Although the term “autoimmunity” is reserved for inappropriate adaptive immune responses that damage tissues of the host, the innate immune system may also cause injury or death, and typically does so when systemic activation occurs in the course of a serious infection. Innate immune responses, which entail cytokine-mediated inflammation and coagulation, evolved to contain small inoculates of microorganisms by encouraging the influx of granulocytes to engulf and destroy these pathogens, and by stimulating the development of an adaptive immune response. The mechanisms that are employed to these ends can be lethal if they are generalized rather than focal. In several examples, the importance of microbes as drivers of inflammation has been cited, and forward-feedback loops may perpetuate inflammation or autoimmunity. It has been reported, for example, that endogenous DNA, signaling via TLR9, is responsible for the generation and perpetuation of antinucleoprotein antibodies in a mouse model of systemic lupus erythematosus.¹³⁴ The involvement of TLRs 3 and 7 may also be important.

In hemophagocytic lymphohistiocytosis (HLH), an amplification loop involving a microbial driver, CTL expansion, and IFN- γ driven myeloid expansion has been well described in mice.¹³⁵ In SHP1 deficiency in mice, autoimmunity and inflammation also depend upon a microbial driver and activation of TIR domain signaling pathways.¹³⁶ NOMID and other mutations capable of activating the NLRP3 inflammasome have been mentioned earlier in this chapter. Beyond this, the innate immune system may also contribute to sterile inflammation (autoinflammatory disease), as witnessed in many human diseases that have so far eluded etiologic decipherment.

CHAPTER 21

DENDRITIC CELLS AND ADAPTIVE IMMUNITY

Madhav Dhodapkar, Crystal L. Mackall, and Ralph M. Steinman*

SUMMARY

Dendritic cells are a multifunctional group of cells that serve as sentinels of the immune system and thus regulate many immune functions. Dendritic cells play a central role in initiating adaptive immune responses to pathogens and initiating antitumor immune responses. Dendritic cell receptors sense environmental stimuli and can respond rapidly to both foreign pathogens and danger signals derived from tissue damage or immune complexes. Through their capacity to present antigen to T cells in immune-activating or immune-dampening contexts, dendritic cells can both induce T-cell proliferation (activation) or lack of activation (tolerance). In this way, dendritic cells help regulate immune responses mediated by T cells and B cells of the adaptive immune system. This chapter describes the varied types and functions of this important class of cells.

FUNCTIONS OF DENDRITIC CELLS

Host defense is mediated by innate and adaptive immune responses, and dendritic cells (DCs) play essential roles in linking together innate and adaptive immunity.^{1–3} The innate immune response provides rapid resistance to pathogens, but the potency of innate responses does not increase following initial exposure. Adaptive responses, mediated by B and T lymphocytes, generate immune memory, resulting in more rapid and more potent responses following antigen reexposure (Chaps. 75 and 76).

DENDRITIC CELLS AND INNATE IMMUNITY

DCs provide innate immune resistance through production of cytokines, including interleukin (IL)-12 and type I interferons, and by activating other innate lymphocytes such as natural killer (NK) cells, NKT cells, and $\gamma\delta$ T cells (Chap. 75). Innate responses are most often initiated by “pattern recognition receptors” (Chap. 20), which respond

Acronyms and Abbreviations: CD, cluster of differentiation; CMV, cytomegalovirus; DC, dendritic cell; GM-CSF, granulocyte-macrophage colony-stimulating factor; GVHD, graft-versus-host disease; GVL, graft-versus-leukemia; Ig, immunoglobulin; IL, interleukin; M-CSF, monocyte colony-stimulating factor; MHC, major histocompatibility complex; NK, natural killer; Th, T helper; TLR, toll-like receptor; TNF, tumor necrosis factor; Tr, T regulatory.

*Deceased. Substantial portions of his contribution have been retained in the current version of this chapter.

to evolutionarily conserved molecules found in microbes, parasites and viruses.^{4,5} Pattern recognition receptors include toll-like receptors (TLRs), nucleotide-binding oligomerization domain-like receptors, retinoic acid-inducible gene 1-like receptors, and numerous C-type lectins. Pattern recognition receptors recognize a wide array of ligands, such as single- or double-stranded RNA, lipopolysaccharides, and other microbial constituents. DCs express pattern recognition receptors and respond to pattern recognition receptor agonists by becoming potent immunostimulatory cells and by presenting captured antigens to T cells in the context of major histocompatibility antigens. Pattern recognition receptors on DCs can also be activated via noninfectious stimuli induced by tissue damage and malignant cells, including uric acid crystals and heat shock and chromatin proteins. Such pathways are likely important for activating DCs toward tumor-associated antigens following transplantation or in disease states such as cancer or allergy.

Activated or matured DCs can prime resting NK cells, which then reciprocally act back on DCs, enhancing DC maturation and initiating adaptive immune responses.⁶ NK cells can also negatively regulate DC function by killing immature DCs, a feature that is important in NK mediated graft-versus-leukemia (GVL), without graft-versus-host disease (GVHD), following hematopoietic stem cell transplantation.⁷ Such immune crosstalk between NK cells and DCs, is emblematic of the exquisite interdependence and complexity of the immune response.^{8–10}

DENDRITIC CELLS AND ADAPTIVE IMMUNITY

Adaptive immunity imparts immune memory to the host, which allows a more rapid and more effective immune response to rechallenge with the same antigen. Adaptive immunity is mediated by B and T lymphocytes, but its induction is largely regulated by DCs. Immune memory increases the frequency and function of antigen-specific lymphocytes, leading to enhanced levels of protective antibodies, cytokines, and killer molecules. Through an elaborate series of gene rearrangements, hypermutation, and selection, antibody on B cells and T-cell receptors on T cells provide remarkable diversity and specificity. This array might be thought of as the largest combinatorial library of specificities in the world!

DCs function as sentinels of the immune system (Table 21–1)^{1,3,11} and provide a critical bridge between innate and adaptive immunity. Indeed, the presence of antigen and lymphocyte is rarely sufficient to induce adaptive immune responses. Rather, a third party, the DC system of antigen-presenting cells provides the pivotal immune initiation signal required to induce an adaptive immune response. DCs sense a wide range of environmental stimuli, producing cytokines, such as IL-12 and type I interferons that help stimulate immune responses. DCs express most types of TLRs, with specific subsets of DCs differentially expressing distinct TLRs; for example, plasmacytoid DCs express significant levels of TLR-7 and TLR-9.¹² DCs can also respond to endogenous stimuli, ranging from inflammatory cytokines, including tumor necrosis factor (TNF)- α , IL-1, or interferons, to byproducts of cell death or tissue damage. DCs capture microbes and tumor cells, processing their component antigens for presentation to the adaptive immune system. DC activation, via innate immune receptors, leads to DC maturation and initiation of adaptive immunity. In addition to antigen processing and presentation, sentinel DCs produce chemokines and cytokines. They migrate to lymphoid tissues, where they recruit naïve antigen-specific lymphocytes and instruct their subsequent development.

A variety of DC subsets exist and the biology of DC activation can vary significantly according to the exposure. During immunization, DCs initiate clonal expansion of T cells and can directly and indirectly influence the growth of B cells. In addition, DCs can modulate differentiation of lymphocytes, such that the properties of the lymphocytes are

TABLE 21–1. Role of Dendritic Cell in Immunity

Sensors: rapid and appropriate differentiation in response to pathogen-associated molecular patterns and other signals
Sentinels: positioned in peripheral tissues to optimize antigen capture and migrate to lymphoid tissues
Tolerance: deletion and anergy of self-reactive lymphocytes and induction of regulatory T cells
Innate resistance: activation of innate lymphocytes, including NK and NKT cells, secretion of protective cytokines
Adaptive immunity: differentiation of quiescent, naïve T cells to form effectors, establishment of memory lymphocytes, antibody responses

appropriate to the invading pathogen.¹³ For example, under the influence of DCs, T cells can preferentially produce interferon- γ (T-helper [Th] type 1 cells) to activate macrophages to resist infection by intracellular microbes; or IL-4, IL-5, and IL-13 (Th2 cells) to mobilize white cells to resist helminths; or IL-17 (Th17 cells) to mobilize phagocytes at body surfaces to resist extracellular bacteria.

An essential counterpart to adaptive immunity is adaptive tolerance, which is the silencing of cells with receptors reactive to self or harmless environmental antigens. T cells develop tolerance centrally in the thymus and peripherally in lymphoid organs.^{14,15} DCs play a role in inducing tolerance, especially with regard to T cells. DCs can silence self-reactive T cells, through either deletion or functional inactivation. DCs can also drive T cells to suppress immunity by expressing IL-10 (T regulatory [Tr]1 cells) or FOXP3.¹⁶

DENDRITIC CELL BIOLOGY

DCs are “antigen-presenting cells.” An antigen-presenting cell is *any* cell that uses its major histocompatibility complex (MHC) products (or other antigen-presenting molecules, such as the CD1 molecules that present glycolipids and lipoglycans) to bind and display (i.e., “present”) fragments of antigen to lymphocytes. DCs are more specialized or professional than other antigen-presenting cells. This is because DCs have efficient and regulated pathways for antigen uptake and processing, and DCs possess dozens of features that allow them to initiate and control immunity (Table 21–2). For example, when DCs mature in response to infection, hundreds, even thousands, of gene transcripts can be upregulated or downregulated.^{17,18}

ANTIGEN UPTAKE AND PROCESSING

DCs express a wide array of endocytic receptors, which enhance the efficiency of antigen capture, processing, and presentation. Many endocytic receptors are predicted to be C-type lectins, and in some cases their natural ligands have not been identified. DCs also express Fc γ and Fc ϵ receptors, which recognize immune complexes, as well as scavenger receptors. Recognition of pathogens by DC receptors can have two outcomes. One outcome is immune activation followed by antigen presentation and development of a productive immune response. Alternatively, pathogens may use DC receptors to evade the host immune response. For example, DC-SIGN (CD209) a lectin expressed on DCs, is used by HIV-1 and cytomegalovirus (CMV) to reach T cells and endothelial cells, respectively^{19,20}; by Dengue virus to replicate within DCs²¹; and by *Mycobacterium tuberculosis* to trigger production of the suppressive cytokine IL-10.²²

Following uptake, efficient processing of antigen yields peptides that bind to MHC class II and class I products. “Exogenous”

TABLE 21–2. Important Components of Dendritic Cell Function

Cell processes or dendrites and motility: numerous and continually probing
Antigen handling: specialized antigen uptake receptors and processing pathways for classic (MHC) and nonclassic (CD1 and others) presenting molecules, including cross-presentation onto MHC class I and CD1
MHC class II products: high and regulated expression
Migration in lymphatics to lymphoid organs and localization to T-cell areas
Environmental sensing: multiple receptors for microbial and non-microbial products and exaggerated responses to the products
Cytokine receptors, including hematopoietins (flt3L and granulocyte-macrophage colony-stimulating factor, but not monocyte colony-stimulating factor, granulocyte colony-stimulating factor)
Chemokine receptors, especially for homing to tissues (CCR6) and lymph nodes (CCR7, CCR2)
Induction of peripheral tolerance via intrinsic and extrinsic pathways
Activation of innate lymphocytes (e.g., natural killer cells)

antigens refer to molecules processed directly following uptake, whereas “endogenous” antigens are processed following biosynthesis in the antigen-presenting cell. Classic pathways of antigen presentation emphasize processing of “exogenous” antigens for presentation on MHC II–peptide complexes to CD4+ T lymphocytes, whereas “endogenous” antigens were targeted for presentation on MHC class I–peptide complexes to CD8+ T cells. However, it is now clear that there is significant overlap in these pathways such that exogenous antigens may also be presented on MHC I products to CD8+ T cells. This pathway is termed *cross-presentation* and is important for initiation of antitumor immune responses. Cross-presentation is well developed in DCs, especially those found in lymphoid tissues, and leads to either tolerance or activation of CD8+ T lymphocytes, depending upon the DC maturation stimulus.²³ For instance, products of dying cells, from transplants, tumors, foci of infection, and self-tissues are endocytosed by DCs then presented on MHC Class I to CD8+ cells.^{24,25} Importantly, cross-presentation of antigens onto MHC class I can involve the proteasome and transporters for antigenic peptides, which are used in the presentation of endogenous antigens.

DCs are a major cell type involved in cross-presentation of proteins,^{26,27} and probably of lipids.^{28,29} Cross-presentation has been documented involving nonreplicating microbes, dying cells, ligands for the DEC205 receptor, and immune complexes, including antibody-coated tumor cells. This pathway allows DCs to induce tolerance or immunity to antigens not synthesized *de novo* in these cells. Fc γ receptors, in addition to mediating presentation, can influence DC maturation, either enhancing maturation through activating forms of the receptor or preventing maturation through inhibitory forms.³⁰ Such consequences of antibody binding to DC Fc receptors, with regard to DC maturation and cross-presentation, are important features for consideration when trying to understand the use of antibodies as therapeutic agents.

Some DCs subsets also express the CD1 family of antigen-presenting molecules. For example, CD1a typically is found on epidermal Langerhans cells in skin, whereas CD1b and CD1c are expressed on dermal DCs. CD1 molecules present glycolipids, whereas microbial glycolipids are the best studied to date with regard to CD1a, CD1b, and

CD1c. CD1d molecules on DCs also efficiently present the synthetic glycolipid α -galactosylceramide.³¹ This process leads to activation of distinct lymphocytes with a restricted T-cell repertoire, the NKT cells.³² NKT cells have significant potential as effector cells because they can produce large amounts of interferon- γ and lyse tumor targets.

A newer “nonclassical” pathway for antigen presentation involves presentation of “endogenous” proteins on MHC class II.³³ This pathway involves autophagy and is also well developed in DCs.³⁴ It allows nuclear, mitochondrial and cytoplasmic proteins to be presented from digestive compartments, including as a first example, the Epstein-Barr nuclear antigen 1.³⁵

MATURATION OF DENDRITIC CELLS

Immature DCs efficiently take up antigen but do not induce immunity, defined as the production of immune effectors and the establishment of memory. For immune induction to occur, DCs require additional stimuli that lead to an intricate differentiation process called “maturation.” Maturation involves changes in endocytic and antigen processing machineries, production of chemokines and cytokines, and expression of many cell-surface molecules, including those of the B7, TNF, and Notch ligand families. DCs have an endocytic system that is tightly regulated and devoted to presentation of captured antigens, rather than clearance and scavenging.

In the case of DCs derived from marrow and monocyte precursors, DC maturation is accompanied by exquisite changes in the endocytic system with attendant consequences for antigen processing and presentation. During maturation, antigen uptake is dampened as a result of inactivation of a rho-guanosine triphosphatase termed *cdc42*.³⁶ At the same time, machinery associated with antigen processing is augmented. Lysosomal processing is activated by assembly of an active proton pump, which acidifies the lysosome so that processing of antigens and the MHC class II associated invariant chain can proceed. MHC-peptide complexes form within the endocytic system of the maturing DCs,^{37,38} then traffic in distinct nonlysosomal compartments to the cell surface. Internalization and degradation of MHC II also occurs via ubiquitination is also inhibited in mature DCs.³⁹ DC maturation also increases presentation on MHC I via, in part, the formation of an “immunoproteasome,” a combinatorial form of proteasome that increases the spectrum of peptides destined to be presented on MHC I.⁴⁰

A hallmark of DC maturation in response to several stimuli is upregulation of costimulatory molecules such as CD80 and CD86, resulting at least in part from production of inflammatory cytokines, particularly TNF- α .³² Importantly however, CD86 upregulation should not be equated directly with immune activation, which requires other DC functions, such as those triggered by CD40 ligation, including production of cytokines such as IL-12 or type I interferons, and/or engagement of other receptors such as CD70.³²

DCs enhance antibody formation by several mechanisms. The classical pathway involves induction of antigen-specific CD4+ helper T cells, which then help B-cell growth and antibody secretion. However, DCs can also directly affect B cells to enhance immunoglobulin (Ig) secretion and isotype switching, including production of the IgA class of antibodies, which contribute to mucosal immunity.^{41,42} DCs can induce a B-cell class switch in a CD40-independent manner, through production of ligands such as B-lymphocyte stimulator (B-cell activating factor belonging to the TNF family [BAFF]) and a proliferation-induced ligand (APRIL), including T-cell-independent induction of IgA antibodies to commensal organisms.⁴³ Plasmacytoid DCs stimulate antibody responses to influenza virus in culture.⁴⁴ Production of antibodies by any of these mechanisms may lead to interaction with DC Fc γ R and thereby an adaptive response by T cells.

DENDRITIC CELL SUBSETS

The primary function of DCs is to survey host tissues and initiate responses upon encountering danger signals. To optimally perform these functions, DCs are present in every tissue of the body, and are enriched in lymphoid tissues. Immature DCs are strategically positioned along body surfaces (skin, airway, gut) and in the interstitial spaces of many organs, such as the heart and kidneys. DCs are able to extend their processes through the tight junctions in epithelia, without altering the epithelial barrier, allowing them to sample antigens from harmless environmental antigens and commensal microorganisms. In the steady state, DCs migrate continuously from tissues into afferent lymphatics and probably blood. By electron microscopy, DCs in lymphoid tissues often are termed *interdigitating cells*, appearing as large stellate cells with a lucent “empty”-appearing cytoplasm.

One method of categorizing DCs is to describe them based upon the tissue in which they reside. Lymphoid tissue-resident DCs have undergone intensive study, especially in murine models. The scarcity of DCs in nonlymphoid tissues, on the other hand, limited understanding of their importance for many years and continues to render study of these cells challenging. Because circulating DCs are the most accessible subset in humans, they have received intense study; however, blood DCs may not reflect accurately the biology of tissue resident cells. Briefly, all DCs subsets are CD45+CD11c+class II+ cells that lack markers associated with T-cell, B-cell, erythroid, granulocytic, and NK lineages. However, such a definition is not complete as some macrophages express this phenotype yet are distinct from the DC lineage. Additional confidence in a DC lineage is provided by expression of Flt-3 (FMS-like tyrosine kinase 3, CD135), which mediates signals important in the differentiation of this lineage, c-kit and/or CCR7.

An alternative method for classifying DC subsets separates the major lineages as classical dendritic cells (cDCs) versus plasmacytoid dendritic cells (pDCs). cDCs are the most plentiful and incorporate lymphoid tissue-resident and nonlymphoid tissue-resident DCs. Although both pDCs and cDCs derive from a common progenitor, pDCs are distinct from cDCs in appearance (they resemble plasma cells) and they reside primarily in blood and lymphoid tissue, but are not found in nonlymphoid tissues. pDCs are important mediators of innate immunity, because of their capacity to rapidly produce high levels of interferon (IFN)- α upon encounter with pathogens that engage the TLR-7 and TLR-9 receptors, which are plentiful in this subset. cDCs are frequently further subdivided into lymphoid-resident cDCs versus nonlymphoid-resident cDCs. In mice, most lymphoid-resident cDCs are CD8 α +CD11b- whereas most nonlymphoid-resident cDCs are CD103+CD11b-. CD8 α +CD11b- lymphoid tissue-resident cDC have a similar origin, phenotype, and transcriptional profile as CD103+CD11b- nonlymphoid-resident cDC. In contrast, CD11b+ cDCs can be found in both lymphoid and nonlymphoid tissue, and this subset is notable for its ability to derive from monocytes in response to granulocyte-monocyte colony-stimulating factor (GM-CSF), monocyte colony-stimulating factor (M-CSF), and other inflammatory mediators. CD8 α + and CD8 α - cDCs show a remarkable division of labor in terms of the nature of induced host response. While CD8 α + DCs efficiently cross-prime CD8+ T-cell immunity through MHC class I antigen presentation,⁴⁵ CD8 α - DCs stimulate predominantly CD4+ T-cell response through MHC class II presentation.⁴⁶ These differences may be explained in part by the fact that CD8 α + DCs have high endosomal pH, low antigen degradation, high antigen export to cytosol, and more presynthesized stores of MHC class I molecules.^{47,48}

In humans, essentially all DCs lack lineage markers for T cells, B cells, NK cells, and erythroid and granulocytic lineages, and express CD45 and MHC class II. Human pDCs are described as

Lin-classII+CD303(BDCA2)+CD304(BDCA4)+, whereas human cDC blood subsets generally correlate with lymphoid tissue cDC subsets. Human cDCs are either CD1c(BDCA1)+ or CD141(BDCA3)+, with the CD1c+ subset being significantly more plentiful than the CD141+ subset. In humans, BDCA3+ DCs have been proposed as human equivalents of murine CD8 α + DCs, and may have superior cross-presentation capability compared to other human DC subsets.⁴⁹ However, the capacity for cross-presentation is not restricted to this subset of human DCs. The DEC205/CD205 lectin receptor is also a useful marker for DCs in human lymph nodes.⁵⁰ Nonlymphoid tissue-resident DCs in humans remain incompletely characterized, with the exception of Langerhans cells. First described more than 100 years ago, Langerhans cells are cDCs found in the epidermis, characterized by a “tennis racket” appearance by light microscopy as a result of internalized Langerin, which localizes in “Birbeck granules.”⁵¹ Langerhans cells are characterized by expression of CD1a as well as EpCAM and CD207(Langerin). Uncontrolled proliferation of Langerhans cells is responsible for the clinical disorder known as Langerhans cell histiocytosis (LCH).

Further insights into the functional diversity of DC subsets has come from discovery of distinct transcriptional factors that underlie their development and functional properties.⁵² For example, *z*-DC, was identified as a transcriptional factor regulating the development of classical DCs.^{53,54} Functional specialization of DC subsets is likely to impact the next generation of vaccines, as discussed in “Dendritic Cells in Immunotherapy” below.

One of the most important discoveries in DC biology has been identification of a clonogenic DC progenitor within the marrow that is committed to the DC lineage and unable to give rise to other cell types. Such progenitors, described as pro-DCs can generate plasmacytoid and CD8 α + and CD8 α - classical DCs, but no other cell subset.^{55,56} Subsequent work confirmed that the committed DC progenitor derives from a more primitive cell that is capable of giving rise to monocytes and macrophages.⁵⁷ Progenitors can also be identified that specifically gave rise to cDCs but not pDCs.⁵⁶ In mice, administration of Flt-3 ligand expands progeny of DC-committed progenitors. This series of discoveries dispelled the notion that DCs *in vivo* were largely derived from inflammation driven monocyte differentiation and firmly established DCs as a distinct hematopoietic lineage. Still, in states of inflammation, DCs can be induced from mature monocytes in the presence of inflammatory mediators such as GM-CSF and M-CSF.

● DENDRITIC CELLS IN IMMUNOTHERAPY

In view of their central role as antigen-presenting cells, DCs have been targeted to both boost T-cell immunity in the setting of resistance against pathogens/tumors or suppress T cells in the setting of autoimmune disease.⁵⁸ Although both are relevant to hematologic diseases, much of the current effort has been in the context of vaccination to boost T-cell immunity against tumors. Immunity to standard subcutaneously injected protein vaccines is also likely impacted by the biology of lymph node-resident and migratory DC subsets.⁵⁹ Two broad strategies have been attempted to harness the ability of DCs to boost T-cell immunity. One approach involves adoptive transfer of antigen-loaded DCs.⁶⁰ In most of these studies, DCs were generated *ex vivo* from precursors such as blood monocytes, although some of these studies also utilized more primitive progenitors, such as CD34+ hematopoietic stem cells or circulating DCs.⁶¹ One of the first studies involved the injection of idiotype-pulsed DCs against lymphoma.⁶² Most of these studies were small, and while DCs were well tolerated, they led to only modest clinical effects in terms of objective tumor regression. Although these

studies provided important fundamental insights into DC biology, such as the link between DC maturation and their immunogenicity,^{63,64} they did not exploit the biology of naturally occurring DCs and their subsets. These studies also emphasized the need to combine vaccine-based approaches with strategies to overcome suppressive elements in the tumor bed, including inhibitory immune checkpoints, and address the vaccine-induced induction of regulatory T cells.⁶⁵ Recent promising clinical results with T-cell immune checkpoint blockade such as with antibodies against PD1/PDL1 in human cancer is setting the stage for the next generation of combination therapies with vaccines.^{66,67} In addition to T cells, DCs are also being explored to activate other immune cells such as innate NKT cells. Combination of NKT-cell-targeted vaccine with low-dose lenalidomide led to synergistic immune activation and tumor regressions in early myeloma.⁶⁸

Another strategy involves targeting antigens directly to DCs *in situ*. Coupling antigens to antibodies against DEC205, an antigen-uptake receptor on DCs, leads to enhanced activation of T-cell immunity in several models.⁶⁸ Even in this setting, DC activation is essential to elicit immunity and targeting antigens to DEC205 in steady state results in the induction of tolerance.⁶⁹ Early clinical studies with targeting antigens to DEC205 combined with approaches to activate DCs demonstrate clear induction of humoral and cellular immune responses.⁷⁰ Promising but preliminary results in patients who receive T-cell checkpoint blockade following the vaccine supports the investigation of combination approaches.⁷⁰ Other emerging approaches to targeting DCs *in situ* include nanoparticles. These technologies hold promise for flexibility and personalization of the vaccine, but the nature of optimal DC subset or adjuvant/DC maturation stimulus remains to be clarified.⁷¹ It is notable that potent human vaccines, such as the yellow fever vaccine, simultaneously engage multiple DC subsets,⁷² raising the prospect that to optimize the generation of T-cell immunity a combination of DC subsets will need to be targeted *in vivo*.⁷³

A setting where the biology of DCs plays a central role in hematology is allogeneic stem cell transplantation. The immunologic activity of donor T cells in allogeneic stem cell transplantation is a critical factor for eradicating residual malignancy, a process termed GVL, but can also lead to detrimental GVHD. There is considerable evidence that the induction of GVHD is dependent on the remaining host antigen-presenting cells of which DCs are the most potent.^{74,75} The role of DCs in mediating the GVL effect is less-well understood, although a role for DCs has been implicated.⁷⁶ DC subsets, particularly pDCs, have also emerged as critical regulators of autoimmune hematologic disorders such as immune thrombocytopenia in children.⁷⁷

Consequently, targeting DCs may be of benefit in the setting of autoimmunity as well as GVHD.

