozymes are activated by the rise in intracellular platelet Ca²⁺ that occurs during agonist-stimulated activation, whereas other isozymes are activated in a Ca²⁺-independent manner. Studies in mice¹⁴⁴⁶ and in a patient with recurrent small intestinal ulcers and platelet dysfunction¹⁴⁴⁷ have identified cytosolic PLA₂ α as the principal PL responsible for the liberation of the AA that is essential for eicosanoid biosynthesis in platelets. Ligand binding to integrin $\alpha_{IIb}\beta_3$ activates cytosolic PLA₂ α , perhaps through one or more intermediary proteins.¹⁴⁴⁸

AA is subsequently metabolized by cyclooxygenase (COX) to generate PGs and TX and by LOX to generate leukotrienes (LTs) and hydroxyeicosatetraenoic acids (HPETEs). The main COX in platelets, COX-1, metabolizes AA to PGG₂, which is subsequently converted to PGH₂.^{1449,1450} TX synthase next converts PGH₂ to TXA₂, which is spontaneously and rapidly converted to the inactive metabolite, TXB₂.¹⁴⁵¹ TXA₂ and its precursor, PGH₂, can both stimulate platelet TX receptors to induce platelet aggregation.^{1451–1453} An inducible COX (COX-2) is present in many cells involved in mediating the inflammatory response and megakaryocytes, but only trace amounts are present in normal platelets.^{1454,1455} COX inhibitors such as aspirin inhibit platelet function by inhibiting COX-1 and decreasing TXA₂ production.¹⁴⁵¹ It has been hypothesized that some patients whose platelets are resistant to aspirin inhibition may have increased amounts of COX-2, which is not as readily inhibited by aspirin as COX-1.¹⁴⁵² Selective COX-2 inhibitor drugs are associated with increased risk of thrombosis and this is ascribed to their inhibition of endothelial cell prostacyclin production without the compensatory inhibition of TXA production via COX-1.¹⁴⁵⁶

TXA₂ is a potent platelet agonist that exerts its effects via interaction with specific members of the thromboxane prostanoid receptor (TP) family of G-protein-coupled receptors. There are two TP isoforms in human platelets (TP α and TP β), which arise from alternative splicing of exon 3 of the TP gene; TP β , but not TP α , undergoes agonist-induced internalization.¹⁴⁵⁷ Although both TP α and TP β mRNA can be detected in platelet lysates, it appears that TP α is the dominant form.¹⁴⁵⁸ The TXA₂ receptor has been localized to the platelet plasma membrane and on sodium dodecylsulfate (SDS)-polyacrylamide gel electrophoresis it migrates as a broad band of Mr 55,000 to 57,000,^{1459,1460} the range a result of variability in glycosylation.¹⁴⁵⁸ Pharmacologic studies suggest the existence of two distinct TXA₂ receptor subtypes based on differing affinities for agonist ligands. The low-affinity binding sites may mediate platelet aggregation and granule secretion, whereas the high-affinity sites seem to be associated with platelet shape change.¹⁴⁶¹ Studies of TP-deficient mice demonstrate that this gene locus is responsible for most, if not all, the biologic effects attributed to TXA₂.¹⁴⁶² Bleeding times in these mice are prolonged, confirming the importance of this pathway in normal hemostasis. Platelet aggregation to collagen, but not ADP, is delayed, demonstrating the importance of TXA₂ production to the collagen response in platelets. TXA₂ pathways activate G α_q ,^{1415,1463} G α_{12} and G α_{13} ,^{1464,1465} G α_{11} ,¹⁴⁶⁶ and G α_i2 .^{1467,1468} Activation of G α_q is essential for aggregation and secretion whereas the G $\alpha_{12/13}$ -pathways

contribute to shape change and aggregation.^{1469–1471} It is unclear whether TP directly couples to $G_{\alpha I}$ ¹⁴⁷² or activates this pathway indirectly via released ADP.^{1467,1470} A significant portion of PGH_2/TXA_2 -induced platelet aggregation is actually mediated by secreted ADP, because ADP scavenger systems inhibit aggregation induced by a stable PGH_2/TXA_2 analogue either partially (30 percent)¹⁴⁷³ or totally.¹⁴⁷²

AA can also be converted to LTs and lipoxins by the sequential actions of LOX and other enzymes. Platelets from most animal species lack 5-LOX, but possess 12-LOX. Consequently, AA liberated by cytosolic $PLA_2\alpha$ can be oxygenated by 12-LOX to generate 12-HPETE, an unstable intermediate that is reduced by glutathione peroxidase or other mechanisms to generate HETE. The generation of 12-HPETE in platelets is slower and more sustained than the generation of TXA_2 .¹⁴⁷⁴ Platelets from mice deficient in the platelet-type 12-LOX are hypersensitive to stimulation by ADP, suggesting an inhibitory role for this pathway in platelet activation by ADP.¹⁴⁷⁵ 12-LOX activity in platelets can be regulated by signaling through the GPVI collagen receptor.¹⁴⁷⁶ Because they lack 5-LOX, platelets do not generate LTB_4 , nor do they appear to possess LTB_4 receptors.¹⁴⁷⁷ However, they participate in LT and lipoxin (LX) generation through transcellular metabolism involving leukocytes. Leukocyte metabolism of AA, some of which may be derived from platelets, by 5-LOX generates LTA_4 , which is then released and can be transformed by glutathione-S-transferase in platelets to LTC_4 .¹⁴⁷⁸ The generation of LTC_4 by platelets requires P-selectin-mediated adhesion to leukocytes.¹⁴⁷⁹ Leukocyte-derived LTA_4 can also be converted by platelets to the anti-inflammatory metabolite LXA_4 by the actions of 12-LOX in platelets.¹⁴⁸⁰

Thrombin

Thrombin is derived from the inactive zymogen, prothrombin, which circulates in plasma. When acted upon by the prothrombinase complex (FXa, FVa, Ca^{2+}) assembled on the membrane of activated platelets and other cells, prothrombin is cleaved into thrombin¹⁴⁸¹ (Chap. 113), one of the most potent platelet agonists. The proteolytic activity of thrombin is required for its role as a platelet agonist.¹⁴⁸² Thrombin activates PAR-1, a seven-transmembrane G-protein-coupled receptor on platelets and other cells,^{514,1483,1484} by cleaving an extracellular 41-amino-acid peptide from the N-terminus of the receptor (Fig. 112–16). Removal of this peptide results in a new aminoterminus, which acts as a “tethered ligand,” by binding to another region of PAR-1 to activate the receptor and initiate signal transduction. Short peptides modeled after the “tethered ligand” region (e.g., SFLLRN) also activate PAR-1 signaling. The 41-amino-acid cleavage product of PAR-1 can also induce platelet aggregation by a poorly defined mechanism.¹⁴⁸⁵ PAR-1 can also be cleaved to an active form by MMP-1 when platelets are stimulated with collagen, but the cleavage site is two amino acids N-terminal to the thrombin cleavage.¹³⁹⁰ A crystal structure of PAR-1 bound to vorapaxar, a small molecule antagonist recently approved for secondary prophylaxis of cardiovascular disease,¹⁴⁸⁶ has been solved and provides insights into PAR-1 activation by the SFLLRN-tethered ligand.¹⁴⁸⁷

Cloning of PAR-1 and gene deletion experiments in mice led to the discovery of additional members of the PAR family^{1483,1488,1489}: PAR-1 and PAR-4 are the main thrombin signaling receptors on human platelets; PAR-3 and PAR-4 mediate thrombin activation on mouse platelets; and PAR-2 is a receptor for trypsin and other proteases. Short endogenous peptide sequences that function as selective agonists have been identified for PAR-1 (SFLLR), PAR-2 (SLIGK), and PAR-4 (GYPGQV). On human platelets, a full response to thrombin requires both PAR-1 and PAR-4.^{1489,1490} The receptors display distinct kinetics of activation and desensitization; PAR-1 mediates a substantial portion of thrombin signaling, but PAR-4 contributes at high doses of thrombin.^{1490–1493} PAR-3 and PAR-4 serve as thrombin receptors on murine platelets,¹⁴⁸⁸ where PAR-4 is the primary signaling molecule¹⁴⁹⁴ and PAR-3 functions

Figure 112–16. Protease-activated receptor (PAR)-1 activation by thrombin. Thrombin cleaves PAR-1 N-terminus and exposes a new N-terminal peptide SFLLRN, which can bind to and activate the transmembrane core of PAR-1. PAR-1 can activate several G proteins, including G_i , $G_{12/13}$, and G_q . (Reproduced with permission from Zhang C, Srinivasan Y, Arlow DH, et al: High-resolution crystal structure of human protease-activated receptor 1. *Nature* 492(7429):387–392, 2012.)

as a cofactor for the cleavage and activation of PAR-4 by thrombin.¹⁴⁹⁵ Deficiency of either PAR-4 or PAR-3 results in a bleeding defect and protection from experimental thrombosis in mice.^{1494,1496}

When platelets are exposed to a subaggregating concentration of thrombin, they become relatively insensitive to subsequent stimulation with an aggregating concentration of thrombin, a process termed homologous desensitization. This involves rapid receptor internalization and alterations in the thrombin receptor signaling systems.¹⁴⁹⁷ Trafficking of the thrombin receptor to lysosomes is dictated by the amino acid sequence in the cytoplasmic tail of PAR-1 and requires phosphorylation. In comparison with PAR-1, activation-dependent internalization of PAR-4 occurs to a lesser extent and termination of PAR-4 signaling occurs more slowly,¹⁴⁹³ resulting in distinct patterns of signaling through each receptor.

PAR-1 activation can be either proinflammatory or antiinflammatory, depending on the dose of thrombin. PAR-1 activation in nonhematopoietic cells contributes to the innate immune response to viral infection with influenza A and coxsackievirus B3 in animal models¹⁴⁹⁹ but in other models PAR-1 activation enhances influenza A pathogenicity in response to severe infection and PAR-1 deficiency offers protection.¹⁵⁰⁰ Thus, the relative roles of platelet PAR-1 and tissue-specific PAR-1 in viral infections are complex.¹⁵⁰¹

Thrombin can bind to GPIIb α , and platelets from patients lacking the GPIIb/IX complex (Bernard-Soulier syndrome) have decreased thrombin-induced platelet aggregation (Chap. 121). A region on GPIIb α with three sulfated tyrosines and a large number of anionic amino acids, with homology to the high-affinity thrombin inhibitor hirudin, contains the thrombin binding site.^{1132,1502} Tertiary structures of the extracellular, aminoterminus domain of GPIIb α bound to thrombin indicate that two thrombin molecules interact with each GPIIb α .^{1503,1504} This bivalent interaction may allow thrombin to serve as a bridge linking GPIIb α receptors on the same or adjacent platelets.^{1132,1502} Binding of thrombin to GPIIb may also enhance activation via PAR-1. Thrombin can activate platelets via interaction with GPIIb even when both PAR-1 and PAR-4 have been desensitized, and there may be a still unidentified mechanism by which thrombin activates platelets independent of PAR-1, PAR-4, and GPIIb.¹⁵⁰⁵

Tachykinins: Substance P and Endokinins A and B

The tachykinin neurotransmitter substance P induces platelet aggregation and the release reaction at micromolar concentrations and enhances aggregation induced by other agonists at lower concentrations.¹⁵⁰⁶ Platelets express two seven-transmembrane G-coupled-receptors for substance P (NK₁ and NK₂) and NK₁ has been implicated in mediating the response to substance P.¹⁵⁰⁷ In addition, an amidated peptide from the C-terminus of the related tachykinins, endokinins A and B (GKASQFFGLM-NH₂), initiates platelet aggregation. Substance P has also been identified in platelets and platelets secrete substance P when activated.

Chemokines: Chemokine Receptors CCR1, CCR3, CCR4, CXCR1, CXCR4

Based on monoclonal antibody binding and/or mRNA expression studies, platelets and/or megakaryocytes have been reported to express the seven-transmembrane G-protein-coupled chemokine receptors CCR1, CCR3, CCR4, CXCR1, and CXCR4 (reviewed in Refs. 762 and 1508). These receptors may play a role in megakaryopoiesis and platelet production. In addition, a number of chemokines, in particular PF4 (CXCL4), CXCL12, CCL13, and CCL22, have been variably found to be able to either augment platelet activation and aggregation induced by other agonists, or to actually fully initiate platelet adhesion, activation, and aggregation. Because high concentrations of the chemokines relative to plasma concentrations are required to demonstrate these effects, it is unclear what role these receptors play in platelet physiology, but it is possible that local chemokine levels are higher in areas of inflammation.

Lipid Mediators (Platelet-Activating Factor, Lysophosphatidic Acid, and Sphingosine-1-Phosphate)

PAF (a mixture of 1-O-hexadecyl-2-acetyl-sn-glycero-3-phosphocholine and 1-O-octadecyl-2-acetyl-sn-glycero-3-phosphocholine¹⁵⁰⁹) is a phospholipid ether produced by platelets, leukocytes, and other cells. PAF is a potent platelet agonist and mediator of inflammation. Cellular responses to PAF are mediated by a specific seven-transmembrane G-protein-coupled receptor.^{1510,1511} PAF induces G-protein-dependent inhibition of adenylyl cyclase and activation of PLC,¹⁵¹² which cause phosphoinositide turnover, leading to the activation of PKC and an increase in intracellular Ca²⁺.¹⁵¹¹ PAF also indirectly activates PLA₂, which causes release of AA from the platelet membrane.¹⁵¹³ All of these effects contribute to the overall platelet response to PAF. PAF is catabolized by PAF acetylhydrolase and this enzyme may play an important role in inflammation and atherosclerosis.¹⁵¹⁴

LDLs activate human platelets, and oxidized LDLs are more potent platelet activators. One active component in oxidized LDLs is oxidized phosphatidylcholine (oxPC₃₆), which increases with diet-induced hyperlipidemia. oxPC₃₆ signals through CD36¹³²⁵ via phosphorylation of the MAPKs p38 and c-Jun N-terminal kinase.¹³²³ Platelet activation by oxidized LDLs in the absence of hyperlipidemia may also require SR A.¹³²⁴ Increases in levels of oxPC₃₆ with hyperlipidemia may provide an explanation for observations that atherogenic mice have a prothrombotic phenotype as indicated *in vivo* by decreased tail-bleed time and propensity to thrombosis in response to either ferric chloride or photochemical injury, and *in vitro* by increased platelet aggregation.^{1325,1515}

Activated platelets likely contribute to lysophosphatidic acid (LPA) generation in blood¹⁵¹⁶ via lysophospholipase D (lysoPLD)-catalyzed hydrolysis of a lysophosphatidyl choline (LPC).¹⁵¹⁷ Autotaxin, initially identified as a tumor-cell derived motility factor, appears to be responsible for the majority of lysoPLD activity in serum; it is also responsible for the formation of LPA from LPC¹⁵¹⁸ and release of autotaxin from platelets may promote tumor cell metastasis through the generation of

LPA.¹⁵¹⁹ Mild oxidation of LDL generates LPA, and the LPA component of oxidized LDL in the lipid-rich thrombogenic core of atherosclerotic lesions exposed during plaque rupture may be an important platelet activator.¹⁵²⁰

In human platelets, LPA elicits shape change,¹⁵²¹ platelet-monocyte aggregate formation,¹⁵²² and fibronectin-matrix assembly¹⁵²³; it also potentiates ADP-induced platelet aggregation. LPA signaling pathways couple by activation of the small G-protein Rho,¹⁵²¹ Src kinase activity, and calcium entry,¹⁵²⁴ with little activation of Gq-dependent pathways.¹⁵²⁵ Some of the platelet responses to LPA in whole blood are attenuated by P2Y₁ and P2Y₁₂ receptor antagonists, suggesting that released ADP may play an important role in mediating aspects of the response to LPA.¹⁵²⁴ The platelet receptor(s) responsible for LPA signaling are not known.

S1P is a weaker activator of platelets than LPA and requires high concentrations (>10 μM) to induce platelet aggregation,¹⁵²⁶ raising the possibility that a contaminant or a S1P-derived metabolite may account for its biologic activity.¹⁵²⁷ S1P elicits platelet shape change,¹⁵²⁸ activates protein kinases, and stimulates fibronectin matrix assembly.¹⁵²³ Paradoxically, S1P has also been reported to inhibit thrombin- and epinephrine-induced platelet aggregation.¹⁵²⁹

Serotonin

Platelets serve as the major serotonin (5-hydroxytryptophan [5HT]) storage site in the circulation because they have the capacity to take it up actively and store it in dense granules. The release of serotonin from dense granules during platelet activation may amplify platelet aggregation and granule release. Serotonergic receptors, which are seven-transmembrane G-protein-coupled receptors, exist in seven main subfamilies termed 5HT₁ to 5HT₇.¹⁵³⁰ The receptor that mediates serotonin's effects on platelet function is of the 5HT_{2A} subtype and is identical to the 5HT_{2A} receptor present in the brain frontal cortex.¹⁵³¹⁻¹⁵³⁴ The 5HT₂ receptor-blocking compound ketanserin antagonizes serotonin's stimulatory effects on platelets and neurons.¹⁵³⁵ Two naturally occurring amino acid substitutions have been identified in the receptor.¹⁵³⁶ Platelets from patients heterozygous for the H452Y polymorphism have a blunted calcium response when stimulated with serotonin compared to platelets from patients homozygous for H452.¹⁵³⁶ Silent polymorphisms in the 5HT_{2A} gene (T102C in exon 1 and -1438A/G in the promoter region) have been correlated with nonfatal acute MIs and enhanced 5HT_{2A} receptor-mediated small platelet aggregate formation.¹⁵³⁷ Many studies have been performed correlating platelet serotonin transporter activity and 5HT_{2A} receptors with a number of neuropsychiatric disorders.¹⁵³⁸⁻¹⁵⁴² There is some concern, however, about the correlation between 5HT_{2A} receptors on platelets and those in the brain.¹⁵⁴³ Hyper-responsive 5HT_{2A} receptors have been implicated in the association between depression and increased risk of cardiovascular events.¹⁵⁴⁴

Addition of serotonin in micromolar concentrations to platelets *in vitro* causes elevation of intracellular calcium, PLC activation, protein phosphorylation, and mild aggregation.^{1545,1546} In whole blood, serotonin does not itself cause platelet aggregation, but it does enhance aggregation induced by ADP and thrombin.¹⁵⁴⁷ Serotonin released from platelets can cause vasoconstriction of blood vessels that have suffered endothelial damage,¹⁵⁴⁸ further promoting thrombus formation. Inhibition of serotonin's action has a favorable effect in animal models of thrombosis and vascular damage, but it is not clear whether the benefit derives from effects on platelet aggregation or vasoconstriction.¹⁵⁴⁹ Mice deficient in serotonin have prolonged bleeding times, suggesting a physiologic role for serotonin in hemostasis.¹⁵⁵⁰

A role for serotonin in linking procoagulant proteins to activated platelets has been described. Serotonin can attach via a transglutaminase-dependent reaction to multiple substrates, including fibrinogen, VWF,

thrombospondin, fibronectin, and α_2 -antiplasmin. These serotonylated proteins then associate to a subpopulation of activated platelets termed “coated” platelets, perhaps via interactions with fibrinogen or thrombospondin.^{1550,1551} Tissue transglutaminase in platelets can also catalyze the addition of serotonin to the small G-proteins Rab4 and RhoA in a reaction that renders them constitutively active and promotes α -granule secretion.¹⁵⁵²

The serotonin transporter (SERT), which takes up and releases serotonin, contributes to platelet stores of serotonin. Expression of SERT is required for normal ADP- and thrombin-mediated aggregation of mouse platelets.¹⁵⁵³ Furthermore, SERT activity is enhanced by ligand binding to integrin $\alpha_{IIb}\beta_3$. Case reports have suggested an association between the use of a serotonin reuptake inhibitor and bleeding abnormalities.¹⁵⁵⁴ Reports conflict as to whether these antidepressants may protect from MI or reduce the complications of acute thrombosis. In mice, platelet release of serotonin is essential for liver regeneration following partial hepatectomy.¹⁵⁵⁵

Vasopressin: V_1 -Type Receptor

Vasopressin interacts with platelets to induce shape change, aggregation, and dense granule release.¹⁵⁵⁶ These events follow an induced rise in intracellular calcium and PLC activation.¹⁵⁵⁷ The platelet binding site is classified pharmacologically as a V_1 -type receptor,¹⁵⁵⁸ and radiolabeled vasopressin binds with a K_D of 1 to 10 nM.¹⁵⁵⁹ Unlike the case with V_2 receptors that activate adenylate cyclase, the V_1 receptors appear to activate PLC,¹⁵⁶⁰ perhaps via coupling through G α q11.¹⁵⁶¹ There are fewer than 100 binding sites for vasopressin per platelet,¹⁵⁶² and there is controversy as to whether physiologic concentrations of vasopressin are sufficiently high to activate platelets directly^{1563,1564}; even if vasopressin does not directly activate platelets, it may be able to enhance platelet activation induced by other agonists. Vasopressin V_{1a} receptor antagonists inhibit vasopressin-induced platelet aggregation.^{1565,1566}

Angiotensin II: AT1-Type Receptor

Platelets express angiotensin II (AngII) AT1-type receptors.¹⁵⁶⁷ AngII treatment of platelet-rich plasma results in shape change but not platelet aggregation.^{1568,1569} Infusion of AngII into normal volunteers results in platelet activation as assessed by plasma β -thromboglobulin levels and platelet surface expression of P-selectin and fibrinogen binding sites.¹⁵⁷⁰ Certain AT1 receptor antagonists, such as losartan and irbesartan, competitively inhibit TXA₂ receptors on platelets.^{1569,1571,1572} AT1 receptor antagonists stimulate NO release from isolated platelets.¹⁵⁷³ In hypertensive rats treated with losartan, platelet function appears to be attenuated,¹⁵⁷⁴ but data in humans on the effects of administering AT1 receptor antagonists are inconsistent.^{1575–1578}

Thrombospondin: Integrin-Associated Protein (Cd47)

Thrombospondin (TSP), a large disulfide-bonded trimer (subunit Mr 160,000), is both a platelet α -granule protein and an extracellular matrix protein present in the subendothelium. TSP is rapidly released from platelets upon thrombin stimulation. In addition to its role as an adhesive protein, TSP also functions as an agonist to stimulate integrin $\alpha_{IIb}\beta_3$ -mediated platelet aggregation.^{386,1579} Multiple potential TSP receptors are present on platelets, including CD36, integrins $\alpha_{IIb}\beta_3$ and $\alpha_V\beta_3$, and integrin-associated protein (termed CD47). Of these receptors, CD47 is most strongly implicated as the major signaling receptor in response to TSP. CD47 was first discovered as a protein that copurifies with integrins, including integrins $\alpha_{IIb}\beta_3$,³⁸⁶ $\alpha_V\beta_3$,¹⁵⁸⁰ and $\alpha_2\beta_1$.¹⁵⁸¹ The sequence of CD47 indicates that it has a single immunoglobulin-like extracellular domain, five membrane spanning regions, and a short cytoplasmic tail.^{391,1579,1580} CD47 probably generates signals independent of integrins and affects integrin function via downstream effects. CD47 couples

physically and functionally to the large G-protein, G α I,¹⁵⁸² which is of note because all known large G-proteins couple to receptors with seven rather than five transmembrane spanning regions. Further downstream signaling probably involves the activation of tyrosine kinases, including Syk, Lyn, and Fak, as well as PLC γ 2.¹⁵⁸³ Studies of mice with targeted deletions of CD47 indicate that it may block the inhibitory effects of NO on platelets,¹⁵⁸⁴ which may contribute to its role in stimulating platelet adhesion to activated endothelium under low shear rates.¹⁵⁸⁵

How other TSP binding sites on platelets contribute to the overall response induced by TSP is not clear. CD36 copurifies with several tyrosine kinases, including Fyn, Lyn, and Yes.¹³¹⁵ However, whether TSP binding to CD36 activates these kinases and whether they then contribute to the observed platelet response is unknown.

TSP also functions as a reductase for VWF; in α granules it appears to reduce VWF multimer size.^{1586,1587} In contrast, TSP also binds to the A3 domain of plasma VWF, where it competes for ADAMTS-13 binding, thus slowing the rate of VWF cleavage, thus favoring large multimers.¹⁵⁸⁷ TSP also makes a small, but significant, contribution to the conversion of latent TGF- β_1 released from platelets to active TGF- β_1 .⁴⁷⁸

Collagen: GPVI and Integrin $\alpha_2\beta_1$

Upon vascular injury, collagens in the subendothelium become exposed to flowing blood and promote both platelet attachment and activation, thereby contributing to normal hemostasis. Collagen is also one of the most thrombogenic substances in atherosclerotic plaques, and upon plaque rupture it is believed to contribute to platelet aggregation and thrombus formation, leading to ischemic damage (Fig. 112–17).¹⁵⁸⁸ The types of collagen present in the subendothelium include: I, III, IV, V, VI, VIII, and XIII,¹⁵⁸⁹ the most abundant being types I and III (greater than 95 percent). Under conditions that mimic physiologic blood flow, platelets adhere tightly to collagen types I, III, and IV, weakly to types VI, VII, and VIII, and not at all to type V. However, under static conditions, platelets can adhere to types I to VIII.¹³³⁵ Collagens are normally acid insoluble fibers, but can form spiral microfibrils when subjected to proteolysis. Differences in the nature of the collagen surface influence its recognition by platelets.¹⁵⁹⁰

Collagen-induced platelet activation probably involves multiple receptors, most notably GPVI and integrin $\alpha_2\beta_1$, with indirect activation of PAR-1 via activation of MMP-1.¹³⁹⁰ GPVI is a Mr 62,000 glycoprotein from the immunoglobulin superfamily^{1591–1594} that functions in concert with the FcR γ -chain, with the latter initiating intracellular signaling.^{804,1167,1168,1595–1598} Other collagen receptors on platelets include CD36¹³⁰⁹ and a Mr 65,000 protein termed GP65.¹⁵⁹⁹ The I (inserted) domain in the α_2 subunit of integrin $\alpha_2\beta_1$ is homologous to a number of collagen-binding domains in other proteins and mediates adhesion of the receptor to collagen. Integrin $\alpha_2\beta_1$ recognizes spiral microfibrils, but not the acid insoluble form of collagen in which the monomers assume a banded pattern.¹⁵⁹⁰ The potential interrelation of all of the collagen receptors is unknown, but GPVI appears to be responsible for platelet interactions with insoluble collagens and GPVI and $\alpha_2\beta_1$ work in concert to recognize collagen spiral microfibrils, perhaps by assembling intracellular proteins into complexes.^{964,1600,1601}

GPVI exists as both monomer and dimer in a stable physical complex with the dimeric FcR γ -chain; FcR γ -chain is absent from GPVI-deficient platelets.^{1168,1171,1180} The tertiary structure of GPVI revealed a dimeric structure with parallel orientation of the collagen binding domains, separated by a distance (5.5 nm) that matches the orientation of the collagen triple helix.¹⁵⁹⁶ Molecular docking studies suggested that collagen interacts with a shallow groove on the surface. The addition of either collagen or an antibody that can crosslink GPVI induces tyrosine phosphorylation of the FcR γ -chain.¹¹⁸⁰ The kinases contributing to this event are probably Fyn and/or Lyn.^{1041,1104,1602} Tyrosine phosphorylation

Figure 112-17. Collagen activation of platelets. The platelet collagen receptor GPVI is physically and functionally coupled to the immunoreceptor tyrosine-based activation motif (ITAM)-containing FcR γ -chain. Upon collagen binding to GPVI, GPVI dimerizes as a result of oxidation of intracytoplasmic thiol groups (not shown) and then tyrosine motifs within the FcR γ -chain are phosphorylated (P) by the Src family kinase Fyn. This action initiates a chain of events that includes recruitment of the tyrosine kinase Syk, which is phosphorylated and activated by Fyn and Lyn, and phosphorylation of adaptor proteins LAP and SLP76. A signaling cascade activates Bruton tyrosine kinase (BTK), phospholipase C (PLC)-2, protein kinase C (PKC), and phosphoinositol 3'-kinase (PI3K). Ultimately integrins $\alpha_2\beta_1$ and $\alpha_{1b}\beta_3$ are converted to a high-affinity ("active") state. Activation of $\alpha_2\beta_1$ promotes firm adhesion to collagen and reinforces intracellular signaling pathways.

of the ITAM on the FcR γ -chain increases the motif's affinity for proteins containing SH2 domains, resulting in the recruitment of such proteins to the FcR γ -chain.^{1041,1044} The nonreceptor tyrosine kinase Syk contains two adjacent SH2 domains and a tyrosine kinase domain. In platelets from normal mice, Syk physically associates with the FcR γ -chain and becomes phosphorylated and activated after collagen stimulation,¹¹⁸⁰ whereas in platelets from mice lacking FcR γ -chain, collagen is unable to induce Syk phosphorylation and activation.¹⁵⁹⁷ Similarly, in platelets lacking GPVI or in platelets in which integrin $\alpha_2\beta_1$ is blocked, collagen-induced Syk phosphorylation is also inhibited, demonstrating that GPVI, integrin $\alpha_2\beta_1$, and Syk all participate in the platelet response to collagen. The β subunit of the integrin $\alpha_2\beta_1$ also displays Tyr residues spaced in a manner reminiscent of an ITAM motif, and thus it is possible that Syk might also associate with this collagen receptor. In addition to Syk,¹⁶⁰³ Src also becomes tyrosine phosphorylated in response to collagen. Although Src is an abundant kinase in platelets, its role in platelet signaling is unclear, as mice lacking Src do not suffer from any obvious bleeding disorder.¹⁶⁰⁵ Syk, on the other hand, appears to play a critical role in collagen activation of platelets as platelets from mice lacking Syk do not aggregate or undergo secretion in response to collagen.¹⁵⁹⁷

Collagen stimulation of platelets also results in tyrosine phosphorylation and activation of PLC γ_2 ,¹⁶⁰⁶ and activation of this enzyme causes PI hydrolysis, leading to integrin $\alpha_{1b}\beta_3$ activation. PLC γ_2 activation occurs downstream of Syk, as evidenced by the findings that collagen is unable to activate PLC γ_2 in platelets pretreated with a Syk-selective inhibitor¹⁶⁰⁷ or in platelets from Syk knockout mice.¹⁵⁹⁷ It is unknown whether Syk activates PLC γ_2 directly, but Bruton tyrosine kinase (BTK) might be positioned between Syk and PLC γ_2 because patients lacking BTK not only exhibit the B-cell deficiency X-linked agammaglobulinemia, but also show reduced platelet responsiveness to collagen and diminished phosphorylation of PLC γ_2 .¹⁶⁰⁸ Signaling via GPVI also activates the other major collagen receptor integrin $\alpha_{1b}\beta_3$,^{1609,1610} perhaps via talin binding to the β_1 cytoplasmic domain,²⁴⁵ elimination of an inhibitory influence of the α_2 cytoplasmic domain,²⁴⁵ and/or extracellular disulfide exchange.⁹⁷³

Intermediate events of GPVI signaling involve the activation of a small G-protein, Rap-1, which has been implicated in integrin activation in platelets and megakaryocytes.¹⁶¹¹ Full GPVI-induced Rap-1 activation appears to involve both release of ADP (acting on the P2Y $_{12}$ ADP receptor) and ADP receptor-independent pathways.¹⁶¹² GPVI signaling

also results in the activation of at least one negative regulator of platelet function, c-CBL, which is tyrosine phosphorylated and activated downstream of Src kinases. Platelets deficient in c-CBL show enhanced aggregation responses in response to GPVI engagement.¹⁶¹³ While much of the GPVI-mediated signaling occurs via the associated FcR γ , the cytoplasmic domain of GPVI also contains a highly basic region that binds calmodulin and a Pro-rich region that binds Src kinases, which also appear to contribute to GPVI-mediated signaling.¹⁶¹⁴ GPVI signaling also leads to the generation of reactive oxygen species.¹⁶¹⁵

Integrin $\alpha_2\beta_1$ can also signal in response to collagen, independent of GPVI and induce phosphorylation and activation of many of the same signaling components attributed to the GPVI-induced signaling cascade, such as Src, Syk, SLP-76, and PLC2. Other components include plasma membrane calcium ATPase and FAK.¹⁶¹⁶ However, separate studies indicate that integrin $\alpha_2\beta_1$ must be in an active conformation in order to participate in this signaling.^{967,1617} Thus it appears that collagen-induced signaling via GPVI activates integrin $\alpha_2\beta_1$, allowing both receptors to participate in the signaling necessary for a full response to collagen.¹⁶¹⁷

The inactive form of MMP-1 (proMMP-1) is associated with integrin $\alpha_2\beta_1$,¹³⁹⁰ as well as integrin $\alpha_{IIb}\beta_3$.¹⁶¹⁸ With collagen activation, MMP-1 becomes activated and then can cleave the N-terminal region of PAR-1, resulting in the generation of a new N-terminal that can insert into the receptor and initiate downstream signaling through the p38 MAPK, Rho-GTP pathway. Of note, the cleavage of PAR-1 by MMP-1 is at a site two amino acids N-terminal to the cleavage site of thrombin. The combined activation of PAR-1, integrin $\alpha_2\beta_1$, and GPVI may account for the high thrombogenicity of collagen surfaces.

The levels of GPVI and integrin $\alpha_2\beta_1$ expressed on platelets vary among individuals, but it is unclear whether there is a correlation between the levels of expression of each of them.^{983,1619-1621} The level of expression of these receptors correlates with the ability of platelets to be stimulated by collagen. GPVI is present on the membranes of the open canalicular system and α granules, but these pools are not detectable on the surface of resting platelets. These pools merge with the plasma membrane pool in stimulated platelets, increasing the apparent surface expression of GPVI by approximately 60 percent.¹⁶²²

CD36 can also bind collagen and antibodies to CD36 partially inhibit platelet adhesion to collagen.^{1623,1624} Platelets from patients lacking CD36 responded normally to collagen in one study,¹⁶²⁵ but showed a minor defect in adhesion to collagen under flow conditions in another.¹⁶²⁶

Platelets stimulated with collagen exhibit several distinct responses. Although elevated cAMP levels normally inhibit platelet aggregation, collagen-stimulated platelets are relatively resistant to inhibition by cAMP.¹⁶²⁷ This may be related to the fact that collagen stimulates the PLC γ isotype, which is insensitive to cAMP-mediated inhibition, whereas other agonists such as thrombin stimulate PLC β , which is inhibited by cAMP. In addition, phosphatase inhibition decreases collagen-, but not thrombin- or ADP-induced platelet aggregation,¹⁶²⁸ suggesting that one or more phosphatases are critical in collagen-induced platelet aggregation.

GPb/IX/V

The GPIb/IX/V complex promotes the initial interactions of platelets with VWF, particularly under conditions of high shear, resulting in platelet tethering. GPIb/IX/V can also initiate signals that activated the integrin $\alpha_{IIb}\beta_3$ receptor, resulting in firm platelet adhesion and aggregation.¹⁰³⁵ Some of the first evidence that the GPIb/IX/V complex could serve as a signaling receptor came from studies in which antibodies to integrin $\alpha_{IIb}\beta_3$ partially inhibited ristocetin-induced

platelet aggregation.²⁸⁴ Subsequently, ristocetin-mediated interaction of VWF with platelets was observed to cause PIP₂ metabolism, activation of PKC, and an increase in intracellular Ca²⁺. Likewise, shear forces initiate signaling through the binding of VWF to GPIb/IX/V.¹⁶²⁹ In heterologous systems such as Chinese hamster ovary (CHO) cells expressing both GPIb/IX and integrin $\alpha_{IIb}\beta_3$, occupancy of GPIb/IX by VWF can lead to activation of $\alpha_{IIb}\beta_3$.^{1630,1631} In platelets, the GPIb/IX/V complex associates with signaling proteins with ITAM motifs, such as Fc γ RIIA receptor¹⁶³² and FcR γ -chain¹¹⁰⁵; however, engagement of GPIb/IX/V alone is sufficient to activate integrin $\alpha_{IIb}\beta_3$.¹⁶³³ The signaling pathway triggered by engagement of GPIb/IX/V is incompletely understood but appears to involve activation of Src^{1523,1633,1634} and PI3K, and recruitment of the adaptor proteins SLP-76 and ADAP (SLAP-130).¹⁶³³ The result is activation of PLC γ_2 ,¹⁶³⁵ PKC, and integrin $\alpha_{IIb}\beta_3$. Signaling through the GPIb/IX/V complex also causes release of AA and generation of TXA₂. A cyclic guanosine monophosphate (cGMP) and MAPK-dependent pathway for GPIb/IX-mediated activation of integrin $\alpha_{IIb}\beta_3$ has also been reported.¹⁶³⁶ The GPIb/IX/V complex binds several intracellular proteins, including filamin (actin binding protein),¹⁰⁹² calmodulin,¹⁶³⁷ and 14-3-3 ζ .^{1090,1638,1639} Activation of c-RAF by 14-3-3 ζ may link GPIb/IX/V signaling to the MAPK signaling pathway; moreover, protein 14-3-3 ζ exists as a dimer, which may allow it to bridge and dimerize GPIb molecules.¹⁶³⁹ In CHO cells, clustering of GPIb/IX promotes stable adhesion via integrin $\alpha_{IIb}\beta_3$.¹⁶⁴⁰

The GPIb/IX/V complex also appears to be involved in transmitting at least one cAMP-dependent inhibitory signal. Thus, elevated cAMP, which activates protein kinase A (PKA), induces phosphorylation of GPIb β on Ser 166.¹⁰⁹¹ Elevated cAMP also normally inhibits agonist-induced platelet actin polymerization. However, in platelets from patients with Bernard-Soulier syndrome, which lack GPIb/IX/V, actin polymerization proceeds normally after collagen stimulation, even when cAMP is elevated, suggesting that cAMP-mediated phosphorylation of GPIb β may be required for the cAMP-mediated inhibition.¹⁶⁴¹

GPV, a Mr 82,000 membrane-spanning protein that is a member of the leucine-rich repeat family and complexes with GPIb/IX, is a substrate for thrombin.¹⁶⁴² GPV-null platelets display enhanced responses to thrombin¹¹⁵⁰ and GPV-null mice have accelerated thrombus growth in response to vascular injury.¹⁶⁴³ Proteolytically inactive thrombin selectively activates mouse platelets lacking GPV and induces thrombosis in GPV-deficient but not wild-type mice.¹¹⁵¹ Together, these observations suggest that GPV may function as a negative regulator of thrombin signaling through GPIb/IX, and in its absence, thrombin may function as a ligand for GPIb/IX.

ADDITIONAL INTERMEDIATE SIGNALING MOLECULES

Calcium

Elevation of intracellular Ca²⁺ has a multitude of effects on platelet physiology.^{1435,1644} The concentration of Ca²⁺ in resting platelets (100 to 500 nM) is very low compared to the plasma concentration of Ca²⁺ (approximately 2 mM). Exposure of platelets to most agonists is accompanied by a rapid, transient rise in the intracellular free Ca²⁺ concentration to micromolar levels, followed by a less-rapid return to normal resting levels. The cytoplasmic Ca²⁺ concentration at any given time is a result of the rates of passive Ca²⁺ influx, active Ca²⁺ extrusion across the plasma membrane, and both active release and/or uptake of Ca²⁺ by the DTS/sarcoplasmic reticulum (see "Dense Tubular System/Sarcoplasmic Reticulum" above), which is a Ca²⁺ storage depot in platelets analogous to the sarcoplasmic reticulum in muscle. Active Ca²⁺ extrusion and uptake of Ca²⁺ are mediated by several pumps (see Fig. 112-3). The cytosolic pool of Ca²⁺ turns over rapidly as a result of a plasma membrane

$\text{Na}^+/\text{Ca}^{2+}$ antiporter, whereas the DTS/sarcoplasmic reticulum contains a more slowly exchanging pool of Ca^{2+} regulated by a $\text{Ca}^{2+}/\text{Mg}^{2+}$ ATPase (sarco-/endoplasmic reticulum Ca^{2+} -ATPase 3 [SERCA3]), a pump that also appears to be located in the plasma membrane.¹⁶⁴⁵ During agonist stimulation, most Ca^{2+} enters the platelet cytosolic compartment through receptor-operated calcium channels (reviewed in Ref. 1646) in the plasma membrane. Collagen, for example, causes Na^+ entry into platelets, which reverses the $\text{Na}^+/\text{Ca}^{2+}$ antiporter to promote Ca^{2+} entry, thus contributing to platelet aggregation.¹⁶⁴⁷ Release of intracellular Ca^{2+} from the DTS/sarcoplasmic reticulum also occurs rapidly in response to agonist stimulation, in large a result of the IP_3 generated as part of the phosphoinositide cycle.^{1646,1648} The release of internal stores of Ca^{2+} results in translocation of STIM1 from the DTS/sarcoplasmic reticulum, followed by activation of the plasma membrane Ca^{2+} channel Orai1, leading to store-operated Ca^{2+} entry.¹¹⁹ Calcium entry is also supported by TRPC6 mediating non-store-operated mechanisms, induced by DAG.^{93,119,1646} The role of TRPC1 remains to be defined.^{93,119,1646} Integrin $\alpha_{\text{IIb}}\beta_3$ may also participate in Ca^{2+} entry.¹⁶⁴⁹

An intracellular rise of Ca^{2+} levels induces numerous downstream events, including activation of Ca^{2+} -sensitive forms of PLA_2 ¹⁶⁵⁰ and PKC¹⁶⁵¹; calmodulin-dependent enzymes such as myosin light-chain kinase, which phosphorylates myosin light chain¹⁶⁵² and promotes cytoskeletal rearrangements required for platelet shape change; and gelsolin, which facilitates actin severing and rearrangement, secretion, and aggregation. In addition, Ca^{2+} probably plays a direct role in controlling the secretory machinery, which mediates the membrane fusion events that result in degranulation and the release reaction. Calcium-dependent proteases or calpains also become activated and play an important role in postaggregation events. The Ca^{2+} binding protein CIB (calcium and integrin binding protein)¹⁶⁵³ binds to the membrane proximal region of $\alpha_{\text{IIb}}\beta_3$ and contributes to platelet spreading.³¹

Phosphoinositide 3'-Kinases

PI3Ks are a family of lipid kinases that phosphorylate the D-3 hydroxyl group of the myoinositol ring of phosphoinositides.^{1655,1656} Class I PI3Ks are heterodimeric protein complexes containing both adaptor and catalytic subunits that use PI, $\text{PI}(4)\text{P}$, and $\text{PI}(4,5)\text{P}_2$ as substrates to form $\text{PI}(3)\text{P}$, $\text{PI}(3,4)\text{P}_2$, and $\text{PI}(3,4,5)\text{P}_3$, respectively. Class Ia (PI3K α , PI3K β , and PI3K δ) and class Ib (PI3K γ) have distinct subunits and regulatory features. The catalytic subunit of class Ia PI3K is a Mr 110,000 to 120,000 protein; the adaptor subunit, p85 (PI3K p85 α), has two SH2 domains, a breakpoint cluster region homology domain, a Pro-rich region, and a single SH3 domain. Members of this class of PI3K possess intrinsic serine-threonine protein kinase activity in addition to lipid kinase activity, and they appear to be regulated, at least in part, by binding of the p85 subunit to tyrosine-phosphorylated proteins. Although platelets possess PI3K α and PI3K δ , the main class Ia member that is thought to contribute to platelet function is PI3K β . PI3K γ has been isolated from platelets and neutrophils and contains both regulatory (p101) and (p110 γ) subunits; the latter is activated by the β/γ subunit of heterodimeric G proteins. Both isoforms of PI3K appear to associate with the platelet cytoskeleton after agonist activation.

In platelets, 3-phosphorylated phosphoinositides are produced in response to a variety of agonists, including thrombin, TXA_2 , LPA, ADP, and collagen, and may mediate early signaling events that precede integrin $\alpha_{\text{IIb}}\beta_3$ activation, as well as late events involved in stabilizing fibrinogen binding and platelet aggregation.¹⁶⁵⁵⁻¹⁶⁵⁷ Thrombin stimulates rapid accumulation of $\text{PI}(3,4,5)\text{P}_3$ and $\text{PI}(3,4)\text{P}_2$,¹⁶⁵⁸ and late production of $\text{PtdIns}(3,4)\text{P}_2$; the latter requires fibrinogen binding to $\alpha_{\text{IIb}}\beta_3$ and calpain activity.¹⁶⁵⁹ Collagen promotes the association of class Ia PI3K via the SH2 domains with tyrosine-phosphorylated forms of Fc γ -chain and the regulatory protein, linker-for-activator T cells, to modulate PI3K.¹⁶⁶⁰

Platelets from mice lacking PI3K p85 α aggregate normally to ADP, thrombin, U46619 and phorbol esters, but display impaired responses to collagen and CRP and diminished tyrosine phosphorylation of the PI3K effectors Btk, Tec, Akt, and PLC γ_2 .¹⁶⁶¹ Fc γ RIIA-induced platelet aggregation requires PI3K activity, which is upstream of PLC γ_2 in the pathway.¹⁶⁶² Genetic deletion of PI3K β in mice results in embryonic lethality, but mice possessing a kinase dead form of the enzyme have been generated. Platelets from these mice have defects in G-protein-coupled receptor (GPCR)-, collagen-, and integrin-mediated signaling pathways.¹⁶⁶³ Platelets from mice lacking PI3K γ isoform aggregate normally to thrombin and collagen but have impaired responses to ADP, and PI3K γ -deficient mice are protected from ADP-induced thromboembolism.¹⁶⁶⁴ Platelets from mice expressing a kinase dead form of PI3K γ have defective GPCR-induced activation of Rap1 and aggregation, but normal responses through GPVI-activated pathways.¹⁶⁶⁵ A working model to explain the observations is that PI3K β serves as a common intermediary of signals elicited by GPCR, collagen, and integrin ligation, whereas PI3K γ primarily affects GPCR-initiated pathways. Many of the biologic actions of PI3K are mediated by their phospholipid products, which bind to specific sequences in proteins. The pleckstrin homology (PH) domains (approximately 100-amino-acids long) present in pleckstrin and other platelet proteins involved in signal transduction, recognize either $\text{PI}(3,4)\text{P}_2$ or $\text{PI}(3,4,5)\text{P}_3$. Binding of $\text{PI}(3,4,5)\text{P}_3$ to the aminoterminal PH domain in PLC γ enhances its activity.¹⁶⁶⁶ $\text{PI}(3,4,5)\text{P}_3$ binding to PH domains in BTK¹⁶⁶⁷ targets BTK to the plasma membrane, where it is further phosphorylated and activated.¹⁶⁶⁸ $\text{PI}(3,4)\text{P}_2$ or $\text{PI}(3,4,5)\text{P}_3$ binding to the PH domains in the serine/threonine kinase Akt (or protein kinase B) changes the conformation of Akt, permitting it to become activated by phosphorylation on Ser and Thr by Akt-kinase (PDK1).^{1669,1670} Akt activation is biphasic, occurring before and after platelet aggregation.¹⁶⁵⁹ Two isoforms of Akt are present in human platelets (Akt1 and Akt2).¹⁶⁷¹ The Akt isoforms have multiple substrates in platelets. One prominent substrate is glycogen synthase kinase (GSK)-3 β , which is inactivated by Akt-mediated phosphorylation. GSK-3 β suppresses platelet function and thrombosis in mice.¹⁶⁷² Akt activation also stimulates NO production and resultant protein kinase G (PKG)-dependent degranulation.¹⁶⁷³ Finally, Akt has been implicated in activation of a cAMP-dependent phosphodiesterase (PDE3A), which plays a role in reducing platelet cAMP levels after thrombin stimulation.¹⁶⁷⁴ Each of these Akt-mediated events is expected to contribute to platelet activation. Deficiency of Akt2 in mice impairs platelet aggregation, secretion, and fibrinogen binding in response to low doses of thrombin and U46619, but has minimal effects on collagen signaling.¹⁶⁷⁵ Akt2 null mice have normal bleeding times, but are protected from experimental thrombosis, as are mice with a deficiency of Akt1.^{1675,1676} Interestingly, in platelets containing either kinase dead PI3K β or PI3K γ , activation of Akt by ADP was abolished, and yet under the same condition, aggregation was only modestly affected,¹⁶⁶³ which raises questions about the role of Akt in these events.

Small G Proteins

Overview The Ras superfamily of small GTPases are intracellular transducers that act as "on-off" switches to facilitate the response to extracellular stimuli. Platelets contain members of the Ras superfamily (Ras, Ral, and Rap), the Rho subfamily (Rho, Rac, and Cdc42), the Rab subfamily (Rab 1, 3, 4, 6, 8, 11, 27, 31, 32),¹⁶⁷⁷⁻¹⁶⁸⁰ and the Arf subfamily (Arf1 or 3 and 6).¹⁶⁸¹

Rho family GTPases are regulators of cytoskeletal remodeling: Cdc42 for filopodia formation, Rac for lamellipodia and membrane ruffling, and Rho for focal adhesion and stress fiber formation.^{1682,1683} Platelets have Cdc42,¹⁶⁸⁴ Rac1,¹⁶⁸⁵ and RhoA.¹⁶⁷⁹ Resting platelets have very low levels of the GTP-bound forms of these GTPases,¹⁶⁸⁶⁻¹⁶⁸⁸ but all

are converted to their GTP-bound states upon platelet activation.^{1689,1690} Thus, receptor-mediated signaling activates Rho family GTPases. Cdc42 and Rac1 are activated at a very early phase of stimulation (approximately 10 sec) and reach maximal activation 30 seconds after stimulation with collagen, thrombin, or ADP.^{1687,1688,1690,1691} This temporal response is consistent with an early role for these GTPases in filopodia and lamellipodia formation. Integrin-dependent secondary signaling is required for full activation of RhoA,¹⁶⁸⁶ but not Cdc42 or Rac1,^{1687,1690} suggesting a role for RhoA in both early (adhesion/aggregation) and late (clot retraction) stages of platelet activation. More detailed descriptions of each subfamily follows.

Ras Platelets contain at least one Ras isoform (H-Ras).¹⁶⁹² Despite its intensively studied functions in proliferation, differentiation, and cell survival in nucleated cells,^{1693,1694} the exact role of Ras and its signaling in platelets is unclear. Platelets do contain most of the downstream Ras effectors: Raf-1, MEK (MAPK/ERK kinase), and ERK (extracellular signal-regulated kinase).¹⁶⁹⁵ Ras and ERK are both known to be activated upon platelet stimulation.¹⁶⁹⁶

Rho Inactivation of RhoA with C3 exoenzyme treatment inhibits agonist induced shape change,^{1697–1699} adhesion/aggregation,^{1686,1698,1700,1701} and formation of focal adhesions.¹⁷⁰¹ Platelets treated with the exoenzyme also show decreased stress fibers formation, a process mediated by Rho kinase-dependent phosphorylation of myosin light chain (MLC).^{1686,1697,1700}

Rac In nucleated cells, Rac1 functions in actin remodeling *via* activation of three downstream effectors; phosphatidylinositol 4-phosphate 5-kinase type I α , p21-Cdc42/Rac-activated kinase, and suppressor of cyclic AMP receptor/WASP-family verprolin-homologous protein.¹⁷⁰² The roles of Rac1 in lamellipodia formation and aggregation have been examined using platelets from mice lacking Rac1. Rac1 deletion does not affect platelet production^{1703–1705} or filopodia formation, but does affect lamellipodia formation upon stimulation with thrombin and collagen.¹⁷⁰⁴ Aggregation was diminished in Rac1^{-/-} platelets when stimulated with low-dose of thrombin or collagen, or when subjected to shear stress under flow condition.^{1704,1705}

Cdc42 The assessment of Cdc42 function in platelets is less clear. Wiskott-Aldrich syndrome is caused by a defect in WASP, which is a downstream effector of Cdc42. However, the platelets from affected individuals have normal shape change, including filopodia formation and Arp2/3 activation (Chap. 121).¹⁷⁰⁶ One study suggested that Cdc42 might function in GPVI-mediated integrin $\alpha_2\beta_1$ activation and subsequent platelet adhesion on collagen-coated surfaces.⁹⁶⁹

Rap Rap GTPases participate in cell adhesion, cell–cell junction formation, and the development of cell polarity in nucleated cells.¹⁷⁰⁷ In platelets, Rap1a, Rap1b, and Rap2 are all activated upon platelet stimulation.^{1708,1709} Platelets from Rap1b^{-/-} mice have a defect in platelet aggregation and decreased integrin $\alpha_{IIb}\beta_3$ activation upon platelet stimulation with ADP or PAR-4 peptide.¹⁷¹⁰ With the discovery of the important role of CalDAG-GEF1, an exchange factor for Rap1 in platelet function, Rap1's role in integrin signaling has been a major focus of research.¹⁷¹¹ Platelets lacking CalDAG-GEF1 have decreased Rap1B activation and integrin $\alpha_{IIb}\beta_3$ activation.¹⁷¹² Integrin $\alpha_{IIb}\beta_3$ activation could be completely blocked by treating CalDAG-GEF1^{-/-} platelets with a PKC inhibitor, suggesting that CalDAG-GEF1 and PKC function independently to activate integrin $\alpha_{IIb}\beta_3$.¹⁷¹³ Studies using CHO cells reconstituted with integrin $\alpha_{IIb}\beta_3$, talin, and Rap1GTP-interacting adapter molecule (RIAM) showed that Rap1GTP-dependent talin recruitment to integrin β_3 by RIAM is required for integrin $\alpha_{IIb}\beta_3$ activation.¹⁷¹⁴ The function of Rap2 remains to be determined; CalDAG-GEF1 does not interact with it.¹⁷¹⁵

Ral In nucleated cells, Ral GTPases (RalA and RalB) are thought to function in regulated exocytosis by recruiting a multisubunit

complex termed “exocyst” for targeting secretory vesicles to specific plasma membrane domains.¹⁷¹⁶ Both RalA and RalB in platelets are associated with platelet dense granules,¹⁷¹⁷ and become rapidly activated in a Ca²⁺-dependent manner upon platelet activation.¹⁷¹⁸ A recombinant Ral-interacting domain of Sec5, a downstream effector of RalA in exocyst complex, inhibits serotonin release from platelet dense bodies, suggesting a role for Ral exocyst in platelet granule release.¹⁷¹⁹

Rab Rab GTPases are the largest family of small GTPases; 63 members are detected in the human genome.¹⁷²⁰ They are highly compartmentalized to different organelle membranes and function by coordinating vesicle transport, including vesicle formation and tethering to their target compartments.¹⁷²⁰ Rab proteins have been shown to play roles in both granule biogenesis and secretion.

Arf Arf family GTPases, in nucleated cells, function in secretory and cytoskeletal processes. Platelets contain Arf1 or 3 and Arf6. Functional studies of Arf6 show that unlike other platelet GTPases, it is in the GTP-bound state in resting platelets and there is a conversion to the GDP-bound state upon platelet activation.¹⁶⁸¹ Inhibitors of this transition disrupt aggregation, secretion, and clot retraction. Further analysis suggests that the Arf6-GTP to Arf6-GDP transition is required for activation of Rho family proteins in platelets.

Calcium-Dependent Proteases (Calpains)

After ligand binding, integrin clustering, and platelet aggregation, neutral, cysteine proteases termed *calpains* become activated by a rise in intracellular Ca²⁺.²²⁹ The most important and best-studied calpains in platelets are: μ -calpain (calpain-1), which is activated by micromolar concentrations of Ca²⁺ and accounts for 80 percent of the Cys protease activity in platelets, and m-calpain (calpain-2), which requires millimolar levels of Ca²⁺ for activation.¹⁷²¹ Each calpain consists of a common Mr 30,000 regulatory subunit paired with a unique catalytic subunit of Mr 80,000. Activated μ -calpain cleaves numerous proteins,²²⁹ including cytoskeletal proteins (e.g., filamin [actin binding protein], talin, WASP, and cortactin), tyrosine kinases (e.g., BTK, Src, Syk, and FAK), tyrosine phosphatases (e.g., protein tyrosine phosphatase 1B [PTP1B also called PTPN1], SHP-1, and PTPMEG), as well as other important platelet proteins (e.g., integrin β_3 , SNAP-23, Vav, PLC- β), and certain isoforms of PKC.¹⁷²¹ Cleavage of talin by calpain *in vitro* enables talin to activate integrin $\alpha_{IIb}\beta_3$,¹⁴⁸ but the role of calpain in activation of integrin $\alpha_{IIb}\beta_3$ by talin in intact platelets is uncertain. Calpain also appears to be upstream of, and able to affect, the activation of the small G proteins Rac and RhoA. Calpain's role in platelet secretion has not been defined, although it is clear that the t-SNARE, SNAP-23 is inactivated by calpain-mediated cleavage.¹⁷²² Thus calpains, through their effects on structural and signaling molecules, appear to affect multiple aspects of platelet function. Mice deficient in μ -calpain demonstrate abnormal platelet aggregation, decreased clot retraction, and reduced tyrosine phosphorylation of several platelet proteins, including the β subunit of integrin $\alpha_{IIb}\beta_3$. These abnormalities in platelet function can be reversed by inhibition of tyrosine phosphatases or by deletion of PTP1B, suggesting that μ -calpain's effects on platelet kinases and phosphatases may be central to its role in platelet function.¹⁷²³

Inside-Out Activation of Integrin $\alpha_{IIb}\beta_3$ and Outside-in Signaling By Activated Integrin $\alpha_{IIb}\beta_3$

The active state of integrin $\alpha_{IIb}\beta_3$ is defined as the conformation that is competent to bind large, soluble, adhesive proteins, such as fibrinogen and VWF, with relatively high affinity. Precise regulation of the activation state of integrin $\alpha_{IIb}\beta_3$ is essential for maintenance of normal hemostasis, such that integrin $\alpha_{IIb}\beta_3$ activation only occurs upon vascular injury. Crystallographic and electron microscope studies suggest that the extracellular portion of both integrin $\alpha_{IIb}\beta_3$ and the

related integrin $\alpha_{\text{Ib}}\beta_3$, are in a bent conformation when inactive and an extended conformation when activated.^{149,843,844} The activation state of integrin $\alpha_{\text{Ib}}\beta_3$ is controlled by the cytoplasmic domains of this integrin in concert with specific intracellular binding proteins. Thus, under basal conditions, interactions between the cytoplasmic domains of integrins α_{Ib} and β_3 maintain the receptor in the resting state. Interrupting the interactions between the cytoplasmic domains results in long range conformational changes that convert the extracellular portion of the integrin to an active state.¹⁷²⁴ Interactions between regions of the integrins α_{Ib} and β_3 transmembrane and cytoplasmic domains near the membrane involve upper and lower membrane clasps and a salt bridge between acidic and basic amino acid residues of each subunit (see “Integrin $\alpha_{\text{Ib}}\beta_3$ ” above).^{871,894,1725,1726} Mutations that disrupt these interactions result in integrin $\alpha_{\text{Ib}}\beta_3$ activation.^{871,894,1726} Cytoskeletal restraints appear to further maintain integrin $\alpha_{\text{Ib}}\beta_3$ in an inactive conformation, because treatment of platelets with low doses of the actin depolymerizing agents activate the integrin.²⁴³ Upon agonist activation, the binding of the cytoskeletal linking proteins talin and kindlin to integrin β_3 may play a key role in the conversion of integrin $\alpha_{\text{Ib}}\beta_3$, as well as several other integrins, to an active conformation.²⁴⁵ One model suggests that filamin binding to the β subunit cytoplasmic tail maintains the receptor in an inactive state by presenting talin binding. The cytoskeletal adapter protein migfilin can displace filamin from the integrin β_3 subunit and facilitate the binding of talin.⁹⁰¹ Talin itself can exist in a conformation that is either less or more favorable for binding to integrin β_3 at multiple sites. The affinity of talin for β integrins increases in response to PI(4,5)P₂ binding to talin.¹⁷²⁷ PIP₂ may be generated locally from PI via the enzyme phosphatidylinositol phosphate kinase type 1 γ , which can bind to talin.^{1728,1729} Talin is composed of a Mr 47,000 head domain and a Mr 190,000 rod domain. The head contains a “FERM” domain named for the proteins four point one (4.1), ezrin, radixin, and moesin, that promotes specific interactions with cytoplasmic regions of multiple proteins. The F3 region of the FERM domain, which resembles a phosphotyrosine binding (PTB) domain,¹⁷³⁰ binds sequentially to membrane distal and proximal regions of integrin β_3 in addition to establishing electrostatic interactions with the lipid head groups, disrupting its interaction with the membrane and integrin α_{Ib} .^{244,871,894,896,1730–1734} This binding site is not available when PI phosphate kinase (PIP2K)I is bound to talin, so presumably any prebound PIP2KI would be displaced from talin upon talin interaction with integrin β_3 .¹⁷³⁵ After talin binding the reorganization of the transmembrane and intracytoplasmic domains disrupt the interaction of integrins α_{Ib} and β_3 and this is transmitted to the ectodomain.^{871,894,1724} The β_3 cytoplasmic domain can also bind proteins that connect it to the cytoskeleton such as α -actinin, ICAP1, filamin, Src, and skelemin, and so it has been proposed that interactions of the integrin β_3 subunit with the actin–myosin contraction apparatus via the cytoskeleton may supply the energy needed to adopt the extended conformation of integrin $\alpha_{\text{Ib}}\beta_3$ with the swing out of the of integrin β_3 hybrid domain away from the of βA (I-like) domain.²⁵⁰ The rod-like region of talin has also been reported to interact with integrin β_3 .¹⁷³⁶ and an unknown region of talin has been reported to interact with integrin α_{Ib} .¹⁷³⁷ While these interactions may serve to stabilize or subsequently cluster the integrin, their exact roles are unknown.

Members of the kindlin family of focal adhesion proteins that contain PTB domains serve as integrin activators,^{1738–1740} perhaps functioning to facilitate talin–integrin interactions. Kindlin-2 binds the C-terminus of integrin β_3 in a region containing the conserved TS(752) T sequence and NITY(759) motif and acts synergically with talin to promote integrin $\alpha_{\text{Ib}}\beta_3$ activation in a recombinant expression system.¹⁷³⁸ Whereas kindlin-2 is widely distributed, kindlin-3 expression is limited to hematopoietic cells, including platelets. Genetic deletion of kindlin-3 in mice results in a severe bleeding phenotype and defective activation

of integrin $\alpha_{\text{Ib}}\beta_3$ on platelets.¹⁷⁴¹ Mutations in kindlin-3 have been described in patients with leukocyte adhesion deficiency-III, which is characterized by abnormalities in leukocyte and platelet integrin activation and function (Chap. 121).^{1742–1745} In fact, the bleeding symptoms are even more severe than those in Glanzmann thrombasthenia and the platelet aggregation defects are similar. Mutational analysis also identified the NXXY motif (Tyr795) and preceding threonine-region in kindlin binding to integrin β_1 .¹⁷⁴⁶ Finally, based on model systems, it has been proposed that α_{Ib} transmembrane and cytoplasmic domains from adjacent integrin $\alpha_{\text{Ib}}\beta_3$ receptors may form homodimers and integrin β_3 transmembrane and cytoplasmic domains may form homotrimers, resulting in stabilization of the activated state and clustering of integrin $\alpha_{\text{Ib}}\beta_3$ receptors,^{251,1747} but it is not clear that these interactions are favored under biologic conditions.^{871,894}

Platelet aggregation is commonly described as progressing through two phases: an initial reversible aggregation phase, which is often the response observed with low concentrations of agonists, followed by a stronger, irreversible phase. The irreversible phase of aggregation correlates with TXA₂ production and platelet secretion of ADP. Fibrinogen binding to integrin $\alpha_{\text{Ib}}\beta_3$ and the platelet–platelet contacts that occur during the initial phase of aggregation initiate specific signal transduction events, resulting in positive feedback loops that promote irreversible aggregation, maintain secretion, and initiate later events like clot retraction.²⁹¹

Fibrinogen or VWF binding to the extracellular region of integrin $\alpha_{\text{Ib}}\beta_3$ transmits long-range conformational changes to the integrin cytoplasmic domains, perhaps via a pivot action between the integrin β_3 βA (I-like) and hybrid domains⁸²⁷ that induce signaling from outside the platelet to inside the platelet (outside-in signaling).^{876,879} These conformational changes, along with integrin clustering,⁸³⁸ are likely to be the basis for outside-in signal transduction through integrin $\alpha_{\text{Ib}}\beta_3$, perhaps by altering the association of the cytoplasmic domains with one another and initiating recruitment of proteins with enzymatic activity to the cytoplasmic tails, forming complexes capable of generating signaling molecules.

One important signaling molecule that is constitutively associated with the integrin β_3 cytoplasmic tail is the tyrosine kinase, Src.^{1748–1750} Src binds to the C-terminus of the integrin in resting platelets via its SH3 domain independent of its catalytic activity.¹⁷⁴⁸ This pool of Src in unstimulated platelets appears to exist in a minimally active state with its activity suppressed in part by the Src regulator Csk, which phosphorylates Src at Tyr 529. Platelet adhesion to fibrinogen increases the Src activity associated with integrin $\alpha_{\text{Ib}}\beta_3$ in part because of the dissociation of Csk and subsequent dephosphorylation of Src 529.¹⁷⁵⁰ Full Src activation occurs upon integrin $\alpha_{\text{Ib}}\beta_3$ clustering and transphosphorylation of Src on Tyr 418. Src activation is required for several subsequent signaling events such as the activation of the tyrosine kinase Syk. Syk, along with Src, is required for platelet spreading on fibrinogen.¹⁷⁴⁸ Syk binds to unphosphorylated integrin β_3 via its N-terminus.^{1751,1752} Some of these events have now been visualized in living platelets.¹⁷⁵³ Negative regulators of Src activation include PECAM-1, which can recruit the protein tyrosine phosphatases SHP-1 and SHP-2 via its ITIMs^{1749,1754–1757}; carcinoembryonic antigen-related cell adhesion molecule-1, which also possess ITIMs¹⁷⁵⁸; and perhaps G6b-B^{1759–1761} and TLT-1.¹¹⁶⁶

When platelets are aggregated in response to one of multiple agonists, the integrin β_3 cytoplasmic domain becomes phosphorylated on Tyr.^{902,910} Two sites of potential tyrosine phosphorylation exist on the β_3 cytoplasmic domain and both may be utilized. Several molecules have been identified that bind specifically to the tyrosine-phosphorylated cytoplasmic domain of integrin β_3 . A synthetic integrin β_3 cytoplasmic domain peptide containing phosphate groups on the two candidate Tyr residues binds to the contractile protein myosin,⁹⁰² and this interaction

may facilitate the transmission of cytoskeletal tension from inside the platelet to outside, and thus initiate clot retraction. Recombinant, mutated integrin β_3 that cannot be phosphorylated is unable to support extensive clot retraction when expressed in a cell line.⁹⁰² Other proteins that bind to the diphosphorylated integrin β_3 cytoplasmic domain include the SHC adapter proteins,⁹⁰⁶ which also become tyrosine phosphorylated during platelet aggregation. Therefore, it is possible that the SHC adapter proteins may link diphosphorylated integrin β_3 to the MAPK pathway.^{906,1762} Mice containing mutated integrin β_3 molecules that cannot be phosphorylated exhibit a mild bleeding disorder as evidenced by occasional rebleeding of tail cuts. Moreover platelets derived from these mice form abnormally loose thrombi when activated by shear forces.¹⁷⁶³ Other integrin β_3 cytoplasmic domain binding proteins have been described, including skelemin, a member of a family of proteins that regulate myosin,⁹¹⁴ and talin.

Some signaling events that occur downstream of integrin $\alpha_{IIb}\beta_3$ require only integrin clustering, whereas other events require clustering, ligand binding, and/or platelet aggregation. For example, the tyrosine kinase Syk becomes activated in response to integrin $\alpha_{IIb}\beta_3$ clustering, independent of cytoskeletal assembly, whereas activation of the tyrosine kinase FAK requires integrin clustering, ligand binding and cytoskeletal assembly.¹⁷⁶⁴ In studies conducted in cell lines, activation of Syk downstream of integrin $\alpha_{IIb}\beta_3$ leads to phosphorylation of Vav1, a guanine nucleotide exchange factor for Rac, and lamellipodia formation. Syk and Vav1 cooperate to activate Jun N-terminal kinase, ERK2, and Akt.¹⁷⁶⁴ These pathways are also likely to be involved in postaggregation events in the platelet.

Proteins other than the well-described integrin $\alpha_{IIb}\beta_3$ ligands fibrinogen and VWF also induce signaling events via binding to integrin $\alpha_{IIb}\beta_3$. One such protein is CD40L, a TNF family member that is expressed on a variety of cells including activated platelets. Platelets are also the major source of a soluble form of CD40L.¹⁷⁶⁵ In addition to binding to its classical receptor, CD40, CD40L also binds to integrin $\alpha_{IIb}\beta_3$ on platelets and induces signaling events¹³⁵⁰ that are required for normal arterial thrombus formation in mice.¹³⁴⁸ CD40L may also initiate platelet aggregation by binding to CD40 on platelets.¹³⁴⁹

INHIBITORY PATHWAYS IN PLATELETS

Prostaglandins

Prostaglandins that inhibit platelet activation include PGE₂ (at high concentrations) and PGI₂ (at low concentrations) (also termed *prostaglandin*) (reviewed in Refs. 1766 and 1767). In the vasculature, the endothelium produces PGI₂ and PGE₂, which are important in maintaining vascular patency.¹⁷⁶⁸ Inhibition is initiated by the binding of these PGs to their own specific GPCR.^{1769,1770} PG receptor occupancy converts the G α subunit to the GTP bound, active form, which then activates adenylyl cyclase. Adenylyl cyclase catalyzes the formation of cAMP. The exact amount of cAMP present in the cell is also determined by its rate of breakdown by phosphodiesterases (PDEs). Biochemical studies and studies from gene targeted mice support a primary role for PDE3A in platelets.^{1771–1773} Therefore, agents that inhibit PDE, such as theophylline, caffeine, and the drug cilostazol, also elevate cAMP levels in platelets and other cells.¹⁷⁷⁴ cAMP then activates PKA, which phosphorylates specific target proteins. PKA inhibits platelet activation by several pathways. One mechanism involves PKA-dependent phosphorylation of VASP (discussed under “Nitric Oxide” below). A separate mechanism involves the phosphorylation and inhibition of G α 13, which couples to the TXA₂ receptor, thus impairing this activation pathway.¹⁷⁷⁵ Also, PKA phosphorylates GPIIb β on Ser 166, and negatively regulates the ability of GPIIb to bind VWF.¹⁷⁷⁶ In addition, PKA may phosphorylate and inhibit the IP₃ receptor, which would repress agonist-induced intracellular

Ca²⁺-mobilization.¹⁷⁷⁷ PI metabolism is also affected, as the activities of both PLC and PLA₂ are suppressed.¹⁷⁷⁸ Moreover, PKA also phosphorylates Raf kinase on three sites, which inhibits Raf kinase function in part by inhibiting its binding to the activating protein RasGTP.^{1779,1780} Finally, the small G protein, Rap1b, which contributes to integrin $\alpha_{IIb}\beta_3$ activation,¹⁶¹¹ is phosphorylated by PKA,¹⁷⁸¹ although it appears that this phosphorylation event does not inhibit platelet function¹⁷⁸² and may, in fact, contribute to Rap1b activation.¹⁷⁸³

Paradoxically, in contrast to the inhibitory effects of high levels of PGE₂, low levels of PGE₂ (<10⁻⁶ M) potentiate agonist-induced platelet aggregation by acting via the EP3 receptor to decrease intraplatelet cAMP levels.^{1784,1785} Mice lacking the EP3 receptor are protected from AA-induced thrombosis¹⁷⁸⁶; thus it is possible that PGE₂ present in atherosclerotic lesions contributes to atherothrombosis.

Nitric Oxide

NO is synthesized from L-arginine by NO synthase in endothelial cells, platelets, and other cells. The formation of NO is enhanced at sites of shear stress and by platelet agonists (e.g., thrombin or ADP),¹⁷⁸⁷ and it readily diffuses into platelets.^{1788,1789} Similar to PGI₂ or PGE₂, NO pretreatment of platelets inhibits platelet activation and can reverse platelet aggregation soon after initiation. However, NO works not by elevating cAMP, but instead by increasing cGMP.¹⁷⁹⁰ NO synthase activity in platelets increases during platelet activation, suggesting that NO production is a normal negative feedback mechanism that limits further platelet aggregation. NO and PGI₂ act together synergistically to inhibit platelet activation.¹⁷⁹¹

Elevation in intracellular cGMP levels activates cGMP-dependent PKG, whose downstream targets include ERK and the TXA₂ receptor.¹⁷⁹² In mice, the absence of PKG results in enhanced platelet accumulation along damaged vessels after ischemic injury, supporting an important role for PKG in platelet deposition.¹⁷⁹³ VASP, a member of the Pro-rich, actin-regulatory Ena/VASP protein family, is phosphorylated in response to elevations in either cAMP or cGMP¹⁷⁹⁴ and both PKA and PKG phosphorylate VASP *in vitro*.¹⁷⁹⁵ A role for VASP in inhibition of platelet function was established in studies of VASP-deficient mice: platelets obtained from the mice display increased P-selectin expression and integrin $\alpha_{IIb}\beta_3$ activation in response to agonists,¹⁷⁹⁶ and platelet adhesion at sites of vascular injury or atherosclerosis is enhanced in VASP-deficient mice.¹⁷⁹⁷ The enhanced platelet adhesion in VASP-null mice is not corrected by NO, suggesting that VASP may be a key negative regulator of platelet function in the cGMP-mediated pathways.

Elevation in intracellular cGMP can also increase cAMP levels via inhibition of PDE activity.¹⁷⁹⁸ This crosstalk between cGMP and cAMP-dependent pathways may synergize to contribute to the inhibitory effects of NO on platelet function.

CD39 (ATP Diphosphohydrolase; Ecto-ADPase)

Vascular endothelium regulates platelet function by producing prostacyclin and NO, as well as by expressing CD39 NTPDase1, a plasma membrane-associated ectonucleotide (ATP diphosphohydrolase; ATP-Dase; ecto-ADPase; EC 3.6.1.5) that converts extracellular ATP to ADP, and ADP to AMP.^{1799–1801} CD39 limits the platelet-activating effects of ADP released by damaged tissues, RBCs, and activated platelets; furthermore, AMP generated by CD39 is degraded by an ecto-5'-nucleotidase (CD73; EC 3.1.3.5) to adenosine, an inhibitor of ADP-induced platelet activation, that increases cAMP binding to the A2a adenosine receptor on platelets.¹⁸⁰² Adenosine deaminase (EC 3.5.4.4) degrades adenosine to inosine. CD39 is a Mr 95,000 cell-surface glycoprotein expressed on endothelial cells, subsets of activated natural killer (NK) cells, B cells, monocytes, and T cells. Small amounts may also be on platelets and erythrocytes. It is present in the lymphocytes in chronic lymphocytic

leukemia, which may partially account for the thromboprotection noted in that disorder.¹⁸⁰³ CD39 is localized to lipid raft-like caveolae in the plasma membrane, and the cholesterol content may control enzymatic activity. It contains two putative transmembrane regions separated by an extracellular domain with six glycosylation sites and apyrase-like regions that confer the ecto-ADPase activity. A related molecule, ATP- and ATPase 2, which is found on the basolateral surface of endothelial cells, the adventitia of some blood vessels, and microvascular pericytes, is relatively selective for ATP, and thus it has the capacity to increase platelet aggregation by enhancing the production of ADP from ATP.¹⁷⁹⁹ The physiologic roles of the NTPDases are complex because of their production of variably prothrombotic and antithrombotic agents. It has been postulated that recruitment of microparticles enriched in monocyte CD39/NTPDase1 to thrombi could contribute to the limitation of the size of platelet thrombi. A role for CD39/NTPDase1 in ischemia reperfusion and allograft rejection has also been proposed. Mouse models support the potential of modulating graft rejection and thrombosis by using gene therapy to increase CD39/NTPDase1. A soluble recombinant form of CD39 inhibits platelet aggregation and recruitment *in vitro* and may have potential as an anti-thrombotic agent *in vivo*.¹⁸⁰⁴

CHAPTER 113

MOLECULAR BIOLOGY AND BIOCHEMISTRY OF THE COAGULATION FACTORS AND PATHWAYS OF HEMOSTASIS

Mettine H. A. Bos, Cornelis van 't Veer, and Pieter H. Reitsma

SUMMARY

The coagulation cascade consists of a complex network of reactions that are essential for the conversion of zymogens into enzymes and of inactive procofactors into cofactors. Most of these reactions take place on a membrane surface, which restricts coagulation to the site of injury. Upon initiation, these reactions serve to produce the fibrin that is necessary for the formation of a stable hemostatic plug. In addition, these reactions provide feedback loops that limit and localize thrombus formation and regulate thrombus resolution. This chapter highlights key biochemical characteristics of the individual coagulation factors, essential aspects regarding their synthesis, and the clinical importance of acquired or inherited variations that affect their quantity or function. The coagulation factors are grouped as (1) the vitamin K-dependent zymogens (prothrombin, factor VII, factor IX, factor X, and protein C); (2) the procoagulant cofactors (factor V, factor VIII); (3) the soluble cofactors (protein S, von Willebrand factor); (4) factor XI and the contact system (factor XII, prekallikrein, and high-molecular weight kininogen); (5) the cell-associated cofactors (tissue factor, thrombomodulin, endothelial protein C receptor); (6) the fibrin network (fibrin[ogen], factor XIII, thrombin-activatable fibrinolysis inhibitor); and (7) inhibitors of coagulation (antithrombin, tissue factor pathway inhibitor, protein Z/protein Z-dependent protease inhibitor). [Table 113–1](#) summarizes the major features of the coagulation factors addressed in this chapter. The final sections of this chapter present an overview of the coagulation cascade in which the pathways of hemostasis including the contribution of endothelial cells, blood platelets, and immune cells are described.

Acronyms and Abbreviations: APC, activated protein C; ADP, adenosine diphosphate; AT, antithrombin; C4BP, complement 4b-binding protein; COX, cyclooxygenase; EGF, epidermal growth factor; EPCR, endothelial protein C receptor; ER, endoplasmic reticulum; ERGIC, ER-Golgi intermediate compartment; Gla, γ -carboxy glutamic acid; GP, glycoprotein; HK, high-molecular-weight kininogen; LMAN1, mannose-binding lectin-1; PAI-1, plasminogen activator inhibitor type 1; PAR, protease-activated receptor; PK, prekallikrein; poly-P, polyphosphate; RVV, Russell's viper venom; SHBG, sex hormone-binding globulin; TAFI, thrombin-activatable fibrinolysis inhibitor; TFP1, tissue factor pathway inhibitor; UFH, unfractionated heparin; VWD, von Willebrand disease; VWF, von Willebrand factor; ZPI, protein Z-dependent protease inhibitor.

MOLECULAR BIOLOGY AND BIOCHEMISTRY OF THE COAGULATION FACTORS

THE VITAMIN K-DEPENDENT ZYMOGENS: PROTHROMBIN, FACTOR VII, FACTOR IX, FACTOR X, AND PROTEIN C

The vitamin K-dependent zymogens circulate in an inactive state and require proteolytic activation to function as a serine protease. All share a similar domain structure of a C-terminal serine protease domain and an N-terminal γ -carboxy glutamic acid (Gla) domain, which are connected by two epidermal growth factor (EGF)-like domains or kringle domains ([Fig. 113–1](#)). Each protein domain has a well-defined function and facilitates substrate recognition, interaction with protein cofactors, or binding to a negatively charged lipid surface, such as that of activated platelets or endothelial cells, thereby restricting coagulation to the site of injury. The latter is mediated via the Gla domain, a domain that is characteristic to the vitamin K-dependent proteins.

The high level of protein and gene homology suggests that the vitamin K-dependent zymogens originate from a common ancestral gene as a result of gene duplications.¹ Exon shuffling and tandem duplication may account for the generation of the ancestral gene, in which the functional domains that are encoded by a single exon each were combined and duplicated.² This process may also account for the presence of the kringle domains as opposed to EGF-like domains in prothrombin.

The Gla domain refers to the 42-residue region located in the N-terminus of the mature protein that comprises 9 to 12 glutamic acid residues that are posttranslationally γ -carboxylated into Gla residues by a specific γ -glutamyl carboxylase in the endoplasmic reticulum of hepatocytes.³ This γ -carboxylase requires oxygen, carbon dioxide, and the reduced form of vitamin K for its action, hence the name vitamin K-dependent proteins. For each Glu residue that is carboxylated, one molecule of reduced vitamin K is converted to the epoxide form ([Fig. 113–2](#)). Vitamin K epoxide reductase converts the epoxide form of vitamin K back to the reduced form.⁴ Warfarin and related 4-hydroxycoumarin-containing molecules inhibit the activity of vitamin K epoxide reductase, thereby preventing vitamin K recycling and inhibiting γ -carboxylation. This results in a heterogeneous population of circulating undercarboxylated forms of the vitamin K-dependent proteins with reduced activity. Because warfarin blocks the reductase and not the carboxylase, the inhibitory effect of warfarin can be (temporarily) reversed by administration of vitamin K. Recognition by and interaction with γ -carboxylase is facilitated by the propeptide sequence that is located C-terminal to the signal peptide. The propeptide is highly conserved among the vitamin K-dependent proteins, and amino acids at positions –18, –17, –16, –15, and –10 are critical to recognition by the γ -carboxylase.^{5,6} Following γ -carboxylation, the propeptide is removed through limited proteolysis prior to secretion of the mature protein.