CHAPTER 22

PHARMACOLOGY AND TOXICITY OF ANTINEOPLASTIC DRUGS

Benjamin Izar, Dustin Dzube, James M. Cleary, Constantine S. Mitsiades, Paul G. Richardson, Jeffrey A. Barnes, and Bruce A. Chabner

SUMMARY

The safe and effective use of anticancer drugs in the treatment of hematologic malignancies requires an in-depth knowledge of the pharmacology of these agents. In this field of medicine, the margin of safety is narrow and the potential for serious toxicity is real. At the same time, anticancer drugs cure many hematologic malignancies and provide palliation for others. The discovery and development of treatments for leukemia and lymphoma have provided a paradigm for approaches to the improved treatment of the more common solid tumors.

The intelligent use of these drugs begins with an understanding of their mechanism of action. Cytotoxic anticancer drugs inhibit the synthesis of DNA or directly attack its integrity through the formation of DNA adducts or enzyme-mediated breaks. These DNA-directed actions are recognized by repair processes and by the checkpoints that monitor DNA integrity, including most prominently p53. If DNA damage cannot be repaired, and if the DNA damage reaches thresholds for activating programmed cell death, then DNA damage is translated into tumor regression. Attention has turned to the possibility of identifying molecular targets unique to tumor cells, or dramatically

overexpressed in those cells, including molecules involved in cell signaling and cell-cycle control, but the principles of drug action and resistance to these compounds remain the same. Resistance to drug action can arise from alterations in any one of the critical steps required for drug activity; these steps include drug uptake and distribution through the bloodstream or across the blood–brain barrier; transport across the cell membrane; transformation of the parent drug to its active form within the tumor cell or in the liver; interaction of the drug with its target protein or nucleic acid; enzymatic or chemical inactivation of the agent; drug transport out of the cell; and elimination of the agent from the body through the kidneys or through metabolic transformation. The underlying mutability of tumors leads to the spontaneous generation of cells with alterations in drug uptake, transformation, inactivation, and target binding. In the presence of the selective pressure of drug, resistant tumors replace sensitive cells as the dominant tumor population. Combination chemotherapy overcomes resistance that carries specificity for single agents, but the expression of multidrug resistance genes, as well as loss of the apoptotic response, can result in resistance even to combination drug therapy.

In addition to the molecular determinants of drug action, pharmacokinetics (the disposition of drugs in humans) plays a critical role in determining drug effectiveness and toxicity. Drug regimens are designed to achieve a maximally effective concentration in plasma and tumor cells for an effective duration of exposure. Because of the potential of these agents for toxicity, it is critical for hematologists and oncologists to understand the pathways of drug clearance and to adjust dose in the presence of compromised organ function. Drugs such as methotrexate, hydroxyurea, and the newer purine antagonists (fludarabine and cladribine) are eliminated primarily by renal excretion and should not be used in full doses in patients with renal dysfunction. Similarly, hepatic dysfunction with an elevated serum bilirubin concentration should alert clinicians to decrease doses of the taxanes, vinca alkaloids, and the anthracyclines. In addition, clinicians must be alert to the potential for drug interactions, particularly the ability of drugs that induce or inhibit cytochrome metabolism to alter patterns of drug elimination.

Acronyms and Abbreviations: ABVD, Adriamycin (doxorubicin), bleomycin, vinblastine, and dacarbazine; ADCC, antibody-dependent cellular cytotoxicity; *aKG*, α -ketoglutarate; ALL, acute lymphocytic leukemia; AML, acute myelogenous leukemia; APL, acute promyelocytic leukemia; ara-C, cytarabine; ara-CTP, cytarabine triphosphate; ara-G, arabinosylguanine; ara-GTP, arabinosylguanine triphosphate; ara-U, arabinosyluracil; ATRA, all-*trans* retinoic acid; BCNU, bischloroethylnitrosourea; BCRP, breast cancer resistance protein transporter; BET, bromodomain and extraterminal; BTK, Bruton tyrosine kinase; CHF, congestive heart failure; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; COMFORT, Controlled Myelofibrosis Study with Oral JAK Inhibitor Treatment; CrCl, creatinine clearance; CYP, cytochrome P450; dCK, deoxycytidine kinase; dCTP, deoxycytidine triphosphate; DHFR, dihydrofolate reductase; DNMT, DNA methyltransferase; DTIC, dimethyltriazenoimidazole carboxamide; EPO, erythropoietin; ET, essential thrombocythemia; etoposide, VP-16; EZH2, enhancer of zest homologue 2; FBP, folate-binding protein; GM-CSF, granulocyte-macrophage colony-stimulating factor; HDAC, histone deacetylase; hENT, human equilibrative nucleoside transporter; 2HG, 2-hydroxyglutarate; Hgb, hemoglobin; HGPRT, hypoxanthine guanine phosphoribosyltransferase; IC₅₀, inhibiting growth

by concentration 50 percent; IDH, isocitrate dehydrogenase; IL, interleukin; IMiD, immunomodulatory drug; IRF4, interferon regulatory factor 4; IRIS, International Randomized Study of Interferon and ST1571; JAK, Janus-type tyrosine kinase; JMJC, Juncionji-C domain; MDR, multidrug resistance; MDS, myelodysplastic syndrome; mesna, sodium 2-mercaptoethane sulfonate; MLL, mixed-lineage leukemia; MOPP, nitrogen mustard, vincristine (Oncovin), procarbazine, and prednisone; 6-MP, 6-mercaptopurine; MPN, myeloproliferative neoplasm; MRI, magnetic resonance imaging; MRP, multidrug resistance-associated protein; MTD, maximum tolerated dose; MUGA, multigated acquisition scan; NK, natural killer; OCT1, organic cation transporter-1; PDGFR, platelet-derived growth factor receptor; PEG, monomethoxy polyethylene glycol; PMF, primary myelofibrosis; PRC2, polycomb repressive complex 2; PRPP, phosphoribosyl pyrophosphate; PV, polycythemia vera; RAR α , retinoic acid receptor- α ; REMS, risk evaluation and mitigation strategy; RNR, ribonucleotide reductase; S-AdoMet, S-adenosyl-L-methionine; S-phase, synthetic-phase; STAT, signal transducer and activator of transcription; teniposide, VM-26; 6-TG, 6-thioguanine; TKI, tyrosine kinase inhibitor; Topo II, topoisomerase II; TPMT, 5-thiopurine-methyltransferase; TPO, thrombopoietin.

Inherited genetic variations in drug-metabolizing enzymes may lead to an increased risk of drug toxicity and may alter the antitumor response. The most important of these familial syndromes affecting treatment of leukemia is the deficiency of thiopurine methyltransferase, which slows the elimination of 6-mercaptopurine (6-MP) and leads to unanticipated toxicity during maintenance chemotherapy for acute lymphocytic leukemia. Pharmacokinetic monitoring has a standard role in the use of certain therapies, particularly high-dose methotrexate, and in the evaluation of new drugs or new drug combinations. To ensure appropriate dosing, and management of toxicity, there is no substitute for therapy based on standard protocols and peer-reviewed clinical trials. Adherence to protocols ensures that the pharmacologic variables affecting drug disposition can be taken into account early in the course of treatment and that serious untoward events can be avoided while maintaining effective therapy.

The leukemias and lymphomas have been the initial testing ground for cancer chemotherapy. Because of their rapid rates of proliferation, lack of surgical treatment options, ready access to malignant cells, and availability of mouse models of leukemia, the hematologic malignancies drew the attention of early investigators interested in treating cancer with drugs. The first evidence for activity of a chemical antitumor agent came in 1942, from the experimental work and subsequent clinical trials conducted by Goodman, Gilman, and colleagues at Yale, and their observation that nitrogen mustard caused tumor regression in a patient with Hodgkin lymphoma.¹ Six years later, Sidney Farber, a pathologist at Children's Hospital in Boston, made the even more startling discovery of remission induction by aminopterin and then methotrexate in acute lymphocytic leukemia (ALL). His work ushered in the modern era of chemotherapy.² Over the next 20 years, clinical trials in these diseases established the basic principles of cyclic combination therapy and dose intensification,³ developed effective strategies for management of infectious and hemorrhagic complications, and led to the cure of these diseases with chemotherapy. High-dose chemotherapy with marrow reconstitution has further extended the cure rate in leukemias and lymphomas. As our understanding of the biologic and molecular basis for malignancy has advanced, the concept of molecularly targeted therapy achieved its first striking success with the development of imatinib mesylate for chronic myelogenous leukemia (CML).⁴ Studies of relapsing patients on imatinib provided the first clear evidence for target mutation as a mechanism of clinical drug resistance.⁵ The first effective use of a monoclonal antibody, rituximab, has extended the cure rate for patients with large cell lymphomas, and the first clear demonstration of drug-induced differentiation by all-trans retinoic acid (ATRA) has led to a remarkable improvement in the cure rate of acute promyelocytic leukemia (APL).⁶ Other unique non-cytotoxic drugs with unusual mechanisms of action, such as L-asparaginase, thalidomide, and bortezomib, have become valuable components of regimens for specific kinds of hematologic malignancies. Molecular studies of the abnormalities in pathways that control proliferation and survival lymphomas and leukemias have revealed distinct subsets of disease have identified new therapeutic targets.

BASIC PRINCIPLES OF CANCER CHEMOTHERAPY

The safe and effective use of chemotherapy in clinical practice requires a thorough understanding of the basic aspects of drug action as well as knowledge of the important clinical toxicities, pharmacokinetics, and

drug interactions of the various agents. Antineoplastic chemotherapy is a complex undertaking, with the potential for serious or fatal side effects. Patients are best served if their treatment is based on evidence from clinical trials, which define optimal doses, schedules, and drug combinations. The specific protocol chosen for treatment should be appropriate not only for the stage and histology of the tumor but should consider individual patient comorbidities, age, and susceptibility to specific potential toxicities. Thus, bleomycin is not a safe choice for a patient with serious underlying renal or lung disease, nor is doxorubicin an appropriate drug for use in a patient with a history of congestive heart failure; even in patients with normal cardiac or pulmonary function, total dose limits should be respected for these agents. Even though clinical trials define the benefits and risks of a cohort of patients of a defined age range and physiology, these results may not be easily extrapolated to patients at the extreme ends of the spectrum.

Depending on the major route of drug clearance, doses should be modified for renal or hepatic dysfunction (Table 22-1). Changes in the dose and schedule of a drug (dose-dense chemotherapy) offer potentially greater antitumor effects, but often lead to unique toxicities. With the development of techniques for marrow or blood stem cell storage and replacement of marrow after chemotherapy, potentially lethal doses of chemotherapy can be administered in an attempt to cure malignancies

TABLE 22-1. Dose Modification in Patients with Renal or Hepatic Dysfunction

Renal dysfunction (creatinine clearance <60 mL/min)

Reduce dose in proportion to reduction in creatinine clearance.

Drugs

1. Methotrexate
2. Cisplatin
3. Carboplatin
4. Bleomycin
5. Etoposide
6. Hydroxyurea
7. Deoxycoformycin
8. Fludarabine phosphate
9. Cladribine
10. Topotecan
11. imatinib
12. Dasatinib (likely, but no guidelines available)
13. Lenalidomide

Hepatic dysfunction

For bilirubin >1.5 mg/dL reduce initial dose by 50%.

For bilirubin >3.0 mg/dL reduce initial dose by 75%.

Drugs

1. Amsacrine
2. Doxorubicin
3. Daunorubicin
4. Vincristine
5. Vinblastine
6. Paclitaxel and docetaxel
7. Mitoxantrone
8. Gleevec
9. Dasatinib

refractory to standard regimens. In general, these regimens may produce organ toxicities not seen at conventional doses—including pneumonitis, cardiac failure, vascular endothelial damage, and hepatic and renal insufficiency—and are ordinarily reserved for patients of younger age and with normal baseline organ function.

The success of chemotherapy in curing hematologic malignancy is incompletely understood. Although targeted therapies exploit clear differences in biology conferred by mutations or amplification of key genes, an explanation for the differential effects of cytotoxic drugs on tumor versus normal tissues is less obvious. The greater susceptibility of malignant cells to drug toxicity, as reflected in the phenomenon of leukemia remission induction, with restoration of normal marrow function, may result from the relative resistance of normal marrow stem cells to drug injury. These stem cells exist in a nonreplicating phase of the cell cycle, where they are less susceptible to damage by DNA-directed agents, and they express genes that protect against chemical and hypoxic damage. In addition, there is growing evidence that cancer cells lack cell-cycle checkpoints that recognize DNA damage and activate repair of DNA strand breaks, base deletions, or other lesions induced by chemotherapy. This differential in repair capability may allow normal cells to repair damage and promote recovery from chemotherapy-induced injury.

COMBINATION CHEMOTHERAPY

Most leukemias and lymphomas are highly drug sensitive, but, with the exception of the curability of Burkitt lymphoma (treated with cyclophosphamide) and hairy cell leukemia (treated with cladribine), are rarely, if ever, cured with single-agent chemotherapy. Combination chemotherapy forestalls the emergence of drug-resistant cells and thus is curative in settings where individual agents are ineffective. Empiric principles have resulted from the clinical experience of the past 4 decades of combination therapy. In general, drugs selected for combination therapy should have demonstrable antineoplastic activity, or at least biologic effects, against the tumor in question. The lone exception may be targeted drugs that inhibit signal transduction or angiogenesis; antibodies such as trastuzumab or rituximab may exhibit limited antitumor activity on their own, but may significantly augment the action of cytotoxic agents.⁷ Individual agents in a combination should be chosen based on their different mechanisms of action and lack of a common mechanism of resistance such as multidrug resistance (MDR). The dose-limiting toxicities of the agents chosen should not overlap; otherwise, they could not be used together at or near full doses. The clinical use of specific combinations should be based on preclinical evidence of synergistic interaction, and single-agent activity in the disease in question. Favorable molecular or biochemical drug interactions may be dependent on specific schedules of administration. Pharmacokinetic interactions should be defined in initial trials of drug combinations so as to avoid under- or overdosing of individual agents.

Another important consideration in designing clinical protocols is dose intensity, the dose administered per unit time, which should be maintained throughout a treatment regimen. Achieving this objective may require the use of hematopoietic growth factors to hasten marrow recovery, prevent repeated episodes of febrile neutropenia, and allow ontime administration of the next treatment cycle.

Interdigitation of chemotherapy with surgery and irradiation makes it possible to take advantage of favorable cytokinetic or radiosensitizing effects of chemotherapy, but drugs may enhance radiation or surgical toxicity to normal organs, an interaction that requires careful consideration in designing a multidisciplinary regimen. Thus, 5-fluorouracil and cisplatin are potent radiosensitizers used with radiation therapy to enhance local tumor control in solid tumors.

In the treatment of lymphomas, the toxicity of radiation therapy to sensitive organs such as skin, lung, heart, and brain may be significantly increased by concurrent administration of anthracyclines, a consideration that has prompted the use of radiation therapy either before or after anthracycline antibiotics, but not concurrently. Likewise, bleomycin sensitizes the lungs to damage by high concentration of inspired O₂ during surgery. Antiangiogenic therapies, rarely used in hematologic malignancies, are associated with an increased risk of bowel perforation in patients who have recently undergone intra-abdominal surgery.

CELL KINETICS AND CANCER CHEMOTHERAPY

The cell-killing characteristics of cancer chemotherapeutic agents vary according to their mechanism of action. Many of the most effective agents in antileukemic therapy belong to the antimetabolite class, including cytarabine and methotrexate. These drugs kill cells most effectively during the DNA synthetic phase (S-phase) of the cell cycle. For these agents, a prolonged period of tumor exposure to drug is essential so as to maximize the number of cells exposed during the vulnerable period of the cell cycle. As would be predicted, the antimetabolite drugs are primarily active against rapidly dividing tumors such as acute leukemias and intermediate and high-grade lymphomas. Other anticancer drugs, such as the topoisomerase inhibitors and alkylating agents, do not require cells to be exposed during a specific phase of the cell cycle, although like the antimetabolites, these drugs are generally more effective against actively proliferating cells as compared to resting cells. Still others, most notably the nitrosoureas and busulfan, are equally toxic to dividing and nondividing cells, and at the same time, deplete marrow stem cells. In general, the toxicity of alkylating agents is determined by the total dose of drug, whereas for the cell-cycle-specific drugs (such as methotrexate and cytarabine), both drug concentration and duration of exposure determine cytotoxic effect. However, for drugs that act through alternate mechanisms, such as the taxanes, myelosuppression correlates best with the duration of exposure above a threshold plasma concentration, which is approximately 50 to 100 nM for paclitaxel and 200 nM for docetaxel.⁸

High-dose regimens achieve a number of worthwhile objectives for these agents, including an enhancement of cross-membrane transport, saturation of anabolic pathways inside the cell, and prolongation of the period of effective drug concentration. However, achieving these objectives is realized at the cost of increased toxicity to normal proliferating marrow precursor cells and may produce significant and unexpected damage to normal organs, such as hepatic venoocclusive disease (alkylating agents), cerebellar toxicity (certain alkylating agents and cytarabine [ara-C]), or pulmonary toxicity (nitrosoureas and alkylating agents). Because hematopoietic stem cells can be harvested, stored, and reinfused, dose-limiting toxicities of high-dose chemotherapy are generally those affecting nonhematologic organs.

The choice of an appropriate dose and schedule of drug administration depends on a number of factors: (1) the drug's cell-cycle dependence; (2) the often empirically derived relationship between antitumor effects, drug dose, and schedule; (3) pharmacokinetic behavior and the need to maintain a specific drug concentration for a given period of time; (4) potential interactions with other components of the treatment regimen; and (5) patient tolerance. Multiple clinical trials are required to establish safe and effective single-agent regimens and drug combinations. For molecularly targeted drugs, the aim is to maintain inhibition of the target for prolonged periods of time, keeping drug levels above a threshold for toxicity to tumor cells, but balancing these considerations against the potential for toxicity to normal tissues, such as skin, liver, and intestinal epithelium.

DRUG RESISTANCE

Inadequate treatment of a sensitive tumor tends to select for the outgrowth of drug-resistant clones of the original tumor. The reasons for emergence of drug resistance are manifold. Cancer cells often harbor basic defects in DNA repair as one of their hallmark mutations and spontaneously generate drug-resistant mutants, even in the absence of drug exposure. Thus it has been demonstrated in the specific example of imatinib treatment of CML that drug-resistant cells, carrying specific mutations in the *BCR-ABL* gene, can be identified in marrow prior to treatment and become the dominant tumor population under the selective pressure of drug treatment.⁵ A similar finding of pretreatment mutations explains drug resistance to inhibitors to the epidermal growth factor receptor in non-small-cell lung cancer.⁹ In addition, many cancer drugs, especially alkylating agents, and irradiation are mutagenic and increase the rate of generation of drug-resistant mutants, as demonstrated in the selection of mismatch repair mutants by temozolomide.¹⁰ To discourage the outgrowth of resistant cells, multiple agents with differing mechanisms of resistance should be used simultaneously, because the likelihood of there being a doubly or triply resistant cell is the product of the probabilities of the independent drug-resistant mutations occurring at the same time in a single cell. The probability of a cell division resulting in mutation at any given genetic locus is approximately 10^{-6} for any given episode of cell division in somatic cells; thus the probability of two independent mutations arising in the same cell is 10^{-12} . Mutation rates may be distinctly higher in tumor cells and may be further increased by exposure to alkylating agents and irradiation. Some mutations, such as those affecting apoptosis, may confer resistance to multiple agents of diverse mechanisms of action. Thus, the probability of encountering MDR cells is much higher in reality.

In choosing drugs for combination therapy, one must bear in mind potential mechanisms of resistance. Classical MDR occurs as a consequence of increased expression of drug efflux pumps such as the P-glycoprotein or the MDR-associated proteins (MRPs),^{11,12} and confers resistance to a broad spectrum of agents derived from natural products, including taxanes, anthracyclines, vinca alkaloids, and epipodophyllotoxins, and potentially to a number of “targeted” agents. Other mechanisms of resistance that induce amplification of a target gene, such as dihydrofolate reductase (DHFR)¹³ or *BCR-ABL* kinase,¹⁴ may be highly specific for a single drug. Table 22-2 lists the common mechanisms of resistance. Although the presence of these biochemical changes is not routinely determined in tumor biopsies prior to therapy, these mechanisms should be considered in developing new protocols and in choosing cytotoxic therapy. In relapse after targeted therapy of CML or certain non-small cell lung cancers, the choice of second-line therapies may rely on studies of tumor cell resistance, as reflected in repeat biopsies of solid tumors or cell sampling in CML.

In addition to drug-specific mechanisms of resistance, mutations that abolish recognition of DNA damage, such as the loss of components of the mismatch repair gene complex (MLH6 or MSH2)¹⁵ seem to block initiation of apoptosis by cisplatin, thiopurines, or alkylating agents. Other mutations that block the induction of apoptosis, such as loss of p53¹⁶ or overexpression of the antiapoptotic factors such as BCL-2,¹⁷ may render tumor cells insensitive to a broad array of drugs and modalities, including ionizing irradiation, alkylating agents, antimetabolites, and anthracyclines. Although the specific contribution of p53 mutation and altered apoptosis to clinical resistance is still uncertain, emerging evidence suggests that these factors are commonly associated with clinical resistance and aggressive tumor growth and may be more relevant causes of drug resistance in the clinic than are the classical drug-specific mechanisms found in experimental tumors.

The contribution of tumor stem cells to treatment resistance and disease recurrence is an intriguing, but as yet undefined, possibility. It

is clear that many tissues, including marrow, contain stem cells capable of repopulating organs, even from single cells.¹⁸ Likewise, many tumors contain stem cells, which, on careful evaluation, preserve many of the surface antigens of their normal counterpart, and display resistance to DNA damage, reactive oxygen species generated by drugs or irradiation, and readily export toxic natural products.¹⁹ It is possible, but still to be established, that these drug-resistant stem cells represent the ultimate barrier to successful cancer treatment.

CELL-CYCLE-SPECIFIC AGENTS

A number of anticancer drugs, particularly those developed during the era of cytotoxic chemotherapy, exert their antitumor effects on DNA synthesis. Cells are thus most vulnerable during periods of active DNA synthesis (S-phase), and least affected during quiescent (G_0) stages of their life cycle. Thus tumors that have a high proliferative rate, such as leukemias and aggressive lymphomas, are most vulnerable to these agents.

METHOTREXATE

Farber and associates showed that the folate antagonist aminopterin induced a complete remission in children with ALL, thereby launching the modern era of chemotherapy. Unfortunately, these remissions were short-lived, and the leukemia invariably became resistant to further treatment. Subsequently, methotrexate, a 4-amino, N-10 methyl analogue of folic acid, supplanted aminopterin because it had more predictable side effects. Methotrexate continues to be a key drug in the induction and maintenance therapy of ALL, in the intrathecal prophylaxis and treatment of CNS leukemia, in the primary treatment of CNS lymphomas, and in combination therapy of high-grade lymphomas.

Mechanisms of Action

Methotrexate enters cells through an active uptake process mediated in most tumor cells by the reduced folate transporter²⁰ and is actively effluxed from cells by the MRP class of exporters.²¹ A second uptake transporter, the membrane folate-binding protein (FBP), has lower affinity for methotrexate, but may contribute to uptake of other antifolates, such as pemetrexed. The FBP is found on many solid malignancies, and is an active target for folate analogue- and antibody-mediated drug development. A third, low pH transporter may also participate in methotrexate influx, particularly in the intestine, but its role in tumor uptake is uncertain.²² By virtue of its 4-amino substitution, methotrexate potently inhibits the enzyme DHFR, which recycles oxidized dihydrofolate to its active tetrahydrofolate state. Inhibition of DHFR leads to rapid depletion of the intracellular tetrahydrofolate coenzymes required for thymidylate and purine biosynthesis. As a result, DNA synthesis is blocked and cell replication stops. Methotrexate is retained intracellularly as a consequence of an enzymatic process that adds up to six glutamate moieties in an unusual peptide linkage to the γ -carboxyl group of the drug (Fig. 22-1). Polyglutamation is an important determinant of leukemic cell sensitivity to methotrexate. Methotrexate polyglutamates, in addition to their long persistence in cells and their potent inhibition of DHFR, have greatly increased inhibitory effects on other folate-dependent enzymes, including thymidylate synthase and enzymes that synthesize purines (Fig. 22-2). Cells that convert the drug to polyglutamates efficiently, such as leukemic myeloblasts and lymphoblasts, are more susceptible to the drug than are normal myeloid precursors, which have limited capability for polyglutamation.²³ Accumulation of polyglutamates correlates with increased cytotoxicity and treatment response in childhood lymphoblastic leukemia.²⁴ Hyperdiploid ALLs are particularly efficient in transporting methotrexate and in producing polyglutamated species, factors that may contribute to their favorable

TABLE 22–2. Mechanisms of Resistance to Anticancer Drugs

Mechanisms	Drugs Affected	Clinical Role
1. Decreased drug uptake Reduced folate transporter Nucleoside transporter	Methotrexate cytarabine	ALL AML
2. Increased drug efflux MDR transporter (P-glycoprotein) MRP transporters, breast cancer-resistant protein	Anthracyclines, vinca alkaloids, taxanes, etoposide Anthracyclines, vinca alkaloids, taxanes, etoposide	Myeloma, AML, non-Hodgkin lymphoma Breast cancer
3. Decreased drug activation in tumor Deoxycytidine kinase deletion Hypoxanthine phosphoribosyltransferase deletion Folylpolyglutamation	cytarabine, fludarabine, cladribine, clofarabine 6-Mercaptopurine Methotrexate	AML, CLL, hairy cell leukemia Uncertain Acute leukemias
4. Increased drug inactivation defect Thiopurine methyltransferase Bleomycin hydrolase Glutathione transferase	6-Mercaptopurine Bleomycin Alkylating agents	ALL Uncertain Uncertain
5. Decreased target enzyme Topoisomerase I Topoisomerase II	Camptothecins Anthracyclines, etoposide	Uncertain Uncertain
6. Increased target enzyme Dihydrofolate reductase Thymidylate synthase Adenosine deaminase	Methotrexate 5-Fluorouracil Deoxycoformycin	Acute leukemia, small cell lung cancer Solid tumors Lymphoid tumors
7. Mutated intracellular target BCR-ABL kinase Tubulin Topoisomerase I Topoisomerase II	Imatinib mesylate, dasatinib Vinca alkaloids, taxanes Camptothecins Anthracyclines, etoposide	CML Uncertain Uncertain Uncertain
8. Increase DNA repair Guanine-O-6-methyltransferase Nucleotide excision repair	Procarbazine, nitrosoureas temozolomide Platinating drugs	Brain tumors Ovarian cancer
9. Decreased DNA damage recognition p53 mutation Mismatch DNA repair mutations	Many cancer drugs, radiation Platinating agents, methylating drugs, thiopurines	Leukemias, lymphomas Colon cancer, glioblastoma, leukemias

ALL, acute lymphocytic leukemia; AML, acute myelogenous leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; MDR, multidrug resistance; MRP, multidrug resistance-associated protein. See text for references and explanation.

prognosis.²⁵ Polyglutamates are slowly degraded to their readily effluxed monoglutamate form by γ -glutamyl hydrolase, and a polymorphism (T127I) that decreases γ -glutamyl hydrolase activity is associated with enhanced polyglutamate accumulation in leukemic cells.²⁶ Acquired resistance to methotrexate in patients with leukemia is associated with several different alterations: increased levels of DHFR as a consequence of gene amplification,¹³ defective polyglutamation,²⁷ impaired drug uptake,²⁸ or increased efflux by the MRP class of transporters.²⁹

Clinical Pharmacology

Methotrexate is well absorbed when administered orally at low doses (5 to 10 mg/m²), but when doses exceed 30 mg/m², absorption is

variable. Consequently, doses greater than 25 mg/m² should be administered parenterally.