A correctly γ -carboxylated Gla domain is essential for interaction of the vitamin K-dependent proteins with phosphatidylserine, a negatively charged phospholipid. Under normal conditions, phosphatidylserine is not exposed on the outer membrane leaflet of cells. However, in activated endothelial cells or platelets, phosphatidylserine is part of the extracellular cell surface where it supports blood coagulation reactions. The Gla domain interacts with the anionic cell surface in a calcium-dependent manner. These calcium ions are coordinated by Gla residues and induce a conformational change in the Gla domain that is characterized by the appearance of a hydrophobic surface loop

TABLE 113-1. Characteristics of Coagulation Proteins

	Protein	Plasma Concentration		Mr (kDa)	Plasma Half-Life (Hours)
		($\mu\text{g/mL}$)	(nmol/L)		
ZYMOGENS					
+ Gla domain	Prothrombin (factor II)	100	1400	72	60
	Factor VII	0.5	10	50	3–6
	Factor IX	5	90	55	18–24
	Factor X	10	170	59	34–40
	Protein C	4	65	62	6–8
– Gla domain	Factor XI	5	30	160	60–80
	Factor XII	40	500	80	50–70
	Prekallikrein	40	490	85	35
	Factor XIII ^A *†	–	–	83	–
	Factor XIII ^B *	7	94	76.5	–
	Factor XIII	30	94	320	240
	TAFI	4–15	70–275	60	–
COFACTORS					
Soluble	Factor V [†]	5–10	20	330	12–36
	Factor VIII	0.2	0.7	300	8–12
	VWF	varies	10	500–20,000	8–12
	Protein S [‡]	25	350	75	42
	Protein Z [§]	2.5	40	62	60
	HK	80	670	120	150
Cellular	Tissue factor	–	–	47	–
	Thrombomodulin	–	–	78	–
	EPCR	–	–	49	–
STRUCTURAL PROTEIN					
	Fibrinogen	2500	7400	340	72–120
	A α chain	–	–	66.5	–
	B β chain	–	–	52	–
	γ Chain	–	–	46.5	–
INHIBITORS					
	Antithrombin	150	2500	58	60–72
	TFPI α [¶]	0.01	0.25	40	0.03
	ZPI [§]	4	60	72	60

EPCR, endothelial protein C receptor; HK, high-molecular-weight kininogen; TAFI, thrombin-activatable fibrinolysis inhibitor; TFPI, full-length tissue factor pathway inhibitor; VWF, von Willebrand factor; ZPI, protein Z–dependent protease inhibitor.

*All of the factor XIII^A chain is in complex with factor XIII^B chain; only half of factor XIII^B is in complex with factor XIII^A, the rest is free in plasma.

†Platelets carry significant amounts of factor XIII^A and factor V (20% of circulating factor V).

‡Approximately 60% of protein S is in complex with C4b-binding protein; the remainder circulates as free protein S.

§ZPI circulates in complex with protein Z.

¶TFPI circulates in plasma at 2.5 nM in multiple forms; only 10% of circulating TFPI is the full-length TFPI α .

(Fig. 113-3). Membrane binding by the Gla domain occurs when this hydrophobic surface loop penetrates into the hydrophobic portion of the phospholipid bilayer, which is facilitated by the interaction of the Gla-bound calcium ions with the phosphate head groups of phosphatidylserine.^{7,8} It has been shown that the phosphate head groups of exposed phosphatidylethanolamine are also capable of coordinating calcium ions, thereby contributing to the interaction of the Gla domains with the negatively charged membrane surface.⁹

The serine protease domains of the vitamin K–dependent proteins are highly homologous, as they bear a chymotrypsin-like fold and display trypsin-like activity.¹⁰ Once activated, they cleave peptide bonds following a positively charged amino acid (Lys or Arg). Activation proceeds through proteolysis at one or more sites N-terminal to the serine protease domain (see Fig. 113-1). Subsequently, the newly formed N-terminus inserts into the serine protease domain to form a salt bridge with an Asp residue, which is associated with conformational

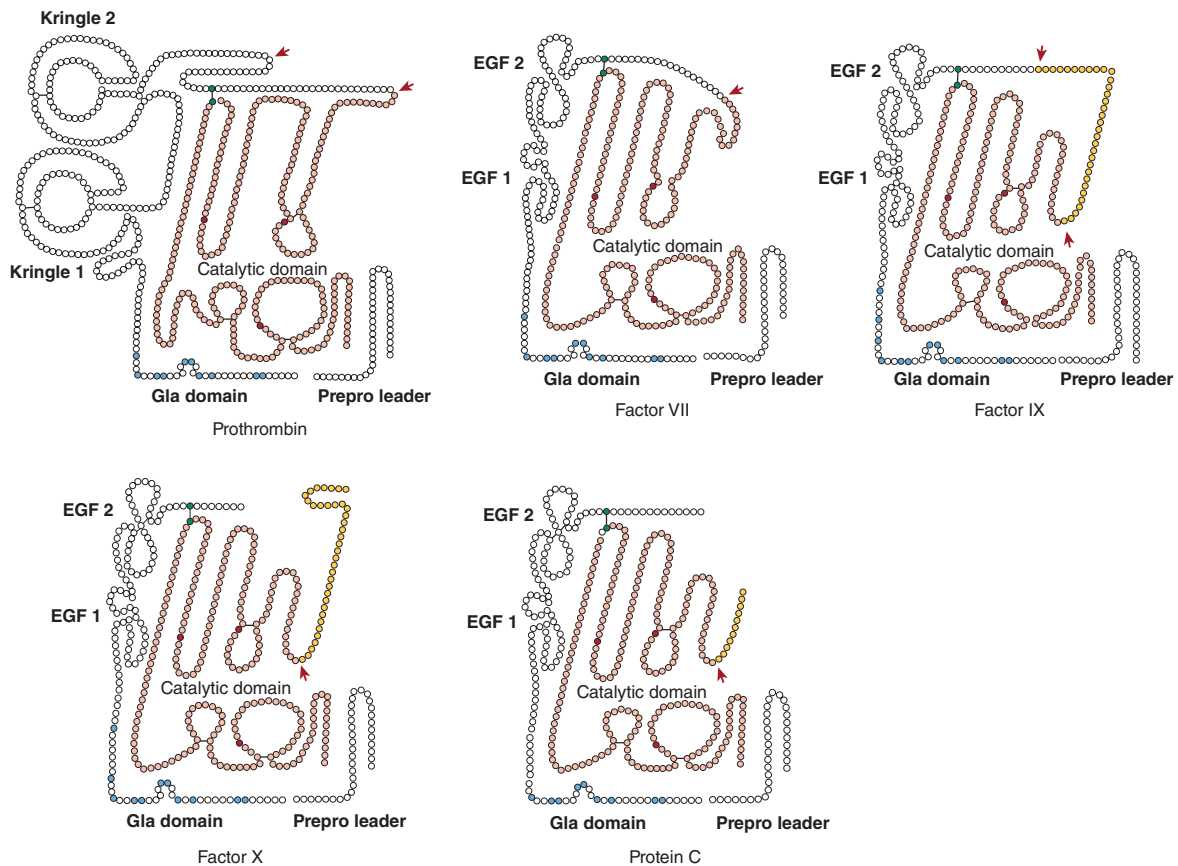

Figure 113-1. Vitamin K–dependent schematic of the vitamin K–dependent zymogens. Each circle represents an amino acid. The prepro leader sequence contains the signal peptide as well as the propeptide that directs γ -carboxylation of glutamic acid (Gla) residues. Cleavage of the prepro sequence from the mature protein is indicated by the separation between the two. The Gla domains are indicated with the Gla residues in blue. Prothrombin has a finger loop followed by two kringle domains. Factors VII, IX, X, and protein C have epidermal growth factor (EGF)-like domains. Prothrombin, factor VII, and factor IX circulate as single-chain molecules. Factor X and protein C circulate as two chains that are disulfide linked. All have homologous serine protease (“catalytic”) domains (shown in light red), in which the active site His, Asp, and Ser residues are indicated in dark red. Cleavages that convert the zymogen to an active enzyme are indicated by the red arrows. In factor IX, factor X, and protein C, the released activation peptide is indicated in yellow. After proteolytic activation, all of the molecules are two-chain disulfide-linked molecules, with the cysteines forming a disulfide bridge (black line) indicated in green. All catalytic domains but that of prothrombin remain attached to the Gla domain following activation.

Figure 113-2. Vitamin K–dependent γ -carboxylation. Glutamic acid residues are converted to γ -carboxy glutamic acid (Gla) residues by a specific γ -carboxylase. This reaction requires oxygen, carbon dioxide (shown in green), and reduced vitamin K in the form of a hydroquinone. Carbon dioxide is incorporated onto the γ -carbon, providing a second carboxylate group on that residue. In the process of this reaction, reduced vitamin K is converted to an epoxide. Reduced vitamin K is recycled by a specific epoxide reductase, a reaction that can be blocked by warfarin and warfarin analogues.

changes in the serine protease domain. These lead to an optimal configuration of the active site through alignment of the active site residues His, Ser, and Asp, and to formation of the substrate-binding exosites, allowing for substrate conversion. The substrate-binding exosites are unique to each vitamin K–dependent protease and are responsible for their highly specific substrate recognition and associated function in coagulation.

Interaction of the vitamin K–dependent proteases with specific cofactors on a (anionic) membrane surface (Table 113-2) further enhances substrate recognition, as the cofactors interact with both the protease and the substrate, bridging the two together. This results in a dramatic enhancement of the catalytic activity (Table 113-3), thereby making the cofactor–protease complex the physiologic relevant enzyme. The increase in catalytic rate has also been attributed to a cofactor-induced conformational change in the protease.¹¹ However, whether this molecular mechanism holds true for all cofactor–protease complexes remains to be determined. Tissue factor is the cofactor for factor VIIa, factor VIIIa is the cofactor for factor IXa, and factor Va is the cofactor for factor Xa, while thrombin does not require a cofactor for its procoagulant activity. However, upon association with the cofactor thrombomodulin, thrombin’s specificity is changed from procoagulant

Figure 113-3. Calcium-dependent association of the glutamic acid (Gla) domain with the anionic phospholipid surface. Non-calcium bound [Protein Data Bank (PDB) structure 2PF2] and calcium bound (PDB structure 1WHE) molecular models of the Gla domain of prothrombin are shown. Circles represent amino acids, with the Gla (GLA) residues indicated in red. Hydrophobic residues involved in membrane insertion are shown in blue. In the absence of calcium, the negatively charged Gla residues are exposed to the solution and the hydrophobic residues are buried. Association of calcium ions (in black) to the Gla residues provides sufficient energy to alter the overall conformation of the Gla domain and expose the hydrophobic residues. Membrane binding by the Gla domain occurs when this hydrophobic surface loop penetrates into the hydrophobic portion of the phospholipid bilayer (drawn schematically), which is facilitated by interaction of the Gla-bound calcium ions with the negatively charged phosphate head groups.

to anticoagulant (cleaving and activating protein C). The complexes are also named for their physiologic substrate: the factor VIIIa–factor IXa complex is termed the “tenase” or “intrinsic tenase” complex; the tissue factor–factor VIIa complex is termed the “extrinsic tenase” complex; and the factor Va–factor Xa complex is termed the “prothrombinase” complex.

PROTHROMBIN (FACTOR II)

Prothrombin, or factor II, which was discovered by Pekelharing in 1894, is one of the four coagulation factors that were described by Paul Morawitz in 1905, in addition to fibrinogen (factor I), thromboplastin

TABLE 113-2. Protease–Cofactor Complexes

Protease	Cofactor	Substrate	Cellular Location
Factor VIIa	Tissue factor	Factor IX Factor X	Many cells*
Factor IXa	Factor VIIIa	Factor X	Platelets
Factor Xa	Factor Va	Prothrombin	Platelets
Thrombin	Thrombomodulin	Protein C	Endothelium
Activated protein C	Protein S	Factor Va Factor VIIIa	Endothelium

*Tissue factor is constitutively expressed on many extravascular cells (e.g., stromal cells, epithelial cells, astrocytes) and is induced by inflammatory mediators in many other cells (e.g., monocytes, endothelial cells).

TABLE 113-3. Cofactor Enhancement of Serine Protease Activity

Cofactor-Protease*	Fold Increase†
TM-Thrombin	11,000
TF-VIIa	31,000
VIIIa-IXa	9,000,000
Va-Xa	390,000

TF, tissue factor; TM, thrombomodulin.

*Macromolecular enzyme complexes assembled in the presence of anionic phospholipids and calcium.

†Relative rates of enzymatic activity represent fold increase of the reaction rate (k_{cat}/K_m) observed for the cofactor-protease complex relative to the reaction rate (k_{cat}/K_m) observed for the protease in absence of the cofactor (see KG Mann, ME Nesheim, WR Church, et al: Surface-dependent reactions of the vitamin K-dependent enzyme complexes. *Blood* 76:1–16, 1990; and R Rawala-Sheikh, SS Ahmad, B Ashby, PN Walsh: Kinetics of coagulation factor X activation by platelet-bound factor IXa. *Biochemistry* 29:2606–2611, 1990).

(thrombokinase, factor III, now tissue factor), and calcium (factor IV).^{12,13} The zymogen prothrombin is primarily synthesized in the liver and circulates in plasma as a single-chain protein of 579 amino acids ($M_r \approx 72,000$) at a concentration of 1.4 μM with a plasma half-life of 60 hours (see Table 113-1).

Protein Structure

Prothrombin is composed of fragment 1 (F1), fragment 2 (F2), and the serine protease domain. F1 consists of the Gla domain, which comprises 10 Gla residues, and the kringle 1 domain; F2 contains the kringle 2 domain (see Fig. 113-1). The two kringle domains, which replace the EGF-like domains present in most vitamin K-dependent zymogens, are conserved secondary protein structures that fold into large loops that are stabilized by three disulfide bonds and schematically resemble a Danish pastry called a “kringle.” Their primary function is to bind other proteins such as the cofactor Va and serine protease factor Xa that activate prothrombin.

Other than γ -carboxylation of Glu residues, prothrombin is post-translationally modified via *N*-glycosylation in the kringle 1 (Asn78, Asn143) and serine protease domains (Asn373), which contributes to the stability of the prothrombin precursor during processing in the endoplasmic reticulum.^{14,15}

Prothrombin Activation and Thrombin Activity

Prothrombin is proteolytically activated by the prothrombinase complex (i.e., factor Va, factor Xa, calcium, and anionic phospholipids) that cleaves at Arg271 and Arg320 (see Fig. 113-1). Cleavage at Arg320 opens the active site of the protease domain, while cleavage at Arg271 removes the activation fragment F1.2 (F1.2). Both cleavages are necessary to generate procoagulant α -thrombin ($\text{II}\alpha$) (Fig. 113-4). The composition of the membrane surface directs the cleavage order in prothrombin and the formation of either the zymogen prethrombin 2 (initial cleavage at Arg271) or the proteolytically active intermediate meizothrombin (initial cleavage at Arg320).^{16,17} Meizothrombin has impaired procoagulant activity as compared to α -thrombin, but superior anticoagulant activity as it displays increased thrombomodulin-dependent protein C activation, which is likely facilitated by membrane binding of meizothrombin through its Gla domain.¹⁸ The snake venom protease Ecarin is capable of generating meizothrombin specifically through proteolysis at Arg323 only. However, this meizothrombin is unstable as a result of autocatalysis

Figure 113-4. Prothrombin to thrombin conversion. A molecular model of prothrombin comprising the γ -carboxy glutamic acid (Gla; GLA) domain, both kringle domains, and the catalytic domain is shown (PDB structures 2PF2, 1HAG, 1A0H, 1HA1). Gla domain-bound calcium ions are indicated in *black*. Cleavage by the factor Va-Xa complex at Arg271 and Arg320 releases thrombin (with the A chain and catalytically active B chain) from the rest of the molecule (fragment 1.2).

at Arg155, thereby removing the Gla domain containing F1. The so formed mezo-des-F1 can be converted to thrombin by prothrombinase, but at a slower rate as it is incapable of membrane binding. Assessment of F1.2 levels reflects prothrombin activation and is commonly used as a marker for thrombin generation.

Thrombin ($\text{II}\alpha$) is a two-chain serine protease ($M_r \approx 37,000$) comprising a light chain of 49 residues (A chain; $M_r \approx 6000$) that is covalently linked to the catalytic heavy chain of 259 residues (B chain; $M_r \approx 31,000$). Thrombin's main function is to induce the formation of a fibrin clot by removing fibrinopeptides A and B from fibrinogen to form fibrin monomers, which then spontaneously polymerize. In addition, thrombin is able to cleave a wide variety of substrates with high specificity, which is mediated via its negatively charged, deep active site cleft and via the anion binding exosites I and II that specifically interact with cofactors and/or substrates.¹⁹ The dynamic structural conformation of thrombin allows for binding to diverse ligands, and the subsequent ligand-induced conformational stabilization, known as thrombin allostery, regulates and controls thrombin activity.^{20,21}

Thrombin initiates important procoagulant pathways by proteolytic activation of the cofactors V and VIII and zymogen factor XI that collectively amplify thrombin and fibrin formation, and by activating factor XIII that crosslinks and stabilizes the fibrin polymers. Another procoagulant function of thrombin is to inhibit fibrinolysis by proteolytic activation of the thrombin-activatable fibrinolysis inhibitor (TAFI), a reaction enhanced by the endothelial-bound cofactor thrombomodulin. Thrombin also has an anticoagulant function and upon binding to the cofactor thrombomodulin, it is capable of proteolytically activating protein C, which inactivates the cofactors Va and VIIIa.

Thrombin activates the seven-transmembrane domain, G-protein-coupled protease-activated receptors (PARs) PAR1, PAR3, and PAR4 that are expressed on a wide range of cell types in the vasculature by proteolytic cleavage of their N-terminal extracellular domains.²²⁻²⁵ Thrombin is one of the strongest platelet activators *in vivo* and activates platelet-expressed PAR1 and PAR4.²⁵ The platelet glycoprotein (GP) Ib (GPIb) serves as a cofactor for thrombin in PAR1 cleavage (Chap. 112). Thrombin-mediated activation of endothelial-PAR1 triggers release of von Willebrand factor (VWF) and P-selectin, which promote rolling and adhesion of platelets and leukocytes. In addition, this stimulates the endothelial production of platelet-activating factor, a potent platelet and leukocyte activator, as well as the production of chemokines, cyclooxygenase (COX)-2, and prostaglandins.²⁵ Thrombin-mediated PAR activation is not only critical for coagulation, but also plays an important role

in inflammatory and proliferative responses associated with vascular injury, such as in atherosclerosis and cancer.²⁶

The physiologic inhibitors of thrombin are the serine protease inhibitors (serpins) antithrombin, heparin cofactor II, protein C inhibitor, and protease nexin 1, with antithrombin being the primary plasma inhibitor. For all four serpins, the rate of thrombin inhibition can be accelerated by glycosaminoglycans, such as heparin (Table 113-4), through mutual binding to the serpin and thrombin (see Fig. 113-2), which ensures rapid inhibition of thrombin at the intact endothelial cell surface where heparin-like glycosaminoglycans are found.

Heparin and heparin-derivatives are clinically used as anticoagulants to inhibit thrombin via antithrombin. Hirudin, which originates from the salivary glands of medicinal leeches, and its recombinant and synthetic derivatives are potent and highly specific inhibitors that directly target the active site and exosite I of thrombin.²⁷ The target-specific oral anticoagulant dabigatran also inhibits thrombin directly with high specificity and reversibly binds the active site of thrombin.^{27,28}

TABLE 113-4. Antithrombin Inhibition of Coagulation Proteases

Protease	Second-Order Association Rate Constants ($M^{-1}s^{-1}$)		
	- Heparin	+ H5	+ UFH
Thrombin	7.7×10^3	1.5×10^4	4.7×10^7
Factor Xa	2.6×10^3	7.6×10^5	6.6×10^6
Factor IXa	58	3.1×10^4	6.2×10^6
TF-Factor VIIa	33	4.9×10^3	1.5×10^4
Factor Xia	3.6×10^2	1.1×10^3	1.8×10^5
Factor Xlla	39	1.9×10^3	6.6×10^4
APC	0.08	1.9	2.1

APC, activated protein C; TF, tissue factor.

The association rate constants characterizing the antithrombin inhibition of coagulation proteases in the absence of heparin or accelerated by H5, the synthetic pentasaccharide fondaparinux, or UFH, unfractionated heparin, which comprises long heparin molecules. *In vivo*, natural glycosaminoglycan molecules on endothelium and other cells accelerate the rate of inhibition. (See ST Olson, R Swanson, E Raub-Segall, et al.³²¹)

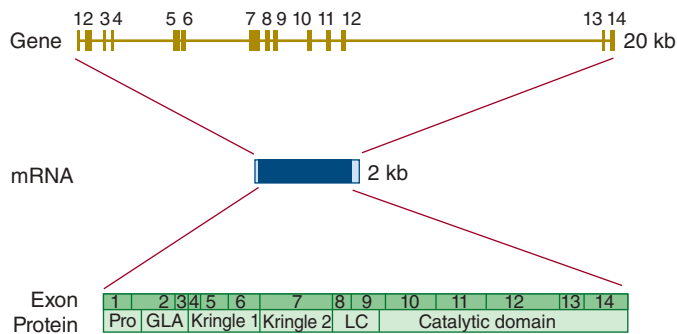

Figure 113-5. Relationship of gene structure to protein structure in prothrombin. The exons, introns, mRNA, and protein structure are as indicated. The mRNA is 2 kb with small 5' and 3' untranslated regions (shown in light blue). In the protein, Pro indicates the pro leader sequence, GLA indicates the γ -carboxy glutamic acid (Gla) domain, Kringles 1 and 2 are indicated, LC indicates the light chain (also known as the A chain), and the serine protease (catalytic) domain is indicated.

Gene Structure and Variations

Prothrombin is encoded by a gene (*F2*) on chromosome 11p11.2 that is approximately 20 kb long.²⁹ The coding sequence is divided over 14 exons that range in size from 25 to 315 bp (Fig. 113-5). The reference sequence of prothrombin mRNA comprises 2018 bases. There are no common, well characterized, splicing variants with known biology.

Homozygosity or compound heterozygosity for loss of function mutations in the prothrombin gene leads to a bleeding tendency. This condition is quite rare with perhaps one case per 2,000,000 newborns.³⁰ Heterozygous carriers of loss-of-function mutations are without a bleeding phenotype. Mutations have been characterized in a relatively small number of cases with homozygous or compound heterozygous prothrombin deficiency (consult the human gene mutation database at <http://www.hgmd.org> for details). The majority of mutations underlying prothrombin deficiency are missense mutations, but several small deletions/insertions have also been reported.

Gain-of-function mutations in the prothrombin gene increase thrombotic risk. The best known variation is G20210A.³¹ This variation of the last nucleotide preceding the poly(A)-tail of the mature mRNA has an effect on 3'-end mRNA processing and increases the level of prothrombin in plasma by approximately 10 to 20 percent in heterozygous individuals.³² This relatively small increase in the level of prothrombin results in a two- to threefold enhanced risk for venous thrombosis. Homozygotes for the G20210A variation are quite rare, and the risk associated with homozygosity has not been measured with certainty. The G20210A variation is relatively common in whites, with a strong south-north gradient in that the variation is most common in southern Europe.³³

FACTOR VII

Factor VII, which was discovered around 1950,³⁴ is synthesized in the liver and circulates in plasma as a single-chain zymogen of 406 amino acids ($M_r \approx 50,000$) at a concentration of 10 nM with a short plasma half-life of 3 to 6 hours (see Table 113-1).

Protein Structure

Factor VII consists of a Gla domain with 10 Gla residues, two EGF-like domains, a connecting region, and the serine protease domain (see Fig. 113-1). Calcium coordination in EGF-1 is mediated by partial hydroxylation of Asn63 and *O*-linked fucosylation of Ser60.³⁵ Further posttranslational modifications of factor VII consist of *O*-linked (Ser52 in EGF-1)

and *N*-linked (Asn154 in the connecting region, Asn322 in the serine protease domain) glycosylation.

Factor VII Activation and Factor VIIa Activity

Factor VII is proteolytically activated once it has formed a high-affinity complex with its cofactor tissue factor. A number of coagulation proteases including thrombin and factors IXa and XIIa are capable of cleaving factor VII at Arg152 to generate factor VIIa (see Fig. 113-1), with factor Xa being considered the most potent and physiologically relevant activator of factor VII.³⁶ Autoactivation can also occur, which is initiated by minute amounts (approximately 0.1 nM) of preexisting factor VIIa.³⁷

Factor VIIa is a two-chain serine protease composed of a light chain ($M_r \approx 20,000$) comprising the Gla and EGF domains and the catalytic heavy chain ($M_r \approx 30,000$), which are covalently linked via a disulfide bond. Factor VIIa activity is only expressed when bound to tissue factor, which induces an active conformation of the factor VIIa serine protease domain (Fig. 113-6).¹¹ Factor VIIa interacts with tissue factor via its Gla and EGF domains.

The tissue factor-factor VIIa complex activates both coagulation factors IX and X, which is considered to be the main initiating step of the extrinsic pathway of coagulation. In addition, the tissue factor-factor VIIa (-factor Xa) complex is not only critical to processes in coagulation, but also to wound healing, angiogenesis, tissue remodeling, and inflammation through proteolytic activation of PAR2.³⁸⁻⁴⁰

The ternary tissue factor-factor VIIa-factor Xa complex is inhibited by the tissue factor pathway inhibitor (TFPI). Tissue factor-factor VIIa is also inhibited by antithrombin, but only in the presence of heparin (see Table 113-4).

Gene Structure and Variations

The gene encoding factor VII (*F7*) is located on chromosome 13q34, is almost 15 kb in length, and comprises 9 exons (Fig. 113-7). The canonical mRNA encoding factor VII comprises 3000 bases.⁴¹ Alternatively spliced transcript variants encoding multiple isoforms have been observed, but their biology is not well characterized.⁴²

Inherited factor VII deficiency is a rare autosomal recessive disorder that affects approximately one in 500,000 newborns.³⁰ Factor VII deficiency is the most common of the inherited rare bleeding disorders,

Figure 113-6. The tissue factor-factor VIIa complex. A molecular model of factor VIIa (PDB structures 1QHK, 1WHF, 1RFN, 1DAN) and the crystal structures of the tissue factor-factor VIIa complex (PDB structure 1DAN) and the extracellular domain of tissue factor (PDB structure 2HFT) are shown. The γ -carboxy glutamic acid (Gla; GLA) domain, epidermal growth factor (EGF)-like domains 1 and 2, and serine protease (catalytic) domain of factor VIIa are indicated. Binding to tissue factor alters the overall structure of factor VIIa.

Figure 113–7. Relationship of gene structure to protein structure in factor VII. The exons, introns, mRNA, and protein structure are as indicated. The mRNA is 2.7 kb with a small 5' untranslated region and a relatively large 3' untranslated region (*light blue*). In the protein, Pro indicates the prepro leader sequence, GLA indicates the γ -carboxy glutamic acid (Gla) domain, and epidermal growth factor (EGF)-1 and -2, as well as the serine protease (catalytic) domain, are indicated. CR indicates the connecting region that comprises the site of proteolytic activation.

although the reported prevalences vary between countries. Homozygotes and compound heterozygotes develop a hemorrhagic diathesis that may vary from mild to severe.

The human gene mutation database (<http://www.hgmd.org>) lists 258 mutations in the factor VII gene. The majority of these are missense mutations, but splicing and regulatory mutations also occur. Small deletions account for almost 10 percent of the documented mutations. Other gross gene abnormalities appear to be uncommon.

The factor VII gene harbors many common polymorphisms of which three are notable: Arg353Gln in the catalytic domain, a 10-bp insertion in the promotor region, and a variable number of 37 bp repeats in intron 7.⁴³ The minor alleles of these polymorphisms are associated with decreased levels of factor VII and explain up to 30 percent of the variation in activated factor VII levels. Furthermore, the minor alleles have been claimed to lower the risk of myocardial infarction. However, this finding has not led to routine genotyping in the management of this disorder. The relationship between factor VII levels, factor VII polymorphisms, and venous thrombosis has not been established with certainty.

FACTOR IX

Factor IX was originally reported in 1952 as “Christmas factor,” named after one of the first identified hemophilia B patients.^{34,44} Factor IX is synthesized in the liver and circulates in plasma as a single-chain zymogen of 415 amino acids ($M_r \approx 55,000$) at a concentration of 90 nM with a half-life of 18 to 24 hours (see Table 113–1).

Protein Structure

Factor IX consists of a Gla domain, two EGF-like domains, a 35-residue activation peptide, and the serine protease domain (see Fig. 113–1). The Gla domain contains 12 Gla residues, of which the 11th and 12th Gla (Glu36 and Glu40) are not evolutionary conserved in other vitamin K-dependent proteins and are not essential for normal factor IX function.⁴⁵

Factor IX comprises several posttranslational modifications that are not only important for its structure and function, but are also involved in the plasma clearance and distribution of factor IX.³⁵ Factor IX is sulfated at Tyr155 and phosphorylated at Ser158 in the activation peptide. Hydroxylation of Asp64 in EGF 1 mediates calcium binding, and while only approximately 40 percent of total plasma factor IX carries this modification, complete absence because of a point mutation

at this position dramatically reduces factor IX activity resulting in hemophilia B.^{46,47} An *O*-linked fucose (Ser61) and glucose (Ser63) are found in the EGF 1 domain, in addition to several *O*-linked glycans in the activation peptide (Thr159, Thr169, Thr172, and Thr179). Further modification of the activation peptide includes *N*-linked glycosylation of Asn residues 157 and 167, which modulates the circulating levels of factor IX.^{48–50}

Factor IX binds with high affinity to the extracellular matrix component collagen IV via residue Lys5 in the Gla domain.^{51,52} Although factor IX variants incapable of collagen IV binding exhibit a greater recovery, collagen IV association generates an extravascular reservoir of factor IX that enables prolonged action of factor IX at a hemostatic relevant region.

Factor IX Activation and Factor IXa Activity

Limited proteolysis of factor IX at both Arg145 and Arg180 by either the tissue factor–factor VIIa complex or factor XIa results in the release of the activation peptide and generation of factor IXa (see Fig. 113–1). Cleavage at Arg180 generates factor IXa α , which displays catalytic activity toward synthetic substrates only, whereas fully active factor IXa β is formed following cleavage at Arg145.^{53,54}

Factor IXa is a two-chain serine protease ($M_r \approx 45,000$) that is composed of a light chain of 145 residues ($M_r \approx 17,000$) and the catalytic heavy chain of 235 residues ($M_r \approx 28,000$), which are covalently linked via a disulfide bond.

Factor IXa has a low catalytic efficiency as a result of impaired access of substrates to the active site that results from steric and electrostatic repulsion.⁵⁵ Reversible interaction with the cofactor VIIIa on anionic membranes and subsequent factor X binding leads to rearrangement of the regions surrounding the active site and proteolytic factor X activation.

The primary plasma inhibitor of factor IXa is the serpin antithrombin, and this inhibition is enhanced by heparin (see Table 113–4), which induces a conformational change in antithrombin that is required for simultaneous active site and exosite interactions with factor IXa.⁵⁶

Gene Structure and Variations

The gene encoding factor IX (*F9*) is located on chromosome Xq27.1 and covers nearly 25 kb.⁵⁷ It is divided into eight exons from which a mature mRNA molecule is transcribed with an ultimate length of 2802 bases (Fig. 113–8).

Figure 113–8. Relationship of gene structure to protein structure in factor IX. The exons, introns, mRNA, and protein structure are as indicated. The mRNA is 2.8 kb with a small 5' untranslated region and a relatively large 3' untranslated region (*light blue*). In the protein, Pro indicates the prepro leader sequence, GLA indicates the γ -carboxy glutamic acid (Gla) domain, and epidermal growth factor (EGF)-1 and -2, as well as the serine protease (catalytic) domain are indicated. AP indicates the activation peptide that is released after cleavage of two bonds.

A defect or deficiency in factor IX leads to hemophilia B. Chapter 123 discusses the prevalence, clinical characteristics, and molecular genetics of hemophilia B in detail.

Conversely, increased levels of factor IX are a strong risk factor for venous thrombosis.⁵⁸ This is in agreement with a rare gain of function mutation (Arg335Leu; factor IX Padua), which renders the protein hyperfunctional and is associated with familial early-onset thrombophilia.⁵⁹

FACTOR X

Factor X was originally reported in the late 1950s as the “Stuart-Prower factor,” named after the first two identified factor X-deficient patients.^{60–62} Factor X is primarily synthesized in the liver and circulates in plasma as a two-chain zymogen of 445 amino acids ($M_r \approx 59,000$) at a concentration of 170 nM with a half-life of 34 to 40 hours (see Table 113–1).

Protein Structure

Factor X is synthesized as a single-chain precursor and during intracellular processing, the three-amino acid peptide Arg140-Lys141-Arg142 is excised. The resulting two-chain zymogen consists of a light chain ($M_r \approx 16,000$), comprising the Gla domain with 11 Gla residues and the EGF domains, which is linked via a disulfide bond to the heavy chain ($M_r \approx 42,000$) that consists of a 52-residue activation peptide and the serine protease domain (see Fig. 113–1).

Hydroxylation of Asp63 mediates calcium binding to the EGF 1 domain and orients the Gla domain, which is essential for factor X clotting activity.³⁵ N-linked glycosylation of the activation peptide residues Asn181 and Asn191 has been implicated in prolonging the factor X half-life.⁶³ Further posttranslational modification of factor X consists of O-linked glycosylation at Thr159 and Thr171 in the activation peptide and Thr443 in the serine protease domain. There is some evidence that glycosylation of the human factor X activation peptide may also contribute to substrate recognition by the intrinsic or extrinsic factor X-activating complex.^{64,65}

Factor X Activation and Factor Xa Activity

Factor X is proteolytically activated by either the factor VIIIa-factor IXa (“intrinsic tenase”) or the tissue factor-factor VIIa (“extrinsic tenase”) enzyme complexes following cleavage at Arg194 in the heavy chain (see Fig. 113–1). This results in the release of the activation peptide and generation of factor Xa, also known as factor Xa α . A snake venom protease from Russell’s viper venom (RVV-X) is capable of generating factor Xa in a similar manner.

Factor Xa consists of the Gla and EGF domains-comprising light chain ($M_r \approx 16,000$) and the catalytic heavy chain ($M_r \approx 29,000$) that are covalently linked via a disulfide bond. Factor Xa reversibly associates with its cofactor factor Va on an anionic membrane surface in the presence of calcium ions to form prothrombinase, the physiologic activator of prothrombin. Factor Xa is also involved in the proteolytic activation of factors V, VII, and VIII.^{66–68}

Similar to thrombin, factor Xa plays a role in other biologic and pathophysiologic processes that are not directly related to coagulation. Factor Xa triggers intracellular signaling via activation of PAR1 and/or PAR2. Factor Xa cleaves PAR2 by itself as well as in complex with tissue factor-factor VIIa. These direct cellular effects of factor Xa contribute to wound healing, tissue remodeling, inflammation, angiogenesis, and atherosclerosis, among others.^{26,69}

Further autocatalytic cleavage at Arg429 near the C-terminus of the factor Xa heavy chain leads to release of a 19-residue peptide, yielding the enzymatically active factor Xa β .^{70–72} Plasmin-mediated cleavage

of factor Xa at adjacent C-terminal Arg or Lys residues also results in the generation of factor Xa β and factor Xa β derivatives.^{73,74} While the coagulation activity is eliminated in the factor Xa β derivatives, they are capable of interacting with the zymogen plasminogen and enhance its tissue plasminogen activator-mediated conversion to plasmin, thereby promoting fibrinolysis.⁷⁵

A primary plasma inhibitor of factor Xa is the serpin antithrombin, and this inhibition is enhanced by heparin (see Table 113–4), which induces a conformational change in antithrombin that is required for simultaneous active site and exosite interactions with factor Xa.⁷⁶ Another potent factor Xa inhibitor is TFPI, which inhibits both the ternary tissue factor-factor VIIa-factor Xa complex as well as free factor Xa, for which protein S functions as a cofactor.^{77,78} Free factor Xa is also inhibited by the protein Z/protein Z-dependent protease inhibitor (ZPI) complex on membranes.⁷⁹

Low-molecular-weight heparin and synthetic derivatives (e.g. fondaparinux) are clinically used as anticoagulants to enhance factor Xa inhibition by antithrombin specifically. The target-specific oral anticoagulants rivaroxaban, apixaban, edoxaban, and analogues directly inhibit both free factor Xa and prothrombinase complex-assembled factor Xa with high specificity through a high-affinity, reversible interaction with the factor Xa active site.^{80–83}

Gene Structure and Variations

The gene encoding factor X (*F10*) is located on chromosome 13q34 and spans almost 27 kb.⁸⁴ The 8 exons in the factor X gene give rise to a mature mRNA of 1560 bases (Fig. 113–9). There are no common alternative splice variants with known biology.

Loss of function mutations in the factor X gene lead to a rare bleeding disorder with a recessive mode of inheritance. Factor X deficiency occurs in approximately one in every 1,000,000 newborns. Most cases of documented factor X deficiency experience serious bleeding problems. In fact, factor X deficiency may be the most severe of the rare congenital bleeding disorders.³⁰ Well over 100 mutations have been documented in cases with factor X deficiency (<http://www.hgmd.org>). The majority of these mutations are missense and nonsense mutations.

Gain-of-function mutations in factor X could potentially increase thrombotic risk, but such mutations have not been documented. There

Figure 113–9. Relationship of gene structure to protein structure in factor X. The exons, introns, mRNA, and protein structure are as indicated. The mRNA is 1.5 kb with a relatively large 5′ untranslated region and a small 3′ untranslated region. In the protein, Pro indicates the pre-pro leader sequence, GLA indicates the γ -carboxy glutamic acid (Gla) domain, and epidermal growth factor (EGF)-1 and -2, as well as the serine protease (catalytic) domain, are indicated. AP indicates the activation peptide. Before secretion, cleavage in this domain processes factor X to the two-chain mature zymogen. A second cleavage releases the activation peptide and generates factor Xa activity.

is uncertainty about whether common gene variations influence the level of factor X in plasma.⁸⁵

PROTEIN C

Protein C, which plays a central role in the anticoagulant pathway, was discovered in 1960, and being the third protein peak ("peak C") observed in a vitamin K-dependent plasma protein purification, it was named protein C.^{86,87} Protein C is synthesized in the liver and circulates in plasma as a two-chain zymogen of 417 amino acids (Mr ≈62,000) at a concentration of 65 nM with a half-life of 6 to 8 hours (see Table 113-1).

Protein Structure

Protein C is synthesized as a single-chain precursor and during intracellular processing amino acids Lys146-Arg147 are excised. The resulting two-chain zymogen consists of a light chain (Mr ≈21,000) comprising the Gla domain with nine Gla residues and the EGF domains, which is linked via a disulfide bond to the heavy chain (Mr ≈41,000) that consists of the 12-residue activation peptide and the serine protease domain (see Fig. 113-1).

In addition to γ -carboxylation, protein C is hydroxylated at Asp71 in the EGF-1 domain, which coordinates calcium binding.³⁵ N-linked glycosylation of Asn97 in EGF-1 and Asn248, Asn313, and Asn329 in the serine protease domain are important for efficient protein secretion, proteolytic processing of Lys146-Arg147, and proteolytic activation.⁸⁸⁻⁹⁰ Some of the total plasma protein C is not glycosylated at either Asn329 (β -protein C) or at both Asn329 and Asn248 (γ -protein C), of which the impact on protein function remains unclear.⁹¹

Protein C Activation and Activated Protein C Activity

Protein C is proteolytically activated by α -thrombin in complex with the endothelial cell surface protein thrombomodulin following cleavage at Arg169 (see Fig. 113-1). The activation peptide is released and the mature serine protease activated protein C (APC) is formed. Activation of protein C is enhanced by its localization on the endothelial surface through association with the endothelial cell protein C receptor (EPCR).⁹² Several snake venom proteases (RVV-X and Protac) are also capable of activating protein C.

APC consists of the disulfide-linked light chain comprising the Gla and EGF domains (Mr ≈21,000) and the catalytic heavy chain (Mr ≈32,000). In complex with its cofactor protein S, APC proteolytically inactivates factors Va and VIIIa in a calcium- and membrane-dependent manner. Intact factor V has been reported to function as a cofactor for the inactivation of factor VIIIa in the presence of protein S.⁹³

Downregulation of thrombin formation through inactivation of these cofactors seems to occur preferentially on the endothelial cell surface as opposed to that of platelets,⁹⁴ where it prevents coagulation and potential thrombosis. However, protein C activation is also accelerated by platelet factor 4 (PF4), which is secreted by activated platelets. Upon interaction with the Gla domain of protein C, PF4 modifies the conformation of protein C, thereby enhancing its affinity for the thrombomodulin-thrombin complex.⁹⁵ This ensures APC generation in close proximity of the injury site where platelets are activated, which serves to impede dissemination of coagulation.

APC also plays a major role in the cytoprotective pathway to prevent vascular damage and stress.⁹⁶ These activities include antiapoptotic activity, antiinflammatory activity, alterations of gene-expression profiles, and endothelial barrier stabilization. Most of these functions require binding to EPCR and PAR1 cleavage.

APC is primarily inhibited by the heparin-dependent serpin protein C inhibitor and by plasminogen activator inhibitor-1 (PAI-1). Because PAI-1 is the major inhibitor of tissue plasminogen

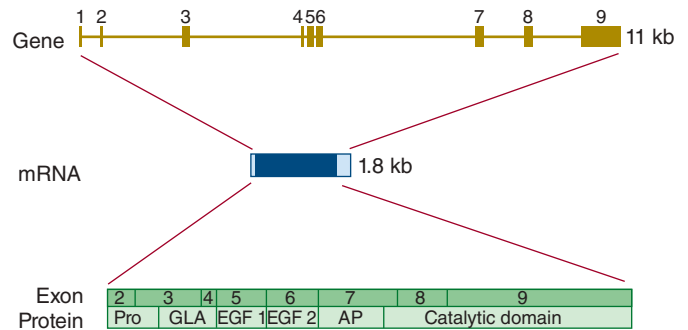

Figure 113-10. Relationship of gene structure to protein structure in protein C. The exons, introns, mRNA, and protein structure are as indicated. The mRNA is 1.8 kb with a small 5' untranslated region coded for by exon 1 and a relatively small 3' untranslated region (*light blue*). In the protein, Pro indicates the prepro leader sequence, GLA indicates the γ -carboxy glutamic acid (Gla) domain, and epidermal growth factor (EGF)-1 and -2, as well as the serine protease (catalytic) domain, are indicated. AP indicates the activation peptide. Before secretion, cleavage in this domain processes protein C to the two-chain mature zymogen. A second cleavage releases the activation peptide and generates activated protein C.

activator, inhibition through complex formation with APC contributes to enhanced fibrinolysis. Chapter 114 discusses these and other factors that attenuate the anticoagulant activity of APC.

Gene Structure and Variations

The protein C gene (*PROC*) is located on chromosome 2q14.3 and spans almost 11 kb.⁹⁷ The gene is divided into nine exons and the mature mRNA has a length of 1790 bases (Fig. 113-10). There are no alternative mRNA species with known biology.

Loss-of-function mutations cause protein C deficiency. In homozygous or compound heterozygous form this leads to life-threatening purpura fulminans at birth which, if left untreated, is fatal.⁹⁸ In cases where there is still some protein C activity detectable, symptoms may be much milder.

Heterozygous protein C deficiency increases the risk of venous thrombosis. This is true for most deficiencies of natural anticoagulants and sets them apart from rare bleeding disorders where heterozygosity for loss of function mutations is mostly asymptomatic. The risk for venous thrombosis is increased approximately 10-fold in heterozygotes for protein C deficiency, albeit that the risk estimates vary considerably between studies.⁹⁹ Family studies in particular suggest a high risk, whereas case-control studies may show markedly lower estimates.¹⁰⁰

Heterozygous protein C deficiency can be categorized as type I or type II. In type I deficiency, antigen levels are approximately 50 percent of normal, whereas in type II deficiency, antigen levels are (near) normal but activity levels are decreased by 50 percent.

The genetic basis of protein C deficiency, consistent with what is observed in general for congenital loss of function disorders, is heterogeneous. In line with this, more than 300 mutations have been documented and are tracked in the human gene mutation database (<http://www.hgmd.org>). Two-thirds of these documented mutations are missense or nonsense.

Several common polymorphisms, in particular in the promoter region of the protein C gene, are known to have a small but measurable effect on plasma protein C levels. Alleles of these polymorphisms that are associated with lower protein C levels are also associated with an increased thrombotic risk, albeit that the effect is small.¹⁰¹ Therefore, it is not surprising that measurement of these polymorphisms have not found any clinical application.

THE PROCOAGULANT COFACTORS V AND VIII

Factors V and VIII both function as cofactors in coagulation and dramatically enhance the catalytic rate of their macromolecular enzyme complexes, resulting in the generation of thrombin and factor Xa, respectively. Apart from their functional equivalence, they also share similar gene structures, amino acid sequences, and protein domain structures, which is not surprising considering that factors V and VIII are assumed to descend from the common ancestral A1-A2-A3 domain-containing copper-binding plasma protein ceruloplasmin through a gene duplication event.¹⁰² After acquiring C-type domains as well as the central B domain, a second gene duplication ultimately separated the ancestral genes of factors V and VIII.

Factors V and VIII undergo similar mechanisms of intracellular processing in the endoplasmic reticulum (ER) and Golgi apparatus. Trafficking through this early secretory pathway involves interaction of factors V and VIII with a receptor complex that consists of the mannose-binding lectin-1 gene product LMAN1 (also called ER-Golgi intermediate compartment (ERGIC)-53) and multiple coagulation deficiency protein 2 (MCFD2).¹⁰³ Defects or deficiencies in one of the two subunits of the receptor complex can result in a combined deficiency of factors V and VIII (Chap. 124).

FACTOR V

In 1943, Norwegian physician Paul Owren discovered the fifth coagulation factor thus far known and named it factor V.^{104–106} Factor V is synthesized in the liver and circulates in plasma as a large single-chain procofactor of 2196 amino acids ($M_r \approx 330,000$) at a concentration of 20 nM with a half-life of 12 to 36 hours (see Table 113–1).

Approximately 20 percent of the total factor V in blood is stored in the α -granules of platelets. Although it was originally thought that megakaryocytes synthesize factor V, studies in humans indicate that platelet factor V originates from plasma through endocytic uptake.^{107–109} Platelet factor V is modified intracellularly such that it is functionally unique compared to its plasma-derived counterpart. It is partially activated, more resistant to inactivation by APC, and has several different posttranslational modifications.¹¹⁰

Platelet factor V is associated with the large multimeric protein multimerin.¹¹¹ Multimerin has a massive repeating structure, with some of the multimers having molecular weights of several million daltons. Although the function of this platelet factor V-specific multimeric chaperon protein is similar to that of VWF, the multimeric chaperon protein of factor VIII in plasma, multimerin and VWF share no structural homology.

Following platelet activation, platelet factor V becomes available at the site of injury and can reach local concentrations that exceed the factor V plasma concentration by more than 100-fold.¹¹² Interestingly, the origin of factor V in mouse platelets differs from humans in that it is synthesized in megakaryocytes and stored into the α -granules before platelets are released from the marrow.^{113,114}

Protein Structure

Factor V has an A1-A2-B-A3-C1-C2 domain structure (Fig. 113–11). The three A-type domains share significant homology with those of ancestral ceruloplasmin as well as with the factor VIII A domains (approximately 50 percent sequence identity). The two C-type domains belong to the family of discoidin domains, which are generally involved in cell adhesion, and share approximately 55 percent sequence identity with the factor VIII C domains. The C domains mediate binding to the anionic phospholipid surface, thereby localizing factor V to the site of injury and facilitating interaction with factor Xa and prothrombin.^{115–118} In contrast, the large central B domain of factor V shows weak homology to the factor VIII B domain or to any other known protein domain. However, this domain comprises so-called basic and acidic regions that are highly conserved throughout evolution and serve to negatively regulate factor V function and prevent activity of the procofactor.^{119,120}

Factor V undergoes extensive posttranslational modifications, including sulfation, phosphorylation, and N-linked glycosylation.^{35,121} Sulfation at sites in the A2 and B domain are involved in the thrombin-mediated proteolytic activation of factor V.¹²² Phosphorylation at Ser692 in the A2 domain enhances the APC-dependent inactivation of the cofactor Va.¹²³ N-linked glycosylation occurs throughout the whole protein; however, the majority of carbohydrates are linked to Asn residues within the B domain and play a role in the LMAN1-MCFD2 receptor complex-mediated trafficking of factor V from the ER to the Golgi in the early secretory pathway.¹⁰³ Partial glycosylation at Asn2181 in the C2 domain of factor V results in a lower binding affinity for negatively charged membranes of the glycosylated form, thereby reducing the factor V procoagulant activity, particularly at low phospholipid concentrations.^{124,125} Furthermore, factor V comprises several disulfide bonds that are important for the three-dimensional structure of the A and C domains.¹²¹

Factor V Procofactor Activation and Factor Va Cofactor Function

Sequential proteolytic cleavage of the procofactor factor V at Arg709, Arg1018, and Arg1545 in the B domain results in release of the inhibitory constraints exerted by the B domain and in the generation of the heterodimeric cofactor Va (see Fig. 113–11).¹²⁶ Maximal cofactor activity correlates with cleavage at Arg1545, which is consistent with the observation that a snake venom protease from RVV-V, which cleaves only at Arg1545, results in full activation. Thrombin has generally been recognized to be the principal activator of factor V. However, recent findings suggest that in the initiation phase of coagulation factor V is primarily activated by factor Xa.¹²⁷ Factor Xa initially cleaves factor V at Arg1018, followed by proteolysis at Arg709 and Arg1545.¹²⁸

Factor Va is composed of a heavy chain ($M_r \approx 105,000$) comprising the A1-A2 domains and the A3-C1-C2 light chain ($M_r \approx 74,000$), which are noncovalently associated via calcium ions. Factor Va is a nonenzymatic cofactor within the prothrombinase complex that greatly accelerates the ability of factor Xa to rapidly convert prothrombin to thrombin.¹²⁹ APC catalyzes the inactivation of factor Va by cleavage at the main sites Arg306 and Arg506, upon which the cleaved A2 fragment

Figure 113–11. The domain structure of factor V. Schematic A1-A2-B-A3-C1-C2 domain representation of factor V. Thrombin cleavage sites (Arg709, Arg1018, Arg1545) are indicated by *green arrows*, and activated protein C (APC) cleavage sites (Arg306, Arg506) by *red arrows*. The *blue* and *red* boxes in the B domain represent the basic and acidic region, respectively, that are highly conserved throughout evolution and serve to negatively regulate factor V function and prevent activity of the procofactor V.

Figure 113-12. Relationship of gene structure to protein structure in factor V. The exons, introns, mRNA, and protein structure are as indicated. The mRNA is 7 kb with some 5' and 3' untranslated sequences (light blue). In the protein, P indicates the propeptide leader sequence, and the A1-A2-B-A3-C1-C2 domains are indicated.

dissociates and factor Va can no longer associate with factor Xa.¹³⁰ A common Arg506Gln mutation in factor V leads to resistance to inactivation by APC (factor V Leiden) and is associated with an increased risk of venous thromboembolism (Chap. 133).¹³¹

Both factor V and an alternatively spliced isoform of factor V (factor V-short), which lacks the major part of the B domain (residues 756 to 1458) and normally circulates in low abundance, interact with full-length TFPI (TFPI α), most likely through the acidic B domain region.^{132,133} The linkage of factor V and TFPI α is considered to attenuate the bleeding phenotype in factor V-deficient patients, as the low TFPI α levels in these patients allow the residual platelet factor V to be sufficient for coagulation.^{132,134} Conversely, increased factor V-short expression caused by an A2440G mutation in the factor V gene leads to a dramatic increase in plasma TFPI α , resulting in a bleeding disorder.¹³³

Gene Structure and Variations

The gene for factor V (*F5*) is located on chromosome 1q23. It is located very close to the genes for the selectin family of leukocyte adhesion molecules. The factor V gene spans approximately 70 kb and consists of 25 exons (Fig. 113-12). The gene structure is very similar to that of the factor VIII gene, with exon-intron boundaries occurring at exactly the same location in 21 out of 24 cases.¹³⁵

Homozygosity or compound heterozygosity for loss-of-function mutations in the factor V gene lead to a bleeding disorder (termed *parahemophilia* or *Owren parahemophilia*).¹³⁶ At the time of writing, 152 mutations in the factor V gene have been collected in the human gene mutation database (www.hgmd.org).

Gain-of-function mutations in the factor V gene increase the risk of thrombosis. This is particularly the case for venous thrombosis and not so much for arterial thrombosis. In whites, the most common gain-of-function mutation in the factor V gene is factor V Leiden (Arg-506Gln), which leads to a plasma abnormality known as APC resistance (Chap. 133).^{137,138}

Figure 113-13. The domain structure of factor VIII. Schematic A1-a1-A2-a2-B-a3-A3-C1-C2 domain representation of factor VIII. The acidic regions denoted by a1, a2, and a3 are indicated, thrombin cleavage sites (Arg372, Arg740, Arg1689) are indicated by green arrows, and activated protein C (APC) cleavage sites (Arg336, Arg562) by red arrows. The variably sized B domain as a result of differential proteolytic processing is indicated.

FACTOR VIII

Factor VIII (antihemophilic factor) was first discovered in 1937, but it was not until 1979 that its purification by Tuddenham and coworkers led to the molecular identification of the protein.^{139,140} Factor VIII is synthesized as a single-chain preprocofactor of 2351 amino acids and, subsequent to intracellular processing, is secreted as a series of metal ion-linked heterodimers due to proteolysis at the A3-B junction and differential processing in the central B domain (Fig. 113-13). The mature factor VIII procofactor comprises 2332 amino acids ($M_r \approx 300,000$) and circulates in a high-affinity complex with its carrier protein VWF at a concentration of approximately 0.7 nM and a circulatory half-life of 8 to 12 hours (see Table 113-1). Complex formation with VWF protects factor VIII from proteolytic degradation, premature ligand binding, and rapid clearance from the circulation.

The primary source of factor VIII is the liver,^{141,142} but extrahepatic synthesis of factor VIII also occurs.^{143,144} While contradictory evidence exists on the cellular origin of both hepatic and extrahepatic factor VIII synthesis, recent studies in mice support that endothelial cells from many tissues and vascular beds synthesize factor VIII, with a large contribution from hepatic sinusoidal endothelial cells.¹⁴⁵⁻¹⁴⁷ This is consistent with observations on factor VIII expression in human endothelial cells from the liver and lung.^{148,149}

Factor VIII is less efficiently secreted from the cell as compared to factor V, because it interacts with the ER-chaperon proteins calnexin and calreticulin, whereas factor V interacts with calreticulin only.¹⁵⁰ Both chaperons preferentially interact with GPs comprising monoglucosylated N-linked oligosaccharides and promote correct folding of proteins that enter the secretory pathway and target misfolded proteins for degradation. Factor VIII, but not factor V, also interacts with the ER-chaperon immunoglobulin-binding protein (BiP/GRP78), which appears to enhance the stability of factor VIII, but also retards its secretion.¹⁵¹ Factor VIII trafficking from the ER to the Golgi is mediated via the LMAN1-MCDF2 receptor complex, similar to factor V.¹⁰³

Several clearance receptors are responsible for actively removing factor VIII from the circulation, which include the low-density lipoprotein (LDL) receptor-related protein 1 (LRP1), the LDL receptor, and receptors that specifically interact with carbohydrate structures on factor VIII.¹⁵²⁻¹⁵⁶

Protein Structure

The A1-A2-B-A3-C1-C2 domain structure of factor VIII shares significant homology with factor V except in the B domain region (see Fig. 113-13). In contrast to factor V, the factor VIII B domain is dispensable for procoagulant activity. The mature factor VIII procofactor comprises a variably sized heavy chain (A1-A2-B; $M_r \approx 200,000$ to 90,000 depending on the extent of proteolysis) and a light chain (A3-C1-C2; $M_r \approx 80,000$). The C-terminal regions of the A1 and A2 domains and the N-terminal portion of the A3 domain contain short segments of 30 to 40 negatively charged residues known as the a1, a2, and a3 regions. Interaction with VWF is facilitated by the a3 region and C1 domain.^{157,158} The C domains mediate binding to the anionic phospholipid surface, thereby localizing factor VIII to the site of injury and facilitating interaction with factor IXa and factor X.¹⁵⁹⁻¹⁶¹

Factor VIII is heavily glycosylated and the majority of the *N*-linked glycosylation sites are found in the B domain, which mediate interaction with the chaperons calnexin and calreticulin and, in part, with the LMAN1–MCDF2 receptor complex.^{103,150,162} Sulfation of tyrosine residues is required for optimal activation by thrombin, maximal activity in complex with factor IXa, and maximal affinity of factor VIIIa for VWF.^{35,163} Factor VIII comprises two phosphorylation sites that are located in the A1 (Thr351) and B (Ser1657) domains.

Factor VIII Procofactor Activation and Factor VIIIa Cofactor Function

Thrombin and factor Xa are the principal activators of the procofactor VIII and generate the cofactor VIIIa through sequential proteolysis at Arg740, Arg372, and Arg1689.^{126,164–166} The heterotrimeric factor VIIIa is composed of the A1 (Mr ≈50,000), A2 (Mr ≈43,000), and the A3-C1-C2 light chain (Mr ≈73,000) subunits (see Fig. 113–13). The A1 and A3-C1-C2 subunits are noncovalently linked through calcium ions, whereas A2 is associated with weak affinity primarily by electrostatic interactions.^{167,168} Once activated, factor VIIIa functions as a cofactor for factor IXa in the phospholipid-dependent conversion of factor X to factor Xa. The rapid and spontaneous loss of factor VIIIa cofactor activity is attributed to A2 domain dissociation from the heterotrimer.^{167,168} Additional proteolysis by APC, factor Xa, or factor IXa also results in the downregulation of factor VIIIa cofactor activity.¹⁶⁹

Gene Structure and Variations

The factor VIII encoding gene (*F8*) is situated at chromosome Xq28. The factor VIII gene contains 26 exons (Fig. 113–14), one more than factor V, because exon 5 of factor V corresponds to exons 5 and 6 of the factor VIII gene.¹⁷⁰ In addition, the gene for factor VIII is much larger than that of factor V, spanning approximately 190 kb. This is largely because six of the introns in the factor VIII gene are much larger than the corresponding *F5* introns. The mRNA for factor VIII is also much larger than the factor V mRNA because of a 1.8 kb 3′-untranslated region.

A defect or deficiency in factor VIII leads to hemophilia A. Chapter 123 discusses the prevalence, clinical characteristics, and molecular genetics of hemophilia A in detail.

High levels of factor VIII are a common and strong risk factor for venous thrombosis. It has been suspected that certain genetic variations in the factor VIII gene might play a role in determining the level of factor VIII; however, such variations have not been identified.¹⁷¹ The ABO blood group does play a role in determining the level of factor VIII, but probably indirectly through an effect on the level of VWF.^{172,173}

Figure 113–14. Relationship of gene structure to protein structure in factor VIII. The exons, introns, mRNA, and protein structure are as indicated. The mRNA is 9 kb with some 5′ untranslated sequence and a large 3′ untranslated region (light blue). In the protein, P indicates the propeptide leader sequence, and the A1-A2-B-A3-C1-C2 domains are indicated.

THE SOLUBLE COFACTORS PROTEIN S AND VON WILLEBRAND FACTOR

PROTEIN S

Protein S, which is named after the city (Seattle) where it was discovered by the group of Earl Davie in 1977, is a vitamin K–dependent single-chain GP of 635 amino acids (Mr ≈75,000) that circulates with a plasma half-life of 42 hours (see Table 113–1). Part of the total protein S pool circulates in a free form at a concentration of 150 nM, whereas the majority (approximately 60 percent; 200 nM) circulates bound to the complement regulatory protein C4b-binding protein (C4BP). Protein S is primarily synthesized in the liver by hepatocytes, in addition to endothelial cells, megakaryocytes, testicular Leydig cells, and osteoblasts.^{174–178}

Protein Structure

The protein structure of protein S differs from the other vitamin K–dependent proteins as it lacks a serine protease domain and, consequently, is not capable of catalytic activity. Protein S is composed of a Gla domain comprising 11 Gla residues, a thrombin-sensitive region (TSR), four EGF domains, and a C-terminal sex hormone-binding globulin (SHBG)-like region that consists of two laminin G-type domains (Fig. 113–15). The SHBG-like domain is involved in the interaction with the β -subunit of C4BP.

Apart from γ -carboxylation of Glu residues, protein S is posttranslationally modified via *N*-glycosylation in the second laminin G-type domain of the SHBG-like region (Asn458, Asn468, Asn489). β -Hydroxylation of Asp95 or Asn residues (Asn136, Asn178, Asn217) in each EGF domain allows for calcium binding that orients the four EGF domains relative to each other.³⁵

Protein S Cofactor Function

Free protein S serves as a cofactor for APC in the proteolytic inactivation of factors Va and VIIIa.^{179,180} Interaction of protein S with APC on a negatively charged membrane surface alters the location of the APC active site relative to factor Va,¹⁸¹ which accounts for the selective protein S-dependent rate enhancement of APC cleavage at Arg306 in factor Va.¹⁸² C4BP-bound protein S also exerts a similar stimulatory effect on Arg306 cleavage, albeit to lower extent, whereas it inhibits the initial APC-mediated factor Va cleavage at Arg506, resulting in an overall inhibition of factor Va inactivation.¹⁸³ Cleavage of the TSR by thrombin and/or factor Xa results in a loss of APC-cofactor activity.¹⁸⁴ Protein S also functions as a cofactor for TFPI α in the inhibition of factor Xa, which is mediated by the SHBG-like region in protein S.^{77,185}

Protein S has been implied to play a role in phagocytosis of apoptotic cells, cell survival, activation of innate immunity, vessel integrity and angiogenesis, and local invasion and metastasis through interaction with a family of protein tyrosine kinase receptors referred to as Tyro-3, Axl and Mer (TAM) receptors.^{186,187}

Gene Structure and Variations

The gene encoding protein S (*PROS1*) is located on the long arm of chromosome 3 (3q11.1), very close to the centromere. A highly homologous protein S pseudogene (*PROSP*) is located on the other side of the centromere. This pseudogene is inactive, as it is not transcribed into mRNA.¹⁸⁸ The active protein S gene encompasses 15 exons and covers a little more than 100 kb (Fig. 113–16). The mRNA sequence consists of 3560 bases. Several alternative transcripts have been identified, but none of these have known biology.

Loss-of-function mutations in *PROS1* lead to protein S deficiency. Several cases of homozygous and compound heterozygous protein S

Figure 113–15. Protein S, factor XI, factor XII, and tissue factor pathway inhibitor (TFPI). Schematic of protein S, factor XI, factor XII, and TFPI α . Each circle represents an amino acid. For protein S: the prepro leader sequence comprising the signal peptide as well as the propeptide is indicated, the γ -carboxy glutamic acid (Gla) domain is indicated with the Gla residues in *blue*, TSR represents the thrombin-sensitive region, the four epidermal growth factor (EGF) domains are indicated, and SHBG represents the sex hormone-binding globulin-like region. For factor XI: the four apple domains are indicated, and the serine protease (catalytic) domain is shown. Cys321 in the apple 4 domain that forms a disulfide link with Cys321 in the other factor XI subunit, thereby mediating dimerization, is indicated in *yellow*. For factor XII: types I and II represent the fibronectin types I and II domains, the two EGF-like domains are indicated, the kringle domain is indicated, Pro indicates the proline-rich region, and the serine protease (catalytic) domain is indicated. For TFPI α : the three Kunitz domains are indicated and the C-terminal sequence of basic residues is indicated in *light blue*. Factors XI and XII have homologous serine protease (“catalytic”) domains (shown in *light red*), in which the active site His, Asp, and Ser residues are indicated in *dark red*. Cleavages that convert the zymogens factor XI and factor XII to an active enzyme are indicated by the *red arrows*. Cysteine residues that form a disulfide bridge (*black line*) are indicated in *green*.

deficiency have been described with extremely low protein S levels. These very rare cases suffer from life-threatening purpura fulminans at birth.¹⁸⁹

Much more common are heterozygous deficiencies of protein S, which can be categorized into three types of deficiency. Type I deficiency is characterized by antigen levels that are approximately 50 percent of normal. In type II deficiency, antigen levels are (near) normal while activity levels are decreased by 50 percent. Type III deficiency is defined by a low level of free protein S. In keeping with this classification, clinical chemistry laboratories may offer a protein S activity assay, free antigen assay, or total antigen assay (or a combination thereof). These assays are not without problems and the evaluation of protein S levels is fraught with complications that need careful attention before a final diagnosis can be made.¹⁹⁰

The genetic basis of protein S deficiency is highly heterogeneous and there are more than 200 entries in the human gene mutation database (www.hgmd.org). Most of these are missense mutations. However, protein S deficiency is often characterized by gross gene deletions, that sometimes even involve neighboring genes.¹⁹¹ The reason for this preponderance of gross gene abnormalities remains unknown.

It is commonly assumed that protein S deficiency increases venous thrombotic risk by 10-fold.¹⁰⁰ This assertion is mainly based on studies in thrombophilic families. In population-based case-control studies, however, the risk increase appears to be much more modest, if present at all.¹⁹² The reason for this discrepancy between family and population-based studies remains enigmatic. The findings argue against including tests for protein S deficiency in a thrombophilia workup of venous thrombosis cases with a negative family history.

Figure 113–16. Relationship of gene structure to protein structure in protein S. The exons, introns, mRNA, and protein structure are as indicated. The mRNA is 2.3 kb with small 5' and 3' untranslated regions (*light blue*). In the protein, Pro indicates the prepro leader sequence, GLA indicates the γ -carboxy glutamic acid (Gla) domain, T indicates the thrombin-sensitive region; E indicates the epidermal growth factor (EGF)-like domains, and the glucocorticoid hormone-binding domain represents the sex hormone-binding globulin (SHBG)-like domain.

VON WILLEBRAND FACTOR

Chapter 126 discusses the structure, function, and molecular biology of VWF in detail. VWF is a large multimeric GP that is required for normal platelet adhesion to components of the vessel wall and that serves as a carrier for factor VIII. It is exclusively synthesized in megakaryocytes and endothelial cells and stored in specialized organelles in platelets and endothelial cells. Release of VWF multimers from these organelles follows upon a stimulus or via unstimulated basal secretion from endothelial cells.¹⁹³ VWF multimers circulate at a concentration of 10 nM with a half-life of 8 to 12 hours (see Table 113–1). Clearance of VWF multimers is mainly mediated by macrophages from the liver and spleen.¹⁹⁴

Large VWF multimers are cleaved by the plasma protease ADAMTS-13 (a disintegrin and metalloproteinase with thrombospondin motifs 13).¹⁹⁵ This cleavage produces the smaller size VWF multimers that circulate in plasma. Reduced ADAMTS-13 activity is linked to various microangiopathies with increased platelet activity.

Protein Structure

The precursor protein of VWF is composed of a 22-residue signal peptide and of a proVWF protein comprising 2791 amino acids that has 14 distinct domains in the order of D1-D2-D'-D3-A1-A2-A3-D4-B1-B2-B3-C1-C2-CK.¹⁹⁶ Upon translocation to the ER, the signal peptide is cleaved off, and the proVWF dimerizes in a tail-to-tail fashion through cysteines in its cysteine knot (CK) domain. During transit through the Golgi apparatus, proVWF dimers multimerize in a head-to-head fashion through the formation of disulfide bonds between cysteine residues in the D3 domain. At the same time, D1 and D2 domains are cleaved off as a single fragment to form the VWF propeptide (741 amino acids), while the remaining domains comprising 2050 amino acid residues and up to 22 carbohydrate chains form mature VWF. In the *trans*-Golgi network, the VWF propeptide promotes mature VWF to assemble into high-molecular-weight multimers ($M_r \approx 500,000$ to 20,000,000). These multimers subsequently aggregate into tubular structures that are packaged into α -granules in megakaryocytes and into Weibel-Palade bodies in endothelial cells.

von Willebrand Factor Function

Upon exocytosis from Weibel-Palade bodies and at high shear rates, multimeric VWF unrolls from a globular to a filamental conformation (often called *VWF strings*), up to many microns long, which becomes a high-affinity surface for the platelet GPIb-V-IX complex. Large VWF

multimers are more active than smaller multimers, which is explained by the fact that the former contain multiple domains that support the interactions between platelets, endothelial cells, and subendothelial collagen.

VWF binds to matrix collagens via its A1 and A3 domains. The A1 domain also mediates binding to platelet GPIb, which is required for the fast capture of platelets.¹⁹⁷ Platelet adhesion to VWF is further supported by VWF immobilization on a surface (collagen, other platelets) and by high shear stress.

VWF complexes with factor VIII through the first 272 residues in the N-terminal region of the mature VWF protein subunit,¹⁹⁸ thereby protecting factor VIII from proteolytic degradation, premature ligand binding, and rapid clearance from the circulation.

Gene Structure and Variations

The VWF gene (*VWF*) is located on chromosome 12p13.3, spans approximately 180 kb, and contains 52 exons.¹⁹⁹ The VWF mRNA is 8.7 kb long. There are no alternative transcripts with known biology. A partially inactive pseudogene that includes exons 23 to 34 is located on chromosome 22p11–13.¹⁹⁹ The VWF gene is very polymorphic, which makes it sometimes difficult to distinguish between disease causing mutations and neutral gene variations.

Qualitative or quantitative deficiencies in VWF cause von Willebrand disease (VWD), a mild to severe bleeding disorder. Quantitative deficiency of VWF leads to type 1 or type 3 VWD, whereas functional defects lead to type 2 VWD. Type 1 VWD is the most common form, but type 3 VWD is the most severe. Chapter 126 discusses VWD in detail.

High levels of VWF are a risk factor for venous and arterial thrombosis. Genome-wide association studies led to the identification of several genomic loci that influence the level of VWF, including the VWF gene itself, the ABO blood group, *STXB5*, and *SCARA5*.²⁰⁰ Polymorphisms in several of these loci are also associated with thrombotic risk.²⁰¹

● FACTOR XI AND THE CONTACT SYSTEM

FACTOR XI

Factor XI, which was discovered in the early 1950s,^{202,203} is synthesized in the liver and secreted as a single-chain zymogen of 607 amino acids ($M_r \approx 80,000$). In the circulation, factor XI is found as a homodimer ($M_r \approx 160,000$) at a concentration of 30 nM with a plasma half-life of 60 to 80 hours (see Table 113–1). All factor XI homodimers circulate in complex with high-molecular-weight kininogen (HK).²⁰⁴ HK is thought to mediate binding of factor XI to negatively charged surfaces, thereby facilitating factor XI activation.²⁰⁵ There is conflicting evidence suggesting that HK may be also involved in the interaction of factor XI with the activated platelet surface via GPIb.²⁰⁶

Protein Structure

Each factor XI subunit comprises four apple domains and a serine protease domain (see Fig. 113–15). The apple domains are structured by three disulfide bonds and form a disk-like platform on which the serine protease domain rests.²⁰⁷ The dimerization of two factor XI subunits is mediated by interactions between the two apple 4 domains that involve a disulfide bond between the Cys321 residues, hydrophobic interactions, and a salt bridge, of which only the latter two are required for dimerization.²⁰⁶ The domain structure of factor XI is highly similar to that of the monomer prekallikrein (PK), the zymogen of the protease kallikrein, which also circulates in complex with HK.²⁰⁶

Factor XI does not bear a Gla domain and thus does not require γ -carboxylation to exert its procoagulant activity. *N*-linked glycosylation

occurs at three sites in the apple 1, 2, and 4 domains (Asn82, Asn114, Asn335) and at two sites in the serine protease domain (Asn432, Asn473).

Factor XI Activation and Activity

Activation of a factor XI subunit to factor XIa proceeds through proteolysis at Arg369 in the N-terminal region of the serine protease domain and yields two-chain activated factor XIa. There are several catalysts capable of factor XI activation, which include the contact factor XIIa, thrombin, or factor XIa itself in the presence of negatively charged surfaces.^{208,209} However, their mechanisms differ as factor XI must be a dimer to be activated by factor XIIa, whereas thrombin and factor XIa lack this requirement.²¹⁰ An activated factor XI dimer may comprise either one (1/2-factor XIa) or two factor XIa subunits.²¹¹

Following activation of factor XI, binding sites for the substrate factor IX become available in the apple 3 domain and serine protease domain of factor XIa.^{212,213} Factor XIa proteolytically activates factor IX to factor IXa in a calcium-dependent but phospholipid-independent manner. Both forms of the factor XIa dimer as well as monomeric factor XIa activate factor IX in a similar manner.²¹¹

Accumulating evidence supports the notion that factor XIIa-dependent activation of factor XI is not essential to normal hemostasis, but is important in pathologic thrombus formation.^{214–216} Thrombin-mediated activation of factor XI, on the other hand, seems most significant under conditions of low tissue factor and is assumed to enhance clot stability through thrombin-activation of TAFI.^{217,218}

Factor XI has been reported to interact with platelet GPIb, which is mediated through a site within the apple 3 domain, and to platelet apolipoprotein E receptor 2 (ApoER2).^{219,220} It has been proposed that the dimeric structure allows for simultaneous interaction with the platelet by one subunit, thereby localizing factor XI to the site of clot formation, while binding to factor IX with the other subunit.²²¹

Factor XIa function is regulated by the serpins protease nexin 1, antithrombin, C1-inhibitor, α_1 -protease inhibitor, protein Z-dependent protease inhibitor, and α_2 -antiplasmin.^{216,222} Platelets also contain a factor XIa inhibitor, the Kunitz-type inhibitor protease nexin 2.²²³

Gene Structure and Variations

The human factor XI gene (*F11*) is 23 kb in length and is localized to chromosome 4q35. It consists of 15 exons and 14 introns (Fig. 113–17). Each of the four apple domains is encoded by two exons. The serine protease domain is encoded by five exons, with an organization similar to the homologous protein PK.

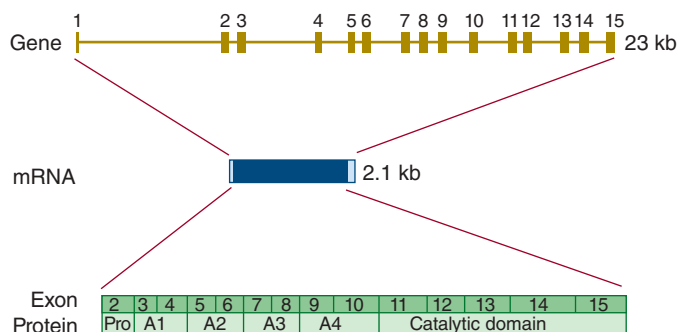

Figure 113–17. Relationship of gene structure to protein structure in factor XI. The exons, introns, mRNA, and protein structure are as indicated. The mRNA is 2.1 kb with small 5' and 3' untranslated regions (*light blue*). In the protein, Pro indicates the prepro leader sequence, A1 to A4 indicate apple domains 1 to 4, and the serine protease (catalytic) domain is indicated.

Deficiencies of factor XI in humans can lead to a bleeding tendency, although not as severe as in hemophilia A or B.²²⁴ Deficiency of factor XI is relatively common among Ashkenazi Jews in Israel.²²⁵ The human gene mutation database lists 232 mutations in the factor XI gene (www.hgmd.org).

Increased levels of factor XI are a risk factor for venous thrombosis.²²⁶ Genetic variations in the form of common single nucleotide polymorphisms (SNPs) seem to play a role in determining the level of factor XI and contribute to thrombotic risk.²²⁷

THE CONTACT SYSTEM: FACTOR XII, PREKALLIKREIN, AND HIGH-MOLECULAR WEIGHT KININOGEN

Factor XII, HK, and PK are part of the contact system in blood coagulation, which is triggered following contact activation of factor XII mediated via a negatively charged surface. PK is synthesized in the liver, circulates as a zymogen, and is highly homologous to factor XI (see Table 113–1). Conversion into the serine protease proceeds through limited proteolysis by activated factor XII, and the generated kallikrein reciprocally activates more factor XII. HK, which is also synthesized in the liver, is a nonenzymatic cofactor that circulates in complex with factor XI or PK (see Table 113–1). HK is cleaved at two sites by kallikrein to release the bioactive nonapeptide bradykinin, a potent vasodilator.

The contact system is at the basis of the activated partial thromboplastin time (APTT) assay that is widely used in clinical practice. In this clinical laboratory test, the negatively charged surface is provided by reagents such as glass, kaolin, celite, or ellagic acid. Factor XIIa activates factor XI, which then activates factor IX. Despite HK and PK being required for a normal APTT, they appear to be dispensable for coagulation *in vivo*.²²⁸ Individuals who are deficient in any of these factors do not have a bleeding tendency, even after significant trauma or surgery. However, factor XII, HK, and PK do participate in bacteremia or inflammatory responses in acute-phase reactions that do not involve the coagulation, but the classical complement system.²²⁸

FACTOR XII

Factor XII was originally reported in 1955 as the “Hageman factor,” named after the first identified factor XII-deficient patient.²²⁹ Factor XII is synthesized in the liver and circulates in plasma as a single-chain zymogen of 596 amino acids (Mr ≈80,000) at a concentration of 500 nM with a half-life of 50 to 70 hours (see Table 113–1).

Protein Structure

Factor XII, which is homologous to plasminogen activators, consists of an N-terminal fibronectin type I domain, an EGF-like domain, a fibronectin type II domain, a second EGF-like domain, a kringle domain, a proline-rich region, and a C-terminal serine protease domain (see Fig. 113–15). The proline-rich region is unique to factor XII, as it is not found in any of the other serine proteases.

Factor XII comprises an O-linked fucose in EGF 1 (Thr90), N-linked glycosylation sites in the kringle domain (Asn230) and the serine protease domain (Asn414), and several O-linked glycosylation sites in the kringle domain and proline-rich region.^{230,231}

Factor XII Activation and Activity

Limited proteolysis by kallikrein at Arg353 in factor XII yields the activated two-chain α -factor XIIa, in which the heavy chain (the fibronectin types I and II domains, both EGF domains, the kringle domain, and proline-rich region; Mr ≈52,000) and light chain (serine protease

domain; Mr \approx 28,000) are linked via a Cys340–Cys467 disulfide bond (see Fig. 113–15). Once activated, α -factor XIIa activates factor XI to factor XIa. Furthermore, α -factor XIIa activates PK, thereby contributing to its own feedback activation.²³²

Factor XII is also known to acquire α -factor XIIa activity upon contact with a negatively charged surface, the latter inducing a conformational change in factor XII.²³³ This conformational change induces a limited amount of proteolytic activity in factor XII, known as autoactivation.^{234,235} Furthermore, the surface-induced active conformation of factor XII is suggested to enhance the proteolytic conversion to α -factor XIIa.²³⁶ The fibronectin types I and II domains, EGF-2, the kringle domain, and the proline-rich region are reported to contribute to interaction with a negatively charged surface.^{237–240} These naturally occurring surfaces include platelet polyphosphate (poly-P), microparticles derived from platelets and erythrocytes, RNA, and collagen.^{241–244}

Further cleavage of α -factor XIIa by kallikrein at Arg334 and Arg343 in the light chain (proline-rich region) results in the generation of β -factor XIIa, which comprises a nine-residue heavy-chain fragment that is disulfide-linked to the light chain.²³⁰ Given the absence of the heavy chain, β -factor XIIa does not interact with anionic surfaces. Even though β -factor XIIa is still capable of activating PK, it no longer activates factor XI.²⁴⁵

Despite its contribution to fibrin formation *in vitro*, factor XII has long been considered to be dispensable for coagulation *in vivo*, because factor XII deficiency is not associated with a bleeding.^{229,246} However, newer *in vivo* studies indicate that factor XII contributes to surface-induced pathologic thrombosis via activation of factor XI.^{215,242,247,248}

The serpin C1 inhibitor is the main plasma inhibitor of α -factor XIIa and β -factor XIIa. In addition, antithrombin (AT) and PAI-1 also inhibit factor XIIa activity. Conditions in which the factor XIIa activity is not properly controlled, such as in C1 inhibitor deficiency states or in case of a constitutively active form of factor XIIa, can result in the disorder hereditary angioedema.²⁴⁹

Gene Structure and Variations

The gene for factor XII is located on chromosome 5q35.3, spans approximately 12 kb, and contains 14 exons.²⁵⁰ The intron–exon structure of the gene is similar to the plasminogen activator family of serine proteases. Portions of the gene are homologous to domains found in fibronectin and tissue-type plasminogen activator.