The concentration of methotrexate in plasma declines in a poly-exponential manner. A very rapid initial disposition phase persists for only a few minutes after intravenous administration. The intermediate disposition phase has a 2- to 4-hour half-life and continues for 12 to 24 hours after dosing. The terminal phase of drug decay is considerably slower, with an 8- to 10-hour half-life, and this phase becomes important in determining drug toxicity and the effectiveness of leucovorin rescue in patients treated with high-dose methotrexate. Methotrexate is primarily excreted unchanged by the kidney, while a minor fraction of the drug (7 to 30 percent) is inactivated by hepatic hydroxylation at

Figure 22-1. Structures of folate, tetrahydrofolate, and its analogue methotrexate. The vitamin is absorbed as a monoglutamate and converted intracellularly to a polyglutamate, in which form it is both physiologically active and is stored in cells. Methotrexate, the 2,4-diamino analogue of folic acid, is shown in the bottom panel and is also converted to a polyglutamate intracellularly. the 7 position. Thus, doses should be reduced in proportion to the decrease in creatinine clearance (CrCl) in patients with renal impairment (CrCl <60 mL/min), because the prolonged exposure to high blood levels may result in life-threatening hematologic and gastrointestinal toxicity.³⁰ High-dose methotrexate (>0.5 g/m²) followed by leucovorin rescue is used to treat patients with high-grade lymphoma, osteosarcoma, and ALL.

In ALL, dose adjustment of methotrexate to maintain a specific area under the concentration \times time (C \times T) curve improves treatment outcome.³¹ Patients receiving high-dose methotrexate can be rescued from drug toxicity by administering small doses of *N*-10-formyltetrahydrofolate (leucovorin), which replenishes the intracellular pool of reduced folates. Leucovorin is administered intravenously or orally in doses of 10 to 15 mg/m² at 6-hour intervals, starting 6 to 24 hours

Figure 22-2. Mechanism of methotrexate action. Sites of enzyme inhibition by methotrexate and its polyglutamates (PG). AICAR, aminoimidazole-carboxamide ribonucleotide; dUMP, deoxyuridine monophosphate; FH₂, dihydrofolate; FH₄, tetrahydrofolate; GAR, glycine amide ribonucleotide.

after the infusion of methotrexate, and continuing until plasma concentrations of the drug fall below $1 \mu\text{M}$. In patients receiving high-dose methotrexate, drug levels are routinely assayed 24 to 48 hours after dosing to determine the rate of drug elimination and the safety of discontinuing leucovorin. Both methotrexate and its hydroxylated metabolite are organic acids, which, like uric acid, are much more soluble in alkaline urine. In patients receiving such therapy, renal toxicity may result from intrarenal precipitation of the parent drug or its 7-OH metabolite, and is generally the primary cause of decreased drug clearance and overwhelming toxicity. Renal dysfunction can be prevented by alkalinizing the urine to pH 7 with intravenous sodium bicarbonate prior to and during therapy. Patients should be given intensive hydration, as well. If drug concentrations in plasma exceed $1 \mu\text{M}$ at 48 hours after high-dose therapy, leucovorin should be continued at higher doses of 50 to 100 mg/m^2 every 6 hours until methotrexate concentrations fall below $0.1 \mu\text{M}$. The higher doses of leucovorin are necessary to compete with methotrexate for transport and polyglutamation. In cases of extreme renal failure, with stable drug levels in the $10 \mu\text{M}$ range, leucovorin will not be effective. In this setting, continuous flow hemodialysis may provide a sustained reduction in drug levels.³² An alternative effective measure in this circumstance is the administration of glucarpidase, a commercially available bacterial enzyme that instantly degrades antifolates³³ and prevents further toxicity.

Adverse Effects

The dose-limiting toxicities of methotrexate are myelosuppression and gastrointestinal toxicity. Toxic doses of methotrexate can induce thrombocytopenia and/or leukopenia, although leukopenia is more common. An early indication of methotrexate toxicity to the gastrointestinal tract is oral mucositis, whereas more severe toxicity may be manifested as diarrhea and gastrointestinal bleeding. Less-common toxic effects of methotrexate are skin rash (10 percent), pneumonitis, and chemical hepatitis. Transaminase elevations are frequently seen after high-dose methotrexate but rapidly return to normal in most patients, and without sequelae, but low-dose chronic administration, as employed to treat psoriasis or rheumatoid arthritis, may lead to portal fibrosis and cirrhosis.

Methotrexate, given intrathecally in doses of 12 mg every 4 days for children older than age 3 years and for adults, is used to prevent or treat meningeal leukemia and lymphoma. Dose adjustment is required for children younger than age 3 years, and should be made according to established protocols. Because the drug distributes poorly into the ventricular system after spinal injection, patients with active meningeal leukemia are frequently treated through an indwelling ventricular reservoir. Toxicities caused by intrathecal administration of methotrexate include acute arachnoiditis with nuchal rigidity and headache, as well as more chronic CNS toxicities, such as dementia, motor deficits, seizures, and coma.³⁴ Rarely, these neurotoxicities develop hours after intrathecal drug administration, but more commonly they occur in the days or weeks after initiation of intrathecal treatment, and are most often seen in patients with active meningeal leukemia. Leucovorin is ineffective in reversing or preventing these toxicities. Patients with such signs should undergo evaluation to rule out progressive CNS tumor, and if malignancy is not found, intrathecal cytarabine should be used for further therapy.

Methotrexate and 6-mercaptopurine (6-MP) are synergistic in their inhibition of purine biosynthesis. L-Asparaginase, an inhibitor of protein synthesis, blocks cells from entering DNA synthesis and antagonizes the effects of methotrexate, when used before the antifolate. The two drugs are not used concurrently.

Nonsteroidal antiinflammatory drugs, which diminish renal blood flow, may reduce methotrexate clearance, as may nephrotoxic

antibiotics and platinum derivatives, and these or other renal toxins should be avoided in patients during high-dose methotrexate.

CYTARABINE (CYTOSINE ARABINOSIDE, ARABINOSYL CYTOSINE, ARA-C)

Ara-C is an antimetabolite analogue of cytidine, differing in the configuration at the substituent on C_2' position of the sugar, in which the C_2' -hydroxyl group is *cis*-oriented relative to the C_1' -*N*-glycosyl bond, in contrast to the *trans* configuration of the ribose nucleoside. Ara-C is a mainstay in the induction of remission in patients with acute myelogenous leukemia (AML).

High doses (1 to 3 g/m^2) of intravenous ara-C given at 12-hour intervals for 6 to 12 doses are more effective alone or in a combination with anthracyclines than conventional doses (100 to $150 \text{ mg/m}^2 \text{ q12h}$) in consolidation therapy of AML, and they confer particular benefit in patients with cytogenetic abnormalities (t[8:21], inv[16], t[9:16], and del[16]) related to the core binding factor that regulates hematopoiesis.³⁵ Other subsets of leukemia may have increased sensitivity to ara-C. ALL patients with mixed lineage leukemia (*MLL*) gene translocations have upregulation of the human equilibrative nucleoside transporter (hENT) and have a greater sensitivity to ara-C.³⁶ AML patients with *K-RAS* gene mutations seem to derive greater benefit from high-dose ara-C than do patients with wild-type *K-RAS* in their tumors.³⁷

Mechanism of Action

Ara-C is converted to the nucleoside triphosphate, cytarabine triphosphate (ara-CTP) intracellularly. The first step is catalyzed by deoxycytidine kinase (dCK); polymorphisms of the *dCK* gene may affect the rate of activation, and ultimately response.³⁸ Ara-CTP is an inhibitor of DNA polymerase and is also incorporated into DNA, where it terminates strand elongation.³⁹ If repair is unsuccessful, apoptosis is initiated. Ara-C and its mononucleotide are deaminated and inactivated by two intracellular enzymes, cytidine deaminase and deoxycytidylate deaminase, respectively.

Acquired ara-C resistance in experimental leukemias consistently results from the loss of dCK.⁴⁰ Other changes implicated in experimental tumors include decreased drug uptake because of decreased expression of the equilibrative nucleoside transporter, increased deamination, increased pool size of competitive deoxycytidine triphosphate, and inhibition of the apoptotic pathway. Some of these changes, particularly loss of dCK activity, have been reported in studies of human leukemia, but these results have not been confirmed in definitive trials.⁴¹

Clinical Pharmacology

Ara-C is administered intravenously either as a bolus injection or, more commonly, as a continuous infusion. It is not orally bioavailable because of its degradation by cytidine deaminase, which is present in the gastrointestinal epithelium and liver. Two standard schedules of administration are used: (1) rapid infusion of 100 mg/m^2 every 12 hours for 7 days; or (2) continuous infusion of 100 to 200 mg/m^2 per day for up to 7 days. Ara-C distributes rapidly throughout total-body water and is eliminated from plasma with a biologic half-life of 7 to 20 minutes. Most of the dose is excreted as arabinosyluracil (ara-U), an inactive metabolite, which is formed in plasma, the liver, granulocytes, and other tissues. Inhibition of ara-C deamination by ara-U may be responsible for the prolongation of the biologic half-life of the drug as larger doses are administered.⁴² Single-bolus injections and short infusions (30 minutes to 1 hour duration) at doses as high as 5 g/m^2 produce little myelotoxicity because of the drug's rapid clearance, whereas continuous intravenous infusion of only 1 g/m^2 over 48 hours produces severe marrow toxicity. High-dose ara-C ($3 \text{ g/m}^2 \text{ q12h}$ for 3 days on days 1, 3, and 5), is routinely used

for consolidation therapy of AML, but lower doses of 1 gm/m² or less should be used in patients older than 60 years to avoid CNS toxicity. Unlike most drugs, a relatively high concentration of ara-C is achieved in the cerebrospinal fluid after intravenous administration, and may approach 50 percent of the corresponding plasma concentration.

Ara-C is also used intrathecally to treat meningeal leukemia. Doses of 50 to 70 mg in adults are usually employed and afford cerebrospinal fluid levels of the drug near 1 mM, which decline with a half-life of 2 hours. Ara-C (50 mg given every 2 weeks) has been impregnated into a gel matrix, in a formulation called DepoCyt, for sustained release into the cerebrospinal fluid, thus avoiding the need for repeated spinal taps. Initial clinical results in spinal lymphomatous meningitis indicate that it has efficacy equal to that of methotrexate.⁴³

Adverse Effects

The dose-limiting toxicity for conventional dosing regimens of intravenous ara-C, 100 to 150 mg/m² per day for 5 to 10 days, is myelosuppression. Nausea and vomiting also occur at these doses, the severity of which increases markedly when higher doses are employed, although repeated administration of the drug results in some tolerance. The nadir of the white count and platelet count occurs at about days 7 to 10 after the last dose of drug. Cerebellar, gastrointestinal, and liver toxicity, as well as conjunctivitis have also been observed when high-dose regimens are used. Hepatotoxicity ranges from abnormalities in serum transaminase levels to frank jaundice. The severity of these effects increases as the duration of therapy is prolonged; however, toxic effects rapidly subside upon discontinuation of treatment. Pulmonary infiltrates as a result of noncardiogenic pulmonary edema, and occasionally associated with severe pulmonary dysfunction, occur in leukemic patients receiving ara-C, as do gastrointestinal ulcerations with bleeding and infrequently perforation. Ara-C treatment is also reported to predispose to *Streptococcus viridans* pneumonia.⁴⁴

In patients older than 60 years of age, and in patients with renal dysfunction, intravenous high-dose ara-C (3 g/m² every 12 hours, days 1, 3, and 5, for six doses) causes a high incidence of cerebellar toxicity, manifested as ataxia and slurred speech.⁴⁵ Confusion and dementia may supervene, leading to a fatal outcome. Cerebellar toxicity is more frequent in patients with abnormal renal function because of slowed elimination of ara-U, with consequent inhibition of ara-C deamination. Intrathecal ara-C is usually well tolerated, but neurologic side effects have been reported (seizures, alterations in mental status).

GEMCITABINE

Although primarily used for solid tumors, gemcitabine, a 2'-2'-difluoro analogue of deoxycytidine, has significant activity against Hodgkin lymphoma. Its mechanism of action is similar to ara-C, in that, as a triphosphate, it competes with deoxycytidine triphosphate for incorporation into the elongating DNA strand, where it terminates DNA synthesis. It is also self-potentiating in that at a second site of action, it inhibits ribonucleotide reductase and thereby reduces competitive pools of deoxycytidine triphosphate (dCTP). It achieves higher nucleotide levels in tumor cells than does ara-CTP, and has a longer intracellular half-life. Its clinical pharmacokinetics are determined primarily by its rapid deamination by cytidine deaminase, yielding a short plasma half-life ($t_{1/2}$) of 15 to 30 minutes. Standard schedules use 1000 mg/m² infused over 30 minutes, and produced peak drug concentrations of 20–60 μM in plasma. Longer infusion times may produce higher intracellular triphosphate concentrations, but the benefit is uncertain.⁴⁶

Resistance in solid tumors arises from low expression of hENT, increased expression of ribonucleotide reductase, and low levels of the initial activating enzyme, dCK. Gemcitabine is an extremely potent

radiosensitizer and should not be used concurrently with radiation therapy except in clinical trials.

Toxicities are acute myelosuppression, mild hepatic enzyme elevations, uncommonly a reversible pneumonitis, and with prolonged usage, a progressive hemolytic uremic syndrome with capillary leak, leading to pleural effusions, ascites, and renal failure.⁴⁷

5-AZACYTIDINE AND 5-AZA-2'-DEOXYCYTIDINE

Both 5-azacytidine and decitabine (5-aza-2'-deoxycytidine), its closely related deoxy analogue, exhibit cytotoxic activity and also induce differentiation of malignant cells at low doses. The latter action results from their incorporation into DNA and their covalent inactivation of DNA methyltransferase. The resulting inhibition of methylation of cytosine bases in DNA leads to enhanced transcription of otherwise silent genes.⁴⁸ The differentiating effects of 5-azacytidine are the basis for the induction of fetal hemoglobin synthesis in patients with sickle cell anemia and thalassemia⁵³ and its approved use in low-dose therapy of myelodysplastic syndromes (MDS). The usual doses of 5-azacytidine are 75 mg/m² subcutaneously or intravenously per day for 7 days, repeated every 28 days, whereas decitabine is used in doses of 20 mg intravenously every day for 5 days every 4 weeks. Responses become apparent in myelodysplasia after two to five courses.

5-Azacytidine and decitabine are rapidly deaminated to chemically unstable uridine metabolites that immediately degrade into inactive products. Pharmacologic activity results from phosphorylation of the parent compound by cytidine kinase (for 5-azacytidine) or dCK (for decitabine), with subsequent conversion to a triphosphate nucleotide that becomes incorporated into DNA. The primary clinical toxicities of both 5-azacytidine and decitabine⁴⁹ include reversible myelosuppression, nausea and vomiting with higher doses, hepatic dysfunction, myalgia, and fever and rash. Resistance likely results from defects in drug activation or alternative mechanisms for gene silencing, such as histone methylation or acetylation.

PURINE ANALOGUES

Purine analogues (Fig. 22-3) occupy an important role in maintenance for childhood ALL, and in the past decade newer analogues have shown remarkable activity in chronic leukemias and small cell lymphomas. With methotrexate, 6-MP is a critical component in the maintenance phase of curative therapy of childhood ALL. Other purine analogues include azathioprine, a prodrug of 6-MP and potent immunosuppressive agent; allopurinol, an inhibitor of xanthine oxidase, useful in the prevention of uric acid nephropathy; 2-chlorodeoxyadenosine, effective in the treatment of hairy cell leukemia and other lymphoid malignancies; 6-thioguanine (6-TG), an infrequently used antileukemic agent; and fludarabine phosphate (2-fluoroara-adenosine monophosphate), an effective agent for chronic lymphocytic leukemia (CLL) and follicular lymphomas, and for suppression of graft-versus-host disease in transplantation. A new purine analogue, nelarabine, is an ara-guanine prodrug, with strong activity against T-cell diseases, including lymphoblastic leukemias and lymphomas.⁵⁰ The basis for this T-cell sensitivity appears to be the resistance of arabinosylguanine (ara-G) to degradation by the catabolic enzyme, purine nucleoside phosphorylase. High levels of arabinosylguanine triphosphate (ara-GTP) accumulate in T-cell neoplasms, leading to Fas ligand-mediated apoptosis. The most recent addition, clofarabine, also an adenosine analogue, has notable activity against childhood ALL and adult AML. Deoxycoformycin, a potent inhibitor of adenosine deaminase, is also effective in the treatment of T-cell malignancies and hairy cell leukemia.

Figure 22-3. Purine analogues.

Mechanism of Action of 6-Thiopurines

Both 6-MP and 6-TG have a thiol group substituted for the 6-hydroxy group of hypoxanthine or guanine, respectively, and are converted to nucleotides by hypoxanthine guanine phosphoribosyltransferase. They block synthesis of purines. The nucleotides of both 6-MP and 6-TG are incorporated into DNA, where they become methylated and are recognized by the mismatch repair system. Attempts to correct miscoding lead to strand breaks and apoptosis.⁵¹ Cell death correlates with the extent of their incorporation into DNA. 6-MP has the added effect of inhibiting *de novo* purine synthesis through the action of its metabolite, methyl-thioinosine monophosphate.⁵²

In experimental tumor cells, resistance to 6-MP is most commonly caused by decreased activity of hypoxanthine guanine phosphoribosyltransferase (HGPRT), by increased efflux by the transporter MRP-4, and by the absence of an effective mismatch repair process. Resistance in human leukemia is poorly understood, but is linked to HGPRT deficiency. Patients differ in their rates of metabolic clearance of 6-MP and in their ability to efflux 6-thiopurines from cells. Rapid systemic clearance of the drug, as mediated by methylation of the thiol group by 5-thiopurine-methyltransferase (TPMT),⁵³ is associated with a high leukemia recurrence rate in ALL maintenance therapy. Low levels of red blood cell thiopurine nucleotides correlate with a high level of activity of TPMT (more often found in patients of African descent) and a high risk of clinical relapse in patients with ALL,⁵⁴ whereas decreased expression of TPMT, resulting from an inherited polymorphism in the number of tandem repeats in the 5' promoter region, is associated with increased drug toxicity. A commercial test for enzyme polymorphism, based on red cell enzyme activity or thioguanine nucleotide content, is available. A second polymorphism of significance involves the cellular efflux protein, MRP-4; an inactive variant is associated with high 6-TG

nucleotide concentrations in cells, and may be responsible for great sensitivity of Japanese patients to 6-thiopurines, as the variant occurs in 18 percent of the Japanese population.⁵⁵ A polymorphism affecting the inosine triphosphate pyrophosphorylase enzyme (rs41320251) responsible for degrading a thiopurine nucleotide intermediate is associated with increased methyl-mercaptopurine nucleotides and a high incidence of febrile neutropenia in children with ALL.⁵⁶

Methotrexate and 6-MP are highly synergistic, possibly because methotrexate blocks the *de novo* synthesis of purines, elevates phosphoribosyl pyrophosphate (PRPP), and enhances the activation of 6-MP. 6-MP blocks warfarin anticoagulation in some patients, leading to a requirement for higher doses of warfarin in patients receiving chronic 6-MP therapy for immunosuppression.

Clinical Pharmacology of 6-Thiopurines

Both 6-TG and 6-MP are given orally at doses of 50 to 100 mg/m² per day. Oral absorption of 6-MP is erratic, as only 16 to 50 percent of an oral dose is systemically available.⁵⁷ Food and antibiotics may decrease absorption. Both 6-MP and 6-TG are inactivated by metabolism, and have half-lives of approximately 1 to 1.5 hour in plasma. Peak plasma levels of 6-MP occur 2 hours after administration and reach 1 to 2 μM. During 6-TG treatment, 6-TG nucleotides accumulate to much higher levels in leukemic cells, as compared to 6-MP. Inactive 6-thiomethyl nucleotides are almost 30-fold higher after 6-MP, than after 6-TG.⁵⁸ 6-MP is inactivated by metabolism to 6-thiouric acid, a reaction catalyzed by xanthine oxidase. Allopurinol inhibits the metabolic inactivation of 6-MP, but not of 6-TG. Therefore, it is generally recommended that dosages of orally administered 6-MP be reduced by 75 percent in patients receiving allopurinol. 6-TG is inactivated primarily by S-methylation, followed by oxidation and desulfuration, but a second pathway,

mediated by guanase and xanthine oxidase, contributes to clearance. Dose reduction is not necessary when 6-TG and allopurinol are administered together.

Adverse Effects of 6-Thiopurines

Both 6-TG and 6-MP are myelotoxic, producing nadirs of white blood cells and platelets at 7 to 10 days after treatment.⁵⁹ Moderate nausea and vomiting may also be observed. Patients may experience mild but rapidly reversible hepatotoxicity after treatment with either compound. Cirrhosis has occurred in some children with leukemia who are receiving long-term therapy with 6-MP. TPMT, which inactivates 6-thiopurines, occurs in several polymorphic forms that fail to metabolize the analogues. Approximately one person in 10 of the white population is heterozygous for ineffective polymorphic forms of the enzyme and will have significantly greater myelosuppression, whereas one patient in 300 is homozygous for the inactive forms, accumulates high concentrations of thioguanine nucleotides in both tumor and normal cells, and is at risk for overwhelming toxicity, even with greatly reduced doses of 6-MP.⁶⁰

Other toxicities may include hypersensitivity reactions (fever, rash), interstitial pneumonitis; pancreatitis; opportunistic infection, and an increased incidence of AML in patients receiving chronic immunosuppressive treatment with 6-MP.

FLUDARABINE PHOSPHATE

Originally synthesized as a deamination-resistant analogue of adenosine, fludarabine phosphate contains two important substitutions: a fluorine attached to the purine ring, which renders the drug resistant to deamination, and an arabinose sugar in place of deoxyribose, which leads to its pharmacologic activity as an inhibitor of DNA synthesis and ribonucleotide reductase. It has outstanding activity in CLL.⁶¹ It is strongly immunosuppressive, like the other purine analogues, and is frequently used for this purpose in nonmyeloablative allogeneic marrow transplantation⁶² and in the treatment of autoimmune diseases.

Activation of fludarabine phosphate requires removal of the phosphate group in plasma to allow cellular uptake by nucleoside transporters, and then intracellular rephosphorylation. Fludarabine is activated to the monophosphate level by dCK. The triphosphate inhibits DNA polymerase and becomes incorporated into both DNA and RNA.⁶³ Its mechanism of cytotoxicity results from DNA chain termination and induction of apoptosis, although it also inhibits ribonucleotide reductase (RNR), a self-potentiating activity that decreases intracellular deoxyadenosine triphosphate (dATP) and increases fludarabine incorporation into DNA.⁶⁴ Its triphosphate has a long intracellular half-life of 15 hours in CLL cells. Resistance has been ascribed to decreased active uptake, a deficiency of dCK, increased efflux, or increased RNR.

The drug is available in the United States as an intravenous preparation, and for oral use. It has 60 to 80 percent bioavailability. Because it is resistant to adenosine deaminase, fludarabine is eliminated primarily by renal excretion (60 percent), with a terminal half-life of 10 hours. For patients treated with fludarabine, the standard intravenous dose is 25 mg/m² daily for 5 days, whereas the approved oral dose is 40 mg/m² daily for 5 days. In patients with renal impairment, a 20 percent dose reduction for a CrCl of 17 to 40 mL/min/m², and a 40 percent dose reduction for a CrCl less than 17 mL/min/m² yields an area under the curve approximately equal to that seen in patients with normal renal function receiving full doses of fludarabine.^{65,66}

When administered at these doses, fludarabine causes only moderate myelosuppression. In CLL patients, its antileukemic effect will lead to a progressive improvement in marrow function over a period of two to three cycles of treatment, with a median time to disease progression of 31 months. However, the drug also exerts cytotoxic effects against both

B and T lymphocytes, lowering CD4 T-cell counts to 150 to 200 cells/ μ L and predisposing patients to opportunistic infections. In patients with a large tumor burden, rapid tumor lysis may rarely lead to hyperuricemia, renal failure, and hypocalcemia (tumor lysis syndrome).⁶⁷ Thus, patients should be well hydrated and their urine alkalinized prior to beginning therapy. The primary acute toxicity is reversible myelosuppression. Peripheral sensory and motor neuropathy may occur during standard-dose therapy; autoimmune phenomena, including prolonged hypothyroidism, neutropenia and hemolytic anemia with both warm and cold antibodies, have been reported.⁶⁸ Approximately 10 percent of CLL patients receiving fludarabine may develop a hypersensitivity syndrome of pulmonary infiltrates, hypoxemia, and fever, responsive to glucocorticoids.⁶⁹ Myelodysplasia and acute leukemias, with chromosome 7p deletions, have been reported as infrequent late complications.⁷⁰

CLADRIBINE (2-CHLORODEOXYADENOSINE, 2-CDA)

The extreme sensitivity of normal and malignant lymphocytes to deamination-resistant purine analogues is further exemplified by the potent activity of cladribine in hairy cell leukemia, CLL, and low-grade lymphomas.⁷¹ A single course of cladribine, typically 0.09 mg/kg per day for 7 days by continuous intravenous infusion, induces complete response in 80 percent of patients with hairy cell leukemia. Administration by subcutaneous injection or by 2-hour intravenous infusion daily for 5 days to the same total dose achieves similar results. The drug has much the same intracellular fate as fludarabine, undergoing phosphorylation by dCK and further conversion to a triphosphate that becomes incorporated into DNA. The triphosphate of cladribine has a long intracellular half-life of 9.7 hours in CLL cells isolated from patients treated with the drug.⁷² The triphosphate has multiple metabolic effects, disrupting oxidative phosphorylation in mitochondria, inhibiting RNR and depleting nicotinamide adenine dinucleotide levels in tumor cells. All of these actions may explain the drug's toxicity to slowly dividing lymphoid malignancies such as hairy cell leukemia and CLL. The actual mechanisms by which cladribine induces DNA strand breaks are not completely understood. However, similar to fludarabine, it inhibits DNA chain extension and daughter strand synthesis.⁷³ Furthermore, the drug's inhibition of RNR lowers levels of the competitive dATP. The cumulative effects of cladribine induce apoptosis (programmed cell death).