Loss-of-function mutations in the factor XII gene do not cause clinical symptoms in the form of a bleeding tendency in homozygous or compound heterozygous individuals, although they have a prolonged APTT.

Several common allelic variations in the factor XII gene have been examined to determine whether these variations influence plasma factor XII levels and whether these are associated with thrombotic risk. Best studied is a 46C>T transition four nucleotides upstream of the start codon. TT homozygotes have lower plasma factor XII levels than CC homozygotes, but there was no relationship with risk for venous thrombosis or myocardial infarction.²⁵¹

THE CELL-ASSOCIATED COFACTORS TISSUE FACTOR, THROMBOMODULIN, AND ENDOTHELIAL PROTEIN C RECEPTOR

TISSUE FACTOR

Tissue factor, also known as thromboplastin or CD142, is the cellular receptor and cofactor for factors VII and VIIa (see Fig. 113–6) and was first described in 1905.¹² Tissue factor is expressed in extravascular

tissue, particularly fibroblasts and smooth muscle cells, where it serves as a hemostatic “envelope,” poised to activate coagulation upon vascular damage. Generally, tissue factor is not exposed to the blood, but endothelial cells and adhered leukocytes may express tissue factor in response to injury or stimuli such as endotoxin or cytokines.

Protein Structure

Although many of the coagulation factors share some degree of homology, the structure of tissue factor is unique. It is the only procoagulant protein that is an integral membrane protein and shares structural homology with class II interferon receptors. Tissue factor consists of 263 amino acids (Mr \approx 47,000) and comprises a 219-residue extracellular domain, a 23-residue hydrophobic transmembrane portion, and a short 21-residue intracellular tail.²⁵² The extracellular domain is made up of two fibronectin type III domains, which each comprise a disulfide bond (Cys49–Cys57, Cys186–Cys209). Elimination of the second disulfide link distorts the coagulant activity of tissue factor.

Tissue Factor Activation and Cofactor Function

The tissue factor–factor VIIa complex is generally acknowledged to be the major physiologic initiator of blood coagulation. The process of coagulation is initiated when an injury ruptures a vessel and allows blood to come into contact with extravascular tissue factor. Escape of blood from the vessel allows factor VII to bind to extravascular tissue factor and initiate coagulation. However, it is very likely that in the absence of injury, tissue factor located in close proximity of the vessels is already associated with factor VIIa.²⁵³ An injury allows the extravascular tissue factor–factor VIIa complexes to come into contact with blood and initiate thrombin generation on activated platelet surfaces. Interaction of tissue factor with factor VII induces conformational changes in the serine protease domain of factor VIIa (see Fig. 113–6), thereby allowing the latter to proteolytically activate factors IX and X.¹¹

Tissue factor does not require proteolytic activation to express its activity. However, it appears that tissue factor can occur in an inactive or “encrypted” state, and procoagulant activity follows after an appropriate stimulus. Even though the exact nature of the molecular mechanism remains to be identified, several models explaining tissue factor decryption have been put forward.

Originally, it was assumed that tissue factor encryption–decryption depends on the phospholipid environment, with decryption following upon expression of negatively charged phosphatidylserine on the membrane surface. Interaction of tissue factor with phosphatidylserine restricts the orientation of the tissue factor–factor VIIa complex, thereby ensuring correct alignment of the factor VIIa active site with the membrane-bound substrates factors X and IX.²⁵⁴ Encryption of tissue factor has been proposed to occur upon localization into lipid rafts, which are known to be poor in phosphatidylserine. In endothelial cells, assembly of the ternary tissue factor–factor VIIa–factor X complex does result in tissue factor translocation to caveolae, which renders tissue factor inactive.²⁵⁵ In addition, cell-membrane anchoring of tissue factor via acylation of palmitic and stearic acids may serve to target tissue factor to specific lipid domains.²⁵⁶

In a second model, the tissue factor–dependent procoagulant activity is explained by oxidation and reduction of the Cys186–Cys209 bond. This disulfide bond is less stable because of its strained conformation, and disruption of this link may cause conformational changes that alter the affinity of tissue factor for factor VIIa.^{257,258} The breaking and formation of this disulfide link is suggested to be modulated by protein disulfide isomerases.²⁵⁵

A final model assumes that decryption relies on the dimerization of tissue factor. Like other members of the class II interferon receptors, tissue factor is capable of dimerization in a manner determined by the

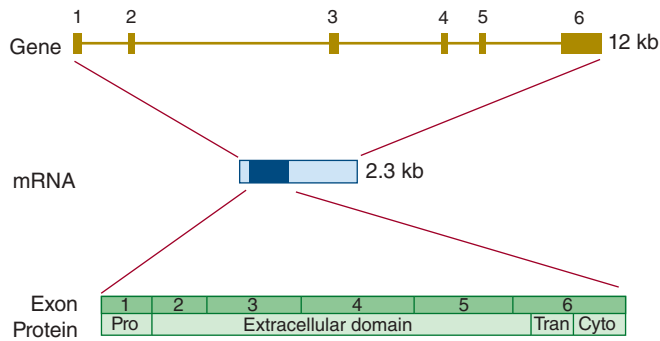

Figure 113–18. Relationship of gene structure to protein structure in tissue factor. The exons, introns, mRNA, and protein structure are as indicated. The mRNA is 2.3 kb with a 5′ untranslated region and a large 3′ untranslated region (light blue). Pro indicates the prepro leader sequence, the extracellular domain is indicated, Tran indicates the transmembrane region, and Cyto indicates the cytoplasmic domain.

redox (oxidation-reduction) environment and the exposure of phosphatidylserine. However, both monomeric and dimeric forms of tissue factor appear to possess procoagulant activity.²⁵⁵

Tissue factor is not only the primary initiator of the extrinsic pathway of coagulation, it also supports activation of PAR2 on endothelial cells and smooth muscle cells. Activation of PAR2 by the tissue factor–factor VIIa(–factor Xa) complex is not necessarily directly relevant for coagulation, but it is currently speculated that this event is important for wound healing, angiogenesis, tissue remodeling, and inflammation.^{38–40}

Gene Structure and Variations

The human tissue factor gene is located on chromosome 1p21-p22. The DNA sequence of the tissue factor gene has been determined and consists of six exons and five introns that span approximately 12 kb (Fig. 113–18).

The primary transcript encoding full-length tissue factor contains six exons, but an alternatively spliced form of tissue factor (asTF) also exists in which exon 5 is spliced out. Because of a 3′ frameshift mutation, the full-length tissue factor transmembrane and cytoplasmic tail are replaced with a hydrophobic C-terminal domain, which renders the asTF soluble. asTF is expressed in lung, pancreas, placenta, heart, endothelium, and monocytes.^{259–261} Although the level of asTF in human plasma may be substantial and amounts to 10 to 30 percent of total tissue factor,²⁶² it remains a matter of debate whether asTF contributes to coagulation.

In theory, variations in the tissue factor gene could influence thrombotic and bleeding risk. There are claims that polymorphisms in the tissue factor gene influence thrombotic risk but these claims have not been sufficiently confirmed.²⁶³

No relationship between loss-of-function mutations and bleeding has been described. This is perhaps not surprising in view of the fact that mice lacking tissue factor die early in gestation.

THROMBOMODULIN

Thrombomodulin, which was first identified by Esmon and colleagues in the early 1980s,^{264,265} is a predominantly endothelial transmembrane protein and functions as an endothelial receptor for thrombin. In addition to endothelium, thrombomodulin has also been detected on a number of other cell types, including megakaryocytes, monocytes, and neutrophils.²⁶⁶

Protein Structure

Mature single-chain thrombomodulin comprises 557 residues (Mr ≈78,000) and is composed of a lectin-like domain, a hydrophobic region, six EGF-like domains, a serine- and threonine-rich region, a transmembrane domain, and a 23-residue cytoplasmic tail. The highly charged lectin-like domains bear homology to the C-type lectins. Post-translational modifications include five N-linked glycosylation sites that are located in the lectin-like and EGF-4 and -5 domains. O-linked glycosylation in the serine- and threonine-rich region (Ser474) supports attachment of a glycosaminoglycan, a chondroitin sulfate moiety, which forms a low-affinity binding site for thrombin.

Thrombomodulin Cofactor Function

Thrombomodulin interacts with thrombin through its EGF-5 and -6 domains in a calcium-dependent manner.²⁶⁷ As a result, thrombin’s procoagulant exosite I is shielded, which causes thrombin’s specificity to switch to the anticoagulant substrate protein C, requiring EGF domains 4 to 6 of thrombomodulin, and to TAFI, requiring EGF-3 to -6.²⁶⁸ Thrombomodulin enhances the thrombin-dependent activation of protein C more than 1000-fold.

As a result of the relatively large endothelial surface area in capillary beds, the thrombomodulin-dependent activation of protein C proceeds efficiently in the microcirculation, which serves a major role in preventing thrombosis from occurring on intact endothelium.²⁶⁹ In larger vessels where the endothelial surface area-blood volume ration is low, the presence of EPCR aids in the interaction with and presentation of protein C to the thrombomodulin-thrombin complex.²⁷⁰

Thrombomodulin also enhances the thrombin-mediated conversion of single-chain urokinase-type plasminogen activator to thrombin-cleaved two-chain urokinase-type plasminogen activator, which interferes with the generation of plasmin. Furthermore, thrombomodulin is a negative regulator of PAR signaling, as thrombomodulin-bound thrombin is incapable of PAR activation.²⁷¹ Based on this and because thrombomodulin is the cofactor responsible for APC generation, thrombomodulin plays an important role, albeit indirect, as an antiinflammatory protein. A direct contribution to suppress inflammation has been attributed to the lectin-like domains and hydrophobic region of thrombomodulin, independent of its anticoagulant activity.²⁷²

Protein C inhibitor is an effective inhibitor of the thrombomodulin-thrombin complex.²⁷³

Proteolysis of thrombomodulin by neutrophil-derived metalloproteinases and possibly rhomboids results in the generation of soluble thrombomodulin.²⁷⁴ Normal plasma levels of soluble thrombomodulin are 3 to 50 ng/mL, but may increase as a result of vascular damage associated with infection, sepsis, or inflammation.²⁷⁴

Gene Structure and Variations

The human thrombomodulin gene (*THBD*) is located on chromosome 20p11.2, spans approximately 3.5 kb, and consists of a single exon (Fig. 113–19). Intronless genes are uncommon in eukaryotes and include rhodopsin, angiogenin, mitochondrial genes, interferons α - and β -adrenergic receptors. Intronless genes represent recent additions to the genome, created mostly by retroposition of processed mRNAs with retained functionality. Genetic variation in thrombomodulin has been studied in conjunction with venous thrombosis, bleeding and atypical hemolytic uremic syndrome (aHUS).

There are early reports that mutations in thrombomodulin are present in patients with venous thrombosis, but it was difficult to prove causality.²⁷⁵ More recent work that made use of thrombomodulin sequencing in relatively large studies support the putative relationship between thrombomodulin function and venous thrombosis.²⁷⁶ Such

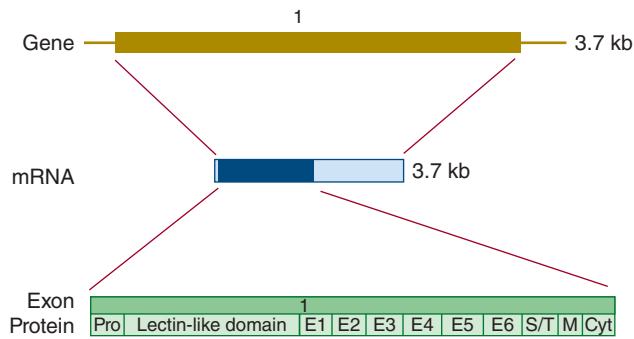

Figure 113–19. Relationship of gene structure to protein structure in thrombomodulin. The thrombomodulin gene has no introns. The exon, mRNA, and protein structure are as indicated. The mRNA is 3.7 kb, with a small 5′ untranslated region and a large 3′ untranslated region (*light blue*). In the protein, Pro indicates the prepro leader sequence, the lectin-like domain is indicated, E indicates the epidermal growth factor (EGF)-like domains, S/T indicates the serine- and threonine-rich region, M indicates the transmembrane region, and Cyt indicates the cytoplasmic domain.

mutations, however, do not explain a large proportion of the heritability of venous thrombosis as they seem to be quite rare.

Recently a novel thrombomodulin mutation, p.Cys537Stop, was described in a family with a history of posttraumatic bleeding.²⁷⁷ The endogenous thrombin potential was markedly reduced at low tissue factor concentrations in heterozygous carriers. Plasma thrombomodulin levels were elevated (433 to 845 ng/mL, normal range 2 to 8 ng/mL), and the addition of exogenous protein C further decreased thrombin generation. It was surmised that as a consequence of the premature stop codon, the truncated thrombomodulin is shed from the endothelial surface into the blood plasma, which would promote systemic protein C activation, thereby explaining the bleeding phenotype.

Missense mutations in thrombomodulin were also reported in patients with aHUS and this involvement in aHUS is probably related to the role of thrombomodulin in the complement system.²⁷⁸ Thrombomodulin binds to C3b and factor H and negatively regulates complement by accelerating factor I-mediated inactivation of C3b. In addition, by promoting activation of TAFI, thrombomodulin also accelerates the inactivation of C3a and C5a. Thrombomodulin variants associated with aHUS had diminished capacity to inactivate C3b and to activate TAFI and were thus less protected from activated complement, thereby providing an explanation for their involvement in aHUS.

ENDOTHELIAL PROTEIN C RECEPTOR

The EPCR, a single-chain transmembrane receptor discovered in 1995 by Fukudome and Esmon,²⁷⁹ binds both protein C and APC. EPCR increases the rate of activation of protein C⁹² and alters the function of APC from anticoagulant to cytoprotective.²⁸⁰ EPCR is mainly expressed by endothelial cells but also by leukocytes and other cell types.

Protein Structure

EPCR is homologous to CD1 and major histocompatibility class I proteins and folds with a β -sheet platform supporting two α -helical regions that form the potential binding pocket for protein C and APC. The mature protein ($M_r \approx 49,000$) consists of 223 amino acids and is glycosylated through four N-linked glycosylation sites (Asn30, Asn47, Asn119, Asn155). EPCR contains a 25-residue long C-terminal transmembrane region with a short 3-residue cytoplasmic tail.

Endothelial Protein C Receptor Function

EPCR enhances the activation of membrane-bound protein C by the thrombomodulin–thrombin complex,⁹² thereby enhancing the APC-mediated anticoagulant pathway.

APC bound to membrane-associated or soluble EPCR is disabled in its anticoagulant capacity. Instead, EPCR-bound APC activates PAR1 in an alternative manner by noncanonical cleavage at a Arg46,²⁸¹ resulting in an increased barrier function of endothelial cells mediated via the β -Arrestin/PI3K (phosphatidylinositol 3′-kinase)/AKT/Rac1 pathway. This is in contrast to the barrier-disruptive Arg41 cleavage of PAR1 by thrombin that activates the G-protein/ERK (extracellular regulated kinase) 1.2/RhoA pathway.²⁸¹

EPCR is essential at the maternal–embryonic interface on trophoblast giant cells where it prevents fibrin formation. Consequently, complete EPCR deficiency leads to embryonic lethality. EPCR-deficient embryos rescued by the presence of EPCR in the trophoblast are viable and thrive, which seems to indicate that EPCR is not essential to blood circulation, at least in mice.²⁸² Additional ligands for EPCR have been discovered such as factor VIIa, *Plasmodium falciparum* erythrocyte membrane protein, and the V(γ)4V(δ)5 T-cell receptor.²⁸³ These additional ligands indicate potential involvement of EPCR in the therapeutic effect of factor VIIa in hemophilia patients, and roles for EPCR in malaria, cytomegalovirus infection, and cancer.

Gene Structure and Variations

The chromosomal location of the EPCR gene (*PROCR*) is 20q11.2 and it contains four exons and spans 6 kb. Exon 1 encodes for the 5′-untranslated region and the signal peptide; exons 2 and 3 encode for almost the entire extracellular region; and exon 4 encodes for the transmembrane domain and cytoplasmic tail. One single mRNA encodes the centrosomal protein CCD41 and EPCR. Deletion of the signal sequence confers the centrosomal location of CCD41, while the unprocessed protein is incorporated into cell membranes as EPCR.

Variants of EPCR with reduced protein C affinity or increased cellular shedding are reported to be associated with unprovoked venous thromboembolism.²⁸⁴

● THE FIBRIN NETWORK: FIBRIN(OGEN), FACTOR XIII, AND THROMBIN-ACTIVABLE FIBRINOLYSIS INHIBITOR

FIBRINOGEN

Fibrinogen, when converted to fibrin, forms the structural meshwork that consolidates an initial platelet plug into a solid hemostatic clot. Fibrinogen is synthesized in the liver and circulates in a concentration of approximately 7.4 μ M. The plasma half-life of fibrinogen is 3 to 5 days, with only a small proportion of the catabolism caused by consumption.²⁸⁵ Fibrinogen is also found in the α -granules of platelets. It was initially assumed that megakaryocytes synthesized fibrinogen. However, although some γ -chain transcripts are present in marrow precursors, it appears that most of the fibrinogen found within platelets is taken up from the plasma by endocytosis.^{286,287}

Protein Structure

Chapter 135 provides a detailed description of the biochemistry of fibrinogen and of fibrin formation and degradation. Fibrinogen is a dimeric GP ($M_r \approx 340,000$) and each of the two subunits contains three disulfide-linked polypeptide chains that are referred to as the A α ($M_r \approx 66,500$), B β ($M_r \approx 52,000$), and γ ($M_r \approx 46,500$) chains. A trinodular model of fibrinogen structure has been established from the crystal structure of fibrinogen (Fig. 113–20).²⁸⁸

Figure 113–20. Structure of fibrinogen. Fibrinogen is a dimer. Each monomer consists of three chains: α shown in light blue, β shown in pink, and γ shown in dark blue. The disulfides that link the two monomers are in the central E domain. The D domains consist primarily of the C-terminal regions of the β and γ chains. The helical region connecting the two domains consists of all three chains intertwined. (Reproduced with permission from Côté HC, Lord ST, Pratt KP: *Gamma-Chain dysfibrinogenemias: Molecular structure-function relationships of naturally occurring mutations in the gamma chain of human fibrinogen*. Blood 92(7):2195–2212, 1998.)

Because human fibrinogen is subject to modification at a number of different sites both during and after biosynthesis, the fibrinogen present in the circulation is a heterogeneous mixture of molecules. These normal variants are caused by alternative splicing, modification of certain amino acids by sulfation, phosphorylation, and hydroxylation, different degrees of glycosylation, and proteolysis. It has been estimated that the number of nonidentical fibrinogen molecules that can be produced by these mechanisms is in excess of 1 million.²⁸⁹ Some of these variations may have significant functional consequences. For example, the level of one variant of fibrinogen with an alternatively spliced γ chain (fibrinogen- γ') is associated with a risk of venous thrombosis.²⁹⁰

Fibrinogen Activation and Fibrin Function

Thrombin binds to the central domain of fibrinogen and proteolytically releases two fibrinopeptides A ($A\alpha$, residues 1 to 16) and two fibrinopeptides B ($B\beta$, residues 1 to 14) from each fibrinogen molecule.²⁹¹ Release of the fibrinopeptides exposes binding sites in the E domain that have complementary sites in the D domains of other fibrin monomers.^{292,293} These complementary binding sites lead to the initial formation of two-stranded protofibrils with a half-staggered overlap configuration (Fig. 113–21). Protofibrils then aggregate into thick fibers that branch into a meshwork of interconnected thick fibers.²⁹⁴ The half-staggered overlap of the fibrin monomers gives a characteristic cross-banded pattern on electron micrographs.²⁹⁵

During fibrin monomer polymerization, other plasma proteins also bind to the surface of the developing meshwork. These include elements of the fibrinolytic system and a variety of adhesive proteins, such as fibronectin, thrombospondin, and VWF. These surface proteins influence the generation, crosslinking, and lysis of fibrin. Fibrin(ogen) also has specific integrin-binding sites that are essential for platelet binding. The thrombin that initiates fibrin polymerization also activates factor XIII, which stabilizes the fibrin polymer by crosslinking. Factor XIIIa also crosslinks other bound proteins, for example, PAI-1, vitronectin, fibronectin, and α_2 -antiplasmin, to the fibrin network.

Once formed, the fibrin mesh can be degraded by the fibrinolytic system. Plasmin cleaves fibrin and fibrinogen in an ordered sequence at arginyl and lysyl bonds, giving rise to a series of soluble degradation products.²⁹⁶ In this process, the crosslink between two D fragments remains intact, resulting in the formation of a fragment consisting of two D domains and one E domain, called D-dimer. Circulating D-dimer concentrations are often measured as a surrogate marker of activated coagulation.

In addition to its obvious procoagulant role in stabilizing the initial platelet hemostatic plug, fibrin can also act as an important inhibitor of thrombin generation. Fibrin functions as “antithrombin I” by sequestering thrombin in the developing fibrin clot, and also by reducing the catalytic activity of fibrin-bound thrombin.²⁹⁷

Gene Structure and Variations

The genes for the three chains of fibrinogen are found within a 50-kb region on chromosome 4 at q23–q32 (Fig. 113–22). The genomic sequences show a high degree of homology, suggesting they were derived through duplication of a common ancestral gene. The homology extends to sites upstream of the gene, suggesting that common regulatory elements may reside in these areas, thus helping to coordinate synthesis of the three chains.

The physiologic importance of fibrinogen is underscored by the bleeding diathesis associated with afibrinogenemia and some dysfibrinogenemias (Chap. 125). Other dysfibrinogenemias are associated with thromboembolic disease. Although afibrinogenemia is associated with a bleeding tendency, it is usually not as severe as classical hemophilia.

FACTOR XIII

The GP factor XIII is a protransglutaminase that, upon activation, crosslinks and stabilizes fibrin clots.²⁹⁸ Plasma factor XIII is a heterotetramer consisting of two factor XIIIa subunits (731 amino acids; Mr \approx 83,000) bound to two factor XIIIb subunits (641 amino

Figure 113–21. Cleavage of fibrinogen and polymerization of fibrin. The structure of fibrinogen is indicated schematically. Cleavage sites for fibrinopeptide A by thrombin are shown. Cleavage of the B peptide is not shown in this figure. Release of fibrinopeptide A exposes binding sites in the E domain that match complementary sites in the D domain. Fibrin monomers polymerize by half-staggered overlaps. Polymerization can also lead to branched structures. (Reproduced with permission from Côté HC, Lord ST, Pratt KP: *Gamma-Chain dysfibrinogenemias: Molecular structure-function relationships of naturally occurring mutations in the gamma chain of human fibrinogen*. Blood 92(7):2195–2212, 1998.)

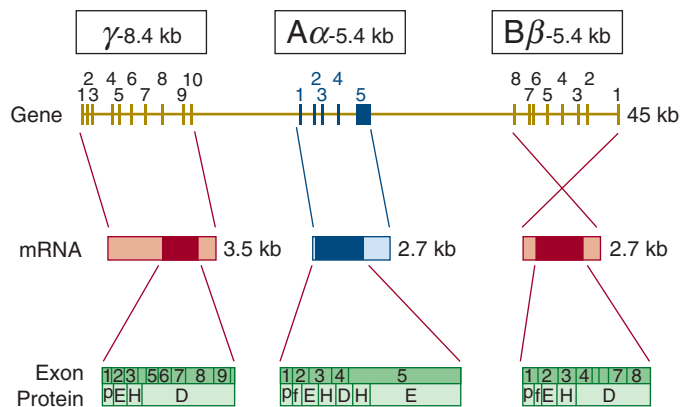

Figure 113-22. Relationship of gene structure to protein structure in fibrinogen. The exons, introns, mRNA, and protein structure for the three chains of fibrinogen are shown. The β chain is translated in the opposite direction from the $A\alpha$ and γ chains. Lighter colors in the mRNA indicate 5' and 3' untranslated regions. In the proteins, P designates the prepro leader sequence, f designates fibrinopeptide (A in $A\alpha$ and B in β), E designates residues in the E domain, H designates residues in the helical connecting region, and D designates residues in the D domain.

acids; $M_r \approx 76,500$) that circulates in plasma as an A2B2 complex ($M_r \approx 320,000$) at a concentration of 94 nM with a plasma half-life of 10 days (Fig. 113-23; see Table 113-1). Factor XIII circulates in plasma associated to fibrinogen via interaction of the factor XIIIIB subunit with the fibrinogen γ' chain.

The A and B subunits of factor XIII are synthesized and expressed separately and assemble in the circulation to the heterotetramer factor XIII-A2B2.²⁹⁹ Factor XIIIa is synthesized in monocytes/macrophages, megakaryocytes, and hepatocytes, whereas factor XIIIb is synthesized exclusively in the liver and kidney.

Protein Structure

The factor XIIIa subunit consists of an activation peptide, a β -sandwich, a catalytic transglutaminase, and two β -barrel domains.²⁹⁸ Factor

XIIIb acts as a carrier protein providing the long plasma half-life of factor XIII. Factor XIIIb consists of 10 Sushi domains in tandem, of which the first two Sushi domains are crucial for the binding to factor XIIIa.

Factor XIII Activation and Factor XIIIa Activity

Factor XIIIa is a proenzyme that is proteolytically activated by thrombin via cleavage at Arg37 (see Fig. 113-23), resulting in release of the activation peptide and dissociation of the factor XIIIb subunit from factor XIII-A2B2, thereby exposing the active site Cys314 of factor XIIIa. Cofactors for the activation of factor XIIIa by thrombin are calcium and fibrin(ogen). Platelets only contain the factor XIIIa (cfactor XIII-A2) dimer that is activated intracellularly in a proteolytic-independent manner through a rise in cytosolic calcium and subsequent conformational change before secretion by the stimulated platelet (see Fig. 113-23).³⁰⁰

Activation of factor XIII by thrombin is not a late event in blood coagulation, as it is activated with the same velocity by thrombin as the cleavage of the fibrinopeptides of fibrinogen.³⁰¹ Factor XIII can also be alternatively activated and inactivated by neutrophil elastase.³⁰²

Factor XIIIa consists of a factor XIII-A2 dimer comprising two activated factor XIIIa subunits that result from either thrombin-activation (factor XIIIa*) or conformational-activation (factor XIIIa^o). The transglutaminase activity of factor XIIIa crosslinks a γ -carbon of glutamine in one protein chain to the ϵ -amino group of lysine in another protein chain in a reaction named transamidation. The specificity of factor XIIIa crosslinking of proteins stems mainly from the recognition by factor XIIIa of specific glutamines, while the crosslink to lysine appears to be random and limited to the ones that are in the vicinity.

When thrombin cleaves the fibrinopeptides A and B of fibrinogen molecules, the binding site on the central E domain for the D domain of other fibrin molecules is uncovered. This initiates lateral aggregation of protofibrils and fiber formation. Factor XIIIa stabilizes the forming of protofibrils by linking two γ chains in adjacent D domains in fibrin polymers. Binding of Arg158 in one subunit of the factor XIIIa dimer to the α C region residue $A\alpha$ Glu396 of fibrin facilitates crosslinking via α C chains to a next fibrin molecule by the other activated factor XIIIa subunit in factor XIIIa.³⁰³

The crosslinking of fibrin γ -chains or α -chains by factor XIIIa has independent and specific effects on clot formation and structure.

Figure 113-23. Factor XIII (FXIII) activation. The structure of the FXIIIa and FXIIIb subunits are indicated schematically. Plasma FXIII (FXIII-A2B2) consists of two FXIIIa (A, in red) subunits bound to two FXIIIb (in green) subunits. Cleavage of the activation peptides from FXIIIa by thrombin releases the FXIIIb subunits (B chains) and induces a conformational change in the FXIIIa subunits that opens the active site. This thrombin cleaved form of FXIIIa is known as FXIIIa or FXIIIa. Cellular FXIII (cFXIII-A2) found in platelets and macrophages consists only of the FXIIIa2 (cFXIII-A2) dimer. Before release by activated platelets, the cFXIII-A2 dimer becomes activated by an increase in intracellular calcium ions (Ca^{2+}) that induces the active conformation without proteolysis of the activation peptide. This calcium activated form of cFXIIIa (cFXIII-A) is known as FXIIIa.

Crosslinks stabilize a clot by incorporation of the plasmin inhibitor α_2 -antiplasmin which makes it resistant to fibrinolytic attack by plasmin.³⁰⁴

Several other processes during clotting are factor XIII-dependent, among which red blood cell incorporation in clots,³⁰⁵ complement factor 3 (C3) crosslinking to fibrin,³⁰⁶ and clot retraction by platelets.³⁰⁷ Factor XIII also plays a role in the functioning of multiple adhesive and contractile proteins and in angiotensin type I receptor crosslinking.³⁰⁸ Fetal specific crosslinking of Fas by factor XIII dampens apoptosis, suggesting that factor XIII may play a role in cell survival prenatally.³⁰⁹ Related to its expression by monocytes/macrophages, factor XIII levels may drop after inhibition of IL-6 receptor signalling by tocilizumab.³¹⁰ Besides its crucial role in hemostasis, factor XIII has important functions during tissue regeneration and infection.³¹¹ Factor XIII is necessary to prevent bleeding/stroke, maintain pregnancy, and aids in wound healing.²⁹⁸

Gene Structure and Function

The factor XIII_A chain gene (*F13A1*) has been localized to chromosome 6 p25.1.³¹² It contains 15 exons, and is larger than 160 kb (Fig. 113–24). The fibrin-binding domain is encoded by exons 2 to 12. The active site, with its reactive thiol at Cys314, is present in exon 7. The gene encoding the factor XIII_B (*F13B*) chain has been localized to chromosome 1q31.3. It has 12 exons and is approximately 28 kb (Fig. 113–25).³¹³ Each Sushi domain is encoded by a single exon. The regulation of factor XIII_B expression is poorly understood. A total of 30 potential start sites are located upstream of the initial methionine.

Homozygosity or compound heterozygosity for loss-of-function mutations in the factor XIII_A or XIII_B genes leads to a severe bleeding disorder that is rare (1 in 2,000,000 of the population).³¹⁴ Factor XIII-deficient newborns often present with bleeding from the umbilical cord. The natural course is characterized by a life-long bleeding tendency and spontaneous miscarriages in affected women. Acquired factor XIII deficiency by development of an inhibitory antibody may lead to fatal bleeding if not treated.³¹⁵

Mutations underlying factor XIII deficiency are more commonly found in the gene encoding factor XIII_A than the one encoding factor XIII_B. In accordance with this, the human gene mutation database lists 107 mutations in the factor XIII_A gene and 19 mutations in the factor XIII_B gene. Mutations in the gene encoding factor XIII_B often lead to low levels of both factor XIII subunits. This is probably because free factor XIII_A has a short plasma half-life.

Figure 113–24. Relationship of gene structure to protein structure in the factor XIII_A chain. The exons, mRNA, and protein structure of the factor XIII_A chain are shown. The mRNA is 4 kb with some 5' untranslated sequence coded in exon 1 and a large 3' untranslated region (light blue). In the protein, AP indicates the activation peptide, and the catalytic domain is indicated.

Figure 113–25. Relationship of gene structure to protein structure in the factor XIII_B chain. The exons, introns, mRNA, and protein structure are as indicated. The mRNA is 2.2 kb with small 3' and 5' untranslated noncoding regions (light blue). In the protein, Pro indicates the propeptide, S1 to S10 indicates the Sushi 1 to 10 domains, and the C-terminal region is indicated by Carb.

A Val34Leu polymorphism associated with fatal atherothrombotic ischemic stroke results in a faster factor XIII_A activation rate by thrombin, which affects clot structure.³¹⁶

THROMBIN-ACTIVABLE FIBRINOLYSIS INHIBITOR

TAFI is the zymogen of a zinc-bound metalloprotease, and is also known as carboxypeptidase B, R, or U. TAFI is synthesized in the liver. Most TAFI present in the blood is in the plasma compartment, which circulates at 70 to 275 nM (see Table 113–1).

Protein Structure

TAFI is a 401-amino-acid proenzyme ($M_r \approx 60,000$) and consists of an N-terminal activation peptide (residues 1 to 76), a linker region (residues 77 to 92), and a catalytic domain (residues 93 to 401). Twenty percent of the protein mass of TAFI is accounted for by carbohydrate side chains that are attached to four sites within the activation peptide (Asn22, Asn51, Asn63) and linker region (Asn86). The active site residues (Glu271, Arg125) and zinc-binding residues (His67, Glu70, His196) in TAFI are conserved between other members of the carboxypeptidase A family.

Thrombin-Activatable Fibrinolysis Inhibitor Activation and Thrombin-Activatable Fibrinolysis Inhibitor-a Activity

TAFI is proteolytically activated by plasmin or thrombin, reactions that are accelerated 1000-fold when thrombin is bound to thrombomodulin. Both enzymes cleave TAFI at Arg92 to give rise to activated TAFI (TAFI_a; $M_r \approx 37,000$) upon release of the activation peptide. TAFI_a catalyzes removal of C-terminal lysine and arginine residues from fibrin and fibrin cleavage products. These residues are important for binding and activation of plasminogen, and removal of these residues by TAFI_a reduces formation of plasmin on clots resulting in decreased clot lysis.

TAFI_a may also have an antiinflammatory role as it can efficiently cleave C-terminal arginines of anaphylatoxins such as bradykinin and the complement activation peptides C3a and C5a.

Inhibitors of TAFI_a have not been identified. Rather, the primary regulatory mechanism of TAFI activity involves its intrinsic thermal instability with a half-life of less than 15 minutes at 37°C.

Gene Structure and Variations

The gene for TAFI (*CPB2*) has been localized to 13q14.13. The gene contains 11 exons with 10 introns and spans 48 kb. Homozygosity or compound heterozygosity for mutations in the gene encoding TAFI have not been described.

In total, 19 SNPs have been identified in the gene encoding TAFI, of which six are in the coding region. Of the latter SNPs, two lead to an amino acid substitution: an Ala/Thr substitution at position 147 and a Thr/Ile substitution at position 325.³¹⁷ There appears to be a strong correlation between plasma levels of TAFI and polymorphisms in the promoter and 3'-region, but their clinical significance is unclear.

Epidemiologic studies have indicated that elevated TAFI levels are correlated with an increased risk of venous thrombosis, albeit that methods to quantify TAFI or TAFIa have limitations.³¹⁸

● INHIBITORS OF COAGULATION: ANTITHROMBIN, TISSUE FACTOR PATHWAY INHIBITOR, AND PROTEIN Z/ PROTEIN Z-DEPENDENT PROTEASE INHIBITOR

ANTITHROMBIN

AT was previously known as AT III as a result of a classification of several AT activities in plasma discovered in the 1950s.³¹⁹ AT is mainly synthesized in the liver and circulates in plasma as a single-chain GP of 432 amino acids (Mr ≈58,000) at a concentration of 2.5 μM with a half-life of 60 to 70 hours (see Table 113-1). AT is a member of the large serpin family and is known as SERPINC1 in the systematic nomenclature.

Protein Structure

AT consists of an N-terminal heparin-binding domain, a carbohydrate-rich domain, and a C-terminal serine protease-binding region that comprises the long, flexible, and surface-exposed reactive center loop. Structural stability is provided by three disulfide bonds, two of which are located in the N-terminal region and one in the serine protease-binding region. Posttranslational modifications comprise four

N-glycosylation sites, with three in the carbohydrate-rich domain (Asn96, Asn135, Asn155) and one in the serine protease-binding region (Asn192).

Antithrombin Function

The primary proteases targeted by AT are thrombin, factor Xa, and factor IXa. In addition, AT also inhibits factors XIa and XIIa, as well as tissue factor-factor VIIa; however, the latter is only inhibited in the presence of heparin.

Similar to other serpins, AT acts as a “suicide” substrate for its target proteases. These cleave at site Arg393 in the reactive center loop of AT, upon which AT is, unlike normal substrates, not released, but forms a 1:1 covalent complex with the protease, thereby blocking the active site. This complex is facilitated by a conformational change of the reactive center loop that folds into the N-terminal region of AT. By doing so, the covalently attached protease is dragged along, resulting in distortion of its serine protease domain and effectively converting the protease back into a zymogen-like state.³²⁰

Heparin and related molecules, such as endothelial-bound glycosaminoglycans, dramatically accelerate the rate of protease inhibition by AT (see Table 113-4) through two distinct mechanisms that characterize inhibition of either factors IXa and Xa or thrombin (Fig. 113-26). In case of the former, binding of a specific pentasaccharide sequence in heparin results in a conformational change in the reactive center loop of AT, which allows for enhanced access by the target protease and is known as allosteric activation of AT (Fig. 113-26, *middle panel*).³²⁰ This results in a 500-fold acceleration of inhibition of factors IXa and Xa.³²¹ The pentasaccharide sequence is present in all forms of heparin including low-molecular-weight heparin and fondaparinux, a synthetic pentasaccharide. Heparin-accelerated thrombin inhibition involves bridging of AT to the protease, which serves to align the two molecules and enhances the rate of complex formation (Fig. 113-26, *right panel*).^{322,323} This mechanism, also known as the template mechanism, requires longer heparin molecules found in unfractionated

Figure 113-26. Effect of glycosaminoglycans on antithrombin inhibition. *Left panel:* Structures of thrombin (PDB structure 1TB6, cyan) and antithrombin (PDB structure 1T1F, green) with Arg393 (P1 residue, red) in the reactive center loop of antithrombin are shown. *Middle panel:* Binding of a specific pentasaccharide sequence (low-molecular-weight heparin [LMWH], blue) to antithrombin (PDB structure 2GD4) alters the conformation of the reactive center loop, thereby increasing exposure of the P1 residue and allowing for access of the target protease (allosteric activation). *Right panel:* A long heparin molecule (blue) interacts with both thrombin and antithrombin (PDB structure 1TB6), which aligns the two molecules and enhances the rate of complex formation (template mechanism).

heparin (UFH). Heparin-bridging of AT also contributes to some extent to the AT-mediated inhibition of factors IXa and Xa, but the majority of rate enhancement is provided by the allosteric activation of AT.

Protease-AT complexes are cleared from the circulation by lipoprotein receptor-related protein (LRP)-1-mediated endocytosis in the liver.^{324,325}

Gene Structure and Variations

The 13.5-kb AT gene (*SERPINC1*) is localized on chromosome 1q25.1 and consists of seven exons. The cDNA is 1395 bp long, whereas the mRNA is approximately 1.4 kb.

Because of its essential role as an inhibitor of coagulation, individuals who are heterozygous for loss-of-function mutations are at increased risk for thrombosis. The prevalence of this condition in the general population is approximately one in 5000 individuals,³²⁶ while it occurs in approximately 5 percent of patients with a history of thromboembolic disease.³²⁷ AT deficiency can be categorized into type I and type II deficiencies.³²⁸ Type I deficiency is characterized by reduced plasma levels of AT; however, homozygous type I deficiency is not compatible with life. Type II deficiency covers all functional AT defects.

The human gene mutation database (www.hgmd.org) lists 274 mutations. Mutations resulting in type I deficiency consist of large deletions, frameshift mutations, premature stop codons, splice-site mutations, and missense mutations. Mutations observed in type II deficiency impair heparin binding or affect the overall protein structure. Chapters 130 and 133 provide a more detailed description of the clinical significance of AT deficiency.

TISSUE FACTOR PATHWAY INHIBITOR

TFPI is a Kunitz-type protease inhibitor that inhibits factor Xa and tissue factor-factor VIIa activity and was discovered by Broze and Miletich in 1987.³²⁹ TFPI circulates in plasma at 2.5 nM in multiple forms of which the majority is either truncated at the C-terminus or lipoprotein-associated. Only 10 percent of the circulating TFPI is the full-length TFPI α form of 276 amino acids (Mr \approx 40,000; see Table 113-1).³³⁰ The half-life of TFPI α in the circulation is only 2 minutes because it readily associates with the vessel wall endothelium.

Protein Structure

Full-length TFPI α consists of three tandem Kunitz domains and a C-terminus that contains a basic region (see Fig. 113-15).³³¹ However, TFPI is very heterogeneous as a result of proteolysis and alternative splicing. The latter gives rise to TFPI β that lacks the third Kunitz domain and C-terminus, but instead includes a sequence that facilitates anchorage to the endothelial cell membrane via GPI linkage.³³²

Endothelial cells and platelets are the main producers of TFPI, with endothelial cells expressing both TFPI α and β , while platelets only produce TFPI α that is secreted upon platelet activation. Although a significant fraction of TFPI β is GPI-linked to the endothelial cells, it is also found in plasma. *In vivo*, most of the full-length TFPI α appears to be bound to endothelial heparan sulphate proteoglycans through its positively charged C-terminus. This because total plasma TFPI levels rise by approximately threefold upon heparin treatment, which is completely attributable to an increase in TFPI α . In addition, TFPI α also circulates in complex with factor V.

Tissue Factor Pathway Inhibitor Function

The physiologic relevance of TFPI stems from its ability to regulate tissue factor-dependent coagulation as well as its direct inhibition of factor factor Xa. TFPI inhibits the tissue factor-factor VIIa complex in a two-step mechanism. TFPI will bind via its second Kunitz domain to the active site of factor Xa, thereby inhibiting the proteolytic capacity of

factor Xa.³³¹ This step is accelerated profoundly via protein S through interactions with the third Kunitz domain of TFPI.^{333,334} The following step is the inhibition of the catalytic activity of tissue factor-factor VIIa complexes by formation of the quaternary tissue factor-factor VIIa-factor Xa-TFPI complex. This complex formation depends on the binding of Kunitz 1 to the factor VIIa active site. Overall, the effects of TFPI as regulator of tissue factor-initiated thrombin generation appear to depend on the fast protein S-dependent TFPI interaction with factor Xa.³³³

TFPI that is truncated at the C-terminus is effective in inhibiting tissue factor-factor VIIa activity; however, this seems to occur too slow to control thrombin generation at least *in vitro*. In contrast, inhibition of tissue factor-factor VIIa activity by GPI-anchored TFPI β is effective and independent of protein S.³³² GPI-anchored TFPI β also acts as an inhibitor of tissue factor-factor VIIa signaling by PARs, a function that TFPI α seems to lack.

TFPI may prevent prothrombinase formation by factor Xa in the presence of the procofactor factor V, factor V that is partially activated by factor Xa, or platelet factor V.³³⁵ However, the factor V-factor Xa prothrombinase complex is not inhibited by TFPI as a result of competition by prothrombin.

The heterogeneity and different activities of the multiple forms of TFPI have frustrated the measurement of TFPI for clinical purposes. However, tests that estimate the free full-length form in plasma indicate an association of low TFPI α levels with venous thrombosis.³³⁶ Low levels of TFPI α are observed in protein S-deficient patients, which may be the result of a lack of association of TFPI with protein S in the circulation and faster clearance of free TFPI α .³³⁷ High TFPI α levels have been observed in patients with increased expression of a splice variant of factor V, known as *factor V-short*. Factor V-short, which lacks the major part of the B domain, interacts with the basic C-terminus of TFPI α , most likely through the acidic B domain region in factor V.^{132,133} Increased factor V-short levels lead to a dramatic increase in plasma TFPI α , resulting in a bleeding disorder.¹³³

TFPI activity is downregulated by proteolysis at the C-terminus, upon which the basic C-terminal region or the third Kunitz domain are removed, thereby impairing inhibition of factor Xa and tissue factor-factor VIIa. Complete inactivation of TFPI is observed after proteolysis by the neutrophil derived proteases elastase and cathepsin G, which also cleave in between Kunitz 1 and 2. In this way, tissue factor-factor VIIa activity may be protected or reactivated during inflammatory processes.³³⁸

The *in vivo* relevance of TFPI was shown by the sensitization of rabbits to tissue factor-triggered disseminated intravascular coagulation after immunodepletion of TFPI.³³⁹ Furthermore, mice lacking the first Kunitz domain of TFPI are not viable.³⁴⁰

Gene Structure and Variations

The human TFPI gene (*TFPI*) is located on chromosome 2q31-q32.1 and has nine exons that span 70 kb. TFPI is synthesized in two alternatively spliced forms, α and β .³³² TFPI β is formed by an alternative splice event after exon 7 such that TFPI β lacks the third Kunitz domain and instead has a unique C-terminus. Exon 2 appears to downregulate translation of the TFPI β splice variant by a unique interaction with a sequence in the 3'-end of the TFPI β mRNA.

Homozygosity or compound heterozygosity for loss of function mutations in the gene encoding TFPI has not been described. Several genetic polymorphisms have been identified and their relationship with venous thrombosis has been investigated. There is one report describing that a T33C polymorphism in intron 7 is highly associated with total TFPI antigen and protects against venous thrombosis,³⁴¹ but this relationship with thrombosis was not confirmed in a subsequent study.³⁴²

PROTEIN Z/PROTEIN Z-DEPENDENT PROTEASE INHIBITOR

ZPI is a serine protease inhibitor (Mr ≈72,000; SERPINA10 in the systematic nomenclature) that inhibits coagulation factors Xa and XIa. ZPI circulates in plasma at 60 nM with a half-life of 60 hours (see Table 113-1).³⁴³ The ZPI-dependent inhibition of factor Xa is enhanced in the presence of protein Z.⁷⁹ Protein Z is a vitamin K-dependent plasma GP (Mr ≈62,000) that circulates at 40 nM (see Table 113-1). In normal plasma, which has a molar excess of ZPI over protein Z, all protein Z circulates in complex with ZPI.³⁴⁴

Protein Structure

ZPI displays 25 to 30 percent homology with other serpins such as AT. Based on this homology, Tyr387 was predicted and confirmed as P1 residue in the reactive center loop of ZPI and shown pivotal for inhibition of factor Xa.³⁴⁵ Unlike other serpins, the N-terminal region of ZPI contains a very acidic domain.

Protein Z consists of a Gla domain, a hydrophobic region, and two EGF-like domains. Even though the C-terminal region of protein Z contains a domain that is homologous to the serine protease domains of the other Gla-containing proteins, it lacks the His and Ser active site residues characteristic for trypsin-like serine proteases.³⁴⁶ Thus, protein Z has no protease activity.

Protein Z/Protein Z-Dependent Protease Inhibitor Function

The protein Z-ZPI complex associates with anionic phospholipid membranes in a calcium-dependent manner mediated by the Gla domain of protein Z, which facilitates formation of the ternary protein Z-ZPI-factor Xa complex. Furthermore, protein Z has also been suggested to induce conformational changes in ZPI, resulting in alignment of the reactive center loop and P1 site of ZPI with the factor Xa active site.³⁴⁷ Together, these effects of protein Z enhance the inhibitory activity of ZPI to factor Xa by 1000-fold. In contrast, ZPI inactivation of factor XIa is protein Z-independent.⁷⁹ Similar to other serpins, ZPI acts as a "suicide" substrate. However, factors Xa and XIa eventually cleave ZPI at the P1 residue Tyr387, which results in release of a 4.2-kDa C-terminal ZPI peptide.⁷⁹

The combination of protein Z and ZPI dramatically delays the initiation and reduces the ultimate rate of thrombin generation in mixtures containing prothrombin, factor V, phospholipids, and calcium. However, in similar mixtures containing factor Va, protein Z and ZPI do not inhibit thrombin generation.⁷⁹ Thus, the major effect of protein Z and ZPI is to dampen the coagulation response prior to the formation of the prothrombinase complex.

In mice, protein Z and ZPI deficiency is associated with a prothrombotic phenotype and both deficiencies dramatically increase mortality in animals with the factor V Leiden mutation. This indicates that protein Z and ZPI deficiency may be risk factors for thrombotic disease in humans.³⁴⁸ Indeed, low protein Z levels appear weakly associated with thrombosis and ischemic stroke in subgroups of some small studies. However, these studies lack power to show a definite interaction with vascular disease.³⁴⁹ Other studies demonstrate a possible association of protein Z and ZPI mutations with thrombosis and pregnancy complications.³⁵⁰

Gene Structure and Variations

The chromosomal location of the ZPI gene (*SERPINA10*) is 14q32.13. The gene encodes six exons and spans almost 10 kb. The gene for protein Z (*PROZ*) is on the long arm of chromosome 13 (q34) in close proximity to the genes for factor X and factor VII. The protein Z gene spans 14 kb and consists of nine exons. The intron/exon boundaries are identical to

the other Gla-containing coagulation proteins. There is an alternative exon that codes for a unique peptide of 22 amino acids in the prepro leader sequence. The gene is transcribed into a 1.6-kb mRNA.

Several mutations and polymorphisms have been described for the gene encoding ZPI,³⁵¹ but the association between such gene variations and risk of venous thrombosis has not been established with certainty.³⁵²

The human gene mutation database lists nine loss-of-function mutations in the protein Z gene. The relationship between these mutations and disease is uncertain at best, but a relationship with ischemic stroke and recurrent fetal loss cannot be excluded.³⁵³⁻³⁵⁵

PATHWAYS OF HEMOSTASIS

Early Coagulation Schemes

With the accumulated knowledge of the biochemistry of hemophilia it was recognized in the 1960s that blood coagulation was regulated by a sequential series of steps in which activation of one clotting factor led to the activation of another, finally leading to a burst of thrombin generation.^{356,357} Each clotting factor was thought to exist as a proenzyme that could be converted to an active enzyme.

Since then the original waterfall reaction scheme of enzymes has been modified extensively. Factors V and VIII were identified as nonenzymatic procofactors for factors Xa and IXa, respectively, and the subsequent clotting events were divided into so-called extrinsic and intrinsic systems (Fig. 113-27). The extrinsic system was shown to consist of factor VIIa and tissue factor, the latter being viewed as extrinsic to the circulating blood. The tissue factor pathway could be activated in clotting tests by a brain tissue extract. The factor XII-dependent intrinsic system could even be activated by china clay (kaolin) and was viewed as being intravascular. Both pathways activate factor X, which, in complex with the activated cofactor Va, converts prothrombin to thrombin.

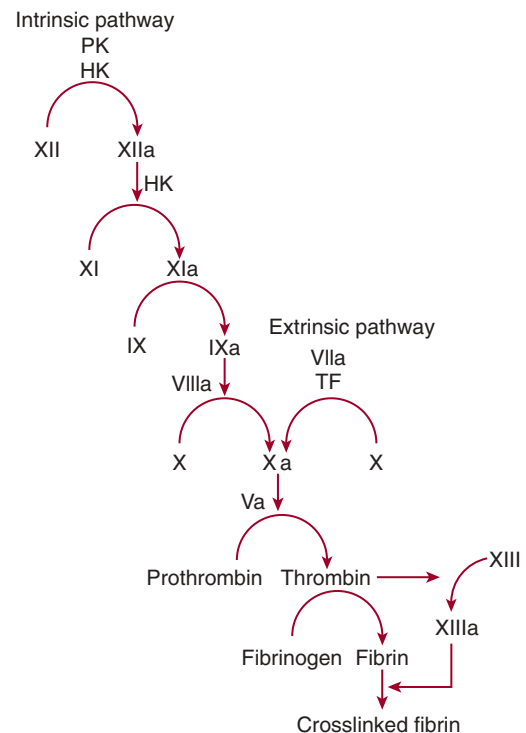

Figure 113-27. Cascade model of coagulation. This model shows successive activation of coagulation factors proceeding from the top of the schematic to thrombin generation and fibrin formation at the bottom of the schematic. The intrinsic and extrinsic pathways are indicated. HK, high-molecular-weight kininogen; PK, prekallikrein; TF, tissue factor.

Although these earlier concepts of coagulation were extremely valuable, investigators recognized that the intrinsic and extrinsic systems could not operate independently. The pivotal role of factor XII for the initiation of intrinsic thrombin generation and lack of bleeding tendency of factor XII deficient individuals was inconsistent with the extreme bleeding associated with a deficiency in factor VIII or IX, participants of the same intrinsic pathway, which urged investigators to search for additional links in the cascades.

Revision of the Coagulation Scheme

Key to the revision of the coagulation model was the purification and characterization of the transmembrane protein tissue factor.^{358,359} A crucial observation was that the tissue factor-factor VIIa complex not only activates factor X, but also factor IX.³⁶⁰ This showed that factor VIII or IX deficiencies, which result in hemophilia A or B, respectively, are in fact abnormalities of the tissue factor-factor VIIa pathway, even though factors VIII and IX are components of the intrinsic system. With the notion that traces of tissue factor-factor VIIa are rapidly inactivated by TFPI, it became clear that factor VIIIa-factor IXa activity is necessary to sustain hemostatic factor Xa and thrombin generation.³⁶¹⁻³⁶⁴ The embryonic lethality caused by both tissue factor as well as TFPI deficiency in mice underscores the importance of tissue factor-mediated thrombin generation and the control thereof.^{340,365} Finally, it was observed that thrombin could directly activate factor XI,³⁶⁶ thus providing an amplification loop once thrombin generation has been initiated: thrombin

→ factor XIa → factor IXa → FXa → thrombin. This model explains the mild bleeding tendency observed in factor XI-deficient patients and the absence of bleeding in factor XII-deficient individuals. A revised coagulation scheme is depicted in Fig. 113-28. This scheme builds on the conclusion that the major initiating event in hemostasis *in vivo* is the formation of the tissue factor-factor VIIa complex at the site of injury.³⁶⁷

It was also recognized that *in vivo* coagulation is regulated by control mechanisms, one of which is the localization of the coagulation reactions to cell surfaces. In addition, earlier and more recent observations emphasized the importance of plasma inhibitors targeting each step of the coagulation process. These include (1) TFPI, which controls tissue factor-factor VIIa and factor Xa activity in cooperation with protein S,^{331,333} (2) thrombomodulin and APC, which inactivate thrombin and factors Va and VIIIa, the latter also in cooperation with protein S,³⁶⁸ (3) AT, which inhibits thrombin and other coagulation proteases,³⁶⁹ and (4) ZPI, which inhibits factor Xa on phospholipid surfaces in cooperation with protein Z prior to incorporation of factor Xa into the prothrombinase complex.⁷⁹ See also Fig. 113-28 for an overview of the inhibitory mechanisms of coagulation.

Most of the essential pathways of tissue factor-dependent thrombin generation and inhibitory control have been captured in a mathematical model based on the empirically derived rate constants of the individual reactions.³⁷⁰ Completion and refinement of such models will aid our understanding of the biochemistry of the coagulation reactions on artificial membranes, given that the enzymatic events on

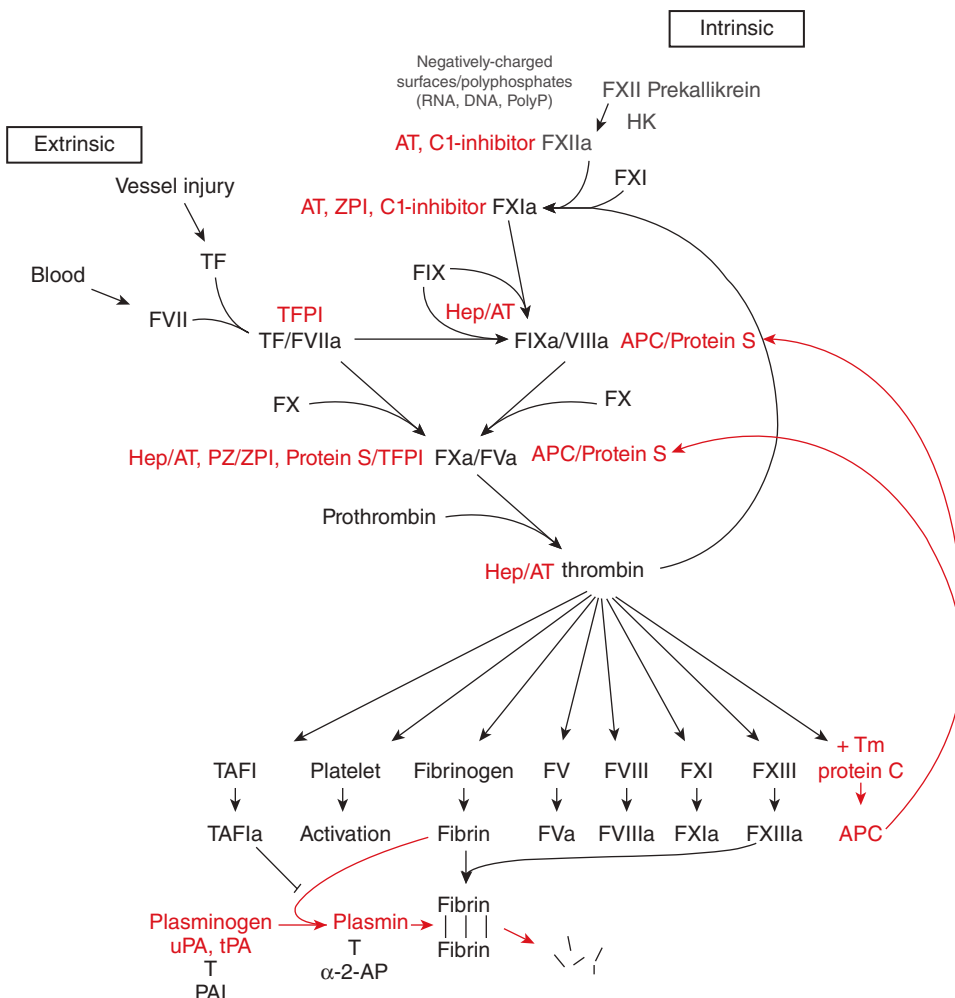

Figure 113-28. Revised model of coagulation. Schematic overview of the coagulation reactions in which several revisions have been made as compared to the classic cascade model of coagulation. The tissue factor-factor VIIa complex of the extrinsic pathway also activates factor IX, and thrombin activates factor XI, in a positive feedback loop. The factor IX-dependent amplification of factor Xa generation is necessary for hemostatic fibrin formation at low tissue factor concentrations, because tissue factor-factor VIIa-mediated factor X activation is inhibited by tissue factor pathway inhibitor (TFPI). Procoagulant extrinsic pathway components are indicated in *black*, the part of the intrinsic coagulation pathway that is not necessary for hemostasis is indicated in *gray*. Anticoagulant mediators are indicated in *red*. AP, antiplasmin; APC, activated protein C; AT, antithrombin; Hep, heparin; HK, high-molecular-weight kinogen; PAI, plasminogen activator inhibitor; PZ, protein Z; TAFI, thrombin-activatable fibrinolysis inhibitor; TF, tissue factor; Tm, thrombomodulin; tPA, tissue plasminogen activator; uPA, urokinase plasminogen activator; ZPI, protein Z-dependent protease inhibitor.

cellular membranes under (reduced) flow are still complicated, which hampers their incorporation into a mathematical model.³⁷⁰

A Cell-Based Scheme of Coagulation

The goal of coagulation is to produce a fibrin clot that seals the site of injury in the vessel wall. This process is initiated when tissue factor-bearing cells are exposed to blood at the damaged site. Tissue factor is anchored to cells via a transmembrane domain and acts as a receptor for plasma factor VII. Both trace amounts of factor VIIa as well as zymogen factor VII that is rapidly converted to factor VIIa by factor Xa and/or autoactivation bind to tissue factor. Tissue factor is expressed around vessels and in the epithelium, where it forms a “hemostatic envelope.” The tissue factor surrounding the vessels may already be in complex with factor VIIa, even in the absence of an injury.²⁵³

The tissue factor–factor VIIa complex catalyzes two very important reactions: (1) activation of factor X to factor Xa and (2) activation of factor IX to IXa. The initial factors Xa and IXa formed on tissue factor-bearing cells may have distinct functions in initiating the process of blood coagulation.³⁷¹ When a vessel is damaged, the blood delivers platelets to the site of injury. These bind to extravascular matrix components to produce the primary hemostatic plug and become partially activated in the process. The platelets are consequently localized in close proximity to active tissue factor–factor VIIa complexes.

The factor Xa formed on the tissue factor-bearing cell interacts with factor Va to form prothrombinase complexes that generate small amounts of thrombin (Fig. 113–29). Although this amount of thrombin may not be sufficient to clot fibrinogen, it is sufficient to initiate events

Figure 113–29. Cellular model of tissue factor–factor VIIa-mediated thrombin generation on tissue factor-bearing cells and propagation on platelets. After the initial generation of factor Xa on tissue factor-bearing cells, subsequent factor Xa generation is shutdown when tissue factor pathway inhibitor (TFPI) reacts with factor Xa to inactivate the tissue factor–factor VIIa complex. The small amount of thrombin generated on the tissue factor-bearing cell plays a critical role in priming platelets for subsequent coagulation steps. This thrombin activates platelets, releases factor V from platelet α -granules, activates factor V, activates factor VIII and releases it from von Willebrand factor (VWF), and activates factor XI. Factor IXa, generated on tissue factor-bearing cells, is only slowly inhibited by plasma inhibitors and can therefore make its way to the primed platelet surface where it binds to factor VIIIa. This factor VIIIa–IXa complex activates factor X on the platelet surface. The generated factor Xa complexes with factor Va and subsequently activates prothrombin, which leads to the burst of thrombin generation responsible for cleaving fibrinogen. Additional factor IXa is supplied by factor XIa on the platelet surface.

that “prime” the clotting system for a subsequent burst of thrombin generation. Experiments using tissue factor–activated whole blood and cell-based systems have shown that platelets can be activated by thrombin that is generated by direct tissue factor–factor VIIa activation of factor Xa.^{371–373} The small amounts of factor Va required for prothrombinase assembly are likely provided by activated platelets, by factor Xa activation, or potentially by noncoagulation proteases secreted by the tissue factor-bearing cells.^{335,374,375}

The small amounts of thrombin generated are capable of accomplishing the following: (1) activating platelets; (2) activating factor V; (3) activating factor VIII and dissociating factor VIII from VWF; and (4) activating factor XI (see Fig. 113–29).^{366,372,373} The activity of the factor Xa formed by the tissue factor–factor VIIa complex will be mostly restricted to the tissue factor-bearing surface because free factor Xa that diffuses off the cell surface is rapidly inhibited by TFPI, AT, and/or the protein Z–ZPI complex. Factor IXa, on the other hand, will most likely act on activated platelets in close proximity to the tissue factor-bearing cell. This is because factor IXa can diffuse to adjacent cell surfaces as it is not inhibited by TFPI and ZPI, while the rate of factor IXa inhibition by AT is much lower than that of factor Xa (see Table 113–4).

The Role of Activated Platelets

Platelets also play a major role in localizing clotting reactions to the site of injury, as they adhere and aggregate at the same location where tissue factor is exposed to blood. Platelet localization and activation are mediated by VWF, thrombin, platelet receptors, and vessel wall components such as collagen (Chap. 112). Once platelets are activated, the cofactors Va and VIIIa are rapidly localized to the platelet membrane surface (see Fig. 113–29). Cofactor binding is mediated in part by the exposure of phosphatidylserine on the platelet membrane, a process resulting from a flip-flop mechanism whereby phosphatidylserine on the inner leaflet of the membrane bilayer flips to the outer membrane leaflet.³⁷⁶ Endothelial cells, platelets, and leukocytes also generate procoagulant microvesicles that sustain thrombin generation. While the procoagulant characteristics of microvesicles have been studied in detail *in vitro*, their relative contribution to coagulation *in vivo* is still subject of debate.

Factor Xa generation is amplified on platelets by localization of factors IXa and XIa through specific binding sites,^{377,378} and thrombin-mediated factor XI activation is enhanced by poly-P that is released by activated platelets (see Fig. 113–29).³⁷⁹ Once formed, factor Xa associates with factor Va on the platelet surface to generate a burst of thrombin that is sufficient to clot fibrinogen and form a hemostatic plug. Subsequently, thrombin-activated factor XIII crosslinks fibrin and stabilizes the hemostatic plug, thereby rendering it impermeable. Thrombin also activates TAFI, which helps to stabilize the fibrin clot. The factor XIa-mediated feedback loop has been implicated to generate ample thrombin required for TAFI activation.³⁸⁰

It should be noted that the balance between the pro- and anticoagulant reactions, the pro- and antifibrinolytic potential, as well as stress on the local vasculature vary greatly in the different the organs, muscles, joints, and other sites in the body. This is probably fundamental to the variation in bleeding phenotypes observed in various coagulation factor deficiencies.³⁸¹ The notion that factors XI and XII are not crucial to hemostasis, but are involved in thrombosis, has led to their identification as new targets to improve the safety of anticoagulant therapy by reducing the risk of bleeding complications.^{382,383}

The Role of Immune Cells

It has become clear that thrombi may have a major physiologic role in immune defense. This so-called immunothrombosis may aid in the recognition, containment, and killing of pathogens.³⁸⁴ However, if not

Role of Plasma Protease Inhibitors

Circulating protease inhibitors are also critical for localizing the coagulation reactions to specific cell surfaces by directly inhibiting proteases that diffuse away from the site of clot formation. Not only are the plasma protease inhibitors key players in confining a clot to the proper location, their synergistic action imposes a threshold effect on the coagulation process.^{363,395,396} Thus, in the presence of inhibitors, coagulation does not proceed unless procoagulant factors are generated in sufficient amounts to overcome the inhibitory mechanisms. In case the triggering event is inadequate, the system returns to baseline rather than continuing through the coagulation process. Under pathologic conditions, the trigger for clotting may be so strong as to overwhelm the control mechanisms, leading to disseminated intravascular coagulation or thrombosis (Chaps. 129 and 133).

ROLE OF FIBRINOLYSIS

Once a hemostatic clot has been formed and protected from fibrinolysis by the action of factor XIII and TAFI, some provision must be made for its eventual removal as wound healing takes place. Dissolution of clots is accomplished by the fibrinolytic system, as discussed in detail in Chap. 135.

The Concept of Basal Coagulation and Anticoagulation

The coagulation process only proceeds when enough thrombin is generated on or near the tissue factor-bearing cell to trigger activation of platelets and cofactors. One may wonder, however, if minute hemostatic plugs are not constantly formed throughout the body to maintain the integrity of the vasculature. Indeed, a low level of coagulation factor activation probably occurs at all times.³⁹⁷ More than 30 years ago, it was shown that fibrinopeptides are continuously cleaved from fibrinogen at low levels in normal individuals.³⁹⁸ Minute amounts of factor VIIa as well as the activation peptides of factors IX and X have also been demonstrated to circulate in the bloodstream of normal individuals.^{399–401} This is known as basal coagulation or idling. Basal activation of coagulation factors likely results from minor injuries that occur during normal daily activities. The basal coagulation must be balanced by basal activity of the anticoagulation and fibrinolytic systems. This is evidenced by the presence of low levels of the protein C activation peptide and tissue plasminogen activator activity in normal individuals.⁴⁰²

CHAPTER 114

CONTROL OF COAGULATION REACTIONS

Laurent O. Mosnier and John H. Griffin

SUMMARY

The blood coagulation system, like a powerful idling engine, is always active and generating thrombin at very low levels, poised for explosive thrombin generation. Positive feedback activation of factors V, VII, VIII, and XI imparts special threshold properties to blood coagulation, making the coagulant response nonlinearly responsive to stimuli. Overt blood coagulation represents a threshold system with apparent all-or-none responses to various levels of stimuli, and an ensemble of opposing reactions determines the ultimate upregulation and downregulation of thrombin generation both locally and systemically. Cellular and humoral anticoagulant mechanisms synergize with plasma coagulation inhibitors to prevent massive thrombin generation in the absence of a substantial procoagulant stimulus. This chapter highlights mechanisms that inhibit blood coagulation, with an emphasis on defects of plasma proteins that cause hereditary thrombophilias. Major thrombophilic defects involve the anticoagulant protein C pathway, comprising multiple cofactors or effectors that additionally include thrombomodulin, endothelial protein C receptor, protein S, high-density lipoprotein, and factor V. Activated protein C exerts multiple protective homeostatic actions, including proteolytic inactivation of factors Va and VIIIa, as well as direct cell-signaling activities involving protease activated receptors 1 and 3, endothelial cell protein C receptor, integrin CD11b/CD18, and apolipoprotein E receptor 2. The factor V Leiden variant causes hereditary activated protein C resistance by impairing the ability of the protein C pathway to inhibit coagulation because it cannot properly cleave factor Va Leiden. Plasma protease inhibitors are also key to block coagulation. Antithrombin inhibits thrombin and factors Xa, IXa, XIa, and XIIa, in reactions stimulated by physiologic heparan sulfate or pharmacologic heparins. Tissue factor pathway inhibitor neutralizes the extrinsic coagulation pathway factors VIIa and Xa. Other plasma protease inhibitors can also neutralize various coagulation proteases.

Control of coagulation reactions is essential for normal hemostasis. As part of the tangled web of host defense systems that respond to vascular injury, the blood coagulation factors (Chap. 113) act in concert with the endothelium and blood cells, especially platelets, to generate a protective fibrin-platelet clot, forming a hemostatic plug. Pathologic thrombosis occurs when the protective

clot is extended beyond its beneficial size, when a clot occurs inappropriately at sites of vascular disease, or when a clot embolizes to other sites in the circulatory bed. For normal hemostasis, both procoagulant and anticoagulant factors must interact with the vascular components and cell surfaces, including the vessel wall (Chap. 115) and platelets (Chap. 112). Moreover, the action of the fibrinolytic system must be integrated with coagulation reactions for timely formation and dissolution of blood clots (Chap. 135). This chapter on control of coagulation highlights the major physiologic mechanisms for downregulation of blood coagulation reactions and the plasma proteins that inhibit blood coagulation, with an emphasis on those mechanisms whose defects are clinically significant based on insights gleaned from consideration of the hereditary thrombophilias (Chap. 130). Chapter 113 provides a complete description of blood coagulation factors and hemostatic pathways.

BLOOD COAGULATION PATHWAYS AND THE PROTEIN C PATHWAYS

Although decades have elapsed since the elaboration of the cascade model^{1,2} for blood coagulation (see Chap. 113, Fig. 113–27), the basic outline of sequential conversions of protease zymogens to active serine proteases is still useful, albeit with important modifications (see Chap. 113, Fig. 113–28), to represent blood coagulation reactions. The major conceptual advances for procoagulant pathways in the past two decades emphasize both positive and negative feedback reactions affecting thrombin generation as depicted in Fig. 114–1.

In positive feedback reactions, procoagulant thrombin activates platelets and factors V, VIII, and XI (Chap. 113).^{3–5} Small amounts of thrombin can be generated by trace amounts of tissue factor via the extrinsic pathway. Subsequently, thrombin can activate factors XI, VIII, and V, thereby stimulating each of the steps in the intrinsic pathway, thereby amplifying thrombin generation (see Fig. 114–1).

In negative feedback reactions, anticoagulant activated protein C (APC) that is generated on endothelial cell surfaces^{6–8} (Fig. 114–2) downregulates coagulation (see Figs. 114–1 and 114–3). Furthermore, APC can exert direct cytoprotective effects on cells via reactions that involve certain receptors, including endothelial cell protein C receptor (EPCR) and protease-activated receptor-1 (PAR-1) (Fig. 114–4), PAR-3, integrin CD11b/CD18, and possibly apolipoprotein E receptor 2 (apoER2).^{7,8} APC's cytoprotective effects include antiinflammatory and antiapoptotic activities, as well as alterations of gene-expression profiles and stabilization of endothelial barriers (see "Activated Protein C Activities" below). Because inflammation, apoptosis, and vascular barrier breakdown contribute significantly to reactions that promote thrombin generation, such direct cytoprotective effects of APC on cells indirectly downregulate thrombin generation.^{7,8}

For APC generation by the protein C cellular pathway, binding of thrombin to thrombomodulin converts the bound thrombin from a procoagulant enzyme to an anticoagulant enzyme that converts the protein C zymogen to an anticoagulant serine protease, APC (see Figs. 114–1 and 114–2). This surface-dependent reaction is enhanced by the EPCR that binds protein C.^{6,9,10} With the aid of its nonenzymatic cofactor, protein S, as well as other potential lipid and protein cofactors, APC inactivates factors Va and VIIIa by highly selective proteolysis, yielding inactive (i) cofactors, that is, factors V_i and VIII_i (see Fig. 114–3 and Chap. 113, Figs. 113–11 and 113–13). Protein S also can directly inhibit factors VIIIa, Xa, and Va.^{11–13} Thus, APC and protein S inhibit multiple steps in the intrinsic coagulation pathway.

Acronyms and Abbreviations: APC, activated protein C; apoER2, apolipoprotein E receptor 2; CD11b/CD18, Mac-1; EPCR, endothelial cell protein C receptor; GLA, γ -carboxyglutamic acid; GPI, glycosylphosphatidylinositol; HDL, high-density lipoprotein; NMDA, *N*-methyl-*D*-aspartate; PAR-1, protease-activated receptor-1; serpin, serine protease inhibitor; SHBG, sex hormone-binding globulin; TFPI, tissue factor pathway inhibitor; TNF, tumor necrosis factor; ZPI, protein Z-dependent protease inhibitor.

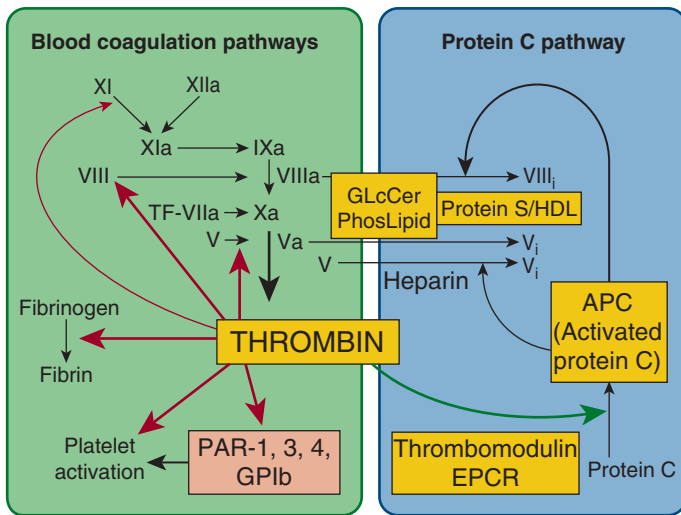

Figure 114-1. Blood coagulation pathways and protein C anticoagulant pathway. Thrombin can be either a procoagulant (*left*) or an anticoagulant (*right*), depending on cofactors and surfaces. Coagulant thrombin clots fibrinogen and activates platelets and factors V, VIII, XI, and XIII. Conversion of zymogen protein C to the active protease, APC, by thrombomodulin-bound thrombin is enhanced by endothelial protein C receptor (EPCR). APC with its nonenzymatic cofactor, protein S, inactivates factors Va and VIIIa by highly selective proteolysis (e.g., at Arg506 and Arg306 in factor Va), yielding inactivated (i) factors Vi and VIIIi. This anticoagulant action may be enhanced by phospholipid (PhosLipid) surfaces on platelets, endothelial cells, or their microparticles. High-density lipoprotein (HDL) can also provide protein S-dependent anticoagulant APC-cofactor activity. Similarly, neutral glycosphingolipids such as glucosylceramide (GLcCer) can enhance APC anticoagulant activity. GPIb, glycoprotein Ib; PAR, protease-activated receptor. (Adapted with permission from Griffin JH: *Blood coagulation. The thrombin paradox.* Nature 378(6555):337–338, 1995.)

At each step in the coagulation pathways, each clotting protease can be inhibited by one or more plasma protease inhibitors in reactions stimulated by negatively charged glycosaminoglycans such as heparan sulfate or heparin (see “Inhibition of Coagulation Proteases by Protease

Figure 114-2. Protein C activation on endothelial cell surface. On an endothelial surface, activated protein C (APC) generation follows binding of protein C (PC) to endothelial protein C receptor (EPCR) where PC is activated by limited proteolysis by the thrombin (IIa)–thrombomodulin (TM) complex. This action of thrombin liberates a dodecapeptide (residues 158 to 169) from protein C to generate the multifunctional protease APC. (Adapted with permission from Mosnier LO, Zlokovic BV, Griffin JH: *The cytoprotective protein C pathway.* Blood 109(8):3161–3172, 2007.)

Figure 114-3. Activated protein C (APC) exerts its anticoagulant activity by proteolytic inactivation of factors Va and VIIIa on membrane surfaces containing phospholipids that are derived from cells, lipoproteins, or cellular microparticles. A variety of lipid and protein cofactors (see Fig. 114-1 legend and text) accelerate the inactivation of factors Va and VIIIa to yield the irreversibly inactivated factors Vi and VIIIi. (Adapted with permission from Mosnier LO, Zlokovic BV, Griffin JH: *The cytoprotective protein C pathway.* Blood 109(8):3161–3172, 2007.)

Inhibitors” below). Given the highly nonlinear nature of the coagulation pathways with both positive and negative feedback reactions, synergy between the protein C pathway and plasma protease inhibitors is important for regulating thrombin generation.

There is continuous activation of coagulation factors at a basal physiologic low level. Plasma from all normal subjects contains circulating active enzymes, factor VIIa,¹⁴ and APC,¹⁵ as well as various polypeptide fragments generated by the action of clotting proteases, namely fibrinopeptides,^{16,17} prothrombin fragment 1+2,¹⁸ and activation peptides for factors IX and X.^{19,20} The presence of multiple clotting factors that require positive feedback activation (e.g., factors V, VIII, XI, and VII

Figure 114-4. Paradigm for activated protein C (APC)'s initiation of cell signaling and multiple cytoprotective effects. Direct effects of APC on cells are initiated by activation of the G-protein-coupled receptor, protease-activated receptor-1 (PAR-1), by endothelial protein C receptor (EPCR)-bound APC. The γ -carboxyglutamic acid (GLA) domain of APC binds to EPCR to help position APC's protease domain for efficient cleavage of the extracellular N-terminal tail of PAR-1, which results in G-protein-coupled receptor activation and subsequent antiinflammatory and antiapoptotic effects, alterations of gene expression profiles, and stabilization of endothelial junctions. (Adapted with permission from Mosnier LO, Zlokovic BV, Griffin JH: *The cytoprotective protein C pathway.* Blood 109(8):3161–3172, 2007.)

imparts special threshold properties to the blood coagulation pathways, making the coagulant response nonlinearly responsive to stimuli. Theoretical analysis of blood coagulation as a threshold system suggests there can be an all-or-none response to various levels of stimulation, depending on the ensemble of activating and inhibitory reactions that defines upregulation and downregulation of thrombin generation.^{21,22} The coagulation system is active, but idling, and is poised for extensive and explosive generation of thrombin. Because of synergy among various cellular and humoral anticoagulant mechanisms that establish a threshold system, the presence of multiple coagulation inhibitors with complementary modes of action prevents massive thrombin generation in the absence of a substantial procoagulant stimulus.

HEREDITARY DEFICIENCIES ASSOCIATED WITH THROMBOTIC DISEASE

Evidence for the physiologic importance of specific factors for controlling coagulation reactions comes from clinical observations and animal model studies. Major identified genetic risk factors for venous thrombosis involve protein structural defects in factor V, protein C, protein S, and antithrombin (Chap. 130). There are also gene regulatory defects associated with thrombotic disease, such as the G20210A polymorphism in the prothrombin gene that causes elevated levels of prothrombin, and defects in protein C gene regulatory elements that decrease the expression of protein C. Deficiencies of thrombomodulin might also be associated with increased risk of arterial thrombosis. Association of hereditary abnormalities of EPCR with increased risks of thrombosis has been suggested, but this remains somewhat controversial.

PROTEIN C PATHWAY COMPONENTS

Figure 114-5 is a schematic of the structures of protein C, protein S, thrombomodulin, and EPCR. These proteins contain multiple domains, each of which may mediate different molecular functions. Values for

the molecular weight, normal plasma concentration, chromosomal location, and gene structures of these factors are given in Table 114-1. Factors Va and VIIIa, as substrates of APC, are also participants in the reactions of the anticoagulant protein C pathway. Moreover, factor V, but not factor V Leiden, appears to act as an APC cofactor for the inactivation of factor VIIIa (see “Factor V as Activated Protein C Cofactor” below).²³

PROTEIN C

In 1976, Stenflo designated a bovine plasma vitamin K-dependent protein that eluted in the third peak (peak C) from an anion exchange column as bovine “protein C.”²⁴ Protein C, actually previously described as the anticoagulant factor autoprotease II-A,²⁵ is a plasma serine protease zymogen that can be converted to an active serine protease by the action of thrombin.