Cladribine is eliminated primarily (>50 percent) by renal excretion, with a terminal plasma half-life of 7 hours. In a patient with renal failure, continuous flow hemodialysis effectively cleared the drug and prevented serious myelosuppression.⁷⁴ Cladribine retains effectiveness in at least a fraction of hairy cell leukemia patients resistant to deoxycoformycin or fludarabine, although clinical experience with sequential use of these drugs is limited. Toxicities of cladribine include transient myelosuppression, fever, tumor lysis syndrome, and occasional opportunistic infections possibly related to immunosuppression. The development of cumulative thrombocytopenia during treatment with repeated courses of the drug may limit its use. Resistance develops in experimental tumors through decreased uptake, loss of the activating enzyme dCK, increased RNR activity, increased efflux,⁷⁵ or by induction of 5'-nucleotidase activity.

CLOFARABINE (2-CHLORO-2'-FLUORO-ARABINOSYLDENINE)

This analogue has halogen substitutions on both the purine ring and arabinose sugar, resulting in a ready uptake and activation, to a highly stable intracellular triphosphate (half-life of 24 hours), which terminates DNA synthesis, inhibits RNR, and induces apoptosis. The usual

adult dose is 52 mg/m² given as a 2-hour infusion daily for 5 days. Clofarabine has a plasma half-life of 6.5 hours. The primary route of clearance is through renal excretion, and dose adjustment according to CrCl is recommended for patients with abnormal renal function.

Toxicities are myelosuppression; uncommonly, fever, hypotension, and pulmonary edema, suggestive of capillary leak caused by cytokine release; hepatic transaminitis; hypokalemia; and hypophosphatemia. As a single agent, the drug is well tolerated as second-line treatment for AML patients with remission rates of 30 percent.⁷⁶

NELARABINE (6-METHOXY-ARABINOSYLGUANINE)

A guanine nucleoside analogue, nelarabine has useful activity as a secondary agent for T-cell lymphoblastic lymphoma and acute T-cell leukemias. Its mode of action is similar to the other purine analogues, in that it becomes incorporated into DNA and terminates DNA synthesis. Its selective action for T cells may relate to the ability of T cells to activate purine nucleosides and the lack of susceptibility of this drug to purine nucleoside phosphorylase, a degradative reaction.

Usual doses are an intravenous 2-hour infusion of 1500 mg/m² for adults on days 1, 3, and 5, and a lower dose of 650 mg/m² per day for 5 days for children. The drug is rapidly demethylated by adenosine deaminase after administration, yielding the ara-G, which is cleared by hydrolysis and has a longer plasma half-life of 3 hours. ara-G is converted intracellularly to its triphosphate⁷⁷ which becomes incorporated into DNA. The primary toxicities are myelosuppression and abnormal liver function tests, but the drug may cause a spectrum of neurologic abnormalities, including seizures, delirium, somnolence, and the Guillain-Barré syndrome of ascending paralysis.

PENTOSTATIN (2'-DEOXYCOFORMYCIN)

Pentostatin contains a unique seven-carbon primary ring system that closely resembles the transition-state intermediate of the adenosine deaminase reaction. As such, pentostatin is a potent inhibitor of the enzyme, leading to accumulation of intracellular adenosine and deoxyadenosine nucleotides. In addition, the triphosphate of pentostatin is incorporated into DNA. The imbalance in purine nucleotide pools produced by pentostatin probably accounts for its cytotoxicity.

Although initial trials of pentostatin demonstrated striking renal and neurologic toxicities at doses of 10 mg/m² intravenously per day or greater, lower doses (4 mg/m² biweekly) are extremely effective in inducing pathologically confirmed complete responses in hairy cell leukemia. At this lower dose, severe depletion of normal T cells occurs and may predispose to opportunistic infection.⁷⁸ The optimal dose may be lower than 4 mg/m² biweekly. The drug is eliminated entirely by renal excretion, necessitating proportional dose reduction in patients with reduced CrCl.

RIBONUCLEOTIDE REDUCTASE INHIBITOR: HYDROXYUREA

Hydroxyurea inhibits RNR, the enzyme that converts ribonucleotide diphosphates to deoxyribonucleotides. It chelates iron, an essential cofactor in the RNR reaction. In malignant disease, hydroxyurea is most commonly used for treating polycythemia vera, essential thrombocytopenia, and the chronic phase of CML and to lower the myeloblast count in patients presenting with AML or blastic crisis of CML. It has also become the standard agent for preventing painful crisis and reducing hospitalization in patients with sickle cell disease and in thalassemia patients with hemoglobin (Hgb) C/SS. Its antisickling activity results

from induction of Hgb F through its activation of a specific promoter for the γ -globin gene. It may also exert antisickling activity and decrease occlusion of small vessels through its generation of nitric oxide, a vasodilator, and through decreased expression of adhesion molecules such as L-selectin, on neutrophils.⁷⁹ Resistance occurs in experimental tumors as a consequence of amplification of the catalytic subunit of RNR or through mutations in RNR that lower affinity for the enzyme.

Clinical Pharmacology

Hydroxyurea is well absorbed orally, even when large doses such as 50 to 75 mg/kg orally are given for rapid lowering of the white blood cell count. In chronic therapy of myeloproliferative neoplasm, starting doses of 15 mg/kg orally are adjusted upward or downward based on neutrophil counts. In managing patients with sickle cell disease, neutrophils should be maintained above 2000 per mL.⁸⁰ Hydroxyurea may also be given intravenously to rapidly lower the white blood cell count in patients with extreme leukemic leukocytosis or thrombocytosis. Peak plasma levels following oral administration are achieved at about 1 hour and decline with a half-life of 3 to 4 hours thereafter. Renal excretion is the major route of drug elimination, and doses should be decreased in proportion to the deficit in CrCl.

Adverse Effects

The major toxicities of hydroxyurea are leukopenia and the induction of megaloblastic changes. Nausea, drug fever, pneumonitis, maculopapular skin rash, and painful leg ulcers have been observed with this drug, although it is generally well tolerated. Hydroxyurea, like ara-C, is an S-phase-specific agent. Accordingly, single large doses cause little toxicity other than myelosuppression. The nadir of the leukocyte count occurs 3 to 5 days after a single dose of drug, and the leukocyte count recovers rapidly. It is a potent teratogen and should not be used in women of childbearing age. Its potential to cause leukemic transformation is uncertain, but small cases series suggest this may occur in patients with a myeloproliferative neoplasm.⁸¹

ANTITUBULINS

VINCA ALKALOIDS

Vinblastine and vincristine are commonly used in the treatment of hematologic neoplasms: vinblastine because of its excellent activity in the treatment of Hodgkin lymphoma and vincristine in lymphomas and childhood leukemia. Both drugs have activity in solid-tumor therapy, particularly in treating childhood sarcomas (vincristine), and testicular cancer (vinblastine).

Mechanism of Action

The vinca alkaloids exert their cytotoxic action by their binding to tubulin, a structural protein found in the cytoplasm of cells. Microtubules, assembled through polymerization of tubulin dimers, form the spindle along which the chromosomes migrate during mitosis. Microtubules are an important structural component of neuronal axons. Binding of the vinca alkaloids to tubulin leads to inhibition of formation of the mitotic spindle,⁸² arresting cells in metaphase and inducing apoptosis. Resistance to the vinca alkaloids may be acquired through the expression of the MDR efflux pump. Alternatively, resistant cells may contain mutant tubulin with decreased avidity of vinca binding.⁸³ The clinical importance of these resistance mechanisms, however, is uncertain.

Clinical Pharmacology

Vincristine and vinblastine are both administered by the intravenous route. The average single dose of vincristine is 1.4 mg/m² and that of

vinblastine 8 to 9 mg/m². Sequential doses of the drugs are usually given at 1- or 2-week intervals. These doses provide peak plasma drug concentrations of approximately 1 μM. The plasma pharmacokinetics of both vinca analogues are characterized by a very rapid initial disposition phase followed by a slow terminal phase of decay, with half-lives of 20 to 85 hours. Almost 70 percent of a dose of vincristine is metabolized by the liver and excreted in the feces. Cytochrome P450 (CYP)-mediated metabolism is also the major route of inactivation of vinblastine, producing a variety of inactive metabolites produced in the liver are excreted in the bile. Inducers of CYP3A4, such as phenylhydantoin, enhance clearance, while inhibitors delay clearance and increase toxicity. The dose of vincristine or vinblastine should be reduced in patients with hepatic impairment. Although specific guidelines for dose reduction have not been developed, a 50 percent decrease in dose is recommended for patients presenting with a bilirubin level of 1.5 to 3 mg/dL and a 75 percent reduction for levels greater than 3 mg/dL. Dose reduction is not necessary for patients with impaired renal function, as very little intact drug is excreted in urine.

Adverse Effects

The dose-limiting side effect of vincristine is neurotoxicity, which usually occurs when the total dose received exceeds 6 mg/m². The initial signs of neurotoxicity are paresthesia of the fingers and lower extremities and loss of deep tendon reflexes. Continued administration may lead to profound loss of motor strength, such as weakness of dorsiflexion of the foot and extension of the wrists. Elderly patients are particularly susceptible to such toxicities. Occasionally, cranial nerve palsies may lead to vocal cord paralysis or diplopia, and severe jaw pain may result from vincristine administration. At high doses of vincristine (>3 mg total single dose), autonomic neuropathy may cause obstipation and paralytic ileus. Sensory changes and reflex abnormalities slowly improve when the drug is discontinued; motor impairment improves less rapidly and may be irreversible. Inappropriate antidiuretic hormone release resulting in symptomatic dilutional hyponatremia has been ascribed to vincristine.

While marrow suppression is not common with vincristine administration, myelosuppression may be noted in patients with impaired marrow function as a consequence of prior treatment with other drugs. Platelet counts are relatively unaffected.

The primary toxicity of vinblastine is leukopenia. The white count reaches a nadir at day 7 and reverses rapidly thereafter. Mucositis may result from higher doses (>8 mg/m²) of vinblastine or when it is used in combination with other cytotoxic drugs. Neurotoxicity is rare, but ileus can occur at high doses.

Both drugs cause severe pain and local toxicity if extravasated. Neither drug should ever be given intrathecally. Vincristine administered inadvertently into the cerebrospinal fluid causes acute neurologic dysfunction, coma, and death. Attempts at replacement of the cerebral spinal fluid with an electrolyte solution, Ringer lactate, supplemented with 15 ml/L of fresh-frozen plasma, have been reported to avert a fatal outcome, but do not prevent severe neurologic sequelae.⁸⁴

TAXANES

The taxanes, paclitaxel, docetaxel, and Abraxane, are a second class of antimetabolic compounds that differ in mechanism and toxicity profile from the vinca alkaloids that are primarily used in patients with solid tumors. Paclitaxel was purified from an extract of the bark of *Taxus brevifolia*, whereas docetaxel is a closely related semisynthetic derivative. Abraxane is paclitaxel embedded in an albumin microparticle. The taxanes bind to the β-tubulin subunit of microtubules and promote the polymerization of microtubules, leading to disordered mitotic spindle

formation and a block in the progression through mitosis.⁸⁵ They induce apoptosis in tumor cells irrespective of the p53 status of the cells and kill cells at 10 nM concentrations or less in cell culture in a time-dependent manner.⁸⁶ In experimental settings, resistance is related to increased drug efflux, mutations in β-tubulin, or increased expression of anti-apoptotic proteins such as survivin,⁸⁷ or of the mitosis-related aurora kinase.⁸⁸

The taxanes are subject to MDR mediated by the *mdr* and *mrp* genes, as well as to β-tubulin mutations. Because they are highly insoluble in aqueous solution, paclitaxel and docetaxel are formulated in lipid-based solvents that cause occasional hypersensitivity reactions. Thus, paclitaxel is given after pretreatment with antihistamines (cimetidine, diphenhydramine), and dexamethasone. Both drugs are cleared primarily by hepatic CYP metabolism, although by different isoenzymes (paclitaxel predominantly by CYP2B6 and docetaxel by CYP3A4) with terminal plasma half-lives of 10 to 13 hours. Their metabolism is stimulated by phenytoin and other CYP-inducing drugs and inhibited by ketoconazole. Their major toxicities, aside from hypersensitivity, are a sharp but brief leukopenia, milder thrombocytopenia, and mucositis. High-dose or repeated cycles of the taxanes cause a sensory and motor peripheral neuropathy that is reversible with drug discontinuation. Occasional patients have experienced atrial conduction block or atrial or ventricular arrhythmias after paclitaxel administration, and the combination of paclitaxel with doxorubicin may produce a greater incidence of congestive heart failure than seen with doxorubicin alone.⁸⁹ A syndrome of progressive fluid retention and peripheral edema occurs in patients receiving multiple cycles of docetaxel and can be at least partially prevented by pretreatment with glucocorticoids.⁹⁰

The taxanes have not found a valuable role in the treatment of hematologic malignancy. However, a number of analogues and new formulations are under development. Abraxane, consisting of paclitaxel bound to albumen microparticles, does not require a lipid solvent, is virtually free of hypersensitivity as a side effect, and enters cells by a separate albumen-mediated transporter. It is approved for treatment of relapsed breast cancer and pancreatic cancer. Cabazitaxel, approved for prostate cancer, is a new analogue with decreased susceptibility to MDR. An entirely new class of natural products, the epothilones, have a similar mechanism of action, are less susceptible to MDR, and have activity against breast cancer.⁹¹

● TOPOISOMERASE INHIBITORS

CAMPTOTHECINS

This group of compounds includes synthetic derivatives of 20 (S)-camptothecin, a naturally product from the *Camptotheca acuminata* tree. The camptothecins interact with a unique target, topoisomerase I, stabilizing the enzyme's complex with DNA and preventing the resealing of DNA single-strand breaks induced by the enzyme. Resistance arises through mutation, deletion, or decreased expression of the topoisomerase I gene. The primary agents in clinical use are irinotecan, which is approved for treatment of colon cancer, and topotecan, approved for second-line treatment of ovarian cancer and small cell lung cancer. Irinotecan, most commonly administered intravenously at a dose of 125 mg/m² once each week for 4 weeks every 42 days, has shown promise against lymphomas in phase II trials performed in Japan.⁹² Response rates of 42 percent in previously treated patients with non-Hodgkin lymphoma, and of 38 percent in patients with refractory or relapsed adult T-cell leukemia-lymphoma, remain to be confirmed. Topotecan has remission-inducing activity in patients with myelodysplasia and chronic myelomonocytic leukemia, both as a single agent (1.5 mg/m² per day for 5 days) and in combination with ara-C.^{93,94} Objective responses have

also been observed in phase I clinical trials in patients with AML.⁹⁵ Irinotecan and topotecan differ substantially in their profile of toxicities and pharmacokinetic behavior. Irinotecan is a water-soluble prodrug that is converted to the active species, SN-38, by carboxyl esterase-mediated cleavage. Irinotecan and SN-38 are both eliminated by glucuronidation and biliary excretion. Therefore, irinotecan must be used with caution and at lower doses in patients with Gilbert disease (and lacking glucuronyl transferase 1A1) or in those with hepatic dysfunction.⁹⁶ In contrast to the hepatic extraction and excretion of irinotecan, approximately two-thirds of the dose of topotecan is eliminated by renal excretion, with the remainder being cleared by biliary excretion. Dose adjustment proportional to CrCl is indicated in patients with renal failure.⁹⁷ Topotecan toxicity consists mainly of myelosuppression and, to a lesser degree, mucositis, whereas irinotecan causes a profound diarrhea, which is responsive to loperamide, and a more modest myelosuppression. The maximum tolerated dose of topotecan for the 5-day schedule of 30-minute intravenous infusions/day is 4.5 mg/m² per day in patients with leukemia.⁹⁸ This is considerably greater than the approved dose for solid tumors, and gastrointestinal side effects, such as mucositis and diarrhea, become dose-limiting at these higher doses.

ANTHRACYCLINE ANTIBIOTICS

The anthracyclines are a unique class of natural products that inhibit topoisomerase II (Topo II), an enzyme important in DNA strand passage allowing the untangling of DNA prior to replication or repair. Doxorubicin, daunorubicin, idarubicin, and epirubicin are closely related in structure, each possessing a rigid planar core to which is linked a daunosamine sugar. The molecules differ in side-chain substitutions attached to the anthracycline ring system, and exhibit different spectra of antitumor activity and toxicity. Mitoxantrone, a closely related, nonglycosidic anthracenedione, has very similar pharmacologic properties to those of the anthracyclines. The anthracyclines are produced by a *Streptomyces* species, whereas mitoxantrone is a synthetic compound. Doxorubicin (Adriamycin) has broad activity against solid and hematologic malignancies. It is an important component of the standard multidrug regimens used to treat Hodgkin lymphoma (doxorubicin, bleomycin, vinblastine, and dacarbazine [ABVD]) and aggressive non-Hodgkin lymphoma (cyclophosphamide, doxorubicin, vincristine, and prednisone). Daunorubicin and idarubicin are used almost exclusively in combination with ara-C for the treatment of AML, whereas epirubicin is primarily effective against solid tumors. Mitoxantrone is employed for the treatment of AML and breast cancer, and as an immunosuppressive for patients with multiple sclerosis. Liposome-encapsulated doxorubicin (Doxil) and daunorubicin derivatives are approved for treatment of solid tumors; they provide a more prolonged, lower peak concentration of drug, and have decreased cardiac toxicity. The daunorubicin liposome is of interest in treating AML.⁹⁹ A novel anthracycline, pixantrone, which has lesser cardiotoxicity, has received conditional approval in Europe for refractory non-Hodgkin B-cell lymphoma.¹⁰⁰

Mechanism of Action

Anthracyclines target the replication and structural integrity of DNA. Their primary mechanism of toxicity stems from their interaction with Topo II, an enzyme that creates DNA strand breaks and promotes strand passage through those breaks. Strand passage is essential in untangling DNA in preparation for replication and repair. Once the strand passage and unwinding is complete, Topo II reseals the broken DNA strands. The anthracyclines inhibit the resealing step by forming a complex with Topo II and the broken DNA strand to which the enzyme is linked. Accumulation of strand breaks activates apoptosis. The planar molecular structure of these drugs promotes their intercalation between

opposing strands of the DNA helix and may contribute to the specificity of sites of DNA breakage. In addition to their inhibition of Topo II, anthracyclines generate free radicals by virtue of the oxidation-reduction cycling of their quinone group, an action catalyzed by the binding of Fe²⁺. Free radical generation is thought to be responsible for their cardiac toxicity.

The importance of the presence of Topo II in determining response to anthracyclines is best illustrated by the greater benefit of anthracycline-based breast cancer treatment in patients with amplification of the target enzyme on chromosome 17, near the *HER2* gene with which it coamplifies.¹⁰¹ Anthracycline-containing regimens are particularly effective in *HER2*-amplified breast cancers.¹⁰²

Anthracyclines enter cells through a passive transport process. Their lipophilic structure allows them to achieve high intracellular concentrations. Anthracyclines are pumped out of the cell by a series of ATP-dependent transporters, including the P-glycoprotein MDR transporter, the breast cancer resistance protein transporter (BCRP) and related efflux pumps.¹¹ Other mechanisms for anthracycline resistance include decreased Topo II activity or Topo II mutations in the enzyme that inhibit drug binding, as well as defects in apoptosis or impaired checkpoint recognition of DNA strand breaks.

Clinical Pharmacology

Daunorubicin and idarubicin are readily converted to active hydroxyl metabolites, whereas doxorubicin produces limited amounts of alcohol metabolite. The alcohols of daunorubicin and doxorubicin are less active as antitumor agents, but do possess cardiotoxic activity.

All anthracyclines are eliminated by the formation of inactive metabolic products (aglycons, side-chain-modified products, glucuronides, sulphates, and oxidative metabolite) in the liver. Only a minor fraction of the dose of any of the anthracyclines is excreted in the urine as the parent drug or alcohol metabolite. The pharmacokinetics of the clinically useful anthracyclines are predominantly influenced by their terminal disposition phase, which exceeds 24 hours. Although prolongation of the half-life of doxorubicin has been reported in studies of patients with compromised liver function, no clear correlations of liver function with toxicity have been established. However, in patients with elevated serum bilirubin levels, initial doses of doxorubicin and daunorubicin should be reduced by 50 percent, and adjust there after according to tolerance. Idarubicin, the only anthracycline amenable to oral administration, has a bioavailability of 20 percent for the parent drug and 40 percent for parent drug plus idarubicinol, the primary active metabolite. Idarubicinol has a very prolonged biologic half-life, ranging from 50 to 60 hours, and is likely responsible for the antitumor activity of this drug. In contrast to the metabolites of doxorubicin and daunorubicin, idarubicinol is eliminated primarily by renal excretion. No dose adjustment for hepatic dysfunction is indicated.

Mitoxantrone has a long terminal half-life of 23 to 42 hours. Only a minor fraction of unchanged drug is excreted in the urine (<10 percent) or stool (<20 percent). The majority of the drug is metabolized or bound to tissues. Patients with impaired hepatic function may have a more prolonged elimination of mitoxantrone.

The usual dose of doxorubicin when administered as a single agent by bolus intravenous injection is 45 to 75 mg/m² every 3 to 4 weeks, depending on the tumor treated and the drug combination. Less cardiac toxicity may result from schedules that avoid high peak plasma concentrations, such as weekly doses (15 to 25 mg/m²) or continuous intravenous infusion over 48 to 96 hours, as in the EPOCH (etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin) regimen.¹⁰³ When given in combination with other myelotoxic agents such as cyclophosphamide, the dose of doxorubicin is usually decreased because of overlapping marrow toxicity. Daunorubicin has been used as

the anthracycline of choice in the treatment of AML. To minimize the cardiotoxic effects of daunorubicin, in standard “3+7” therapy in AML the daunorubicin dosage (45 to 60 mg/m² for adults <60 years) is given daily for 3 days to avoid high peak concentrations, although larger doses (90 mg/m²/day), may produce higher complete remission rates. In the elderly, a lower dose of 30 mg/m² daily for 3 days is typically used in combination therapy.

Adverse Effects

Myelosuppression is the primary acute toxicity of this class of drugs, with a nadir occurring 7 to 10 days after single-dose administration and recovery by 2 weeks. Mitoxantrone produces less nausea and vomiting than does either daunorubicin or doxorubicin. Doxorubicin may cause mucositis, especially when used in maximally tolerated divided doses given over 2 to 3 days or when used in combination with other drugs that cause mucositis. Anthracyclines can also cause radiation recall in previously irradiated tissues, especially when the drug is administered just prior to or in the weeks following irradiation. Alopecia often occurs. Extravasation of these drugs can result in tissue necrosis so they should be administered through an indwelling central venous catheter. Dexrazoxane injected subcutaneously, lessens tissue damage after extravasation.¹⁰⁴ Patients receiving doxorubicin should also be warned that their urine may turn red.

Cardiotoxicity is the major late toxic effect of anthracyclines.¹⁰⁵ Cardiotoxicity most likely results from free radical formation catalyzed by the anthracycline's quinone moiety, although cardiac Topo IIb (not the major topoisomerase involved in DNA replication) may play a role in mediating this effect. Iron as a reduction-oxidation (redox) cofactor contributes to toxicity, as it accumulates in mitochondria during treatment.¹⁰⁶ Cardiac proteins, including the cardiac myosin-binding protein C, show evidence of alkylation and degradation after anthracycline treatment.¹⁰⁷

Clinically, anthracycline-induced cardiotoxicity presents after repeated cycles of treatment. Rarely, acute effects are manifest as arrhythmias, conduction abnormalities, or a “pericarditis–myocarditis syndrome.” The more common long-term consequence is congestive heart failure (CHF), which can develop during or several months after treatment. Studies in breast cancer have demonstrated a 0.5 to 1 percent risk of cardiomyopathy in patients treated with adjuvant anthracyclines.¹⁰⁸ The risk is higher in patients receiving trastuzumab or paclitaxel in combination with doxorubicin.

The risk of anthracycline-induced cardiotoxicity increases with total dose, but is difficult to estimate for any individual patient. In patients with normal cardiac function prior to treatment, the subsequent rate of doxorubicin-induced CHF reaches less than 1 percent at total doses of 400 mg/m², but climbs steeply thereafter to 7 to 20 percent at total doses of 550 mg/m².¹⁰⁹ The threshold for cardiotoxicity varies among the different anthracyclines. For example, the inflection threshold for daunorubicin (600 to 700 mg/m²) is significantly higher than for doxorubicin (400 mg/m²). However, it should be remembered that these thresholds are based on population studies, and for any individual patient the risk is impossible to predict. The clinician must pay close attention to symptoms of CHF, such as dyspnea, cough, orthopnea, and weight gain or ankle edema, throughout a course of treatment and irrespective of total dose.

Besides the cumulative dose of anthracycline, other risk factors for anthracycline-induced cardiomyopathy include mediastinal (mantle) radiation, preexisting heart disease, and patient age, the risk being highest in children younger than the age of 4 years. Children who receive greater than 300 mg/m² have a significant risk of having decreased myocardial contractility, decreased ventricular dimension, and an increased incidence of cardiac events (such as conduction defects, myocardial

infarction, and CHF) in their adult years. The incidence of may be decreased by coadministering dexrazoxane, an iron chelator, during chemotherapy.¹¹⁰ It is recommended that the total doxorubicin dose be limited to 300 mg/m² in children. In addition, children treated with anthracyclines should have long-term cardiology followup.¹¹⁰

Ejection fraction measurements have been helpful in detecting a decline in myocardial function, a sign of impending myocardial failure. Ejection fraction measurements, usually by multigated acquisition scan (MUGA), should be performed to verify normal cardiac function prior to starting anthracycline-based chemotherapy, and should be repeated at the earliest clinical sign of cardiac dysfunction, and before every two cycles of treatment when the total dose of doxorubicin exceeds 300 mg/m². Anthracyclines should be discontinued if the ejection fraction falls below 40 percent, or if the ejection fraction drops a total of 20 percent from pretreatment levels.