Protein C is synthesized in the liver as a polypeptide precursor of 461 residues, with a prepropeptide of 42 amino acids that contains the signal for carboxylation of Glu residues by a carboxylase that forms nine γ -carboxyglutamic acid (GLA) residues and secretion of the mature protein.²⁶⁻²⁸ The mature glycoprotein of Mr 62,000 contains 419 residues (see Chap. 113, Fig. 113-1 and Fig. 114-5) and N-linked carbohydrate, and the majority of the secreted protein C molecules are cleaved by a furin-like endoprotease that releases Lys156-Arg157 and generates a two-chain zymogen that circulates in plasma at 65 nM (4 mcg/mL).²⁹ The heavy and light chains of plasma protein C are covalently linked by a disulfide bond that keeps the serine protease globular domain (residues 170 to 419) covalently tethered to the N-terminal string of three domains, the GLA domain and the epidermal growth factor (EGF)-like domains EGF1 and EGF2.²⁶⁻³⁰

The GLA domain of protein C (residues 1 to 42) and APC is important for a number of functions, including binding to phospholipid-containing membranes (see Chap. 113, Fig. 113-3), thrombomodulin, and EPCR; thus, incomplete carboxylation impairs the functional anticoagulant activity of APC.³¹⁻³³ The two EGF modules in the light chain may contribute to interactions of APC with protein S and of protein C with thrombomodulin.

Figure 114-5. Membrane-bound protein C, protein S, thrombomodulin (TM) and endothelial cell protein C receptor (EPCR). Each protein is a multidomain protein that extends above the surface of cell membranes, and different domains mediate different functions of each protein. Protein C and protein S can bind reversibly to phospholipid membranes through their NH₂-terminal γ -carboxyglutamic acid (GLA) domains which contain nine or 11 GLA residues that bind four to six Ca²⁺ ions. TM and EPCR are integral membrane proteins that are embedded in cell membranes by a single hydrophobic transmembrane sequence. (Adapted with permission from Esmon CT: *The roles of protein C and thrombomodulin in the regulation of blood coagulation*. J Biol Chem 264(9):4743-4746, 1989.)

TABLE 114-1. Characteristics of Blood Coagulation Regulatory Molecules

	Molecular Weight (kDa)	Plasma Concentration (mcg/mL)	Half-Life (h)	Chromosome	Gene (kb)	Exon (N)	Function

NA, not applicable; ND, not determined.

The serine protease domain of protein C is homologous to other trypsin-like proteases, and three-dimensional modeling³⁴ and X-ray crystallographic structures³⁰ reflect the structural similarity of APC to members of the serine protease family of which chymotrypsin is the prototype (see Mather and colleagues³⁰ for conversion of protein C to chymotrypsin numbering). APC's trypsin-like protease domain exerts its anticoagulant activity by highly specific interactions with factors Va and VIIIa followed by cleavage at only two Arg-containing peptide bonds in factors Va and VIIIa (see "Factors Va and VIIIa as Substrates for Activated Protein C" below). These stereo-specific interactions involve both the APC enzymatic active site region and a number of APC residues that are termed *exosites* because they are not located in the immediate vicinity of APC's enzymatic active site. Such APC exosites are essential for specific recognition of the macromolecular substrates, factors Va and VIIIa as well as recognition of cellular APC receptors.³⁵⁻⁴⁴

Protein C and Activated Protein C Therapy

Purified plasma protein C concentrate (Ceprotin) is FDA-approved for treating protein C-deficient patients.⁴⁵ Recombinant APC (Xigris) reduced all-cause 28-day mortality in severe sepsis adult patients in the PROWESS phase III trial in 2001 and was FDA-approved for this indication.⁴⁶ This successful therapy of adult severe sepsis using APC followed preclinical antithrombotic and sepsis studies in baboons.^{47,48} However, a decade later, in the PROWESS-SHOCK trial, recombinant APC did not reduce mortality in adult severe sepsis patients,⁴⁹⁻⁵¹ and Xigris was withdrawn from the market. Animal injury model studies have also shed light on *in vivo* mechanisms for APC beneficial effects in many preclinical injury models and in many models the pharmacologic benefits of APC appear to be independent of APC's anticoagulant actions (see "Activated Protein C Direct Cellular Activities" below).^{7,8}

Protein C Gene

The protein C gene, comprising nine exons and eight introns, is located on chromosome 2q14-21 and spans 11 kb (see Chap. 113, Fig. 113-10,

and Table 114-1).⁵² The protein C gene is homologous to the genes for factors VII, IX, and X (Chap. 113).

Protein C Mutations

Hereditary protein C deficiency associated with thrombosis is caused by numerous mutations (see protein C mutation databases).^{53,54} Based on three-dimensional structures of the protein C, the structural basis for hereditary protein C defects has been rationalized.^{34,55,56} Most mutations that cause type I protein C deficiency, characterized by parallel reductions in activity and antigen, involve amino acid residues that form the hydrophobic cores of the two folded globulin-like domains that are characteristic of serine proteases. These mutations destabilize either the process or the product of protein folding, and they result in unstable molecules that are poorly secreted and/or exhibit a very short circulatory half-life. In contrast, most mutations that cause type II defects (reduced anticoagulant or enzymatic activity but normal antigen levels), that is, circulating dysfunctional molecules, involve polar surface residues that do not affect polypeptide folding or thermodynamic stability; these polar residues presumably are involved in protein-protein interactions important for expression of anticoagulant activity.

Rare variants derived from a founder's mutation appear to be distinctive for races. Two protein C mutations, Arg147Trp and a Lys150 deletion, are significant venous thrombosis risk factors in Chinese but not in Americans of European descent or Japanese.⁵⁷⁻⁵⁹

Severe protein C deficiency as a consequence of homozygous knockout of the mouse protein C gene showed a similar phenotype as severe human protein C deficiency (Chap. 130), with perinatal consumptive coagulopathy in the brain and liver and either death or massive thrombosis that occurred either intrauterine or shortly after birth.⁶⁰

PROTEIN S

Plasma "protein S," which was named in honor of Seattle, the city of its discovery, is a vitamin K-dependent glycoprotein⁶¹ that is synthesized

by hepatocytes, neuroblastoma cells, kidney cells, testis, megakaryocytes, and endothelial cells, and is also found in platelet α -granules.⁶²

Protein S is synthesized as a precursor protein of 676 amino acids, which gives rise to a mature secreted single-chain glycoprotein of 635 residues with three *N*-linked carbohydrate side chains (see Fig. 114–5).^{63,64} Eleven GLA residues in the *N*-terminal region of mature protein S contribute to Ca^{2+} -mediated binding of the protein to phospholipid membranes. The thrombin-sensitive region, residues 47 to 72, follows the GLA-domain (see Fig. 114–5).

The C-terminal region of protein S, residues 270 to 635, the sex hormone-binding globulin-like (SHBG) region contains binding sites for C4b-binding protein (see “Activated Protein C–Independent Anticoagulant Activity of Protein S” below)⁶⁵ and for factor V, as well as factor Va.^{66,67} Protein S, like the homologous gas6, also binds to receptor tyrosine kinases, for example, Axl, and initiates cell signaling, and the SHBG region binds the receptor.⁶⁸ Thus, for the expression of its multiple activities, different domains of protein S exhibit a number of different binding sites for different proteins.

Protein S Gene

The protein S gene, comprising 15 exons and 14 introns, is located on chromosome 3p11.1–11.2 and spans 80 kb (see Fig. 113–16 and Table 114–1).^{69,70} The protein S gene has limited homology with other genes for vitamin K-dependent factors in the GLA and EGF domains and notable homology of the region coding for residues 240 to 635 with genes of the SHBG family. Humans contain a protein S pseudogene that contains several stop codons and is not translated and that is located very near the normal protein S gene on chromosome 3.

Protein S Mutations

The molecular basis for hereditary protein S deficiency associated with venous thrombosis (Chap. 130) is linked to more than 100 different mutations.⁷¹ A protein S polymorphism that is strongly linked to risk for venous thrombosis in Japanese subjects is known as protein S Tokushima. It involves K155E, which ablates APC-cofactor activity.^{57,72} But the K155E apparently is not present in Americans of European ancestry or Chinese populations, thus mirroring the presence of factor V Leiden and prothrombin G20210A that are risk factors in Americans of European descent but not in the Japanese, Chinese, or Americans of African descent populations.⁷³ Another single nucleotide polymorphism present in approximately 1 percent of Americans of European descent is S460P, which is designated protein S Heerlen; it results in absence of *N*-linked carbohydrate on Asn458 but has no accepted significant functional consequence.⁷⁴

THROMBOMODULIN

Thrombomodulin was discovered as an endothelial cell surface receptor that binds protein C and thrombin, thereby accelerating protein C activation.^{75–78} Binding of thrombin to thrombomodulin converts thrombin from a procoagulant enzyme to an anticoagulant enzyme because thrombomodulin-bound thrombin loses its normal ability to clot fibrinogen or activate platelets.^{79,80} Thrombomodulin is a multidomain transmembrane protein comprising an *N*-terminal lectin-like domain, six EGF domains, a Ser/Thr-rich region, a single membrane-spanning sequence, and an intracellular C-terminal tail (see Fig. 114–5).^{5–8,75–83} EGF domains 4, 5, and 6 are essential for activation of protein C, with the latter two domains binding thrombin and the first domain binding protein C. The mature protein has 557-amino-acid residues and variable amounts of *N*- and *O*-linked carbohydrate modifications that cause variability in molecular size. Glycosaminoglycans, notably chondroitin sulfate, covalently attached to the Ser/Thr-rich region, contribute to the functional properties of thrombomodulin by enhancing either

protein C activation by thrombin or by accelerating neutralization of thrombin by protease inhibitors. Modulation of the substrate specificity of thrombin by thrombomodulin involves conformational changes in thrombin caused by binding of thrombomodulin.

Low levels of soluble thrombomodulin circulate in plasma, presumably as a result of limited proteolysis of the protein near its transmembrane cell surface anchor. The functional significance of circulating thrombomodulin is unknown, although variations in its plasma level arise in different clinical conditions.

Recombinant soluble thrombomodulin has been developed for its potential therapeutic value for disseminated intravascular coagulation and has been approved for this indication in Japan.^{77,84}

Thrombomodulin Gene

The thrombomodulin gene, which lacks introns, is located on chromosome 20p11.2 and spans 3.7 kb (see Chap. 113, Fig. 113–19, Fig. 114–5, and Table 114–1).^{77,82} Deletion of the thrombomodulin gene in mice is embryonically lethal.⁸⁵ Downregulation of thrombomodulin gene expression is promoted by a variety of inflammatory agents, including endotoxin, interleukin-1, and tumor necrosis factor (TNF)- α , whereas its expression is upregulated by retinoic acid.^{5–8,86,87} Generally, thrombomodulin is a key member among the counterbalancing factors that contribute to inflammation, thrombin generation, and coagulation in the endothelium.

Thrombomodulin Mutations

Thrombomodulin mutations are well documented in atypical hemolytic uremic syndrome patients,^{78,88} and they may also be associated with an increased risk of arterial thrombosis and myocardial infarction. In contrast, there is less supportive data for association with risk for venous thrombosis (Chap. 130).^{89–92} Atypical hemolytic uremic syndrome is strongly linked to excessive complement activation, and thrombomodulin's lectin-like domain inhibits complement activation.^{77,93} Furthermore, besides promoting protein C activation by thrombin, thrombomodulin also supports activation of the carboxypeptidase, also known as thrombin-activatable fibrinolysis inhibitor (TAFI) that is a potent inactivator of bradykinin and of the activated complement components, C3a and C5a.^{94–96}

ENDOTHELIAL PROTEIN C RECEPTOR

EPCR binds both protein C and APC with similar affinities through their GLA domains and mediates multiple activities of this zymogen or its activated protease, APC.^{9,10,33,86,97–107} The mature EPCR glycoprotein contains 221-amino-acid residues and *N*-linked carbohydrate, giving an Mr of 46,000. EPCR is an integral membrane protein that is homologous to CD1/major histocompatibility complex class I molecules. The *N*-terminus is part of an extracellular domain, which is connected to a single transmembrane sequence that is followed by a short Arg-Arg-Cys-COOH cytoplasmic tail (see Fig. 114–5). The cytoplasmic tail can be palmitoylated, and this modification may help localize EPCR to certain lipid rafts or caveolae. The three-dimensional structure of EPCR determined by X-ray crystallography or inferred by molecular modeling established that the GLA domain of protein C and APC binds to EPCR.^{107,108} EPCR on endothelial surfaces enhances by greater than fivefold the rate of activation of protein C by thrombin–thrombomodulin (see Fig. 114–2). EPCR is also required for the cytoprotective activities of APC by promoting the cleavage of PAR-1 by APC to induce cell-signaling pathways (see Fig. 114–4). Notably, the cytoprotective actions of APC are completely independent of its anticoagulant activity and are based on cell signaling actions (see “Activated Protein C Direct Cellular Activities” below).^{7,8,109–111}

The presence of functional EPCR on the cell surface is regulated by two mechanisms, namely generation of EPCR and clearance of EPCR.

Inflammatory mediators induce EPCR ectodomain shedding from the endothelial cell surface by metalloproteinase TNF- α converting enzyme (known as “TACE”).¹¹² The soluble EPCR ectodomain is found in normal human plasma at 100 ng/mL; however, carriers of the H3 EPCR haplotype that includes a Ser219Gly polymorphism (rs867186) have threefold higher soluble EPCR plasma levels.¹¹³ Higher plasma levels of soluble EPCR are found in patients with disseminated intravascular coagulation or systemic lupus erythematosus, although plasma EPCR levels are not correlated with pathology-related alterations in circulating thrombomodulin levels.¹¹⁴ Soluble EPCR binds the protein C and APC via their GLA domains with an affinity similar to the membrane-bound receptor. Because binding of the APC GLA domain to negatively charged phospholipid membranes is required for its anticoagulant activity, soluble EPCR at relatively high levels in purified reaction mixtures inhibits the anticoagulant action of APC against factor Va, although it does not block the reaction of APC with protease inhibitors.^{10,86,99,115}

The EPCR crystal structure surprisingly revealed a single phospholipid molecule bound in a surface groove on the protein.¹⁰⁷ Secreted phospholipase A₂ group V can modify the lipid in EPCR and cause EPCR to lose its ability to bind protein C and APC.^{116,117} The presence of functional EPCR on the cell surface has important implications for thrombotic and inflammatory vascular disease because EPCR inactivation *in vivo* increases susceptibility to thrombotic and inflammatory diseases.^{10,86,97}

The physiologic requirement for EPCR in mice was established by the embryonic lethality observed for knockout of the murine EPCR gene.¹¹⁸

EPCR has functionally important interactions with multiple molecules beyond protein C and APC. It binds factor VII and factor VIIa.¹⁰ Furthermore, EPCR was recently implicated to play a potentially important role in the pathogenesis of severe malaria.^{119–122}

Endothelial Protein C Receptor Gene

The EPCR gene, comprising four exons and three introns, is located on human chromosome 20q11.2 and spans 6 kb (see Table 114–1).¹²³

PROTEASE-ACTIVATED RECEPTOR-1

PAR-1, discovered as a high-affinity human platelet receptor for thrombin,¹²⁴ is the prototype of a four-member subfamily of G-protein-coupled receptors that share an unusual mechanism of activation, namely activation by proteases.^{124–130} Each PAR contains seven transmembrane helical domains and an extracellular N-terminal tail that is cleaved by an activating protease such that the newly generated aminoterminal is a tethered ligand that triggers activation of the coupled G-protein. Human platelets employ PAR-1 and PAR-4 for activation by thrombin whereas, curiously, murine platelets that are devoid of PAR-1 require PAR-3 and PAR-4 for thrombin's normal effects.^{125,131} PAR-1 is activated by various plasma proteases^{132–135} and is generally required for APC's cytoprotective activities (see “Cellular Receptors for Physiologic Effects of Activated Protein C on Cells” below).^{7,8,110,111}

Protease-Activated Receptor-1 Gene

The PAR-1 gene contains only two introns, is located on chromosome 5q13, and spans 25 kb (see Table 114–1).¹²⁵ Much is known about many factors that can either upregulate or downregulate the PAR-1 gene.^{124–130}

ACTIVATION OF PROTEIN C

Protein C is activated from zymogen to active protease as a result of cleavage by thrombin at the Arg169–Leu170 peptide bond in a reaction that is accelerated by thrombomodulin and EPCR (see Fig. 114–2 and “Thrombomodulin” above).^{5,7,8,76,81,86} Thrombin infusions into animals

generate anticoagulant activity because of APC.^{136,137} Interestingly, thrombin infusion into hyperlipidemic monkeys with atherosclerosis generates less APC and causes a poorer *ex vivo* response to APC compared with normolipidemic control monkeys,¹³⁸ showing that hyperlipidemia and vascular disease can affect protein C activation.

Ischemia causes protein C activation *in vivo*. A brief occlusion of the left anterior descending coronary artery in pigs results in APC generation.¹³⁹ During cerebral ischemia in humans undergoing routine endarterectomy, APC increases in the venous cerebral blood.¹⁴⁰ Protein C is significantly activated during cardiopulmonary bypass, mainly during the minutes immediately after aortic unclamping in the ischemic vascular beds.¹⁴¹ Streptokinase therapy for acute myocardial infarction increases circulating APC.¹⁴²

Circulating APC concentration in normal human subjects is highly correlated with circulating levels of protein C zymogen.¹⁴³ Based on protein C infusion studies in protein C-deficient subjects, the level of circulating APC is strongly determined by the concentration of protein C.¹⁴⁴ EPCR appears to be required for normal protein C activation in response to thrombin infusions in experimental animals.¹⁴⁵ EPCR and thrombomodulin must be in close proximity on cell surfaces (see Fig. 114–2), although this has yet to be experimentally demonstrated.

Thrombomodulin and EPCR appear to differ markedly in their relative distribution densities on blood vessels as the former is abundantly present in the small blood vessels but less so in large vessels, whereas the latter is more abundant in large vessels than in small vessels.^{85,86,146,147} Low levels of thrombomodulin are expressed in brain,¹⁴⁸ and brain-specific activation of protein C in humans occurs during carotid occlusion.¹⁴⁰

Proteolytic cleavage and activation of protein C can also be effected by meizothrombin, plasmin, or factor Xa.^{149–153} On the surface of cultured endothelial cells, negatively charged sulfated polysaccharides in the presence of phospholipid vesicles containing phosphatidylethanolamine can enhance the rate of protein C activation by factor Xa to approach the protein C activation rate of thrombin:thrombomodulin.¹⁵² No data yet indicate whether protein C activation by meizothrombin, plasmin, or factor Xa is physiologically relevant.

Protein C activation is stimulated by platelet factor 4. Both *in vitro* and *in vivo* data imply that platelet factor 4 may play a physiologic role in enhancing APC generation and influencing the activities of the protein C system.^{154–157}

ACTIVATED PROTEIN C ACTIVITIES

The clinical phenotype of severe protein C deficiency in neonatal purpura fulminans implies that APC exerts multiple physiologically essential activities, including potent anticoagulant and antiinflammatory actions (Chap. 130). Recent advances establish that APC's antiinflammatory actions are but one manifestation of its ability to interact directly with cell receptors to provide multiple cytoprotective activities.^{7,8,110,111} These two distinct types of activities of APC—intravascular anticoagulant activity and initiation of cell signaling—are mediated by different sets of molecular interactions, and both types of activities are clinically relevant.

ACTIVATED PROTEIN C ANTICOAGULANT ACTIVITY

Mechanisms for APC's direct anticoagulant activity involve factors V and VIII, the two homologous coagulation cofactors that circulate as inactive molecules and that are converted to active cofactors by limited proteolysis (see Chap. 113, Figs. 113–11 and 113–13). APC circulates at 40 pM (picomolars) in normal humans, and there is an inverse correlation between fibrinopeptide A, the product that is cleaved

from fibrinogen by thrombin, and APC levels in healthy nonsmoking adults, suggesting APC is a significant regulator of basal thrombin activity.^{15,158}

Factors V and VIII are synthesized as large single-chain precursor coagulation cofactors of Mr 330,000, consisting of three homologous A domains (A1, A2, and A3) and two homologous C domains (C1 and C2) with a very large intervening, generally nonhomologous domain, designated the *B domain*, that connects the A2 and A3 domains (Chap. 113). Activation of the inactive precursor form of the two cofactors V and VIII involves limited proteolysis.^{23,159–164} Factor V activation involves cleavages at Arg709, Arg1018, and Arg1545 by thrombin, factor Xa, or other proteases.^{23,164–168} Cleavage at Arg1545 is the key step for generating factor Va activity because this proteolysis releases the B domain that blocks binding of factor Xa to factor Va.^{164,169} The various forms of factor Va (see Chap. 113, Fig. 113–11) are composed of two polypeptide chains, one bearing the A1-A2 domains and the other bearing the A3-C1-C2 domains. Although generally similar to factor V activation, factor VIII activation (see Fig. 113–13) involves formation of a heterotrimer of polypeptide chains containing the A1 domain, the A2 domain, and the A3-C1-C2 domains, respectively. In contrast to heterodimeric factor Va, heterotrimeric factor VIIIa is intrinsically unstable as a consequence of spontaneous dissociation of the A2 domain.¹⁷⁰

Factors Va and VIIIa as Substrates for Activated Protein C

Irreversible proteolytic inactivation of factors Va and VIIIa by APC can be accomplished by proteolysis at Arg506 and Arg306 in factor Va and Arg562 and Arg336 in factor VIIIa (see Chap. 113, Figs. 113–11 and 113–13).^{23,171–173} Currently, the most common identifiable venous thrombosis risk factor involves a mutation of Arg506 to Gln in factor V that results in APC resistance (Chap. 130). The complexities of APC-dependent inactivation of factor Va and VIIIa are compounded by the number of different molecular forms of Va and VIIIa that can be generated by limited proteolysis by a variety of proteases and by their differing susceptibilities to APC and to the different APC cofactors.

Activated Protein C Resistance

APC resistance is defined as an abnormally reduced anticoagulant response of a plasma sample to APC (Chap. 130) and can be caused by many potential abnormalities in the protein C anticoagulant pathway. Such abnormalities could include defective APC cofactors, defective APC substrates, or other molecules that interfere with the normal functioning of the protein C anticoagulant pathway (e.g., autoantibodies against APC, APC cofactors, or APC substrates).

A report of familial venous thrombosis associated with APC resistance without any identifiable defect in four Swedish families¹⁷⁴ led to an intensive search for a genetic explanation that was soon found to involve replacement of G by A at nucleotide 1691 in exon 10 of the factor V gene which causes the amino acid replacement of Arg506 by Gln.^{175–177} This factor V variant, like the prothrombin variant nt G20210A, arose in a single white founder some 18,000 to 29,000 years ago^{178,179} and is known as *Gln506-factor V* or *factor V Leiden*. This mutation is currently a common, but not the only, cause of APC resistance (Chap. 130).

The molecular mechanism for APC resistance of Gln506-factor V is based on the fact that the variant molecule is inactivated 10 times slower than normal Arg506-factor Va.^{23,177,180–182} The variant factor Va exhibits only a partial resistance to APC because cleavage at Arg306 in factor Va also occurs, causing complete loss of factor Va activity.

Plasma and recombinant factor V can exist in two biochemically distinct forms, designated *factor V1* and *factor V2* that differ in *N*-linked carbohydrate on Asn2181, near the phospholipid binding region of the C2 domain as factor V2 has none.^{183,184} Because the *N*-linked carbohydrate appears to decrease the apparent affinity of factor V1 or Va1 for

phospholipid, it reduces the specific clotting activity and susceptibility to APC. Normal plasma contains a mixture of factors V1 and V2. Removal of the carbohydrate attached to factor V increases the rate of inactivation of factor Va by APC, although the clinical significance of this phenomenon is unknown.¹⁸⁵

APC resistance with no identifiable genetic or acquired abnormalities is well described in patients with venous and arterial thrombosis and, at least for research purposes, should be therefore examined in patients with a suspected thrombophilia. Further studies are needed to identify the causes of APC resistance in such patients.^{186–188} One major challenge involves defining the normal range for the clotting assays that are actually used to characterize APC resistance and the multiple plasma analytes or nonplasma assay components that are present in the assays. For example, activated partial thromboplastin time-based assays are not equivalently sensitive as are dilute tissue-factor-based assays to plasma high-density lipoprotein (HDL) levels or oral contraceptive use.^{189–191} Plasma variables, such as elevated prothrombin levels,^{192,193} may affect the response to APC by inhibiting APC anticoagulant actions. Endogenous thrombin potential assays involving dilute tissue factor as the procoagulant initiator provide additional tools for defining and characterizing APC resistance and extend the tools for shedding light on the gray area of APC resistance found in some thrombosis patients that is not linked to currently known factors.

ACTIVATED PROTEIN C ANTICOAGULANT COFACTORS

APC anticoagulant activity is enhanced by a number of factors that may be termed *APC anticoagulant cofactors*; these include Ca²⁺ ions; certain, but not all, phospholipids; protein S; factor V; certain glycosphingolipids; and HDL.

Phospholipids as Activated Protein C Cofactors

Certain phospholipids, such as phosphatidylserine, phosphatidylethanolamine, and cardiolipin, enhance the anticoagulant activity of APC. In addition, phosphatidylethanolamine and cardiolipin stimulate the APC anticoagulant pathway activities much more than they stimulate the procoagulant pathway activities.^{194–197}

Protein S as Activated Protein C Cofactor

Protein S structure–activity relationships are informed by much biochemical work and the large number of mutations.^{71,198} Protein S, as an anticoagulant APC cofactor, forms a 1:1 complex with APC and enhances by 10- to 20-fold the rate of APC's cleavage at Arg306 in factor Va but not the Arg506 cleavage.^{181,182} Part of the mechanism for this activity of protein S may be related to its ability to bring the active site of APC closer to the plane of the phospholipid membrane on which the APC–protein S complex is located when the complex is formed.^{199,200} Protein S also facilitates the action of APC against factor VIIIa.²⁰¹ Protein S enhances APC's action, in part at least, by ablating the ability of factor Xa to protect factor Va from APC.²⁰² The GLA domain, thrombin-sensitive region, and EGF1 and EGF2 domains of protein S are implicated in binding APC for expression of anticoagulant activity by the APC–protein S complex.^{198,203–206} Cleavage of the thrombin-sensitive region by thrombin abolishes normal binding of protein S to phospholipid and its normal APC-cofactor anticoagulant activity.^{205,207}

Factor V as Activated Protein C Cofactor

Factor V apparently can have anticoagulant as well as procoagulant properties because it enhances the anticoagulant action of APC against factors VIIIa and Va in a reaction in which protein S acts synergistically with factor V.^{23,208–211} Cleavage at Arg1545, which optimizes factor

Va procoagulant activity, ablates the molecule's anticoagulant cofactor activity. However, when factor V is cleaved at Arg506 by APC, its APC cofactor activity is increased 10-fold. This suggests that Gln506-factor V has two potential prothrombotic defects, namely, resistance of the variant factor Va to APC inactivation and resistance of the variant factor V to activation of its APC cofactor function.^{23,209–211}

High-Density Lipoprotein as Activated Protein C Cofactor

HDL can exert antithrombotic activity through multiple mechanisms.²¹² HDL enhances the anticoagulant activity of APC both in plasma and in purified reaction mixtures, and this APC cofactor activity requires protein S and involves, at least in part, stimulation of APC's cleavage at Arg306 in factor Va.^{189,190} HDL is heterogeneous in both protein and lipid composition, and the components responsible for this activity have not been identified, although large HDL, but not small HDL, possesses APC anticoagulant cofactor activity.¹⁹⁰ Venous thrombosis in males and in subjects experiencing venous thrombosis recurrence are associated with a pattern of dyslipoproteinemia and low HDL, consistent with the hypothesis that deficiency of large HDL is a risk factor for venous thrombosis.^{213,214}

Glycosphingolipids as Activated Protein C Cofactors

Although both procoagulant and anticoagulant reactions are markedly enhanced by the presence of negatively charged phospholipid surfaces *in vitro*, certain lipoproteins, for example, HDL,¹⁸⁹ and certain lipids, for example, glycosphingolipids and sphingosine,^{215–218} selectively enhance anticoagulant reactions in plasma. Plasma glucosylceramide deficiency is a biomarker and may be a potential risk factor for venous thrombosis.²¹⁵ Sphingosine and several of its common analogues are potent inhibitors of thrombin generation in plasma and on cell surfaces because they inhibit interactions between factors Va and Xa.²¹⁸ Further studies are needed to characterize the anticoagulant or procoagulant properties of minor abundance plasma and their significance for clinical thrombotic events.

ACTIVATED PROTEIN C DIRECT CELLULAR ACTIVITIES

As noted in Chap. 113, control of coagulation reactions does not occur in the absence of an integrated host defense system that involves a number of biologic processes involving multiple overlapping and integrated pathways. Reactions of the innate and acquired immune system including inflammatory processes, blood coagulation reactions, fibrinolysis, and thrombotic processes are intertwined *in vivo* via multiple molecular and cellular mechanisms.^{5,7,8,81,86,87,212,219,220} In addition to its anticoagulant activity, APC acts directly on cells to cause multiple cytoprotective effects. Cytoprotective actions of APC include antiapoptotic and anti-inflammatory activities, beneficial changes in gene-expression profiles, and endothelial barrier stabilization. These cytoprotective activities of APC generally require EPCR, involve APC's ability to activate PAR-1, and may also require additional receptors such as PAR-3, sphingosine-1-phosphate receptor 1, integrin CD11b/CD18, apoER2, EGF receptor, and/or Tie2.^{7,8,86,110,221–227}

Pharmacologic APC infusions showed benefits in numerous animal injury model systems, with the most informative animal studies to date being in sepsis models and in neuroprotection experiments.^{7,8,110,111,226,227} Protein engineering permitted the molecular dissection of APC's anticoagulant activity from its cytoprotective activities^{7,8,37,40–44,228} and led to proof of principle that APC's cell signaling activities are both necessary and most likely sufficient for reducing lethality in murine septic shock models^{42,229} and for providing neuroprotective effects in ischemic stroke models.^{226,227,230–232} Notably, recombinant APC mutants that have little anticoagulant activity (<10 percent) but normal cell-signaling activity

are able to convey beneficial effects in multiple injury and disease models with diminished risks for bleeding that would be anticipated with wild-type APC therapy.^{8,40–44}

Activated Protein C Neuroprotective Effects

Neuroprotective effects of APC have been convincingly demonstrated in rodent ischemic stroke models and *N*-methyl-D-aspartate (NMDA) excitotoxic injury models.^{8,223,226,227,231,233–242} APC not only provides direct cytoprotection *in vitro* and *in vivo* for brain endothelium against ischemic injury but also directly protects neurons against NMDA-induced excitotoxic injury both *in vivo* and *in vitro*. APC mutants with reduced anticoagulant activity were as neuroprotective as wild-type APC, and certain cellular receptors were required for APC's neuroprotection, strongly implying that neuroprotection by APC involves its actions directly on the endothelium and on neurons. Remarkably, in the ischemic penumbra in a murine stroke model, APC caused neovascularization and neurogenesis.^{223,240,243–245} The extensive preclinical studies on APC's neuroprotective effects paved the pathway for translation of the 3K3A-APC variant to potential neuroprotective therapy for acute ischemic stroke.^{246,247} Because of the greatly reduced anticoagulant activity of 3K3A-APC (<10 percent of normal), high-dose bolus dosing in healthy volunteers can achieve circulating APC levels that are 100-fold higher than those used in the PROWESS or PROWESS-SHOCK sepsis trials without notable anticoagulant effects.^{46,49,246}

Cellular Receptors for Physiologic Effects of Activated Protein C on Cells

The ability of exogenously administered APC to alter gene-expression profiles of cultured endothelial cells, to stabilize endothelial barriers, to reduce lethality caused by endotoxin in murine sepsis models, to prevent apoptosis of stressed endothelial cells, and to provide neuroprotection requires EPCR and PAR-1, strongly supporting the EPCR–PAR-1 cell-signaling pathway as key for APC's pharmacologic benefits (see Fig. 114–4).^{7,8,40–43,221,225,229,233,234,236,237,244,248–251}

Although few details are known about intracellular mechanisms for APC's multiple cytoprotective actions, some mechanistic details for APC's cell signaling have become clear, as depicted in Fig. 114–6.⁸ Multiple considerations help explain how PAR-1 can mediate thrombin's disruption of endothelial barrier leading to vascular leakage while, paradoxically, the same receptor mediates APC's endothelial barrier protection, preventing vascular leakage.^{249,250} First, PAR-1-mediated APC signaling occurs in caveolae microdomains that contain EPCR whereas PAR-1-mediated thrombin signaling is not limited to caveolae (Fig. 114–6).^{252,253} Second, different cleavages in the extracellular N-terminus of PAR-1, either at the canonical Arg41 thrombin-cleavage site (i.e., widely recognized as the essential thrombin cleavage site) or at the novel Arg46 APC-cleavage site, results in very different signaling initiated by different tethered N-terminal peptide sequences which begin at either residue 42 or residue 47.^{124,254,255} Third, following thrombin cleavage at Arg41, PAR-1 initiates signaling involving G proteins, extracellular signal-regulated kinase (ERK)1/2 and RhoA, whereas, following APC cleavage at Arg46, PAR-1 initiates signaling involving β -arrestin-2, phosphatidylinositide 3'-kinase (PI3K)/Akt, and Rac1.²⁵⁶ Fourth, peptides mimicking the N-terminus of cleaved PAR-1 are peptide agonists with pharmacologic effects resembling those of the respective proteases that cleave PAR-1 differentially. For example, "thrombin receptor activating peptides (TRAPs)" that begin with Ser 42 promote G-protein-mediated signaling similar to thrombin. In contrast, peptides that begins with Asn 47 (TR47) promote APC-like signaling.²⁵⁴ TRAP but not TR47 promotes ERK1/2 phosphorylation on endothelial cells whereas TR47 but not TRAP promotes Akt phosphorylation.²⁵⁴ The different and opposite induction of signaling pathways is also mirrored in different and

Figure 114-6. Biased protease-activated receptor (PAR)-1 signaling dependent on activation by thrombin or activated protein C (APC). Activation of PAR-1 by thrombin results in endothelial barrier-disruptive signaling (**A**) but activation of PAR-1 by APC in caveolae that also contain endothelial cell protein C receptor (EPCR) results in endothelial barrier-protective signaling (**B**).^{252,253} The different PAR-1 signaling induced by thrombin and APC are caused by different proteolysis cleavage sites in PAR-1 for thrombin and APC.²⁵⁴ Thrombin activates PAR-1 by cleavage at Arg41 (**C**). Synthetic agonist peptides with the N-terminal tethered-ligand sequence beginning with residue 42 are known as TRAP (thrombin receptor-activating peptide) and cause thrombin-like effects on cells. APC activates PAR-1 by cleavage at Arg46 (**C**). A synthetic agonist peptide with the N-terminal tethered-ligand sequence beginning with residue 47 (TR47) causes APC-like effects on cells. Activation of PAR-1 by thrombin or TRAP induces PAR-1 conformations such that the intracellular loops of PAR-1 preferentially interact with G proteins (termed “G-protein biased”) resulting in G-protein–dependent signaling whereas activation of PAR-1 by APC or TR47 induces PAR-1 conformations that preferentially interact with β -arrestin-2 (termed “ β -arrestin biased”) resulting in β -arrestin-2–dependent signaling (**D**).^{254,256} The implication of biased PAR-1 signaling are evident by the differences in phosphorylation of extracellular signal-regulated kinase (ERK)1/2 compared to Akt because TRAP, but not TR47, induces phosphorylation of ERK1/2, whereas TR47 but not TRAP induces phosphorylation of Akt (**E**).²⁵⁴ (Reproduced with permission of Griffin JH, Zlokovic BV, Mosnier LO: Activated protein C: Biased for translation. *Blood* 125(19):2898–2907, 2015.)

opposite functional effects, as thrombin peptide and TRAP cause endothelial barrier disruption and proinflammatory effects whereas APC and the TR47 peptide cause barrier-protective and antiinflammatory effects. Thus, PAR-1 displays biased signaling depending on the activation cleavage sites and the generated tethered-ligand with absolutely opposing outcomes for the cell, the tissue, and the host depending on which coagulation system protease, thrombin or APC, is cleaving PAR-1.

Other receptors are recognized that may also play key roles for APC's beneficial signaling effects, including PAR-3 and sphingosine-1-phosphate receptor-1.^{249,250,257,258} ApoER2 can initiate Disabled-1-dependent pathway activation of the PI3K-Akt cell-survival pathway, which may ultimately help explain additional aspects of APC's cytoprotection.²⁵⁹

Although most studies demonstrating the cell-signaling activities of APC have focused on pharmacologic levels of APC, several reports of murine injury models demonstrate the physiologic importance of cell signaling by endogenous APC,^{260–262} implying that defects in APC's endogenous cytoprotective actions might have pathophysiologic relevance. Future investigations on APC cellular receptors and on intracellular mechanisms involved in the protein C cellular pathway will likely provide novel clinical insights with diagnostic and therapeutic potential.

● INHIBITION OF ACTIVATED PROTEIN C

Blood contains circulating APC in a well-defined normal concentration range that contributes to antithrombotic surveillance mechanisms and possibly to homeostatic cell signaling.^{15,142,144} Circulating APC levels are determined by the balance between countervailing mechanisms for APC generation and for APC inhibition and clearance. APC generation is influenced by protein C zymogen levels, endogenous thrombin generation, and the availability of thrombomodulin and EPCR. Clearance of circulating APC is based on inhibition of APC by protease inhibitors and clearance of APC:inhibitor complexes.^{263–269} The major plasma inhibitors of APC include α_1 -antitrypsin, protein C inhibitor, and α_2 -macroglobulin.

● ACTIVATED PROTEIN C-INDEPENDENT ANTICOAGULANT ACTIVITY OF PROTEIN S

Because hereditary protein S deficiency^{270,271} is strongly linked to increased venous thrombosis risk (Chap. 130), protein S is a significant physiologic anticoagulant factor.^{71,198} In addition to its anticoagulant cofactor activity for APC, protein S can also inhibit coagulation reactions independently of APC. Several plausible mechanisms have been described for protein S's anticoagulant activity independent of APC. First, protein S can bind directly to procoagulant factors Xa and Va and thereby inhibit directly the activity of the prothrombinase complex.^{11–13} The thrombin-sensitive region and the EGF3 domains of protein S (see Fig. 114–5) likely bind factor Xa, contributing to APC-independent anticoagulant activity.^{206,272,273} Second, protein S can also bind factor VIIIa and inhibit activation of factor X by factor IXa–factor VIIIa complexes.^{274–276} Third, protein S binds tissue factor pathway inhibitor (TFPI) and enhances its ability to inhibit factor Xa.^{277–279} Zn^{2+} ions might play a key role for APC-independent protein S activity.²⁸⁰ It is not easy to decipher the relative importance of each of these or other mechanisms for APC-independent anticoagulant activities of protein S or to establish their physiologic relevance, but infusions of protein S without APC are antithrombotic in baboon thrombosis models.²⁸¹

The activities of protein S can be strongly influenced by C4b-binding protein, a plasma protein that enhances inactivation of the complement

cascade by binding to C4b and promoting its proteolytic inactivation by the protease, factor I. C4b-binding protein reversibly binds protein S with high affinity,^{282–284} and formation of this complex affects some but not all of the anticoagulant activities of protein S.^{71,198,271,285} Because of the influence of C4b-binding protein on protein S activities and plasma levels, interpretation of clinical assays for protein S requires evaluation of free and bound protein S as plasma contains approximately 240 nM protein S–C4b-binding protein complexes and 120 nM free protein S.²⁸³ C4b-binding protein is a heteropolymer containing six or seven α chains that are disulfide-linked to a single β chain that binds protein S.^{286,287} Residues 30 to 45 of the β chain bind with high affinity to the C-terminal SHBG domain of protein S.^{65,288,289} During an acute phase reaction, the level of the C4b-binding protein α chain, but not the β chain, is increased, so that the acute phase change in total C4b-binding protein does not alter the level of free and bound protein S.²⁹⁰

Another potential mechanism for the antithrombotic actions protein S is based on its APC-independent direct interactions with cells that might contribute to its antithrombotic actions. Protein S promotes clearance of apoptotic cells,^{68,71,198,291–294} and this antiapoptotic activity of protein S might contribute to its antithrombotic activity. Protein S has direct effects on cells by activating one or more transmembrane receptor tyrosine kinases.^{68,198,292} Protein S is a potent neuroprotectant as it can protect brain endothelium against ischemic injury in murine stroke models and can protect neurons against NMDA-induced excitotoxic injury, presumably acting via transmembrane receptor tyrosine kinases.^{295–299}

● INHIBITION OF COAGULATION PROTEASES BY PROTEASE INHIBITORS

Antithrombin, initially designated *antithrombin III*, is clinically the best known inhibitor of clotting factor proteases. Antithrombin can neutralize all coagulation proteases in reactions that are enhanced by heparin and related glycosaminoglycans (see Chap. 113 and Fig. 113–28).³⁰⁰ However, antithrombin does not inhibit the anticoagulant protease APC. TFPI can neutralize factors VIIa and Xa, proteases of the extrinsic coagulation pathway.^{277,278,301–303} In addition, other plasma protease inhibitors such as α_1 -antitrypsin, heparin cofactor II, protein C inhibitor, α_2 -macroglobulin, or protein Z–dependent protease inhibitor, can neutralize various coagulation proteases, although the ultimate clinical significance of these reactions is less-well defined than the clinical relevance of antithrombin for thrombophilia (Chap. 130). Antithrombin is key for anticoagulant therapy based on the heparin-stimulated inhibition of thrombin and factor Xa.

ANTITHROMBIN AND HEPARINS

Antithrombin is synthesized in the liver and is present in plasma at 150 mcg/mL, and it is a typical member of the serine protease inhibitor (SERPIN) superfamily and is denoted as SERPIN1.^{300,304–306} Based on X-ray crystallographic studies,^{307–311} models of serpin–protease complexes in various reaction states have emerged and the mechanism for the effects of heparin on the reaction of thrombin with antithrombin is reasonably clear.

The neutralization of proteases by antithrombin is a result of a stable enzyme–antithrombin complex that is formed by a molecular mechanism characteristic of inhibitory serpins.^{304–307,309–312} Following binding of a protease to a “reactive site” loop in a serpin, a single peptide bond in the serpin is cleaved with formation of an acyl–enzyme intermediate via the active site Ser residue. This metastable enzyme–serpin complex can either break apart because of deacylation, or it can form a more stable covalent enzyme–serpin complex. To break apart the enzyme–serpin covalent complex, deacylation liberates the cleaved

product and regenerates the active site Ser residue of the protease. However, serpins have an ability to undergo major conformational changes following cleavage at the reactive site residue that can distort that protease's active site region and lock the enzyme into the protease-serpin complex in which both the serpin and the protease are essentially deformed.^{304–307,309–312} The dominant structural feature of native serpins is a large five-stranded β -sheet that defines the structure of an ellipsoidal protein. Following cleavage at the reactive residue in the reactive center loop by a protease, this extended loop is able to partially or completely insert itself into the five-stranded β -sheet, forming a very stable six-stranded β -sheet. If this insertion reaction proceeds before deacylation occurs, then the protease remains covalently attached to the reactive center P1 residue through the protease's active site Ser residue, and a stable covalent protease-inhibitor complex with each protein in an altered conformation is formed.^{307,308}

Heparin enhancement of the rate of reaction between antithrombin and thrombin or other clotting factors is caused by two distinct effects of heparin, one involving conformational effects on antithrombin and the other involving "approximation" effects on both antithrombin and thrombin.^{300,307,308,311–315} For the first effect, a particular pentasaccharide sequence within heparin binds antithrombin and potently causes a conformational change that converts antithrombin from its native state of moderate reactivity to a conformation with relatively high reactivity. This pentasaccharide contains a specific sulfated sequence of glucosamine and iduronic acid residues,^{300,307,308,311–315} and when it is present in a large heparin molecule, in low-molecular-weight heparin, or in a synthetic pentasaccharide, it alters antithrombin conformation and greatly accelerates the reaction of antithrombin, especially with factor Xa. Synthetic pentasaccharides, such as fondaparinux, which are analogues of the naturally occurring sequence, are often termed to be indirect factor Xa inhibitors and have significant clinical utility. For the second mechanistic effect, namely the approximation effect, unfractionated heparin or low-molecular-weight heparins simultaneously bind to antithrombin and the target protease to promote frequent and geometrically productive encounters between protease and inhibitor, thus increasing the reaction rate. Heparan sulfates to some extent can also act in this manner.

The mature antithrombin polypeptide chain contains 432-amino-acid residues after cleavage of a propeptide from a 464-amino-acid-residue precursor.³¹⁶ It has four sites for *N*-linked carbohydrate attachment,

one of which (Asn135) is variably glycosylated, giving rise to a β -isoform that has higher affinity for heparin.^{317,318} Heparin binding to antithrombin is mediated by a number of positively charged Arg and Lys residues in the N-terminal region of the molecule, including Lys11, Arg13, Arg47, Lys114, Lys125, and Arg129, whereas the reactive center loop containing the scissile peptide bond at Arg393-Ser394 is near the C-terminus.³¹¹

ANTITHROMBIN GENE

The antithrombin gene comprising seven exons and six introns spans 13.4 kb and is located on chromosome 1q23–25 (see Table 114–1).^{319,320}

ANTITHROMBIN MUTATIONS

Hereditary deficiencies of antithrombin are risk factors for venous thrombosis (Chap. 130). More than 100 different antithrombin mutations are associated with thrombosis. An extensive database of mutations is published³²¹ and is available at <http://www1.imperial.ac.uk/departmentsofmedicine/divisions/experimentalmedicine/haematology/coag/antithrombin/>.

Mutations that cause antithrombin deficiency are scattered throughout the gene. Molecular defects can be classified as type I, characterized by parallel decreases in antigen and activity, or type II, characterized by circulating dysfunctional molecules such that plasma has decreased functional activity but normal or near-normal antigen levels. Type II defects are further classified based on whether the dysfunction involves only reactive center defects that can be tested in the absence of heparin, only heparin-binding defects that can be tested only in the presence of heparin, or both of these defects (pleiotropic effects). Reactive center defects carry the largest risk of thrombosis, whereas heparin-binding defects are associated with less risk of venous thrombosis (Chap. 130).

TISSUE FACTOR PATHWAY INHIBITOR

TFPI, also known as *lipoprotein-associated coagulation inhibitor* or *extrinsic pathway inhibitor*, has a predicted mature protein sequence of 276 residues and a Mr of 34,000. However, TFPI is a complex protein and has at least three isoforms in blood vessels.^{277,301–303,322–327} There are two alternatively spliced forms of TFPI designated TFPI α and TFPI β (Fig. 114–7).^{323,324}

Figure 114–7. Tissue factor pathway inhibitor (TFPI) exists in multiple forms, TFPI α and TFPI β , because of alternative splicing. Mature, full-length TFPI α is a multivalent protease inhibitor containing three Kunitz-type protease inhibitor domains (K1, K2, and K3) and a highly positively charged basic amino acid cluster near the C-terminus (blue circles). TFPI β contains K1 and K2 but lacks K3 and the basic amino acid cluster, but it can acquire a glycosylphosphatidylinositol (GPI) moiety that anchors it to cell membranes. As indicated by color overlays, K1 and K2 inhibit factor (F) Vlla and FXa, respectively. Both TFPI α and TFPI β can form a quaternary complex with tissue factor (TF), FVlla and FXa. However, TFPI α but not TFPI β can interact with protein S or certain forms of FVa/FV via K3 or the positive amino acid cluster, respectively. Via such interactions, protein S or FVa/FV can promote inhibition of FXa with no involvement of FVlla or tissue factor. TFPI α is the predominant form in plasma, whereas TFPI β is the predominant form on the endothelium. (Reproduced with permission from Wood JP, Ellery PE, Maroney SA, Mast AE: *Biology of tissue factor pathway inhibitor*. Blood 123(19):2934–2943, 2014.)

TFPI α is the full-length mature protein that contains an acidic N-terminal sequence, three homologous but distinct Kunitz-type protease inhibitor domains (K1, K2, K3), and a C-terminal positively charged basic amino acid sequence (Fig. 114–7). TFPI β contains K1 and K2 but an unrelated sequence replaces the K3 domain and the C-terminus. TFPI β can be covalently modified by addition of glycosylphosphatidylinositol (GPI) that localizes TFPI β to cell membranes (Fig. 114–7). Some TFPI in plasma is present as a disulfide-linked heterodimer of TFPI–apolipoprotein A-II,^{327,328} but the functional significance of the apoA-II appendage is unknown. TFPI in its multiple forms is a significant inhibitor of the coagulation pathways that can function synergistically with the protein C pathway and antithrombin to suppress thrombin generation.

TFPI is synthesized by endothelial cells, megakaryocytes, and smooth muscle cells.^{301–303} Free TFPI in plasma is TFPI α but it is a minor fraction of the amount of TFPI in blood vessels. More than half of TFPI α in plasma is associated with lipoproteins, especially HDL and low-density lipoprotein. TFPI α is also the main form within platelet and it is secreted by activated platelets. A substantial amount of TFPI α is released from the vessel wall when heparin is infused.³²⁹ TFPI β is membrane bound, especially to endothelium, because of its GPI anchor.

The interaction of TFPI with lipoproteins reduces its anticoagulant activity measured *in vitro* though the physiologic significance of TFPI's binding to various lipoproteins remains uncertain. In addition to binding lipoproteins, TFPI α but not TFPI β binds to protein S and to certain forms of factor Va/factor V.^{277–279,330–333} Different regions of TFPI α , namely the K3 domain or the basic amino acid cluster, respectively, are responsible for binding protein S or factors Va/V (see Fig. 114–7). Inhibition of factor Xa by TFPI α is accelerated by protein S and by certain but not all forms of factor Va (see below).

TFPI neutralizes factors Xa and VIIa by multiple complicated mechanisms.^{277,301–303} In each mechanism, the K1 domain binds and inhibits factor VIIa while the K2 domain inhibits factor Xa (see Fig. 114–7). No protease has yet been identified as the target of the K3 protease inhibitor domain. In one mechanism, initially the K2 domain of TFPI reacts with and inhibits the enzyme activity of factor Xa. Subsequently, this binary complex reacts with factor VIIa in the tissue factor–factor VIIa complex to form a quaternary protein complex on a membrane with both proteases neutralized. In an alternative proposed scheme, TFPI first reacts with factor VIIa in a tissue factor–factor VIIa complex that has generated factor Xa, and thereafter it rapidly reacts with factor Xa before it can dissociate from the ternary tissue factor–factor VIIa–factor Xa complex. Possibly each proposal is valid. Some argue that because some kinetic studies showed that TFPI requires factor Xa for kinetically favorable reactions with factor VIIa, TFPI does not shut off the initiation of the extrinsic pathway by tissue factor until some significant though small amount of factor Xa is generated, in which case TFPI provides negative feedback inhibition of the generation of factor Xa by the factor VIIa–tissue factor complex. An additional property of TFPI α involves its inhibition of factor Xa in the absence of factor VIIa, and this reaction is accelerated by protein S and by certain forms of factor Va.^{277–279,330–333} In contrast to the anticoagulant factors, antithrombin, protein C, and protein S, for which hereditary deficiencies are linked to significantly increased risk for venous thrombosis (Chap. 130), no clear pattern for increased risk of thrombosis has been definitively established for TFPI deficiency in humans. In mice, knockout of TFPI is embryonically lethal.³³⁴ In a highly informative kindred that presented with a serious bleeding diathesis, highly elevated plasma TFPI levels were linked to increased bleeding risk, indicating that TFPI functions in man as a physiologically significant inhibitor of coagulation.^{322,332} The genetic mutation causing elevated plasma TFPI levels was in the factor V gene, not the TFPI gene. The mutated factor V, named “factor V-short,” has a higher affinity for TFPI α than wild-type factor

V, thereby binding more TFPI α and prolonging its half-life. Factor V-short may also enhance inhibition of factor Xa by TFPI with the effect of increasing bleeding risk. This genetic disorder, as well as previous studies showing that inhibition of TFPI reduced bleeding in preclinical hemophilia models, lends support for ongoing efforts to develop TFPI inhibitors for reducing bleeding in some hemophilia subjects, especially those with anti-factor VIII inhibitors.

TFPI GENE

The sequence of TFPI was established from cloning of its complementary DNA. The gene contains nine exons, spans 85 kb, and is located on chromosome 2q31–32.1 (see Table 114–1).^{335,336}

OTHER PROTEASE INHIBITORS

HEPARIN COFACTOR II

Heparin cofactor II, a serpin whose inhibitory activity is enhanced by dermatan sulfate, inhibits thrombin *in vivo* and *in vitro* by an approximation mechanism.^{337–340} A few reports link heparin cofactor II deficiency to venous thrombosis, but no significant clinical relevance has been established.³⁴¹ Curiously, a severe heparin cofactor II deficiency was reported in an asymptomatic subject.³⁴² Some studies imply that heparin cofactor II may play significant roles in arterial vascular wall processes, but definitive mechanisms remain to be elucidated.

PROTEIN Z-DEPENDENT PROTEASE INHIBITOR

Protein Z–dependent protease inhibitor (ZPI) is a plasma serpin that inhibits factors Xa, XIa, and IXa, but not factor XIIa or thrombin.^{343–350} Protein Z, which is a vitamin K–dependent protein that contains a GLA domain, two EGF-like domains, and a protease-like domain,³⁵¹ stimulates factor Xa inhibition by ZPI. Curiously, the protease-like domain of protein Z lacks any protease activity because it has mutations at two of the three active site triad residues. The major hypothesis for stimulation of inhibition of factor Xa by protein Z is based on a structural model in which three proteins assemble on a phospholipid membrane via the two GLA domains (see Fig. 114–7).³⁵¹ In this putative ternary complex, the protease-like domain and the second EGF-like domain of protein Z bind ZPI in an alignment that facilitates reaction of factor Xa with the reactive center loop of ZPI.

In plasma, ZPI is in slight protein molar excess over protein Z with which it associates noncovalently, and it has been speculated, but not proven, that almost all plasma protein Z is associated with ZPI.^{352–357} If the ZPI is a physiologic coagulation inhibitor, the deficiency of either protein Z or ZPI might be associated with thrombosis. Knocking out the protein Z gene in a mouse does not produce a remarkable phenotype unless protein Z deficiency coexists with factor V Leiden, in which case the mouse exhibits a hypercoagulable, prothrombotic state.³⁵³ This murine observation is mirrored by one clinical report that subnormal levels of protein Z are associated with venous thrombosis in subjects who are heterozygous for factor V Leiden.³⁵⁴ Some associations between venous thrombosis and defects in protein Z or ZPI have been reported but not uniformly confirmed.^{352,354–357} An association with peripheral arterial disease was reported.³⁵⁸ However, to date no convincing pattern between thrombosis and defects in either protein Z or ZPI has been firmly established.

OTHER MINOR PROTEASE INHIBITORS

Thrombin in plasma can be inhibited not only by antithrombin but also by α_2 -macroglobulin, an acute-phase reactant. No association between

defects in bleeding or thrombosis has been confirmed for this inhibitor. In purified reaction mixtures, protein C inhibitor also efficiently neutralizes thrombin in the presence of thrombomodulin,³⁵⁹ although no studies show that this is a physiologic reaction or that it is associated with thrombosis.

CHAPTER 115

VASCULAR FUNCTION IN HEMOSTASIS

Katherine A. Hajjar, Aaron J. Marcus*, and William Muller

SUMMARY

Blood vessels, especially their endothelial lining, play a critical role in the maintenance of vascular fluidity, arrest of hemorrhage (hemostasis), prevention of occlusive vascular phenomena (thrombosis), and regulation of inflammatory cell processes. The endothelium extends to all recesses of the body and maintains an intimate association with flowing blood and blood cells. However, endothelial cell morphologies, gene-expression profiles, and functions vary among different vascular beds. For example, in straight arterial segments, but not at branch points or curvatures of the arteries or veins, endothelial cells align themselves in parallel to the direction of blood flow. Similarly, endothelial cells in post capillary venules are primarily responsible for mediating adhesion and transmigration of leukocytes, whereas arteriolar endothelium is important for regulation of vasomotor tone. Proteomic studies have revealed that endothelial cells have the unique capacity to express and elaborate thromboregulatory molecules, which can be classified according to their chronologic appearance following vascular injury. Early thromboregulators appear prior to thrombin formation and late thromboregulators arrive after thrombin has formed. This chapter reviews some of the mechanisms by which the vascular wall regulates hemostasis, and discuss their implications for vascular health and disease (Table 115–1).

Acronyms and Abbreviations: APC, activated protein C; Apo, apolipoprotein; APS, antiphospholipid syndrome; C5a, complement factor 5a; CAM, cell adhesion molecule; COX, cyclooxygenase; DAG, diacylglycerol; DDAVP, deamino D-arginine vasopressin; EPCR, endothelial protein C receptor; GMP, guanosine monophosphate; IL, interleukin; IP₃, inositol triphosphate; Lp(a), lipoprotein(a); NFκB, nuclear factor kappa B; NO, nitric oxide; NOS, nitric oxide synthase; PAF, platelet-activating factor; PDGF, platelet-derived growth factor; PECAM, platelet endothelial cell adhesion molecule; PGI₂, prostacyclin; PGIS, prostacyclin synthase; PSGL, P-selectin glycoprotein ligand; scu-PA, single-chain urokinase-type plasminogen activator; TAFI, thrombin-activatable fibrinolysis inhibitor; TF, tissue factor; TFPI, tissue factor pathway inhibitor; TM, thrombomodulin; TNF, tumor necrosis factor; t-PA, tissue-type plasminogen activator; VWF, von Willebrand factor.

VASCULAR FUNCTION IN HEMOSTASIS: INTRODUCTION

The endothelium represents a dynamic interface between flowing blood and the vessel wall, and produces a variety of factors that regulate blood fluidity (Fig. 115–1). Endothelial cells are subject to unique shear stress forces, to soluble factors in the blood, and to signals emanating from cells in the circulation, vascular wall, and tissues, all of which create region-specific phenotypes.^{1–3} In addition to modulating vascular permeability and fragility, the endothelium regulates the fluid state of blood through its thromboresistant nature, profibrinolytic properties, and antiinflammatory potential. These activities maintain vascular patency.⁴

ENDOTHELIAL CELL HETEROGENEITY

The heterogeneity of endothelial cells is mediated by two mechanisms.^{5,6} First, extracellular biochemical and biomechanical signals trigger posttranscriptional and/or posttranslational changes that vary across the vascular tree. Second, certain site-specific properties of the endothelium are genetically programmed, and therefore, independent of the extracellular milieu. This phenotypic variability serves at least two important purposes: (1) It allows endothelial cells to meet the specific metabolic needs of the surrounding tissue. For example, the tight junctions of the blood–brain barrier protect neurons from fluctuations in composition of the aqueous blood supply, whereas the fenestrated discontinuous endothelium of hepatic sinusoids allows ready access of nutrient-rich portal venous blood for the metabolic systems in hepatocytes; and (2) phenotypic variability provides endothelial cells with site-specific mechanisms for thriving within many different microenvironments. For example, endothelial cells in the inner medulla of the kidney must survive the relatively hypoxic and hyperosmolar local environment, whereas endothelial cells in the pulmonary capillary bed have adapted to an oxygen-rich environment.

A rapid endothelial cell response is required for sudden environmental perturbations. Translational control mechanisms, which are more immediate than transcriptional changes, provide regulatory responses for up to 10 percent of genes expressed in endothelial cells.⁷ Because of their close association with both flowing blood and solid tissues, endothelial cells are subject to a broad spectrum of agonistic and inhibitory external signals that frequently require rapid functional and phenotypic responses. Clinically, such stimuli are associated with sepsis, inflammation, ischemia–reperfusion injury, and direct mechanical vascular trauma induced clinically by stents, balloon catheters, and graft procedures.

ENDOTHELIAL PRODUCTION OF THROMBOREGULATORY MOLECULES

Thromboregulatory compounds, such as eicosanoids, nitric oxide, and the ecto-ATP/Dase-1/CD39, control platelet and vascular reactivity during the early stages of thrombus formation (Table 115–2).⁸ Eicosanoids are hydrocarbon compounds derived from essential fatty acids in the diet. The most important endothelial eicosanoid is prostacyclin (PGI₂), which blocks platelet reactivity, induces vascular relaxation, and stimulates cytokine production.⁹ Nitric oxide (NO) is a naturally occurring gas released from vascular endothelial cells in response to binding of vasodilators to endothelial cell membrane receptors. Thus, it is a short-lived vasodilator and inhibitor of platelet reactivity. By

*Dr. Aaron Marcus died on May 6, 2015

TABLE 115-1. Chronology of Endothelial Cell Thromboregulators

Early thromboregulators
Nitric oxide (NO)
Eicosanoids (prostacyclin and prostaglandin D ₂)
Endothelial cell CD39/ENTPDase1
Endothelin
Late thromboregulators
Endothelin
Antithrombin
Endothelial cell/heparin proteoglycans
Tissue factor pathway inhibitor
Thrombomodulin-protein C-protein S pathway
Fibrinolytic system (plasminogen activators, inhibitors, and receptors)
Inflammatory thromboregulators
Thrombomodulin-protein C-protein S pathway
Cellular adhesion molecules
Selectins

Figure 115-1. Schematic of endothelial cell thromboregulatory molecules. Products that are secreted and exert their effects in the fluid phase are represented by *arrows*. Cell-surface-associated molecules are shown as *rectangles*. Metabolites synthesized by endothelial cells are indicated. Thromboregulators that modulate platelet activation, recruitment, and blood vessel contractility are shown on the *left*. Agents that regulate components of the coagulation cascade and/or fibrinolytic system are located at the *top*. Inflammatory molecules whose expression or activity is directed by inflammatory mediators are shown at the *right*. A2, annexin 2; AT, antithrombin; CAMs, cellular adhesion molecules; CD39, endothelial cell ecto-ADPase/CD39; EPCR, endothelial cell protein C receptor; ET, endothelin; FVIIa, factor VIIa; HS, heparan sulfate; JAMs, junctional adhesion molecules; NO, nitric oxide; PC, protein C; PGI₂, prostacyclin; PLG, plasminogen; TF, tissue factor; TFPI, tissue factor pathway inhibitor; TM, thrombomodulin; t-PA, tissue plasminogen activator; u-PA, urokinase plasminogen activator; uPAR, urokinase plasminogen activator receptor. These components are discussed further in the text.

activating guanylate cyclase, the resulting increase in cyclic guanylate monophosphate (GMP) inhibits platelet function and induces vascular relaxation.^{10,11} Endothelial cell ecto-ATP/Dase-1/CD39 is a membrane-associated apyrase that metabolizes adenosine diphosphate (ADP) in the primary platelet releasate, preventing further platelet activation and recruitment.^{12,13}

Late thromboregulators produced by endothelial cells act either to prevent excessive thrombin generation or to promote lysis of intravascular thrombi (see Table 115-1). Antithrombin, a natural anticoagulant, acts as an inhibitor of thrombin and factor Xa in the circulation. Endothelial cell heparan proteoglycans act as cofactors for antithrombin. The tissue factor pathway inhibitor (TFPI) inhibits the complex between factor VIIa and tissue factor (TF). The thrombomodulin/endothelial cell protein C receptor (EPCR)/protein C system in the vascular wall regulates hemostasis through inactivation of procoagulant cofactors, and antiinflammatory activity.¹⁴ The fibrinolytic system is intimately involved with the vascular endothelium because endothelial cells not only synthesize and secrete tissue plasminogen activator (t-PA), but also regulate formation of plasmin from its precursor, plasminogen, through the expression of receptors.¹⁵ Impairment of fibrinolytic potential can play a central role in the etiology of occlusive vascular disease.¹⁶ Finally, endothelial cell adhesion molecules, including the cell adhesion molecules (CAMs: mucosal addressin cell adhesion molecule [MAdCAM]-1, intercellular adhesion molecule [ICAM]-1, vascular cell adhesion molecule [VCAM]-1, and platelet endothelial cell adhesion molecule [PECAM]-1) and the selectins (P- and E-selectin), are glycoproteins that modulate multiple interactions between the endothelium and various classes of circulating leukocytes, thereby modulating vascular patency.¹⁷ Together, these mechanisms define *thromboregulation*, the processes by which blood cells and cells of the vessel wall, through their close proximity, interact to facilitate or inhibit thrombus formation.¹⁸

The physiologic defense systems that render endothelial surfaces and blood cells antithrombotic can be overwhelmed by excessive shear stress, increased turbulence, injury, inflammation, and severe atherosclerosis.¹⁹ These events transform the endothelial cells into a prothrombotic and antifibrinolytic phenotype,²⁰ which is accompanied by upregulation of leukocyte and endothelial CAMs, increased expression of TF, and accumulation of monocytes/macrophages in the vessel wall.²¹ These events commonly occur at the site of fissured atherosclerotic plaques in the coronary and cerebrovascular circulation.²² Because the eicosanoids such as PGI₂ (prostacyclin [PGI₂]), as well as NO, and the ecto-ATP/Dase-1/CD39 group reach peak activity very early in the hemostatic/thrombotic cascade (Figs. 115-2 to 115-4), they represent potential targets for therapeutic intervention in the sequence of events beginning with platelet activation, and leading to coagulation, thrombosis, and atherogenesis.^{21,22} Finally, functional and physical contacts between platelets and endothelial cells are of critical importance for the maintenance of vascular integrity and cell permeability.^{1,23}

TABLE 115-2. Early Pro- and Antithrombotic Thromboregulators Associated with Human Endothelial Cells

Class	Type	Site of Action	Aspirin Sensitivity	Mode of Action
Eicosanoids	PGI ₂ , PGD ₂	Fluid phase autacoid	Sensitive	Elevation of platelet cAMP
Nitrovasodilators	EDRF/NO	Fluid phase autacoid	Insensitive	Elevation of platelet cGMP
Ectonucleotidases	CD39/ENTPD1	Endothelial cell surface	Insensitive	Enzymatic removal of secreted ADP
Thromboxane	TXA ₂	Fluid phase vasoconstrictor	Sensitive	Lowers platelet cAMP and platelet agonist
Endothelins	ET-1, ET-2	Fluid phase vasoconstrictor	Insensitive	Direct vasoconstrictor peptide

ADP, adenosine diphosphate; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; EDRF, endothelium-derived relaxing factor; ET, endothelin; NO, nitric oxide; PGD₂, prostaglandin D₂; PGI₂, prostacyclin; TXA₂, thromboxane A₂.

Figure 115-2. Following injury to the blood vessel wall, platelets adhere to the damaged surface of the endothelial cell. Concomitant with adhesion platelets and endothelial cells become activated. P-selectin is expressed on the endothelial cell surface. Platelet surface receptors glycosylphosphatidylinositol (GPI)ba and P-selectin glycoprotein ligand (PSGL)-1 interact with endothelial P-selectin, thereby mediating platelet rolling. Firm adhesion is mediated by the integrin $\alpha_{IIb}\beta_3$. In parallel with these intercellular events, platelet activation and release occur. The enzyme CD39 on the endothelial surface modulates the ambient concentration of adenosine diphosphate (ADP) by metabolizing it.^{7,8} 5-HT, 5-hydroxytryptamine; TXA₂, thromboxane A₂. (Adapted with permission from Gawaz M, Langer H, May AE: Platelets in inflammation and atherogenesis. J Clin Invest 11(12):3378–3384, 2005.)

THE EICOSANOID PATHWAY IN BIOLOGY AND MEDICINE: CELL-CELL INTERACTIONS AND TRANSCELLULAR METABOLISM

Dietary fatty acids give rise to arachidonic acid, the starting point for synthesis of other eicosanoids. Originating from different cells, intermediates in the arachidonic acid pathway can interact with each other to produce new products with new biologic activities. Oxygenation and further enzymatic transformation of arachidonic acid gives rise to eicosanoids (formerly classified as PGs) and hydroxy acids, such as the leukotrienes. Eicosanoids are autocooids, an important group of transient, physiologically active endogenous substances, that act within the immediate environment of the cell, where they promote or inhibit a biologic function.²⁴ These autocooids have a very short life span and may act within a few seconds, a phenomenon that is clinically important but difficult to study experimentally.

In 1975, Hamberg and colleagues discovered that a new eicosanoid, PGI₂, was derived from arachidonic acid in endothelial cells.²⁵ Soon thereafter, Moncada realized that the effects of PGI₂ opposed those of

thromboxane, namely vasodilation and inhibition of platelet aggregation.^{26,27} The biologic half-life of PGI₂ was found to be 10 to 20 seconds. In addition, it was determined that the first step in arachidonic acid oxidation and conversion, which is carried out by cyclooxygenase (COX)-1, is inhibited by aspirin (acetylsalicylic acid), which donates an acetyl group that inactivates COX-1 and inhibits platelet function.²⁸

BIOSYNTHESIS OF PROSTACYCLIN IN ENDOTHELIAL CELLS

PGI₂ is the major and most important eicosanoid produced by endothelial cells. A broad range of stimuli, including hormones, biochemicals, or physical forces such as shear stress can elicit release of PGI₂. Kinetic studies revealed two distinct patterns of PGI₂ production: (1) rapid release, independent of new COX-1 mRNA or protein synthesis, and (2) slower production reflecting increased COX-2 expression.

In the case of rapid stimulation of PGI₂ production, as induced by thrombin, histamine, bradykinin, and ionophore, the response plateaus at 10 minutes.²⁹ These agonists activate phospholipase C which generates inositol triphosphate (IP₃) and diacylglycerol (DAG). The released IP₃ induces an elevation of intracellular calcium, which translocates phospholipase A to the outer portion of the nuclear envelope and

Figure 115-3. Adherent activated platelets induce an inflammatory response in endothelial cells. Platelet adhesion involving $\alpha_{IIb}\beta_3$ induces exposure of P-selectin (CD62P) and release of platelet CD40 ligand (CD40L) and interleukin (IL)-1 β which then stimulate endothelial cells to respond with an inflammatory reaction that supports prothrombotic and proatherogenic alterations in the endothelium. IL-8 and MCP-1 (monocyte chemoattractant protein-1) are the principal chemoattractants for neutrophils and monocytes. ICAM, intercellular adhesion molecule; MMP, matrix metalloproteinase; u-PA, urokinase plasminogen activator; uPAR, urokinase plasminogen activator receptor; VCAM, vascular cell adhesion molecule. (Adapted with permission from Gawaz M, Langer H, May AE: Platelets in inflammation and atherogenesis. J Clin Invest 11(12): 3378–3384, 2005.)

Figure 115-4. Adherent/activated platelets promote an inflammatory response in monocytes. The platelets mainly interact with monocyte P-selectin glycoprotein ligand (PSGL)-1 with monocytic PSGL-1 via P-selectin and with monocyte Mac-1 ($\alpha_{IIb}\beta_3$) via $\alpha_{IIb}\beta_3$ (and fibrinogen bridging) or glycosylphosphatidylinositol (GPI)IIb. Through this mechanism platelets initiate monocyte secretion of chemokines, cytokines, and procoagulant tissue factor. These serve to upregulate and activate adhesion receptors and proteases. In parallel, they induce monocyte differentiation into macrophages. Therefore platelet-monocyte interactions provide a prothrombotic and atherogenic milieu at the vascular wall, which can eventually support plaque formation. IL, interleukin; JAM, junctional adhesion molecule; MCP, monocyte chemoattractant protein; MIP, macrophage inhibitory protein; MMP, matrix metalloproteinase; NFκB, nuclear factor kappa B; u-PA, urokinase plasminogen activator; uPAR, urokinase plasminogen activator receptor; TNF, tumor necrosis factor; VLA, very late antigen. (Adapted with permission from Gawaz M, Langer H, May AE: Platelets in inflammation and atherogenesis. *J Clin Invest* 11(12):3378–3384, 2005.)

endoplasmic reticulum. Phospholipase A then couples functionally to COX-1, which is located on the luminal membrane. Prostacyclin synthase (PGIS) colocalizes with COX-1 in endothelial cells. Activated phospholipase A2 (cPLA2) catalyzes the release of arachidonic acid from membrane phospholipids, and the free arachidonate interacts with COX-1 and is converted to the endoperoxide PGH₂. PGIS converts prostaglandin H₂ (PGH₂) to PGI₂. The half-life of COX-1 is approximately 10 minutes, whereupon it autoinactivates.

Stimulation of PGI₂ production by proinflammatory cytokines and growth factors, such as lipopolysaccharide (LPS), interleukin (IL)-1β, tumor necrosis factor (TNF)-α, and platelet-derived growth factor (PDGF), is a slower, more sustained process.²⁹ In response to these agonists, PGI₂ production occurs within 30 to 60 minutes, and parallels the time course of production induced by COX-2, but not COX-1.

THE TWO ISOFORMS OF PROSTACYCLIN G/H SYNTHASE

The recognition that there was a constitutive and an inducible cyclooxygenase (COX-1 and COX-2, respectively), was a major advance.³⁰ Cloning studies of an immediate to early response gene from 3T3 fibroblasts revealed that the COX-2 complementary DNA was highly homologous to

that of COX-1.^{30–34} COX-2 is inducible in endothelial cells by prothrombotic, inflammatory, or mitogenic stimuli, and in neutrophils by inflammatory stimuli.^{35,36}

Within a specific species, there is approximately 60 percent homology between deduced amino acid sequences of COX-1 (576 residues) and COX-2 (587 residues). The C-terminal sequence of 18 amino acids in COX-2 is absent in COX-1. Therefore, antibodies directed at this C-terminal sequence can identify COX-2 in tissues by immunoblot. The catalytic activity of both COX enzymes are similar and all amino acids critical for COX-1 activity are conserved in COX-2. The active site in COX-1 is slightly larger than that of COX-2, a fact that has impacted design of COX inhibitors. COX-2 contains mannose, and an N-glycosylation site within the 18-amino acid C-terminal sequence. An N-glycosylation site at Asn410 is required for COX-1 to fold into its active conformation.

The gene for COX-1 is located on chromosome 9 and spans 22 kb of genomic DNA, while the gene for COX-2 is located on chromosome 1 and spans 8 kb of DNA. Transcription of COX-2 proceeds via several signaling mechanisms initiated by cyclic adenosine monophosphate (cAMP)/protein kinase A, protein kinase C, tyrosine kinases, and pathways activated by growth factors, endotoxin, and cytokines.^{33,37–39} The discoveries of COX-1 and COX-2 were of great importance and have led to new concepts concerning the structure and function of COX-induced autacoids.⁴⁰

PROSTACYCLIN AS AN AUTACOID

PGI₂ is released from stimulated endothelial cells by a broad range of agonists, and plays a critical role in the maintenance of vascular integrity by promoting thromboresistance and inhibiting inflammatory responses in the vasculature. Production of PGI₂ is dynamically regulated to meet the challenges arising from frequent prothrombotic and proinflammatory events.²⁹ As an autacoid, PGI₂ has a half-life of 3 minutes, whereupon it undergoes chemical hydrolysis to 6-keto-PGF_{1α}. It acts on the type I platelet PG receptor (IP) by increasing cAMP levels in a paracrine manner.⁴¹ IP is a 7-transmembrane, G-protein- and adenylyl cyclase-coupled receptor. The latter binds to and activates protein kinase A (PKA), resulting in inhibition of platelet activation and recruitment.⁴² Physical or chemical perturbation of endothelial cells results in enhanced PGI₂ production, which increases platelet cAMP resulting in abolition of platelet shape change, inhibition of platelet secretion and recruitment, and impaired binding of von Willebrand factor (VWF) and fibrinogen to the platelet surface. PGI₂ also inhibits platelet adhesion to subendothelium, especially at high shear rates.⁴³

The discovery of PGI₂ revealed that the vascular endothelium had a protective effect on blood fluidity.^{2,8} It also meant that PGI₂ released from endothelial cells could counteract the effect of excessive thromboxane formation. In addition, it was appreciated that intermediates in the synthesis of PGI₂ from arachidonic acid could interact with other cells and tissues. Thus, PGI₂ could be synthesized from platelet-derived endoperoxides by cultured human endothelial cells.⁴⁴ Because of a low threshold for toxicity (hypotension and diarrhea), PGI₂ does not display a satisfactory therapeutic window. An interesting compendium of eicosanoid-related disorders is described in a review on eicosanoids in health and disease.⁴⁵

● NITRIC OXIDE: AN ENDOTHELIAL VASODILATOR AND INHIBITOR OF PLATELET ACTIVATION AND RECRUITMENT

In vascular endothelial cells, NO synthase (NOS) catalyzes formation of NO from L-arginine, in the presence of nicotinamide adenine dinucleotide phosphate (NADPH) and oxygen.⁴⁶ The L-arginine is subsequently

converted to citrulline and NO. The endothelial cell isoform of NO synthase (eNOS or the NOS3 gene product) functions constitutively, and is further activated by receptor-agonists that elevate intracellular calcium. Major stimuli include ADP, thrombin, bradykinin, and shear stress.⁴³ Shear forces induce transcriptional activation of the eNOS gene because its promoter contains a shear response consensus sequence (GAGACC). The NO that forms activates guanylate cyclase, thereby generating cyclic GMP. NO becomes oxidized to nitrite and then to nitrate, which is measurable in blood samples. NO in the circulation is rapidly inactivated by erythrocytes.^{11,47,48} NO has a vasodilatory effect on the pulmonary vasculature, and, in patients with congestive heart failure, its inhalation decreases pulmonary hypertension and increases pulmonary ventilation.^{10,11,47-54} Acetylcholine released by activated nerve terminals in the vessel wall activate the endothelial cell to produce and release NO. This NO effect also explains the action of nitroglycerin, which has long been used to treat patients with angina resulting from coronary artery disease.⁵⁴

Importantly, production of NO by endothelial cells is impaired in the presence of the thiol-containing amino acid, homocysteine. Cynomolgus monkeys with diet-induced hyperhomocysteinemia demonstrated reduced blood flow in the lower extremity and an impaired response to endothelial cell-dependent vasodilators.⁵¹ Similarly, production of NO by endothelial cells *in vitro* is significantly inhibited in the presence of homocysteine, possibly by a mechanism involving impairment of the enzyme glutathione peroxidase.^{52,53}

STRUCTURE AND BIOCHEMICAL PROPERTIES OF NITRIC OXIDE SYNTHASE

There are two isoforms of NOS, the constitutive form (eNOS), synthesized by the endothelial cell and regulated by Ca²⁺ and calmodulin, and the cytokine-inducible, posttranscriptionally regulated form (iNOS).⁴⁷ Both constitutive and inducible forms are mainly cytosolic, although a membrane-bound constitutive NOS isoform containing a myristoylation consensus sequence has been isolated from bovine aortic endothelial cells.⁴³ eNOS has a molecular mass of 144 kDa and shares 57 percent amino acid sequence identity with neuronal NOS. The cofactor (6R-tetrahydro-L-biopterin [H₄B]) participates in inducible and constitutive NOS isoform reactions. It is thought that H₄B stabilizes the enzyme in a manner allowing for maximum activity of the NOS subunit to which the pterin binds.^{10,11,47,54}

BLOCKADE OF PLATELET AGGREGATION AND SECRETION BY NITRIC OXIDE

Platelet activation and recruitment in response to all agonists, such as ADP, collagen, epinephrine, and thrombin, is blocked by NO. Blockade also occurs *in vivo* via formation of NO from endothelium.¹⁰ Importantly, the inhibitory action of NO is not affected by aspirin either *in vivo* or *ex vivo*. Therefore, NO production is not caused by participation of endothelial cell eicosanoids.