As cardiotoxicity of anthracyclines results from the generation of free radicals by an anthracycline–iron complex, dexrazoxane, an iron chelator, decreases free radical formation *in vitro* and decreases the risk of cardiotoxicity in children receiving treatment for ALL, and in adults with metastatic breast cancer.¹¹⁰ Fortunately, dexrazoxane does not cause any apparent diminution of antitumor activity. Adding dexrazoxane to an anthracycline-based regimen represents an alternative to discontinuing anthracyclines in patients who are approaching total-dose thresholds of drug, but who still require treatment. Two trials have shown a higher rate of secondary leukemia and MDS in patients receiving doxorubicin and dexrazoxane.^{111,112} In adult patients, dexrazoxane should be added only in patients who have received a total dose of at least 300 mg/m² doxorubicin or 540 mg/m² epirubicin.

Treatment with Topo II inhibitors, including anthracyclines, mitoxantrone, and the epipodophyllotoxins (see “Epipodophyllotoxins” below), increases the risk of AML. AML typically develops 6 months to 5 years after exposure to the Topo II inhibitor.¹⁰⁷ This heightened risk derives from the increased DNA double-strand breaks generated by the Topo II inhibitor. These double-stranded DNA breaks can give rise to balanced chromosomal translocations involving the *MLL* or *PML* genes.¹¹¹ Anthracyclines and mitoxantrone have affinity for specific DNA sequences and cause translocations at specific hot spots in the genome, including a 6-base pair breakpoint region in the *PML* gene causing the 15;17 translocation, the 11q23 translocation involving the *MLL* gene, and the 11;20 translocation involving the *NUP98* gene.^{113,114}

EPIPODOPHYLLOTOXINS

Two semisynthetic derivatives of podophyllotoxin, VP-16 (etoposide) and VM-26 (teniposide), inhibit Topo II and have significant clinical activity in hematologic malignancies. Etoposide has been incorporated into combination therapy regimens for Hodgkin lymphoma, large cell non-Hodgkin lymphomas, leukemias, and various solid tumors, and is a frequent component of high-dose chemotherapy regimens. Teniposide has limited value in clinical oncology. Its use is generally restricted to childhood acute leukemia, where it appears to be synergistic with ara-C. These compounds induce double-stranded breaks in DNA through their sequence-specific binding to DNA in complex with Topo II.¹¹⁵ One mechanism of resistance is increased expression of the MDR drug exporter.¹¹ A second mechanism results from decreased Topo II activity or mutation of the enzyme, resulting in decreased drug binding.^{116,117}

Clinical Pharmacology

Etoposide is administered in doses of 100 to 120 mg/m² per day for 3 days, either consecutively or every other day. Approximately 30 to 40 percent of an intravenous dose of etoposide is excreted intact in the urine, while the remainder is cleared by hepatic glucuronidation

or demethylation; thus, doses of etoposide require modification for patients with compromised renal or hepatic function.¹¹⁸ The plasma half-life of etoposide is 15 hours. The clinical activity of etoposide is highly schedule dependent. Single conventional doses are essentially without antitumor effect as compared to consecutive daily doses for 3 to 5 days. The pharmacokinetics of teniposide are very similar to those of etoposide, with a terminal plasma half-life of 20 to 48 hours. However, little parent drug appears intact in the urine, and dose modification for patients with renal dysfunction is unnecessary.

Adverse Effects

When administered intravenously, both etoposide and teniposide should be infused over a 30-minute period to avoid hypotensive episodes. The major toxicity of both drugs is leukopenia, which is rapidly reversible; thrombocytopenia is less common. Nausea and vomiting often follow etoposide administration. Alopecia may occur with both drugs. Other toxicities, such as fever, mild elevation of liver function tests, and peripheral neuropathy, are relatively uncommon. Because the major toxicity of etoposide is limited to the marrow, this drug is a valuable component of high-dose regimens used with marrow transplantation. In high-dose etoposide protocols (1.5 g/m² or greater given over 3 to 5 days) oropharyngeal mucositis becomes a prominent toxicity. Less-frequent high-dose toxicities include hepatocellular damage and, rarely, anaphylactic-like symptoms, probably related to the formulation vehicle. Secondary AML associated with translocation at 11q23 or the *PML* gene may follow etoposide treatment in children with ALL¹¹⁹ and in adults with solid tumors.¹²⁰

● AGENTS ACTIVE THROUGHOUT THE CELL CYCLE

THE ALKYLATING DRUGS

These drugs are important in the treatment of hematopoietic malignancies either as single agents or as components of standard- or high-dose regimens. Their role as treatment for both acute and chronic hematologic malignancies results from their unique mechanism of cell killing and their lack of cell-cycle specificity. They may eradicate noncycling cells that escape cycle-active components of the treatment. Although these agents share the common property of forming covalent bonds with electron-rich sites on DNA (oxygen and nitrogen substituents), they exhibit important differences in their intrinsic reactivity, route of cellular uptake, favored sites of alkylation on DNA bases, and the specific mechanism of DNA repair that determines cell survival. These differences are borne out in experimental settings, where cross-resistance to alkylating agents is incomplete. Thus, protocols employing multiple alkylators, particularly in high-dose regimens, have a rational basis.¹²¹ Alkylating agents differ as well in their patterns of toxicity. The majority of these drugs cause myelosuppression and mucositis as their primary acute toxicities, as well as delayed pulmonary fibrosis and late secondary leukemias. These secondary leukemias often arise after a period of myelodysplasia, are usually highly drug resistant AML, and carry defects in chromosomes 5 or 7. Busulfan, bischloroethylnitrosourea (BCNU), or cyclophosphamide are most likely to cause vascular endothelial damage (hepatic venoocclusive disease) when used in high doses. However, these same drugs are often used in high-dose regimens, as they cause less mucositis than other alkylating agents. 4-Hydroperoxycyclophosphamide, an activated analogue of cyclophosphamide, appears to spare marrow stem cells relative to tumor cells and has been used for *in vitro* purging of marrow in autologous transplantation.¹²²

Although platinum analogues are not true alkylating agents in that they form metal adducts rather than carbon adducts with DNA, RNA, and protein, their range of toxicities and mechanisms of resistance have much in common with the classical alkylators. They have few indications in hematologic malignancy, aside from carboplatin and its role in high-dose chemotherapy for lymphomas. Their DNA adducts are subject to repair by nucleotide excision repair and double-strand break repair, processes dependent on functional p53 activity.¹²³ Polymorphisms of the repair pathways, especially the mismatch repair process, may be associated with drug resistance,¹²⁴ whereas errors in double-strand break repair (as found in *BRCA1*- and *BRCA2*-solid tumors), may create sensitivity to platinating drugs.

Mechanism of Action

All alkylating agents (Fig. 22-4) have in common the generation of highly reactive carbonium intermediates that attack electron-rich sites on DNA, such as the *N*-7, *O*-2, and *O*-6 positions of guanine and the *N*-1, *N*-3, and *N*-7 positions of adenine. For many of these agents, the alkylating group must undergo a preliminary activation reaction mediated either by chemical rearrangement of the molecule, as in the case of nitrogen mustard and the nitrosoureas, or by metabolic activation followed by chemical rearrangement, as for cyclophosphamide, ifosfamide, and procarbazine. Most alkylating agents have two reactive sites, usually two chloroethyl groups, enabling them to form intrastrand and, less frequently, interstrand crosslinks.

A second class of alkylating drugs, exemplified by busulfan, dimethyltriazenoimidazole carboxamide (DTIC) and the closely related temozolomide, and procarbazine, produce only single-strand alkylation but may be highly carcinogenic, as, for example, procarbazine. In general, all the commonly used alkylating drugs, including cyclophosphamide, ifosfamide, melphalan, chlorambucil, and the methylating drugs, produce the same spectrum of myelosuppressive, carcinogenic, and genotoxic actions, and depend on an intact mismatch repair system to recognize their adducts and initiate apoptosis.

Experimental systems have elucidated the mechanisms of resistance to alkylating agents.¹²⁵ Some mechanisms are specific for certain alkylating agents (e.g., impaired uptake of nitrogen mustard as a consequence of an alteration in the membrane carrier for choline, or deletion of the amino acid carrier used by melphalan), whereas others appear to be less specific (e.g., drug inactivation associated with an increase in intracellular sulfhydryl compounds, and enhanced nucleotide-excision repair of DNA adducts). The primary resistance mechanisms for various alkylating drugs, as documented in experimental tumors, include increased degradation by aldehyde dehydrogenase (specifically for cyclophosphamide)¹²⁶; increased conjugation of the reactive intermediates with glutathione or glutathione transferase (all chloroethylating agents and platinum analogues); increased repair of the *O*-6 guanine alkyl lesions by a specific alkyl transferase (nitrosoureas, procarbazine, temozolomide, and dacarbazine)¹²⁷; increased nucleotide excision repair (all platinum derivatives and chloroethylating agents, except possibly nitrosoureas); decreased uptake (melphalan, nitrogen mustard); decreased ability to recognize DNA damage because of defective mismatch repair, especially the loss of the MLH6 component¹²⁸ (most alkylating agents and platinum derivatives); and defective recognition of DNA alkylation and strand breaks and initiation of apoptosis (p53 loss-of-function mutants), which affects all alkylators. The basis of alkylating agent resistance in the clinic is still incompletely understood.

Clinical Pharmacology

In general, the alkylating agents and their reactive intermediates have short residence times in the systemic circulation and within cells. They are eliminated predominantly by hydrolysis of the reactive site, by

Figure 22-4. Mechanism of action of alkylating agents attacking a purine base in DNA. (Reproduced with permission from Brunton L, Chabner B, and Knollman B: Goodman & Gilman's The Pharmacological Basis of Therapeutics, 12th ed. New York, NY: McGraw-Hill; 2011.)

chemical or biochemical conjugation to the sulfhydryl groups of glutathione or proteins, or by oxidative metabolism in the case of ifosfamide and cyclophosphamide. Therefore, dose reduction is not required in patients with diminished renal or hepatic function.

A few of the drugs require enzymatic activation. Cyclophosphamide and ifosfamide are closely related molecules that undergo hepatic CYP-mediated activation. Their active metabolites include a highly labile phosphoramidate mustard and a second toxic metabolite, acrolein, which is excreted in the urine.¹²⁹ To counteract toxicity of acrolein to kidneys and bladder, mercaptoethane sulfonate (mesna) is administered simultaneously in equivalent doses to the alkylator. Procarbazine and DTIC require metabolic activation by hepatic CYP isoenzymes, whereas temozolomide, a structural congener of DTIC, spontaneously activates to a methylating intermediate, and has become the preferred drug for treating glioblastomas.

Nitrogen mustard is a highly reactive compound in its parent form, and thus can be administered topically for treatment of skin cancers and cutaneous lymphoma. It is a potent vesicant, and care must be taken in the mixing and administering the drug. It is still a preferred component of combination therapy in conjunction with vincristine (Oncovin), procarbazine and prednisone (MOPP) for childhood Hodgkin lymphoma. Extravasation may lead to severe tissue injury. The second-generation alkylating agents, which include cyclophosphamide, melphalan, busulfan, and chlorambucil, are more chemically stable and absorbed reasonably well when given orally.

The newest alkylating drug, bendamustine, is approved for both CLL and relapsed lymphomas, and consists of a purine base with a *bis*-chloroethyl side chain. In experimental systems it is only partially cross-resistant with other alkylators, and produces a bulky DNA adduct that is slowly removed by base excision repair. It strongly induces p53 phosphorylation and apoptosis, as well as cell necrosis, a distinct cell

death response.¹³⁰ Bendamustine metabolism produces two minor toxic metabolites: hydroxylation of its 4 position and *N*-demethylation. The bulk of parent drug is eliminated through its reactivity with sulfhydryls and adduct formation. The drug displays much the same pattern of toxicity of other alkylating drugs, with perhaps less myelosuppression.

Carboplatin, often used in high-dose therapy of lymphomas, is primarily excreted by the kidneys. Its dosing is based on renal function, aiming at a specific area under the curve of 5 to 7, according to the formula:

$$\text{Dose (mg/m}^2\text{)} = \frac{\text{Area under the curve} \times (\text{glomerular filtration rate} + 25)}{\text{glomerular filtration rate} + 25}$$

Adverse Effects of Alkylating Agents

Marrow toxicity, which is cumulative and a function of total dose, is the most important acute toxic effect of alkylators. Nitrosoureas produce a characteristic delayed myelosuppression that reaches a nadir 4 to 6 weeks after administration. Busulfan, like the nitrosoureas, depletes stem cells and can cause profound marrow hypoplasia or permanent aplasia. The dose-limiting toxicity of DTIC is nausea and vomiting rather than marrow suppression. Carboplatin causes an acute thrombocytopenia, as well as a more chronic sensory neuropathy.

Other common toxicities include denudation of the gastrointestinal epithelium, pneumonitis, cardiac, and endothelial damage, which become evident during high-dose therapy. Virtually every organ system may be damaged by alkylating agents. Because alkylating agents react with DNA, mutations and secondary leukemias are major long-term effects of these agents. This hazard appears to be related to the total dose administered. The monofunctional methylating agents (e.g., procarbazine) are especially potent in this regard. All alkylating agents, but particularly busulfan and the nitrosoureas, may produce pulmonary

fibrosis. The nitrosoureas also cause nephrotoxicity, particularly after total doses of 1200 mg/m² BCNU, whereas cyclophosphamide and ifosfamide cause chronic bladder toxicity, hemorrhage, and, in rare cases, bladder carcinomas. Urinary toxicity of the latter two agents is prevented by coadministration of mesna, a sulfhydryl that detoxifies acrolein at acid pH.

High-Dose Alkylating Agent Therapy

The development of hematopoietic cell transplantation has made it possible to administer doses of chemotherapy that would otherwise produce life-threatening aplasia. To be of benefit, however, high-dose therapy must employ agents that have a relatively steep dose-response relationship. The drugs used must not have lethal extramedullary toxicity at high doses. Among the classes of cytotoxics, alkylators have a particularly favorable linear relationship between dose and cytotoxicity in experimental tumor systems. Extramedullary organ toxicities are infrequent until doses are increased manyfold, making them ideal candidates for high-dose regimens. Depending on the agent and the toxicity profile, doses may only be escalated by as little as twofold as seen with cisplatin because of renal toxicity, or to as high as 18-fold in the case of thiotepa (Table 22-3).¹³¹⁻¹³⁷ However, when agents are combined into a high-dose regimen, overlapping extramedullary toxicities of the agents must be considered so as to avoid serious organ compromise (Table 22-4).¹³⁸⁻¹⁴² Overlapping extramedullary toxicities (particularly the risk of pulmonary or hepatic dysfunction or secondary leukemia) cannot be completely avoided, but rational drug selection can minimize the dose reductions of the individual agents, compared to their single-agent maximum tolerated dose (MTD), while at the same time ensuring safety of the combination regimen. This is illustrated in

TABLE 22-3. Dose-Limiting Extramedullary Toxicities of Single-Agent Chemotherapy

Drug	Maximum Tolerated Dose (mg/m ²)*	Increase Over Standard Dose [†]	Major Toxicities [‡]
Cyclophosphamide	7000	7.0	Cardiac
Ifosfamide	16,000	2.7	Renal, CNS
Thiotepa [§]	1005	18.0	GI, CNS
Melphalan [§]	180	5.6	GI
Busulfan [§]	640	9.0	GI, hepatic
BCNU [§]	1050	5.3	Lung, hepatic
Cisplatin	200	2.0	Renal, neuropathy
Carboplatin [§]	2000	5.0	Hepatic, renal
Etoposide	3000	6.0	GI
Cytarabine	3000	10-30	Neurologic, mucositis

BCNU, bischloroethyl nitrosourea; GI, gastrointestinal.

*Independent of hematopoietic toxicity. Dose may be given over multiple days.

[†]Fold increase. This is an approximation because standard doses may vary.

[‡]All drugs listed in this table cause vascular endothelial damage and venoocclusive disease, as well as late secondary leukemias.

[§]With stem cell support.

Table 22-4, which shows the fraction of the single-agent MTD that can be administered in combination with other drugs. As might be expected, this fraction is quite variable depending on the drug combinations, with the average fractional MTD used in combination ranging from 0.5 to 1. Depending on the regimen, significant gastrointestinal, pulmonary, hepatic, and/or renal toxicities are encountered and become dose limiting. For these reasons, high-dose regimens are safest in patients who are younger (<70 years) and who have had minimal prior chemotherapy and radiation therapy.

AGENTS OF DIVERSE MECHANISMS

BLEOMYCIN

Bleomycin is a mixture of cytotoxic peptides produced by the fungus *Streptomyces verticillus*.¹⁴³ Because it has antitumor activity with minimal marrow toxicity, it is commonly used as part of combination regimens (such as ABVD) to treat Hodgkin lymphoma and with cisplatin and vinblastine to treat germ cell tumors. Bleomycin acts by causing both single- and double-strand breaks in DNA. These breaks form as a consequence of a bleomycin-Fe (II) complex that binds to DNA and undergoes redox cycling with molecular oxygen. The drug's reactive complex abstracts a proton from deoxyribose, leading to cleavage of the sugar at the 3'-carbon.¹⁴⁴ In experimental tumors, resistance to bleomycin has been attributed to increased tumor cell concentrations of an aminohydrolase that cleaves and inactivates the drug.¹⁴⁵ Some resistant cell lines exhibit enhanced capacity to repair strand breaks, and in others, resistance results from decreased drug accumulation. Additional factors, such as increased free radical detoxification, may also influence toxicity. The tumor specificity of bleomycin, its severe cutaneous and pulmonary toxicity, and its lack of toxicity to marrow and the gastrointestinal tract may be a result of widely differing levels of metal ions and bleomycin hydrolase, the detoxifying enzyme, in these tissues. A polymorphism in the hydrolase gene, identified by SNP A1450G, may confer resistance to the drug as the result of its enhanced hydrolase activity.¹⁴⁶ Cell killing occurs throughout the cell cycle.

Clinical Pharmacology

Bleomycin may be administered intravenously or intramuscularly in doses of 10 to 20 U/m² per week to cumulative doses of 250 U for systemic therapy, as well as intrapleurally or intraperitoneally for control of malignant effusions. The half-life of drug elimination from plasma is estimated to be 2 to 3 hours. After a single intravenous injection, more than half the dose is excreted, unchanged, in the urine within 24 hours.¹⁴⁷ Bleomycin elimination may be markedly impaired in patients with poor renal function; such patients are at risk of overwhelming skin and lung toxicity. Dose reduction by 50 percent should be considered in patients with a CrCl in the range of 30 to 80 mL/min, and drug should be withheld in the presence of CrCl less than 30 mL/min.

Adverse Effects

Bleomycin has minimal effects on normal marrow; however, in patients given other myelosuppressive drugs or who are recovering from marrow toxicity from these agents, additional mild myelosuppression may be observed. The primary toxicities that result from bleomycin are pulmonary fibrosis and skin changes. In experimental settings, the drug activates the Hedgehog pathway and induces the secretion of numerous cytokines, including interleukin (IL)-6, tumor necrosis factor- α and transforming growth factor- β , by alveolar macrophages and inflammatory cells, leading to collagen deposition.¹⁴⁸ The risk of pulmonary toxicity is related to the cumulative dose administered, increasing to 10 percent in patients given more than 450 mg. Risk is also greater in

TABLE 22-4. Toxicities and Doses of High-Dose Regimens Administered with Stem Cell Support

Regimen	Dose (mg/m ²)	Fraction of MTD*	Major Toxicities	Tumor Targets	Reference
Cyclophosphamide	6000	0.86	GI, cardiac	Breast	135
Thiotepa	500	0.5			
Carboplatin	800	0.4			
Cyclophosphamide	6000	0.86	Lung, GI	Lymphomas	136
BCNU	300	0.29			
Etoposide	750	0.25			
Busulfan	640	1.0	Lung, GI, hepatic	Lymphoma	137
Cyclophosphamide	8000	1.0			
Ifosfamide	16,000	1.0	Renal, hepatic, GI	Lymphomas	138
Carboplatin	1800	0.9			
Etoposide	1500	0.5			
Cyclophosphamide	5625	0.8	Cardiac, hepatic, renal	Breast	139
BCNU	600	0.57			
Cisplatin	164	0.82

*This is the fraction of the single-agent MTD (see Table 22-3, Col. 2).

patients older than age 60 years,¹⁴⁹ in patients with underlying lung disease, in patients receiving bleomycin who are given high oxygen concentrations, and in patients who have had previous radiotherapy to the lungs. Single intravenous doses of 25 mg/m² or more predispose to this toxic effect. Symptoms of pulmonary toxicity include cough and dyspnea. Chest radiographs show nonspecific infiltrates, especially in the lower lobes. Chest computed tomography changes may show extensive infiltrates, fibrosis in later stages of evolution, atelectasis, or cavitation. Positron emission tomography scans are strongly positive. Open-lung biopsy may be required to distinguish bleomycin pulmonary toxicity from infection or malignant disease. Pathologic findings of bleomycin toxicity include an inflammatory alveolar infiltrate with edema, pulmonary hyaline formation, and squamous metaplasia of the alveolar lining cells. These changes progress to intraalveolar and interstitial fibrosis over a period of months. Patients with bleomycin lung toxicity have a measurable decrease in carbon monoxide diffusing capacity, a test of possible value in predicting potential pulmonary toxicity.¹⁵⁰ Because there is no specific therapy for patients with bleomycin lung toxicity, close attention should be paid to early pulmonary symptoms and radiographic changes. In patients with bleomycin pulmonary toxicity, some improvement may be seen on discontinuation of the drug, but the pulmonary fibrosis is usually not reversible. Glucocorticoids may decrease inflammation, but are of no proven benefit once fibrosis has occurred. O₂ supplementation must be avoided, as it promotes the oxidative injury to pulmonary tissue.

The dermatologic toxicity of bleomycin is also dose related. Erythema, hyperpigmentation, hyperkeratosis, and even ulceration may occur when the drug is given in conventional daily doses for longer than 2 to 3 weeks. Areas of skin pressure, especially of the hands, fingers, and joints, are initially affected, and Raynaud phenomenon may become apparent in the distal digits. Nail changes and alopecia may also occur with continued use of the drug. In combination regimens (e.g., ABVD) where bleomycin is used intermittently, skin toxicity is rarely a dose-limiting problem.

Fever and malaise after injection are common symptoms and may be alleviated by acetaminophen. Hypersensitivity reactions have also been observed. Idiosyncratic cardiovascular collapse has been rarely noted. A 1- or 2-mg test dose administered to such susceptible patients

may result in hypotension, tachycardia, pulmonary insufficiency, or anaphylactoid reactions within 30 to 60 minutes. Their occurrence precludes further treatment with bleomycin.

L-ASPARAGINASE

The enzyme L-asparaginase is used clinically in the treatment of lymphoid malignancies, particularly in poor-risk B-cell ALL, T-cell ALL, natural killer (NK)-cell leukemia, and in high-grade lymphomas.

Mechanism of Action

The cells causing these lymphoid malignancies require exogenous L-asparagine for growth; they obtain this amino acid from the systemic pool of amino acids generated by the liver. The enzyme L-asparaginase, which catalyzes the hydrolysis of asparagine to aspartic acid and ammonia, rapidly depletes L-asparagine from plasma and induces an asparagine deficiency in lymphoid malignant cells. Resistant tumors are able to respond by induction of asparagine synthetase,¹⁵¹ thereby restoring intracellular pools of asparagine. For reasons not well understood, hyperdiploid ALL cells are particularly sensitive to L-asparaginase, whereas cells containing the BCR-ABL translocation are more resistant.¹⁵²

Three L-asparaginase preparations are available in the United States.¹⁵³ The product purified from *Escherichia coli* is employed as a first-line agent, while a second preparation (pegaspargase), derived by attachment of polyethylene glycol to the *E. coli* enzyme, is used for first-time therapy and for patients hypersensitive to the unmodified enzyme. A third preparation, purified from *Erwinia chrysanthemi*, can be obtained from the National Cancer Institute of the United States for patients hypersensitive to the *E. coli* enzyme or to pegaspargase. The various preparations differ in their pharmacokinetics, immunogenicity, and recommended doses. The *E. coli* enzyme is usually given in doses of 6000 to 10,000 IU intramuscularly every third day for 3 to 4 weeks, although much higher doses (25,000 IU once weekly) may be more effective in ALL treatment. Levels are maintained continuously above 0.2 IU/mL plasma, leading to total abolition of asparagine in the systemic circulation. The *E. coli* enzyme has an elimination half-life of 14 to 24 hours. Monomethoxypolyethylene glycol (PEG) conjugated to

the *E. coli* enzyme reduces its immunogenicity and extends its half-life to 6 days. Pegaspargase is used in patients hypersensitive to the unmodified enzyme, in doses of 2500 IU/m² intramuscularly every 2 weeks. Single doses deplete L-asparagine from plasma for 2 to 3 weeks. Some patients develop hypersensitive to both preparations of *E. coli* enzyme, particularly if first exposed to the unmodified enzyme; they may be treated with enzyme from *Erwinia*, which has a low incidence of hypersensitivity and approximately equal catalytic activity to the *E. coli* preparation, but a more rapid clearance.¹⁵⁴ Consequently, the *Erwinia* enzyme must be used in higher doses.

Adverse Effects

Reactions to the first dose are uncommon, but after two or more doses of the unmodified enzyme, hypersensitivity may develop in up to 20 percent of patients, varying from urticarial reactions to hypotension, laryngospasm, and cardiac arrest. Skin testing to predict allergic reactions is helpful in some, but not all, cases, and should be performed to confirm a clinical suspicion of hypersensitivity. Hypersensitive patients may have antibodies to L-asparaginase in their plasma. More than half the patients with such circulating antibodies will not display an overt allergic reaction to the drug, but these patients may have more rapid disappearance of drug from plasma and an inadequate clearance of asparagine from plasma and cells, leading to therapeutic failure. Patients who are treated with L-asparaginase should be observed carefully for several hours after dosing, and epinephrine should be available in case anaphylactic reactions occur. Anaphylaxis is less likely when *E. coli* L-asparaginase is given intramuscularly than when it is administered intravenously. Pegaspargase has much reduced immunogenicity and hypersensitivity reactions are uncommon. However, up to 20 percent of patients previously exposed to unmodified L-asparaginase will develop allergy to subsequent pegaspargase, with undetectable enzyme levels in plasma, and an additional 8 percent will have silent inactivation of the enzyme. The other major toxic effects of L-asparaginase are a consequence of the ability of this drug to inhibit protein synthesis in normal tissues. Inhibition of protein synthesis in the liver will result in hypoalbuminemia, a decrease in clotting factors, a decrease in serum lipoproteins, and a marked increase in plasma triglycerides. Inhibition of insulin production may lead to hyperglycemia. The clotting abnormalities that are regularly observed as a consequence of L-asparaginase treatment include initial decreases in the anticoagulant factors antithrombin III,

protein C, and protein S, leading to either arterial or venous thrombosis in occasional patients, and a predilection to thrombosis of cortical sinus vessels.¹⁵⁵ With more prolonged therapy, bleeding sequelae may result from inhibition of the synthesis of procoagulant proteins such as fibrinogen and factors II, VII, IX, and X. Consequently, monitoring of coagulation factors is recommended. High doses of L-asparaginase may cause cerebral dysfunction that manifests as confusion, stupor, seizures, or coma, and cortical sinus thrombosis has been documented by magnetic resonance imaging scan in such patients.¹⁵⁶ Clinical thromboembolic episodes may occur in up to 35 percent of children with ALL.¹⁵⁷ These events are mostly asymptomatic thrombi associated with central venous catheters; less frequently, cortical sinus and atrial thrombi may occur. Altered mental status may also result from hyperammonemia and diabetic ketoacidosis.¹⁵⁸ Preexisting clotting abnormalities, such as antiphospholipid antibodies or factor V Leiden deficiency, may predispose to thromboembolic complications.¹⁵⁹

Acute nonhemorrhagic pancreatitis occurs as a complication of L-asparaginase treatment, especially in patients who have extreme elevations of plasma triglycerides (>2 g/dL).¹⁶⁰ Because L-asparaginase manifests little toxicity in marrow or gastrointestinal mucosa, it has been used in combination with other drugs that do have such toxicities.

● IMMUNOMODULATORY DRUGS

THALIDOMIDE, LENALIDOMIDE, AND POMALIDOMIDE

Thalidomide (α -phthalimidoglutarimide; Fig. 22-5), approved in 1953 as a sedative, was withdrawn shortly thereafter because of its teratogenicity. It causes dysmelia (i.e., stunted limb growth) when used during early pregnancy. However, it has since reemerged as an important antibacterial and antitumor agent, with clear effectiveness against leprosy and myeloma, especially when combined with other agents.¹⁶¹ Its analogues, lenalidomide and pomalidomide (see Fig. 22-5), have proven to be less toxic, and more effective for treating relapsed and refractory patients with myeloma. Lenalidomide is highly active in first-line combination therapy with dexamethasone, and also with bortezomib¹⁶² for myeloma, as well as being approved for the treatment of myelodysplasia in patients with the 5q- variant of this syndrome. The newest immunomodulatory

Figure 22-5. Thalidomide, lenalidomide and pomalidomide. (Reproduced with permission from Brunton L, Chabner B, and Knollman B: Goodman & Gilman's The Pharmacological Basis of Therapeutics, 12th ed. New York, NY: McGraw-Hill; 2011.)

drug (IMiD), pomalidomide, is approved for patients refractory to lenalidomide and bortezomib.¹⁶³

The mechanism of action of thalidomide and analogues is incompletely understood, as the compounds have a number of different actions, including a prominent antiangiogenic effect against tumors,¹⁶⁴ immune modulation, and inhibition of cytokine secretion. They inhibit neovascularization in the mouse cornea, block proliferation of endothelial cells in culture,¹⁶⁵ and inhibit secretions of vascular endothelial growth factor and other angiogenic cytokines.¹⁶⁶ Thalidomide potently stimulates phosphorylation of the CD28 costimulatory molecule.¹⁶⁷ This effect can lead to enhancement of T-cell function and activation of signaling pathways. Thalidomide has inhibitory effects on cytokine secretion, lowering levels of tumor necrosis factor- α and γ -interferon in leprosy patients. In addition it enhances NK-cell numbers and function, suppresses T-regulatory cells, and stimulates cytolytic T-cell function. It downregulates interferon regulatory factor 4 (IRF4), a myeloma survival factor. Although lenalidomide and pomalidomide have not been studied as extensively as thalidomide preclinically, they have the same spectrum of biologic actions but with greater potency.

An additional IMiD site of action related to degradation of key proteins has been identified. The IMiDs interact with cereblon, a protein that forms a complex with ubiquitin E3, and thereby promote the degradation of myc protein and other transcription factors. This effect on E3 and cereblon binding partners has been implicated in the teratogenic effects and antitumor activity of the IMiD compounds.¹⁶⁸

Clinical Pharmacology of Thalidomide and Its Congeners

Thalidomide consists of two enantiomers that rapidly interconvert in solution and biologic fluids. Its two imide bonds are unstable and undergo hydrolysis in solution. The poorly soluble drug undergoes slow and somewhat variable oral absorption with peak levels achieved in 2.9 to 4.3 hours^{169,170} after oral doses ranging from 50 to 400 mg. There is no evidence for induction of metabolism on a daily dosing regimen. Drug concentrations in plasma decay with a half-life of 5 to 7 hours, the major pathways for elimination including spontaneous hydrolysis of the imide esters, and further CYP-mediated metabolism by the liver. At high doses of 1200 mg, the rate of clearance of drug from plasma decreases. Less than 1 percent of the drug is excreted unchanged in the urine. No dose adjustment is required for renal dysfunction, although its propensity for causing neuropathy may aggravate any underlying neuropathy secondary to prior exposures, renal failure or amyloidosis, making dose reduction prudent, especially when used in combination with other agents.

Lenalidomide is well absorbed orally in doses up to 400 mg, and usually given in doses up to 25 mg daily; it exhibits a plasma half-life of 3 hours. Approximately 70 percent of administered drug is excreted unchanged by the renal route, the remainder appearing in the feces unchanged. Dose adjustments are therefore recommended for patients in moderate (10 mg/day for CrCl of 30 to 50 mL/min) or severe (10 mg every other day for CrCl <30 mL/min) renal failure. For those on dialysis, the recommended dose is 5 mg once daily, with the same day dose given following dialysis.

Pomalidomide is given orally in doses of up to 4 mg per day. It has a long plasma half-life of 7.5 hours in myeloma patients, and is eliminated by CYP1A2 and CYP3A4 hydroxylation in the liver with minimal renal clearance. Inducers or inhibitors of CYP3A4 metabolism (prominently antibiotics and HIV drugs) and inhibitors of the MDR1 efflux transporter (natural products and targeted cancer therapies) should be used in combination with pomalidomide with caution.¹⁷¹

Clinical Use

Thalidomide has been evaluated against a number of human malignancies, with occasional responses in brain tumors, renal cell cancer,

hepatoma, and Kaposi sarcoma. It has established value in treating myeloma refractory to first-line chemotherapy, as well as in newly diagnosed patients.^{172,173} In responding patients, all aspects of the disease, including marrow infiltration with tumor cells, anemia, and performance status, improved with therapy. Thalidomide has synergistic myeloma-inhibiting activity with glucocorticoids, interferon- α , bortezomib, and cytotoxic agents. However, lenalidomide, which has less-prominent side effects and probably greater efficacy, has replaced thalidomide in first-line regimens for myeloma. Pomalidomide is reserved for patients refractory to lenalidomide and bortezomib, and retains impressive activity in this setting.

Thalidomide is generally well tolerated in oral doses of 50 to 1200 mg daily, although higher doses are more challenging. In treating myeloma, a 1-month trial is usually sufficient to observe a decline in paraprotein and an improvement in symptoms, with doses typically used ranging from 50 to 200 mg/daily. Doses can be escalated up to 200 mg every 2 weeks until dose-limiting toxicity is reached at 600 to 800 mg/day, but these higher doses are rarely used. Patients older than age 65 years are less tolerant of side effects, particularly sedation, constipation, fatigue, and peripheral sensory neuropathy, and receive a median dose of at most 400 mg/day, with lower doses (e.g., 100 mg/day) being preferable,¹⁷⁴ whereas younger patients may tolerate up to a median of at most 800 mg/day, although again lower doses (e.g., 200 mg/day) are preferable. With extended treatment at doses below 400 mg/day, the peripheral sensory neuropathy may become bothersome, but usually improves with dose reduction or drug discontinuation. To avoid undue sedation, the drug is given either in divided doses, morning and evening, or as a single evening dose. Other side effects include rash, dizziness and orthostatic hypotension, neutropenia, mood changes or depression, and nausea. Hypersensitivity and bradycardia also have been reported. Rarely patients may develop an interstitial pneumonitis or fulminant hepatic failure.

Trials of thalidomide in combination with cytotoxic drugs or biologics originally disclosed some unexpected toxicities.¹⁷⁵ Thalidomide in combination with doxorubicin or with prednisone is associated with an increased incidence of thromboembolism, a complication that can be prevented by concurrent treatment with low-molecular-weight heparin or aspirin.¹⁷⁶ Because of its teratogenicity, patients of childbearing age should take precautions to prevent pregnancy while on therapy. In trials of thalidomide and interferon against renal cell carcinoma, in which high doses of interferon (9 million IU subcutaneously three times per week) were used, four of 13 patients developed complex partial seizures and visual disturbances.¹⁷⁷ Two of 19 patients on thalidomide with low-dose interferon (1.5 to 3 million IU three times weekly) developed complex partial seizures in a trial against melanoma.

In the United States, thalidomide and its analogues are approved for use under a special risk evaluation and mitigation strategy (REMS), with restricted pharmacy access and a special consent form, to assure that pregnant women are not given these agents.

The analogue, lenalidomide, with significant activity against myeloma, causes much less sedation, constipation, and neurotoxicity, but prominent myelosuppression in 20 percent of patients. It is proving to be highly effective in remission induction with bortezomib and prednisone or with prednisone alone. Used in oral doses of up to 25 mg/day for 21 of 28 days, it is dramatically effective in normalizing hematologic parameters in the subset of patients with myelodysplasia who have a 5q- deletion on cytogenetics. A gene expression profile characteristic of lenalidomide responders has been reported.¹⁷⁸ Lenalidomide produces dramatic tumor swelling (tumor flare reaction) and tumor lysis in patients with CLL, a potentially fatal complication, even in patients with disease refractory to conventional agents. In CLL, it is equally effective in patients with poor prognostic cytogenetics (chromosomes 11 and

17 deletions). It must be started in low doses (beginning at 2.5 to 5 mg/day and escalating thereafter) to avoid tumor flare reaction and renal failure.¹⁷⁹ It has rarely been associated with severe hepatic and renal toxicity.

Like thalidomide, lenalidomide in combination with anthracyclines or glucocorticoids causes a 15 percent incidence of thrombotic events, and in these combinations should be administered with low-molecular-weight heparin, although prospective trials of anticoagulation are lacking.¹⁸⁰

Pomalidomide's prominent toxicity is neutropenia in 50 to 60 percent of patients, and thrombocytopenia in 25 percent. It has little sedating effects and causes neuropathy in 10 percent or fewer subjects. It is highly active in relapsed, refractory myeloma and particularly in combination with various agents, including dexamethasone and proteasome inhibitors, such as bortezomib and carfilzomib. Rare toxicities include thromboembolism (3 percent) and isolated cases of hepatic failure.¹⁶³

DIFFERENTIATING AGENTS

Certain chemical agents have the ability to cause terminal differentiation (maturation) of malignant cells.^{181,182} The most prominent among these are members of the vitamin A family (carotenes and retinoids), vitamin D and its analogues, phenylacetic acid, various cytotoxic agents used in low concentrations (such as hydroxyurea), inhibitors of DNA methylation such as 5-azacytidine and 5-aza-2'-deoxycytidine or decitabine, and inhibitors of histone deacetylase, exemplified by vorinostat, depsipeptide, and various benzamides.¹⁸³ In addition, biologic agents such as the interferons and interleukins induce terminal differentiation of both malignant and normal cells, but the role of terminal differentiation in the anticancer action of these drugs in humans is uncertain, as they have multiple biologic effects.

RETINOIDS

As the first effective terminal differentiating agent in cancer therapy, ATRA induces complete responses in a high percentage of patients with APL, and has become a standard member of the combination regimen for treatment and cure of this disease.¹⁸⁴ ATRA acts through binding to a nuclear receptor formed by the heterodimerization of the retinoic acid receptor- α (RAR α) and its partner, the retinoid X receptor. In APL, an abnormal fusion protein, composed of portions of the RAR α and a unique transcription factor (the *PML* gene product), results from the characteristic 15;17 chromosomal translocation found in this disease.¹⁸⁵ The fusion protein has a lower affinity for retinoids than does the wild-type molecule. High concentrations of retinoids are required to displace a corepressor bound to the protein, and activate key differentiation factors such as CCAAT/enhancer binding protein (C/EBP) and PU.1.¹⁸⁶ The fusion protein forms a variety of homo- and heterodimers that regulate genes and increase leukemic stem cell renewal, and suppress apoptosis and DNA repair, further contributing to progression of leukemia. In experimental settings, resistance to ATRA differentiating activity results from mutation or loss of retinoid binding in the *PML-RAR α* fusion gene, indicating that the fusion gene product plays a role in retinoid responsiveness, and sensitivity can be restored by transfection of a functional RAR α gene.¹⁸⁷

ATRA is administered to APL patients in oral doses of 25 to 45 mg/m² per day until complete remission is achieved and reaches peak serum levels of 300 ng/mL 1 to 2 hours after administration.¹⁸⁸ It is also used in remission maintenance, with 6-MP, methotrexate, or ara-C. The parent drug disappears from serum with a half-life of less than 1 hour during the initial course of treatment, but its rate of clearance greatly accelerates with continued treatment, a factor that may contribute to resistance

to ATRA therapy. Induction of CYP26A1-mediated metabolism is suspected to underlie this accelerated clearance, and may account for the high rate of disease recurrence if ATRA is used as a single agent.¹⁸⁹ The primary toxicities of ATRA resemble those of other retinoids and vitamin A, specifically dry skin, cheilitis, mild and reversible hepatic dysfunction, bone tenderness and hyperostosis on radiography, hypercalcemia, hyperlipidemia, and occasional cases of pseudotumor cerebri. Imidazole antifungals block the degradation of ATRA and may lead to hypercalcemia and renal failure. In addition, approximately 15 percent of patients with APL, particularly those with an initial leukemic cell count greater than 5000/ μ L, develop a syndrome of hyperleukocytosis, fever, altered mental status, pleural and pericardial effusions, and respiratory failure (the "retinoic acid syndrome").¹⁹⁰ Hyperleukocytosis and leukocyte adherence to small vessels results from a rapid increase in the number of mature leukemic cells in the blood and from the increased expression of integrins on the leukemic cell surface and secretion of cytokines in response to ATRA. In patients with white blood cell counts above 20×10^3 cells/ μ L, pleural and pericardial effusions and peripheral edema develop rapidly, and respiratory distress, cardiac failure, and renal insufficiency may lead to death. Anecdotal reports indicate that high-dose glucocorticoids reverse this syndrome, which is mediated by leukocyte adhesion and clogging of small vessels and/or by cytokine release.¹⁹¹ The early introduction of cytotoxic chemotherapy during remission induction, and the use of dexamethasone sodium phosphate (10 mg twice daily for 3 or more days in patients with initial leukemic counts of greater than 5000 cells/ μ L), drastically lower the incidence of the syndrome and improve the safety of ATRA therapy.

ARSENIC TRIOXIDE

In the 1930s, arsenic was used to treat CML and other malignancies with little effect. Based on further clinical trials of arsenic trioxide (As₂O₃) in Harbin, China, in 1992, it resurfaced as an impressively effective treatment for relapsed APL, and appears to also be active against myeloma and myelodysplasia.¹⁹² Its mechanism of action probably stems from its ability to promote free radical production.¹⁹³ It inhibits the detoxification of free radicals and inactivates glutathione, an important radical scavenger.¹⁹⁴ It promotes degradation of the PML-RAR α fusion protein,¹⁹⁵ and upregulates p53 and proapoptotic proteins. The cumulative effect is to induce maturation and promote apoptosis in APL cells. In addition, it has antiangiogenic effects. The sum of these actions is potent antitumor activity in some but not all tumor cells. In APL patients refractory to ATRA and conventional chemotherapy, it produces strikingly durable complete responses, and is therefore under study as a part of primary treatment regimens for this disease.

Patients are treated with a 2-hour intravenous infusion of 0.15 mg/kg day for up to 60 days, or until marrow remission is achieved, with further consolidation therapy beginning 3 weeks after remission. Remissions appear in 2 to 3 months with evidence of leukemic cell differentiation and a progressive blood leukocytosis after 2 weeks of therapy.¹⁹⁶ Side effects of arsenic trioxide in APL may include hyperglycemia, elevated liver enzymes, and hypokalemia, none of which require discontinuation of therapy. Occasional patients complain of fatigue, dysesthesias, and lightheadedness. A pulmonary distress syndrome, similar to that encountered with APL cell maturation after ATRA therapy, occurs in approximately 10 percent of patients, and is managed with glucocorticoids, oxygen, and temporary withholding of arsenic trioxide. Arsenic trioxide prolongs the cardiac QT interval, and uncommonly produces atrial or ventricular arrhythmias; it is important to maintain serum potassium at normal concentrations during arsenic trioxide therapy, and to avoid use of other drugs that prolong the QT interval, such as macrolide antibiotics, methadone, or quinidine.

Torsade de pointes occurs infrequently during arsenic trioxide treatment, but requires immediate treatment with intravenous magnesium sulfate, potassium repletion, and defibrillation if the arrhythmia and hemodynamic instability persist.¹⁹⁷

A maximum plasma concentration of 5.5 to 7.3 μM was achieved in the initial studies from China, and small amounts of drug and the methylated metabolite are eliminated in the urine, the rest remaining in tissues.¹⁹⁸

EPIGENETIC AGENTS

DEMETHYLATING AGENTS

DNA methyltransferases (DNMTs) regulate transcription by methylating CpG promoter regions of DNA and thereby silencing gene expression. Mutations associated with AML, including isocitrate dehydrogenase 1 and 2 (IDH1 and IDH2) mutations, TET2, and mutations that activate DNMT, result in increased DNA methylation. Hypermethylation blocks differentiation and drives cellular proliferation. Two DNA demethylating agents, azacitidine and decitabine, have been approved for treatment of MDS. Both drugs become incorporated into DNA, substituting for cytosine bases, and form a suicide covalent bond with DNMT. The two drugs differ in their activation pathways and in their effects on nucleic acid methylation. Decitabine is phosphorylated by dCK whereas azacitidine is activated by cytidine kinase. Decitabine nucleotide is incorporated only into DNA, while azacitidine is found in both RNA and DNA. The clinical response to these drugs has not been correlated with either global changes in DNA methylation or with methylation of specific genes. Indeed, while traditional thinking has taught that DNA methylation invariably leads to gene silencing, newer studies have demonstrated that many actively transcribed genes have high levels of DNA methylation and that the tissue context and specific patterns of methylated DNA may play an important role in determining transcriptional activity.¹⁹⁹

Azacitidine received FDA approval for therapy of MDS on the basis of reported improvement in Hgb, white cells, or platelets, delayed progression to AML, improved quality of life, and improved overall survival.²⁰⁰ In a more recent four-arm phase III trial in higher-risk MDS patients, azacitidine was compared with best supportive care, low-dose ara-C, or induction chemotherapy with anthracycline and ara-C. The median overall survival was 24.5 months in the azacitidine arm compared with 15 months for the other arms.²⁰¹

Decitabine was approved on the basis of a 30 percent overall hematologic response rate in MDS patients.²⁰² For those with intermediate- or high-risk disease, time to AML or death was significantly delayed, but there is no improvement as yet in overall survival with this drug.²⁰³ While the two agents have not been compared head to head in MDS, a meta-analysis showed a significant overall survival benefit versus supportive care only for azacitidine.²⁰⁴ A retrospective review found no significant difference in efficacy between the two compounds except in patients older than 65 years of age, for whom azacitidine resulted in improved survival and a more favorable toxicity profile.

Both agents increase HgbF levels in sickle cell anemia and thalassemia, and reduce symptomatic episodes, but have been superseded by hydroxyurea for this indication.

Azacitidine is approved for parenteral or subcutaneous administration at 75 mg/m²/day for 7 days every 28 days, a regimen that has been shown to result in maximal DNA hypomethylation. A daily-times-five regimen appears to have similar efficacy.²⁰⁵ The median number of cycles needed for response is three, but 80 percent of responses occurred before the sixth cycle.²⁰⁶ An oral formulation is currently being developed and has demonstrated activity in MDS and chronic

myelomonocytic leukemia. The decitabine dose resulting in optimal hypomethylation is 20 mg/m² intravenously daily for 5 days every 4 weeks,²⁰⁵ although alternative schedules employing lower doses have been used. Dose adjustment and delays in repeat cycles may become necessary because of myelosuppression.

The primary clinical toxicities of both drugs include reversible myelosuppression, nausea and vomiting with higher doses, hepatic dysfunction, myalgias, fever, and rash. Both compounds are rapidly deaminated and converted to a chemically unstable azauridine or aza-deoxyuridine metabolite that immediately degrades into inactive products.²⁰²

A significant portion of patients with MDS does not respond to demethylating agents, and all will ultimately relapse. Azacitidine is initially phosphorylated by a different kinase (uridine-cytidine kinase) and so may benefit patients unresponsive to azacytidine.²⁰⁵

Clinical trials of azacytosine nucleosides with histone deacetylase (HDAC) inhibitors have demonstrated promising results in phase I trials in MDS and AML.^{205,207} Second-generation hypomethylating agents are currently in clinical trials and hold the promise of more convenient dosing schedules and improved toxicity profiles.²⁰⁵

HISTONE DEACETYLASE INHIBITORS

Histone acetylation is an important determinant of gene expression and is regulated by the addition and removal of acetyl groups from lysine amino acid residues on histones. The removal of acetyl groups facilitates chromatin compaction thereby decreasing gene expression and is mediated by HDACs. The four classes of HDACs are differentially expressed. HDACs 1 to 3 are overexpressed in many cancer types. Overexpression of these HDACs is associated with repression of tumor suppressor and DNA repair genes, and confers a poor prognosis.^{208,209} HDAC inhibitors reverse these changes. They maintain chromatin acetylation and decompaction and promote expression of tumor-suppressor genes, thereby inducing terminal differentiation and apoptosis of tumor cells. Interestingly, HDACs may paradoxically play a role as tumor suppressors as well, as knockout models in mice exhibit spontaneous tumorigenesis through a p53-mediated mechanism.^{208,210,211} HDACs deacetylate multiple nonhistone proteins, including p53 and members of the DNA repair complex, but these actions have uncertain significance.

Three HDAC inhibitors are approved for clinical use: vorinostat and romidepsin. Vorinostat is a hydroxamic acid derivative, whereas romidepsin is a natural product produced by *Chromobacterium violaceum*. Both HDAC inhibitors block the zinc-dependent enzymatic activity of these HDACs and work predominantly against class 1 HDACs (HDACs 1 to 3).²¹² In lymphoma cells, romidepsin was able to overcome the pro-survival effects of BCL-2 whereas vorinostat was not.

HDAC inhibitors are active in cutaneous T-cell lymphoma. Pabrinostat was recently approved, in combination with bortezomib and dexamethasone, for relapsed multiple myeloma. Romidepsin is useful against peripheral T-cell lymphoma. FDA approval of vorinostat was based upon an overall partial response rate of 30 percent and a median response duration of 168 days in patients with cutaneous T-cell lymphoma who had progressed on at least two prior regimens.²¹³ Romidepsin was approved for use in cutaneous T-cell lymphoma as well after clinical trials demonstrated an overall response rate of 34 percent, including 7 percent complete responses in previously treated patients.²¹⁴

Romidepsin is approved for use in patients with who have received at least one prior therapy.²¹² In these patients it achieved objective response rates of up to 38 percent. The median progression free survival for the 15 percent of patients in complete remission was 29 months.^{215,216}

Vorinostat is administered orally at 400 mg/day. It is predominantly cleared by glucuronidation and side chain oxidation by cytochrome metabolism, and should be dose reduced to 300 mg/day for mild and

moderate hepatic impairment. It is contraindicated in patients with severe hepatic impairment.²¹⁷ It has a plasma half-life of 2 hours, although histones remain hyperacetylated for many hours. Renal elimination does not play a major role in the drug's clearance.²¹⁸ Romidepsin is administered as a 4-hour intravenous infusion of 14 mg/m² on days 1, 8, and 15 of a 28-day treatment cycle. A dose reduction to 10 mg/m² is possible in patients who experience high-grade toxicities.²¹⁹ Romidepsin is metabolized primarily by CYP3A4 and by glucuronidation, and is rapidly cleared with a short half-life of approximately 3.5 hours. Asian patients with the 2B57 genotype of uridine diphosphate (UDP)-glucuronyl transferase may experience delayed clearance and increased toxicity.

Both HDACs are generally well tolerated. The most common adverse events for vorinostat are diarrhea, fatigue, nausea, and anorexia, and laboratory abnormalities including hyperglycemia, thrombocytopenia, and proteinuria.²¹³ For romidepsin, nausea, vomiting, infection, fatigue, and myelosuppression were the primary toxicities.²¹² Significant QTc prolongation and T-wave flattening but the electrocardiogram (ECG) changes were not associated with clinical cardiotoxicity. Still, it is important to ensure electrolyte levels are normalized prior to and throughout therapy.

Multiple newer HDACs have been extensively tested in clinical trials, although none has proven superior to vorinostat or romidepsin. One new agent, panobinostat, has demonstrated promising results in phase II trials against cutaneous T-cell lymphoma, Hodgkin lymphoma, and Waldenström macroglobulinemia.²⁰⁸

FUTURE EPIGENETIC TARGETS

Isocitrate Dehydrogenase 2 Inhibitors

Isocitrate dehydrogenase (IDH) is a metabolic enzyme that converts isocitrate to α -ketoglutarate (α KG) (Fig. 22–6), a cofactor in dioxygenase reaction that precedes demethylation of histones and the DNA.