In addition to eNOS, the NOS3 gene product, endothelial cells stimulated by agonists such as cytokines express the inducible form of NO synthase, iNOS, the NOS2 gene product. Through this mechanism, NO can further inhibit platelet reactivity and reduce basal vessel tone by inducing relaxation of vascular smooth muscle. The biochemical basis for the reaction is that NO binds to the heme prosthetic group of guanylyl cyclase. The inhibitory effect of NO on platelet activation can be monitored by measuring surface expression of P-selectin. The ability of NO to inhibit mobilization of intracellular platelet calcium results in reduction of the conformational changes in platelet membrane glycoprotein (GP)IIb/IIIa, an absolute requirement for fibrinogen binding

and subsequent platelet aggregation. There is a broad spectrum of other effects of NO, including inhibition of leukocyte adhesion to endothelial cell surfaces, inhibition of smooth muscle migration, and reduction of smooth muscle cell proliferation. These phenomena suggest that secretion of NO into the microenvironment is a major component of the response to vascular injury⁴³

● INHIBITION OF PLATELET ACTIVATION AND RECRUITMENT BY ECTO-ATP/DASE1-CD39

In addition to the platelet inhibition by PGI₂ and NO, endothelial cells inhibit platelet function via the action of endothelial cell ecto-ATP/Dase-1/CD39, an ecto-apyrase with ADPase and adenosine triphosphatase (ATPase) activities. The cluster designation symbol for this compound is CD39, the product of the *ENTPDI*, ectonucleotide triphosphate diphosphohydrolase gene.⁵⁵ CD39 is localized mainly in endothelial cells and leukocytes. In endothelial cells, CD39 is located on the cell surface with the major portion of the molecule facing the vessel lumen.^{12,13,56} The enzyme has both N- and C-terminal transmembrane regions with small cytosolic portions anchoring the molecule.⁵⁷ In addition to CD39, CD73 (5'-nucleotidase) is present on vascular cells and converts the adenosine monophosphate (AMP) generated from CD39 metabolism to adenosine (Fig. 115-5). In contrast to all other known platelet inhibitors, acting in concert with CD73, CD39 can convert the local environment from a prothrombotic ADP/ATP-rich entity to an antithrombotic adenosine-rich environment.⁵⁸ This phenomenon was evident from observations that platelets became unresponsive to all agonists when in motion or in proximity to endothelial cells, even when eicosanoid and NO production were blocked.² Importantly, CD39 and CD73 do not exert their action on the platelet *per se* but act in series to metabolize ATP and ADP secreted from activated platelets to AMP and hence to adenosine.^{13,59} ADP released from activated platelets is metabolized by CD39, thereby inhibiting ADP-induced platelet activation, release and aggregation (Fig. 115-5).

Most platelet agonists initiate secretion of dense granule contents within 15 to 20 seconds. The enhanced metabolism of ATP and ADP by therapeutically administered soluble CD39 would also reduce secondary autoamplification and recruitment, and, consequently, thrombus formation.^{9,27,60} Because CD39 and CD73 are probably acting together, they will theoretically increase levels of endogenous adenosine and elevate the threshold for platelet activation in the local microenvironment. In a murine model, soluble CD39 administration ameliorates the extent of stroke and reverses excessive platelet reactivity without bleeding complications, even if administered 3 hours following stroke induction.⁶¹ Therapeutic benefit of soluble CD39 has also been demonstrated in animal models of cardiac ischemia,⁶² in the development of atherosclerosis,⁶³ regulation of leukocyte proinflammatory activity,⁶⁴ inhibition of metastasis,⁶⁵ and in transplantation medicine.⁶⁶ That the preclinical therapeutic use of soluble CD39 could abrogate thrombosis without inducing the hemorrhage seen with the use of existing anti-platelet therapies⁶⁷ could provide a therapeutic advantage over existing therapies for thrombotic disorders, including those who are resistant to existing therapeutic paradigms.⁹ CD39 represents a major control system for blood fluidity.⁶⁸

● THE PROTEIN C PATHWAY

The protein C pathway⁶⁹ plays a critical role in the prevention of thrombosis and is an integral part of the host inflammatory response. This pathway is initiated on the endothelial cell surface when thrombin

Figure 115-5. Released platelet adenosine diphosphate (ADP) is a major control system for hemostasis: ADP → adenosine monophosphate (AMP) → adenosine. Perturbation of endothelial cells, as a consequence of vascular injury, initiates the release of newly synthesized prostacyclin as well as nitric oxide, both of which inhibit platelet reactivity in the fluid phase. The apyrase CD39 is a cell-associated inhibitory thromboregulator. CD39 is substrate-activated and, in concert with CD73, brings the reaction to completion with the formation of adenosine.^{309,310} The early metabolic deletion of ADP from the system may serve as a biologic safeguard to avoid excessive platelet accumulation, which would result in thrombosis.^{21,22,309,310} NO, nitric oxide; PGI₂, prostacyclin.

combines with the endothelial receptor protein thrombomodulin (TM). Although thrombin is capable of slowly activating protein C, this reaction is markedly inhibited in the presence of physiologic concentrations of calcium ions. Upon binding of thrombin to TM, the rate of protein C activation is dramatically enhanced and becomes dependent on the presence of calcium. The detailed biochemistry of this activation reaction has been reviewed elsewhere.⁷⁰ Another protein found predominantly in large vessels, the EPCR, can bind protein C and further augment its activation by the thrombin-TM complex.⁷⁰ Activated protein C (APC) can dissociate from EPCR and interact with protein S on either the endothelial cell or other membrane surface to exert its anticoagulant function. The function of APC can be found in several reviews.^{14,71-73}

By far, the best known function of TM is its role in protein C activation. When thrombin is bound to TM, it is no longer able to clot fibrinogen, activate platelets, activate factors V and VIII,⁷⁴ or interact with the protease-activated receptors.^{75,76} Instead, thrombin-TM acts as a direct anticoagulant. TM also promotes the activation by thrombin of the plasma thrombin-activatable fibrinolysis inhibitor (TAFI).⁷⁷ TAFI inhibits plasmin-mediated fibrinolysis by removing carboxy-terminal lysine residues from fibrin, thereby reducing available binding sites for plasminogen and t-PA. In addition, TAFI is the major enzyme responsible for the removal of a C-terminal arginine from complement factor 5a (C5a),^{78,79} leading to the inactivation of this potent anaphylotoxin generated during complement activation. Other vasoactive substances may also be inactivated by this enzyme. TM also accelerates the proteolytic inactivation of prourokinase (also called single-chain urokinase-type plasminogen activator [scu-PA]) by thrombin,^{80,81} which may affect both fibrinolysis and tissue remodeling.⁸² Despite these antifibrinolytic effects of TM, many *in vivo* experiments have demonstrated that soluble TM infusion results in a net antithrombotic and/or antiinflammatory effect.⁸³

Independent of its effect on hemostasis, TM is essential to normal fetal development. When the TM gene is deleted by homologous recombination in mice, embryos die on day 8.5, prior to the development of a functional cardiovascular system,⁸⁴ implying that TM has functions in addition to its anticoagulant and antifibrinolytic properties. Both TM⁸⁵

and EPCR⁸⁶ are highly expressed on the giant trophoblast cells of the placenta. If TM expression is maintained on these cells, the TM null embryos survive past this blockade point.^{87,88}

The EPCR is a 220-amino-acid, type 1 transmembrane protein.⁸⁹⁻⁹² EPCR has two extracellular domains that show structural homology with the α and β domains of major histocompatibility complex (MHC) class 1 molecules, most notably the CD1d family. Because there are three Cys residues in the extracellular domain, the possibility of cross-linking with another protein exists. The cytoplasmic domain of human EPCR is only three amino acids long, Arg-Arg-Cys. The terminal Cys can be acylated with palmitate, which may have functional consequences.⁹³ Both protein C and APC bind to EPCR with similar affinity, approximately 30 nM.⁸⁹ Binding requires the presence of calcium and is enhanced in the presence of magnesium ions. In addition, a soluble form of EPCR found normally in plasma⁹⁴ is also capable of binding both protein C and APC with equivalent affinity.

EPCR augments protein C activation by the thrombin-TM complex *in vitro* and *in vivo*, primarily by decreasing the K_m (Michaelis-Menten dissociation constant) for protein C.^{70,95,96} Just as thrombin changes its function from procoagulant to anticoagulant when it binds to TM, it appears that APC bound to EPCR undergoes a similar switch from anticoagulant to antiinflammatory molecule.^{97,98} Unfortunately, however, early studies that suggested a possible therapeutic role for APC in human sepsis have not been borne out in clinical trials.⁹⁹ Deletion of the EPCR gene by homologous recombination leads to early embryonic lethality around day 9.5,¹⁰⁰ at which time EPCR is highly expressed in the giant trophoblasts of the placenta, but not in the embryo itself.⁸⁶ In contrast to TM knockout animals,¹⁰¹ the placentas of EPCR knockout embryos show significant fibrin deposition at the fetal maternal interface.

VASCULAR FIBRINOLYSIS

Plasmin, the major clot-dissolving protease in humans, is formed upon the cleavage of a single peptide bond within the zymogen plasminogen (Chap. 135). This tightly regulated reaction is strongly influenced by cells of the blood vessel wall, including endothelial cells, smooth

muscles cells, and macrophages, which express plasminogen activators, plasminogen activator inhibitors, and fibrinolytic receptors.

ENDOTHELIAL CELL PRODUCTION OF FIBRINOLYTIC PROTEINS

In 1958, Todd demonstrated that human blood vessels possess fibrinolytic activity that is dependent upon an intact endothelium.^{102,103} We now know that the endothelium is the principal source of t-PA *in vivo* where it appears to be highly restricted to small blood vessels in specific anatomic locations, a pattern that likely reflects the heterogeneity of endothelial cells as they respond to a myriad of tissue-specific cues.^{104,105} In the baboon, for example, sites of t-PA production include 7 to 30 μm precapillary arterioles and postcapillary venules, but not large arteries and veins.¹⁰⁶ In the mouse lung, similarly, bronchial, but not pulmonary, endothelial cells express t-PA.¹⁰⁷ Moreover, enhanced expression of t-PA at branch points of pulmonary blood vessels may reflect stimulation by laminar shear stress.¹⁰⁸ In addition, peripheral sympathetic neurons that invest the walls of small arteries may represent a significant source of circulating t-PA.¹⁰⁹

Although *in vitro* studies suggest that t-PA expression in cultured endothelial cells is regulated by a wide array of factors, only a few of these pathways have been confirmed *in vivo*. Thrombin,¹¹⁰ histamine,^{111,112} oxygen radicals,¹¹³ phorbol myristate acetate,¹¹⁴ DDAVP (deamino D-arginine vasopressin),¹¹⁵ and butyric acid liberated from dibutyl cAMP¹¹⁶ all increase t-PA mRNA in cultured endothelial cells. Both thrombin and histamine appear to act via receptor-mediated activation of the protein kinase C pathway.¹⁰⁵ Laminar shear stress stimulates both t-PA secretion¹¹⁷ and steady-state mRNA levels.¹¹⁸ Hyperosmotic stress and repetitive stretch also enhance t-PA expression.^{119,120} In addition, differentiating agents, such as retinoids,^{121,122} stimulate transcription of t-PA in endothelial cells *in vitro*.

In vivo, the circulating half-life of t-PA is approximately 5 minutes. Infusion of DDAVP, bradykinin, platelet-activating factor (PAF), endothelin, or thrombin is associated with an acute release of t-PA, and a burst of fibrinolytic activity can be detected within minutes.¹²³ In the mouse lung, exposure to hyperoxia leads to 4.5-fold upregulation of t-PA mRNA in small-vessel endothelial cells.¹⁰⁷ In humans, infusion of TNF into patients with malignancy is associated with an increase in plasma t-PA.¹²³ Deficient release of t-PA in response to venous occlusion in humans is associated with deep venous thrombosis,¹²⁴ as well as atrophic blanche and other cutaneous vasculitides.¹²⁵

In vivo, urokinase plasminogen activator (u-PA) is not a product of resting endothelium,¹²⁶ but is produced primarily by renal tubular epithelium.¹²⁷ Expression of u-PA mRNA in endothelium, however, is strongly stimulated during wound repair and physiologic angiogenesis within ovarian follicles, corpus luteum, and maternal decidua.¹²⁸ Endothelial cells passaged in culture do synthesize u-PA,¹²⁹ and expression of its mRNA is stimulated by TNF- α by 5- to 30-fold.¹³⁰ Small increases in u-PA have also been observed *in vitro* in response to IL-1 and LPS.^{131–133}

The association of u-PA with the blood vessel wall appears to reflect its association with the u-PA receptor (uPAR) which may fulfill a variety of nonproteolytic functions ranging from directed cell migration to cellular adhesion, differentiation, and proliferation (Fig. 115–6).¹³⁴ In the adult mouse, uPAR mRNA is not normally detected by *in situ* hybridization in the endothelium of either large or small blood vessels.¹³⁵ However, upon stimulation with endotoxin, expression is detected in endothelium lining aorta, as well as arteries, veins, and capillaries in heart, kidney, brain, and liver,¹³⁵ and in renal tubular epithelial cells.¹²⁷

Plasminogen activator inhibitor (PAI)-1 is likely to function as a major regulator of plasmin generation in the vicinity of the endothelial cell. Thrombin, IL-1, transforming growth factor β , TNF, lipoprotein(a) (Lp[a]), and LPS all induce dramatic increases in steady state PAI-1 message levels.^{110,131,132,136,137} Heparin-binding growth factor 1 reduces

Figure 115–6. Schematic of principal endothelial cell fibrinolytic receptors. **A.** The annexin A2/S100A10 heterotetrameric complex. Annexin A2 consists of a hydrophilic aminoterminal tail domain (A-Tail, approximately 3 kDa), and a membrane-oriented carboxyl terminal core domain (approximately 33 kDa).^{311,312} The tail domain contains residues required for tissue-type plasminogen activator (t-PA) binding. The core domain is composed of four homologous annexin repeats (A1, A2, A3, and A4), each consisting of five α -helical regions that contribute to calcium-dependent phospholipid binding sites. Repeat 2 appears to be most important for the interaction of annexin A2 with the endothelial cell surface. Plasminogen (PLG) binding requires lysine residue 307 within helix C of repeat 4. **B.** Urokinase plasminogen activator receptor (uPAR) is a 55- to 60-kDa, glycosylphosphatidylinositol-linked protein that consists of three disulfide-linked domains (U1, U2, U3).³¹⁴ Domain 1 contains sequences required for urokinase plasminogen activator (u-PA) binding, while domains 2 and 3 mediate the receptor's interaction with matrix proteins such as vitronectin. Domain 3 contains glycosylphosphatidylinositol-linked membrane anchor. (A, adapted with permission from Gerke V, Creutz CE, Moss SE: *Annexins: linking Ca²⁺ signalling to membrane dynamics*. Nat Rev Mol Cell Biol 6(6):449–461.)

PAI-1 mRNA production by cultured endothelial cells, but has no effect on t-PA.¹³⁸ Thus, synthesis and secretion of PAI-1 by the endothelial cell *in vitro* appears to be regulated independently of t-PA.

In vivo, elevated levels of circulating PAI-1 have been linked epidemiologically to risk for myocardial infarction.¹²⁴ Although the liver is the major source of plasma PAI-1, endothelial expression of PAI-1 is detected near neovascular sprouts during decidual neovascularization in the ovary.¹²⁸ In addition, inflammatory cytokines are powerful stimuli for induction of PAI-1 in a variety of tissues including liver, as injection of TNF in both rats and humans with active malignancy results in a striking increase plasma concentrations of PAI-1.^{105,123}

The endothelial cell coreceptor for t-PA and plasminogen, the annexin A2/S100A10 complex (see Fig. 115–6), appears to be expressed constitutively *in vivo* by endothelial cells in a wide variety of tissues in the chicken,¹³⁹ mouse,¹⁴⁰ rat,¹⁴¹ and human.¹⁴² Annexin A2 is upregulated transcriptionally by hypoxia both *in vivo* and in endothelial cells *in vitro*,¹⁴³ and by nerve growth factor in neuronal-like PC12 cells.¹⁴⁴ In addition, the *in vitro* transition of human monocyte to macrophage is associated with a severalfold increase in both annexin A2 protein and steady state mRNA expression.¹⁴⁵

The evidence that the annexin A2 system plays a role in maintaining vascular patency includes the findings that (1) overexpression of annexin A2 in blast cells in acute promyelocytic leukemia blast cells increases plasmin production and contributes to hyperfibrinolytic bleeding,^{146–149} (2) systemic injection of annexin A2 diminishes thrombotic vascular occlusion resulting from vascular injury in experimental animals,¹⁵⁰ (3) annexin A2-deficient mice display fibrin deposition on microvessels and impaired clearance of arterial thrombi following vascular injury,¹⁵¹ (4) high titer antibodies directed against annexin A2 are associated with thrombosis in antiphospholipid syndrome and in individuals with cerebral venous thrombosis,^{152,153} and (5) that polymorphisms in the ANXA2 gene are associated with cerebral vascular occlusion and osteonecrosis of bone in patients with sickle cell disease.^{154–156} Whether defects in S100A10, which could serve either as a chaperone for annexin A2 or as a direct binding site for plasminogen,¹⁵⁷ might also be associated with these clinical entities remains to be determined.

NONFIBRINOLYTIC VASCULAR FUNCTIONS OF PLASMIN

Although not yet demonstrated *in vivo*, plasmin may inactivate factor Va *in vitro* by cleaving both the heavy and light chains of this 168-kDa protein, in a manner that is distinct from the action of activated protein C.^{158,159} Plasmin can also inactivate factor VIIIa, a procoagulant cofactor that is structurally related to factor Va.¹⁶⁰ In addition, platelet GPIIb/IIIa and GPIb, the cell surface receptors for fibrinogen and VWF, respectively, are both plasmin substrates.^{161,162} Thus, plasmin formation in the vicinity of a hemostatic plug could lead to impaired adhesion and poor aggregation in response to agonists. *In vivo*, prolonged bleeding times were found in patients 90 minutes after t-PA infusion for thrombolysis, suggesting early impairment of platelet function upon plasmin generation.¹⁶³ However, there is also evidence that platelets may promote thrombotic reocclusion following successful thrombolytic therapy.¹⁶⁴

FIBRINOLYTIC FUNCTION IN VASCULAR INJURY

Transgenic mouse models of vascular disease have helped to elucidate the complex role of the fibrinolytic system in atherosclerosis (Table 115–3).^{165,166} In mice, the general effects of plasminogen deficiency include runting, fibrin deposition in intra- and extravascular locations, and premature death.^{167,168} In addition, the mice display

TABLE 115–3. The Fibrinolytic System in Cardiovascular Disease—Transgenic Mouse Models

Genotype	Result	Reference(s)
Atherogenesis:		
PLG ^{-/-} ApoE ^{-/-}	Increased atherogenesis	178
t-PA ^{-/-} ApoE ^{-/-}	Unchanged atherogenesis	179
u-PA ^{-/-} ApoE ^{-/-}	Unchanged atherogenesis	179
PAI-1 ^{-/-} ApoE ^{-/-}	Decrease in early plaque size; increase in advanced plaque size	180–182
Transplant arteriosclerosis:		
PLG ^{-/-}	Reduced leukocyte invasion in transplantation model; reduced extent of disease	185
Coronary ligation:		
u-PA ^{-/-}	Protection from ventricular rupture; but poor revascularization and late death from heart failure	186
t-PA ^{-/-}	No protection	186
uPAR ^{-/-}	No protection	186
Aortic aneurysm:		
u-PA ^{-/-} ApoE ^{-/-}	Protected	179
t-PA ^{-/-} ApoE ^{-/-}	Not protected	179
Early oxidative injury:		
PAI-1 ^{-/-}	Attenuated thrombotic occlusion (Rose Bengal)	194
PAI-1 ^{-/-}	Attenuated thrombotic occlusion (FeCl ₃)	195
u-PA ^{-/-}	Increased thrombosis (FeCl ₃)	196
t-PA ^{-/-}	Increased thrombosis (FeCl ₃)	196
A2 ^{-/-}	Increased thrombosis (FeCl ₃)	155
Restenosis with prominent thrombosis:		
PAI-1 ^{-/-}	No neointima (Cu cuff)	199
PAI-1 ^{-/-}	Reduced neointima (ligation)	317
PAI-1 ^{-/-}	Reduced neointima (FeCl ₃)	317
PAI-1 ^{-/-} ApoE ^{-/-}	Reduced neointima (FeCl ₃)	198
Restenosis without prominent thrombosis:		
PLG ^{-/-}	Reduced neointima (electrical)	187, 188
t-PA ^{-/-}	No change (electrical or mechanical)	187, 189
u-PA ^{-/-}	Reduced neointima (electrical or mechanical)	187, 189
u-PA ^{-/-} t-PA ^{-/-}	Reduced neointima (electrical or mechanical)	187, 189
uPAR ^{-/-}	No change (electrical)	190
PAI-1 ^{-/-}	Increased neointima (ligation)	318
PAI-1 ^{-/-}	Increased neointima (electrical or mechanical)	191

impaired healing of cutaneous wounds,¹⁶⁹ a response that appears to depend largely on the fibrinolytic action of plasmin as loss of fibrinogen eliminates these defects.¹⁷⁰ Mice doubly deficient in plasminogen and apolipoprotein E (ApoE) showed an increased predisposition to atherosclerosis compared to animals deficient in ApoE alone (Fig. 115-7A).¹⁷¹ Mice with ApoE deficiency combined with deficiency of either u-PA or t-PA showed the same predilection for early fatty streaks and advanced plaques as was observed in mice with isolated ApoE deficiency, suggesting that complete elimination of plasmin generating activity is required to exacerbate the proatherogenic state.¹⁷² Finally, mice doubly deficient in ApoE and PAI-1 exhibit no change in early plaque size at the aortic root,^{173,174} decreased early plaque size at the carotid bifurcation,^{173,174} but increased advanced plaque size with accelerated deposition of matrix.¹⁷⁵

Once the atherosclerotic plaque is established, plasmin may affect its evolution by mediating invasion of leukocytes (see Table 115-3).¹⁷⁶ In the peritoneal cavity, recruitment of inflammatory cells is profoundly influenced by the presence or absence of plasminogen.¹⁷⁷ In transplant-associated arteriosclerosis, the extent of disease is significantly reduced in plasminogen-deficient mice, reflecting, at least in part, reduced influx of macrophages, with an associated reduction in medial necrosis, fragmentation of elastic laminae, and remodeling of the adventitia.¹⁷⁸ Thus, the role of plasmin in degrading fibrin and other matrix constituents in the early lesion limits atherosclerosis, whereas its ability to promote cellular invasion later on appears to promote atherogenesis.

During aortic aneurysm formation in mice, deficiency of u-PA, but not t-PA, was associated with reduced medial destruction and impaired activation of downstream plasmin-dependent matrix metalloproteinases (Fig. 115-7B and Table 115-3).¹⁷² Similarly, u-PA-, but not t-PA-, deficient mice were protected from cardiac rupture secondary to ventricular aneurysm. In this study, temporary administration of PAI-1 or the general matrix metalloproteinase inhibitor, tissue inhibitor of metalloproteinase (TIMP)-1, completely protected wild-type mice from aortic rupture, reinforcing the concept that plasmin-based protease activity promotes aneurysm progression.¹⁷⁹

Vascular remodeling may occur following acute arterial injury induced by interventions for vascular compromise, leading to vascular

restenosis (Fig. 115-7C and Table 115-3). This process reflects leukocyte invasion, proliferation and migration of smooth muscle cells, deposition of extracellular matrix, and reendothelialization. Electrical or mechanical injury studies in gene-targeted mice indicate that neointima formation, an initial step in restenosis, requires intact expression of plasminogen and u-PA, but not t-PA.¹⁸⁰⁻¹⁸² Interestingly, loss of uPAR has no effect on neointima formation,¹⁸³ whereas loss of PAI-1 is associated with increased neointimal stenosis.^{184,185} In these injury models, which do not induce severe thrombosis, it is thought that vascular occlusion, reflecting migration of smooth muscle cells and leukocytes, is impaired when fibrinolytic potential is attenuated.¹⁸⁶

In the ferric chloride, Rose Bengal, and copper cuff models, on the other hand, thrombosis is observed within minutes of arterial injury (see Fig. 115-7 and Table 115-3). In these systems, deficiency of PAI-1 is associated with later and less-extensive thrombotic occlusion of the injured artery,^{187,188} while loss of u-PA is associated with more rapid and more significant thrombotic occlusion.¹⁸⁹ At the same time, the absence of PAI-1 led to reduced vascular stenosis, regardless of whether ApoE was absent^{190,191} or present.^{192,193} In balloon-injured rat carotid arteries, finally, transduction of a PAI-1-expressing gene led to increased restenosis of the vessel, again suggesting that clearance of the initial thrombus may have longterm effects on vessel patency and neointima formation.¹⁹⁴ In these models, the predominant effect of the fibrinolytic system may be to clear the initial thrombus, which may provide a provisional scaffolding for later restenosis.

FIBRINOLYTIC ASSEMBLY AND VASCULAR DISEASE

Endothelial cells use receptors, primarily uPAR and the annexin A2/S100A10 system, to assemble the fibrinolytic system on their surface (Chap. 135; Fig. 115-6). Recent evidence suggests that impairment of receptor-mediated fibrinolytic assembly may lead to vascular compromise.

Figure 115-7. Working model for the actions of the fibrinolytic system in vascular disease. **A.** Plaque formation. Atheromatous plaque is thought to form in response to endothelial cell (EC) (orange) injury or perturbation. Following the initial injury, perturbed endothelial cells may fail to clear fibrin on the blood vessel surface, and may also promote adhesion and invasion of leukocytes (blue). In addition, smooth muscle cells arising in the tunica media invade the developing plaque within the intima (green). Endothelial cells may utilize cell-surface receptors for focal activation of plasmin to maintain a thromboresistant vascular surface. Leukocytes, macrophages, and smooth muscle cells may use plasmin to migrate into the evolving plaque (cells outlined in red). **B.** Aneurysm. Fragmentation and dissolution of the elastic laminae of the arterial wall may occur upon matrix metalloproteinase activation via plasmin-dependent pathways, possibly mediated by smooth muscle cells. Cells migrating outward toward the adventitial surface of the vessel induce further matrix degradation, and the potential for rupture. **C.** Restenosis. In response to vascular injury, smooth muscle cells proliferate and, together with leukocytes, invade the subendothelial space establishing a thickened neointima that compromises vascular patency. In all three scenarios, cell migration is thought to require plasmin activity, possibly in association with cell surfaces. EEL, external elastic lamina; IEL, internal elastic lamina.

LIPOPROTEIN(A)

Lp(a) is a low-density lipoprotein (LDL)-like particle that is an independent risk factor for atherosclerosis.^{195–197} In addition to the apolipoprotein B-100 found on LDL, Lp(a) contains a disulfide-linked moiety called apolipoprotein(a) [apo(a)]. Apo(a) shares a remarkable degree of homology with plasminogen, as it possesses multiple tandem repeats of a kringle IV-like domain, a single domain resembling kringle V, and a pseudoprotease domain.^{198,199} Plasminogen and apo(a), furthermore, are closely linked on chromosome 6 and appear to have arisen from a common ancestral gene.²⁰⁰

Whereas Lp(a) levels are only transiently responsive to diet,^{201,202} plasma levels appear to be subject to mendelian inheritance.^{203–205} Plasma Lp(a) concentrations correlate inversely with the ratio of kringle IV to kringle V encoding domains within the apo(a) gene,^{206,207} such that larger apo(a) gene products are associated with lower plasma concentrations of apo(a). In addition, Lp(a) is an acute phase reactant in the postsurgical and post-myocardial infarction setting,²⁰⁴ and in patients with cancer,²⁰⁵ suggesting a role for soluble inflammatory mediators in regulating its synthesis or assembly. Apo(a) possesses a high-affinity lysine binding site within kringle 4 that closely resembles that of kringle 1 of plasminogen,²⁰⁸ and kringle 37 of the originally cloned apo(a) resembles the lysine-binding plasminogen kringle 4 of plasminogen.²⁰⁹ *In vivo*, Lp(a) colocalizes histologically with fibrin in atheromatous tissue.²¹⁰

When apo(a) is overexpressed in transgenic mice,²¹¹ cell-associated plasmin activity is reduced such that the animals are resistant to t-PA thrombolysis.²¹² Three potential explanations for the prothrombotic, proatherogenic effect of Lp(a) include (1) the observation that both Lp(a) and apo(a) inhibit Lys-plasminogen binding to endothelial cells (half-maximal inhibitory dose [ID₅₀] = 36-fold excess),²¹³ and to annexin A2,²¹⁴ with affinity similar to that for plasminogen^{215–217}; (2) endothelial cell exposure to Lp(a) *in vitro* enhances expression of PAI-1¹³⁷; and (3) Lp(a) may act as a competitive inhibitor of t-PA in the presence of fibrinogen,²¹⁸ or as an uncompetitive inhibitor of the fibrin-dependent enhancement of t-PA-induced plasmin generation.²¹⁹ Overexpression of Lp(a) in mice receiving a high-fat diet results in atherosclerosis-like lesions containing anti-apo(a) cross-reactive material.²²⁰ Deposition of both lipid and apo(a) was reduced in mice expressing apo(a) in which lysine binding sites had been mutated.²²¹ Thus, lysine binding sites of apo(a) appear to allow it to compete with plasminogen for cell surface receptors, thereby increasing atherogenicity.

HOMOCYSTEINE

Homocysteine is a thiol-containing amino acid that accumulates in nutritional deficiencies of vitamin B₆, vitamin B₁₂, or folic acid, or in inherited abnormalities of cystathionine β -synthase, methylene tetrahydrofolate reductase, or methionine synthase.²²² Multiple studies have shown homocysteine to be an independent risk factor for atherosclerosis,²²³ venous thromboembolism, and death.²²⁴ Homocysteine lowering in patients with inborn errors of homocysteine metabolism leads to a striking reduction in cardiovascular morbidity, but supplementation with B vitamins in patients with established cardiovascular disease is of no benefit.²²⁵ *In vitro*, homocysteine-treated endothelial cells bound approximately 50 percent less t-PA than untreated cells, and activated approximately 50 percent less plasminogen.²²⁶ Mass spectrometry studies indicate that homocysteine directly disables the t-PA binding domain of annexin A2 by forming a covalent adduction product with cysteine 9 within the tail domain of purified annexin A2, thus inhibiting its ability to bind t-PA.²²⁷ Mice on a high homocysteine-generating diet, moreover, displayed dysfunctional annexin A2, and loss of both fibrinolytic and angiogenic potential. This phenotype mimicked that of

annexin A2-deficient mice, and was overcome upon intravenous infusion of unmodified annexin A2.²²⁸

ANTIPHOSPHOLIPID SYNDROME

Antiphospholipid syndrome (APS) is an autoimmune disorder characterized by thrombosis, recurrent pregnancy loss, and persistently positive antiphospholipid antibodies.^{229,230} Compared to patients with lupus erythematosus, nonimmune thrombosis, or healthy controls, a relatively high proportion of patients with APS and severe thrombosis (22 percent) has antibodies directed against annexin A2. Antiannexin A2 antibodies may block t-PA-dependent cell-surface plasmin generation, and also induce expression of procoagulant molecules, such as TF.¹⁵² These events may require crosslinking of β_2 -GPI bound to closely associated cell-surface A2,^{231,232} and signaling via myeloid differentiation protein 88 (MyD88) and nuclear factor kappa B (NF κ B)-dependent pathway.²³³ Additional evidence shows that A2 is required for the pathogenic effects of antiphospholipid antibodies in mice.²³⁴ High-titer antiannexin A2 antibodies are also associated with cerebral vein thrombosis in patients without the full diagnostic criteria for APS.¹⁵³

ROLE OF ADHESION MOLECULES

A proinflammatory environment is also prothrombotic. Endothelial cells express molecules that regulate binding of leukocytes to their surface during inflammation. These interactions have both direct and indirect roles in hemostasis and thrombosis, and, in some cases, interactions of leukocytes and platelets with inflamed endothelial cells feed forward to promote thrombosis.²³⁵ Moreover, the inflammatory response itself results in the expression of adhesion molecules and mediators that secondarily promote hemostasis. In addition, membrane microparticles derived from platelets, leukocytes, and perhaps endothelium, provide circulating sources of TF, proinflammatory lipids, and other molecules that have the potential to regulate thrombosis and inflammation at a distance from the primary site.^{236–240}

MOLECULAR CHANGES IN AN INFLAMMATORY MILIEU

IMMEDIATE CHANGES

Either histamine or thrombin produced locally at the site of inflammation by degranulation of resident tissue mast cells stimulates the overlying endothelial cells to express P-selectin on their surfaces.²⁴¹ This change occurs within minutes and is caused by the rapid fusion of Weibel-Palade bodies, with the plasma membrane bringing P-selectin to the surface. Along with P-selectin expression, fusion of the Weibel-Palade bodies also results in the release of VWF into the local environment.

P-selectin serves as a leukocyte receptor for P-selectin glycoprotein ligand (PSGL)-1, L-selectin, and other ligands.²⁴² PSGL-1 is a specific sialomucin containing sialylated, fucosylated O-linked oligosaccharides as well as an unusual sulfated tyrosine residue motif.²⁴³ Dimerization of PSGL-1 is required for optimal recognition of P-selectin.²⁴⁴ Adhesive interactions between P-selectin and its ligands result in the tethering of passing leukocytes to, and rolling on, the surface of the endothelial cell as the first step in leukocyte emigration. PSGL-1 also interacts with P-selectin expressed on platelets that have become activated and adherent to endothelium.^{45,245} L-selectin, another member of the selectin family, is constitutively expressed on most leukocytes. It binds to sialylated, fucosylated GP ligands expressed by endothelial cells in response to

inflammation, as well as to CD34 constitutively expressed by cells of the high endothelial venules.

Adhesion of leukocytes to the endothelium at the site of inflammation results in their rolling along the luminal surface, which slows their movement and brings them into contact with a wide variety of chemical mediators that trigger the next stage of leukocyte emigration—tight adhesion to the endothelial surface. These mediators include surface-bound chemokines,²⁴⁶ new adhesion molecules expressed by the endothelium in response to inflammatory cytokines,²⁴⁷ PAF,²⁴⁸ soluble chemokines,²⁴⁹ and ligands that crosslink leukocyte CD31^{250–252} and seem to work by stimulating the activation of leukocyte integrin adhesion molecules by so-called inside-out signaling. This process involves a conformational change and/or clustering of the two chains of these heterodimeric surface molecules such that the affinity or avidity, respectively, for their ligands on the surfaces of endothelial cells is increased.²⁵³ The ligands identified are members of a third family of adhesion molecules, the immunoglobulin gene superfamily.²⁵⁴

Table 115–4 lists some of the more common leukocyte/endothelial CAM pairs participating in the inflammatory response. It is interesting to note that the mucosal addressin MAdCAM-1, a unique molecule expressed by endothelial cells of high endothelial venules of mesenteric

lymph nodes and Peyer patches, has structural features of both a mucin and an immunoglobulin superfamily molecule. It can bind both L-selectin and the leukocyte integrin $\alpha_4\beta_7$, expressed by a subset of memory T cells. It is believed to interact with L-selectin through its mucin (carbohydrate) domain and with $\alpha_4\beta_7$ through its immunoglobulin domains. Until recently, identified protein ligands for L-selectin (MAdCAM-1 and CD34) have been demonstrated to bind to L-selectin only in the context of lymphocyte homing, although recent evidence now suggests that they may play a role in rolling during inflammation.²⁵⁵ Interestingly, intravital microscopy shows that leukocytes may roll on already adherent leukocytes and platelets through the interactions of L-selectin and PSGL-1 to amplify the inflammatory process.^{256,257}

PAF is made and secreted acutely by leukocytes, mast cells, and endothelial cells at the site of inflammation. PAF (1-alkyl-2-acetyl-sn-glycero-3-phosphocholine) is produced enzymatically from phosphatidyl choline in the plasma membrane. Although its role as an activator of neutrophils in this environment has been established,²⁴⁸ it appears to be a relatively weak agonist of platelet activation in this location.

Adherent leukocytes migrate to nearby interendothelial junctions by repeated cycles of adhesion in the front and disadhesion in the rear.^{254,258} At the junction, additional distinct molecular interactions

TABLE 115–4. Common Leukocyte–Endothelial Cell Adhesion Molecule Pairs in Inflammation

Leukocyte Molecule	CD and Integrin Nomenclature	Leukocytes Expressing	Action	Endothelial Counter Ligand	CD Number
L-selectin	CD62L	PMN, Mo, T, B, NK	Tethering, rolling	MAdCAM-1*	Pending
				GP105–120	CD34
PSGL-1	CD162	PMN, Mo, T, B, NK	Tethering, rolling	P-selectin	CD62P
Sialyl LewisX ESL-1†, CLA†	CD15s	PMN, Mo, T, B, NK	Tethering, rolling	E-selectin	CD62E
LFA-1	CD11a/CD18 ($\alpha_4\beta_2$)	PMN, Mo, T, B, NK	Tight adhesion	ICAM-1	CD54
				ICAM-2	CD102
				ICAM-3	CD50
				Adhesion, diapedesis	JAM-A
Mac-1	CD11b/CD18	PMN, Mo, NK	Tight adhesion	ICAM-1	CD54
VLA-4	CD49d/CD29	Mo, B, Eo† > NK, T	Tight adhesion [§] Rolling	VCAM-1	CD106

CD99	CD99	All leukocytes to varying degrees	Diapedesis	CD99	CD99
JAM-C?	Pending	T	Diapedesis	JAM-C?	Pending

B, B lymphocytes; CLA, cutaneous lymphocyte antigen; Eo, eosinophils; ESL-1, E-selectin ligand; GP, glycoprotein; ICAM, intercellular adhesion molecule; JAM, junctional adhesion molecule; MAdCAM-1, mucosal addressin cell-adhesion molecule; Mo, monocytes; NK, natural killer cells; PECAM, platelet endothelial adhesion molecule; PMN, polymorphonuclear neutrophils; PSGL, P-selectin glycoprotein ligand; T, T lymphocytes; VCAM, vascular cell adhesion molecule; VLA, very-late antigen.

PMN, neutrophils; *MAdCAM-1 and CD34 have been shown to be important for homing of T cells to lymph nodes via high endothelial venules. The protein structures bearing the L-selectin ligands, including CD15s, at sites of inflammation have not been identified.

†ESL-1, a protein with homology to fibroblast growth factor receptor, has been identified in mice. CLA, a molecule on the surface of skin-homing T cells related to PSGL-1, directs them to skin via E-selectin expressed on dermal venules.

‡Expression of VLA-4 on granulocytes is limited to eosinophils and basophils. Adult human neutrophils do not express it under normal circumstances.

§Although VLA-4/VCAM-1 interactions are generally thought to be important for tight adhesion of leukocytes to endothelium, there are reports^{319,320} that leukocytes can use VLA-4 to roll on endothelial VCAM-1, as well.

between leukocytes and endothelial cells regulate transendothelial migration for the vast majority of neutrophils, monocytes, and natural killer (NK) cells. Transendothelial migration and the nomenclature of the junctional adhesion molecule (JAM) family are reviewed elsewhere.^{17,259,260} PECAM/CD31 on the leukocyte contacts the same molecule concentrated at the endothelial junctions in a homophilic manner.^{261–263} Although the relevant signal(s) transduced by this interaction remain unclear, a transient rise in endothelial cell intracellular calcium is required for transmigration.²⁶⁴ Blocking the function of either leukocyte PECAM or endothelial cell PECAM arrests the leukocyte poised over the junction,^{263,265,266} a phenotype very similar to that seen when the rise in intracellular calcium is blocked by the chelator, bis(2-amino-5-methylphenoxy)ethane-*N,N,N',N'*-tetraacetic acid tetraacetoxymethyl ester (MAPTAM).²⁶⁴

Because anti-PECAM reagents never block diapedesis completely, PECAM-independent pathways of transendothelial migration must exist. The leukocyte integrins $\alpha_4\beta_1$ (very-late antigen [VLA]-4) and $\alpha_1\beta_2/\alpha_M\beta_2$ (lymphocyte function-associated antigen [LFA]-1/macrophage [Mac]-1) and their endothelial counter-receptors VCAM-1 and ICAM-1, have been implicated in transmigration.²⁵⁴ Interaction of leukocyte LFA-1 with JAM-A on endothelial cells has also been implicated in leukocyte recruitment.²⁶⁷ Antibodies directed against JAM-C also blocked migration of lymphocytes across endothelial cell monolayers, implicating its role in lymphocyte migration.²⁶⁸ In addition, under certain specialized conditions, there appear to be pathways across the endothelial cell that bypass the intercellular junction.^{269,270}

CD99 is a GP expressed on leukocytes, platelets, and erythrocytes, and concentrated at the endothelial cell borders. CD99 controls a step in diapedesis distal to the step controlled by PECAM both *in vitro* and *in vivo*,^{271–273} by interfering with homophilic interaction between leukocyte CD99 and endothelial cell CD99-arrested monocytes. Their leading edges were below the endothelial cell monolayer, while their trailinguropods remained on the apical surface of the endothelial cell.

At the onset of most acute inflammatory responses, vascular permeability transiently increases as a result of histamine release. The endothelial junctions are soon re-established, and the junctions are closed to the leukocytes that arrive at the scene over the next hour. Studies performed both *in vivo* and *in vitro* indicate that, during subsequent diapedesis, leukocytes penetrate the vessel wall without further compromising the vascular permeability barrier.^{264,274} Cortactin-deficient mice, for example, have constitutively leaky vascular junctions in the postcapillary venule circulation, and an exaggerated response to histamine, yet leukocyte recruitment is diminished because of inefficient clustering of ICAM-1,²⁷⁵ which prevents exposure of subendothelial collagen and VWF deposits to circulating platelets. Although PECAM-1 has no known role in binding platelets to endothelial cells, it has been hypothesized to maintain the tight apposition of endothelial cells and leukocytes during diapedesis.²⁶³

ACUTE CHANGES

In addition to stimulating endothelial cell immediate responses, cytokines and inflammatory mediators released at the site of inflammation activate new endothelial cell genetic programs. Within several hours of exposure to mediator, *de novo* synthesis of mRNA and protein establishes an inflammatory endothelial cell phenotype that is both procoagulant and proadhesive.

Inflammatory cytokines such as TNF- α and IL-1 induce endothelial cell surface expression of several important CAMs. Expression of E-selectin peaks at 4 to 6 hours *in vitro*, but may be maintained by interferon (IFN)- γ for several days *in vivo*.^{276,277} E-selectin mediates the slow rolling of leukocytes bearing sialylated, fucosylated carbohydrate

receptors similar to sialylated Lewis X antigen.²⁷⁸ Endothelial cell P-selectin stimulated by thrombin or histamine is transient, but can be prolonged to hours or days by IL-3, IL-4, or oncostatin M stimulation of human endothelium, and by TNF- α stimulation of murine, but not human endothelium.^{279–282}

In general, expression of the immunoglobulin superfamily members ICAM-1 and VCAM-1 is induced by the same stimuli that induce E-selectin. Some specializations exist, at least *in vitro*. For example, IL-4 induces VCAM-1 but not E-selectin or ICAM-1 in microvascular endothelial cells.^{283,284} These molecules serve as counter-receptors for the leukocyte integrins in the tight adhesion step.

CHRONIC CHANGES

Stimulation of endothelial cells over several days with IFN- γ leads to surface expression of MHC class II molecules (human leukocyte antigen [HLA]-DR and -DQ). In human tissues such as skin and gut, class II is commonly seen even in the absence of overt inflammation, and is thought to be a result of chronic exposure of these sites to subclinical inflammation and antigenic stimulation. When costimulatory molecules such as CD40, ICAM-1, or LFA-3 are induced by inflammatory stimuli, the endothelial cell becomes capable (at least *in vitro*) of acting as an antigen presenting cell that can stimulate CD4+ memory T cells. This mechanism may stimulate graft rejection by the host when the endothelium belongs to an organ graft with foreign MHC class II.^{285–287}

In contrast, the expression of the adhesion molecule ICAM-2 does not change in response to inflammatory mediators. PECAM-1 shows a unique expression pattern in response to IFN- γ *in vitro*²⁸⁸ and *in vivo*,²⁸⁹ as its distribution becomes diffuse over the surface of the cell, rather than being concentrated at intercellular borders. *In vitro* chronic exposure of human umbilical vein endothelial cells to a combination of IFN- γ and TNF- α at relatively high doses leads to a decrease in total PECAM-1 expression.²⁹⁰ Such a response has not been described to date *in vivo*.

ADHESION MOLECULES IN A THROMBOTIC MILIEU

Activation of the hemostatic system exposes leukocytes to ligands that promote their adhesion and recruitment to the vessel wall. For example, *in vitro* thrombin induces E-selectin expression and IL-8 secretion by human umbilical vein endothelial cells.²⁹¹ These changes are classically induced by inflammatory cytokines such as IL-1 and TNF- α . Table 115–5 lists some mediators that could have dual roles in inflammation and hemostasis/thrombosis.

LEUKOCYTE–PLATELET AND ENDOTHELIAL CELL–PLATELET INTERACTIONS

Activated platelets bind to circulating lymphocytes in a P-selectin-dependent manner. This interaction can facilitate leukocyte rolling on the endothelium²⁹² and also allows homing of lymphocytes to peripheral lymph nodes in the absence of L-selectin, because P-selectin on the adherent platelets will interact with the peripheral lymph node addressin.²⁹³ *In vitro*, neutrophils are capable of rolling on immobilized platelets via PSGL-1 on the leukocyte interacting with degranulated P-selectin on the platelet membranes.²⁹⁴ Moreover, $\alpha_M\beta_2$ (CD11b/CD18)-dependent arrest and tight adhesion of neutrophils to bound platelets following P-selectin-dependent rolling has been described.^{294,295} The endothelial ligand for this is not known. ICAM-2 has been found on the surface of activated platelets, but it is not a ligand for $\alpha_M\beta_2$. In

TABLE 115-5. Dual Roles of Inflammatory Mediators in Thrombosis and Hemostasis

Mediator	Role in Inflammation	Role in Thrombosis or Hemostasis
Histamine, thrombin	P-selectin expression induced on vascular endothelium	Degranulation of Weibel-Palade bodies; extrusion of VWF
Platelet-activating factor	Activation of leukocyte integrins	Activation of platelets
Expression of P-selectin glycoprotein ligand 1 (PSGL-1)	Adhesion of leukocytes to endothelial P-selectin	Adhesion of platelets to adherent leukocytes via P-selectin bidirectionally
Adherent platelets	Leukocyte rolling on platelet P-selectin; tight adhesion to platelet membrane component	Thrombosis
Fibrinogen	Adhesion of leukocytes to fibrinogen via CD11b/CD18	Bridging of platelets to VWF and matrix via α_{IIb}/β_{III}
Thrombin	Induction of E-selectin expression and IL-8 secretion by endothelial cells	Fibrinogen formation and platelet aggregation
Leukocyte Integrin CD11b/CD18	Adhesion of leukocytes to endothelium; phagocytosis CD11b/CD18	Binding and activation of factor X, adhesion of platelets via GPIIb; adhesion of platelets via JAM-C

GP, glycoprotein; IL, interleukin; JAM, junctional adhesion molecule; VWF, von Willebrand factor.

fact, antibodies against neither ICAM-2 nor its neutrophil receptor α_L (CD11) blocked this adhesion.^{295,296} On the other hand, neutrophil $\alpha_M\beta_2$ reportedly binds to fibrinogen, which may be present on the surfaces of activated platelets bound to $\alpha_{IIb}\beta_3$ (GPIIb/IIIa). Two additional platelet surface molecules, GPIIb and JAM-C, have been demonstrated as ligands for leukocyte CD11b/CD18. GPIIb is part of the GP1b-IX-V complex,^{297,298} and JAM-C was originally described as a component of epithelial and endothelial cell tight junctions.

Platelets can interact with activated endothelial cells. Platelets express PSGL-1 and can use this expression to interact with P-selectin on the surfaces of activated endothelial cells.²⁹⁹ Activated platelets can also bind to endothelial cells via fibrinogen, fibrin, or VWF, forming a molecular bridge between platelet GPIIb/IIIa and endothelial cell integrin $\alpha\beta_3$ and ICAM-1.

Ultralarge VWF molecules are stored in Weibel-Palade bodies and released upon inflammatory endothelial cell activation. Ultralarge VWF molecules are normally cleaved by endothelial cell-surface proteases, notably the metalloprotease ADAMTS13 (a disintegrin and metalloprotease with thrombospondin repeats 13). Data in mice suggest that ADAMTS13 plays a homeostatic role in dampening inflammation.³⁰⁰ In ADAMTS13-deficient mice, platelets bound to ultralarge VWF molecules on the endothelial surface and supported slower leukocyte rolling on venules at rest and greater leukocyte extravasation in models of inflammation.³⁰⁰

LEUKOCYTE-ENDOTHELIAL CELL MATRIX INTERACTIONS THAT PROMOTE COAGULATION

The same proinflammatory stimuli that stimulate *de novo* expression of E-selectin and VCAM-1, and augment expression of ICAM-1 for the recruitment of leukocytes, may stimulate synthesis and expression of TF by endothelial cells.³⁰¹ Furthermore, adhesion of monocytic cell lines to cytokine-activated endothelial cells in culture leads to rapidly increased TF-related procoagulant activity. This effect is partially blocked by a monoclonal antibody directed against E-selectin on endothelium and is mimicked by crosslinking Le^x on the monocyte cell lines.³⁰² A similar increase in TF gene expression can be induced by crosslinking α_4 or β_1 integrin chains, the components of VLA-4 on monocytic cell lines.³⁰³

During prolonged interaction of peripheral blood monocytes with human endothelial cells, monocytes that migrated across endothelial cell monolayers expressed functional cell surface TF.³⁰⁴ Over the next several days, approximately half of these monocytes differentiated into immature dendritic cells bearing even higher levels of TF, and migrated back across the intact endothelial cell monolayer. This migration could be blocked by soluble fragments of TF. Therefore, in this system, TF was hypothesized to support both adhesion and a possible procoagulant role.³⁰⁴

Leukocytes that bind to P-selectin exposed on the surfaces of platelets on adherent thrombi promote the conversion of fibrinogen to fibrin.³⁰⁵ The leukocyte integrin CD11b/CD18 has been shown to bind fibrinogen.³⁰⁶ The same integrin has a conformational form that binds coagulation factor X.³⁰⁷ Monocytic cells are capable of activating the bound factor X to factor Xa when activated,³⁰⁸ defining a pathway for activation of factor X that is independent of TF.

CHAPTER 116

CLASSIFICATION, CLINICAL MANIFESTATIONS, AND EVALUATION OF DISORDERS OF HEMOSTASIS

Marcel Levi, Uri Seligsohn, and Kenneth Kaushansky

SUMMARY

Evaluation of a hemostatic disorder is commonly initiated when (1) a patient or referring physician suspects a bleeding tendency, (2) a bleeding tendency is discovered in one or more family members, (3) an abnormal coagulation assay result is obtained from an individual as part of a routine examination, (4) an abnormal assay result is obtained from a patient during preparation for surgery, or (5) a patient has unexplained diffuse bleeding during or after surgery or following trauma. Evaluation of a possible hemostatic disorder in each of these scenarios is a stepwise process that requires knowledge of the various classes of hemostatic disorders commonly found under the particular circumstances. The patient's history, the results of physical examination, and an initial set of hemostatic tests usually enable a tentative diagnosis. However, more specific tests are commonly necessary to make a definitive diagnosis. This chapter reviews the necessary steps.

CLASSIFICATION OF HEMOSTATIC DISORDERS

Hemostatic disorders can conveniently be classified as either hereditary or acquired (Table 116-1). Alternatively, hemostatic disorders can be classified according to the mechanism of the defect. Of the acquired disorders, the thrombocytopenias are the most frequently encountered entities. Thrombocytopenias can result from reduced production of platelets, excessive destruction caused by antibodies or other consumptive processes, or pooling of platelets in the spleen, as in hypersplenism (Chap. 119); however, if hypersplenism is the sole cause of a hemostatic disorder, it is rarely severe enough to cause pathologic bleeding.

BLEEDING HISTORY

The bleeding history is a crucial element in the evaluation of a patient with a hemorrhagic disorder. The bleeding history helps define the subsequent diagnostic approach and the likelihood of future bleeding.

Acronyms and Abbreviations: aPTT, activated partial thromboplastin time; DIC, disseminated intravascular coagulation; ELISA, enzyme-linked immunosorbent assay; PT, prothrombin time; RCF, ristocetin cofactor.

Eliciting and interpreting all of the relevant information requires a systematic and methodical approach. The following points are worth considering:

1. Patients vary in their responses to hemorrhagic symptoms. Some patients ignore significant symptoms, whereas other patients are highly sensitive to even minor symptoms. When asked in standardized questionnaires, many normal, healthy people indicate they have excessive bleeding or bruising.^{1,2} Therefore, some experts believe the question "Do you bruise easily?" is virtually worthless. Women are more likely to respond that they have excessive bleeding or bruising than are men.
2. Patients with severe hemorrhagic disorders invariably have very abnormal bleeding histories, for example, severe hemophilia A or hemophilia B, type 3 (homozygous) von Willebrand disease, and Glanzmann thrombasthenia. Importantly, these patients may experience spontaneous bleeding episodes.
3. The diagnostic value of any specific symptom varies in the different disorders. Therefore, recognizing typical patterns of bleeding is important (Table 116-2). Unprovoked hemarthroses and muscle hemorrhages suggest one of the hemophilias, whereas mucocutaneous bleeding (epistaxis, gingival bleeding, menorrhagia) are more characteristic of patients with qualitative platelet disorders, thrombocytopenia, or von Willebrand disease.
4. Assessing the extent of hemorrhage against the background of any trauma or provocation that may have elicited the hemorrhage is important. If a patient has never had a significant hemostatic challenge, such as tooth extraction, surgery, trauma, or childbirth, the lack of a significant bleeding history is much less valuable in excluding a mild hemorrhagic disorder. For example, a significant percentage of patients with mild von Willebrand disease or mild forms of hemophilia may have negative bleeding histories,¹ even though they may be at considerable risk for excessive bleeding after surgery or other interventions. Thus, these diagnoses must be considered even in elderly patients if their first severe hemostatic challenge occurs at that age.
5. Obtaining objective confirmation of the subjective information conveyed in the bleeding history is valuable. Objective data include (1) previous hospital or physician visits for bleeding symptoms, (2) results of previous laboratory evaluations, (3) previous transfusions of blood products for bleeding episodes, and (4) a history of anemia and/or previous treatment with iron.
6. Although self-administered questionnaires may provide useful background information, they cannot substitute for a dialogue between the physician and the patient. Thus, history taking in general, but especially in the often subtle histories related to hemostatic disorders, is an intellectually active process involving data collection, hypothesis development, new question formulation, additional data gathering, and new hypothesis development. However, this iterative procedure has its limitations even when it is carefully pursued.^{3,4}
7. A medication history is a crucial component of the bleeding history, with particular attention to nonprescription drugs, such as aspirin and nonsteroidal antiinflammatory agents, which may affect bleeding symptoms. A medication history is especially important in patients with thrombocytopenia, because drug-induced thrombocytopenia is common (Chap. 120 and see Table 116-1). Medication also may affect hemostasis through deleterious effects on the liver or kidney functions. The increased use of herbal and alternative medicines poses particular problems, because patients may not readily share information about what they are taking, and the dose they are taking of any particular active ingredient may

TABLE 116-1. Classification of Disorders of Hemostasis

Major Types	Disorders	Examples
Acquired	Thrombocytopenias	Autoimmune and alloimmune, drug-induced, hypersplenism, hypoplastic (primary, myelosuppressive therapy, myelophthitic marrow infiltration), disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura, hemolytic-uremic syndrome (Chaps. 117, 129, and 132)
	Liver diseases	Cirrhosis, acute hepatic failure, liver transplantation (Chap. 128), thrombopoietin deficiency
	Renal failure	
	Vitamin K deficiency	Malabsorption syndrome, hemorrhagic disease of the newborn, prolonged antibiotic therapy, malnutrition, prolonged biliary obstruction
	Hematologic disorders	Acute leukemias (particularly promyelocytic), myelodysplasias, monoclonal gammopathies, essential thrombocythemia (Chaps. 85–87 and 106)
	Acquired antibodies against coagulation factors	Neutralizing antibodies against factors V, VIII, and XIII, accelerated clearance of antibody-factor complexes, e.g., acquired von Willebrand disease, hypoprothrombinemia associated with anti-phospholipid antibodies (Chaps. 126, 127, and 131)
	DIC	Acute (sepsis, malignancies, trauma, obstetric complications) and chronic (malignancies, giant hemangiomas, retained products of conception) (Chap. 129)
	Drugs	Antiplatelet agents, anticoagulants, antithrombins, and thrombolytic, hepatotoxic, and nephrotoxic agents (Chaps. 25 and 133–135)
Inherited	Vascular	Nonpalpable purpura (“senile,” solar, and factitious purpura), use of corticosteroids, vitamin C deficiency, child abuse, thromboembolic, purpura fulminans; palpable-purpura (Henoch-Schönlein, vasculitis, dysproteinemias; Chap. 122), amyloidosis
	Deficiencies of coagulation factors	Hemophilia A (factor VIII deficiency), hemophilia B (factor IX deficiency), deficiencies of fibrinogen factors II, V, VII, X, XI, and XIII and von Willebrand disease (Chaps. 123–126)
	Platelet disorders	Glanzmann thrombasthenia, Bernard-Soulier syndrome, platelet granule disorders (Chap. 120)
	Fibrinolytic disorders	α_2 -Antiplasmin deficiency, plasminogen activator inhibitor-1 deficiency (Chap. 135)
	Vascular	Hemorrhagic telangiectasias (Chap. 122)
Connective tissue disorders	Ehlers-Danlos syndrome (Chap. 122)	

be difficult to determine. *Ginkgo biloba* and ginseng are the most commonly used herbals that can cause platelet dysfunction and induce bleeding.⁵ Other dietary supplements can display similar effects.^{5,6}

8. A nutrition history should be obtained to assess the likelihood of (1) vitamin K deficiency, especially if the patient also is taking broad-spectrum antibiotics, (2) vitamin C deficiency, especially if the patient has skin bleeding consistent with scurvy (perifollicular purpura), and (3) general malnutrition and/or malabsorption.
9. Several tissues have an increased local fibrinolytic activity. Such tissues include the urinary tract, endometrium, and mucous membranes of the nose and oral cavity. These sites are particularly likely to have prolonged oozing of blood after trauma in patients with hemostatic abnormalities. Excessive bleeding following tooth extraction is one of the most common manifestations. Bleeding resulting from defects in fibrin crosslinking (factor XIII deficiency) or fibrinolytic defects may often manifest as delayed bleeding after trauma.
10. Bleeding isolated to a single organ or system (e.g., hematuria, hematemesis, melena, hemoptysis, or recurrent nosebleeds) is less likely to result from a hemostatic abnormality than from a local cause such as neoplasm, ulcer, or angiodysplasia. Thus, careful anatomic evaluation of the involved organ or system should be performed.
11. Bleeding may result from blood vessel disorders such as hereditary hemorrhagic telangiectasias, Cushing disease, scurvy, or Ehlers-Danlos syndrome. Many primary dermatologic disorders also have a purpuric or hemorrhagic component and must also be considered in the differential diagnosis (Chap. 122).
12. A family history is particularly important when hereditary disorders are considered. Patients usually will not spontaneously offer a history of consanguinity, so specific inquiry should be made about this possibility. A diagram of the patient's genealogic tree, extending back at least two generations, should be included to document consideration of genetic disorders. A sex-linked pattern of inheritance is consistent with hemophilia A or B (Chap. 123). An autosomal dominant pattern is characteristic of most forms of von Willebrand disease (Chap. 126). An autosomal recessive pattern is typical for all other coagulation factor deficiencies (Chap. 124), inherited platelet disorders (Chap. 120), and the rare, severe (homozygous), type 3 von Willebrand disease. Population genetic information may be helpful; for example, the higher prevalence of factor XI deficiency in Ashkenazi Jews (Chap. 124).
13. The history should include information on diseases and organs that may affect hemostasis, such as cirrhosis, renal insufficiency, myeloproliferative neoplasms (e.g., essential thrombocythemia), acute leukemia, myelodysplasia, systemic lupus erythematosus, and Gaucher disease.

TABLE 116-2. Clinical Manifestations Typically Associated with Specific Hemostatic Disorders

Clinical Manifestations	Hemostatic Disorders
Mucocutaneous bleeding	Thrombocytopenias, platelet dysfunction, von Willebrand disease
Cephalhematomas in newborns, hemarthroses, hematuria, and intramuscular, intracerebral, and retroperitoneal hemorrhages	Severe hemophilias A and B, severe deficiencies of factor VII, X, or XIII, severe type 3 von Willebrand disease, afibrinogenemia
Injury-related bleeding and mild spontaneous bleeding	Mild and moderate hemophilias A and B, severe factor XI deficiency, moderate deficiencies of fibrinogen and factors II, V, VII, or X, combined factors V and VIII deficiency, α_2 -antiplasmin deficiency
Bleeding from stump of umbilical cord and habitual abortions	Afibrinogenemia, hypofibrinogenemia, dysfibrinogenemia, factor XIII deficiency
Impaired wound healing	Factor XIII deficiency
Facial purpura in newborns	Glanzmann thrombasthenia, severe thrombocytopenia
Recurrent severe epistaxis and chronic iron deficiency anemia	Hereditary hemorrhagic telangiectasias

CLINICAL MANIFESTATIONS

Individual hemorrhagic symptoms often require detailed analysis before the significance of the symptoms and the resulting diagnosis or therapy can be determined. Some of the more common symptoms are discussed below, and Table 116–2 summarizes clinical manifestations that are typical for specific hemostatic disorders.

1. Epistaxis is one of the most common signs of platelet disorders and von Willebrand disease. It also is the most common symptom of hereditary hemorrhagic telangiectasia. In the latter condition, epistaxis almost always becomes more severe with advancing age. Epistaxis is not uncommon in normal children, but it usually resolves before puberty. Dry air heating systems can provoke epistaxis even in otherwise normal individuals. Bleeding confined to a single nostril more likely results from a local vascular problem than a systemic coagulopathy.
2. Gingival hemorrhage is very common in patients with both qualitative and quantitative platelet abnormalities and von Willebrand disease. Occasional gum bleeding occurs in normal individuals, especially if they use a hard bristle tooth brush and dental hygiene procedures. Thus, establishing whether the bleeding is excessive may be difficult. Frequent gingival hemorrhage can occur in individuals with normal hemostasis if they have gingivitis.
3. Oral mucous membrane bleeding in the form of blood blisters is a common manifestation of severe thrombocytopenia. Such bleeding usually has a predilection for sites where teeth can traumatize the inner surface of the cheek.
4. Skin hemorrhage in the form of petechiae and ecchymoses are common manifestations of hemostatic disorders. However, skin hemorrhage also is common among individuals without hemostatic

disorders. Excessive bruising is more common in women than men. Moreover, women frequently note that the severity of their bruising varies with the phase of their menstrual cycle, although the most severe phase of the cycle may differ in different women. Features that help establish the severity of skin hemorrhage include the size of the bruises, the frequency of bruising, whether the bruises occur spontaneously or only with trauma, and the appearance of bruises on regions of the body that usually are not traumatized, such as the trunk and back. The color of the bruise may yield information. Red bruises on the extensor surfaces of the arms and hands indicate loss of supporting tissues, as occurs in Cushing syndrome, glucocorticoid therapy, senile purpura, and damage from chronic sun exposure. Jet-black bruises may be caused by warfarin-induced skin necrosis and similar disorders. Easy bruising can also occur in patients with Ehlers-Danlos syndrome manifested by distensible skin or extraordinary ligament laxness, and in patients with hyperflexibility of the thumb.⁸

5. Tooth extractions are common hemostatic challenges and may be helpful in defining the risk of bleeding. Molar extractions are greater hemostatic challenges than extractions of other teeth. Objective data regarding excessive bleeding based on the need for blood products or the need to pack or suture the extraction site are valuable.
6. Excessive bleeding in response to razor nicks is common in patients with platelet disorders or von Willebrand disease.
7. Hemoptysis almost never is the presenting symptom of a bleeding disorder and is rare even in patients with serious bleeding disorders. However, blood-tinged sputum in association with upper respiratory tract infections may be more common in patients with hemostatic disorders.
8. Hematemesis, like hemoptysis, almost never is the presenting symptom of a hemostatic disorder. However, a hemostatic disorder may lead to hematemesis because of an anatomic abnormality in the upper gastrointestinal tract and bleeding may be more severe than expected. Some hemostatic disorders more likely result in hematemesis because of a combination of effects, such as liver disease with deficient synthesis of coagulation proteins and with esophageal varices and aspirin ingestion with gastritis.
9. Hematuria is rarely the presenting symptom of a hemostatic disorder except for the hemophilias. However, hemostatic disorders can exacerbate hematuria caused by other disorders, including simple urinary tract infections.
10. Rectal bleeding in individuals with normal hemostasis most often results from hemorrhoids. However, von Willebrand disease and platelet disorders may contribute to repeated episodes of rectal bleeding when associated with a number of different underlying causes, including diverticula, hemorrhoids, or angiodysplasia. Melena is also only rarely the presenting symptom of a hemorrhagic disorder. However, repeated episodes of melena may occur in patients with hemorrhagic disorders.
11. Menorrhagia is common in women with platelet disorders and von Willebrand disease. In general, menstrual bleeding is considered excessive if the patient indicates she has heavy flow for more than 3 days or total flow for more than 7 days. However, an objective distinction between menorrhagia (loss of more than 80 mL blood per period) and normal blood loss can only be made by a visual assessment technique using pictorial charts of towels or tampons.⁷
12. Postpartum hemorrhage. Childbirth poses a considerable hemostatic challenge. Consequently, patients with bleeding disorders commonly manifest excessive bleeding during or after labor necessitating blood transfusion. An exception may be mild and moderate von Willebrand disease due to the vast increase in von Willebrand factor during pregnancy.

13. Habitual spontaneous abortions raise the possibility that the patient has a quantitative or qualitative abnormality of fibrinogen (Chap. 125), factor XIII deficiency (Chap. 124), or the antiphospholipid syndrome (Chap. 131). There is also an association between infertility and spontaneous abortion in patients with inherited thrombophilia (Chap. 130).
14. Hemarthroses are the hallmark abnormality in the hemophilic; they are rare in other disorders except in severe factor VII deficiency and type 3 von Willebrand disease (Chaps. 124 and 126). Because discoloration of the skin overlying the joint with hemarthroses does not occur, patients may not recognize that their symptoms (pain, swelling, and limitation of motion) are caused by bleeding into their joints.
15. Excessive hemorrhage associated with surgical procedures is common in patients with hemorrhagic disorders. Procedures involving tissues with increased local fibrinolytic activity like urinary tract, nose, tonsils and oral cavity are particularly prone to bleed.
16. Excessive bleeding following circumcision is common in males with severe hemostatic disorders such as hemophilia A, hemophilia B, or Glanzmann thromboasthenia, and often is the patient's first symptom.
17. Bleeding from the umbilical stump is characteristic of factor XIII deficiency (Chap. 124) and afibrinogenemia (Chap. 125).

PHYSICAL EXAMINATION

Physical examination is essential for identifying signs of bleeding or their sequelae and for signs of a possible underlying disorder that can cause the hemostatic derangement (see Table 116-1). Careful examination of the skin is essential for detecting petechiae and ecchymoses. These signs may be prominent on the legs, where the hydrostatic pressure is greatest, or around the hair follicles in vitamin C deficiency.

Telangiectasias may range from pinpoint erythematous dots that blanch with pressure to classic cherry angiomas ranging in size up to several centimeters. Many normal individuals develop increasing numbers of telangiectasias with aging. Patients with hereditary hemorrhagic telangiectasia have more florid lesions that characteristically affect the vermilion border of the lips and the tongue (including the underside of the tongue), but not all patients have these classic features. Thus, a systematic search of the integument is necessary. Spider telangiectasias found in patients with chronic liver disease have a more splotchy and serpiginous appearance than the telangiectasias associated with hereditary hemorrhagic telangiectasia. In addition, the telangiectasias tend to be concentrated on the shoulders, chest, and face.

Chapter 122 details the differential diagnosis of nonpalpable purpuras and palpable purpuras. Hematomas, ecchymoses, and protracted oozing should be sought at venipuncture sites, injection sites, and arterial and venous catheter insertion sites. Joint deformities and limited joint mobility are suggestive of severe hemophilia A or B, severe deficiency of factor VII, or type 3 von Willebrand disease (Chaps. 123, 124, and 126). Hyperelasticity of the skin and hyperextensibility of joints are typical of Ehlers-Danlos syndrome, and hyperextensibility of only the thumb probably is a variant.⁸

EVALUATION BASED ON BLEEDING HISTORY, PHYSICAL EXAMINATION, AND BASIC LABORATORY TESTS

The patient's history and results of physical examination provide important information on the likelihood of the patient having a hemostatic defect and the possible cause of the defect, if one is present.

However, performing an initial set of widely available and inexpensive tests, including prothrombin time (PT), activated partial thromboplastin time (aPTT), and platelet count, is important for the following reasons: (1) The patient's history sometimes is unreliable; (2) the patient may have a mild hemostatic abnormality that has not manifested itself for lack of hemostatic challenge; (3) the patient may have developed an acquired hemostatic defect that has remained asymptomatic; and (4) the tests may reveal more than one abnormality.⁹

Figure 116-1 shows a series of algorithms that integrate the patient's bleeding history and the results of the initial hemostatic tests. A prolonged aPTT as a sole abnormality can be caused by a deficiency of factor VIII, IX, XI, or XII; presence of heparin; or by an inhibitor, which can be either factor specific, such as an antibody against factor VIII, or factor nonspecific, such as the presence of heparin or a lupus anticoagulant (Fig. 116-1A). A prolonged PT as the sole finding can indicate a factor VII deficiency, a mild vitamin K deficiency, or the presence of an inhibitor (Fig. 116-1B). Abnormalities of both PT and aPTT may indicate a deficiency of fibrinogen, prothrombin, factor V or factor X, an inhibitor to one of these factors, or a combined deficiency of coagulation factors (Fig. 116-1C).

To distinguish between a deficiency state and the presence of an inhibitor, repeating the abnormal test, the PT and/or aPTT, using a 1:1 mixture of the patient's plasma and normal plasma is useful. If the mixture normalizes the prolonged PT or aPTT, a deficiency state is likely, as most coagulation tests are calibrated to produce a normal result if each of the relevant factor levels are 50 percent of normal or greater. If the mixture still yields a significantly prolonged PT or aPTT, an inhibitor probably is present. Some inhibitors, such as antibodies to factor VIII, require time to inhibit the factor VIII activity in the assay, whereas other inhibitors, such as lupus anticoagulant or heparin, do not. Consequently, incubating the mixture for 1 or 2 hours at 37°C before performing the coagulation assay is desirable.

When none of the initial test results (PT, aPTT, and platelet count) is abnormal and the patient exhibits bleeding manifestations, ristocetin cofactor (RCF) or von Willebrand factor activity and examination of the blood film can be helpful for distinguishing among various candidate hemostatic abnormalities. The bleeding time is not used anymore because the test is highly operator and situational (room temperature, skin circulation, etc.) dependent and is not sufficiently reliable to be useful in the diagnostic process. Instead, many laboratories have introduced the platelet function analyzer (PFA) to detect qualitative defects in primary hemostasis. Figure 116-2 shows an algorithm that includes these secondary tests. Patients with type 1 and type 2 von Willebrand disease often have normal findings on initial laboratory tests because factor VIII levels are sufficiently high (>30 U/dL) for a normal aPTT result (Chap. 126). Examination of the blood film is helpful for distinguishing between Bernard-Soulier syndrome and von Willebrand disease because giant platelets are characteristic of the former (Chap. 120). Distinguishing mild-type von Willebrand disease from normal is difficult because levels of von Willebrand factor in the normal population is highly variable, partly accounted for by differing von Willebrand factor levels in individuals with different ABO blood types. In fact, some investigators have questioned whether patients with von Willebrand factor levels as low as 35 percent should be labeled as having von Willebrand disease.¹⁰ The likelihood of having von Willebrand disease is a function of bleeding history, the von Willebrand factor level, and the number of first-degree family members with reduced von Willebrand factor levels.¹¹

The ristocetin-induced platelet aggregation test is useful for distinguishing type 2B and platelet-type von Willebrand disease from the other types of von Willebrand disease. In type 2B and platelet-type von Willebrand disease, an enhanced response to low concentrations

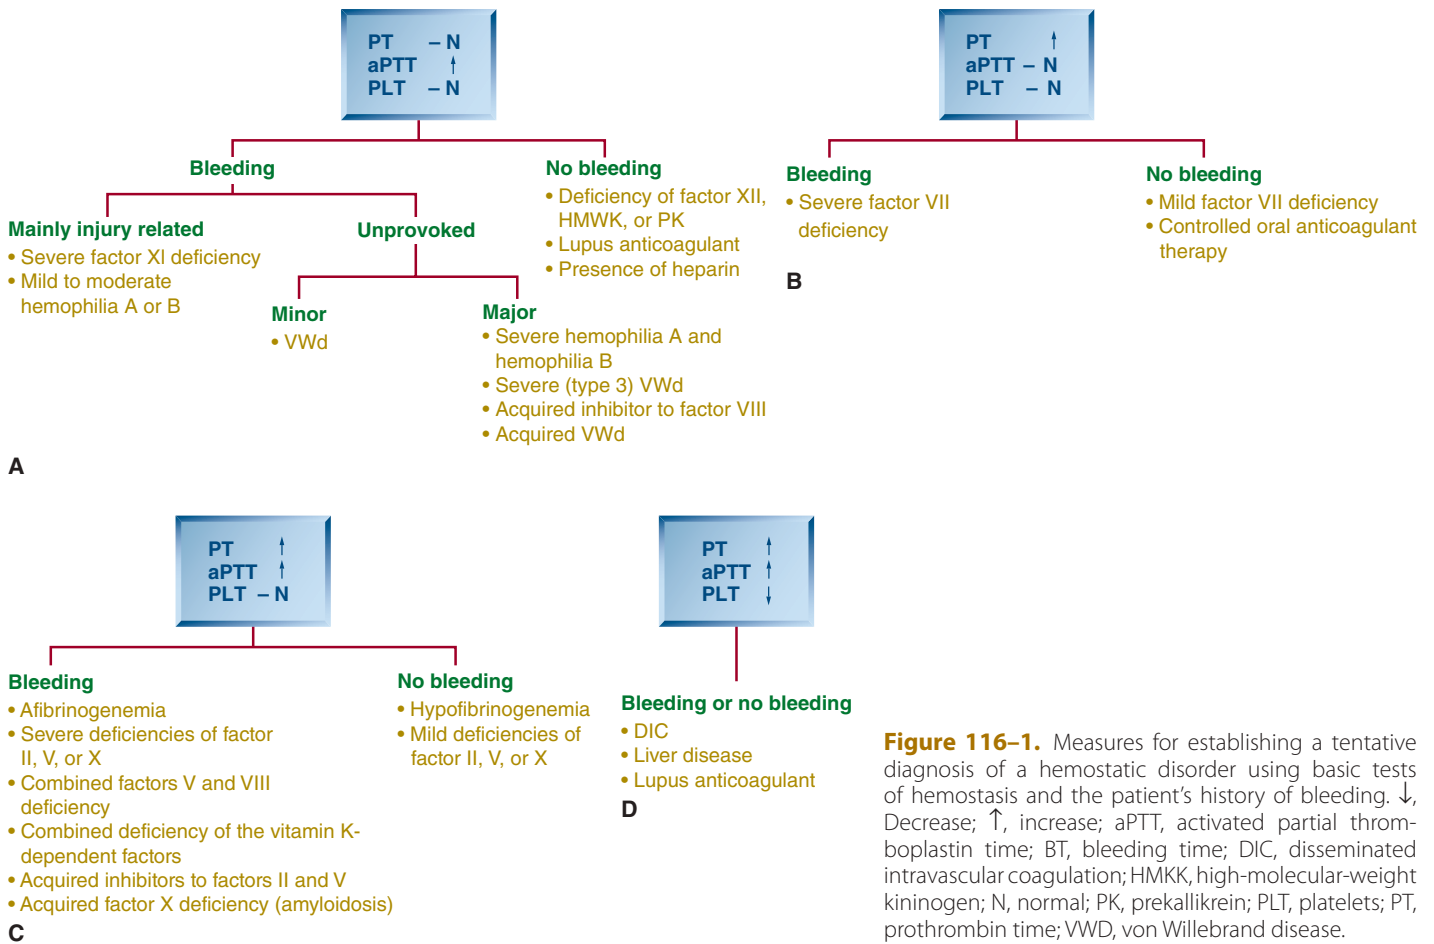

Figure 116-1. Measures for establishing a tentative diagnosis of a hemostatic disorder using basic tests of hemostasis and the patient's history of bleeding. ↓, Decrease; ↑, increase; aPTT, activated partial thromboplastin time; BT, bleeding time; DIC, disseminated intravascular coagulation; HMWK, high-molecular-weight kininogen; N, normal; PK, prekallikrein; PLT, platelets; PT, prothrombin time; VWD, von Willebrand disease.

of ristocetin is observed, whereas in the other types of von Willebrand disease, a decreased response is found. Total absence of platelet aggregates in a blood film prepared from non-anticoagulated blood and absent clot retraction are characteristic of Glanzmann thrombasthenia (Chap. 120).

Another simple test that may be useful for distinguishing among hemostatic disorders is the thrombin time (i.e., time for plasma to clot

after adding thrombin). The thrombin time is prolonged in (1) afibrinogenemia, hypofibrinogenemia, and dysfibrinogenemias (Chap. 125), (2) the presence of heparin, (3) disseminated intravascular coagulation (DIC) causing increased levels of fibrin(ogen) degradation products, which inhibit fibrin monomer polymerization (see Fig. 116-1D and Chap. 129), and (4) patients with amyloidosis and an immunoglobulin inhibitor of thrombin.¹²

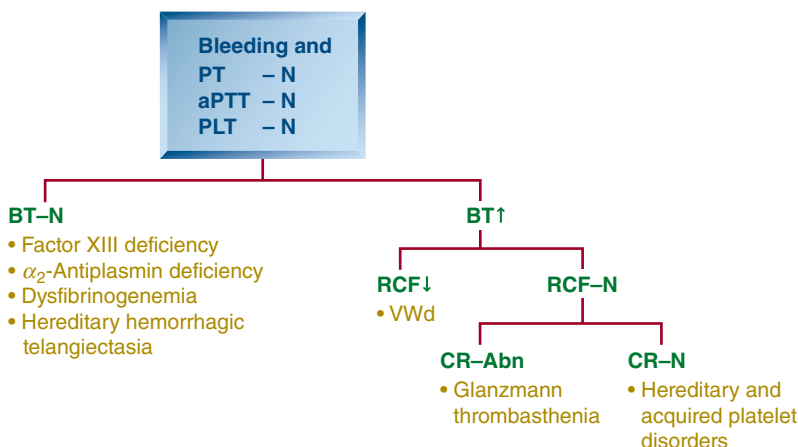

Figure 116-2. Tentative diagnoses in patients with bleeding manifestations and normal primary hemostatic tests using secondary tests. ↓, Decrease; ↑, increase; Abn, abnormal; aPTT, activated partial thromboplastin time; BT, bleeding time; CR, clot retraction; N, normal; PK, prekallikrein; PLT, platelets; PT, prothrombin time; RCF, ristocetin cofactor activity; VWD, von Willebrand disease.

● PREOPERATIVE ASSESSMENT OF HEMOSTASIS

Because surgical procedures are a great challenge to the hemostatic system, careful assessment of the risk of bleeding in every patient is important. The risk assessment is based on the bleeding history, physical examination, the underlying disorder if any, the type and site of surgery that is planned, and the results of basic hemostatic tests (PT, aPTT, platelet count). Several studies indicate that unselected coagulation tests have no significant predictive value of perioperative bleeding, and that patients with a negative bleeding history do not require routine coagulation screening.¹³ However, this conclusion does not consider that patients with mild to moderate bleeding disorders who can bleed excessively following surgery may have a negative bleeding history because they have not been challenged; obtaining a good bleeding history is an expertise that is not shared by all physicians; and if bleeding occurs during or after surgery for whatever reason, the basic tests performed preoperatively are an essential reference for determining the cause of bleeding.

Table 116-3 lists low-risk and high-risk conditions. A critical analysis of each potential cause of bleeding should be undertaken for the high-risk conditions. In addition to the extent of the surgical trauma, the magnitude of the fibrinolytic activity at the surgical site must be considered. For example, prostatectomy carries considerable risk of prolonged bleeding because of the presence of high fibrinolytic activity in the urine. Some surgical procedures can be anticipated to cause hemostatic abnormalities, such as operations in which extracorporeal circulation is used (because the extracorporeal circuits and/or the anticoagulation cause platelet dysfunction) and operations on patients with extensive malignancies or brain injury, which can give rise to DIC. Finally, the ability to institute local hemostatic measures should be considered. Thus, liver, lung, and kidney biopsies, although considered minor procedures, have a significant risk of bleeding because local measures, such as direct pressure, cannot be used to control bleeding.

TABLE 116-3. Evaluation of Bleeding Risk During Surgery

Assessed Factor	Risk of Bleeding	
	Low	High
Bleeding history	Negative	Positive*
Underlying conditions that compromise hemostasis (see Table 116-1)	Absent	Present
Initial hemostatic tests	Normal	Abnormal
Type of surgery	Minor	Major
	Not expected to induce a hemostatic defect at a site without local fibrinolysis	Expected to induce a hemostatic defect [†] at a site with local fibrinolysis [‡]
	Local hemostatic measures effective	Local hemostatic measures ineffective [§]

*Spontaneous bleeding episodes or injury-related hemorrhage.

[†]Open heart surgery or brain surgery.

[‡]Prostatectomy, tonsillectomy, oral or nasal surgery.

[§]Liver, lung, or kidney biopsy.

● SPECIFIC ASSAYS FOR ESTABLISHING THE DIAGNOSIS

A tentative diagnosis can be made by following the stepwise process of evaluation outlined in Figs. 116-1 and 116-2. However, further testing usually is required to establish a definitive diagnosis.

THROMBOCYTOPENIAS

When the laboratory reports an abnormally low platelet count, looking at the blood film to exclude pseudothrombocytopenia as a result of anticoagulant-induced platelet clumping (e.g., induced by ethylenediaminetetraacetic acid [EDTA]) is essential.¹⁴ Examination of the blood film also can reveal the presence of giant platelets, as in some inherited thrombocytopenias; giant platelets and Döhle bodies in leukocytes, as in May-Hegglin and other MYH9 platelet syndromes; moderately enlarged platelets, as in immune thrombocytopenia or other conditions associated with shortened platelet survival; small platelets, as in Wiskott-Aldrich syndrome; schistocytes and burr cells, as in the hemolytic uremic syndrome and thrombotic thrombocytopenic purpura, and occasionally in DIC; rouleaux formation, as in monoclonal gammopathies; macrocytosis and/or hypersegmentation, as in vitamin B₁₂ or folic acid deficiency; and abnormal white blood cells, as in leukemias and myeloproliferative disorders. Chapter 117 further discusses the evaluation and differential diagnosis of the thrombocytopenias.

FACTOR DEFICIENCIES

Coagulation factors usually are assayed by measuring their clotting activity. The most common assays analyze the ability of dilutions of the patient's plasma to correct the clotting time of a plasma known to be deficient in the factor being measured (substrate plasma). The results are compared to the ability of dilutions of a normal reference plasma to correct the abnormality in the substrate plasma. The activities of factors II, V, VII, and X usually are determined in PT-based assays, whereas the activities of factors VIII, IX, XI, and XII, prekallikrein, and high-molecular-weight kininogen are measured in aPTT-based assays. The plasma level of fibrinogen most commonly is measured by assessing the time required for thrombin to clot the patient's diluted plasma (Clauss method).¹⁵ Several assays of transglutaminase activity are available for measuring factor XIII activity,¹⁶ but a simple qualitative test based on dissolving a fibrin clot in 5 M urea usually is sufficient (Chap. 124). The RCF function of von Willebrand factor can be measured by the ability of the patient's plasma to support the agglutination of a suspension of formaldehyde-fixed normal platelets by ristocetin.¹⁷ This activity is defined as *RCF activity*. As with the coagulation factor assays, the results using patient plasma are compared to the results obtained with a normal reference plasma.

To determine whether a coagulation factor activity deficiency results from a quantitative decrease in protein or a qualitative abnormality in the protein, immunologic assays can be performed using specific polyclonal or monoclonal antibodies to assess the presence of the protein, independent of its function. Electroimmunoassays, enzyme-linked immunosorbent assays (ELISAs), and immunoradiometric assays all have been used successfully. Crossed immunoelectrophoresis measures both the immunologic reactivity and the mobility of the protein in an electric field; thus, it can detect protein abnormalities that affect electrophoretic migration. The abnormalities include the presence of antibody-antigen complexes that migrate differently from the protein itself, such as antiprothrombin-prothrombin complexes in patients with systemic lupus erythematosus or antiphospholipid syndrome. Diagnosis of the specific type of von Willebrand disease requires additional tests of the multimeric structure of plasma and, perhaps, platelet von Willebrand factor.

INHIBITORS TO COAGULATION FACTORS

If an inhibitor is suspected as a result of a prolonged PT or aPTT performed on a 1:1 mixture of the patient's plasma and normal plasma, further studies can help define the nature of the inhibitor and its titer. Among inhibitors that do not require incubation (i.e., immediate-type), perhaps the most common cause is the presence of heparin in the sample. This cause can be verified by finding a prolonged thrombin time on a test of the patient's plasma that is corrected with toluidine blue or other agents that neutralize heparin. The lupus anticoagulant also does not require incubation, and several methods for its detection are available (Chap. 131). However, with lupus anticoagulant, the PT usually is less prolonged than is the aPTT, and aPTT reagents have markedly different sensitivity to lupus-type anticoagulant depending on the amount of phosphatidyl serine present in each reagent.

Immunoglobulin inhibitors to specific coagulation factors may develop either after factor replacement therapy in patients with inherited deficiencies of coagulation factors (Chaps. 123 and 124) or spontaneously in patients without factor deficiencies (Chap. 127). Antibodies that neutralize factor activity frequently can be detected by incubating the patient's plasma with normal plasma, usually for 2 hours at 37°C, and then assaying the specific factor. The Bethesda assay originally was designed to quantify factor VIII inhibitors but can be modified to detect other inhibitors of coagulation factors (Chap. 123).¹⁸ Some inhibitors do not directly neutralize clotting activity; instead they reduce factor levels by forming complexes with coagulation factors, which then are rapidly cleared from the circulation. Such plasmas do not produce prolonged clotting times when mixed 1:1 with normal plasma and thus may be confused with inherited deficiency states. More elaborate assays are required to identify this type of inhibitor, which may, for example, produce severe deficiency of prothrombin in some patients with the anti-phospholipid syndrome (Chap. 131) and deficiency of von Willebrand factor in some acquired forms of von Willebrand disease (Chap. 126).¹⁹

PLATELET FUNCTION DISORDERS

Some laboratories nowadays routinely use an automated PFA to detect qualitative defects in primary hemostasis. Use of the RCF activity assay, platelet aggregation, and/or clot retraction are useful for assessing whether the patient has von Willebrand disease or a platelet function

disorder (see Fig. 116–2). Chapter 120 contains a flow diagram of the steps required to diagnose the different qualitative disorders of platelet function. Additional platelet function assays and glycoprotein analysis may be required to establish the diagnosis.

CHAPTER 117

THROMBOCYTOPENIA

Reyhan Diz-Küçükkaya and José A. López

SUMMARY

Thrombocytopenia is one of the most frequent causes for hematologic consultation in the practice of medicine, and may be life threatening. Although the normal platelet count in humans (150 to $400 \times 10^9/L$) far exceeds the minimal level required to avoid pathologic hemorrhage ($<50 \times 10^9/L$), a number of medical conditions either increasing the destruction of platelets or reducing their production, enhance the risk of bleeding. This chapter discusses an approach to the diagnosis of thrombocytopenia, grouping various causes by mechanism of action, and describing our current understanding of the pathogenesis, treatment and prognosis. In the vast majority of patients, a cause for thrombocytopenia can be identified, and effective therapy instituted.

DEFINITION AND HISTORY

Platelets are anucleate blood cells produced in the marrow by polyploid cells termed megakaryocytes and were described in the 19th century after the application of the improved compound microscope allowed these very small cellules, approximately $2 \mu\text{M}$ in diameter,

to be identified. Many early investigators are associated with the discovery of blood platelets, including Donné, Hayem, Bizzozero, and Osler, but it was James Homer Wright who, in 1906, using his special stain (later called Wright stain), described the morphology of platelets with their central granular area and marginal hyaline zone and established that they were the product of the fragmentation of marrow megakaryocytes. Clot retraction was discovered long before platelets, but Hayem, through a series of studies, showed retraction to be dependent on platelets. During the mid-20th century the aggregation of platelets, their adherence to collagen of damaged tissues, their acceleration of blood coagulation, and their relationship to the bleeding time and the biochemistry underlying several of these processes were described by scientists, among whom were Paul Owren, Kenneth Brinkhaus, Edwin Chargaff, Ernst Lüscher, Marjorie Zucker, and William Duke.

Platelets circulate in close contact with the endothelium, continually monitoring its integrity. When the vessel wall is damaged, platelets bind to subendothelial proteins, initiating the process of primary hemostasis. At sites of blood loss, the platelets aggregate to form a vessel sealing plug to halt bleeding. Activated platelets at sites of injury also provide a surface for assembly of coagulation reactions, resulting in the production of fibrin and consolidation of the thrombus. Both qualitative and quantitative deficiencies of the platelets cause bleeding. Platelets also have important functions in inflammation, tissue remodeling and wound healing.¹

Approximately 1×10^{11} platelets are produced per day by an adult human, a number that can be increased 20-fold or more, if necessary.² One-third of the platelets are stored in the spleen, the remaining two-thirds circulate in blood vessels.³ Disorders that increase splenic volume cause more platelets to be trapped in the spleen, lowering the concentration of circulating platelets, although alone, this redistribution rarely causes a significant bleeding diathesis.

Under normal conditions, human platelets have a mean life span in the circulation of between 7 and 10 days.^{4,5} Patients with thrombocytopenia secondary to platelet destruction have a markedly decreased platelet survival.^{6,7} Patients with thrombocytopenia from marrow failure have mildly decreased platelet survival, mostly because the body's fixed daily consumption of platelets accounts for a progressively larger fraction of the reduced total daily production as the platelet count drops.⁸ Platelet turnover is a measure of the net effect of platelet production and platelet destruction under steady-state conditions.⁷ Several studies using ¹¹¹In oxine-labeled platelets have established that, under normal conditions, platelet turnover in humans ranges from 40 to $50 \times 10^9/L$ per day.⁷ Although a high platelet turnover is expected in patients with immune thrombocytopenia (ITP), platelet production is not always increased in this disorder.⁷ Low platelet production may result from binding of the antiplatelet antibodies to megakaryocytes, inhibiting their maturation or leading to their destruction, causing an inappropriately muted marrow response to the degree of thrombocytopenia.⁹

Every day approximately 10 to 12 percent of circulating platelets are removed by the mononuclear phagocyte system, primarily by macrophages in the spleen and liver. Although the precise mechanisms of platelet clearance are not completely understood, changes that occur as the platelets circulate are thought to lead them to be recognized by macrophages. One of these changes is the progressive loss of sialic acid from platelet surface proteins. Studies in animals and humans with anticancer drugs that inhibit apoptotic pathways have also identified a role for apoptotic proteins in platelet survival and clearance. According to these studies, a classical intrinsic apoptosis pathway regulates the life span of circulating platelets, and antiapoptotic proteins, especially Bcl_{xL}, maintain platelet viability by restraining apoptosis.¹⁰

THE PLATELET COUNT

The normal platelet count (defined as the values between percentiles 2.5 to 97.5 in normal individuals) is given as 150 to $400 \times 10^9/L$; classically, thrombocytopenia is defined as a platelet count of less than $150 \times 10^9/L$. However, a sustained lower platelet count (100 to $150 \times 10^9/L$) can be seen in otherwise healthy individuals.^{11,12} Long-term observation of individuals with platelet counts between 100 and $150 \times 10^9/L$ showed that 88 percent of these individuals had subsequently reached normal platelet counts or remained stable. In those individuals, the probability of developing ITP was 6.9 percent, an autoimmune disease other than ITP 12 percent, and myelodysplastic syndrome (MDS) 2 percent, after 64 months of followup. All patients with MDS in this cohort were found to be older than age 65 years.¹³

THROMBOCYTOPENIA

Thrombocytopenia can be classified as severe (platelet count less than $20 \times 10^9/L$), moderate (platelet count 20 to $70 \times 10^9/L$), or mild (above $70 \times 10^9/L$).¹⁴ Although easy bruising occurs in patients with platelet counts less than $50 \times 10^9/L$ and spontaneous life-threatening bleeding can be expected in patients with platelet counts less than $15 \times 10^9/L$, bleeding symptomatology is largely determined by comorbid conditions affecting platelets or the coagulation system, including liver cirrhosis, uremia, disseminated intravascular coagulation (DIC), or antiplatelet drug usage.

In clinical practice, platelet counting is automated, and includes several different technologies: impedance, optical, two-dimensional laser, and optical-fluorescence methods. Although automated cell counter technology has progressed considerably during recent decades, the analytic performances of these machines for platelet counts and platelet indices is still not perfect, especially in patients with severe thrombocytopenia and macrothrombocytopenia.¹⁵⁻¹⁷ Each step between the sampling of blood and its analysis is important: the blood sample should be obtained by a clean venipuncture without dilution with other IV solutions or drugs. Blood/anticoagulant ratio should be as recommended. The International Council for Standardization in Hematology (ICSH) recommends use of ethylenediaminetetraacetic acid (EDTA) as the anticoagulant. Adequate mixing of the blood sample with EDTA (the final EDTA concentration should be 1.5 to 2.2 mg/mL) is crucial to prevent clumping of the platelets. Blood samples should be kept at room temperature and analyzed within 6 hours of phlebotomy. If a sample is to be analyzed more than 6 hours after it is drawn, it can be kept at 4°C for 24 hours. The blood count analyzer should be cleaned according to laboratory standards.¹⁷

Although thrombocytopenia is variably attributed to single factors such as decreased platelet production, increased platelet destruction, or abnormal splenic pooling, combinations of factors are often involved in clinical settings. For instance, the thrombocytopenia seen in patients with viral infection can result from many factors, including platelet destruction (e.g., through an autoimmune mechanism or drug toxicity) or decreased platelet production because of direct megakaryocyte infection by the virus. Table 117-1 lists the multiple causes of thrombocytopenia and classifies them by pathogenesis.

● PSEUDO (SPURIOUS) THROMBOCYTOPENIA

Pseudothrombocytopenia (or spurious thrombocytopenia) is a relatively uncommon phenomenon with multiple causes, including *ex vivo* agglutination of platelets, the presence of abnormally large platelets (improper counting), or improper preparation of blood samples.

The incidence of pseudothrombocytopenia reported in different studies ranges from 0.09 to 0.21 percent, which accounts for 15 to 30 percent of

TABLE 117-1. Classification of Thrombocytopenia

I. Pseudo (spurious) thrombocytopenia
A. Antibody-induced platelet aggregation
B. Platelet satellitism
C. Antiphospholipid antibodies
D. Glycoprotein IIb/IIIa antagonists
E. Miscellaneous
II. Thrombocytopenia resulting from impaired platelet production
A. Inherited platelet disorders
B. Acquired marrow disorders
1. Nutritional deficiencies and alcohol-induced thrombocytopenia
2. Clonal hematological diseases (myelodysplastic syndrome, leukemias, myeloma, lymphoma, paroxysmal nocturnal hemoglobinuria)
3. Aplastic anemia
4. Marrow metastasis by solid tumors
5. Marrow infiltration by infectious agents (HIV, tuberculosis, brucellosis, etc.)
6. Hemophagocytosis
7. Immune thrombocytopenia (ITP)
8. Drug-induced thrombocytopenia
9. Pregnancy-related thrombocytopenia
III. Thrombocytopenia resulting from increased platelet destruction
A. Immune thrombocytopenia
1. Autoimmune thrombocytopenia (primary and secondary ITP)
2. Alloimmune thrombocytopenia
B. Thrombotic microangiopathies (TTP, hemolytic uremic syndrome [HUS])
C. Disseminated intravascular coagulopathy (DIC)
D. Pregnancy-related thrombocytopenia
E. Hemangiomas (Kasabach-Merritt phenomenon)
F. Drug-induced immune thrombocytopenia (quinidine, heparin, abciximab)
G. Artificial surfaces (hemodialysis, cardiopulmonary bypass, extracorporeal membrane oxygenation)
H. Type 2B von Willebrand disease
IV. Thrombocytopenia resulting from abnormal distribution of the platelets
A. Hypersplenism
B. Hypothermia
C. Massive blood transfusions
D. Excessive fluid infusions
V. Miscellaneous Causes
A. Cyclic thrombocytopenia, acquired pure megakaryocytic thrombocytopenia

all cases of isolated thrombocytopenia.¹⁸⁻²⁵ Pseudothrombocytopenia has been reported in association with the use of EDTA as an anticoagulant, with platelet cold agglutinins,²⁶ and with myeloma.²⁷ A very interesting report demonstrates pseudothrombocytopenia caused by platelet phagocytosis *ex vivo* in the presence of EDTA anticoagulant.²⁸ An example of

ex vivo platelet clumping is shown in Chap. 1, Fig. 1–6H, accompanied by platelet–neutrophil satellitism (see “Platelet Satellitism” below).

ANTIBODY-INDUCED PLATELET AGGLUTINATION

Platelet agglutination *ex vivo* can be induced by antiplatelet antibodies or by activation of the platelets during collection. The responsible antibodies do not appear to be associated with a pathologic process, as they are found in normal individuals. One hypothesis put forth to explain their presence is that the antibodies are responsible for clearing aged and damaged platelets. Most antibodies implicated in pseudothrombocytopenia recognize platelet membrane glycoproteins that are modified to expose new epitopes when calcium is chelated. Typically, the artifact is most prominent in the presence of EDTA, but other anticoagulants can also cause platelet clumping, including sodium citrate, sodium oxalate, acid citrate dextrose, and heparin. The antibodies usually are of the immunoglobulin (Ig) G type; IgM and IgA antibodies also have been described.^{29–31} Most antibodies react at room temperature; thus, the reaction can be prevented by keeping the blood sample at 37°C. In 20 percent of cases, however, the antibodies, usually of the IgM type, are reactive at both 22°C and 37°C.³⁰ Clumping usually is evident within 60 minutes after the blood is drawn, but may require incubations of 2 to 3 hours. Agglutination can be reproduced by incubating plasma from patients with pseudothrombocytopenia with blood from normal individuals in the presence of EDTA.

In most cases, the antibodies are directed against the integrin $\alpha_{IIb}\beta_3$ (also termed glycoprotein [GP] IIb/IIIa), a conclusion supported by the observation that platelets from patients with Glanzmann thrombasthenia, who lack the integrin $\alpha_{IIb}\beta_3$ complex, fail to agglutinate in the presence of patient sera.^{32–35} Moreover, pretreatment of fresh blood with anti–integrin $\alpha_{IIb}\beta_3$ dramatically reduces EDTA-induced platelet agglutination.³⁶ The responsible epitope normally is cryptic and located in the integrin α_{IIb} subunit. Low temperature and calcium chelation combine to change the conformation of integrin $\alpha_{IIb}\beta_3$ and expose the epitope.³³

PLATELET SATELLITISM

Antibodies directed against integrin $\alpha_{IIb}\beta_3$ may react simultaneously with the leukocyte Fc γ receptor III (Fc γ RIII) and attach the platelets to neutrophils and monocytes, inducing a phenomenon known as *platelet-leukocyte satellitism*,³² another form of pseudothrombocytopenia (Fig. 117–1). These antibodies fail to produce satellitism in the presence

of platelets from patients with type I Glanzmann thrombasthenia or in the presence of neutrophils from patients with congenital absence of Fc γ RIII.³² Typically, the platelets form a rosette around the periphery of leukocytes. Neutrophils are most frequently involved, but the phenomenon also is occasionally observed with monocytes.^{37,38} These antibodies also are naturally occurring, and their presence does not clearly correlate with any specific clinical situation, disease, or drug. As with the antibodies that induce only platelet clumping, exposure of a cryptic antigen on EDTA-treated platelets and leukocytes may trigger this phenomenon.

ANTIPHOSPHOLIPID ANTIBODIES

Some antiplatelet antibodies from patients with pseudothrombocytopenia crossreact with negatively charged phospholipids and may exhibit anticardiolipin activity.³⁰ The sera of these patients lose their ability to clump platelets when adsorbed onto either cardiolipin or activated normal platelets, supporting the hypothesis that antibody subpopulations directed against negatively charged phospholipids can bind to antigens modified by EDTA on the platelet membrane. Another possibility is that the antigens in this case are negatively charged phospholipids on the surface of platelets.

INTEGRIN $\alpha_{IIb}\beta_3$ ANTAGONISTS

Thrombocytopenia has been described in patients suffering from acute coronary syndromes treated with the abciximab and other integrin $\alpha_{IIb}\beta_3$ antagonists.^{39–41} Abciximab is associated with both pseudothrombocytopenia and true thrombocytopenia. The mechanism for platelet clumping with abciximab is unknown; the drug itself likely is not cross-linking the platelets because it is monovalent. More likely, other agglutinins bind integrin $\alpha_{IIb}\beta_3$ at new epitopes induced by the combination of abciximab binding and calcium chelation. True abciximab-induced thrombocytopenia occurs in approximately 0.3 to 1 percent of patients treated with the drug.⁴² The mechanism is incompletely understood, but likely includes reaction of preformed antibodies with a neoepitope expressed after binding of abciximab to integrin $\alpha_{IIb}\beta_3$ (ligand-induced binding sites) or abciximab-induced platelet activation with subsequent platelet sequestration from the circulation. In some abciximab-treated patients, high antibody titers are detected in the plasma.

The incidence of pseudothrombocytopenia and thrombocytopenia related to abciximab was determined in four large placebo-controlled trials:⁴⁰ c7E3 Fab Antiplatelet Therapy in Unstable Refractory Angina (CAPTURE), Evaluation of 7E3 for the Prevention of Ischemic

Figure 117–1. Platelet satellitism. **A.** Direct (non–anticoagulated) marrow film. No platelet satellitism. **B.** A concentrated marrow film anticoagulated with disodium ethylenediaminetetraacetic acid (Na₂EDTA) from same specimen as in **(A)**. Note platelets are adherent to the mature neutrophil surface (satellitism) in the presence of Na₂EDTA. The neutrophil precursors do not have surface features that interact with platelets, apparently a feature only present after the final steps in maturation. (Reproduced with permission from Lichtman’s Atlas of Hematology, www.accessmedicine.com.)

Complications (EPIC), Evaluation of Percutaneous Transluminal Coronary Angioplasty to Improve Long-term Outcome of α IIb/IIIa Receptor Blockade (EPILOG), and Evaluation of Platelet IIb/IIIa Inhibitor for Stenting (EPISTENT). In these studies, pseudothrombocytopenia accounted for more than one-third of low platelet counts in patients undergoing coronary interventions and treated with abciximab. These studies demonstrated that pseudothrombocytopenia is a benign laboratory condition not associated with increased bleeding, stroke, transfusion requirements, or the need for repeat revascularization.

MISCELLANEOUS ASSOCIATIONS

Some studies suggest that platelet agglutinins occur more frequently in hospitalized patients and in association with medical conditions such as autoimmune diseases, malignancy, liver disease, and sepsis.^{25,43–46} However, others found no association with any particular pathology or with use of specific drugs.³⁰

One study showed that antibodies from patients with pseudothrombocytopenia can induce agglutination of donor platelets in the presence of EDTA. This agglutination was prevented by warming the donor platelets to 37°C or by pretreating the platelets with aspirin, prostaglandin E₁, apyrase, and monoclonal antibodies against integrin $\alpha_{IIb}\beta_3$ that block the binding site for fibrinogen and von Willebrand factor (VWF), or arg-gly-asp (RGD) peptide, which binds the site on integrin $\alpha_{IIb}\beta_3$ that recognizes cytoadhesive proteins.³³ Whether the same reaction occurs *in vivo* is not known, but in that case the antibodies should have a slow reactivity, or else bleeding would sometimes occur.

MANAGEMENT OF THE PATIENTS WITH PSEUDOTHROMBOCYTOPENIA

An (unexpected) low platelet count reported by automated cell counters should be confirmed by microscopic examination of the blood film. Automated cell counters identify platelets merely based on their small volumes in comparison to those of other blood cells, generally defined as volumes between 2 and 20 fL. Because platelet clumps tend to exceed 20 fL, the clumps may be counted as leukocytes,¹⁸ and even if counted as platelets, several platelets are counted as one. Thus, pseudothrombocytopenia may be accompanied by pseudoleukocytosis.^{5,21,24,47} The greater the delay in processing of anticoagulated blood, the greater is the degree of platelet clumping and the greater the potential for artifact.²¹ Platelet clumping can be prevented by collecting the sample in EDTA and maintaining its temperature at 37°C. Even with these measures, however, clumping will still occur in approximately 20 percent of cases.³⁰

Another alternative is use of sodium citrate, which chelates calcium more weakly than does EDTA but still causes platelet clumping in approximately 10 to 20 percent of cases with EDTA-induced clumping. In some patients, an accurate platelet count can be obtained only by sampling blood directly into ammonium oxalate and manually counting the platelets using a Bruker chamber.³⁰ Flow cytometry may help for determining exact platelet number by immunostaining of the platelets.

Platelet agglutinins are not associated with bleeding or thrombosis, so they appear to have no clinical implications, except that they may lead to unnecessary therapy because of misdiagnosis. Transplacental transmission of agglutinins has been documented, but the pseudothrombocytopenia induced by these antibodies in the neonate resolves spontaneously.^{48,49} No complications have been reported when platelet agglutinins are discovered during pregnancy.^{48,50} Transfusion of blood products from patients with pseudothrombocytopenia produces an acceptable corrected count increment in the recipient, again supporting its benign nature.²³ Thus, the clinical importance of

pseudothrombocytopenia concerns conditions with which it is confused rather than any pathology associated with the condition. It is important that this syndrome be recognized promptly to avoid unnecessary diagnostic tests and treatment.

● INHERITED PLATELET DISORDERS

Megakaryopoiesis and thrombopoiesis are regulated by a number of hematopoietic growth factors and transcription factors (Chap. 113). Any genetic defect affecting platelet production, function or morphology may cause inherited platelet disorders (IPDs; Chap. 121). In recent decades, knowledge of normal megakaryocyte and platelet physiology has grown enormously,⁵¹ aided in part by the study of IPDs.^{52,53}

IPDs are a very heterogeneous group of disorders. Some disorders, such as Bernard-Soulier syndrome, appear to be restricted to platelets,⁵⁴ whereas others appear as a part of a complex pathology, as seen in thrombocytopenia with absent radii (TAR) syndrome (Fig. 117–2). In some IPDs, the platelet count may be normal despite severely impaired platelet function, such as in Glanzmann thrombasthenia. Other disorders are accompanied by abnormal platelet numbers, usually thrombocytopenia. Table 117–2 summarizes the inherited thrombocytopenias.

Severe forms of IPDs that present as a bleeding tendency early in childhood are rare. IPD patients usually present with mucocutaneous bleeding, such as with purpura, epistaxis, and/or gingival bleeding. Menorrhagia and bleeding during pregnancy and labor are common problems in female patients. Spontaneous life-threatening bleeding is rare, including intracranial hemorrhage, massive gastrointestinal or genitourinary bleeding. Recent molecular investigations of IPD patients and their families with bleeding diathesis demonstrated that most IPDs cause mild bleeding tendencies, and IPDs may be more prevalent than previously thought.⁵⁵ In these milder cases, a bleeding diathesis may only be diagnosed after an episode of excessive bleeding, such as during surgery or following trauma.

Diagnosis of IPD presents a significant challenge because of the heterogeneity of clinical and laboratory findings of the patients with the same disorder, even in the same family. IPD patients with isolated macrothrombocytopenia share common clinical and basic laboratory features with certain acquired platelet disorders and are sometimes misdiagnosed. It is very important to distinguish IPD patients from those with acquired platelet disorders, such as ITP, to avoid unnecessary or potentially harmful treatments. Helpful in this regard is information obtained during the history, including a family history of bleeding and consanguinity in the family, because the majority of IPDs are inherited as autosomal recessive traits. Because some IPDs are associated with increased risk of developing myeloid malignancies, the patient and family should be asked about a family history of myeloid malignancies. The presence of skeletal, facial, ocular, audiological, neurologic, renal, cardiac, and immune problems associated with platelet disorders may also suggest IPD.^{51,56}

Laboratory evaluation of a potential IPD should start with a careful blood film investigation, which could be helpful for patients with MYH9-related diseases (giant platelets and Döhle-like inclusion bodies within leukocytes; Fig. 117–3), Bernard-Soulier syndrome (macrothrombocytopenia), Gray platelet syndrome (pale platelets), and sitosterolemia (giant platelets surrounded by a circle of vacuoles, stomatocytosis). Platelet function analyzer (PFA-100) occlusion times are usually found to be prolonged. The skin bleeding time is not recommended for screening, because it is invasive and poorly reproducible. Although the PFA-100 test is very sensitive in detecting Bernard-Soulier syndrome and platelet-type von Willebrand disease (VWD), it may be normal in patients with variant forms of these disorders, or patients

Figure 117-2. Thrombocytopenia with absent radii (TAR) syndrome. Radiograph of right forearm. A 48-year-old woman with repeated platelet counts in the range of 85 to $100 \times 10^9/L$. Bleeding time was 11 minutes. No laboratory evidence of von Willebrand disease. Marrow examination was normal. Both forearms were short and bowed with angulated wrists and normal hands. No family history of forearm deformity. **A.** Anterior-posterior film of right arm. **B.** Lateral film of right arm. Absence of radius and bowed, hypertrophied ulna (arrows). Woodlock, Unity Health Systems, Rochester, NY.)

with storage pool deficiencies.⁵⁷ Light transmission aggregometry (LTA) using different concentrations of adenosine diphosphate (ADP), collagen, ristocetin, epinephrine, and arachidonic acid is accepted as a gold standard in diagnosing IPDs, but, again, may be normal in variant forms of IPDs and in some patients with storage pool diseases. Measurement of platelet nucleotide content and release is recommended in patients with platelet granule deficiencies. Flow cytometric analysis is very informative in patients with platelet surface GP deficiencies such as Bernard-Soulier syndrome. Marrow biopsy is needed in patients who have pancytopenia or severe thrombocytopenia, as in Fanconi anemia and congenital amegakaryocytic thrombocytopenia (CAMT), respectively. Unfortunately, these tests may help diagnose only a small portion of the IPD patients. Further tests are only available in specialized centers, and include electron microscopy, Western blotting, and others. Electron microscopy is able to define characteristic ultrastructural abnormalities; Western blotting, enzyme-linked immunosorbent assay (ELISA), or radioimmunoassay can be used for qualitative and quantitative analysis of specific platelet proteins.^{51,56} Even with these expensive, complicated, and time-consuming tests, the results are inconclusive in nearly half of patients being evaluated for IPD.⁵⁶ Genetic analysis is often able to determine the underlying molecular pathology, but the very large number of candidate genes limits the traditional target gene approach. Within the past decade, next-generation sequencing techniques have not only improved the speed and cost of genetic investigations, but have also begun to generate very interesting data about the genetic causes of IPD.^{52,53}

● NUTRITIONAL DEFICIENCIES AND ALCOHOL-INDUCED THROMBOCYTOPENIA

Iron, vitamin B₁₂, and folic acid deficiencies are the nutrient deficiencies most widely recognized to impair blood cell production. Severe nutritional deficiencies primarily cause anemia, rarely causing bicytopenia or pancytopenia. Isolated thrombocytopenia is rare in patients with nutritional deficiencies.

Iron is present in all human cells, and mediates electron transfer reactions. Iron is a key component of hemoglobin, and iron deficiency causes a hypochromic and microcytic anemia (Chap. 42). Iron-deficiency anemia (IDA) generally develops after acute or chronic bleeding, and is usually accompanied by thrombocytosis rather than thrombocytopenia. Thrombocytopenia associated with IDA is relatively rare, reported in only 2.3 percent and 2.4 percent of pediatric and adult IDA patients, respectively.^{58,59}

Cobalamin (vitamin B₁₂) and folate are both required for DNA synthesis and repair, but humans can synthesize neither vitamin. Dietary deficiencies, impaired absorption, or inhibition with drugs (as seen in methotrexate therapy) of these vitamins can cause megaloblastic anemia (Chap. 41). Mild thrombocytopenia occurs in approximately 20 percent of patients with megaloblastic anemia resulting from vitamin B₁₂ deficiency in the United States.⁶⁰ The frequency may be higher in patients with folic acid deficiency because of the high frequency of

concomitant alcohol abuse (Chap. 41). One large study of 139 patients examined the rates of cytopenias associated with megaloblastic anemia in India.⁶¹ In this study, 76 percent had isolated vitamin B₁₂ deficiency, 7 percent had isolated folate deficiency, 9 percent had a combined deficiency, and 8 percent had normal vitamin levels. All were anemic by definition, and 80 percent had thrombocytopenia with mild to moderate depression of the platelet count. More than half of those with thrombocytopenia were also neutropenic. The authors of this study suggested that the cytopenias tended to progress from isolated anemia, to anemia plus thrombocytopenia, to pancytopenia, with the degree of cytopenia related to the severity of vitamin deficiency. Occasionally, thrombocytopenia is severe in patients with megaloblastic anemia and, when accompanied by fever, hepatomegaly, and splenomegaly, and may suggest a diagnosis of acute leukemia. In these syndromes, the primary mechanism of thrombocytopenia is ineffective platelet production⁶²; marrow megakaryocyte number usually is normal or increased. Abnormalities of megakaryocyte morphology are much less distinctive than the characteristic erythroid and myeloid defects, but often nuclear abnormalities are seen, with nuclei of larger size and dispersed nuclear segments, rather than single polyploid nuclei.⁶³ Thrombocytopenia may be seen in association with vitamin B₁₂ deficiency when the latter results from autoantibodies against parietal cells or intrinsic factor and is associated with ITP.^{64,65} Various other autoimmune disorders can coexist with pernicious anemia, including autoimmune vitiligo and autoimmune thyroiditis.⁶⁶ Abnormalities of platelet function are sometimes seen associated with vitamin B₁₂ deficiency.^{67,68} Diminished platelet aggregation and reduced release of ADP and ATP from granule stores in response to different agonists have been reported, and vitamin deficiency has been suggested to induce an acquired storage pool disease (Chap. 41).⁶⁸

Copper deficiency is usually seen in patients who have undergone gastric bypass surgery, and may cause anemia, leukopenia, and thrombocytopenia associated with neurologic deficits resembling vitamin B₁₂ deficiency. Patients with copper deficiency also may be misdiagnosed as having MDS, because increased ring sideroblasts and dysplastic precursor cells can be seen on marrow smears.^{69,70}

Acute and chronic alcohol (ethanol) consumption affects hematopoiesis and blood cell survival both directly and indirectly. Alcohol is one of the leading causes of thrombocytopenia in Western countries. Acute ethanol intoxication in healthy volunteers induces thrombocytopenia.⁷¹ Platelet counts in these cases are usually mildly decreased (generally more than $100 \times 10^9/L$); severe thrombocytopenia is quite rare. Acute ethanol-induced thrombocytopenia usually resolves within 5 to 21 days with cessation of ethanol ingestion, sometimes with a transient rebound thrombocytosis that may reach up to $1,000,000 \times 10^9/L$.⁷² Although the mechanism of acute alcohol-related thrombocytopenia is not clear, it has been suggested that metabolites of ethanol, especially acetaldehyde, impair the late stages of platelet production and increase platelet destruction.⁷³ Thus, thrombocytopenia associated with acute alcohol ingestion would be expected to be more frequent in those with poor nutrition (delayed oxidation of acetaldehyde) and those with partial acetaldehyde dehydrogenase deficiency. Thrombocytopenia induced by alcohol ingestion is accompanied by a decreased number of marrow megakaryocytes. Vacuolated proerythroblasts and granulocyte precursors are sometimes seen, as are multinuclear erythroblasts and megablasts.⁷⁴ Vacuolization of the periphery of mature megakaryocytes has been reported.⁷⁵ Alcoholism (chronic ethanol consumption, which is defined as consumption of more than 80 g of ethanol per day), on the other hand, may cause thrombocytopenia by other mechanisms, such as alcoholic liver cirrhosis (both splenomegaly and thrombopoietin deficiency), folic acid deficiency, and alcohol-induced marrow suppression.⁷⁴⁻⁷⁸

Figure 117-3. MYH9 abnormality. **A.** Blood film. May-Hegglin anomaly. Macrothrombocytes, thrombocytopenia, and light-blue cytoplasmic inclusions in neutrophils. Note two giant platelets approximately the diameter of red cells. The neutrophil has a large gray-blue inclusion in the cytoplasm at the 9 o'clock position. **B.** Blood film. Neutrophil of an individual with a mutation (E1841K) in exon 38 of the MYH9 gene. This mutation results in macrothrombocytopenia and Döhle-body-like inclusions in neutrophils (*arrow*). **C.** Blood film. Immunofluorescent analysis with antibodies to the A heavy chain of nonmuscle myosin in the neutrophils of the same patient as in **(B)**. The fluorescent body in the neutrophil indicates that the inclusion contains precipitated nonmuscle myosin heavy chains, characteristic of this family of disorders. ● ACQUIRED PURE AMEGAKARYOCYTIC THROMBOCYTOPENIA

Thrombocytopenia attributable to pure aplasia or hypoplasia of megakaryocytes is rare.⁷⁹ More common are instances in which amegakaryocytic thrombocytopenia anticipates the development of full-blown MDS or aplastic anemia and is associated with subtle abnormalities of other lineages, such as macrocytosis and dyserythropoiesis.⁸⁰⁻⁸⁴ Most commonly the disorder is caused by autoimmune suppression of megakaryocyte development, either idiopathic,⁸⁵ associated with autoimmune disorders such as systemic lupus erythematosus (SLE)⁸⁶ and eosinophilic fasciitis, or associated with infections such as hepatitis C.⁸⁷ Antibodies against thrombopoietin (TPO)⁸⁸ have been described to cause the disorder, as have antibodies against the TPO receptor.⁸⁹ Patients may achieve durable remission with therapies designed to blunt the autoimmune response, such as cyclosporine or antithymocyte globulin (ATG).⁹⁰

IMMUNE THROMBOCYTOPENIA

Table 117-3 summarizes the various types of ITP.

PRIMARY IMMUNE THROMBOCYTOPENIA

ITP, formerly known as autoimmune thrombocytopenic purpura, is the most common cause of isolated thrombocytopenia in clinical practice. ITP is characterized by immune-mediated platelet destruction and impaired platelet production. ITP occurs in every age group. Childhood ITP typically is acute in onset, often developing after a viral infection or vaccination. Although thrombocytopenia may be severe, it usually resolves spontaneously, within a few weeks up to 6 months.⁹¹ In contrast to childhood ITP, adult ITP generally is a chronic disease of insidious onset and rarely resolves spontaneously.

"Purpura" was recognized by Hippocrates (c. 460 to c. 370 BC) and Galen (AD 129 to c. 200/c. 216) as a sign associated with fever. Chronic purpura was first described in details by Ibn-i Sina (Avicenna, c. 980 to c. 1037) in his famous book "The Canon of Medicine." In 1705, Werlof suggested that purpura was related to infections and described it as "morbus maculosus haemorrhagicus." Patients with purpura were

diagnosed as having "Werlof disease" for centuries. After the discovery of platelets and their role in hemostasis, the relationship between purpura and low-platelet count was understood.⁹²

In 1915, Erich Frank renamed this disorder as "essential thrombocytopenia," and suggested that platelet production from megakaryocytes was impaired because of a toxic substance produced by the spleen.⁹³ Kaznelson, inspired by Frank's theory, proposed splenectomy for a patient with chronic thrombocytopenic purpura. The treatment was successful, and splenectomy was first-line therapy for ITP until the introduction of glucocorticoids in 1950s.

In the first issue of the journal *Blood* (in 1946) Damashek and Miller reviewed the megakaryocyte count and marrow morphology of patients with "idiopathic thrombocytopenic purpura."⁹⁴ They showed that most ITP patients had an increased number of megakaryocytes, but very few of them were producing platelets, so "actual platelet-producing tissue" might be decreased.⁹⁴

Although Marino first showed that antiplatelet antibodies might cause thrombocytopenia in animal studies in 1905, the Harrington-Hollingsworth experiment (1951) was an important milestone in the understanding of autoantibody-directed platelet destruction in the pathophysiology of ITP. In this pioneering work, normal volunteers (including Harrington himself, who received the highest dose) were infused with the plasma from patients with ITP, resulting in severe thrombocytopenia in the recipients, and they postulated that ITP could be caused by antiplatelet antibodies.^{95,96} Subsequently, Shulman and coworkers⁹⁷ showed that the thrombocytopenic effect of ITP plasma was dose-dependent and associated with the globulin fraction. In the 1950s, glucocorticoids began to be used to treat ITP, and they became first-line therapy for adults. Shortly thereafter other immunosuppressive agents were introduced for the treatment of chronic ITP.⁹²

In the early 1970s, two groups showed that platelets from chronic ITP patients had elevated levels of platelet-associated immunoglobulin G (PAIgG).^{98,99} In 1982, the first platelet target was identified: autoantibodies from patients with ITP failed to bind platelets deficient in the integrin $\alpha_{IIb}\beta_3$ complex (i.e., from patients with Glanzmann thrombasthenia).¹⁰⁰ In the late 1980s, two specific assays for the target antigens were described: the immunobead assay¹⁰¹ and the monoclonal antibody-specific immobilization of platelet antigens (MAIPA) assay.¹⁰² These assays showed that the majority of antiplatelet antibodies in patients with ITP are directed against integrin $\alpha_{IIb}\beta_3$ (GPIIb-IIIa) (approximately 80 percent), and the remainder are against the GPIb-IX-V complex and other platelet GPs such as GPIV and integrin $\alpha_v\beta_1$ (GPIa-IIa).^{103,104} Some sera contain antibodies that recognize several antigens. Most antiplatelet autoantibodies are IgG; the remainder are IgM and IgA. Unfortunately, elevated levels of PAIgG later were found in patients with non-ITP. Therefore, PAIgG could not be used as a specific laboratory test for ITP in the same way that the direct antiglobulin test is used for the diagnosis of autoimmune hemolytic anemia.^{105,106} To date there is still no specific laboratory test for ITP, the diagnosis of ITP being based on exclusion of other causes.

Antibody-coated platelets bind tissue macrophages through Fc γ receptors, leading to their destruction primarily in the spleen and, to a lesser extent, in the liver and marrow.^{97,107,108} In 1981, Imbach reported successful treatment of pediatric ITP with intravenous immunoglobulin (IVIG) and suggested that the mechanism could involve blockade of macrophage Fc receptors. IVIG became first-line therapy in children, and now is also used in adults when a prompt increase in the platelet count is desired.¹⁰⁹

Early studies of PAIgG reported that the antibodies in ITP were polyclonal.¹¹⁰ However, later studies showed that at least some ITP patients had clonal B-cell proliferation, as determined by DNA analysis for immunoglobulin heavy- and light-chain rearrangements and by flow cytometry of B cells from blood and spleen for surface Ig light chains.^{111,112} This led to the use in ITP of the chimeric anti-CD20 monoclonal antibody, rituximab, which was designed for the treatment of CD20-positive B-cell lymphomas. The rapid elimination of B cells with rituximab encouraged the use of this agent in the treatment of ITP.

Numerous abnormalities in cell-mediated immunity have been described in patients with ITP, including abnormalities in antigen-presenting cells, T lymphocytes, and cytokine release. Under normal conditions, antigen-presenting cells recognize and process foreign antigens and express the antigens on their surface in association with major histocompatibility complex (MHC) molecules. MHC-antigen complexes activate resting (naïve) CD4+ T cells to differentiate into a variety of phenotypes such as T-helper 1 (Th1) and T-helper 2 (Th2), Th17, and T-regulatory (Treg) cells. Th1 cells are involved in cell-mediated immunity and host defense against intracellular bacteria and protozoa. Th2 cells are involved in humoral immunity and host defense

against extracellular parasites. Th17 cells are involved in host defense against extracellular bacteria and fungi. Treg cells (formerly known as suppressor T cells) play an important role in self-tolerance by inhibiting autoimmune responses. Abnormal T-cell responses drive the differentiation of autoreactive B-cell clones and autoantibody secretion. In patients with ITP, both Th1 and Th17 cells have been found to be upregulated, whereas the number and the suppressor functions of the Treg cells were found to be decreased.¹¹³⁻¹¹⁵ This imbalance is believed to induce an autoimmune responses against the platelets. It is unclear whether these abnormalities are causative or represent an epiphenomenon.^{114,115} In addition, CD8+ cytotoxic T cells might be involved in the pathogenesis of ITP through cell-mediated destruction of platelets and megakaryocytes and through suppression of megakaryocytes, impairing platelet production.¹¹⁵⁻¹¹⁷

Antiplatelet autoantibodies may also activate platelet destruction by activating complement through the classical complement pathway. Increased platelet-associated C3, C4, and C9 have been demonstrated on the platelets from patients with ITP.^{118,119} *In vitro* studies show that, in the presence of antiplatelet antibodies, C3 and C4 can bind platelets, increase the phagocytosis of the platelets by macrophages, and can cause their lysis by stimulating assembly of the membrane attack complex.^{120,121}

Early studies demonstrated that platelet survival is shortened in ITP patients and returns to normal after splenectomy-induced remission.¹²² Platelet transfusion only transiently increases a patient's platelet count, and the transfused platelets also have a shortened survival, reflecting the fact that the major problem in ITP is platelet destruction. However, later studies showed that platelet life span was not short enough to account for the observed thrombocytopenia on the basis of destruction alone, again suggesting a concomitant defect in platelet production.¹²³ Potential mechanisms for this observation were provided by later studies that autoantibodies against platelet surface GPs might interfere with the maturation of megakaryocytes, resulting in reduced platelet production, contributing to the severity of thrombocytopenia in some ITP patients.¹²⁴ Antibodies that target the GPIb-IX-V complex may induce thrombocytopenia by decreasing platelet production, as GPIb autoantibodies inhibit megakaryopoiesis *in vitro*,¹²⁴ and GPIb monoclonal antibodies inhibit proplatelet formation *in vitro*.¹²⁵

In 1958, a hematopoietic growth factor regulating platelet production was proposed and named TPO by Kelemen.¹²⁶ Although interleukin (IL)-3, IL-6, IL-11, granulocyte-macrophage colony-stimulating factor, and c-KIT ligand increase megakaryocyte or platelet counts *in vivo* and *in vitro*, animal studies of these factors proved that they are not the main regulator of megakaryopoiesis.¹²⁷ In 1994, TPO was first characterized by five independent groups. TPO binds to its receptor MPL (formerly known as c-MPL), enhances megakaryocyte colony formation, and increases the size, number, and ploidy of megakaryocytes, and platelet production (Chap. 113).¹²⁸⁻¹³⁰ TPO is synthesized in greatest quantity in the liver but is found in other organs (kidney, muscle, and marrow stromal cells).¹²⁸ TPO is also required to maintain the viability of hematopoietic stem cells.¹³¹ The regulation of TPO production is complex. Hepatic production of TPO is both constitutive (in the steady state) and inducible (by inflammation), and the concentration of TPO to which megakaryocytes are exposed is also determined by the platelet concentration. Platelets, bearing TPO receptors, remove the hormone from the circulation, at least partially accounting for the inverse relationship between TPO and platelet levels. TPO levels are markedly elevated in patients with thrombocytopenia associated with megakaryocytic hypoplasia, including disorders such as aplastic anemia or acute leukemia. In most reports, ITP patients have normal or slightly elevated TPO levels whether measured in plasma or serum, but the levels are always lower than the concentrations found in thrombocytopenia

resulting from megakaryocytic hypoplasia.^{128–130,132,133} Initial studies with recombinant and pegylated TPO molecules showed successful responses in patients with thrombocytopenia, but development of auto-antibodies against these molecules restricted their use in clinical settings. Based on the success of creating erythropoietin receptor agonist peptides, a number of screening efforts were undertaken to design small peptides or organic molecules that might bind to the TPO receptor and stimulate thrombopoiesis. One such molecule contains four copies of a 14-amino-acid peptide grafted onto an Ig Fc domain, forming a “peptibody” termed romiplostim. This agent, which binds to a region of the TPO receptor that overlaps that bound by authentic TPO, was shown to increase platelet counts in patients with ITP who had failed other modalities,¹³⁴ and was approved by the FDA for this indication in 2008. Another small organic thrombopoietic molecule, eltrombopag, was developed almost simultaneously¹³⁵ and approved in 2008 by FDA for the same indications.¹²⁷ This agent activates TPO receptor signaling by binding to the transmembrane domain of the receptor, a site quite distinct from the binding site for TPO and romiplostim. Both TPO-receptor agonists are currently being evaluated for additional clinical indications in clinical trials.¹³⁶

Some patients with ITP appear to display a genetic predisposition. ITP has been documented in monozygotic twins¹³⁷ and shown to be highly prevalent in some families.¹³⁸ In addition to contributing to the development of ITP, like in other autoimmune disorders heredity may also affect the response to ITP therapy. Human leukocyte antigen (HLA) class I and class II allele frequencies in patients with ITP have been studied by several investigators, with inconsistent results. Some investigators reported an increased frequency of HLA-Aw32, -DRw2, and -DRB1*0410.^{108,139–141} Investigation has focused on genetic differences associated with dysregulation of immune tolerance and humoral immunity, but results have been inconclusive. For example, genetic polymorphisms of cytotoxic T-lymphocyte antigen (CTLA)-4, tumor necrosis factor, and Fcγ receptors IIA and IIIA have been suggested to influence the development of ITP and the response to therapy,^{141–143} but as yet no strong association has been found.

Accumulating data indicate that the pathophysiology of ITP is more complex than previously thought, with ITP comprising a heterogeneous group of disorders with different etiologies and responding to different treatment modalities. The identification of the different subsets of ITP patients will help to better define treatment options.

Definition and Classification

Although ITP has been recognized for centuries, there is as yet no consensus on either the definition or management of the disease. In 1996, the American Society of Hematology (ASH)¹⁴⁴ published practice guidelines for the diagnosis and management of ITP. In 2003, the British Committee for Standards in Haematology published its own guidelines.¹⁴⁵ In spite of these guidelines, the heterogeneity of the definitions and clinical criteria used in different studies has made it difficult to interpret the data regarding the incidence, pathogenesis, and treatment of ITP. In 2008, the International Working Group (IWG) proposed a standardization of terminology, definitions, and outcome criteria for ITP patients.¹⁴⁶ In 2010, an international consensus report on the investigation and management of ITP was published.¹⁴⁷ Shortly thereafter, in 2011, ASH updated its 1996 ITP guidelines.¹⁴⁸

The IWG definition proposed use of the term “immune thrombocytopenia” instead of “idiopathic thrombocytopenic purpura” as the basis for the ITP acronym, because the immune nature of ITP is clear but most ITP patients do not have purpura. A platelet count of $100 \times 10^9/L$ was proposed as the threshold level to entertain the diagnosis of ITP, because a sustained lower platelet count (100 to $150 \times 10^9/L$) can be seen in otherwise healthy individuals,^{11,12} and long-term observation of these

indicate that 88 percent reach normal platelet counts or remain stable.¹³ ITP is classified based on the absence or presence of other diseases as “primary” or “secondary.” “Primary ITP” denotes the absence of any other identified pathology. All other autoimmune thrombocytopenias are classified as “secondary ITP” (see Table 117–3), and the associated primary disorder is indicated in parenthesis, for example “secondary ITP (SLE-associated)” or “secondary ITP (drug-induced).” Heparin-induced thrombocytopenia (HIT) or alloimmune thrombocytopenias are not classified as ITP, and maintain their standard classifications.¹⁴⁶

The IWG described three phases of ITP: (1) newly diagnosed ITP (within 3 months of diagnosis); (2) persistent ITP (patients who do not achieve a stable remission between 3 and 12 months after diagnosis); and (3) chronic ITP (continuing for more than 12 months). ITP was formerly classified as mild, moderate, and severe depending on the platelet counts. However, the degree of thrombocytopenia does not always correlate with bleeding. The IWG proposed that the term “severe ITP” only be used for patients with clinically significant bleeding requiring additional therapy regardless of platelet count.¹⁴⁶

One of the major problems with comparing ITP studies had been the definition of response to therapy. The IWG proposed the following terms and criteria for response to ITP treatment: “complete response, CR” (platelet count exceeding $100 \times 10^9/L$ and no bleeding symptoms), “response, R” (platelet count higher than $30 \times 10^9/L$ or at least a two-fold increase from the baseline count and no bleeding symptoms), “no response, NR” (platelet count below $30 \times 10^9/L$ or less than a twofold increase from the baseline count, or presence of bleeding symptoms). “Duration of response” is measured from the time between first measured CR or R to relapse. “Corticosteroid dependence” is defined as the need for ongoing or repeated glucocorticoid use for at least 2 months to maintain CR or R. Patients who relapsed after splenectomy (failure to maintain CR or R) and required therapy are classified as “refractory ITP.” “On-demand therapy” is a term used for therapies employed to temporarily increase the platelet count in special situations such as trauma or surgery. “Adjunctive therapies” are treatments that are not designed to increase platelet counts, but that may decrease bleeding symptoms by other means, for example, treatment with oral contraceptives or antifibrinolytic drugs.¹⁴⁶

Incidence

ITP is relatively common, but demographic studies have yielded a wide range of incidence rates largely because of differences in the age and gender distribution of the populations studied and differences in cut-off platelet counts used to define the disease. ITP can affect males and females of any age. In one detailed study, the reported incidence of ITP was 3.9 per 100,000 per year. Although the overall incidence was higher in women than in men, a male predominance was seen in patients younger than 18 years of age and older than 65 years of age.¹⁴⁹

Clinical Features

ITP is of acute onset in children, often developing after vaccination or after a viral illness, and resolves spontaneously in 90 percent of cases. In adults, however, ITP usually is a chronic disease. Table 117–4 highlights the differences in ITP in children and adults. Approximately 25 percent of adult ITP patients are diagnosed incidentally on routine complete blood counts. Symptoms and signs of ITP depend not only on the platelet count, but also on the nature of coexisting conditions that can increase the tendency to bleed, such as uremia, trauma, and ingestion of drugs that affect platelet function (Table 117–5). Approximately one-third of patients have platelet counts greater than $30 \times 10^9/L$ at diagnosis and no significant bleeding.¹⁵⁰ Common bleeding signs include purpura (ecchymoses and petechiae), epistaxis, menorrhagia, and gingival bleeding. Hematuria, hemoptysis, and gastrointestinal bleeding

TABLE 117-4. Clinical Features of Idiopathic Thrombocytopenic Purpura in Children and Adults

	Children	Adults
Occurrence		
Peak age (years)	2–4	15–40
Sex (Female-to-Male)	Equal	1.2–1.7
Presentation		
Onset	Acute (most with symptoms lasting <1 week)	Insidious (most with symptoms lasting >2 months)
Symptoms	Purpura (<10% with severe bleeding)	Purpura (typically bleeding not severe)
Platelet count	Most cases <20,000/ μ L	Most cases <20,000/ μ L
Course		
Spontaneous remission	83%	2%
Chronic disease	24%	43%
Response to splenectomy	71%	66%
Eventual complete recovery	89%	64%
Morbidity and mortality		
Cerebral hemorrhage	<1%	3%
Hemorrhagic death	<1%	4%
Mortality of chronic refractory disease	2%	5%

are less common. Intracerebral hemorrhage is rare and generally occurs in patients with platelet counts less than $10 \times 10^9/L$ and usually is associated with trauma or vascular lesions. The incidence of life-threatening complications is highest in patients older than age 60 years.^{150–154} The majority of ITP patients have a good prognosis, the mortality rate being only slightly higher than that of the general population. However, ITP

TABLE 117-5. Situations That Increase the Bleeding Risk in Immune Thrombocytopenia Patients

Drugs: Anticoagulants, antiplatelet drugs, nonsteroidal antiinflammatory drugs, chemotherapy
Gastrointestinal pathologies that may cause bleeding (e.g., active peptic ulcer, inflammatory bowel disease)
Miscellaneous disorders that disturb hemostasis (e.g., congenital bleeding disorders, hepatic cirrhosis, uremia)
Older age (>60 years)
Nutritional factors such as herbal teas, kinin, and tonic water
Previous history of bleeding
Sport and occupational activities that increase bleeding risk
Trauma, surgery, and childbirth
Uncontrolled hypertension

patients who present with severe thrombocytopenia ($<30 \times 10^9/L$) and do not respond to any therapy within 2 years, have a fourfold increased risk of death compared to the general population.¹⁵⁵

The purpuric lesions seen in ITP are not palpable, do not blanch with pressure, and often develop on distal regions of the extremities and on skin areas exposed to pressure (e.g., around tight belts and stockings and at tourniquet sites). Hemorrhagic bullae, which may develop in the buccal mucosa, generally reflect acute, severe thrombocytopenia. Bleeding after surgery, trauma, or tooth extraction is common.

Besides the physical findings associated with platelet-type bleeding, the history and physical examination are usually unremarkable, except for the possibility of similar symptoms in other family members. Family history is especially important to discriminate familial thrombocytopenic syndromes from ITP. The spleen usually is not enlarged but may be palpable in some patients, a finding considered to occur with the same incidence as in normal adults.¹⁵⁶ Constitutional symptoms, such as fever, significant weight loss, marked splenomegaly, hepatomegaly, and lymphadenopathy provide evidence that the thrombocytopenia has another cause. The presence of skeletal, cardiac, renal abnormalities, hearing loss, albinism, or immune deficiencies in patients with thrombocytopenia should trigger suspicion of IPDs.

Fatigue is one of the common, but often neglected, complaints of patients with primary ITP. In a survey including UK and U.S. ITP cohorts, the prevalence of fatigue was found to be significantly higher in adult primary ITP patients (39 percent and 22 percent for the UK and U.S. cohorts, respectively) compared with healthy controls.¹⁵⁷ Fatigue has also been described in 20 percent of pediatric patients with ITP; fatigue resolved with the elevation of platelet counts.¹⁵⁸ Although glucocorticoids and immunosuppressive agents may induce fatigue, fatigue can occur in untreated ITP patients. The mechanism of fatigue in patients with ITP is unknown.

Patients with ITP are at slightly increased risk of venous and arterial thrombosis.¹⁵⁹ A recent retrospective study evaluating 986 patients with ITP showed the cumulative incidences of venous and arterial thrombosis to be 1.4 percent and 3.2 percent, respectively. This study found that increased thrombotic risk was associated with splenectomy, older age (>60 years), with the presence of more than two thrombotic risk factors at the time of diagnosis, and with glucocorticoid therapy.¹⁶⁰

Laboratory Features

In ITP patients the blood film usually demonstrates isolated thrombocytopenia without erythrocyte or leukocyte abnormalities. Platelet anisocytosis is a common finding. Mean platelet volume and platelet distribution width are increased. Platelets may be abnormally large or abnormally small. The former reflect accelerated platelet production,¹⁶¹ and the latter represent platelet fragments associated with platelet destruction.¹⁶² The observation of giant platelets should trigger consideration of IPDs, which often are misdiagnosed as ITP.¹⁶³ The bleeding time correlates inversely with platelet count if the count is less than $50 \times 10^9/L$, but may be normal in patients with mild or moderate thrombocytopenia,¹⁶⁴ making it an unreliable test for use in such patients. The ultrastructure of ITP platelets viewed by electron microscopy is similar to that of normal platelets.¹⁶⁵

Hemoglobin concentration and hematocrit are generally normal in patients with ITP. Anemia that is not easily explained (e.g., resulting from iron deficiency in bleeding patients or associated with thalassemia minor in endemic areas) must be investigated further. Autoimmune hemolytic anemia with a positive direct antiglobulin (Coombs) test and reticulocytosis may accompany ITP; this association is termed *Evans syndrome*.¹⁶⁶ Neither erythrocyte poikilocytosis nor schistocytes should be present. Total leukocyte counts and differential are generally normal.

Although atypical lymphocytes and eosinophilia may occur in children with ITP, leukocytosis and leukopenia with immature cells are not consistent with the diagnosis.

Marrow examination, which is not always required to make a diagnosis of ITP in adults, generally reveals a normal or increased number of megakaryocytes of normal morphology, although a decreased number of megakaryocytes does not rule out ITP. Erythropoiesis and myelopoiesis are normal. The international consensus report states that a marrow examination should usually be reserved for patients older than age 60 years, for those with systemic symptoms or other signs, and for those for whom splenectomy is contemplated. Biopsy for morphologic examination should be carried out, along with aspirate for flow cytometric and cytogenetic analysis.¹⁴⁷ The ASH 2011 guidelines, however, conclude that a marrow examination is unnecessary when the presentation is typical, even if the patients are older or being considered for splenectomy.¹⁴⁸

In ITP patients, initial workup should be targeted to exclude secondary causes of thrombocytopenia (see Table 117-3). Testing for viral etiology (hepatitis C virus [HCV], HIV, and in endemic areas hepatitis B virus [HBV]) and *Helicobacter pylori* is also recommended.^{147,148} Quantitative immunoglobulin assessment should be considered for pediatric cases to rule out common variable immunodeficiency (CVID).¹⁴⁷ Mild thrombocytopenia has been reported in patients with hypo- or hyperthyroidism, which returns to normal after appropriate therapy. Thyroid-stimulating hormone (TSH) and antithyroid antibodies may help to evaluate thyroid status in those patients.¹⁴⁷ Other tests to consider include blood group analysis and a pregnancy test for female patients of childbearing age, antiphospholipid antibodies, antinuclear antibody (ANA), viral polymerase chain reaction (PCR) for parvovirus, and cytomegalovirus (CMV). The results of these tests can change the treatment strategy.¹⁴⁷ On the other hand, the ASH 2011 guidelines do not recommend routine testing for antiphospholipid antibodies and ANAs in the initial workup of ITP,¹⁴⁸ unless signs or symptoms of an autoimmune disorder are present in the patient. Other tests, such as TPO levels, reticulated platelets, PAIgG, platelet survival studies, bleeding time, and serum complement levels are not recommended for the diagnosis and management of ITP patients in either of these guidelines.^{147,148}

Therapy and Course

What little is known of the natural course of moderate or severe ITP derives from before the glucocorticoid era, and suggests that left untreated, ITP in adults typically is a chronic disease, in contrast to ITP in children. In adults, the rate of spontaneous remission is reported as 9 percent,¹⁶⁷ and can occur even after 3 years in patients who present with severe thrombocytopenia.¹⁶⁸ Although ITP is a benign disease, side effects of the therapies can cause serious morbidity and even mortality. Treatment for patients with ITP should be based on bleeding signs and symptoms and on the presence of factors that increase the bleeding risk (see Table 117-5). Possible side effects of the drugs and other treatments used in ITP should always be considered.

Initial Management

Observation Because a significant portion of ITP patients are diagnosed incidentally in routine evaluation, signs and symptoms of bleeding are important in determining whether any treatment is required. The primary therapeutic goal is not simply to increase the platelet count, but to reach a safe platelet count where the risk of bleeding is minimal. Patients with no bleeding and consistent platelet counts in excess of $30 \times 10^9/L$ do not require treatment and can be observed periodically. These patients are at low risk for clinically important bleeding. Simple observation is not recommended for patients with platelet counts lower

than $10 \times 10^9/L$, in those with platelet counts between 10 and $30 \times 10^9/L$ and significant mucosal bleeding, or in those with risk factors for bleeding (see Table 117-5).¹⁶⁹ The presence of extensive purpura or hemorrhagic bullae in mucosal tissues (wet purpura) should be regarded as a harbinger of life-threatening bleeding and treated as such. Because ITP patients often have large platelets that may not be recognized by automated cell counters, a blood film should be evaluated before starting therapy in ITP patients with very-low platelet counts who are not bleeding. Identification of secondary ITP cases is very important, and management of these patients should include treatment of the underlying pathology, if possible.

Emergency Treatment of Acute Bleeding Resulting from Severe Thrombocytopenia

Bleeding symptoms generally are not severe in adult patients with ITP, even with very-low platelet counts. However, life-threatening bleeding can occur, especially after trauma. Emergency treatment should be instituted in patients with intracranial or gastrointestinal bleeding, massive hematuria or internal hematoma, or those in need of emergency surgical intervention or about to go into labor. Patients who experience significant bleeding should be hospitalized and monitored closely. Recommended treatment includes IVIG and parenteral glucocorticoids in combination. IVIG is given as 1 g/kg per day for 2 days, and high-dose parenteral glucocorticoid therapy includes high-dose prednisone or methylprednisolone (1 g/day for 1 to 3 days). In most patients, IVIG increases the platelet count within 2 to 3 days.^{147,148} Although platelet transfusions may not increase the platelet counts because the transfused platelets are destroyed rapidly, they nevertheless may contribute to the formation of platelet plugs at sites of bleeding and improve hemostasis. Platelet transfusion following IVIG infusion may increase the platelet count because IVIG may improve platelet survival.^{147,148,170} Aminocaproic acid, which inhibits fibrinolysis, can be used to reduce bleeding¹⁷⁰ and is safe except in the presence of hematuria, in which case it can cause thrombi of the glomeruli, renal pelves, and ureters. This agent does not affect platelet count or function. Aminocaproic acid is usually administered intravenously (initial dose 0.1 g/kg over 30 minutes, then given either by continuous infusion at 0.5 to 1.0 g/h or as an equivalent intermittent dose every 2 to 4 hours). Aminocaproic acid also can be administered orally in a similar dose in emergency situations because it is absorbed very rapidly from the gastrointestinal tract.^{147,148} Vincristine can be used in combination with glucocorticoids and IVIG in older patients.¹⁰⁸ Other hemostatic therapies, such as recombinant factor VIIa and fibrinogen infusions, have been reported to be effective in some ITP patients with life-threatening bleeding, but the risk-to-benefit ratio needs to be evaluated in controlled studies.^{171,172} Emergency splenectomy has been reported to be successful in refractory ITP with bleeding, but reports of its use in this situation are rare.¹⁷³ Because of this, this therapy should only be considered in the most dire circumstances. Although there are some case reports describing successful results with plasmapheresis, this treatment is not recommended in current ITP guidelines.^{147,148}

Glucocorticoid Therapy Glucocorticoids are accepted as the standard therapy for initial treatment in adult patients with ITP.^{147,148} Glucocorticoids increase the platelet count in several ways, including by inhibiting phagocytosis of antibody-coated platelets by macrophages, decreasing autoantibody production, and improving marrow platelet production.^{174,175} These agents also appear to reduce capillary leakage, thereby decreasing blood loss.¹⁷⁶ The major drawback of glucocorticoid therapy is that often the adverse effects of the treatment are worse than the disease itself. Important side effects, which can be severe, include facial swelling (chipmunk or moon facies), weight gain, folliculitis, hyperglycemia, hypertension, cataracts, osteoporosis, aseptic bone necrosis, opportunistic infections, and behavioral disturbances.^{177,178}

Still under investigation is which glucocorticoid and dosing regimen is best for raising the platelet count. Prednisolone, dexamethasone and methylprednisolone are all used. Generally, oral prednisone 1 to 2 mg/kg per day (or methylprednisolone at equivalent doses) is preferred as first-line therapy.^{147,148} Patients usually respond to prednisone therapy within 3 weeks. In approximately two-thirds of patients, platelet counts increase to greater than $50 \times 10^9/L$ within 1 week, but decrease again when the prednisone dose is decreased.^{152,177} Although no consensus exists regarding the duration of initial therapy, treatment should continue until platelet counts reach a safe range. In patients who respond, the recommendation is to continue glucocorticoid therapy 1 mg/kg per day for a total of 3 weeks before initiating a slow tapering of doses.¹⁴⁸ Sustained remission rates with glucocorticoid therapy are variable, reported rates ranging from 5 to 50 percent.^{108,155,177} If the patient does not respond to 3 weeks of prednisone therapy, other therapeutic options should be considered.

In addition to the standard 1 to 2 mg/kg per day dose of prednisone, lower^{179,180} and higher doses^{181–184} of prednisone, dexamethasone, and methylprednisolone have been investigated, with good results. The major aim of the high-dose glucocorticoid regimens is to reduce duration of therapy, and therefore reduce the side effects of the glucocorticoids. Studies with dexamethasone 40 mg/day for 4 consecutive days for one course, or with the same dose for four courses given every 2 weeks have been reported to produce responses in 50 percent and 89.2 percent of newly diagnosed ITP patients, respectively.^{185,186} High-dose methylprednisolone therapy has also been shown to be effective, with an 80 percent response rate.¹⁸⁷ Despite the favorable results of these studies, high-dose glucocorticoid regimens as first-line therapy still have not been validated with randomized controlled trials. ASH 2011 guidelines recommend longer courses of standard doses of glucocorticoids (prednisone 1 to 2 mg/kg per day) as a first-line treatment of ITP.¹⁴⁸

Splenectomy Splenectomy was demonstrated to be an effective treatment for patients with ITP a century ago¹⁸⁸ and after the glucocorticoid era, it has been used for decades as a standard second-line therapy. The spleen is the major site both for synthesis of antiplatelet antibodies and for destruction of antibody-coated platelets. Splenectomy will decrease antibody production and platelet destruction, and will be effective in patients in whom antibody-mediated platelet destruction rather than platelet production is the major cause of thrombocytopenia. Although splenectomy has been reported to be less preferred in recent ITP cohorts because of the emergence of new therapies such as TPO receptor agonists and rituximab,¹⁸⁹ splenectomy still produces the highest cure rates for ITP patients compared to all other therapies. Approximately 85 percent of patients with persistent or chronic ITP respond well to splenectomy, and 60 to 66 percent of the patients remain in remission after 5 years.^{189–191} These high cure rates makes splenectomy an important therapeutic option in the treatment of chronic ITP. The duration of the disease prior to splenectomy does not affect the outcome of the procedure, as it can be effective even years after ITP is diagnosed.^{192,193} Splenectomy can be performed during pregnancy (preferably during the second trimester), and does not affect the response rates to other treatments except anti-D therapy in chronic ITP patients. Also, the cost of splenectomy is lower than that of newer treatments such as rituximab and TPO-receptor agonists.¹⁹¹

On the other hand, splenectomy is an invasive procedure, causes the permanent loss of an organ, and increases the risk of serious bacterial infection, bleeding and thrombosis. Because ITP can remit spontaneously, splenectomy should be postponed at least 6 to 12 months after diagnosis if possible.^{147,148} Splenectomy is not recommended in patients with CVID, with chronic infections such as chronic hepatitis and HIV, or with known thrombophilia.

No validated clinical or laboratory tests exist that can predict whether splenectomy will be effective in elevating platelet counts in ITP patients. Although it has been suggested that ITP patients with predominant splenic sequestration (as determined by radioisotope techniques) have better response rates than patients with predominantly nonsplenic sequestration, these data have not been validated in other studies¹⁸⁹ and the required radioisotope techniques are not widely available.

Over the past decade minimally invasive laparoscopic splenectomy has gained preference over open splenectomy. Modern laparoscopic approaches reduce mortality rates (<1 percent), even in patients with severe thrombocytopenia.¹⁹⁴ The mortality rate increases in older patients, in patients with severe thrombocytopenia, and in the presence of coexisting illnesses.^{177,195} Postsplenectomy sepsis is a major cause of morbidity and mortality in ITP. Extended steroid or other immunosuppressive therapy preceding splenectomy may increase the risk of perioperative infection. To minimize the risk of sepsis, patients should be immunized at least 2 weeks before splenectomy with polyvalent pneumococcal vaccine, *Haemophilus influenzae* type B vaccine, and quadrivalent meningococcal polysaccharide vaccine.¹⁹⁶ Interestingly, newer studies of ITP patients undergoing splenectomy show enteric organisms to be responsible for most of the cases of postsplenectomy sepsis, probably because of the widespread vaccination of ITP patients.¹⁹¹ Splenectomized patients should be informed to be alert for the symptoms and signs of infection and be prepared for an emergency situation. Any fever should be carefully evaluated, and the patient treated with broad-spectrum antibiotics.

Splenectomy also increases the risk of thrombosis in ITP patients. In a large cohort of 9976 ITP patients, in whom 1762 underwent splenectomy; the cumulative incidences of abdominal venous thromboembolism and deep vein thrombosis/pulmonary embolism were increased in splenectomized patients compared to nonsplenectomized patients (1.6 percent vs. 1 percent for abdominal venous thrombosis, 4.3 percent vs. 1.7 percent for deep vein thrombosis–pulmonary embolism, respectively).¹⁹⁷ Several mechanisms may contribute to this enhanced risk for thrombosis, including postsplenectomy thrombocytosis and a failure to clear platelets, other cells and microparticles that express the procoagulant lipid phosphatidylserine. Perioperative measures such as antiembolic stockings and anticoagulant prophylaxis should be considered in those cases.

Both the time required to reach a normal platelet count and the magnitude of platelet recovery are accepted as useful predictors of the long-term efficacy of splenectomy. In most cases, platelet counts recover within 10 days. Patients who attain a normal platelet count within 3 days of splenectomy generally have a good long-term response.¹⁹⁸ In patients refractory to splenectomy, the presence of accessory splenic tissue should be suspected, particularly if the blood film shows no evidence of splenectomy (i.e., pitting and Howell-Jolly bodies are absent in the erythrocytes; Chap. 55). Such patients should be screened with sensitive radionuclide or magnetic resonance scans to identify residual or accessory splenic tissue.

Intravenous Immunoglobulin IVIG was first shown to be effective in childhood ITP in 1981,¹⁰⁹ then later in adult patients.¹⁹⁹ IVIG rapidly increases the platelet count in more than 75 percent of patients with chronic ITP and normalizes the platelet count in approximately 50 percent of the patients.^{177,178} The effect of IVIG is similar whether or not the patient has undergone splenectomy and is transient, generally lasting only 3 to 4 weeks. Postulated mechanisms for the action of IVIG include blockade of macrophage Fc receptors, which slows clearance of antibody-coated platelets, antiidiotype neutralization of antiplatelet autoantibodies, cytokine modulation, immunomodulation (increased suppressor T-cell function and decreased autoantibody production),

complement neutralization, and dendritic cell priming.^{178,200,201} The recommended total dose of IVIG is 2 g/kg administered either as 0.4 g/kg per day on 5 consecutive days or as 1 g/kg per day on 2 consecutive days. If the need to increase the platelet count is urgent, the preferred dosing is 1 g/kg per day for 2 days combined with glucocorticoids.¹⁴⁸ For maintenance therapy, 0.5 to 1.0 g/kg as a single dose may be used, administered every 3 to 4 weeks, or as needed. Although the annual total world consumption of IVIG exceeds 100 tons, the cost of IVIG is still high, and this also limits the use of IVIG in adults.²⁰² Adverse effects of IVIG therapy include headache, backache, nausea, fever, aseptic meningitis, alloimmune hemolysis, hepatitis, renal failure, pulmonary insufficiency, and thrombosis. Anaphylactic reactions may occur in patients with congenital IgA deficiency.¹⁷⁷ The patient may become refractory to the effect with repeated infusions of IVIG.²⁰³ IVIG is used as a first-line therapy in childhood ITP, because the thrombocytopenia is usually transient. In adult ITP, however, IVIG is usually reserved for patients with life-threatening bleeding, when a prompt increase in platelet count is needed,^{147,148} or as first-line therapy when glucocorticoids are contraindicated.¹⁴⁸

Anti-(Rh)D Anti-(Rh)D is a polyclonal γ -globulin containing high titers of antibodies against the Rh₀(D) antigen of erythrocytes. It is administered intravenously for treatment of ITP. Anti-(Rh)D binds Rh-positive erythrocytes and leads to their destruction in the spleen. Because splenic Fc receptors are blocked, more antibody-coated platelets survive in the circulation.^{204,205} Anti-(Rh)D also can also modulate Fc γ receptor expression and regulate the production of various cytokines, including IL-6, IL-10, and tumor necrosis factor- α .²⁰⁶ A positive direct antiglobulin test, a decrease in serum haptoglobin levels, and mild and transient hemolysis occur in all Rh-positive patients after anti-(Rh)D infusion, generally without requiring a blood transfusion.²⁰⁵ The rate of serious hemolytic reactions has been estimated as one in 1115 patients; any reaction occurs within 4 hours of administration in almost all cases.²⁰⁷ Anti-(Rh)D therapy is not effective in patients who have undergone splenectomy or in Rh-negative patients, and is not recommended in patients with a positive direct antiglobulin test.¹⁴⁸

It is recommended that anti-(Rh)D be given as a single dose of 50 to 100 mcg/kg by intravenous infusion over 3 to 5 minutes.^{204,208,209} Adverse effects of anti-(Rh)D therapy resemble those observed with both γ -globulin infusion and autoimmune hemolytic anemia; symptoms include headache, asthenia, chills, fever, abdominal pain, diarrhea, vomiting, dizziness, and myalgia. Patients can experience immediate anaphylactic reactions and both type I (IgE-mediated) and type III (immune complex-mediated) hypersensitivity reactions.^{204,205,208,210,211} Although anti-(Rh)D reportedly increases platelet counts within 1 week in more than 70 percent of patients who are Rh-positive and have their spleen,²¹² and may obviate the need for splenectomy,²¹¹ a randomized, controlled trial comparing anti-(Rh)D with conventional therapy showed no differences in the rates of spontaneous remission or the need for splenectomy.²⁰⁹ Anti-(Rh)D is listed in current ASH ITP guidelines as a first-line agent when glucocorticoids are contraindicated.¹⁴⁸ Anti-(Rh)D is currently not available in Europe.

Rituximab B lymphocytes play many roles in the pathophysiology of ITP, including producing antibodies, presenting antigens, and regulating the functions of T cells and dendritic cells. B cells are targeted therapeutically with rituximab, a chimeric monoclonal antibody against CD20, which binds B cells and causes Fc-mediated lysis, thereby depleting these cells from blood, lymph nodes, and marrow. Rituximab rapidly depletes B cells in patients with autoimmune diseases, with the effect usually lasting 6 to 12 months.^{114,213–217}

The optimal dosing regimen and duration of therapy have not been determined for patients with ITP. Usual rituximab doses are in the range of 100 to 375 mg/m². Most studies have used weekly infusion for 4 consecutive weeks at, the dose used to treat B-cell lymphoma (375 mg/m²). Studies with low-dose rituximab (100 mg weekly for 4 weeks) showed similar activity to the standard dose.²¹⁸ Published studies with rituximab, however, have generally not been controlled and are extremely heterogeneous in terms of rituximab dosing and response criteria. Approximately 40 to 60 percent of the ITP patients demonstrate a response to rituximab at 1 year, and 20 to 25 percent of those have a long-term response (at 5 years).^{215,219} Splenectomy does not affect response rates to rituximab therapy.^{135,216} In ITP patients who have relapsed more than 1 year after rituximab therapy, retreatment with the drug will induce similar responses in 75 percent of patients who responded initially.²²⁰ In spite of the apparent benefit of rituximab, its use is still considered “off-label” for ITP.

Different patterns of response have been reported in ITP patients treated with rituximab. Although the majority of patients responded within 4 to 6 weeks (early responders), response was delayed for several months in some patients (late responders). In ITP patients who responded to rituximab, the increase in platelet count was associated with reduction in the quantity of platelet-associated autoantibodies. Rituximab also indirectly affects T cells, as depletion of autoreactive B cells prevents T-cell activation. Interestingly, despite the depletion of peripheral B cells, platelet-associated autoantibodies were still found in the plasma of ITP patients who do not respond to rituximab.²²¹ A study analyzing the spleens of ITP patients who did not respond to rituximab therapy demonstrated the presence in the spleen of long-lived plasma cells that produced antiplatelet antibodies for as long as 6 months after rituximab therapy ended. However, this class of cells was not found in the spleens of patients who had not received rituximab. The authors of this study suggested that depletion of peripheral B cells by rituximab promotes the differentiation of long-lived plasma cells in the spleen of ITP patients, which might be responsible for the persistence of antiplatelet antibodies.²²²

In a meta-analysis of 306 ITP patients treated with rituximab, adverse reactions were reported as mild-to-moderate in 66 patients (21.6 percent) and life-threatening in 10 patients (3.7 percent); nine patients (2.9 percent) died.²¹⁵ Although some of these deaths were attributed to ITP-related complications and not to rituximab itself, this mortality rate is higher than expected. Infusion-related reactions in rituximab therapy can be severe, and rarely fatal. Premedication with methylprednisolone is recommended to avoid these reactions.²¹⁹ The risk of infection can increase as a result of depletion of B cells, decreased antibody production, and, rarely, neutropenia.²¹⁹ Treatment can also reactivate latent viruses, especially hepatitis B. Alteration of T- and B-cell populations, and decreased antibody titers against HBV may stimulate HBV replication, and rarely cause fatal fulminant hepatitis. All patients should be screened for HBV before rituximab therapy.²²³ Although preventive lamivudine or entecavir can be used in HBV-positive ITP patients, it is instead recommended that alternative therapies be used.²¹⁹ Other viral reactivation syndromes are less common; progressive multifocal leukoencephalopathy (caused by reactivation of polyomavirus JC) is extremely rare.