Figure 22–6. Isocitrate dehydrogenase (IDH) mutations produce 2-hydroxyglutarate (2HG), an inhibitor of demethylation reactions. The R-isomer of 2HG activates *EGLN1* gene encoded enzymes, prolyl hydroxylases, which, in turn, activate the ubiquitination and degradation of hypoxia inducible factors (HIFs). (Reproduced with permission from Schulze A, Harris AL: *How cancer metabolism is tuned for proliferation and vulnerable to disruption*. *Nature* 491(7424):364–373, 2012.)

Certain cancers, including subsets of AML, gliomas, intrahepatic cholangiosarcomas, breast and lung cancers, and central chondrosarcomas harbor IDH1/2 mutations that confer a gain of function. These mutated enzymes (commonly mutated at arginine 132 of IDH1 or arginine 170 of IDH2) convert α KG to the oncometabolite (R)-2-hydroxyglutarate (2HG). High concentrations of 2HG inhibit histone and DNA demethylation by competing with the dioxygenase function of the TET family of enzymes and Jumonji-C domain (JMJC) family of histone lysine demethylases. The result of IDH mutations is hypermethylation of both DNA and histones and a block in differentiation.²²⁰ IDH1 or IDH2 mutations are present in 25 percent of AML where they confer a favorable prognosis. At the same time, IDH mutations in MDS and other myeloproliferative neoplasms may place patients at an increased risk for transformation to AML.²²¹ High levels of 2HG are measurable in plasma and urine in patients with IDH mutations, and may serve as a sensitive measure of treatment response and may reflect the presence of minimal residual disease.²²² 2HG in IDH mutant solid tumors may also be imaged by magnetic resonance imaging (MRI) spectroscopy.

Small molecule inhibitors of IDH mutant enzymes have been identified. One such inhibitor binds at the dimer interface in an allosteric fashion and exhibits uncompetitive inhibition of mutant IDH2, with great specificity for mutant IDH2 as compared to the wild-type enzyme. Mutant AML cells cultured *ex vivo* in the presence of these inhibitors undergo differentiation.²²⁰

An oral formulation of the mutant IDH2 inhibitor has shown promising remission-inducing activity in its initial clinical trial.^{220A}

DOT1L Inhibitors

Histone methylation also plays a role in transcriptional regulation. Histone methylation leads to exposure of DNA promoter sites, with effects on gene expression. DOT1L, a histone methyltransferase, catalyzes the hypermethylation of specific lysine residues on histone H3 (H3K79), and thereby regulates RNA polymerase II-mediated transcriptional elongation. In leukemias characterized by translocations involving the *MLL* gene, fusion proteins are created that recruit DOT1L to transcription factor (*HOXA9* and *MEIS1*) promoter sites, resulting in leukemogenesis. *MLL* translocations are seen in 5 to 10 percent of acute leukemias of lymphoid, myeloid, or mixed/indeterminate lineages and are especially common in infant acute leukemias and secondary AML induced by Topo II inhibitors.²²¹ An aminonucleoside DOT1L inhibitor has entered clinical trials. It occupies the S-adenosyl-L-methionine (SAME) binding pocket of DOT1L and induces conformational changes, thereby contributing to high-affinity binding and specificity of the inhibitor.

Preclinical data demonstrate nanomolar antiproliferative activity specific for *MLL*-rearranged cell lines, and in a rat xenograft model of *MLL*-rearranged leukemia, addition of the inhibitor led to complete tumor regression. Based upon these preclinical data, the DOT1L inhibitor has recently entered clinical trials in relapsed/refractory patients with leukemia involving the translocation of the *MLL* gene at 11q23 (NCT01684150).²²¹

Enhancer of Zest Homologue 2 Inhibitors

Enhancer of zest homologue 2 (*EZH2*) is the catalytic subunit of the polycomb repressive complex 2 (*PRC2*), and methylates lysine K-27 on histone H3 as well as other nonhistone targets. Monoallelic point mutations in *EZH2* lead to increased catalytic activity and hyperdimethylation or hypertrimethylation of H3K27 with concomitant transcriptional repression of DNA-damage response pathways in germinal center diffuse large B-cell lymphoma and follicular lymphoma.²²³ The Y641 residue is most commonly mutated with up to 22 percent of germinal center diffuse large B-cell lymphoma and 10 percent of follicular

lymphoma harboring the mutation.²²³ Interestingly, loss-of-function mutations of EZH2 in myeloid malignancies confer a worse prognosis, suggesting that EZH2 may act either as an oncogene or as a tumor suppressor depending on context and site of mutation.

EZH2 inhibitors have been identified through high-throughput biochemical assays using mutant EZH2 with the PRC2 complex and histone substrates. Preclinical data demonstrate increased EZH2 inhibitor selectivity for cell lines carrying activating EZH2 mutations. In mouse models with subcutaneous xenografts of diffuse large B-cell lymphoma cell lines harboring EZH2 activating mutations, marked tumor regression was observed. Based upon these results, EZH2 inhibitors are now in early phase 1 and phase 2 clinical trials in patients with relapsed and refractory diffuse large B-cell lymphoma with EZH2 mutations.²²⁴

Bromodomain and Extraterminal Inhibitors

The class of bromodomain and extraterminal (BET) family of proteins couple histone acetylation with transcriptional activation by recognizing acetylated lysine residues in histones and recruiting members of the pTEF-b complex to promoters.²²⁵ BET proteins also interact with nonhistone acetylated proteins including p53. BET inhibitors selectively bind to the high conserved bromodomains of the BET proteins thereby inhibiting their ability to bind acetylated lysine residues within histones.

Preclinical data²²⁶ with BET inhibitors demonstrate activity in both myeloma and AML, particularly in cell lines containing MLL fusion proteins or mutant NPM1c+. BET inhibitors induce early cell-cycle arrest and apoptosis via inhibition of c-MYC and other downstream targets.²²⁶ Survival benefits have also been seen in MLL mouse models. HDAC and BET inhibitors act synergistically by maintaining both histone lysine residues and p53 in an acetylated state thereby inducing greater reliance on BET mediated transcription.^{227,228} Based upon these results the first BET inhibitors have entered early phase clinical trials.²²⁹

SMALL MOLECULES WITH SPECIAL MOLECULAR TARGETS

BCR-ABL TYROSINE KINASE INHIBITORS

The era of targeted cancer therapy was pioneered in the treatment of CML with imatinib mesylate. This carefully designed compound is an inhibitor of ABL tyrosine kinase activity and particularly efficacious against the mutant ABL characteristic of the BCR-ABL fusion protein. This protein is a result of the translocation t(9;22)(q24,q11.2), also known as Philadelphia chromosome, a transforming genetic event, which produces growth factor independent proliferation and sensitizes affected leukemic cells to inhibition with imatinib and other tyrosine kinase inhibitors (TKIs).²³⁰ Imatinib was selected for clinical study by scientists at Ciba-Geigy (later Novartis) based on a high-throughput screen for kinase inhibition and was the first drug of this class approved in 2001 for the treatment of CML based on the large phase III International Randomized Study of Interferon and ST1571 (IRIS) trial, which showed induction of durable remissions in a large proportion of patients.^{231,232} Since then the three additional second-generation agents dasatinib, nilotinib and bosutinib, as well as the third-generation TKI ponatinib, have been approved for imatinib-refractory or intolerant patients (Table 22-5). Another non-TKI agent, omacetaxine is approved for patients with resistance or intolerance to two or more TKIs.²³³

Mechanism of Action

Imatinib, nilotinib, dasatinib, bosutinib, and ponatinib (Fig. 22-7) are all inhibitors of the BCR-ABL kinase, as well as the c-KIT kinase²³⁴ and the platelet-derived growth factor receptor (PDGFR) kinase. The c-KIT

kinase is the target for imatinib in the treatment of gastrointestinal stromal tumors,²³⁵ while activating mutations of PDGFR are the target of inhibition in the treatment of hypereosinophilia syndrome,²³⁶ chronic myelomonocytic leukemia,²³⁷ MDS with PDGFR rearrangement^{237A} and dermatofibrosarcoma protuberans.²³⁸ Dasatinib and ponatinib also inhibit the Src family kinases, an important secondary target in CML.²³⁹ Dasatinib (inhibiting growth by concentration 50 percent [IC₅₀] = <1 nM), nilotinib (IC₅₀ = <20 nM),²⁴⁰ bosutinib (IC₅₀ = <1 nM), and ponatinib (IC₅₀ = <1 nM and 10 nM for T315I) are more potent inhibitors of BCR-ABL compared to imatinib (IC₅₀ = 100 nM). Crystallographic and mutagenesis studies indicate that imatinib and nilotinib bind to a segment of the BCR-ABL tyrosine kinase domain that fixes the enzyme in a closed or inactive state, in which the protein is unable to bind its substrate, ATP.²⁴⁰⁻²⁴² The contact points between imatinib and the enzyme become sites of mutations in drug-resistant leukemic cells, preventing tight binding of the drug and locking the enzyme in its active configuration, in which it has access to substrate. Nilotinib has been modified to overcome a number of resistance mutations to imatinib.^{239,241,243-245} Dasatinib is unique in that it is able to bind BCR-ABL in both the active and inactive configuration, which may be one of the mechanisms that allows it to overcome resistance.²³⁹ Importantly, ponatinib is the only agent with significant activity against the most common resistance mutation T315I, a gatekeeper mutation that prevents other TKIs from binding to the ATP binding site of BCR-ABL.²⁴⁶

Clinical Pharmacology

The BCR-ABL kinase inhibitors are all well absorbed by the oral route and subject to clearance by hepatic CYP3A4 metabolism. The absorption of dasatinib and ponatinib is pH-dependent and may be affected by the use of H₂ blockers and proton pump inhibitors. The absorption of bosutinib may be impaired by concomitant magnesium intake. The bioavailability of nilotinib is increased if taken with meals and therefore should be taken on an empty stomach. Clearance of imatinib is delayed in patients with renal dysfunction, apparently as a result of decreased P450 activity in the presence of renal failure. Limited data indicate that imatinib penetrates poorly into the cerebrospinal fluid, achieving concentrations of 1 percent of simultaneous drug levels in the systemic circulation.²⁴⁷ There are no data about the penetration of other BCR-ABL inhibitors in the cerebral spinal fluid.

All FDA-approved BCR-ABL inhibitors are more than 94 percent protein bound, largely by α_1 -acid glycoprotein, a binding protein present in higher concentrations in humans than in mice.²⁴⁸ Thus, therapeutic studies in mice may overpredict drug activity. α_1 -Acid glycoprotein concentrations vary over a fourfold range in human subjects, and total drug concentrations in plasma appear to be a function of α_1 -acid glycoprotein levels. Drugs that compete for binding sites with α_1 -acid glycoprotein, such as clindamycin, displace imatinib mesylate from binding to α_1 -acid glycoprotein and, in mice, increase the concentration of drug found in cells.

There is significant variability among different BCR-ABL inhibitors with regard to their bioavailability. Imatinib has the highest bioavailability (98 percent), followed by bosutinib (23 to 64 percent), nilotinib (50 percent), and dasatinib (14 to 34 percent), while the bioavailability is unknown for ponatinib.

Despite their unparalleled benefit in the treatment of patients with CML and other malignancies, resistance to TKIs represent a major limitation. Although there are multiple mechanisms of resistance, one can divide resistance to TKIs into two general categories: primary resistance, which refers to a *de novo* lack of response to a drug, and secondary (acquired) resistance, in which resistance to a drug emerges after a period of drug response. The most important and most frequently found resistance mechanisms to TKIs are point mutations in three

TABLE 22-5. Tyrosine Kinase Inhibitors in Treatment of Chronic Myelogenous Leukemia

	Targets	Unique Pharmacokinetics	Mechanism of Clearance	Half-Life	Dosing	Drug Interactions	Toxicity
Imatinib	BCR-ABL, c-Kit, platelet-derived growth factor receptor (PDGFR)	98 percent bioavailability; transport via OCT-1	Hepatic; dose adjustments for severe hepatic and renal impairment	18 hours	Once daily at 400–800 mg	CYP3A4 inducers (dexamethasone, phenytoin, carbamazepine, etc.) CYP3A4 inhibitors (aprepitant, clarithromycin, itraconazole, etc.)	Dose-related fluid retention, heart failure, hepatotoxicity, nausea and vomiting, diarrhea, abdominal pain, skin reactions, myelosuppression
Dasatinib	BCR-ABL, c-Kit, PDGFR, Src family kinases	pH-dependent absorption	Hepatic	3–5 hours	Once daily at 100 mg or twice daily at 70 mg	CYP3A4 inducers (dexamethasone, phenytoin, carbamazepine, etc.) CYP3A4 inhibitors (aprepitant, clarithromycin, itraconazole, etc.) Antacids, H ₂ blockers, proton pump inhibitors	Fluid retention (>20%) including pleural and pericardial effusions, heart failure, hepatotoxicity, nausea and vomiting, diarrhea, abdominal pain, skin reactions, myelosuppression, QT prolongation (<i>in vitro</i>), hypocalcemia, hypophosphatemia
Nilotinib	BCR-ABL, c-Kit, PDGFR	Increased bioavailability if taken with food	Hepatic	17 hours	Twice daily at 400 mg	CYP3A4 inducers (dexamethasone, phenytoin, carbamazepine, etc.) CYP3A4 inhibitors (aprepitant, clarithromycin, itraconazole, etc.) Drugs that prolong the QT interval	Fluid retention, heart failure, hepatotoxicity, nausea and vomiting, diarrhea, abdominal pain, skin reactions, myelosuppression, QT prolongation, hypocalcemia, hypophosphatemia, elevated serum lipase and amylase
Bosutinib	BCR-ABL, SRC, LYN, HCK	Absorption may be affected by magnesium intake	Hepatic; dose adjustments for severe hepatic and renal impairment	22 hours	Once daily at 500–600 mg	CYP3A4 inducers (dexamethasone, phenytoin, carbamazepine, etc.) CYP3A4 inhibitors (aprepitant, clarithromycin, itraconazole, etc.) Antacids, H ₂ blockers, proton pump inhibitors	Myelosuppression, skin reactions, QT prolongation, Fluid retention, diarrhea, hypophosphatemia, hyper-/hypomagnesemia
Ponatinib	BCR-ABL (including T315I), VEGFR, PDGFR, FGFR, SRC, KIT, RET, TIE-2, FLT-3	pH-dependent absorption	Hepatic	24 hours	Once daily at 30–45 mg	CYP3A4 inducers (dexamethasone, phenytoin, carbamazepine, etc.) CYP3A4 inhibitors (aprepitant, clarithromycin, itraconazole, etc.) Ponatinib is an inhibitor of ABCG2 and P-glycoprotein	Arterial thrombosis, hepatotoxicity, gastrointestinal perforation, wound healing complications, hemorrhage, myelosuppression, cardiac arrhythmias, pancreatitis

different segments of the kinase domain leading to inability of the drug to effectively inhibit the BCR-ABL kinase activity.²⁴⁹ The most common mutations associated with clinical resistance affect amino acids 255 and 315, both of which serve as contact points; these mutations confer high-level resistance to imatinib and nilotinib. There is variable efficacy of different BCR-ABL inhibitors to particular resistance mutations. For example, dasatinib can bind to both the active and inactive conformation and can overcome resistance to substitution at 255 but not 315.^{241,250} Nilotinib has good activity against most resistance mutations, but lacks activity against substitutions at 255 and 315. Of all approved TKIs, ponatinib is the only agent with activity against the gatekeeper mutation T315I. In a phase II trial of heavily pretreated patients with Philadelphia chromosome positive leukemias, including those who failed dasatinib

or nilotinib and with T315I mutations, ponatinib produced major cytogenetic responses in more than half of the patients.²⁴⁶

Mutations also affect the phosphate-binding region and the “activation loop” of the domain with varying degrees of associated resistance. Some mutations, such as at amino acids 351 and 355, confer low levels of resistance to imatinib, while these tumor cells remaining sensitive to higher imatinib doses and also sensitive to both nilotinib and dasatinib.^{241,251} This may explain the clinical response of some resistant patients to dose escalation of imatinib.

Some kinase mutations known to cause drug resistance may be present at low allelic frequencies prior to initiation of therapy. Malignant cells carrying these mutations may grow out under the pressure of drug and are therefore detected at higher rates after drug exposure.

This observation was made particularly in patients with Philadelphia chromosome–positive ALL or with CML progressing to blastic crisis^{252,253} and strongly supports the hypothesis that drug-resistant cells arise through spontaneous mutation, and are further selected by drug exposure.

The site of the resistance mutation has predictive and prognostic implications. Among CML patients, mutations are detectable in some patients receiving imatinib, including one-third of those undergoing treatment in the accelerated phase and in late (longer than 4 years from diagnosis) chronic phase CML.²⁵² Most patients with mutations demonstrate clinical resistance at the time a mutation is detected, or shortly thereafter. Prior to the development of second generation TKIs, mutations involving the phosphate binding loop were associated with rapid disease progression and death within a median of 4.5 months. The availability of highly active second- and third-generation TKIs that are effective against all known kinase mutations resulted in improved disease control and overall survival in these patients.^{246,254–256} As first-line agents, nilotinib and dasatinib are similarly effective, demonstrating high rates of progression free survival and overall survival. The choice of a second-line TKI depends on disease and patient characteristics as well as the side-effect profile of the different agents. For example, currently, there is no alternative to ponatinib for CML with T315I mutation. In patients with targeted CHF or pleural effusions, dasatinib should be avoided given high rate of pleural effusions in up to 35 percent of patients. These patients should be given nilotinib or bosutinib instead. In patients with severe diabetes or a history of pancreatitis, one should avoid nilotinib and choose another second-generation TKI when possible. Patients who fail two or more TKIs, including those with T315I mutation, may also respond to omacetaxine mepesuccinate, a cytotoxic natural product that was FDA approved.²³³

In addition to kinase mutation, amplification of the wild-type kinase gene, leading to overexpression of the enzyme, has been identified in tumor samples from a few patients with resistance to treatment.²⁵⁷ The *MDR* gene, which codes for a drug efflux protein, confers resistance to imatinib experimentally²⁵⁸; thus far this mechanism has not been implicated in clinical resistance. In addition to efflux mechanisms, influx mechanisms may also play an important role. Recent studies indicate that imatinib but not nilotinib or dasatinib is taken into cells via the organic cation transporter-1 (OCT1) and that downregulation of this pathway may confer resistance.²⁵⁹

Not all resistance is explained by kinase amplification or mutation, or by pharmacokinetic factors. There is a growing awareness of the appearance of mutant Philadelphia chromosome–negative clones carrying the karyotype of myelodysplastic cells in patients receiving imatinib for CML, and a few cases of progression to MDS and AML have been reported.^{260,261} Ongoing research into novel agents for resistant CML includes evaluation of HDAC inhibitors, heat shock protein inhibitors, and targeted therapies of alternative pathways.

Adverse Effects

Imatinib, dasatinib, nilotinib, and bosutinib have modest toxicity. All cause low levels of gastrointestinal distress, including nausea and vomiting. Significant diarrhea occurs more frequently with use of imatinib and bosutinib. All can promote fluid retention resulting in peripheral edema and pleural effusions, with dasatinib causing significantly more edema than the other drugs of this class.^{262,263} Although all agents cause rashes, imatinib and bosutinib tend to promote more-severe (grades III/IV) rashes in up to one-third of patients. Mild elevation of transaminases is seen with all BCR-ABL inhibitors, but more-severe elevation with bosutinib. Bilirubinemia is a rather uncommon adverse effect but it is frequently observed with use of nilotinib. Dasatinib and nilotinib cause a prolongation of the QT interval that is not seen in patients

receiving other TKIs. Other nonhematologic adverse effects include hypophosphatemia (primarily dasatinib and nilotinib), muscle pain, pancreatitis, and weight gain (particularly imatinib). All agents can induce neutropenia, anemia and thrombocytopenia that can require transfusion support, dose reduction, or discontinuation. Most nonhematologic adverse reactions are self-limited and respond to dose adjustments. After the adverse events have resolved, many times the drug may be retitrated back to initial dosing. Ponatinib poses a clearly increased risk of arterial thrombosis, and should be used with caution in patients with a history of myocardial infarction, angina, stroke, or peripheral arterial disease.

JANUS KINASE INHIBITORS

Myeloproliferative neoplasms (MPNs) are a group of heterogeneous clonal hematopoietic stem cell disorders that include CML and “BCR-ABL–negative” MPNs polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF).²⁶⁴ A phenotypic characteristic of these disease is the accumulation of mature-appearing myeloid cells. The majority of patients with BCR-ABL–negative MPNs carry a mutation in the Janus-type tyrosine kinase (*JAK*) gene, the most common being *JAK*^{V617F}.^{265–267} Family members of the JAKs include JAK1 to JAK3 and TYK. Physiologically, JAK are necessary for intracellular signal transduction of receptors that have no intrinsic tyrosine kinase activity, such as receptors for erythropoietin (EPO), thrombopoietin (TPO), and granulocyte-macrophage colony-stimulating factor (GM-CSF).²⁶⁸ Upon ligand binding to the receptor, JAK autophosphorylation leads to binding of signal transducer and activator of transcription (STAT), which dimerizes with another STAT protein, translocates into the nucleus, and promotes transcription of STAT-responsive genes, which are involved in the control of cell proliferation, apoptosis, and cell differentiation.²⁶⁵ The substitution mutation *JAK2*^{V617F} is the most common gain-of-function alteration and occurs in 65 to 97 percent of cases in PV, 23 to 57 percent of cases in ET, and 34 to 57 percent of cases in PMF.^{261–263} Expression of this mutation results in ligand independent growth or increased sensitivity to the cytokine/growth factor.

In 2011 the FDA approved the first specific JAK inhibitor ruxolitinib (Jakafi) for the treatment of PMF, PV, and ET. This approval was the consequence of two phase III trials: Controlled Myelofibrosis Study with Oral JAK Inhibitor Treatment (COMFORT)-I trial that investigated the activity of ruxolitinib (15 mg or 20 mg orally twice daily) versus placebo in 309 patients with PMF, PV, or ET, and the COMFORT-II trial that assessed ruxolitinib versus best available therapy in 219 patients with PMF, PV, or ET.^{266,267} In the COMFORT-I trial, ruxolitinib produced greater than 35 percent spleen volume reduction (primary outcome) in 42 percent of patients at 24 weeks, improved symptom control, and overall survival compared to the placebo group. In the COMFORT-II trial 28 percent versus 0 percent of patients had greater than 35 percent spleen volume reduction, as well as superior reduction of disease-related symptoms, functionality and quality of life with modest toxicities compared to best available treatment (mostly hydroxyurea and glucocorticoids).

Mechanism of Action

Ruxolitinib inhibits all JAK kinases independent of their mutational status and to similar degree independent from the disease subtype. There is variable activity against JAK1 ($IC_{50} = 1$ nM), JAK2 ($IC_{50} = 7.2$ nM), TYK2 ($IC_{50} = 9.3$ nM), and JAK3 ($IC_{50} = 98$ nM), respectively. Molecular dynamics simulations suggest that ruxolitinib targets the ATP-binding site of the kinase in its active conformation.²⁶⁸ Administration of ruxolitinib results in decreased expression of STAT responsive genes.

Clinical Pharmacology

Ruxolitinib is orally administered, rapidly absorbed, and with a high bioavailability of at least 95 percent. It undergoes CYP3A4-dependent metabolism and is primarily eliminated in urine. The elimination half-life is approximately 3 hours. High-throughput *in vitro* screens identified mutations that confer primary resistance to ruxolitinib, including the gatekeeper mutation M929I.²⁶⁹

Adverse Effects

Most nonhematologic adverse effects are relatively infrequent and mild in nature. These include, but are not limited to, diarrhea, nausea, peripheral edema, nasopharyngitis, pyrexia, arthralgia, cough, and dyspnea. Ruxolitinib can cause anemia and thrombocytopenia that may require transfusions. However, toxicity can be ameliorated with dose reduction or treatment interruptions and only a very small portion of patients had to discontinue the drug. The rate of higher-grade neutropenia was low (~7 percent).^{266,267}

IBRUTINIB

CLL is a slowly progressive, indolent hematologic malignancy of mature B lymphocytes.²⁷⁰ For decades, alkylating agents were the mainstay for treatment of CLL, with modest benefit for survival. The addition of rituximab, an antibody directed against CD20 on B lymphocytes, improves survival in CLL patients.²⁷¹ However, subsets of patients with particular deletion, such as 17p13.1, have poor response to this treatment. Furthermore, none of the available therapies are curative.²⁷¹ Although no common driver mutation is found in CLL, Bruton tyrosine kinase (BTK), a downstream mediator of the B-cell receptor, appears to be critical for B-cell activation, proliferation, and survival. A selective BTK inhibitor, ibrutinib, was developed and proved highly active in high-risk relapsed CLL. It achieved a high rate of overall (88 percent) and progression-free survival (75 percent) at 26 months of followup.²⁷² In a subsequent phase III trial including 391 patients with previously treated CLL, ibrutinib was compared to ofatumumab (an anti-CD20 antibody approved for relapsed CLL). Ibrutinib achieved a superior overall response rate, progression-free and overall survival.²⁷³ Based on these findings, ibrutinib was granted accelerated approval by the FDA for this indication. It has also been approved for the treatment of patients with mantle cell lymphoma.

Mechanism of Action

Ibrutinib irreversibly inhibits the BTK active site by forming a covalent bond with a cysteine residue. Inhibition of the BTK results in disruption of activation of multiple downstream pathways important for B-cell activation, proliferation, and adhesion.

Clinical Pharmacology

Ibrutinib is orally administered once daily. The bioavailability has not been established. The half-life is 4 to 6 hours. Ibrutinib is metabolized in the liver primarily by CYP3A4 and only minimally cleared intact in urine (1 percent). No dose adjustments are required for liver or renal dysfunction. Dose adjustment may be necessary for patients who have more than grade 3 hematologic or nonhematologic adverse effect. Using whole exome sequencing, distinct resistance mutations were identified in six patients.²⁷⁴ In five patients, a cysteine-to-serine mutation (C481S) at the binding site of BTK was found. Interestingly, the resulting protein remains sensitive to ibrutinib; however, inhibition in this case is reversible. Three other mutations (L845F, R665W, and S707Y) found in two patients involving a downstream target of BTK, phospholipase γ 2

(PLC γ 2). Currently, it is unclear whether dose escalation may overcome these resistance mechanisms.