Thrombopoietin Receptor Agonists The observation that platelet production in patients with ITP is impaired, the massive megakaryopoiesis seen in the marrow of mice and humans treated with recombinant TPO (far greater than seen in patients with ITP), and the unexpectedly normal or only modestly elevated TPO levels in patients with ITP suggested the potential benefit of megakaryocyte-stimulation therapy in patients with refractory ITP. Early use of an altered form of a recombinant TPO molecule to stimulate platelet production in normal

platelet donors was halted because of its stimulation of autoantibodies that cleared endogenous TPO. Because of this untoward effect, the use of recombinant TPO was abandoned, and a search for molecules that might bind to and stimulate the TPO receptor ensued. Since then, the TPO receptor agonists romiplostim and eltrombopag have been clinically shown to stimulate platelet production.^{224,225}

Romiplostim This drug is a peptibody that carries four copies of a 14-amino-acid TPO-receptor-binding peptide fused to an immunoglobulin scaffold, and binds to the TPO-binding site of the TPO receptor with high affinity. The TPO receptor agonist induces megakaryocyte proliferation and differentiation by activating Janus-type tyrosine kinase (JAK)-signal transducer and activator of transcription (STAT) and mitogen-activated protein (MAP) kinase pathways.²²⁴ The insertion of dimeric peptide into the IgG₁ heavy chain increases the half-life of the molecule.²²⁵ Romiplostim has no homology with endogenous TPO, thus the risk of the development of antibodies against TPO is very low. Romiplostim and TPO may also increase platelet responses to agonists. Weekly subcutaneous injection of romiplostim at doses of 1 to 3 mcg/kg produced a dose-dependent increase in the platelet count, starting from day 5, with peak platelet levels reached by days 12 to 15, and platelet counts returning to baseline by day 28.^{131,135,224} Therapy for ITP is usually initiated at a dose of 1 mcg/kg per week, and the dose is then increased by 1 mcg/kg to a maximum of 10 mcg/kg until the patient reaches target platelet counts ($>50 \times 10^9/L$). Higher starting doses up to the maximum dose can be used in emergency situations. If the platelet count does not increase to safe levels after 4 weeks of romiplostim treatment at the maximum dose, the drug should be discontinued. Because platelet responses are highly variable, patients should be evaluated periodically, and the dose adjusted based on the platelet counts. Although discontinuation of romiplostim is recommended when the platelet count exceeds $400 \times 10^9/L$, it should be kept in mind that platelet counts can drop to extremely low levels. Close monitoring of the platelet counts is therefore crucial. Romiplostim can be used in patients with hepatic or renal insufficiency, but is not recommended in pregnant patients because it can cross the placenta. Two parallel placebo-controlled trials examined response rates to romiplostim in both splenectomized and nonsplenectomized patients treated for 24 weeks.¹³⁴ Durable platelet responses and overall platelet responses were achieved by 38 percent and 79 percent of splenectomized patients, and by 61 percent and 88 percent of nonsplenectomized patients who were given the drug. A newer study evaluating long-term (up to 5 years) results of romiplostim therapy showed that a platelet count of greater than $50 \times 10^9/L$ was achieved at least once by 95 percent of treated ITP patients.²²⁶

Eltrombopag This agent is a small (442 Da) nonpeptide molecule that binds to the transmembrane domain of the TPO receptor and triggers megakaryocyte growth and differentiation, increasing platelet production. Eltrombopag has some distinctive features compared to recombinant human thrombopoietin (rhTPO) and romiplostim: Eltrombopag does not compete with TPO binding, and while it induces the phosphorylation of STAT proteins, it does not affect the AKT pathway.²²⁷ Eltrombopag has no effect on platelet activation in response to agonists.²²⁵ In healthy volunteers, daily doses given for 10 days elevated platelet counts beginning at 8 days and peaking at 16 days. Eltrombopag is used orally at daily doses of 25 to 75 mg, and should be given 2 hours before or after meals because food can affect its absorption. Ethnic differences in eltrombopag pharmacokinetics have been described. Lower initial doses and slower titration is preferred in East Asian patients.²²⁸ Divalent cations such as calcium interfere with absorption of the drug, so it should not be taken with dairy products or antacids. Eltrombopag can also interfere with the uptake and metabolism of statins, increasing

their plasma concentrations. Eltrombopag is metabolized in the liver, and causes liver function abnormalities in approximately 13 percent of patients administered the drug. Reduced initial doses are recommended in patients with liver disease.²²⁵ Eltrombopag increases platelet counts ($50 \times 10^9/L$) in 80 percent of splenectomized and 88 percent of nonsplenectomized chronic ITP patients.²²⁹ A newer study evaluated repeated short-term doses of eltrombopag (50 mg daily for up to 6 weeks followed by up to 4 weeks off therapy over three cycles) and suggested that eltrombopag can be used as on-demand therapy and repeated courses would be effective and safe.²³⁰

Newer Thrombopoietin Receptor Agonists Other congeners are currently being evaluated. An oral, nonpeptide TPO-receptor agonist, avatrombopag, binds to the transmembrane domain of TPO receptor, and increases platelet counts. Lack of significant food interaction is an important feature of this new drug.¹³⁶ Its use is pending FDA approval.

Common side effects of TPO receptor agonists include mild headache, arthralgia, nasopharyngitis, fatigue, diarrhea, and nausea. These side effects are generally mild and usually of insufficient severity to cause the discontinuation of the drugs. Abnormalities of liver function tests (elevated alanine aminotransferase [ALT], aspartate aminotransferase [AST], and bilirubin levels) occur in approximately 2 percent of ITP patients receiving eltrombopag therapy but not with romiplostim.²²⁵ Autoantibodies against romiplostim may develop but rarely have neutralizing activity.

TPO-receptor agonists can induce extreme thrombocytosis, sometimes exceeding $1000 \times 10^9/L$. Careful dose titration is very important, because cessation of the TPO-receptor agonists cause rebound thrombocytopenia in approximately 10 percent of ITP patients.²²⁵ Rates of thromboembolic events were reported as 6.5 percent and 4 percent with extended romiplostim and eltrombopag treatment, respectively.^{225,230} The authors of these studies concluded that thromboembolic events are not associated with the dose of TPO receptor agonists or platelet counts, and at least one acquired and inherited thrombotic risk factor was present in most of the patients who experienced thrombosis while they were taking TPO-receptor agonists.^{226,230} Nevertheless, the frequency of thrombosis in these studies was slightly higher than observed in other ITP studies.¹⁶⁰ Secondary myelofibrosis (increased marrow reticulin) is sometimes associated with therapy with TPO receptor agonists, and is usually reversible. Concerns have also been expressed that these drugs might accelerate the progression of hematologic and solid malignancies. Under normal circumstances, expression of the TPO receptor (mpl) is highly restricted to hematological tissues including marrow, spleen, placenta, brain and fetal liver cells. TPO receptor expression has been demonstrated on the leukemic cells of patients with acute myelogenous leukemia (AML) and MDS, but not in lymphoid malignancies, myeloproliferative neoplasms, or other nonhematologic malignancies.²³¹ Although romiplostim therapy was discontinued in a study of its use in patients with low-/intermediate-risk MDS and thrombocytopenia because of increased blast and AML rates (interim hazard ratio: 2.51), long-term analysis of the study showed similar survival and AML rates in the romiplostim and control groups.²³² The question of whether use of TPO-receptor agonists increases the risk of leukemia warrants further study.

Azathioprine This purine analogue is converted to 6-mercaptopurine following gastrointestinal absorption and works by suppressing the immune response. At least 4 months of azathioprine therapy at doses ranging from 50 to 250 mg/day are necessary to evaluate therapeutic efficacy. One study reported that azathioprine produced a sustained normalization of the platelet counts in up to 45 percent of patients with refractory ITP.²³³ Azathioprine can be used in pregnancy if necessary (see "Thrombocytopenia During Pregnancy" below). As with other

immunosuppressive drugs, major adverse effects are marrow suppression and possible increased risk of secondary malignancy.^{177,234}

Cyclophosphamide This alkylating drug can be used orally (50 to 200 mg/day) or parenterally (1.0 to 1.5 g/m² IV every 4 weeks) in patients with refractory ITP.^{235,236} It increases platelet counts in 60 to 80 percent of patients with ITP, and 20 to 40 percent of those patients will remain in remission for 2 to 3 years¹⁷⁷ after receiving 2 to 3 months of therapy. Its beneficial action is linked to its immunosuppression. The major complications of cyclophosphamide therapy are marrow suppression, hemorrhagic cystitis, infertility, alopecia, and secondary malignancy.

Cyclosporine Cyclosporine is an immunosuppressive drug inhibiting T-cell function, and is primarily used to prevent rejection in patients with organ transplantation. Although cyclosporine may induce a durable remission in patients with ITP when used at relatively low doses (2.5 to 3.0 mg/kg/day),²³⁷ experience with cyclosporine in ITP patients is usually based on small case series. Cyclosporine has several side effects, some potentially serious, including fever, increased risk of opportunistic infections, gingival hyperplasia, diarrhea, peptic ulcer, pancreatitis, renal dysfunction, elevated liver enzymes, hypertension, peripheral neuropathy, convulsions, hirsutism, and increased risk of secondary malignancy.

Danazol This synthetic androgen, with reduced virilizing effects compared to other androgens, has been used to treat patients with refractory ITP. Given at doses of 400 to 800 mg/day for at least 6 months, reported response rates range from 10 to 80 percent.^{177,234} Danazol is postulated to decrease Fc receptor numbers on phagocytic cells by antagonizing the effects of estrogens.¹⁵³ Danazol should not be given to pregnant women or patients with liver disease. Common side effects of danazol therapy are weight gain, fluid retention, seborrhea, hirsutism, secondary amenorrhea, vocal changes, acne, hepatic toxicity, headache, lethargy, cholesterol spectrum abnormalities (i.e., reduced high-density lipoprotein [HDL] cholesterol) and myalgia. Because liver dysfunction is common with these doses of danazol therapy, liver function should be evaluated monthly.^{153,177,234}

Dapsone Dapsone possesses antibacterial and antiinflammatory effects; it is primarily used for leprosy, malaria, and some types of dermatitis. When used at a dose of 75 to 100 mg/day, dapsone may increase platelet counts in patients with persistent, refractory, or chronic ITP.^{147,238,239} The median time to response is long, up to 2 months. Partial and CR rates are approximately 50 percent and 20 percent, respectively, but platelet counts return to baseline levels after discontinuation of the therapy.^{238,239} The mechanism of dapsone action in ITP is not known. The most important side effects are nausea, headache, skin rashes, hepatitis, cholestasis, dose-dependent hemolysis, and methemoglobinemia. Dapsone should not be given to patients with glucose-6-phosphate dehydrogenase deficiency.

Vinca Alkaloids Both vincristine and vinblastine transiently increase the platelet count in approximately 70 percent of ITP patients within 5 to 21 days, but produce sustained remissions in only 10 percent of treated patients.^{108,153,177,234} The recommended dose of vincristine is 1 to 2 mg and of vinblastine is 0.1 mg/kg (maximum: 10 mg), both given by bolus injection at 1-week intervals for a minimum of three courses. It has been proposed that vinca alkaloids bind to platelet microtubules and thereby are transported to the spleen, where they subsequently inhibit the phagocytic functions of splenic macrophages. They may also stimulate megakaryopoiesis. Peripheral neuropathy, neutropenia, jaw pain, alopecia, and constipation are complications of treatment with vinca alkaloids.^{234,240–242}

Other Therapies ITP patients with *H. pylori* infection should receive eradication therapy.¹⁴⁸ Many other therapies, including interferon- α ,²⁴³ immunoabsorption with staphylococcal protein A,²⁴⁴ ascorbic acid,²⁴⁵ colchicine,²⁴⁶ and plasmapheresis,²⁴⁷ have been studied for refractory ITP cases, but none has been clearly demonstrated to be effective.

Accessory Therapies Adjunctive therapies include agents designed to reduce bleeding without necessarily affecting the platelet count. Aminocaproic acid or tranexamic acid, both of which inhibit fibrinolysis, can be used for excessive mucosal bleeding. Local bleeding can be controlled by compression and use of gelatin sponges, fibrin sealants, or antifibrinolytic-embedded gauze. Avoiding the use of antiplatelet drugs, contact sports, and activities that increase bleeding risk, and educating patients about maintaining dental hygiene are very important. Menorrhagia is a common problem in patients with chronic ITP; gynecologic evaluation of uterine problems is crucial. Oral contraceptives and hormonal intrauterine devices together with antifibrinolytic drugs may help to reduce excessive menstrual bleeding in these patients.

SECONDARY IMMUNE THROMBOCYTOPENIA

Secondary ITP is defined as immune-mediated platelet destruction in the presence of other conditions, including infections, lymphoproliferative disorders, solid tumors, SLE, or the antiphospholipid syndrome (APS) (Fig. 117–4). ITP can sometimes be the presenting sign of the illness, or may develop during the course of the disease or with certain therapies. Thrombocytopenia in a patient with chronic disease may develop for other reasons, and the diagnosis of immune-mediated platelet destruction may require more detailed tests. Generally,

Figure 117–4. Estimated fraction of the various forms of secondary ITP based on clinical experience of the authors. The incidence of *Helicobacter pylori* (HP) ranges from approximately 1 percent in the United States to 60 percent in Italy and Japan. The incidence of the HIV and hepatitis C virus approximates 20 percent in some populations. Miscellaneous causes of immune thrombocytopenia, for example, post-transfusion purpura, myelodysplasia, drugs that lead to the production of autoantibodies, and other conditions, are not discussed further in this chapter. Post marrow or solid-organ transplantation autoimmune lymphoproliferative syndrome (ALPS) occurred in approximately 1 percent of the authors' patients. In the absence of a systematic analysis of the incidence of secondary ITP, the data shown represent the authors' assessment based on our experience and the findings reported in the literature. APS, antiphospholipid syndrome; CLL, chronic lymphocytic leukemia; CVID, common variable immune deficiency; SLE, systemic lupus erythematosus. (Reproduced with permission from Cines DB, Bussel JB, Liebman HA, Luning Prak ET. The ITP syndrome: Pathogenic and clinical diversity. *Blood* 113(26):6511–6521, 2009.)

thrombocytopenia is not severe in patients with secondary ITP, but bleeding risk may be enhanced at a particular platelet count because of the underlying disorder. The treatment strategy should be tailored to the individual patient.

IMMUNE THROMBOCYTOPENIA IN PATIENTS WITH ANTIPHOSPHOLIPID SYNDROME, SYSTEMIC LUPUS ERYTHEMATOSUS AND OTHER CONNECTIVE TISSUE DISORDERS

Thrombocytopenia in the Antiphospholipid Syndrome

APS is characterized by recurrent arterial and/or venous thrombosis and well-defined morbidity during pregnancy in the presence of antiphospholipid antibodies (APLAs) (Chap. 132).²⁴⁹ APS may affect any organ in the body, including the heart, brain, kidney, skin, lung, and placenta. This syndrome predominantly affects females (female-to-male ratio 5:1), especially during the childbearing years.²⁵⁰ APLAs (lupus anticoagulant; anticardiolipin antibodies; anti- β_2 -GPI antibodies) represent a heterogeneous family of antibodies that react with anionic phospholipids and phospholipid-protein complexes. Despite overwhelming evidence that APLAs are associated with thrombosis, the mechanisms remain uncertain. Many have been proposed, including endothelial cell damage and apoptosis, inhibition of prostacyclin release from endothelial cells, inhibition of the protein C-protein S anticoagulant system, induction of tissue factor, activation of platelets and the complement system, interference with antithrombin, impairment of fibrinolytic activity, and inhibition of annexin V binding to membrane phospholipids, eliminating the antithrombotic effect of annexin V.²⁵¹⁻²⁵⁴ APS is considered one of the most common causes of acquired thrombophilia.^{255,256}

Thrombocytopenia is reported in approximately 20 to 40 percent of patients with APS, usually is mild (70 to $120 \times 10^9/L$), and does not require clinical intervention. Severe thrombocytopenia (platelet counts $<50 \times 10^9/L$) occurs in 5 to 10 percent of patients.²⁵⁷⁻²⁵⁹ Although thrombocytopenia was a clinical criterion used to define the syndrome in the initial classification of APS,²⁶⁰ it was not included in the most recently proposed classification.²⁶¹ Because ITP patients who present with APLAs are at increased risk for thrombosis,²⁶² measurement of APLA, especially lupus anticoagulant, in patients diagnosed with ITP may identify a subgroup at high risk for developing APS. The pathogenesis of thrombocytopenia in APS is not clear. Potential mechanisms explaining thrombocytopenia in APS patients include APLA-related direct platelet destruction, immune platelet destruction by antibodies against platelet GPs, complement-mediated platelet destruction, and platelet aggregation and consumption. Evidence indicates APLAs bind platelet membranes and cause platelet destruction, but the link is not definitive. Some investigators suggest that antibodies against platelet GPs, rather than APLAs, are responsible for thrombocytopenia in patients with APS. Antibodies against the integrin $\alpha_{IIb}\beta_3$ or GPIb-IX-V complexes are found in approximately 40 percent of thrombocytopenic patients with APS.²⁶³ Such antibodies do not cross-react with antibodies against phospholipids or β_2 -GPI.²⁶⁴ Immunosuppressive treatment in these patients increases the platelet count and reduces the titers of anti-GP antibodies but not the titers of APLAs.²⁶⁵ These data suggest that thrombocytopenia is a secondary immune phenomenon that develops concomitantly with APS. Against this conclusion, platelet antigens in thrombocytopenic patients with APS were found to be different from those in ITP and the antibodies to display virtually no reactivity with membrane GPs.²⁶⁶ CD40 ligand on platelets is another possible antibody target. Anti-CD40 ligand antibodies have been found in patients with APS (13 percent) and ITP (12 percent), but not in healthy controls; and it was suggested

that these antibodies cause thrombocytopenia.²⁶⁷ Platelet activation, aggregation, and consumption (APS-associated thrombotic microangiopathy) may also contribute to thrombocytopenia.²⁵⁹ Another issue of clinical importance in evaluating thrombocytopenia associated with APS is the risk for future development of thrombosis. In one study in which APS patients were divided into three groups according to platelet counts as normal, moderately thrombocytopenic (50 to $100 \times 10^9/L$), or severely thrombocytopenic ($<50 \times 10^9/L$), the rates of future thrombosis were 40 percent, 32 percent, and 9 percent, respectively.²⁶⁸ These data show that moderate thrombocytopenia does not prevent thrombosis in patients with APS. Antithrombotic prophylaxis should be considered in these patients whenever it is possible.^{257,268}

Although thrombocytopenia is a common finding in patients with APS, bleeding complications are rare, even with severe thrombocytopenia. Bleeding in an APS patient with moderate thrombocytopenia should trigger evaluation for the presence of antiprothrombin antibodies²⁶⁹ and other disorders that may affect hemostasis, such as DIC, liver insufficiency, and uremia. Severe thrombocytopenia may require therapy, with treatment strategies similar to those used for patients with ITP. Glucocorticoids are effective in only 15 percent of patients.²⁵⁷ IVIG and immunosuppressive drugs such as azathioprine and cyclophosphamide can be used in patients with severe bleeding and “catastrophic” APS. In general, splenectomy should be postponed as long as possible, and is only preferred in patients with severe bleeding. Splenectomy may produce sustained remission in approximately two-thirds of patients as in patients with primary ITP.^{167,270,271} Because of their increased risk of thrombosis, patients should be prophylactically anticoagulated in the immediate postoperative period. Rituximab has been used to treat refractory thrombocytopenia in patients with APS, with a wide range of results.²⁷²⁻²⁷⁴ Although there is no consensus on dosing and schedule with rituximab therapy, it is generally administered as in patients with ITP (see ITP therapy in “Therapy and Course” above). TPO receptor agonists may increase thrombosis risk in patients with APS and SLE and these diagnoses in a patient with ITP were accepted as exclusion criteria in some randomized controlled studies of TPO-receptor agonists.¹³⁶ Two case reports described acute renal failure (one was a result of thrombotic microangiopathy) after use of eltrombopag.^{275,276}

Thrombocytopenia in Patients with Systemic Lupus Erythematosus and Other Connective Tissue Disorders

SLE is a complex autoimmune disease that primarily afflicts women of childbearing age. The autoimmune attack in SLE is not organ specific; it may affect any tissue in the body. The diagnostic criteria for SLE are based on a classification system proposed by the American College of Rheumatology.^{277,278} The presence of hematologic findings (leukopenia, thrombocytopenia, or hemolytic anemia) is one of the criteria in the diagnosis and classification of SLE. Thrombocytopenia is common in patients with SLE, occurring in 20 to 40 percent of patients, and may be a presenting symptom.²⁷⁹ Immunologic destruction of platelets is also seen in several other autoimmune conditions, including polyarteritis nodosa, rheumatoid arthritis, mixed connective tissue disease, and Sjögren syndrome, albeit at much lower rates than in SLE.

The causes of thrombocytopenia in SLE are many and include platelet destruction (ITP, DIC, thrombotic thrombocytopenic purpura [TTP] or hemolytic uremic syndrome [HUS], sepsis, drugs), ineffective hematopoiesis (megaloblastic anemia), abnormal platelet pooling (hypersplenism), marrow hypoplasia (from drugs and infections), and dilutional thrombocytopenia related to therapy. Severe thrombocytopenia is relatively rare, occurring in 5 percent of patients.²⁷⁹ Although clinically significant bleeding is uncommon even in patients with severe

thrombocytopenia, fatal gastrointestinal, cerebral, and pulmonary bleeding have been reported. Among the many potential contributors to thrombocytopenia in SLE patients, platelet destruction by autoantibodies is the major mechanism. Antiplatelet antibodies are present in up to 60 percent of SLE patients.^{280,281} The presence of antiplatelet antibodies is correlated with low platelet counts and increased disease severity.²⁸¹ Besides the antiplatelet antibodies, APLAs (see “Thrombocytopenia in the Antiphospholipid Syndrome” above) and circulating immune complexes that bind platelets may nonspecifically accelerate platelet destruction.²⁸² Specific antiplatelet antibodies, especially those against integrin, have an important role in the pathogenesis of thrombocytopenia in SLE patients.^{280,281,283} In general, marrow megakaryocytes are normal or increased, and platelet production is not affected in SLE patients with thrombocytopenia. However, decreased numbers of megakaryocytes and even amegakaryocytic thrombocytopenia have been reported.^{86,284} High levels of TPO in the plasma, and both anti-TPO and anti-TPO receptor antibodies have been reported in SLE patients,^{285,286} the latter associated with a decrease in marrow megakaryocytes and thrombocytopenia.²⁸⁶ Thrombocytopenia in SLE is associated with serious organ pathology, leading to neuropsychiatric disease,²⁸⁷ renal disease,^{288,289} and APS,²⁹⁰ and is an independent indicator of poor prognosis.^{289,291,292} A study of selected SLE families in which at least one affected member was thrombocytopenic reported genetic linkage to loci at chromosomes 11p13 and 1q22–23.²⁹³ A severe lupus phenotype was much more common in patients with thrombocytopenia and their affected family members than in patients from families with no thrombocytopenic patients. Therefore, thrombocytopenia in a family member may herald severe lupus in familial SLE.

There are no well-established treatment strategies for severe thrombocytopenia in patients with SLE. Because SLE ranges in severity from milder forms with easily controlled symptoms and signs to severe forms that can be fatal, the treatment of severe thrombocytopenia should be tailored to the individual patient. Patients with severe thrombocytopenia are generally treated with glucocorticoids as first-line therapy, but sustained remission is infrequent. Because most patients with severe thrombocytopenia also have nephritis and neurologic symptoms, they receive immunosuppressive therapy either alone or combination with glucocorticoids.^{294–297} IVIG is reserved for use in patients with severe bleeding.^{298,299} It is well-known that B lymphocytes play an important role in the pathogenesis of SLE. Although lymphopenia is common in patients with active SLE, autoantibody-producing B cells have been shown to be expanded, and B cells were found to be more sensitive to inflammatory cytokines.³⁰⁰ B-cell targeted therapy—rituximab—is effective in the treatment of refractory SLE patients, especially those with nephritis and severe thrombocytopenia.³⁰⁰ A retrospective study evaluating the long-term effects of rituximab therapy in 65 patients with refractory ITP associated with SLE and mixed connective tissue disease reported an overall response rate of 80 percent.³⁰¹ Although case series indicate that splenectomy yields sustained remission in 61 percent of SLE patients with severe thrombocytopenia²⁹⁵ and is relatively safe in terms of perioperative complications,³⁰² splenectomy may increase the risk of thrombotic complications in SLE patients,³⁰³ and may also increase the risk of infection if the patients require further immunosuppressive therapy.

THROMBOCYTOPENIA IN INFECTIOUS DISEASES

The first recorded observation of purpura was made in patients with fever, and purpura was accepted as a sign of severe infections for centuries. Thrombocytopenia can be seen in patients with viral, bacterial, fungal and parasitic infections. Infection can decrease platelet levels

in several ways: by decreasing production in the marrow, by increased immune destruction, or by inducing microangiopathy as seen in patients with infection induced DIC or HUS. In addition, drugs used for the treatment of an infection can contribute to thrombocytopenia (see “Drug-Induced Thrombocytopenia” below).

Viral infections are an important cause of secondary ITP. ITP can be seen after a viral infection, especially in children, and usually resolves within 2 to 8 weeks. In patients with viral infections such as rubella, mumps, and infectious mononucleosis, thrombocytopenia can be present with other clinical signs and symptoms. Adult patients with isolated thrombocytopenia with no obvious causes should be screened for HIV, HCV and, in endemic areas, for HBV. Because other clinical symptoms and signs associated with infection with these viruses may not be present initially, and it may not be possible to distinguish these cases from primary ITP.

HIV is a leading cause of isolated thrombocytopenia in Western countries. Thrombocytopenia associated with HIV infection has numerous causes, many of which can be present simultaneously. These include accelerated platelet destruction primarily related to immune complexes, decreased platelet production, especially in advanced disease, splenic sequestration, and, rarely, platelet consumption associated with TTP. Medications, concurrent infections such as hepatitis C, and hematologic malignancies may contribute to the development of thrombocytopenia (Chap. 83).^{304–307}

HCV is another important cause of thrombocytopenia in adults. It is a hepatotropic RNA virus of the Flaviviridae family. HCV infection is chronic in approximately 85 percent of the infected individuals and progresses to cirrhosis in 20 percent of these individuals. The World Health Organization (WHO) estimates that approximately 3 percent of the world's population is infected with HCV, the prevalence ranging from 0.5 to 2 percent in Western countries to 20 percent in some underdeveloped countries.³⁰⁸ HCV causes thrombocytopenia through different mechanisms, including hypersplenism, decreased TPO level associated with liver insufficiency, the effect of drugs (pegylated interferon [IFN] and ribavirin), and immune-mediated platelet destruction.³⁰⁹ Immune dysregulation in HCV is associated with several autoimmune disorders, including arthritis, Sjögren syndrome, cryoglobulinemia, and immune cytopenias.³¹⁰ As a potential mechanism of immune destruction, one study demonstrated binding of both free and IgG-complexed HCV to platelets.³¹¹ In secondary ITP associated with HCV infection, antiviral therapy with pegylated IFN and ribavirin will decrease viral load and may also treat thrombocytopenia. However, platelet counts can be unaffected or even decrease after these therapies. Severe thrombocytopenia interferes with optimal HCV treatment, and may increase bleeding risk. In this situation, the ASH 2011 guideline recommends IVIG as a first-line therapy, because glucocorticoids may increase viral load.¹⁴⁸ Glucocorticoids and splenectomy both appear to be effective treatments for thrombocytopenia, but their use should be balanced against other considerations after discussion with a hepatologist. TPO receptor agonists may increase the risk of abdominal thrombosis in HCV patients with liver cirrhosis.³¹²

The potential role of *H. pylori* in the pathogenesis of chronic ITP is controversial. Japanese and Italian studies showed that eradication of *H. pylori* with antibiotics resulted in marked platelet count increases in patients with ITP. However, this success was not reproduced in American and other European studies.³¹³ It appears that response rates are higher in countries where *H. pylori* infection is endemic. ITP patients treated for *H. pylori* had higher platelet counts than untreated ITP patients, even if the therapy was unsuccessful in eradicating the infection.³¹⁴ It has therefore been speculated that the antibiotic therapy, rather than eradication of *H. pylori*, may be the factor improving platelet counts. However, meta-analysis found that *H. pylori* eradication therapy

was much more likely to increase platelet counts in patients with *H. pylori* infection than in uninfected patients,³¹⁵ strengthening the case for a causal relationship between infection and thrombocytopenia. On the other hand, eradication was shown to be less effective in patients with severe thrombocytopenia.³⁰⁹ The recent ASH ITP guideline suggests that ITP patients be screened for *H. pylori* and for eradication therapy to be used if testing is positive.¹⁴⁸

● THROMBOCYTOPENIA DURING PREGNANCY

Thrombocytopenia is the second most common hematologic problem in pregnancy, after anemia. Table 117-6 lists the major causes of thrombocytopenia in pregnancy (Chap. 7). Platelet counts tend to decrease during normal pregnancy, and mild thrombocytopenia (platelet counts ranging from 120 to 150 × 10⁹/L) occurs with moderate frequency, especially during the third trimester.^{316,317} Bleeding symptoms are generally mild, even in patients with severe thrombocytopenia, probably because of the procoagulant state of pregnancy. Nevertheless, it is important to investigate the cause of thrombocytopenia and exclude the disorders associated with significant morbidity such as eclampsia and hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome (Table 117-6). A medical history should include previous blood counts, history of other diseases, nutritional status, and intake of drugs and herbal supplements. It is important to be alert to constitutional symptoms including fever, and, especially, weight loss; neurologic abnormalities, arthritis, rash, and icterus. Key steps in the evaluation of thrombocytopenia in a pregnant woman include blood pressure measurement, evaluation of coagulation parameters, liver and kidney function tests, and examination of the blood film. Physical examination of the abdomen may be difficult in the third trimester and abdominal ultrasound may be required to detect organomegaly. If there are no suspicious clinical or laboratory findings, marrow aspiration is considered unnecessary.^{317,318}

TABLE 117-6. Causes of Thrombocytopenia During Pregnancy

Acute fatty liver of pregnancy
Antiphospholipid syndrome and systemic lupus erythematosus
Marrow disorders (e.g., aplastic anemia, acute leukemia)
Disseminated intravascular coagulation
Drugs (mostly heparins and antibiotics)
Gestational thrombocytopenia
Hemolysis, elevated liver function tests, low platelets (HELLP) syndrome
Hypersplenism
Immune thrombocytopenic purpura
Nutritional deficiencies including folate deficiency
Preeclampsia, eclampsia
Pseudothrombocytopenia
Thrombotic thrombocytopenic purpura-hemolytic uremic syndrome
Viral infections

GESTATIONAL THROMBOCYTOPENIA

Gestational thrombocytopenia is detected in 5 to 7 percent of otherwise healthy pregnant women, accounting for 64 to 80 percent of patients with thrombocytopenia at term.³¹⁹⁻³²¹ Gestational thrombocytopenia is a benign disorder and is not associated with an increased risk of bleeding. Platelet counts are greater than 70 × 10⁹/L^{316,317,319,320} and return to normal after delivery.

The pathogenesis of gestational thrombocytopenia is unknown. Several mechanisms have been proposed, including hemodilution, a compensated state of subclinical coagulopathy, endothelial cell injury, and immune destruction. Some authors have proposed platelet consumption by the placenta and hormonal depression of megakaryopoiesis as causes of gestational thrombocytopenia, as suggested by the rapid return of the platelet count to normal after delivery and by the transient normalization of the platelet count during pregnancy in some cases of essential thrombocythemia.³²¹⁻³²⁴ Discriminating gestational thrombocytopenia from ITP can be difficult because ITP is also common in young women, and is often exacerbated by pregnancy. Neither condition can be definitively diagnosed by currently available tests. The diagnosis of ITP is favored if the patient had a previous episode of ITP unassociated with pregnancy or if the thrombocytopenia is severe and associated with bleeding that occurs in the first trimester. In healthy pregnant women, a platelet count greater than 70 × 10⁹/L late in pregnancy does not require intensive investigation, because bleeding is not likely in the woman or her newborn child.³²⁵

IMMUNE THROMBOCYTOPENIA IN PREGNANCY

ITP is responsible for 4 to 5 percent of all cases of pregnancy-associated thrombocytopenia.^{319,321} Pregnancy itself may induce ITP, or exacerbate preexisting ITP, but generally the platelet count returns to the prepregnancy level after delivery. Diagnosis of ITP in a pregnant woman requires the exclusion of other causes of thrombocytopenia as in a nonpregnant woman, but also requires the evaluation of other pregnancy-related causes (see Table 117-6). However, the management of ITP during pregnancy is different than in nonpregnant women. First, many of the drugs used to treat ITP may complicate pregnancy-related problems such as gestational diabetes, hypertension, and psychiatric disorders. Second, the fetus can also be affected by ITP and its treatment. Antiplatelet antibodies can cross the placenta, decrease the fetal platelet count, and sometimes cause bleeding.³²⁰ ITP drugs can affect fetal development and growth, a fact to be considered in selecting therapy during pregnancy. And third, all pregnancies will end with delivery of the baby, a process that may happen unexpectedly. Preparation for delivery in a pregnant ITP patient requires close collaboration between the hematologist, the obstetrician, and the neonatologist.

In the management of pregnancy-related ITP, bleeding symptoms and platelet counts should be considered.^{147,148} Although previous guidelines have defined threshold platelet levels for treatment during pregnancy and labor, these numbers are arbitrary and not based on randomized controlled studies. Generally, observation without therapy is appropriate if the platelet count is greater than 30 × 10⁹/L and the patient has no bleeding symptoms. Therapy is required for a pregnant woman who is bleeding, has a platelet count less than 20 × 10⁹/L in any trimester, or has a platelet count of 20 to 30 × 10⁹/L in the third trimester.^{147,318} Platelet counts should be increased to safe levels (generally >30 × 10⁹/L) if invasive procedures are planned. Glucocorticoids are the preferred initial therapy for these patients. Because of their side effects, glucocorticoids should be used at the minimal dose that will keep platelet counts in a safe range. The recommended starting dose of prednisone is 10 mg/day,

which can be modified as appropriate.^{147,318} Fetal side effects will be minimal with a low-dose glucocorticoid regimen, because approximately 90 percent of the glucocorticoid dose is metabolized in the placenta.³¹⁷ IVIG is indicated in pregnant patients who do not respond to or tolerate glucocorticoid treatment, or when it is necessary to rapidly increase the platelet count. A dose of 1 g/kg per day for 2 days, or 400 mg/kg per day for 5 days can be used alone, or combined with low-dose prednisone. If the initial therapy with glucocorticoids and IVIG fails, all second-line therapies generate some concern. Anti-(Rh)D can cause severe hemolytic reactions in both the mother and the fetus, and should be used only in patients refractory to glucocorticoids and IVIG.^{148,318} Experience with azathioprine and cyclosporine in pregnancy is largely based on the case series from patients with rheumatologic disorders and solid-organ transplantation. These studies reported that exposure to these drugs during pregnancy was not associated with an increase in the risk of negative pregnancy outcomes and had no significant toxicity to the fetus.³²⁶ Splenectomy can be used in pregnant ITP patients who are unresponsive or intolerant to available drugs and at significant risk of bleeding. If splenectomy is necessary, it is preferable that it be performed during the second trimester.^{147,191}

Rituximab is not an optimal drug for use during pregnancy. It can cross the placenta, and transfer from mother to fetus increases with gestational age. The half-life of the drug is also very long; rituximab can be found in blood 6 months after of an infusion. In a review evaluating 231 pregnancies with rituximab exposure reported in the literature, most of the patients had SLE, rheumatoid arthritis, and B-cell lymphoma, with rituximab being used in combination with other drugs. This retrospective study showed low risk of premature births, hematologic abnormalities and birth defects. However, because of the lack of controlled studies, it is recommended that women avoid pregnancy for 1 year after rituximab infusion.³²⁷

TPO receptor agonists were found to cause fetal loss and reduced fetal body weight in animal studies, and there is no data on humans.³²⁸ Vinca alkaloids, cyclophosphamide, and danazol are not recommended during pregnancy.

The optimal mode of delivery in pregnant ITP patients has not been determined. Because earlier studies reported that thrombocytopenic neonates have an increased risk for intracranial hemorrhage, some physicians recommend delivering the baby by cesarean section in women with ITP to avoid injuries to the fetus during passage through the birth canal.³²⁹ However, because of the rarity of intracerebral hemorrhage, there are no data proving the effectiveness of cesarean delivery in reducing the occurrence of intracerebral hemorrhage in the thrombocytopenic fetus.³²² Measurement of platelet counts in infants before delivery, such as by percutaneous umbilical cord blood sampling or fetal scalp vein sampling after cervical dilatation, is not recommended routinely because the risk of bleeding during these procedures is high.³³⁰⁻³³² The mother's platelet count at delivery does not correlate with the infant's platelet count. In ITP patients who gave birth more than once, however, the first infant's platelet count at birth may be a predictor of severe thrombocytopenia in subsequent pregnancies and may justify further obstetric management.^{322,331,333} On the other hand, discordances in degree of thrombocytopenia between dichorionic twins in ITP indicate that fetal factors also are important.³³⁴ In conclusion, there is as yet no definitive method to predict fetal platelet count in pregnant ITP patients, and the method of delivery should be determined by obstetrical evaluation. During vaginal delivery, the target maternal platelet count should be $50 \times 10^9/L$ or higher. If cesarean section or epidural anesthesia is required, the platelet count should be maintained over 70 to $80 \times 10^9/L$.^{147,148,318} Glucocorticoids, IVIG and platelet transfusions may help to keep platelet counts in a safe range in these patients. Blood products should be available for possible severe bleeding during labor,

although it is quite rare even in ITP patients with platelet counts lower than $20 \times 10^9/L$.

Severe neonatal thrombocytopenia (platelet counts $<20 \times 10^9/L$) occurs in 3 to 5 percent of ITP pregnancies and moderate neonatal thrombocytopenia (platelet counts $<50 \times 10^9/L$) in 9 percent.³³⁰ Severe bleeding occurs in less than 1 percent of the babies. If the newborn is thrombocytopenic, the platelet count should be measured daily for 1 week. IVIG is preferred in neonates with severe thrombocytopenia. Platelet transfusions and glucocorticoids are added if bleeding is life-threatening.

If thrombocytopenia associated with SLE and APS has been complicated with prior pregnancy loss and thromboembolism, pregnant patients should receive antithrombotic prophylaxis with low molecular heparin and/or aspirin if possible. Although there is no defined threshold platelet level for these patients, platelet counts over $50 \times 10^9/L$ are considered safe for both anticoagulant and antiplatelet therapy.³¹⁸

MICROANGIOPATHIC DISORDERS IN PREGNANCY: PREECLAMPSIA-ECLAMPSIA, HELLP, THROMBOTIC THROMBOCYTOPENIC PURPURA-HEMOLYTIC UREMIC SYNDROME, AND ACUTE FATTY LIVER OF PREGNANCY

Preeclampsia

This condition is a systemic disorder characterized by new onset hypertension after 20 weeks of gestation, and primarily occurs near term. Although proteinuria occurs in the majority of these cases, the American College of Obstetricians and Gynecologists (ACOG) 2012 classification accepts the presence of one of the following in the absence of proteinuria: thrombocytopenia (less than $100 \times 10^9/L$), abnormal liver function tests, renal insufficiency, pulmonary edema, or cerebral and visual symptoms. *Eclampsia* is defined by the occurrence of epileptic seizures in a preeclamptic woman during the peripartum period.³³⁵⁻³³⁷ Preeclampsia complicates 5 to 8 percent of all pregnancies, and is a major contributor to maternal and fetal morbidity and mortality (Chap. 7).^{335,338} Thrombocytopenia is seen in approximately 50 percent of women with preeclampsia, with the severity of thrombocytopenia correlating with the severity of the preeclampsia.³³⁹

Attempts to define the pathogenesis of preeclampsia have engendered numerous theories.³⁴⁰ One clear aspect of the pathogenesis is the requirement for a placenta, given that the condition can be produced in abdominal pregnancies and molar pregnancies.³⁴¹ The disease appears to be initiated by defective invasion of the uterine spiral arteries by placental cytotrophoblasts. During normal implantation, these cells convert from epithelial to endothelial morphology, a process called *pseudovasculogenesis*.^{342,343} In preeclampsia, this process is defective, resulting in diminished maternal blood flow to the placenta and placental hypoxia. Through unknown mechanisms, the production of membrane and soluble forms of the vascular endothelial growth factor (VEGF) receptor fms-like tyrosine kinase-1 (Flt1) is increased,³⁴⁴ with resultant increases of soluble Flt1 (sFlt1) in the amniotic fluid³⁴⁵ and maternal circulation.³⁴⁶ sFlt1 is the product of an alternately spliced form of the Flt1 messenger RNA that lacks the transmembrane and cytoplasmic domains present in the full-length receptor. A large volume of evidence implicates sFlt1 as playing a key role in the pathogenesis of preeclampsia. By binding to VEGF and the related placental growth factor, sFlt1 blocks their favorable effects on vascular endothelium. Its expression in rats produces a syndrome akin to preeclampsia: hypertension and proteinuria associated with glomerular endotheliosis (occlusion of glomerular capillaries by swollen endothelial cells). Endoglin is another angiogenic receptor expressed on endothelial cells

and placental syncytiotrophoblasts, functioning as a coreceptor for the potent angiogenic factor transforming growth factor- β .³⁴⁷ Expression of its messenger RNA is increased in preeclamptic placenta.³⁴⁷ The levels of the soluble extracellular domain, produced by proteolysis, are elevated in the blood of preeclamptic patients. In pregnant rats, soluble endoglin works synergistically with sFlt1 to produce vascular damage and a HELLP-like syndrome.³⁴⁷ These findings strongly suggest that a tonic level of VEGF-like angiogenic factors is required to maintain the normal function of vascular endothelial cells and that this process is dysregulated during preeclampsia/eclampsia.

The connection between preeclampsia and thrombocytopenia is not clear, although many cases have evidence of activation of blood coagulation detected by elevated levels of fibrin-degradation products and thrombin-antithrombin complexes.³²¹ Low levels of the VWF-cleaving metalloprotease ADAMTS13 (a disintegrin and metalloprotease with a thrombospondin type 1 motif member 13) have also been described,³⁴⁸ as have elevated levels of VWF, including the hyperadhesive ultralarge forms.³⁴⁹

HELLP Syndrome

This syndrome occurs in the peripartum period and is defined by the presence of microangiopathic hemolytic anemia, elevated liver enzymes, and low platelets. In approximately 70 to 80 percent of patients, HELLP occurs in the setting of preeclampsia.³⁵⁰ Microangiopathic hemolysis results from shearing of the erythrocytes as they pass through arterioles occluded by platelet-fibrin deposits. Adhesion and aggregation of platelets on damaged and activated endothelium presumably accounts for the low platelet count (Chap. 114). HELLP shares a number of features with TTP, including the presence of microangiopathic hemolysis and thrombocytopenia. Involvement of the central nervous system is a more prominent feature of TTP, whereas HELLP more commonly displays severe liver function abnormalities (Chaps. 7, 49, and 124).³⁵¹ Because the two syndromes can be confused with one other, one study attempted to distinguish the two by measuring the activity of ADAMTS13, which usually is absent or severely deficient in TTP.³⁴⁸ The study found that essentially all 17 patients in a cohort with the HELLP syndrome had mild to moderate reductions in the activity of ADAMTS13 in the plasma, and none was severely deficient.

Acute Fatty Liver of Pregnancy

This abnormality is a very severe, but fortunately very rare (1 in 20,000 to 100,000 pregnancies) condition that occurs during the third trimester of pregnancy or early postpartum period. Acute fatty liver of pregnancy (AFLP) is characterized by microvesicular fatty infiltration of liver resulting in hepatic failure and encephalopathy. The "Swansea Criteria" used for the diagnosis of AFLP include encephalopathy, vomiting, abdominal pain, polydipsia/polyuria, elevated transaminases, elevated ammonia, elevated uric acid, elevated bilirubin, leukocytosis, coagulopathy, renal impairment, hypoglycemia, ascites or bright liver on ultrasound evaluation, and microvesicular steatosis on liver biopsy. Six or more of these criteria should be present in a patient who has no obvious reason for hepatic failure. Both maternal and fetal mortality rates are high, ranging from 7 to 18 percent and 9 to 23 percent, respectively.³⁵²

Delivery of the fetus is the most effective treatment for preeclampsia, HELLP syndrome and AFLP. The platelet count nadir and the peak of serum lactate dehydrogenase may occur postpartum, during the first postpartum day in most patients, but as late as 5 to 7 days in some. For patients with severe thrombocytopenia and microangiopathic hemolytic anemia, plasma exchange may be indicated if the fetus cannot be delivered or if improvement does not follow delivery. This treatment is empirically based on the similarity of the clinical picture to that of TTP. Postpartum day 3 often is considered the limit for supportive therapy

in anticipation of a spontaneous recovery.³⁴⁸ If thrombocytopenia and hemolysis (as assessed by serum lactate dehydrogenase levels) continue to worsen beyond this time, intervention with plasma exchange is appropriate for the presumed diagnosis of TTP-HUS (Chap. 133). At this point, TTP-HUS cannot be distinguished from atypical preeclampsia/HELLP syndrome, for which plasma exchange treatment may be beneficial.³⁵³ Earlier intervention with plasma exchange is indicated for more severe clinical problems, such as neurologic abnormalities or acute, anuric renal failure. In patients with AFLP, however, liver insufficiency, encephalopathy and coagulopathy may not improve despite immediate delivery and intensive supportive care. These patients may require liver transplantation.³⁵²

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

The platelet count in the fetus reaches normal adult levels ($>150 \times 10^9/L$) after the first trimester, and is maintained throughout gestation. However, thrombocytopenia is more common in preterm infants, of several potential etiologies. Severe thrombocytopenia ($<50 \times 10^9/L$) is an important finding in neonates, and should be carefully managed because of high bleeding risk (Chap. 6).³⁵⁴

Fetal-neonatal alloimmune thrombocytopenia (NAIT) is a leading cause of severe thrombocytopenia and life-threatening bleeding in neonates. NAIT is caused by the transplacental transfer of maternal alloantibodies against fetal platelet antigens inherited from the father. NAIT resembles neonatal alloimmune hemolytic anemia (Rh hemolytic disease of the newborn) in many aspects. In both diseases, maternal alloantibodies against fetal blood cell antigens cross the placenta and destroy antigen-positive fetal cells, resulting in significant fetal/neonatal morbidity and mortality. However, unlike neonatal alloimmune hemolytic anemia, which tends to spare the first-born child, the first child is affected in 40 to 60 percent of NAIT cases.³¹⁷ Transplacental transfer of antiplatelet antibodies can also occur in babies born from mothers with ITP. Nevertheless, maternal ITP rarely causes serious thrombocytopenia or bleeding in the fetus, whereas thrombocytopenia tends to be more severe and the rate of intracranial hemorrhage is higher (10 to 20 percent) in NAIT.¹⁰⁶ In contrast to maternal ITP, in NAIT the maternal platelet count is normal, a key differential diagnostic finding.

PREVALENCE AND PATHOGENESIS

The estimated frequency of NAIT varies from 1 in 500 to 1 in 2000 livebirths.^{355,356} Maternal alloantibodies against human platelet alloantigens (HPAs) are responsible for platelet destruction in NAIT. In populations of European ancestry, the most frequently implicated antigens are HPA-1a or Pl^{A1} (78 percent of cases) and HPA-5b or Br^a (19 percent of cases).³⁵⁷ These antigens are rare in Asian populations. HPA-4a (80 percent of cases) and HPA-3a (15 percent of cases) are responsible for platelet destruction in the majority of Asian NAIT cases. Besides targeting the HPA system, anti-HLA-2 antibodies have been reported, but whether they are responsible for NAIT is not clear.^{355,358,359}

The frequency of NAIT in populations of European ancestry is lower than would be expected given that the prevalence of HPA-1a negativity is 2.5 percent. Only 10 percent of HPA-1a-negative mothers exposed to HPA-1a-positive platelets during pregnancy become immunized. HPA alloimmunization is strongly correlated with the presence of specific class II HLA antigens, with increased risk demonstrated in HPA-1a-negative mothers expressing HLA-B8, HLA-DR3, and HLA-DR52a antigens.^{317,360,361} The presence of the HLA-DRB3*0101

allele in HPA-1a–negative women increases the NAIT risk as much as 140-fold.³⁶¹

NAIT tends to be clinically more severe in cases with alloantibodies against HPA-1a.¹⁰⁶ HPA-1 (PI^A) antigens are expressed on platelet integrin β_3 . Anti-HPA-1a antibodies possibly impair platelet aggregation, which may explain the severity of bleeding symptoms.³⁶²

CLINICAL FEATURES

IgG alloantibodies can cross the placenta as early as week 14 of pregnancy, and placental passage increases with gestational age.³⁵⁵ These antibodies bind to fetal platelets and lead to their destruction. In severe cases, intracranial hemorrhage and hydrocephalus may develop and cause fetal death or severe neurologic sequelae. The diagnosis can be difficult in the first affected fetus in a family. Ultrasonography is usually not helpful unless it detects bleeding or hydrocephalus. Unexplained fetal deaths in the maternal history or fetal hydrocephalus or bleeding in previous pregnancies may alert the physician to the possibility of NAIT. Usually the diagnosis of NAIT is possible after birth. NAIT should be suspected in a thrombocytopenic neonate with extensive purpura or visceral hemorrhage but no evidence of sepsis, skeletal anomalies, or other systemic diseases that may cause thrombocytopenia, including maternal ITP. Affected babies may have no signs or symptoms (13 to 59 percent of cases), or they may have signs of bleeding (18 to 65 percent of cases) or intracranial hemorrhage (22 to 23 percent of cases).³⁶³ In a case series of 88 infants with NAIT resulting from anti-HPA-1a antibodies, 90 percent had purpura, 66 percent had hematomas, 30 percent had gastrointestinal bleeding, and 14 percent had intracerebral hemorrhage. Bleeding may be delayed, as the platelet count usually falls further during the first several days of life. Death or neurologic impairment occurs in up to 25 percent of infants. Platelet counts recover to normal in 1 to 2 weeks.³⁶⁴

The diagnosis of NAIT usually can be confirmed by tests for circulating maternal alloantibodies against fetal antigens (usually by MAIPA) or modified antigen capture enzyme-linked immunosorbent assay (MACE) or by platelet typing of the parents and neonate by either genotyping or ELISA. These tests may fail to yield the diagnosis because private HPA antigens may be responsible for NAIT.^{317,322,357}

MANAGEMENT

Postnatal

In the clinical setting, the confirmation of a diagnosis of NAIT by platelet genotyping, MAIPA, or MACE will require days; thus, an infant born with severe thrombocytopenia with no obvious cause such as sepsis should be regarded as having NAIT. The alternatives in the management of affected neonates are IVIG, glucocorticoids (alone or combined with IVIG), and platelet transfusions. IVIG and/or glucocorticoid therapy may increase platelet counts rapidly, although a substantial increase of platelet counts usually occurs after 24 to 72 hours.³⁵⁷ In cases with severe bleeding, platelets should be transfused. Transfused platelets should be ABO and (Rh)D compatible and HPA-1a–negative if possible.³⁶⁵ If such platelet suspensions are not available, transfusion of washed and irradiated maternal platelets to the affected fetus is another alternative.¹⁰⁶ Repeated platelet transfusions may be required.³¹⁷ All affected infants should be screened with ultrasound for intracranial hemorrhage.³⁶⁶

Prenatal

Pregnant women who had a previous thrombocytopenic infant attributable to NAIT should be carefully monitored in a center with experience with NAIT, because thrombocytopenia will be more severe in a second affected child. Current therapeutic alternatives for antenatal management of NAIT are unsatisfactory. Fetal platelet typing is important, but

available tests usually require invasive procedures such as amniocentesis or fetal blood sampling. Cell-free fetal DNA obtained from maternal blood has been studied for fetal platelet genotyping.³⁶⁷ However, these tests need validation. The treatment options in high-risk NAIT are weekly IVIG administration to the mother, with or without glucocorticoids, serial *in utero* platelet transfusions, *in utero* IVIG administration, and early delivery (after 32 weeks of gestation). Maternal IVIG administration at a dose of 1 g/kg per week with or without glucocorticoids may increase fetal platelet counts,³⁶⁸ although not all studies support this conclusion.^{355,362} IVIG can be administered directly to severely thrombocytopenic fetuses, although this also may fail to raise fetal platelet counts.³⁶⁹ In patients who do not respond to IVIG and glucocorticoid administration, serial transfusion of matched platelets should be considered. Matched platelet transfusions will only transiently increase the fetal platelet count because the transfused platelets also are targeted by the offending antibodies.³¹⁷ Serial platelet transfusions may increase the cumulative risk of hemorrhage and procedure-related hemorrhage and fetal loss.³⁶² In severely thrombocytopenic fetuses, early delivery by cesarean section may reduce the risk of intracranial hemorrhage.³⁶² New therapeutic strategies are under investigation, including vaccines and competitive molecules that competitively bind anti-HPA-1a antibodies.³⁶⁵

● ABNORMAL PLATELET DISTRIBUTION OR POOLING

SPLENOMEGALY AND HYPERSPLENISM

Splenomegaly may lead to thrombocytopenia by inducing a reversible pooling of up to 90 percent of total body platelets.^{370,371} This process can be thought of as an exaggeration of normal splenic pooling, in which approximately one-third of the platelet mass is contained within the spleen at any one time (Chap. 55). The survival of platelets within the spleen can be normal or moderately reduced. Thus, the total blood platelet pool in a patient with splenomegaly could be normal even when the counts measured in venous blood are only 20 percent of normal. Platelet production is usually normal in patients with splenomegaly, as estimated by dividing the total body platelet mass by the platelet life span.³⁷⁰ This finding provides further evidence that platelet production is more closely tied to total platelet mass than to circulating platelet count.

The most common disorder causing thrombocytopenia because of splenic pooling is chronic liver disease with portal hypertension and congestive splenomegaly. In patients with cirrhosis and portal hypertension, moderate thrombocytopenia is the rule. However, in such cases the thrombocytopenia often results from both splenic pooling and reduced hepatic production of TPO.

Thrombocytopenia associated with splenomegaly is often of no clinical importance and generally does not require therapy. Signs and symptoms are related to the primary disorder, and bleeding manifestations result primarily from coagulation abnormalities caused by the underlying liver disease. This finding is consistent with the relatively moderate degree of thrombocytopenia, the near-normal total body content of platelets,³⁷⁰ and the ability to mobilize platelets from the spleen to replenish losses.³⁷² When splenectomy is performed for another reason, however, the platelet count predictably returns to normal or thrombocytosis may even occur.³⁷⁰ Platelet counts may also return to normal in patients following surgical correction of portal hypertension by portosystemic shunting.³⁷³ Platelet transfusions usually are not needed for splenomegaly-associated thrombocytopenia and rarely produce significant increases in the platelet count because as much as 90 percent of the transfused platelets will be sequestered in the spleen.

HYPERSPLENISM

Hypersplenism is distinguished from uncomplicated splenomegaly in that pooling is accompanied by increased destruction of platelets, leukocytes, and erythrocytes in association with increased marrow precursors of the deficient lines and correction of the cytopenia by splenectomy.^{374–377} The clinical manifestations, laboratory findings, and specific treatment are aimed at the underlying disease (Chap. 55).³⁷⁸

Imaging studies, such as computed tomographic scans, can be useful for defining the size of the spleen and identifying intrasplenic and extrasplenic disease. Magnetic resonance imaging defines the blood flow pattern, which is especially useful for detecting portal or splenic vein thromboses. Cell survival studies using radiolabeled platelets or red blood cells can be helpful for identifying hypersequestration when weighing the need for splenectomy. Most patients with splenomegaly require therapy for the underlying disease rather than for thrombocytopenia.

● THROMBOCYTOPENIA ASSOCIATED WITH MASSIVE TRANSFUSION

Several definitions are used for massive transfusion including transfusion of one blood volume or more than 10 units of packed red blood cells (RBCs) in 24 hours and transfusion of more than 4 units of packed RBC over 1 hour.³⁷⁹ Massive transfusion is required in patients with uncontrolled and heavy bleeding. One study of patients requiring massive transfusion demonstrated that mild thrombocytopenia (47 to $100 \times 10^9/L$) occurred in all patients after transfusion of 15 red cell units, and more severe thrombocytopenia (25 to $61 \times 10^9/L$) developed after 20 red cell units.^{380,381} Several factors contribute to thrombocytopenia in massive transfusion, including direct loss of platelets in the exsanguinated blood, dilution of platelets by the transfused RBCs, DIC triggered by the disease responsible for the blood loss or that develops after trauma, and hypothermia (Chap. 140). Massively transfused patients should be treated with fresh-frozen plasma to replace coagulation factors, and with platelets.³⁸² The precise ratio of platelets to red cells has not been determined, but studies show that massively transfused trauma patients demonstrated improved survival with increased transfusion of platelet concentrates.^{383,384}

● THROMBOCYTOPENIA RESULTING FROM HYPOTHERMIA

Transient thrombocytopenia occurs during hypothermia, in both animals and humans, when the body temperature falls below $25^\circ C$.³⁸⁵ The degree of thrombocytopenia correlates with the degree of the body temperature drop. Thus, thrombocytopenia is less severe in cardiac surgery patients supported by normothermic systemic perfusion ($35^\circ C$ to $37^\circ C$) than in those supported by moderately hypothermic systemic perfusion ($25^\circ C$ to $29^\circ C$).³⁸⁶ In this case, the drop in platelet count likely results from splenic and hepatic pooling³⁸⁷ and from cold activation and clearance of platelets. Cold induces clustering of the GPIIb complex and rearrangement of its carbohydrate chains, which then serve as ligands for the macrophage integrin $\alpha_M\beta_2$, which mediates their clearance in hepatic macrophages.^{388,389} In hypothermic dogs, radiolabeled platelets are sequestered in the spleen, liver, and other organs; the platelets return to the circulation when normal body temperature is restored.^{385,390} The clinical relevance of these observations is illustrated by reports of patients, often elderly, who are hypothermic after periods of unconsciousness in inadequately heated rooms. In one report, a 69-year-old woman had 13 admissions over an 8-year period with

repeated hypothermia, her temperature ranging from $31^\circ C$ to $34^\circ C$ during the hospitalizations. On each admission she was thrombocytopenic (platelet count 7 to $39 \times 10^9/L$). With no therapy other than rewarming, platelet counts returned to normal in 4 to 10 days.³⁹¹ However, a review of 75 patients admitted with hypothermia (body temperatures $26^\circ C$ to $35^\circ C$) demonstrated that only three patients were thrombocytopenic.³⁹¹

● THROMBOCYTOPENIA RESULTING FROM PLATELET TRAPPING: KASABACH-MERRITT SYNDROME

Kasabach-Merritt syndrome is defined as profound thrombocytopenia related to platelet trapping within a vascular tumor, either a Kaposi-like hemangioendothelioma or a tufted angioma.^{392–395} The syndrome presents predominantly during infancy, but several adult cases have been reported.³⁹⁶ These vascular tumors should be differentiated from vascular malformations such as classic benign hemangiomas. Benign hemangiomas usually are superficial, multiple, not associated with severe thrombocytopenia or DIC (Chap. 130), and usually disappear during childhood. On the other hand, Kaposi-like hemangioendothelioma and tufted angioma are low-grade malignant vascular tumors associated with high morbidity and mortality.

Vascular tumors usually are solitary, can reach 20 cm in diameter, and can be superficial or invade internal organs and the retroperitoneum.^{397–399} Superficial tumors can be recognized by the local red to purple discoloration of the skin. The histologic types more frequently associated with Kasabach-Merritt syndrome are Kaposi-like hemangioendothelioma and tufted angiomas or angiolymphomas.^{392,393,400,401} Kaposi-like hemangioendothelioma is a locally aggressive, low-grade malignant tumor characterized by infiltrating sheets or lobules of poorly formed vascular channels and aberrant lymphatic vessels. These tumors are composed predominantly of plump, round, oval, and/or spindle endothelial cells with hemosiderin deposits.³⁹² A tufted angioma is a lesion characterized by the presence of vascular tufts and aggregates of round dilated capillaries, lymphangiomas, microthrombi, and hemosiderin deposits.^{392,393,402,403} Electron microscopic examination shows abnormal endothelial cells with prominent cytoplasmic projections and wide intercellular gaps, fibrin deposition, and platelet aggregates within the vessels.³⁹³ The histology of the tumor is useful for differentiating the vascular tumors associated with Kasabach-Merritt syndrome from benign capillary hemangiomas.⁴⁰⁴

Thrombocytopenia in Kasabach-Merritt syndrome usually is severe and associated with DIC.⁴⁰⁵ Contributing factors include “platelet trapping” by abnormally proliferating endothelium within the hemangioma^{406,407} and platelet consumption associated with DIC. Platelet trapping has been demonstrated by immunohistochemical staining of the tumors with anti-CD61 antibodies (a marker of platelets and megakaryocytes)⁴⁰⁸ and by nuclear studies using ^{51}Cr -labeled platelets⁴⁰⁹ and ^{111}In platelet scintigraphy to monitor response to therapy.^{410,411} How platelets become trapped is not clear. Initial physical entrapment of the platelets within twisted abnormal vessels may favor their adhesion to abnormal endothelium, which can lead to platelet activation and aggregation followed by activation of the coagulation cascade, fibrin deposition, and formation of microthrombi. Excessive flow and shear rates generated by arteriovenous shunting within the tumor further increase the level of platelet activation. Continuous thrombus formation leads to platelet consumption and activation of the fibrinolytic cascade. Severe thrombocytopenia and DIC result.

The mainstay of treatment is eradication of the tumor. Several specific therapeutic modalities have been proposed, but none has been established as consistently effective.⁴¹² Among the therapies are

high-dose glucocorticoids,⁴¹² IFN- α ,^{412,413} vincristine,⁴¹⁴ cyclophosphamide,⁴¹⁵ combination chemotherapy,⁴¹⁶ and radiation.^{417–419} For severe cases, interventions such as arterial embolization,^{420,421} surgical resection,^{422,423} and pneumatic compression can be attempted.

The mortality rate for advanced Kasabach-Merritt syndrome is approximately 12 percent; the rate is higher when associated with retroperitoneal or intraabdominal tumors. Patients die of complications resulting from DIC, low platelet count, and infections secondary to immunosuppression.

● CYCLIC THROMBOCYTOPENIA

Cyclic thrombocytopenia (CTP) is a very rare acquired disorder characterized by a periodic decrease in the platelet count, sometimes followed by rebound thrombocytosis without therapy ($>500 \times 10^9/L$).⁴²⁴ Fluctuating levels of endogenous TPO, inversely related to the platelet count, was reported in one case.⁴²⁵ Each thrombocytopenic cycle typically spans a period of 3 to 6 weeks, and women are more often affected than men. The platelet counts may fluctuate across a wide range. In reported cases, the median nadir and peak platelet counts were $10 \times 10^9/L$ (range: 1 to $90 \times 10^9/L$) and $330 \times 10^9/L$ (range: 72 to $2300 \times 10^9/L$), respectively.⁴²⁶ Rebound thrombocytosis is an important and distinctive feature of CTP. Although some cases are reported as associated with myeloproliferative neoplasms, most CTP cases are idiopathic.^{427,428} The pathophysiology is unclear and a number of potential mechanisms have been proposed, including autoimmune platelet destruction, megakaryocytic hypoplasia/aplasia, infections, and hormonal disturbances. Although most premenopausal female CTP patients studied have had low platelet counts during their menstrual periods, hysterectomy with bilateral salpingo-oophorectomy has not been shown to affect the course of the platelet fluctuations.⁴²⁶

The clinical presentation of CTP is similar to that of ITP. The bleeding tendency ranges from asymptomatic, to easy bruising, gingival bleeding, recurrent epistaxis, menorrhagia, and hematuria, to more serious bleeding, including gastrointestinal or central nervous system hemorrhage.⁴²⁶ CTP is rarely considered in the differential diagnosis of thrombocytopenia, so patients are usually diagnosed and treated as having ITP. CTP is a rare disorder, but the diagnosis should be considered in patients with “ITP” who have not responded to therapies such as glucocorticoids, splenectomy, and IVIG, and who have rebound thrombocytosis. Responses have been reported to respond to hormone therapy and cyclosporine. In female patients, oral contraceptives may be useful to prolong the menstrual cycle and cover low-platelet-count days. Antifibrinolytic drugs such as aminocaproic acid or tranexamic acid may also be useful to decrease bleeding symptoms.

● DRUG-INDUCED THROMBOCYTOPENIA

Development of thrombocytopenia after quinine was first described by Vipan in 1865, and since then a large number of drugs have been found to cause thrombocytopenia. Drugs should be considered as potentially causative in any thrombocytopenic patient on medication, taking herbal remedies, or using iodinated radiocontrast solutions.⁴²⁹ Drug-induced thrombocytopenia generally affects only a small percentage of patients taking a particular drug, and is usually not severe, although it can be fatal. Genetic and environmental factors both influence susceptibility to drugs. Discontinuation of the causative drug(s) is the main treatment strategy; glucocorticoids may help in some patients. Drugs may cause thrombocytopenia by different mechanisms. Dose-dependent myelosuppression and immune destruction of the platelets are two well-known causes. One of the most severe and life-threatening forms of drug-induced thrombocytopenia is HIT, an immune-mediated

disorder caused by antibodies that recognize a neoepitope in platelet factor 4 that is exposed when platelet factor 4 binds heparin. The result is activation of platelets and the coagulation cascade and, ultimately, venous and arterial thrombosis. HIT affects up to 5 percent of patients exposed to therapeutic doses of unfractionated heparin (Chap. 133). This section discusses drugs, other than heparins, that cause isolated thrombocytopenia by immune platelet destruction; Chap. 34 discusses drug-induced aplastic anemia with thrombocytopenia.

ETIOLOGY

Reviews of drug-induced thrombocytopenia often contain such extensive lists of implicated drugs, many of which are commonly used, that they are not helpful for decisions regarding which therapy to interrupt first. To address the issue of which drugs most likely cause thrombocytopenia, a systematic review of all published case reports defined levels of evidence to document the causal relation between the drug and thrombocytopenia.⁴³⁰ This review distinguished drugs with definite or probable causal relationships from those for which the evidence was weaker.⁴³⁰ Table 117–7 lists the drugs for which there is definite evidence of a causal role in producing thrombocytopenia (which includes recurrent thrombocytopenia with rechallenge in the same patient) and drugs for which the causal relation to thrombocytopenia has been validated by at least two reports with probable evidence (thus meeting all of the criteria for definite evidence except for the lack of rechallenge). Quinidine is by far the most commonly cited drug. Other commonly cited drugs are similar to drugs documented in a case-control study.⁴³¹ A remarkable observation from the systematic review was how many case reports did not provide sufficient clinical information to allow a determination of even a probable causal relation.³¹⁹

PATHOGENESIS

Thrombocytopenia is usually assumed to result from immune platelet destruction by drug-dependent antibodies.⁴²⁹ Most of these antibodies bind the platelets only in the presence of the offending drugs. Drugs may trigger different immune mechanisms, as depicted in Table 117–8.

Drugs may bind covalently to membrane proteins, and may induce hapten-dependent antibodies in patients receiving penicillin and cephalosporin. In quinine-induced thrombocytopenia, antibodies bind to membrane proteins only in the presence of soluble drug. In patients receiving tirofiban or eptifibatid, the drug binds to integrin $\alpha_{IIb}\beta_3$, creating a conformation-dependent neoepitope and inducing antibody production. Gold salts and procainamide, however, may induce true autoantibodies, with those induced by gold being unique in targeting platelet GPV.⁴³² These antibodies can bind and destroy platelets in the absence of the drug. In HIT, heparin–platelet factor 4 complexes induce autoantibodies.

Initial experimental observations suggested that drug–antibody complexes bind to platelets via the platelet Fc γ receptor. This mechanism is confirmed for HIT (see below in this section), but for other drugs, the drug-dependent antibodies appear to bind to platelets via their Fab regions.⁴³³

The target antigens are the major platelet surface GPs (GPIb-IX-V and integrin $\alpha_{IIb}\beta_3$). Different drugs may provoke drug-dependent antibodies that preferentially react with one of these GPs, or drug-dependent antibodies from a single patient may react with multiple epitopes on both GPs. For example, a study of sera from 15 patients with quinine-induced thrombocytopenia demonstrated that, in the presence of quinine, the antibodies bound to two distinct domains on GPIb-IX, one on GPIb α , and one on GPIIX. Some patients had only one of the antibodies; some had both.⁴³⁴ The same domains on GPIb-IX also appear to be the antigenic targets for quinidine- and ranitidine-dependent

TABLE 117-7. Drugs Causing Thrombocytopenia

CASES: 1			
Adefovir dipivoxil (1, 0)	Diflunisal (0, 1)	Isotretinoin (0, 1)	Penicillin (0, 1)

Table of drugs that cause thrombocytopenia supported by one or more patient case reports with level I (definite) or level II (probable) clinical evidence. The table is broken down by the total number of single case reports with the individual number of level I cases and level II reports denoted in parentheses, respectively. The full list of articles reviewed, the methodology for establishing levels of evidence, and a complete updated database are available at www.ouhsc.edu/platelets/.

Data from www.ouhsc.edu/platelets/ditp.html.

TABLE 117-8. Mechanisms Underlying Drug-Induced Immune Thrombocytopenia

Classification	Mechanism	Incidence	Example
Hapten-dependent antibody	Hapten links covalently to membrane protein and induces drug-specific immune response	Very rare	Penicillin, possibly some cephalosporin antibiotics
Quinine-type drug	Drug induces antibody that binds to membrane protein in presence of soluble drug	26 cases per 1 million users of quinine per week; probably fewer cases with other drugs	Quinine, sulfonamide antibiotics, nonsteroidal antiinflammatory drugs
Fiban-type drug	Drug reacts with glycoprotein IIb/IIIa to induce a conformational change (neoepitope) recognized by antibody (not yet confirmed)	0.2–0.5%	Tirofiban, eptifibatid
Drug-specific antibody	Antibody recognizes murine component of chimeric Fab fragment specific for platelet membrane glycoprotein IIIa	0.5–1.0% after first exposure; 10–14% after second exposure	Abciximab
Autoantibody	Drug induces antibody that reacts with autologous platelets in absence of drug	1% with gold; very rare with procainamide and other drugs	Gold salts, procainamide
Immune complex	Drug binds to platelet factor 4, producing immune complex for which antibody is specific; immune complex activates platelets through Fc receptors	3–6% among patients treated with unfractionated heparin for 7 days; rare with low-molecular-weight heparin	Heparins

antiplatelet antibodies.^{434,435} Definition of the specific epitope involved in patient reactions with drug-dependent antibodies may not only elucidate the mechanism of drug-induced thrombocytopenia but also identify polymorphisms in GPIIb-IX that cause sensitivity in producing drug-dependent antiplatelet antibodies. Sulfonamides, quinidine, and quinine are frequent causes of drug-induced thrombocytopenia. Studies of sera from 15 patients with thrombocytopenia caused by sulfamethoxazole or sulfisoxazole demonstrated that the antigenic epitope was part of integrin $\alpha_{IIb}\beta_3$.⁴³⁶ Some antibodies from patients with quinidine- and quinine-dependent antiplatelet antibodies also react with integrin $\alpha_{IIb}\beta_3$.⁴³⁷

In addition to specificity for discrete epitopes on platelet surface GPs, drug-dependent antibodies are highly specific for the structure of the drug. For example, no cross-reactivity occurs between quinidine and quinine-dependent antibodies or between sulfamethoxazole and sulfisoxazole-dependent antibodies, even though both pairs of drugs have similar structures. Therefore, the neoantigens produced by drug binding to platelets create discrete epitopes that are sensitive to minor changes in drug structure.

The implications of this mechanism for platelet destruction are apparent. A patient with prior sensitivity to the drug has preformed antibodies that immediately react with the altered platelets upon repeat drug exposure, as demonstrated. An exception to this situation is the immediate acute thrombocytopenia that may occur with initial administration of antithrombotic agents that bind platelet integrin $\alpha_{IIb}\beta_3$,^{42,438} especially abciximab. Abciximab is a humanized monoclonal antibody fragment that lacks the Fc domain, so thrombocytopenia is not caused by phagocytosis of the platelets by macrophages. Patients experiencing thrombocytopenia after receiving integrin $\alpha_{IIb}\beta_3$ inhibitors have been postulated to have preformed antibodies to epitopes exposed on the integrin by drug binding. These could be the same antibodies that cause *in vitro* EDTA-dependent platelet agglutination and pseudothrombocytopenia (see “Pseudo (Spurious) Thrombopenia” above).^{33,439,440}

DIAGNOSIS

The diagnosis of drug-induced thrombocytopenia can be made only by recovery from thrombocytopenia upon discontinuation of the drug and can be confirmed if thrombocytopenia recurs with rechallenge by

the drug. Prompt recovery within 5 to 7 days is usual.⁴³⁰ Gold-induced thrombocytopenia is an exception because gold salts are retained for long periods of time within the body and thrombocytopenia can persist for months, becoming indistinguishable from ITP.⁴⁴¹ Rechallenge with a suspected drug is dangerous, because severe thrombocytopenia can develop rapidly with even very small drug doses. However, when multiple drugs are potentially involved and all are important for management, it may be appropriate to reintroduce them individually, followed by several days of close observation. In general, the smallest possible dose of the drug should be administered. The administration should be performed under direct supervision of the patient, with platelets available for bleeding should it occur. If rechallenge leads to thrombocytopenia, the patient should be advised to wear a Medic Alert bracelet. For common drugs, especially those that can be purchased without a prescription, it may be safer to supervise a rechallenge and unequivocally document risk rather than risk future unintentional use.

Laboratory assays can detect drug-dependent antibodies, and positive results can support a clinical diagnosis. However, the laboratory role remains largely investigational because results are not promptly available when a clinical decision must be made about discontinuing a drug. Furthermore, no laboratory test has been validated that supports continuing a suspected drug with no adverse effects following a negative laboratory test.

Drug-dependent antibodies can be detected by flow cytometric techniques,⁴³⁶ MAIPA,⁴⁴² and solid-phase red cell adherence assays.⁴⁴³ Strongly positive tests are apparent, but distinction of positive from negative tests is arbitrary and not yet clinically validated. Positive tests for heparin-dependent antibodies have been reported in patients without thrombocytopenia,^{444–446} and patients with clinical evidence for drug-induced thrombocytopenia may have negative tests using multiple techniques.^{436,447}

CLINICAL AND LABORATORY FEATURES

In patients with newly discovered thrombocytopenia, all medications should be identified. Not only should the history explore use of prescription medications, use of nonprescription drugs should also be queried, including products containing acetaminophen,⁴³⁰ and drinks that may contain quinine (“tonic water”).^{448,449} Drug-induced thrombocytopenia

is typically severe. Among the 247 case reports with evidence for a definite or probable causal relation of the drug to thrombocytopenia, 23 patients (9 percent) had major bleeding, including two patients who died of bleeding,⁴³⁰ and 68 patients (28 percent) had overt but minor bleeding; 96 patients (39 percent) had only purpura or trivial bleeding, and the remainder had no bleeding.⁴³⁰ The time from beginning the drug to the initial occurrence of thrombocytopenia varies from 1 day to 3 years, but the median time is 14 days. With rechallenge, acute thrombocytopenia may occur within minutes but almost always within 3 days.⁴³⁰ Patients may have other signs and symptoms of drug sensitivity, such as nausea and vomiting, rash, fever, and abnormal liver function tests.⁴⁵⁰ Laboratory data may demonstrate leukopenia, indicating that the drug-dependent antibodies target multiple cell types.⁴⁵⁰ Patients who have systemic adverse reactions to drugs manifesting as TTP or HUS are described in Chap. 133.

TREATMENT

Withdrawal of the offending drug is the most important therapeutic measure. Prednisone is commonly given because the distinction of drug-induced thrombocytopenia from ITP is almost never clear initially; however, glucocorticoids do not appear to speed recovery.⁴⁵⁰ In patients with major bleeding, emergency treatment should be the same as for ITP: platelet transfusions, high doses of parenteral methylprednisolone, and possibly IVIG.³¹⁹

CHAPTER 118

HEPARIN-INDUCED THROMBOCYTOPENIA

Adam Cuker and Mortimer Poncz

SUMMARY

Heparin-induced thrombocytopenia (HIT) is a prothrombotic complication of treatment with heparin. It is associated with mild-to-moderate thrombocytopenia, although the main clinical concern is the high frequency of both arterial and venous thromboembolism, which may be limb- or life-threatening. HIT is an immune complex-based disorder involving platelet factor 4 complexed to negatively charged multimeric molecules, especially surface heparan side chains. It is initiated by exposure to heparin, particularly unfractionated heparin. There is growing understanding of the unusual nature of the underlying immune response in HIT, why certain individuals develop this disorder, and why HIT is prothrombotic. Diagnosis is based upon an assessment of clinical probability and specialized laboratory testing. Management involves immediate cessation of heparin and initiation of parenteral inhibitors of thrombin or factor Xa.

DEFINITION AND HISTORY

Heparin-induced thrombocytopenia (HIT) is a complication of heparin therapy in which there is a fall in platelet count and an unusually high incidence of arterial and/or venous thromboembolic complications in association with heparin therapy.

Although clinical usage of heparin as an anticoagulant began in the late 1950s, it was not until the early 1970s that a small percentage of treated patients were noted to develop a complication consisting of thrombocytopenia with paradoxical, life-threatening thromboemboli (for a historical review see Ref. 1). In the 1980s, it became clear that HIT was caused by immunoglobulin (Ig) G antibodies that activate platelets. It was also recognized that HIT could be divided into two types, the classic immune-mediated prothrombotic disease that is the focus of this chapter (formerly called HIT type II), and a benign nonimmune condition associated with a mild, immediate, and transient drop in platelet count and no increased risk of thrombosis (formerly called HIT type I).² In this chapter, “HIT” means the immune-mediated form of the disease.

In the 1970s and 1980s, it became clear that HIT antibodies activated both platelets and endothelial cells.^{3,4} Further analysis showed that blocking platelet FcγRIIA inhibited platelet activation by HIT sera *in vitro*,⁵ suggesting that platelet activation involved an immune

complex. In the early 1990s, this complex was identified as heparin bound to the platelet-specific chemokine, platelet factor 4 (PF4).⁶ Over the past 20 years, additional insights into the mechanism(s) underlying this immune complex disorder have emerged that have advanced our understanding of why this disorder is particularly prothrombotic and occurs in a only a small subset of patients. Additionally, advances have been made on the clinical side with respect to prevention, diagnosis, and treatment.

EPIDEMIOLOGY

The frequency of HIT in heparin-treated patients ranges from less than 0.1 percent to 5.0 percent, depending on patient- and heparin-specific risk factors. These include the patient population, gender, nature of the heparin used, and duration of heparin exposure (Table 118–1).

The most important determinant of risk is the patient population. In a meta-analysis of seven prospective studies, the incidence of HIT was greater among surgical than medical patients (odds ratio [OR]: 3.25; 95 percent confidence interval [CI]: 1.98 to 5.35).⁷ The incidence of HIT approaches 5 percent in patients who receive unfractionated heparin (UFH) after major orthopedic surgery.⁸ Patients undergoing surgery with cardiopulmonary bypass have a very high frequency of anti-PF4/heparin antibody seroconversion (50 to 75 percent by postoperative day 10), but a lesser incidence of HIT (0.5 to 1.0 percent).^{8–10} HIT occurs in 0.5 to 1.0 percent of medical patients⁷ and in less than 0.1 percent of pregnant women^{11,12} and children.¹³ In a randomized trial of trauma patients, major trauma was associated with a significantly greater incidence of HIT than minor trauma (2.2 percent vs. 0.0 percent, $p = 0.01$) despite identical heparin exposure.¹⁴

Female sex is also a risk factor for HIT. A meta-analysis found an approximately twofold greater risk of HIT in women than men (OR: 2.37; 95 percent CI: 1.37 to 4.09). Analyses of a German database and a randomized trial of UFH versus low-molecular-weight heparin (LMWH) after orthopedic surgery yielded similar findings.⁷

HIT is more common with UFH than LMWH in surgical patients. In a meta-analysis of 15 studies, primarily involving orthopedic surgery patients, the incidence of HIT with UFH and LMWH was 2.6 percent and 0.2 percent, respectively.¹⁵ Data are conflicting on whether the risk of HIT is reduced with LMWH in medical patients.^{7,16,17} Fondaparinux, a synthetic pentasaccharide anticoagulant, is associated with a nearly negligible risk of HIT, although several cases of fondaparinux-associated HIT have been reported.¹⁸

Duration of heparin exposure also influences the risk of HIT. In a meta-analysis of 3529 patients receiving UFH thromboprophylaxis for 6 or more days, the incidence of HIT was 2.6 percent.¹⁵ Review of a hospital database indicated that briefer courses induce a substantially lower incidence of HIT (0.2 percent).¹⁹

High-quality data on the impact of dose and route of administration of heparin on the risk of HIT are lacking. Some studies suggest a lower rate of HIT with prophylactic dose subcutaneous UFH than therapeutic dose intravenous UFH,¹⁹ but these analyses are confounded by differences in the patients that receive these treatments including the clinical indication for heparin. Rarely, HIT has been reported with very low doses of heparin such as with use of heparin flushes or heparin-bonded catheters.^{20,21}

ETIOLOGY AND PATHOGENESIS

The development of HIT antibodies is nonclassical in that these antibodies typically begin as IgG and not IgM,²² may disappear after a few months, and may not reappear with heparin reexposure.²³ It has been proposed that the initial antigen exposure involves PF4 complexed with

Acronyms and Abbreviations: CI, confidence interval; DIC, disseminated intravascular coagulation; GAG, glycosaminoglycan; HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; LMWH, low-molecular-weight heparin; MTHFR, methylenetetrahydrofolate reductase; PF4, platelet factor 4; UFH, unfractionated heparin.

TABLE 118-1. Heparin-Induced Thrombocytopenia Risk Factors

Patient-Specific Factors	Heparin-Specific Factors
Patient population (surgical > medical > obstetric > pediatric)	Type of heparin (unfractionated heparin > low-molecular-weight heparin)
Major trauma > minor trauma	Duration of heparin (~5 days > shorter courses)
Sex (female > male)	

bacterial wall (Fig. 118-1) and that antibodies against this complex may be an important antimicrobial defensive mechanism.²⁴ These antigenic complexes, as well as circulating PF4-heparin complexes, are detected by splenic marginal B cells that subsequently produce pathogenic HIT antibodies.²⁵

The nature of the antigenic heparin-PF4 complex has been partially defined. At the concentrations reached at sites of injury, PF4

exists as a tetramer. Crystal structure analysis shows that this tetramer is encircled by a ring of positive charge (Fig. 118-2),²⁶ and heparin is thought to bind to this region.²⁷ There are two closely spaced HIT antibody recognition domains (Fig. 118-2).²⁸ These domains are distinct from the heparin-binding domain. About half of patients have antibodies that react with one or the other HIT antigenic domain and one-third of patients do not have antibodies that react to either domain, suggesting that there are other HIT antigenic sites on PF4. Studies of antihuman PF4 monoclonal antibodies suggest that unlike nonpathogenic anti-PF4 antibodies, HIT antibodies markedly increase their binding affinity for PF4 maintained in a tetrameric as opposed to dimeric state.²⁹ Moreover, tetrameric PF4 and UFH need to be at approximately 1:1 molar ratio for optimal HIT antigenicity.^{30,31} At this ratio, ultralarge complexes (>670 kDa) of PF4 and heparin form that appear as visible colloidal complexes, and these are likely to be the antigenic source in HIT.^{32,33} At higher or lower ratios, PF4 predominantly forms smaller and less antigenic PF4-heparin complexes. Ultralarge complexes are inefficiently formed with LMWH, offering a potential explanation as to why this class of agents is associated with a lower incidence of HIT compared with UFH. Fondaparinux does not form

Figure 118-1. Proposed etiology of the immune response in heparin-induced thrombocytopenia (HIT). **A.** Proposed first exposure to HIT antigenic complex either during microbial invasion²⁴ or within growing atherosclerotic plaques, which are known to contain both platelet factor 4 (PF4) and immune-responsive cells.⁴⁹ In both cases, soluble PF4 and negatively charged molecules must be presented to B cells and result in an initial immunoglobulin M—perhaps low affinity—response. **B.** On exposure to heparin, especially unfractionated heparin, complexes form with free PF4 and are presented to splenic marginal B cells,²⁵ which subsequently produce pathogenic HIT antibodies that bind with high affinity to PF4 complexed to surface GAG complexes.²⁹ The concentrated binding of HIT antibodies to surface PF4-GAG complexes may enhance FcγRIIA aggregation and subsequent platelet activation.

counterintuitive in that it may prevent HIT by partially or completely removing surface-bound PF4 (Fig. 118-3).³⁵ If the level of circulating, free human PF4 in the mice was initially low relative to the level of infused heparin, all surface-bound PF4 and detectable surface antigenicity would be removed and the circulating HIT antibodies would have no targets on platelets and other vascular cells (Fig. 118-3). HIT therefore would not develop in spite of the presence of heparin and circulating HIT antibody. On the other hand, if the level of circulating free human PF4 in the mice was initially high relative to the infused heparin, not all surface-bound PF4 would be removed. Circulating HIT antibodies could then target and activate platelets and other vascular cells, leading to thrombocytopenia and thrombosis (Fig. 118-3).

Most patients likely begin with little PF4 bound to surface glycosaminoglycans (GAGs). After therapeutic heparinization, the level of surface PF4 goes down markedly so that the platelets cannot be targeted by anti-PF4-heparin HIT antibodies. However, patients with high levels of surface PF4 and significant surface PF4 antigenic complexes remaining after heparinization may be at risk for binding of pathogenic anti-PF4-heparin HIT antibodies to platelets and other vascular cells. Bound pathogenic antibodies lead to thrombocytopenia by clearance of antibody-coated platelets by the reticuloendothelial system. Bound antibodies also lead to platelet activation through FcγRIIA and the formation of procoagulant platelet microparticles that contribute to thrombosis.³⁶

As part of this activation, HIT antibodies also bind to endothelial cells likely via PF4-surface GAG complexes,^{4,37} leading to local vascular activation and contributing to further local thrombosis. Additionally, HIT antibodies activate PF4-targeted monocytes^{38,39} and neutrophils.⁴⁰ Monocyte activation may involve its surface Fcγ receptors⁴¹ with subsequent increased tissue factor expression and other changes consistent with a prothrombotic and inflammatory state. Monocyte and neutrophil GAGs are more complex than GAGs on the surface of platelets, which are mostly chondroitin sulfate⁴² and have relatively low affinity for PF4.⁴³ Monocytes and neutrophils bind PF4 with greater avidity and are more resistant to removal of bound PF4 by circulating heparin than platelets. In HIT, they may be preferentially targeted and activated relative to the platelets, contributing to the prothrombotic state of this immune thrombocytopenia.⁴⁴

Are there any genetic polymorphisms that are associated with an increased risk of developing HIT or developing thrombosis after HIT begins? No clear linkage has been shown with known thrombophilic polymorphisms including Factor V^{Leiden}, Prothrombin^{G20210A}, MTHFR^{C677T}, $\alpha_{IIb}\beta_3$, and $\alpha_1\beta_2$.⁴⁵ Studies addressing a functional FcγRIIA^{R/H131} polymorphism had varied outcome.^{46,47} It is unclear whether patients with HIT have a higher density of FcγRIIA on their platelets.⁴⁸ High IgG affinity for the heparin-PF4 complex appears to affect the risk of developing HIT.

The model shown in Fig. 118-3 suggests that individuals with high PF4 content in their platelets and/or sustained platelet activation as might be seen in patients with significant atherosclerosis, a postsurgery state, or trauma would be most likely to develop HIT after heparinization and HIT antibody development. However, a relationship between formation of HIT antibodies and the degree of atherosclerosis in patients undergoing cardiopulmonary bypass surgery was not noted.⁴⁹ If levels of PF4 on the surface of circulating cells determine risk of developing HIT, this would offer a potential method for prescreening patients prior to heparinization and eliminate those at increased risk of HIT or as a useful tool in heparinized patients who develop thrombocytopenia to see whether they potentially can develop HIT. Theoretically, only those heparinized individuals with detectable surface PF4 would be potential candidates for developing HIT if they concurrently develop pathogenic antibodies.

CLINICAL DIAGNOSIS

The clinical hallmark of HIT is development of thrombocytopenia in the setting of a proximate heparin exposure. The combination of thrombocytopenia and heparin exposure in hospitalized patients is common and has poor specificity for HIT.⁵⁰ Therefore, other clinical clues must be sought in estimating the clinical likelihood of HIT. These include timing, degree of platelet count fall, nadir platelet count, presence of thromboembolism or hemorrhage, and the likelihood of other causes of thrombocytopenia.

TIMING

The platelet count in HIT characteristically begins to fall 5 to 10 days after initial heparin exposure.²³ There are three exceptions to this rule: (1) in rapid-onset HIT, patients with recent heparin exposure (within the previous 90 days) and preformed anti-PF4-heparin IgG experience a fall in platelet count immediately upon reexposure; (2) in delayed-onset HIT, clinical manifestations develop a median of 10 to 14 days after heparin is discontinued^{51,52}; and (3) a small number of patients with spontaneous HIT have been reported. These patients present with a thrombotic thrombocytopenic disorder reminiscent of HIT in the absence of recognized heparin exposure.⁵³ Both delayed-onset HIT and spontaneous HIT occur in the absence of circulating heparin and may involve pathogenic HIT antibodies that recognize complexes of PF4 and endogenous GAGs on blood and vascular cells.

DEGREE OF FALL IN PLATELET COUNT

The percentage fall in platelet count is measured from the peak platelet count after initiation of heparin to the nadir platelet count. Most patients with HIT experience a 50 percent or greater fall in platelet count; a more modest decline (30 to 50 percent) occurs in approximately 10 percent of patients.⁵⁴

NADIR PLATELET COUNT

As opposed to most other forms of drug-induced immune thrombocytopenia, thrombocytopenia associated with HIT is characteristically mild or moderate. The median nadir platelet count is approximately $60 \times 10^9/L$ and rarely falls below $20 \times 10^9/L$ in the absence of concomitant disseminated intravascular coagulation (DIC).⁵⁴ The nadir platelet count in HIT need not meet the traditional definition of thrombocytopenia ($<150 \times 10^9/L$). For example, patients with postoperative thrombocytosis may experience a subsequent greater than 50 percent decline in platelet count attributable to HIT that does not fall below this threshold.⁵⁵

THROMBOSIS

Thromboembolism is the presenting feature in up to 25 percent of patients with HIT and complicates approximately half of all cases.^{56,57} Lower-extremity deep vein thrombosis and pulmonary embolism are the most common thrombotic manifestations, outnumbering arterial events by approximately 2:1.⁵⁶ Major venous obstruction can lead to limb gangrene. Catheter-associated upper extremity deep venous thrombosis is common.⁵⁸ Arterial thromboembolism most frequently involves the extremities, but may also manifest as stroke or myocardial infarction.⁵⁶ Thrombosis of other vascular beds including cerebral sinuses, mesenteric vessels, and adrenal veins is well-documented as is thrombotic occlusion of vascular grafts, fistulas, and extracorporeal circuitry.

HEMORRHAGE

In contrast to most other forms of drug-induced immune thrombocytopenia, spontaneous hemorrhage is rare in HIT, even when thrombocytopenia is severe. In a prospective study, bleeding complications were not increased in HIT patients compared with nonthrombocytopenic controls.⁵⁹

UNUSUAL CLINICAL MANIFESTATIONS

Rare sequelae of HIT include anaphylactoid reactions after intravenous heparin bolus, transient global amnesia, and skin necrosis at subcutaneous heparin injection sites.^{60,61} Curiously, these phenomena may occur in the absence of thrombocytopenia. Nonnecrotizing erythematous injection site lesions are generally caused by delayed type IV hypersensitivity rather than HIT.⁶²

OTHER CAUSES

The likelihood of other etiologies of thrombocytopenia must be carefully considered in patients with suspected HIT. Common causes of hospital-acquired thrombocytopenia include infection; drugs other than heparin; DIC; dilution; and intravascular devices and extracorporeal circuits such as intraaortic balloon pumps, cardiopulmonary bypass, and extracorporeal membrane oxygenation.⁶³

Clinical scoring systems have been developed to permit estimation of the probability of HIT based on the aforementioned features. The most extensively studied of these systems, the 4T score,⁶⁴ classifies the probability of HIT as low, intermediate, or high on the basis of four criteria: Thrombocytopenia, Timing, Thrombosis or other sequelae, and the likelihood of other causes of thrombocytopenia (Table 118-2). In a meta-analysis of 13 studies, the negative predictive value of a low probability 4T score was 99.8 percent (95 percent CI: 97.0 to 100.0). The positive predictive value of an intermediate and high probability 4T score was 14 percent (95 percent CI: 9 to 22) and 64 percent (95 percent CI: 40 to 82), respectively.⁶⁵ The 4T score is limited by moderate interobserver agreement.⁶⁶ An alternative scoring system, the HIT Expert Probability (HEP) Score, exhibited improved reliability and favorable operating characteristics in a retrospective study, but remains to be prospectively validated.⁶⁷

LABORATORY DIAGNOSIS

In light of the complexity and limited positive predictive value of clinical diagnosis,⁶⁵ clinicians rely heavily on laboratory testing to aid in diagnosis. Laboratory assays for HIT fall into two categories: immunoassays and functional assays.

IMMUNOASSAYS

These assays detect the presence of circulating anti-PF4-heparin antibodies, irrespective of whether they are able to activate platelets and cause disease. The prototypical immunoassay is the solid-phase enzyme-linked immunosorbent assay (ELISA), in which dilute patient serum is added to microtiter wells coated with complexes of PF4-heparin (or PF4-polyvinylsulfonate).⁶ The polyspecific ELISA detects circulating anti-PF4-heparin IgG, IgM, and IgA. At the manufacturer-recommended cutoff, the sensitivity and specificity of this assay for HIT are 94 to 100 percent and 81 to 93 percent, respectively.^{22,68-70}

A key limitation of the polyspecific ELISA is its specificity. False-positive results are common and may result from detection of nonpathogenic anti-PF4-heparin antibodies⁶⁹ or antiphospholipid antibodies against either PF4⁷¹ or PF4-bound β_2 -glycoprotein I.⁷² Specificity may be improved by raising the optical density (OD) cutoff. OD is directly associated with the 4T and HEP scores,⁶⁷ the risk of thrombosis,⁷³ and the likelihood of a positive functional assay.⁷⁴ In a Canadian study, only one of 37 patient samples exhibiting a weakly positive OD (0.40 to 0.99) demonstrated heparin-dependent platelet activation compared with 33 out of 37 samples with a strongly positive OD (>2.0).⁷⁴ In a recent analysis of 1958 patients, increasing the cutoff from a manufacturer-recommended threshold of 0.4 to 0.8 OD units increased specificity from 85 percent to 93 percent with a slight reduction in sensitivity from 100 percent to 98 percent.⁷⁵

Several modifications have been made to the PF4-heparin ELISA with the goal of improving specificity. Because pathogenic antibodies are primarily of the IgG class, detection systems specific for IgG have been developed. In a pooled analysis of studies comparing the IgG-specific and polyspecific ELISA, the former showed greater specificity (93.5 percent vs. 89.4 percent) at the cost of reduced sensitivity (95.8 percent vs. 98.1 percent).⁷⁶ Another modification involves the addition of a high heparin confirmatory step, in which reduction of the OD by 50 percent or more with the addition of excess heparin (100 U/mL) is considered to affirm the presence of heparin-dependent antibodies.⁷⁷ This method improves specificity, but false-positives remain common and false-negatives may also occur, particularly at high OD values.^{78,79}

Another limitation of the PF4-heparin ELISA is turnaround time. Although the analytical turnaround time of the ELISA is only approximately 2 hours, the assay is most cost-effective when multiple samples are run in batch. Consequently, many laboratories perform the ELISA only once or twice a week, leaving clinicians to make critical initial management decisions without the benefit of laboratory results. This drawback of the ELISA has spawned the development of several rapid immunoassays, which are designed to accommodate single samples and

TABLE 118-2. The 4T Score*

Clinical Sign	Points Per Category		
	0	1	2
Thrombocytopenia (acute)	Very low nadir ($<10 \times 10^9/L$) or $<30\%$ fall	Low nadir ($10-20 \times 10^9/L$) or 30-50% fall	Moderate nadir ($20-100 \times 10^9/L$) or $>50\%$ fall
Timing of first event (thrombocytopenia or thrombosis)	≤ 4 Days (unless prior heparin exposure in last 3 months)	Within 5-10 days (but not well documented) or ≤ 1 day (with exposure in last 3 months)	Documented occurrence in 5-10 days or ≤ 1 day with recent prior exposure
Thrombotic-related event	None	Progressive, recurrent, or suspected (unconfirmed) thrombosis; erythematous nonnecrotic skin lesions	New thrombosis (confirmed) or skin necrosis or systemic reaction after heparin bolus
Thrombocytopenia (other causes)	Definite other cause is present	Possible other cause is present	No other strong explanation for thrombocytopenia

*Scores of 0-3, 4-5, and 6-8 are classified as low, intermediate, and high probability, respectively.⁶⁴

TABLE 118-3. Properties of Rapid Platelet Factor 4–Heparin Immunoassays

Assay	Antibody Class Detection	Sensitivity	Specificity	Turnaround Time (Minutes)	Regulatory Approval
Particle gel immunoassay ^{68,80,81}	IgG	0.91–0.94	0.87–0.95	20	Asia, Canada, Europe
Lateral flow immunoassay ^{80,82}	IgG	0.98–1.00	0.82–0.93	15	Europe
Latex particle-enhanced immunoturbidimetric assay ^{83,84}	IgG, IgA, IgM	1.00	0.76	13	Europe
Chemiluminescence assay ⁸⁴⁻⁸⁶	IgG, IgA, IgM	0.98–1.00	0.73–0.82	30	Europe
Chemiluminescence assay ⁸⁴⁻⁸⁶	IgG	0.96–1.00	0.85–0.97	30	Europe

Ig, immunoglobulin.

yield results in minutes. Table 118-3 summarizes the properties of these rapid assays.^{68,80-86} The latex particle-enhanced immunoturbidimetric assay and chemiluminescence assays are instrument-based and must be performed on proprietary analyzers. A rapid particle immunofiltration assay is approved in the United States, but published data suggest that it has unacceptable diagnostic accuracy.⁸⁷ A modified version of the assay⁸⁸ requires further study.

FUNCTIONAL ASSAYS

Functional assays are more specific than commercial immunoassays because they detect only the subset of antibodies capable of inducing platelet activation in a heparin-dependent manner. The prototypical functional assays are the ¹⁴C-serotonin release assay (SRA) and the heparin-induced platelet-activation assay (HIPA). In the SRA, various concentrations of heparin and heat-inactivated patient serum are added to washed donor platelets radiolabeled with ¹⁴C. A positive test is signified by heparin-dependent release of ¹⁴C-serotonin.⁸⁹ The HIPA is based on a similar principle, but uses visual assessment of platelet aggregation as an end point.⁹⁰ The sensitivity and specificity of the SRA and HIPA are said to exceed 95 percent, but universally accepted reference standards against which to measure their performance do not exist.⁶³

Washed platelet functional assays are technically demanding. Both the SRA and HIPA require reactive donor platelets and the SRA requires radioisotope. Because these reagents are impracticable for most clinical laboratories, functional assays are performed at only a small number of reference laboratories around the world. Even among such laboratories, test methodology, result interpretation, and reporting are not well-standardized.⁹¹

Novel immunoassays and functional assays for HIT designed to overcome the limitations of assays currently in use are in development.^{92,93}

MANAGEMENT

NONHEPARIN ANTICOAGULANTS

Management of HIT requires immediate withdrawal of heparin, including cessation of heparin flushes and removal of heparin-coated catheters. However, discontinuation of heparin alone is insufficient to prevent thromboembolism. Historical studies of untreated patients document a 5 to 10 percent daily risk of thrombosis in the first 48 hours after heparin is stopped and a 30-day cumulative incidence of thrombosis of approximately 50 percent.^{57,94} Discontinuation of heparin must therefore be accompanied by initiation of a rapid-acting, parenteral, nonheparin anticoagulant.⁹⁵ Table 118-4 summarizes the properties of nonheparin anticoagulants used to treat HIT.

Argatroban and bivalirudin are direct thrombin inhibitors. Argatroban is the only FDA-approved drug for treatment of HIT available in the

United States. Its approval was based on two open-label single-arm studies in which argatroban-treated subjects were compared with untreated historical controls.^{96,97} In a pooled analysis of these two studies, argatroban reduced the relative risk of new thrombosis by two-thirds. The incidence of major bleeding was approximately 1 percent per day.⁹⁸ An important limitation of these studies was that serologic confirmation of HIT was not required for enrollment. Indeed, 36.4 percent of subjects were found to be anti-PF4–heparin antibody-negative on *post hoc* testing,⁹⁹ suggesting that a sizable proportion of the study population did not have HIT.

Bivalirudin is a hirudin analogue. It is approved for patients with and without HIT undergoing percutaneous vascular procedures. It is not approved for treatment of HIT, although it has been used off-label for this indication, particularly in patients with critical illness and multiorgan failure¹⁰⁰ and those undergoing cardiac surgery.¹⁰¹ Published evidence supporting its use is limited to retrospective single-center cohort studies.^{100,102,103}

Two other direct thrombin inhibitors have been studied as treatments for HIT. Lepirudin, a recombinant hirudin, was shown to reduce the risk of thromboembolism compared with untreated historical controls, but is no longer available.⁹⁴ A randomized clinical trial of desirudin closed because of poor accrual after only 16 subjects had been randomized.¹⁰⁴

Danaparoid and fondaparinux are indirect factor Xa inhibitors. Danaparoid is approved for treatment of HIT in multiple jurisdictions, but is no longer marketed in the United States and drug shortages have limited its availability elsewhere. In an open-label randomized trial, 42 patients with HIT complicated by thrombosis were allocated to receive either danaparoid or dextran 70. Significantly more subjects in the danaparoid arm were judged to have complete recovery from thrombosis at hospital discharge (56 percent vs. 14 percent; $p = 0.02$).¹⁰⁵ *In vitro* crossreactivity of HIT antibodies with danaparoid occurs in some patients, although the clinical relevance of this phenomenon has not been established.¹⁰⁶

Fondaparinux is not approved for treatment of HIT, nor is it recommended in the 2012 American College of Chest Physicians Guidelines.⁹⁵ Its use is supported by several small case series and retrospective cohort studies.¹⁰⁷⁻¹¹⁰ In a pooled analysis involving 71 patients, no new thrombotic events were reported. Four patients suffered major hemorrhage.⁶³ A small number of cases of HIT induced or exacerbated by fondaparinux have been reported, although the attribution to fondaparinux in at least some of these cases remains uncertain.¹¹¹ Fondaparinux is more convenient to use than other agents given the ease of once-daily administration and a potential lack of need for monitoring (see Table 118-4). This may, in part, account for its increasing use. In a recent multicenter German registry of patients with suspected HIT, a greater proportion of patients were treated with fondaparinux (40 percent) than with danaparoid (23.6 percent) or argatroban (16.4 percent).¹¹²

Oral direct inhibitors of thrombin (e.g., dabigatran) and factor Xa (e.g., rivaroxaban, apixaban, edoxaban) do not induce platelet

TABLE 118-4. Anticoagulants Used to Treat Heparin-Induced Thrombocytopenia

Drug	Initial Dosing	Monitoring	Clearance (Half-Life)
DIRECT THROMBIN INHIBITORS			
Argatroban	Bolus: None Continuous infusion: Normal organ function → 2 mcg/kg/min Liver dysfunction (total bilirubin >1.5 mg/dL), heart failure, postcardiac surgery, anasarca → 0.5–1.2 mcg/kg/min	Adjust dose to aPTT of 1.5–3.0 × patient baseline	Hepatobiliary (40–50 min)
Bivalirudin	Bolus: None Continuous infusion: Normal organ function → 0.15 mg/kg/h Renal or hepatic insufficiency → consider dose reduction	Adjust dose to aPTT of 1.5–2.5 × patient baseline	Enzymatic and renal (25 min)
INDIRECT FACTOR Xa INHIBITORS			
Danaparoid	Bolus: <60 kg → 1500 U 60–75 kg → 2250 U 75–90 kg → 3000 U >90 kg → 3750 U Accelerated initial infusion: 400 U/h × 4 h, then 300 U/h × 4 h Maintenance infusion: Normal renal function → 200 U/h Renal insufficiency → 150 U/h	Adjust to anti-factor Xa of 0.5–0.8 U/mL	Renal (24 h)
Fondaparinux	<50 kg → 5 mg SC daily 50–100 kg → 7.5 mg SC daily >100 kg → 10 mg SC daily Cl _{Cr} 30–50 mL/min → use caution Cl _{Cr} <30 mL/min → contraindicated	None	Renal (17–20 h)

aPTT, activated partial thromboplastin time; Cl_{Cr}, creatinine clearance.

aggregation or PF4 release in the presence of HIT-positive sera *in vitro*¹¹³ and constitute biologically rational approaches to the treatment of HIT. However, clinical evidence is limited to a small number of case reports^{114,115} and use of these agents for HIT cannot be recommended outside of a clinical trial. One such trial of rivaroxaban in patients with suspected HIT began enrollment in 2013 and is ongoing.¹¹⁶

An important toxicity of anticoagulants used for treatment of HIT is major bleeding, a risk compounded by the absence of effective reversal agents. Novel therapeutic approaches that target pathways proximal to activation of coagulation may provide effective antithrombotic therapy without the degree of bleeding risk associated with anticoagulants. Candidate strategies include a desulfated form of heparin with minimal anticoagulant activity¹¹³ and small molecule PF4 antagonists,¹¹⁷ which interfere with formation of PF4–heparin complexes; inhibitors of FcγRIIA-mediated platelet activation by HIT immune complexes; and inhibitors of splenic tyrosine kinase and Ca²⁺¹¹⁸ and diacylglycerol-regulated guanine nucleotide exchange factor I,¹¹⁹ which disrupt intracellular transduction triggered by immune complex binding.

WHO TO TREAT

Because of the frequency of heparin use and thrombocytopenia among hospitalized patients, the modest specificity of immunologic assays, and clinicians' fears of missing a case of HIT, overdiagnosis and unnecessary

treatment with nonheparin anticoagulants of patients without HIT is common.¹²⁰ Inappropriate use of these agents is associated with increased costs and bleeding risk.¹²¹ In light of the very-high negative predictive value (99.8 percent) of a low-probability 4T score,⁶⁵ a reasonable first step toward reducing unnecessary treatment is to avoid use of nonheparin anticoagulants in patients with a low-probability 4T score. Heparin should be discontinued and a nonheparin anticoagulant initiated in patients with an intermediate- or high-probability 4T score until the results of HIT laboratory testing become available.^{65,95,122}

TRANSITIONING TO A VITAMIN K ANTAGONIST

Warfarin and other vitamin K antagonists should not be prescribed as the initial anticoagulant in patients with acute HIT because their use increases the risk of venous limb gangrene as a result of rapid lowering of protein C activity.¹²³ For patients receiving a vitamin K antagonist at the time HIT is diagnosed, the vitamin K antagonist should be discontinued and its effects reversed with vitamin K. A vitamin K antagonist may be initiated once the platelet count has recovered to a stable plateau. Large loading doses (e.g., warfarin >5 mg/day) should be avoided. The vitamin K antagonist should be overlapped with a parenteral nonheparin anticoagulant for at least 5 days and until the international normalized ratio (INR) has reached its intended target.^{63,95} If the patient is being transitioned from argatroban to warfarin, guidelines regarding

the appropriate INR target should be followed,¹²⁴ because both argatroban and warfarin increase the INR. This target will vary according to the sensitivity of the prothrombin time reagent to argatroban used in each institution.

DURATION OF ANTICOAGULATION

Patients with HIT-associated thromboembolism are typically treated with therapeutic anticoagulation for 3 to 6 months. The optimal duration of anticoagulation in patients with HIT without thrombosis (i.e., isolated HIT) is unknown. In a historical series of untreated patients with isolated HIT, the cumulative incidence of thromboembolism at 30 days was 53 percent.⁵⁷ Most events occurred within 10 days of heparin cessation, corresponding to the platelet recovery phase. It is therefore generally accepted that anticoagulation be continued in patients with isolated HIT until platelet count recovery. Some authorities recommend longer courses (e.g., 4 weeks).¹²²

PLATELET TRANSFUSION

There is a long-held concern that platelet transfusion may precipitate thrombosis in HIT by “adding fuel to the fire.” Two case series challenge this dogma. Collectively, these series included 41 patients with suspected HIT who underwent platelet transfusion. None developed thrombosis during extended followup.^{125,126} Nevertheless, because HIT is characteristically prothrombotic rather than prohemorrhagic, prophylactic platelet transfusion is rarely indicated. Transfusion may be considered in the setting of clinically significant bleeding, high bleeding risk, or diagnostic uncertainty.

HEPARIN REEXPOSURE IN PATIENTS WITH A HISTORY OF HEPARIN-INDUCED THROMBOCYTOPENIA

In general, heparin reexposure should be avoided in patients with a history of HIT because of the risk of recurrence.¹²⁷ An exception to this rule is the use of intraoperative heparin in patients with a history of HIT who are undergoing cardiovascular surgery. The HIT immune response wanes over time. Functional assays become negative at a median of 50 days after heparin cessation, whereas anti-PF4–heparin antibody titers decline more slowly and are no longer detectable in 60 percent of patients by day 100.²³ HIT laboratory testing can be used to determine the safety of heparin reexposure during cardiovascular surgery. Patients with a negative immunologic and functional assay may safely receive UFH during surgery. This was first demonstrated in 10 patients with a history of HIT undergoing cardiac surgery, none of whom developed clinical recurrence.¹²⁸ In a newer report, 11 of 17 such patients developed recrudescence of anti-PF4–heparin antibodies, but only one developed HIT.¹²⁹ Heparin should be strictly avoided in patients with a positive functional assay. If possible, surgery should be delayed in these individuals until functional and immunologic assays become negative. If surgery cannot be delayed, a nonheparin anticoagulant (e.g., bivalirudin) should be used.¹⁰¹ Appropriate intraoperative anticoagulation of patients with a functional assay that has become negative, but an immunologic assay that remains positive is uncertain. The 2012 American College of Chest Physicians Guidelines recommend a nonheparin anticoagulant in this setting.⁹⁵ However, intraoperative heparin was used uneventfully in three such patients undergoing urgent heart transplantation.¹³⁰ When heparin is administered to patients with HIT, it should be limited to the intraoperative setting. Pre- and postoperative exposure should be scrupulously avoided, though patients with a history of HIT who are (inadvertently) reexposed to longer courses of heparin do not always develop recurrent HIT.¹²⁹

In light of its documented efficacy and safety in large coronary angiography trials, bivalirudin is recommended over heparin in patients with a history of HIT who require percutaneous vascular procedures, irrespective of the results of HIT laboratory testing.⁹⁵

HEMODIALYSIS

Although approximately 10 percent of patients on chronic hemodialysis develop circulating anti-PF4–heparin antibodies,¹³¹ the incidence of HIT in this population is less than 1 percent.¹³² Ongoing heparin exposure during dialysis in patients with a history of HIT is contraindicated. Alternative strategies including regional citrate, saline flushing, danaparoid, argatroban, and vitamin K antagonists use have been reported.⁹⁵

PREGNANCY

HIT is rare (<0.1 percent) in pregnant women exposed to heparin.^{11,12} When it does occur, initiation of a nonheparin anticoagulant is warranted. The largest published experience is with danaparoid. A retrospective cohort of 30 women with acute HIT received danaparoid during pregnancy.¹³³ Five patients developed thrombosis and three developed major bleeding. Danaparoid does not cross the placenta and there was no measurable anti-Xa activity in the cord blood of six neonates who were tested after delivery. If danaparoid is unavailable, fondaparinux may be considered though evidence supporting its use in pregnant women with HIT is limited to case reports^{134,135} and partial transplacental passage has been demonstrated.¹³⁶

CHAPTER 119

REACTIVE THROMBOCYTOSIS

Kenneth Kaushansky

SUMMARY

The three major pathophysiologic causes of thrombocytosis are (1) clonal, including essential (or primary) thrombocythemia and other myeloproliferative neoplasms; (2) familial, including rare cases of nonclonal myeloproliferation resulting from thrombopoietin and thrombopoietin receptor mutations; and (3) reactive, in which thrombocytosis occurs secondary to a variety of acute and chronic clinical conditions. This chapter deals with the latter causes of thrombocytosis.

The upper limit of the normal platelet count in most clinical laboratories is between 350,000/ μL ($350 \times 10^9/\text{L}$) and 450,000/ μL ($450 \times 10^9/\text{L}$). In a sample of 10,000 healthy individuals 18 to 65 years of age, 1 percent had platelet counts greater than 400,000/ μL . Only in eight of these 99 individuals was thrombocytosis confirmed 6 months to 1 year later.¹ Nevertheless, it is clear that thrombocytosis is a feature of several important disorders, including cancer, and that even a high normal platelet count is associated with morbidity and mortality. In a longitudinal study of healthy Norwegian men, a platelet count in the top quartile of the normal range (from $275 \times 10^9/\text{L}$ to $350 \times 10^9/\text{L}$) was associated with a twofold increase in cardiovascular mortality over a 12-year followup.² Whether the platelet count per se, or an underlying inflammatory condition resulting in both thrombocytosis and accelerated atherogenesis is responsible for these observations is not certain. The causes of thrombocytosis in which the platelet count exceeds the upper limit can be broadly categorized as (1) clonal, including essential thrombocythemia and other myeloproliferative neoplasms, (2) familial, and (3) reactive, or secondary (see Chap. 85, Table 85-1). This chapter focuses on the causes and molecular mechanisms that underlie reactive, or secondary, thrombocytosis; clonal and familial thrombocytosis are discussed in detail in Chap. 85.

● NORMAL THROMBOPOIESIS

The regulation of platelet production is discussed extensively in Chap. 111, but a brief discussion here provides the appropriate background for discussion of reactive thrombocytosis. Thrombopoietin (TPO), the

ligand for the megakaryocytic growth factor receptor c-Mpl, is the major humoral regulator of megakaryocyte survival, growth, and development, although, curiously, it does not stimulate the final step in thrombopoiesis: platelet release from megakaryocyte proplatelet processes. Although TPO supports the entire continuum of megakaryocyte development from stem cell to mature megakaryocyte,³ other cytokines including interleukin (IL)-6,⁴ IL-3,^{5,6} IL-11,⁷ leukemia inhibitory factor (LIF),^{8,9} fibroblast growth factor (FGF)-4,¹⁰ stromal cell-derived factor (SDF)-1,^{10,11} interferon (IFN)- γ ,¹² and granulocyte-macrophage colony-stimulating factor (GM-CSF)¹³ also affect thrombopoiesis, both *in vitro* and *in vivo*. Many of these cytokines act in synergy with other cytokines, including TPO.^{11,12,14}

The regulation of thrombopoiesis occurs primarily by humoral mechanisms, with the levels of TPO inversely related to platelet counts.^{15,16} In contrast, other cytokines shown to affect megakaryopoiesis *in vitro* do not vary with platelet levels.¹⁷ Despite these important insights, the regulation of TPO blood levels is complex, and incompletely understood. The liver produces approximately half of all the hormone that circulates, based on platelet production in liver specific knockout mice.¹⁸ However, platelet levels do not affect hepatic TPO production; instead, platelets themselves have an important role in regulating plasma levels, as their receptors for TPO (c-mpl) remove it from plasma.¹⁹ Thus, as the platelet count drops, increased free plasma TPO levels stimulate megakaryopoiesis; conversely, as the platelet count rises, depletion of free plasma TPO decreases platelet production. This modulatory mechanism results in the steady-state level of platelet production. However, marrow stromal cells also produce TPO,²⁰ and are responsive to platelet products which serve to down-modulate expression of the hormone.²¹ A third mechanism by which platelets regulate TPO levels occurs through the Ashwell-Morell hepatocyte receptor, whereby their binding of senescent platelets leads to stimulation of hepatocyte signaling pathways and subsequent expression of TPO.²²

● ENHANCED THROMBOPOIESIS IN PATHOLOGIC STATES

THROMBOCYTOSIS IN INFLAMMATORY CONDITIONS

Inflammation is the most common cause of secondary thrombocytosis. In one survey, thrombocytosis was believed secondary to one or more inflammatory conditions in nearly 80 percent of all patients with an elevated platelet count. Table 119-1 lists the clinical conditions associated with reactive thrombocytosis. The most common diagnoses in such patients are inflammatory bowel disease and rheumatoid arthritis,²³ although most conditions in which the erythrocyte sedimentation rate or C-reactive protein is elevated have been reported to cause secondary thrombocytosis. Although several cytokines and lymphokines are elevated in the blood of such patients, the most compelling evidence suggests that IL-6 and IFN- γ are responsible for the thrombocytosis seen in patients with inflammation.

Interleukin-6

IL-6 was cloned by several groups of investigators using a number of distinct assays, including antiviral activity, myeloma cell growth, hepatocyte growth, and immunoglobulin secretion.²⁴ The recombinant protein was later found to affect megakaryocyte growth and differentiation, both *in vitro* and *in vivo*.^{4,25,26} The IL-6 gene is present on the short arm of human chromosome 7, and encodes a 26-kDa polypeptide produced in almost all tissues from T cells, fibroblasts, macrophages, and stromal cells, and is a key regulator of the inflammatory response.²⁷

Acronyms and Abbreviations: EPO, erythropoietin; ESA, erythropoiesis-stimulating agent; FGF, fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; JAK, Janus kinase; LIF, leukemia inhibitory factor; MHC, major histocompatibility complex; NF, nuclear factor; SDF, stromal cell-derived factor; STAT, signal transducer and activator of transcription; TPO, thrombopoietin.

TABLE 119-1. Major Causes of Thrombocytosis

A. Reactive (secondary) thrombocytosis
1. Transient reactive processes
2. Acute blood loss
3. Recovery (“rebound”) from thrombocytopenia
4. Acute infection, inflammation
5. Response to exercise
B. Sustained processes
1. Iron deficiency
2. Postsplenectomy, asplenic states
3. Malignancies
4. Chronic inflammatory and infectious diseases (inflammatory bowel disease, rheumatoid arteritis, tuberculosis, chronic pneumonitis)
5. Response to drugs (vincristine, epinephrine, all- <i>trans</i> -retinoic acid, some antibiotics, cytokines, and growth factors)
6. Hemolytic anemia

IL-6 production is dependent on the presence of IL-1 and tumor necrosis factor (TNF)- α , cytokines produced by lymphocytes and monocytes in response to phagocytosis of microorganisms, the binding of immune complexes, and several other innate immune stimuli. IL-6 production is regulated primarily by transcriptional enhancement; regulatory elements responsible for IL-6 promoter activation include nuclear factor- κ B (NF κ B), adapter protein (AP)-1, CCAAT/enhancer binding protein (C/EBP) α and C/EBP β .

Although not critical for steady-state thrombopoiesis, as the combined genetic elimination of *c-mpl* and the signaling component of the IL-6 receptor (gp130) produces no more severe thrombocytopenia than elimination of *c-mpl* alone,²⁹ IL-6 contributes to inflammatory thrombopoiesis, primarily by stimulating the hepatic production of TPO.³⁰ Most studies report that patients with inflammation display an increased level of TPO,^{31,32} but TPO is not the only cytokine responsible for this effect,³³ especially when corrected for the thrombocytosis, which would normally act to reduce levels of the hormone. Stimulation of hepatocytes with IL-6 results in enhanced production of TPO mRNA and protein.^{34,35}

INTERFERON- γ

A second inflammatory cytokine that contributes to inflammatory thrombopoiesis is IFN- γ . The interferons are proteins first defined by their ability to induce an antiviral state in mammalian cells. Biochemical fractionation revealed three classes of interferons: IFN- α , a family of 17 distinct but highly homologous molecules; IFN- β , a single molecule more distantly related to the various isoforms of IFN- α ; and IFN- γ , a unique molecule that shares functional properties but not structure with the others. IFN- γ exerts the most profound hematologic effects of the three classes of protein, including direct suppression of erythroid colony-forming cell growth and the activation of macrophages to secrete a number of inflammatory cytokines; several comprehensive reviews on IFN- γ have been published.^{36,37}

IFN- γ is produced by activated T lymphocytes and natural killer (NK) cells in response to T-cell antigen crosslinking and in response to stimulation by the inflammatory mediators TNF- α , IL-12, and IL-15.³⁸ Prominent hematologic effects include activation of macrophages to assume an inflammatory phenotype (e.g., secretion of TNF- α and enhanced tumor cell killing), upregulation of major histocompatibility

complex (MHC) class I and class II molecules enhancing antigen recognition responses,³⁷ and inhibition of proliferative responses in stem cells and erythroid progenitors.^{39,40} These latter effects accounts for the association of IFN- γ and aplastic anemia⁴¹ are discussed more fully in Chap. 35. However, in stark contrast to the inhibitory effects of IFN- γ on erythropoiesis, the cytokine stimulates megakaryocyte growth and differentiation.⁴² This is likely related to its stimulation of signal transducer and activator of transcription (STAT)-1 in megakaryocytes, as transgenic expression of the transcription factor mimics the effect of the cytokine, and corrects the thrombocytopenia seen in a genetic model system.⁴³ These findings argue that IFN- γ also contributes to the thrombocytosis seen in inflammatory states in humans.

Notwithstanding the above two mechanisms, patients with inflammatory conditions and thrombocytosis might have an additional cause of the elevated platelet count. The evaluation of iron deficiency is often difficult in patients with inflammation, as the most reliable indicator of tissue iron stores, serum ferritin, is an acute-phase reactant, possibly obscuring a diagnosis of iron deficiency in patients with an inflammatory condition. In a recent study of patients with inflammatory bowel disease, thrombocytosis was eliminated in half of the subjects by the administration or iron.⁴⁴

THROMBOCYTOSIS CAUSED BY IRON DEFICIENCY

Although most patients with inflammation-related thrombocytosis display increased production of the hormone, TPO levels in patients with iron deficiency and thrombocytosis are not elevated.⁴⁵ In contrast, erythropoietin (EPO) levels are elevated in patients with iron-deficiency anemia, and are thought by some to be the responsible for the thrombocytosis seen in iron deficiency, at least in part. Consistent with this hypothesis, administration of EPO to animals and humans leads to a modest increase in the platelet count.⁴⁶ Although some have suggested that this is a result of cross-reactivity of EPO on the TPO receptor,⁴⁷ direct EPO- and TPO-receptor binding studies refute this hypothesis.⁴⁸ Rather, megakaryocytic progenitors display EPO receptors, and their binding of the hormone leads to many of the same intracellular biochemical signals as induced by TPO (Chap. 17).

However, several lines of evidence indicate that pathophysiologic mechanisms other than anemia must be responsible, at least in part, for the thrombocytosis seen in patients with iron deficiency. For example, many patients with iron-deficiency anemia do not have thrombocytosis.⁴⁵ Moreover, EPO levels are elevated in nearly all types of anemia, but iron deficiency is the only type of anemia that is regularly associated with thrombocytosis, other than the anemia of chronic inflammation, in which the inflammatory state that causes the anemia by modulation of hepcidin levels (Chap. 37) also causes thrombocytosis (as discussed in “Thrombocytosis in Inflammatory Conditions” above). Thus, although several lines of evidence suggest that enhanced levels of EPO as a consequence of the anemia associated with iron deficiency contribute to this form of reactive thrombocytosis, elevated EPO levels cannot completely account for it.

THERAPEUTIC ERYTHROPOIETIN AND ENHANCED CARDIOVASCULAR MORTALITY

Several reports have linked the use of large doses of EPO or other erythropoiesis-stimulating agents (ESAs) to enhanced cardiovascular mortality,⁴⁹ and in patients with renal insufficiency, to progression to dialysis in patients with renal insufficiency,⁵⁰ although not all studies concur with these landmark results.⁵¹ Although also discussed in Chap. 18, this finding is presented here because evidence is accumulating that the rapid expansion of erythropoiesis caused by pharmacologic levels of

EPO often induces functional iron deficiency. If so, because iron deficiency leads to thrombocytosis, the excessive cardiovascular morbidity and mortality associated with the administration of EPO and ESAs to patients is hypothesized to be secondary to the thrombocytosis. Consistent with this view is that even a high normal platelet count was found associated with enhanced cardiovascular morbidity and mortality in a longitudinal study of healthy Norwegian men.² In support of this hypothesis (that the excessive cardiovascular morbidity and mortality is secondary to the thrombocytosis) is the finding that patients with renal insufficiency on high therapeutic doses of EPO (>20,000 U/week) and hemoglobin (Hgb) values in excess of 13 g/dL are more likely to develop functional iron deficiency and thrombocytosis, and that those individuals in whom the platelet count exceeds 300,000/ μ L display a statistically significantly higher 3-year mortality rate.⁵² An alternate explanation is that EPO directly increases thrombopoiesis independently of iron deficiency and/or enhances the vascular reactivity of platelets. This hypothesis is based on the finding that megakaryocytes and platelets bear EPO receptors,⁵³ and that TPO, which stimulates very similar signaling pathways as EPO in receptor-bearing cells (Chap. 17), primes platelets to enhanced aggregation responses to classic platelet agonists.⁵⁴ Still other researchers have hypothesized that an alternate form of the EPO receptor, made up of the classic EPO receptor and the β subunit of the GM-CSF, IL-3, and IL-5 receptors, is displayed on vascular endothelial cells,⁵⁵ and in that site could mediate enhanced vascular events. Thus, given the widespread use of ESAs in patients with anemia caused by cancer, kidney failure, myelodysplastic syndromes, and many other conditions, verifying these hypotheses or disproving them and establishing new ones appears to be important and a field ripe for new discovery.

CLINICAL FEATURES OF REACTIVE THROMBOCYTOSIS

The clinical features of secondary thrombocytosis are almost always a result of the underlying disorder provoking the reaction, usually an inflammatory condition or iron-deficiency anemia. It is also highly unusual for the thrombocytosis per se to provoke any untoward symptoms. Although pathologic thrombosis is a major feature of primary thrombocythemia (Chap. 85), it is virtually absent in reactive thrombocytosis, unless provoked by other features of the underlying condition (e.g., vasculitis) or completely unrelated conditions in the patient (e.g., atherosclerotic disease). Whether this is because patients with reactive thrombocytosis do not have as high platelet counts, on average, as patients with primary thrombocythemia⁵⁶; or because they have smaller mean platelet volumes⁵⁶; or are a result of the activated signaling characteristic of the platelets or other blood cells in patients with myeloproliferative diseases; or because of the presence of a mutant Janus kinase (JAK) 2,⁵⁷ or a constitutively active TPO receptor,⁵⁸ is uncertain at this time. Nevertheless, because vascular complications of reactive thrombocytosis are so unlikely to be a consequence of the elevated platelet count, treatment of the thrombocytosis per se is not recommended in reactive thrombocytosis except in very unusual circumstances.

CHAPTER 120

HEREDITARY QUALITATIVE PLATELET DISORDERS

A. Koneti Rao and Barry S. Collier

SUMMARY

Abnormalities of platelet function manifest themselves primarily as excessive hemorrhage at mucocutaneous sites, with ecchymoses, petechiae, epistaxis, gingival hemorrhage, and menorrhagia most common. Both quantitative and qualitative platelet abnormalities can produce these symptoms, so it is necessary to exclude thrombocytopenia (Chap. 117) by performing a platelet count. Chapter 121 discusses acquired qualitative platelet abnormalities and this chapter discusses the hereditary qualitative platelet abnormalities.

The hereditary qualitative platelet disorders can be classified according to the major locus of the defect (see Table 120–1 and Fig. 120–1). Thus, abnormalities of platelet glycoproteins, platelet granules, and signal transduction and secretion can all result in hemorrhagic diatheses and prolonged bleeding times. Glanzmann thrombasthenia results from abnormalities in one of two integrin subunits, either α_{IIb} (glycoprotein [GP] IIb) or β_3 (GPIIIa), resulting in loss or dysfunction of the $\alpha_{IIb}\beta_3$ (GPIIb/IIIa) receptor. This results in a profound defect in platelet aggregation and secondary defects in platelet adhesion, secretion,

and platelet coagulant activity. Heterozygous gain of function mutations in $\alpha_{IIb}\beta_3$ can result in a syndrome of macrothrombocytopenia. Loss of the platelet GPIIb–IX–V complex because of abnormalities in GPIIb α , GPIIb β , or GPIIX results in the Bernard-Soulier syndrome, which is characterized by giant platelets and modest thrombocytopenia. The major defect is in platelet adhesion because of a decrease in platelet interactions with von Willebrand factor, but abnormalities in $\alpha_{IIb}\beta_3$ activation and thrombin-induced aggregation are also present. A gain of function defect in GPIIb α (platelet-type [pseudo-] von Willebrand disease) can produce a hemorrhagic disorder via depletion of high-molecular-weight von Willebrand multimers. Inherited defects in platelet dense or α granules, agonist receptors, or proteins and mechanisms involved in signal transduction and secretion also lead to platelet dysfunction and produce hemorrhagic symptoms.

Abnormalities of platelet coagulant activity, that is, the ability of platelets to facilitate thrombin generation (Chap. 112), can lead to a hemorrhagic diathesis. Impaired platelet function may occur in association with mutations in transcription factors RUNX1, GATA-1, FLI-1, and GFI1B, and these patients have thrombocytopenia as well.

platelet abnormalities and this chapter discusses hereditary qualitative platelet abnormalities.

Following injury to the blood vessel, platelets adhere to exposed subendothelium by a process that involves, among other events, the interaction of a plasma protein, von Willebrand factor (VWF), and a specific glycoprotein complex on the platelet surface, the glycoprotein (GP) Ib–IX–V complex. Adhesion is followed by recruitment of additional platelets that form clumps (aggregation), which involves binding of fibrinogen to specific platelet surface receptors, a complex comprised of integrin $\alpha_{IIb}\beta_3$ (GPIIb–IIIa). Platelet activation is required for fibrinogen binding; resting platelets do not bind fibrinogen. Activated platelets release the contents of their granules (secretion), including adenosine diphosphate (ADP) and serotonin from the dense granules, which causes the recruitment of additional platelets. Moreover, platelets play a major role in coagulation mechanisms; several key enzymatic reactions occur on the platelet membrane phospholipid surface. A number of physiologic agonists interact with platelet surface receptors to induce responses, including a change in platelet shape from discoid to spherical (shape change), aggregation, secretion, and thromboxane A_2 (TXA₂) production. The binding of agonists to their platelet receptors initiates numerous intracellular events (Chap. 112) including the production or release of several messenger molecules. One pathway leads to the hydrolysis of phosphoinositide (PI) by phospholipase C leading to the formation of diacylglycerol and inositol 1,4,5-triphosphate [IP₃]. These and other mediators induce or modulate the various platelet responses of Ca²⁺ mobilization, protein phosphorylation, aggregation, secretion, and thromboxane production. Numerous other mechanisms, such as activation of tyrosine kinases and phosphatases, are also triggered by platelet activation (Chap. 112). Inherited or acquired defects in the above and other platelet mechanisms may lead to impaired platelet function and a bleeding diathesis.

CLASSIFICATION OF HEREDITARY QUALITATIVE PLATELET DISORDERS

The hereditary qualitative platelet disorders can be classified according to the major locus of the defect (Table 120–1 and Fig. 120–1). Glanzmann thrombasthenia (GT) is caused by abnormalities in either integrin α_{IIb}

PLATELET FUNCTION IN HEMOSTASIS

Abnormalities of platelet function manifest themselves primarily as excessive hemorrhage at mucocutaneous sites, with ecchymoses, petechiae, epistaxis, gingival hemorrhage, and menorrhagia being most common. Mild platelet function abnormalities will not cause spontaneous bleeding but may cause (excessive) hemorrhage after trauma or medical interventions. Both quantitative and qualitative platelet abnormalities can produce these symptoms, so it is necessary to exclude thrombocytopenia (Chap. 117) by performing a platelet count. Although no longer performed widely, a prolonged bleeding time in a patient with a normal platelet count is suggestive of a qualitative platelet abnormality. Some patients may have abnormalities in both platelet number and function. Chapter 121 discusses acquired qualitative

Acronyms and Abbreviations: ADP, adenosine diphosphate; BSS, Bernard-Soulier syndrome; β TG, β -thromboglobulin; BLOC, biogenesis of lysosome-related organelles complex; cAMP, cyclic adenosine monophosphate; EDTA, ethylenediaminetetraacetic acid; GFI1b, growth factor independent 1B; GPS, gray platelet syndrome; GT, Glanzmann thrombasthenia; HLA, human leukocyte antigen; HPS, Hermansky-Pudlak syndrome; Ig, immunoglobulin; LAD, leukocyte adhesion deficiency; MIDAS, metal ion-dependent adhesion site; PAR, protease-activated receptor; PF4, platelet factor 4; PKC, protein kinase C; PLC, phospholipase C; rFVIIa, recombinant factor VIIa; TGF, transforming growth factor; TXA₂, thromboxane A₂; VWD, von Willebrand disease; VWF, von Willebrand factor.

TABLE 120-1. Inherited Disorders of Platelet Function

- I. Abnormalities of glycoprotein adhesion receptors
 - A. Integrin $\alpha_{IIb}\beta_3$ (Glycoprotein IIb/IIIa; CD41/CD61): Glanzmann thrombasthenia
 - B. Glycoproteins Ib (CD42b,c)/IX (CD42a)/V: Bernard-Soulier syndrome
 - C. Glycoprotein Iba (CD42b,c): Platelet-type (Pseudo-) von Willebrand disease
 - D. Integrin $\alpha_2\beta_1$ (Glycoprotein Ia/IIa; VLA-2; CD49b/CD29)
 - E. CD36 (Glycoprotein IV)
 - F. Glycoprotein VI
- II. Abnormalities of platelet granules
 - A. δ -Storage pool deficiency
 - B. Gray platelet syndrome (α -storage pool deficiency)
 - C. α,δ -Storage pool deficiency
 - D. Quebec platelet disorder
- III. Abnormalities of platelet signaling and secretion
 - A. Defects in platelet agonist receptors or agonist-specific signal transduction (thromboxane A_2 receptor defect, adenosine diphosphate [ADP] receptor defects [P2Y₁₂, P2X₁], epinephrine receptor defect, platelet activating factor receptor defect)
 - B. Defects in guanosine triphosphate (GTP)-binding proteins (Gaq deficiency, Gas hyperfunction and genetic variation in extra-large Gas, Gai1 deficiency, CaLDAG-GEFI deficiency)
 - C. Phospholipase C (PLC)- β_2 deficiency and defects in PLC activation
 - D. Defects in protein phosphorylation protein kinase C (PKC)- θ deficiency
 - E. Defects in arachidonic acid metabolism and thromboxane production (phospholipase A_2 deficiency cyclooxygenase [prostaglandin H₂ synthase-1 deficiency], thromboxane synthase deficiency)
- IV. Abnormalities of platelet coagulant activity (Scott syndrome)
- V. Abnormalities of a cytoskeletal structural protein: β_1 tubulin, filamin A
- VI. Abnormalities in cytoskeletal linking proteins
 - A. Wiskott-Aldrich syndrome protein (WASP)
 - B. Kindlin-3: Leukocyte adhesion defect (LAD)-III; LAD-1 variant; integrin activation deficiency disease defect (IADD)
- VII. Abnormalities of transcription factors leading to functional defects
 - A. RUNX1 (familial platelet dysfunction with predisposition to acute myelogenous leukemia)
 - B. GATA-1
 - C. FLI1 (dimorphic dysmorphic platelets with giant α granules and thrombocytopenia; Paris-Trousseau/Jacobsen syndrome)
 - D. GFI1B

(GPIIb) or β_3 (GPIIIa), resulting in loss or dysfunction of the integrin $\alpha_{IIb}\beta_3$ receptor. This results in a profound defect in platelet aggregation and secondary defects in platelet adhesion, secretion, and coagulant activity. Loss of the platelet GPIb-IX-V complex because of abnormalities in GPIb α , GPIb β , or GPIX results in the Bernard-Soulier syndrome (BSS), which is characterized by giant platelets and thrombocytopenia. The major defect is in platelet adhesion owing to a decrease in platelet

interactions with VWF. A gain-of-function defect in GPIb α (platelet-type [pseudo] von Willebrand disease [VWD]) can also produce a hemorrhagic disorder via depletion of high-molecular-weight VWF multimers. Defects in secretion of granule contents because of deficiencies in the granules or in the mechanisms that mediate secretion results in impaired platelet function. Inherited defects in agonist receptors or proteins or mediators involved in signal transduction or thromboxane synthesis may also produce hemorrhagic symptoms. Abnormalities of platelet coagulant activity, that is, the ability of platelets to facilitate thrombin generation (Chap. 113), and in cytoskeletal-linking proteins, can also lead to a hemorrhagic diathesis. Lastly, it is becoming clear that some patients may have abnormalities multiple aspects of platelet function and number related to a mutation in a hematopoietic transcription factor that regulates gene expression in megakaryocytes and platelets.

● CLINICAL MANIFESTATIONS

Disorders of platelet function are characterized by highly variable mucocutaneous bleeding manifestations and excessive hemorrhage following surgical procedures or trauma. These include ecchymoses, petechiae, epistaxis, gingival bleeding, and menorrhagia. Spontaneous hemarthrosis are distinctly rare, distinguishing them from the hemophilias, and deep hematomas and spontaneous central nervous system bleeding are highly unusual in these patients. Postpartum hemorrhage and postsurgical bleeding may be severe in some patients. In general, most patients with platelet function defects have mild to moderate bleeding manifestations, but may be severe in some entities, such as the GT and the BSS. Individual patients with the same functional defect or even the same genetic defect may also vary in the intensity of bleeding manifestations, suggesting one or more disease-modifying genes exist. Moreover, the severity of bleeding symptoms may vary over the lifetime of the same individual, implying that factors in addition to the platelet defect may be contributing to the bleeding risk. Sometimes, a mild platelet function defect becomes clinically manifest when the patient uses medication interfering with primary hemostasis (e.g., nonsteroidal antiinflammatory drugs [NSAIDs]).

Although normal in many of the inherited platelet function defects, the platelet count may be decreased in some entities, such as the BSS and the gray platelet syndrome (GPS) and in association with mutations in hematopoietic transcription factors. Most patients with platelet function defects, but not all, have a prolonged bleeding time, a test no longer available in most centers because of its inherent inaccuracies. *In vitro* platelet aggregation and secretion studies provide evidence for the dysfunction but are not generally predictive of the severity of clinical manifestations. In some patients, such as those with abnormal platelet coagulant activities, these studies may be normal. Some patients with platelet dysfunction are initially detected through abnormalities on testing with the platelet function analyzer (PFA-100).

● GENERAL APPROACH TO PATIENTS WITH MUCOCUTANEOUS BLEEDING SYMPTOMS FOR ABNORMALITIES IN PLATELET NUMBER OR FUNCTION

Platelet disorders are characterized by alterations in platelet number or function or both. A general approach is shown in Fig. 120-1. A reduced platelet count can occur as an isolated platelet disorder (inherited or acquired) or with evidence of a concomitant defect in platelet function. Platelet size and examination of the blood film may provide insights

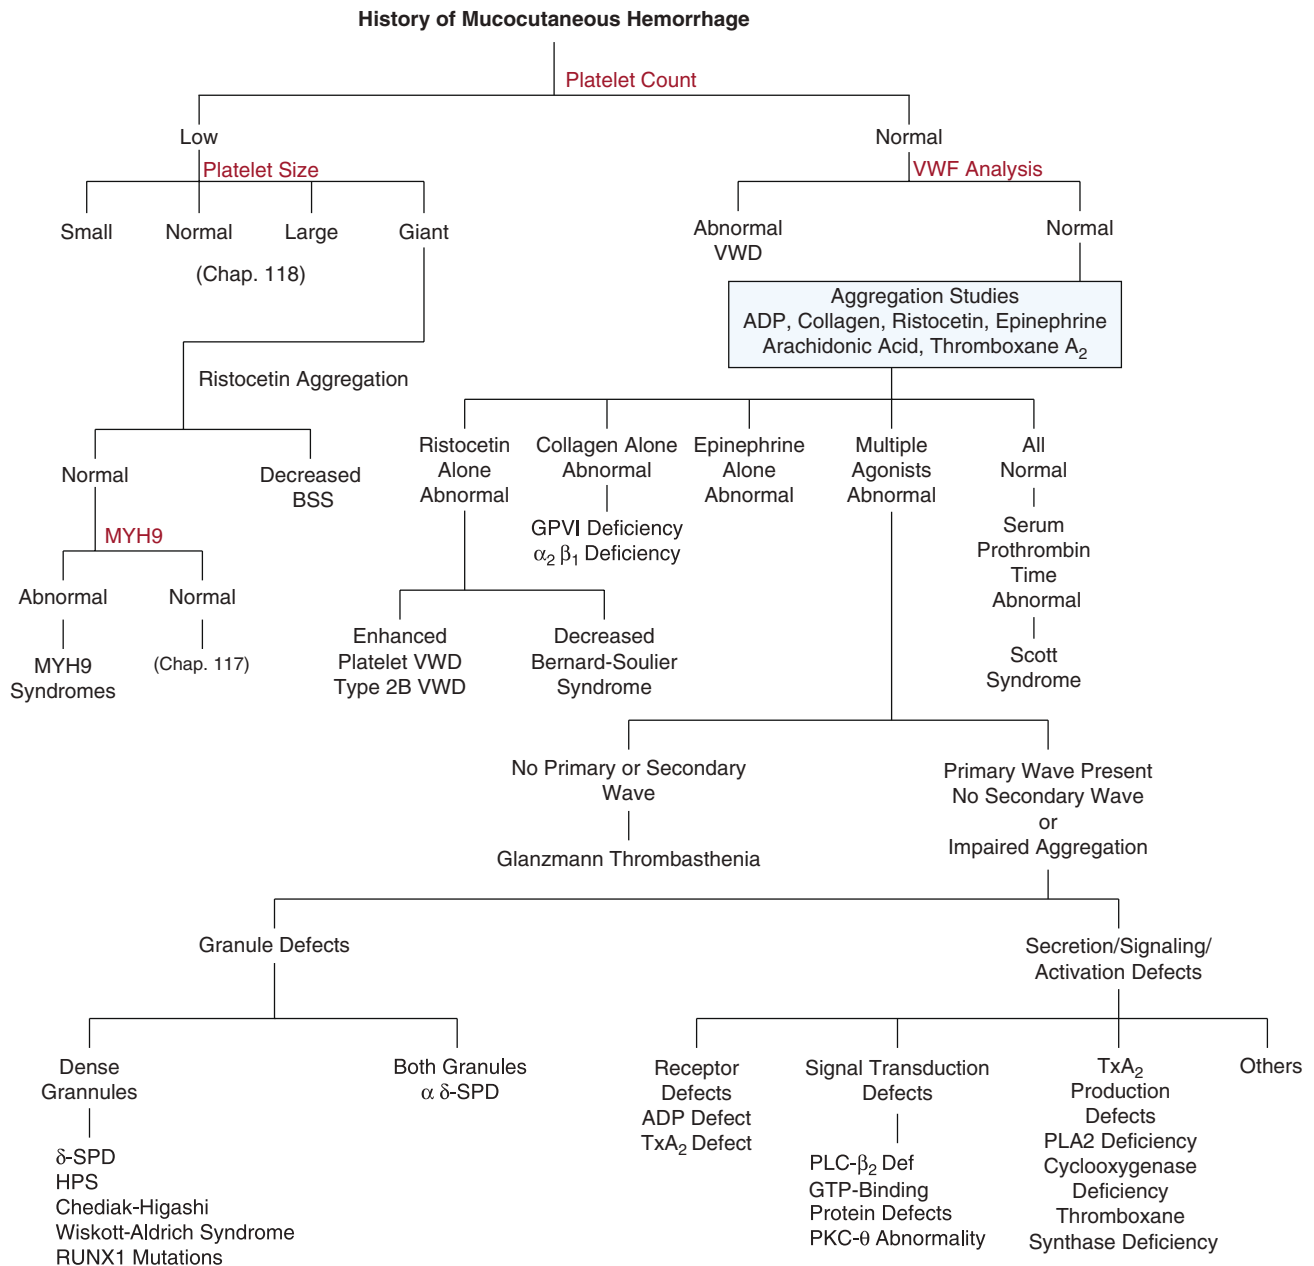

Figure 120–1. Evaluation of patients for inherited abnormalities in platelet number or function. The major and well-recognized entities are shown here. A reduced platelet count occurs in patients with purely quantitative platelet disorders (inherited or acquired) as well as in patients who have inherited qualitative platelet disorders. Chapter 117 discusses inherited thrombocytopenias. Notable among patients with thrombocytopenia and inherited platelet dysfunction is the Bernard-Soulier syndrome (BSS), which is characterized by giant platelets. Patients with the Gray platelet syndrome are characterized by thrombocytopenia and gray appearance of platelets on the blood smear due to paucity of granules. Platelet aggregation studies can provide clues regarding the nature of the underlying platelet abnormality. Decreased response to ristocetin alone with normal responses to other agonists is found in the BSS and von Willebrand disease (VWD; type I and type III). The response to ristocetin is enhanced in VWD type IIB and the platelet-type VWD. Impaired response to collagen or epinephrine alone may suggest a defect in their respective receptors. Patients with adenosine diphosphate (ADP) and thromboxane receptor defects have impaired responses to multiple agonists because of the feedback amplification provided by ADP and thromboxane A_2 (TXA_2) when activated by different agonists. Absence of both primary and secondary waves of aggregation in response to all physiologic agonists occurs in Glanzmann thrombasthenia (GT). A heterogeneous group of platelet defects are characterized by a decreased secondary wave of platelet aggregation in response to ADP and epinephrine, and diminished responses to low doses of collagen, TXA_2 and thrombin. They can be broadly separated into granule defects (involving dense [δ] or both dense and α granules) and defects in the platelet secretion or release reaction associated with normal dense granule stores. The granule defects may occur in isolation or in association with other syndromes. Secretion abnormalities arise from defects in mechanisms that regulate the release of granule contents, and include defects at the level of platelet receptors (ADP, TXA_2), signaling events involving guanosine triphosphate (GTP)-binding proteins that link surface receptors to intracellular enzymes, phospholipase C activation, and protein phosphorylation (protein kinase C [PKC]- θ). They may also arise from defects in TXA_2 synthesis because of deficiencies of phospholipase A_2 (PLA_2), cyclooxygenase, or thromboxane synthase. Patients with the Scott syndrome are characterized by a normal bleeding time, normal responses in aggregation studies, and a shortened prothrombin time, which reflects the defect in the platelet-coagulant protein interactions. Additional details on the various entities are described in the section “General Approach to Patients with Mucocutaneous Bleeding Symptoms for Abnormalities in Platelet Number or Function.” GP, glycoprotein; PLA_2 , phospholipase A_2 ; PLC, phospholipase C; SPD, storage pool deficiency; u-PA, urokinase plasminogen activator; VWF, von Willebrand factor.

into the underlying mechanism or cause. Platelet size provides clues in some entities (Chap. 117).^{1,2} Decreased platelet size is characteristic of the Wiskott-Aldrich syndrome. In the Paris-Trousseau/Jacobsen syndrome, thrombocytopenia is associated with giant α granules in a subpopulation of platelets in association with mutations in the transcription factor *FLII*. Transcription factor *RUNX1* mutations are associated with familial thrombocytopenia, abnormal platelet function, and predisposition to leukemia. Large platelets that lack the purple granules on the peripheral smear are observed in the GPS (α -storage pool disease). The diagnosis is obtained with biochemical analysis of α -granule contents. Patients with platelet-type (pseudo-) VWD and type 2b VWD have moderate thrombocytopenia and large platelets. Studies of GPIb function and biochemistry establish the diagnosis. Patients who are hemizygous for GPIb β because of deletion of 22q11.2, those with mutations in transcription factor *GATA-1* or β_1 tubulin (R318W), and some patients who are heterozygous for defects in GPIb/IX have variable thrombocytopenia and large platelets. Mutations that activate $\alpha_{IIb}\beta_3$ are also associated with large platelets and thrombocytopenia. The platelets in BSS are truly giant; the diagnosis is confirmed with biochemical and functional analyses of the GPIb-IX-V complex.

A variety of methods have been developed to assess platelet function and new instrumentation continues to be developed.³⁻⁸ Platelet aggregation studies performed using platelet-rich plasma can loosely separate patients into those with defects in the primary wave of platelet aggregation (dependent on either fibrinogen, VWF, their respective receptors, or agonist receptors for collagen, ADP, TXA₂) and those with defects in the secondary wave of aggregation. Enhanced ristocetin-induced platelet aggregation at low doses of ristocetin is characteristic of patients with platelet-type VWD (who have a defect in the GPIb receptor) and patients with type 2b VWD (who have gain-of-function defect in VWF) (Chap. 126). These two diseases differ in the binding of the patient's VWF to normal platelets, or the ability of purified VWF, cryoprecipitate or asialo-VWF to aggregate patient platelets; the diagnosis of platelet-type VWD or its confirmation requires genetic analysis of GPIb.

Neither ristocetin nor the snake venom botrocetin induces platelet aggregation if the plasma lacks functional VWF, as in VWD (Chap. 126), or if the platelets lack functional GPIb-IX complexes, as in BSS. The defect in VWD, but not BSS, can be corrected by adding normal plasma or purified VWF. Direct analysis of VWF and the platelet GPIb-IX complex are used to confirm the diagnosis.

Patients whose plasma lacks fibrinogen (afibrinogenemia; Chap. 125) or whose platelets cannot bind fibrinogen because of abnormal $\alpha_{IIb}\beta_3$ receptors (GT) or inability to activate integrin $\alpha_{IIb}\beta_3$ (leukocyte adhesion deficiency [LAD]-3) as the result of a kindlin-3 abnormality will have no primary wave of platelet aggregation in response to all physiologic agonists, including ADP, epinephrine, collagen, TXA₂, and thrombin. Simple coagulation tests (prothrombin time, partial thromboplastin time, and measurement of plasma fibrinogen) and analysis of platelet integrin $\alpha_{IIb}\beta_3$ receptors, and kindlin-3 can differentiate between these two groups. Isolated defects in the primary response to collagen have been observed in patients with abnormalities in platelet integrin $\alpha_2\beta_1$ (GPIa/IIa) or GPVI. Platelet glycoprotein analysis can separate these from each other. Because antibodies to GPVI can result in receptor depletion from circulating platelets, a search for anti-GPVI should be undertaken in patients with reduced platelet GPVI. Defects in ADP, epinephrine, or TXA₂ receptors will result in decreased platelet aggregation in response to the specific agonist. However, patients with isolated ADP and TXA₂ receptor abnormalities have impaired aggregation in response to other agonists as well because of the feedback potentiation provided by ADP and TXA₂.

A very heterogeneous group of platelet defects can result in a decreased secondary wave of platelet aggregation in response to ADP and epinephrine and diminished responses to low doses of collagen

and thrombin. They can be separated into granule defects and defects in platelet secretion or the release reaction. Operationally, these two groups can be separated on the basis of their release of dense granule contents in response to high doses of thrombin. High-dose thrombin activation can overcome most or all of the release reaction (secretion) abnormalities, so platelets from patients with these disorders will release normal amounts of granule contents; in contrast, patients with reduced granule contents have abnormal granule release responses even when using high doses of thrombin. α -Granule contents and dense-body contents can be measured immunologically and biochemically; electron microscopy can establish granule defects. Specific analysis of the genes or proteins implicated in the different granule biogenesis abnormalities (Wiskott-Aldrich syndrome [*WASP*], Hermansky-Pudlak syndrome [*HPS1-9*], Chédiak-Higashi syndrome [*LYST*], Paris-Trousseau/Jacobsen syndrome [*FLII*], and inherited platelet disorder with predisposition to leukemia [*RUNX1*]) can establish the diagnosis. The Quebec platelet disorder is characterized by increased urokinase plasminogen activator (u-PA) in α -granules and degradation of several α -granule proteins. The diagnosis can be established by immunoblot analysis or analysis of u-PA activity and confirmed by genetic analysis of *u-PA*. Secretion abnormalities arise as a result of defects in mechanisms that regulate the secretion of granule contents, and may include abnormalities at various levels, including surface receptors, guanosine triphosphate (GTP)-binding proteins that link surface receptors to intracellular enzymes, phospholipase C (PLC) activation, and protein phosphorylation (protein kinase C [PKC]- θ). They also arise from defects in TXA₂ synthesis caused by deficiencies of phospholipase A₂ (PLA₂), cyclooxygenase, or thromboxane synthase. Specific studies on signal transduction mechanisms, PI metabolism, Ca²⁺ mobilization, protein phosphorylation, and thromboxane production are needed to define these defects. Because transcription factor abnormalities can affect the expression of multiple proteins involved in megakaryopoiesis and platelet function, they can simultaneously produce alterations in platelet count, structure, and function.

In the disorder of platelet coagulant activity (Scott syndrome) platelet aggregation studies are normal and the serum prothrombin time is the preferred screening assay. Other tests of platelet coagulant activity, microvesiculation, and phospholipid transfer are used to establish the diagnosis.

The introduction of microfluidic multiparameter assessments of platelet function,^{7,8} coupled with advances in proteomics, RNA expression profiling, and DNA sequencing are shifting the diagnosis of platelet function disorders from a target gene approach to one in which unbiased comprehensive functional and genetic analyses are employed. These methods have identified mutations in *RUNX1* and *FLI-1*⁹ in patients with platelet function disorders, in *NBEAL2* in GPS,¹⁰⁻¹² in *TMEM16* in the Scott syndrome,¹³ and in *RBM8A* in thrombocytopenia with absent radii (TAR) syndrome.^{14,15} Many additional genetic alterations, including ones that affect multiple systems, are likely to be identified in the near future as these techniques are employed more broadly.

● ABNORMALITIES OF ADHESION RECEPTORS

INTEGRIN $\alpha_{IIb}\beta_3$ (GLYCOPROTEIN IIB/IIIa; CD41/CD61)–GLANZMANN THROMBASTHENIA

Definition and History

GT is an inherited hemorrhagic disorder characterized by a severe reduction in, or absence of, platelet aggregation in response to multiple physiologic agonists as a result of qualitative or quantitative

abnormalities of platelet integrin α_{IIb} (GPIIb; CD41) and/or integrin β_3 (GPIIIa; CD61).¹⁶

In 1918, Eduard Glanzmann, a Swiss pediatrician, described a group of patients with hemorrhagic symptoms and a defect in platelet function, namely the ability to retract clots (“weak” platelets or thrombasthenia).¹⁷ Subsequent studies demonstrated that thrombasthenic patients have prolonged bleeding times and that their platelets fail to aggregate in response to physiologic agonists^{18–21} and have markedly reduced^{18,20–22} platelet fibrinogen. In the mid-1970s, Nurden and Caen²³ and Phillips and colleagues²⁴ discovered that thrombasthenic platelets are deficient in both integrin α_{IIb} and β_3 . Later studies demonstrated that integrin α_{IIb} and β_3 form a calcium-dependent complex in the platelet membrane that functions as a receptor for fibrinogen and other adhesive glycoproteins.^{25–28} Cloning and sequencing of the complementary DNAs for integrin α_{IIb} ²⁹ and β_3 ³⁰ identified them as separate protein subunits that are members of the integrin receptor superfamily³¹ and permitted the molecular biological characterization of patients with the disorder (see database of Glanzmann patients <http://med.mssm.edu/glanzmanndb>).

Etiology and Pathogenesis

GT is a rare disorder characterized by autosomal recessive inheritance with a worldwide distribution. In regions where consanguineous matings are common, groups of patients with the disorder have been identified, and in several populations founder mutations have been identified by analyzing polymorphisms in the DNA surrounding the affected mutation. These include 42 patients from South India; 39 patients from the Iraqi-Jewish population in Israel; 46 Arab patients from Israel,

Jordan, and Saudi Arabia; 30 patients from Italy; a smaller number of patients from three Gypsy families; and 43 patients from Pakistan.^{22,32–40} Perhaps the highest frequency of a GT mutation is found in the Iraqi-Jewish population where the most common mutation causing GT was found in six of 700 individuals.³⁹

The platelet integrin $\alpha_{IIb}\beta_3$ receptor is required for platelet aggregation induced by all physiologic agonists (ADP, epinephrine, thrombin, collagen, TXA₂) (Chap. 112).⁴¹ Consequently, abnormalities in the receptor result in a failure of platelet plug formation at sites of vascular injury, and excessive bleeding.

The integrin $\alpha_{IIb}\beta_3$ receptor is also responsible for the uptake of fibrinogen from plasma into α granules,⁴² hence, patients with GT have markedly reduced platelet fibrinogen.^{18,20,21,43,44} Clot retraction requires platelets with intact integrin $\alpha_{IIb}\beta_3$ receptors,^{45,46} and is, therefore, usually abnormal in GT.¹⁸

Defects in either integrin α_{IIb} or β_3 result in the same functional defect because both subunits are required for receptor function (Chap. 112). Biosynthetic studies indicate that integrin α_{IIb} and β_3 form a complex soon after protein synthesis in the rough endoplasmic reticulum^{47–49}; subsequent posttranslational processing⁵⁰ and transport to the platelet membrane require that the complex be intact (Fig. 120–2).^{51,52} Complex formation protects each of the glycoproteins from proteolytic digestion,^{47–50} so if either integrin α_{IIb} or β_3 is absent or unable to form a normal complex, the other subunit will be rapidly degraded, most likely through a proteasomal mechanism. Thus, a deficiency in either glycoprotein produces a deficiency in both. Because complex formation and vesicular transport are also required for proteolytic processing of pro- α_{IIb} into its constituent $\alpha_{IIb}\alpha$ and $\alpha_{IIb}\beta$ subunits,⁵⁰ if these processes do

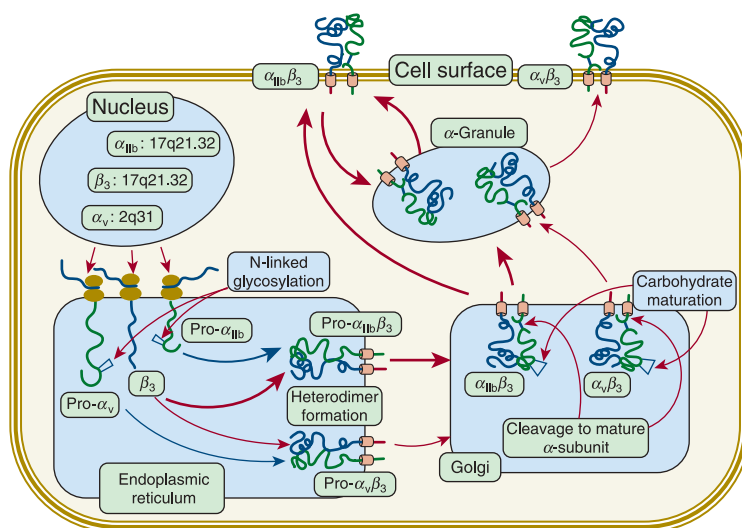

Figure 120–2. Biogenesis of integrin $\alpha_{IIb}\beta_3$ and integrin $\alpha_v\beta_3$ receptors. The nuclear genes for integrins α_{IIb} (chromosome localization 17q21.32; gene designation *ITGA2B*; 30 exons), α_v (2q31; *ITGAV*; 30 exons), and β_3 (17q21.32; *ITGB3*; 14 exons) are transcribed into messenger RNA and translated by ribosomes attached to the membranes of the endoplasmic reticulum (ER). The proteins undergo initial glycosylation and form the integrins $\alpha_{IIb}\beta_3$ and $\alpha_v\beta_3$ heterodimers in the ER. It is presumed that many more integrin $\alpha_{IIb}\beta_3$ complexes form than $\alpha_v\beta_3$ complexes because the final copy number of platelet integrin $\alpha_{IIb}\beta_3$ receptors is approximately 100,000 whereas it is only 50 to 100 for $\alpha_v\beta_3$. This is shown schematically by the differences in the width of the arrows depicting integrin $\alpha_{IIb}\beta_3$ versus $\alpha_v\beta_3$ complex formation. The heteroduplexes are transported to the Golgi where the carbohydrate chains undergo modification to their mature structures and both α_{IIb} and α_v subunits undergo proteolytic cleavage within a disulfide-bonded loop, resulting in two-chain forms of the receptor subunits. Mature integrin $\alpha_{IIb}\beta_3$ receptors are transported to α -granule membranes, where they undergo cycling to and from the plasma membrane. This process results in the internalization of fibrinogen and perhaps other plasma proteins. Integrin $\alpha_{IIb}\beta_3$ may be transported directly to the plasma membrane and is transported to α granule membranes. Of the total of approximately 100,000 integrin $\alpha_{IIb}\beta_3$ receptors, approximately two-thirds are on the surface at any given time and the remaining one-third can be brought to the surface by platelet activation. The distribution of integrin $\alpha_v\beta_3$ between the plasma membrane and α granules, and the potential cycling of the receptors between α granules and the plasma membrane have not been defined. (Used with permission from Dr. W. Beau Mitchell, New York Blood Center, New York, NY)

not occur normally, the very small amount of residual integrin α_{IIb} will be pro- α_{IIb} , not mature α_{IIb} .⁵³ Pro- α_{IIb} has been reported to bind to the membrane-bound endoplasmic reticulum chaperone calnexin, providing a potential mechanism for assessing whether the protein has undergone proper folding (calnexin cycle) and perhaps explaining how the receptor adopts a bent configuration.^{54,55}