Adverse Effects

The vast majority of adverse effects to ibrutinib are mild in nature. Almost half of the patients experience diarrhea, and approximately one-third of patients develop upper respiratory infections, cough, or fatigue. Other adverse effects include nausea, vomiting, constipation, pyrexia, rashes, edema, hypertension, and headaches. Approximately 15 percent of patients developed grades 3 to 4 neutropenia, dose reduction allowed continuation of the drug.^{272,273}

PROTEASOME INHIBITORS

Bortezomib and Carfilzomib

This class of agents targets the ubiquitin-proteasome pathway, the complex regulatory system whereby normal and malignant cells eliminate potentially toxic misfolded proteins and control the intracellular levels of important regulatory proteins.²⁷⁵ The importance of this pathway and its substrates in diverse aspects of the pathophysiology of human tumors creates opportunities for therapeutic interventions. The multimeric 20S core particle of the proteasome exhibits three distinct proteolytic activities, namely chymotryptic, tryptic, and post-glutamyl peptide hydrolytic-like activities. Both bortezomib (previously known as PS-341) and carfilzomib (Fig. 22–8) inhibit the chymotryptic-like activity by binding to the β 5 subunit of the 20S core. Bortezomib, a boronic dipeptide, is a reversible inhibitor of the chymotryptic-like activity, while carfilzomib, an epoxyketone, forms with the β 5 subunit an irreversible adduct through two covalent bonds.²⁷⁶ Bortezomib has potent clinical activity against myeloma^{277–279} and other plasma cell dyscrasias, including amyloidosis²⁸⁰ and Waldenström macroglobulinemia,²⁸¹ and is also active in mantle cell lymphoma.^{282,283} Bortezomib induces complex molecular sequelae, such as decreased levels of antiapoptotic molecules

Figure 22–8. Bortezomib and carfilzomib.

(including nuclear factor [NF]- κ B, caspase inhibitors, and Bcl-2 family members),^{284–287} The composite outcome of these events is an irreversible commitment of myeloma cells to apoptosis,²⁸⁵ as well as the sensitization of myeloma cells to diverse established agents (e.g., alkylator,^{287,288} anthracyclines,^{287,289} and thalidomide derivatives) or investigational agents such as HDAC inhibitors²⁸⁷. As a result, bortezomib has been a key component of diverse antimyeloma combination regimens.²⁹⁰ However, patients eventually develop resistance to bortezomib or experience sensory peripheral neuropathy,²⁹¹ the main dose-limiting toxicity for this drug. Carfilzomib and other second-generation proteasome inhibitors were thus developed to circumvent these limitations. In 2012, carfilzomib received FDA accelerated approval for the treatment of myeloma patients relapsed and refractory to bortezomib and at least one thalidomide derivative.²⁹² The observation that carfilzomib can be active in some bortezomib-refractory cases has been attributed to the fact that new proteasomes must be synthesized to fully restore proteasome capacity in cells treated with this irreversible inhibitor. However, the reversible-versus-irreversible nature of a proteasome inhibitor may not be the only determinant of its clinical activity; for example, another second-generation proteasome inhibitor in clinical trials, MLN2238, and its clinically administered prodrug, ixazomib (MLN9708), exhibit preclinical²⁹³ and clinical activity in bortezomib-resistant cells, despite reversible binding to β 5.²⁹⁴

Despite the important role of the proteasome for normal cells, the administration of bortezomib and carfilzomib is associated with a clinically meaningful therapeutic window, likely because the clinically achievable levels of these agents do not completely shut down the chymotrypsin-like activity²⁹⁵ of the proteasome and also spare its other proteolytic (trypsin-like and caspase-like)²⁹⁶ activities. Consequently, there is only modest (<40 percent) decrease in the overall rate of protein degradation in either normal or tumor cells. Although normal cells can recover from this degree of perturbation, malignant plasma cells may not, because their available active proteasome particles (“proteasome capacity”) are apparently close to their functional saturation by the increased quantities of unassembled or misfolded proteins (“proteasome

load”), such as immunoglobulins.²⁹⁷ It is not yet determined, if this concept also applies to mantle cell lymphoma.

The safety profile of both bortezomib and carfilzomib includes thrombocytopenia, possibly reflecting a requirement for constitutive proteasome activity in platelets to degrade the apoptosis regulator, Bax, and preserve their normal life span.²⁹⁸ Unlike bortezomib, carfilzomib does not cause peripheral neuropathy, but cardiopulmonary side effects (e.g., dyspnea, hypoxemia, pulmonary hypertension) and serum creatinine elevations have been reported.²⁹² These differences may be explained by reports that bortezomib, but not carfilzomib, also inhibits the neuroprotective molecule, Htra2/Omi,²⁹⁹ and blocks a number of serum proteases, including cathepsin G and cathepsin A, which may contribute to renal injury.^{300–302}; inhibition of proteases may contribute to renal injury.³⁰³ The mechanistic basis for cardiopulmonary adverse events with proteasome inhibition remains under investigation.

The clinical activity of bortezomib and carfilzomib, as well as the promising early studies with additional second-generation proteasome inhibitors, has validated the notion that pathways for intracellular regulation of protein homeostasis represent an important therapeutic target for plasma cell dyscrasias, mantle cell lymphoma, and potentially other neoplasias.

● THERAPEUTIC MONOCLONAL ANTIBODIES

Monoclonal antibodies are an important class of agents for the treatment of hematologic malignancies. As a group, lymphoid cells express a variety of antigens that are attractive targets for monoclonal-based therapy, as shown in Table 22–6. Development of monoclonal antibodies against specific targets has been largely accomplished by the empiric method of immunizing mice against human tumor cells and screening the hybridomas for antibodies of interest. Because murine antibodies have a short half-life and induce a human antimouse antibody immune response, they are partially or fully humanized when used as therapeutic

TABLE 22–6. Dose and Toxicity of FDA-Approved Monoclonal Antibody-Based Drugs

Drug	Mechanism	Dose and Schedule	Major Toxicity
Rituximab	Antibody-dependent cytotoxicity, complement activation, induction of apoptosis	375 mg/m ² infusion weekly \times 4 as single agent, 375 mg/m ² infusion in combination with chemotherapy	Infusion related; late-onset neutropenia
Ofatumumab	Antibody-dependent cellular cytotoxicity, complement-dependent cytotoxicity	8 weekly followed by 4 monthly infusions during a 24-week period (dose 1 = 300 mg; doses 2 to 12 = 2000 mg)	Infusion related; late-onset neutropenia
Obinutuzumab	Direct cell death and antibody-dependent cellular cytotoxicity	100 mg infusion on cycle 1 day 1, 900 mg on day 2; 1000 mg on days 8 and 15 of cycle 1 and subsequently 1000 mg on day 1 of cycles 2 through 6 in combination with chlorambucil	Infusion reactions, neutropenia
Alemtuzumab	Complement activation, antibody-dependent cytotoxicity, possible induction of apoptosis	Escalation 3, 10, 30 mg infusion TIW followed by 30 mg TIW for 4 to 12 weeks	Infusion-related toxicity with fever, rash, and dyspnea; T-cell depletion with increased infections
Brentuximab vedotin	Antibody drug conjugate comprising an anti-CD 30 monoclonal antibody linked to mono-methylauristatin E	1.8 mg/kg infusion every 3 weeks	Peripheral neuropathy, neutropenia
⁹⁰ Y-ibritumomab tiuxetan	Targeted radiotherapy	0.4 mCi/kg infusion	Hematologic toxicity, myelodysplasia

reagents. Presently, several monoclonal antibodies have received FDA approval for non-Hodgkin lymphoma and CLL, including rituximab and alemtuzumab. Although several mechanism(s) of action have been described for monoclonal antibodies, including direct induction of apoptosis, antibody-dependent cellular cytotoxicity (ADCC), and complement-dependent cytotoxicity, the clinically important mechanisms for most antibodies remain uncertain.³⁰⁴

Monoclonal antibodies may also be engineered to combine the antibody with a toxin (immunotoxin) or a radioactive isotope (radioimmunconjugates), or to contain a second specificity (bispecific antibodies).^{305–307} For example, it is possible to conjugate an antibody with specificity to B-cell lymphomas with an antibody against CD3, which binds to and activates normal T cells, so as to enhance T-cell-mediated lysis of the lymphoma cell. One such example of a bispecific antibody blinatumomab contains anti-CD3 and anti-CD19 specificity. Monoclonal antibodies raised against the immunoglobulin idiotype on a B-cell lymphoma represent another therapeutic strategy, which was first reported in 1982 by Miller and associates.³⁰⁸

NAKED MONOCLONAL ANTIBODIES

Rituximab

Rituximab, the first monoclonal to receive FDA approval, is a chimeric antibody containing the human immunoglobulin G_1 and κ constant regions with murine variable regions. Rituximab targets the B-cell antigen CD20 expressed on the surface of normal B cells and on more than 90 percent of B-cell neoplasms, and is present from the pre-B-cell stage through terminal differentiation to plasma cells.³⁰⁹ To date, the biologic functions of CD20 remain uncertain, although incubation of B cells with anti-CD20 antibody has variable effects on cell-cycle progression, depending on the monoclonal antibody type.^{310,311} Monoclonal antibody binding to CD20 generates transmembrane signals that produce a number of events including autophosphorylation and activation of serine/tyrosine protein kinases, and induction of c-myc oncogene expression and major histocompatibility complex class II molecules.³¹² CD20 promotes transmembrane Ca^{2+} conductance through its possible function as a Ca^{2+} channel.³¹² These studies demonstrate the importance of CD20 in B-cell regulation, but do not in themselves indicate how ligation of the receptor produces cell death independent of ADCC or complement-mediated pathways.

Rituximab was initially approved as a single agent for relapsed indolent lymphomas, but it has shown activity in a wide variety of clinical settings. It is approved in combination with chemotherapy for the initial treatment of follicular and diffuse large B cell lymphoma.^{313,314} Rituximab has also been shown to be effective in combination with chemotherapy for CLL and indolent B-cell non-Hodgkin lymphomas including mantle cell lymphoma, Waldenström macroglobulinemia, and marginal lymphomas.³¹³ It is used in combination with salvage chemotherapy for many indolent and aggressive B-cell non-Hodgkin lymphomas even after prior rituximab treatment.³¹⁵ The use of maintenance rituximab has gained increased acceptance based the demonstration of delayed time to progression and improved overall survival in the relapse setting.^{316–318}

Rituximab is given by intravenous infusion both as a single agent and in combination with chemotherapy at a dose of 375 mg/m². As a single agent it is given weekly for 4 weeks with maintenance dosing every 3 to 6 months. It has a half-life of approximately 22 days.³¹⁹ Given the risk of infusional reactions, pretreatment with antihistamines, acetaminophen, and glucocorticoids have become standard. During the first administration, the rate must be increased slowly to prevent infusional reactions. Infusions are started at 50 mg/h and in the absence of infusion reactions the rate can be increased in 50 mg/h increments every 30

minutes to a maximum rate of 400 mg/h. On subsequent infusion in the absence of reactions, infusions may start at 100 mg/h and increased in 100 mg/h increments every 30 minutes to a maximum rate of 400 mg/h. Patients with a high degree of circulating tumor cells are at increased risk for tumor lysis syndrome and are given a reduced dose of 50 mg/m² on day 1 of treatment in addition to standard tumor lysis prophylaxis. The remainder of the dose can then be given on day 3.

Resistance to rituximab may occur by down regulation of CD20, impaired ADCC, decreased complement activation, limited effects on signaling and induction of apoptosis, and inadequate blood levels.^{304,320} Studies in relapsed indolent B-cell non-Hodgkin lymphoma have shown a correlation between higher mean serum rituximab levels and clinical responses,³²¹ suggesting that dose escalation may be a way to overcome rituximab resistance. Also polymorphisms in two of the receptors for the antibody Fc region responsible for complement activation, FcγRIIIa, and FcγRIIa may predict the clinical response to rituximab monotherapy in patients with follicular lymphoma but not in CLL.^{322,323}

Rituximab has a several known toxicities including infusional reactions which can be life-threatening. Most are usually mild and include fever, chills, throat itching, urticaria, and mild hypotension, all of which can respond to decreased infusion rates and antihistamines. There are reports of severe mucocutaneous skin reactions including Stevens-Johnson syndrome.³²⁴ Reactivation of hepatitis B virus also has been reported and it is recommended that patients be screened for hepatitis B prior to initiation of therapy. There also are case reports of progressive multifocal leukoencephalopathy caused by the John Cunningham virus and resulting in death.³²⁵ Hypogammaglobulinemia and delayed neutropenia may occur from 1 to 5 months after administration with resultant serious infections.^{326,327}

Ofatumumab

Ofatumumab is a fully human immunoglobulin G_1 kappa (IgG₁κ), monoclonal antibody which targets a unique epitope on the CD20 antigen found on the surface of normal and malignant pre-B and mature B cells. Ofatumumab offers many potential advantages over rituximab. It has an increased affinity for CD20 compared to rituximab.³²⁸ *In vitro* experiments have shown it is superior to rituximab in ability to induce cell lysis.³²⁸ Ofatumumab and rituximab both show similar antibody-dependent cellular cytotoxicity, but ofatumumab displays increased complement dependent cytotoxicity.³²⁹ In addition, ofatumumab is a fully human monoclonal antibody with a low incidence of human-antihuman antibody formation.³³⁰

Ofatumumab has been approved for use in patients with CLL refractory to fludarabine and alemtuzumab. In a phase II trial, 138 patients received eight weekly infusions of ofatumumab followed by four monthly infusions during a 24-week period (dose 1 = 300 mg; doses 2 to 12 = 2000 mg). The overall response rate was 58 percent with median progression-free survival of approximately 14 months.³³¹ No dose-limiting effects were observed in the phases I/II studies of ofatumumab. Most common adverse reactions (>10 percent) were infusion reactions, neutropenia, pneumonia, pyrexia, cough, diarrhea, anemia, fatigue, dyspnea, rash, nausea, bronchitis, and upper respiratory tract infections. Similar to rituximab above, ofatumumab is being investigated in combination with chemotherapy for both indolent and aggressive B cell non-Hodgkin lymphoma.

Obinutuzumab

Obinutuzumab is a third naked monoclonal antibody that targets the CD20 antigen. It differs from rituximab in that it is a glycoengineered type 2 antibody that, in preclinical studies, showed improved efficacy by inducing direct cell death and by enhanced ADCC.³³² Obinutuzumab was recently approved in combination with chlorambucil of

the treatment of patients with previously untreated CLL. This approval was based on a phase III, 781-person trial with three arms comparing single-agent chlorambucil versus chlorambucil plus rituximab versus chlorambucil plus obinutuzumab.³³³ A main feature of this trial was that it enrolled mainly older patients (median age: 73 years) with multiple medical comorbidities representative of the majority of patients diagnosed with CLL. The median progression-free survival was greatly improved in obinutuzumab plus chlorambucil arm at 26.7 months versus 11.1 months with chlorambucil alone and 16.3 months with rituximab plus chlorambucil. Obinutuzumab is similar to other monoclonal antibodies associated with infusion reactions. The first dose was split over 2 days with the patient receiving 100 mg intravenously on cycle 1 day 1 and 900 mg on day 2. Patients then received 1000 mg on days 8 and 15 of cycle 1 and subsequently 1000 mg on days 1 of cycles 2 through 6. Patients concurrently received chlorambucil orally at a dose of 0.5 mg/kg on days 1 and 15 of each cycle. This combination was, in general, well tolerated. There was a slightly increased risk of grade 3 neutropenia (33 vs. 28 percent) compared to the rituximab control group, but no increased risk of infection (12 vs. 14 percent). Other common toxicities included infusion reactions, anemia, thrombocytopenia, and leukopenia.

Alemtuzumab

Alemtuzumab is a humanized monoclonal antibody targeted against the CD52 antigen present on the surface of normal neutrophils and lymphocytes as well as most B- and T-cell lymphomas.³³⁴ CD52 is expressed at reasonable levels and does not modulate with antibody binding, making it a good target for unconjugated monoclonal antibodies. Mechanistically, alemtuzumab can induce tumor cell death through ADCC and complement dependent cytotoxicity.³³⁵ Clinical activity has been demonstrated in CLL, including in patients with purine analogue refractory disease.^{336,337} In refractory CLL, overall response rates are approximately 38 percent with complete responses of 6 percent in multiple series. Response rates in patients with untreated CLL are higher (overall response rates of 83 percent and complete responses of 24 percent).³³⁶ The most concerning side effects are acute infusion reactions and depletion of normal neutrophils and T cells. Opportunistic infections are a serious consequence, particularly in patients who

have received purine analogues.^{336,337} Patients should receive antibiotic prophylaxis against *Pneumocystis carinii* and herpes virus during treatment. Serious infections with cytomegalovirus are seen and monitoring is recommended. Alemtuzumab in combination with chemotherapy has been explored in the treatment of T-cell lymphomas but trials were limited by significant infectious complications.³³⁸

Elotuzumab, Daratumumab, and Others

A number of naked antibodies have been developed for the therapeutic targeting of myeloma. Mechanistically, this approach depends on the recruitment of ADCC, complement-dependent cytotoxicity, and apoptosis, as well as growth arrest via the selected targeting of signaling pathways (Fig. 22-9).³³⁹ Targets include surface molecules as well as signaling molecules (Table 22-7).³³⁹ Of these antibodies, one of the most promising is elotuzumab, which specifically targets CS1 (also known as SLAMF7) through which its mechanism of action includes the enhancement of NK-cell activation directly via SLAMF7 and indirectly by CD16, as well as the targeted killing of SLAMF7-expressing myeloma cells by ADCC.^{340,341} Combinatorial strategies for this particular approach have been especially promising, including regimens with lenalidomide and dexamethasone where high qualities of response and impressive progression-free survival have been seen.³⁴¹

Separately, daratumumab as a first-in-class monoclonal antibody that effectively targets CD38 has shown particularly encouraging activity as both a monotherapy and in combination.³⁴² Similarly, the CD38-targeting monoclonal antibody SAR650984 has shown impressive activity, validating this as an appropriate target as well as further supporting the therapeutic potential of this class of antibodies.^{339,340} Combination studies are ongoing and the outlook for the rational development of several monoclonal antibody combinations in myeloma now looks very promising.^{341,342}

IMMUNOTOXINS

Immunotoxins combine immune proteins such as antibodies, antibody Fab fragments, or interleukins and toxins such as ricin A chain or *Pseudomonas* exotoxin. These molecules have the advantage of the high specificity of the protein for its receptor or antigen, and its ability to

internalize once bound to its receptor, together with the potency of the toxin molecule. Two agents, denileukin diftitox (which combines IL-2 and the catalytically active fragment of diphtheria toxin) with activity in non-Hodgkin lymphoma and gemtuzumab ozogamicin (composed of an antibody that recognizes CD33 linked to a potent chemical toxin, calicheamicin) with activity in AML, show a proof of principle but have been removed from the market.^{343,344} Brentuximab vedotin is currently the only approved antibody drug conjugate for hematologic malignancies but several others are in development.

Brentuximab Vedotin

Brentuximab vedotin is an antibody drug conjugate comprising an anti-CD30 monoclonal antibody conjugated by a protease-cleavable linker to the potent antimicrotubule agent monomethylauristatin E. When brentuximab vedotin binds to CD30-expressing cells, it is internalized with proteolytic cleavage of the linker resulting in release of monomethylauristatin E, disrupting the microtubule network within the cell, and subsequently inducing cell-cycle arrest and apoptotic death of the cells.³⁴⁵ It is approved for the treatment of Hodgkin lymphoma after the failure of an autologous stem cell transplant or after the failure of at least two prior multiagent chemotherapy regimens in patients who were not candidates for transplantation. It is also approved for the treatment of patients with systemic anaplastic large cell lymphoma after the failure of at least one prior multiagent chemotherapy regimen. In a study of refractory Hodgkin lymphoma, brentuximab vedotin had an

impressive overall response rate of 75 percent and a complete remission rate of 34 percent with 96 percent of patients having some improvement in their disease.³⁴⁶ The median progression-free survival for all patients was 5.6 months but notably the median duration of response for those achieving a complete remission was 20.5 months. In refractory anaplastic large cell lymphoma, a similarly impressive overall response rate of 86 percent was seen with 57 percent of patients achieving a complete remission and 97 percent of patients having a reduction in tumor volume.³⁰⁷ The overall duration of response was 12.6 months and those in a complete remission experiencing a duration of response of 13.2 months. Dosing is at 1.8 mg/kg as an intravenous infusion every 3 weeks. Dose reductions to 1.2 mg/kg are recommended for patients with hepatic or severe renal impairment. The main toxicity is cumulative peripheral neuropathy reported in up to 54 percent of the patients in the above trials. Patients experiencing new or worsening peripheral neuropathy may require a delay, dose reduction, or discontinuation of brentuximab vedotin. Other common toxicities include neutropenia, thrombocytopenia, fatigue, and nausea.

RADIOIMMUNOCONJUGATES

Radioimmunoconjugates provide monoclonal antibody targeted delivery of radioactive particles to tumor cells.^{306,347} Iodine-131 is a commonly used radioisotope because it is readily available, relatively inexpensive, and easily conjugated to a monoclonal antibody. The β -emitter ⁹⁰Y has emerged as an attractive alternative to ¹³¹I, based on its higher energy and longer path length, which may be more effective in tumors with larger diameters. It also has a short half-life and remains conjugated, even after endocytosis, providing a safer profile for outpatient use. Clinically, radioimmunoconjugates were developed with murine monoclonal antibodies against CD20 conjugated with ¹³¹I (tositumomab) or ⁹⁰Y (ibritumomab tiuxetan). Response rates in relapsed lymphoma of 65 to 80 percent were achieved.^{306,347,348} Both drugs were well tolerated with most toxicity attributable to marrow suppression; however, there have been worrisome reports of secondary leukemias. Collaboration between treating physicians and nuclear medicine departments is required for administration. ¹³¹I tositumomab is no longer available, but ⁹⁰Y ibritumomab tiuxetan remains in clinical use and is being investigated as a consolidation therapy and as conditioning prior to hematopoietic cell transplant.

CHAPTER 23

HEMATOPOIETIC CELL TRANSPLANTATION

Andrew R. Rezvani, Robert Lowsky, and Robert S. Negrin

SUMMARY

Over the past 60 years, the field of hematopoietic cell transplantation (HCT) has evolved from experimental animal models of marrow transplantation to curative therapy for tens of thousands of people yearly who are affected by a wide variety of marrow failure states, myeloid and lymphoid malignancies, immune deficiencies, and inborn errors of metabolism. Advances in transplantation immune biology combined with improvements in supportive care have made this evolution possible and have ushered in the modern era of HCT. This chapter discusses the biologic principles and clinical applications of HCT along with its future applications. Selected results demonstrating important principles are highlighted.

Acronyms and Abbreviations: ALL, acute lymphoblastic leukemia; ALK+, anaplastic lymphoma kinase–positive; AML, acute myeloid leukemia; APC, antigen-presenting cells; ASBMT, American Society for Blood & Marrow Transplantation; ATG, antithymocyte globulin; BCNU, 1,3-bis(2-chloroethyl)-1-nitrosourea; BEAM, BCNU, etoposide, cytarabine, and melphalan; BMT-CTN, Blood & Marrow Transplant Clinical Trials Network; BU, busulfan; CIBMTR, Center for International Blood and Marrow Transplant Research; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; CMV, cytomegalovirus; CR, complete remission; CR1, first complete remission; CT, computed tomography; CXCL12, extracellular-matrix-bound stromal cell–derived factor-1; CXCR4, chemokine-related receptor 4; CY, cyclophosphamide; DAH, diffuse alveolar hemorrhage; DLI, donor lymphocyte infusion; EBMT, European Society for Blood and Marrow Transplantation; ECP, extracorporeal photopheresis; FDG, 18-fluorodeoxyglucose; FLU, fludarabine; G-CSF, granulocyte colony-stimulating factor; GI, gastrointestinal; GM-CSF, granulocyte-monocyte colony-stimulating factor; GVHD, graft-versus-host disease; GVT, graft-versus-tumor; HCT, hematopoietic cell transplantation; HCT-CI, HCT-specific Comorbidity Index; HL, Hodgkin lymphoma; HLA, human leukocyte antigen; HSC, hematopoietic stem cell; HSV, herpes simplex virus; IFN, interferon; Ig, immunoglobulin; IL, interleukin; IPS, idiopathic pneumonia syndrome; KTLS, c-kit⁺, Thy-1.1^{lo}, lineage marker^{−/lo}, and Sca-1⁺; MDS, myelodysplastic syndrome; MHC, major histocompatibility complex; MMF, mycophenolate mofetil; MSC, mesenchymal stromal cell; MTX, methotrexate; NHL, non-Hodgkin lymphoma; NIH, National Institutes of Health; NK, natural killer; NMDP, National Marrow Donor Program; PAM, Pretransplant Assessment of Mortality; PBPC, peripheral blood progenitor cell; PCA, patient-controlled anesthesia; PCR, polymerase chain reaction; PET, positron emission tomography; Ph, Philadelphia chromosome; PSGL-1, P-selectin glycoprotein ligand-1; PTLD, posttransplantation lymphoproliferative disorder; RIC, reduced-intensity conditioning; SCID, severe combined immunodeficiency; SOS, sinusoidal obstruction syndrome; SRL, sirolimus; TAC, tacrolimus; TBI, total-body irradiation; Th, T-cell helper; TKI, tyrosine kinase inhibitor; TLI, total lymphoid irradiation; TNF, tumor necrosis factor; TPN, total parenteral nutrition; T_{reg}, regulatory T cell; TRM, transplant-related mortality; UCB, umbilical cord blood; VCAM, vascular cell adhesion molecule; VOD, venoocclusive disease; VZV, varicella-zoster virus.

HISTORY

The successful clinical application of hematopoietic cell transplantation (HCT) required a century of key developmental discoveries (Table 23–1). Between 1868 and 1906, European and American investigators established that marrow cells were the source of blood cell production. In 1939, the first documented human marrow transplant was performed in a patient with gold-induced marrow aplasia.¹ The patient was infused intravenously with marrow from a brother with an identical ABO blood type. The transplant was not successful, and the patient died 5 days after the marrow infusion.

In 1922, a Danish investigator modified radiation injury in guinea pigs by shielding their femora against radiation, preventing the typical radiation-induced thrombocytopenia and hemorrhage.² This work went essentially unnoticed for more than 2 decades. The period of 1949 to 1954 was marked by a political climate concerned with the threat of continued atomic warfare, which stimulated support for experiments studying the effects of irradiation and led to the development of the field of organ and marrow transplantation. Jacobson and colleagues found that mice could survive an otherwise lethal irradiation exposure if the spleen (a hematopoietic organ in the mouse) was protected by lead foil.³ Soon afterward, Lorenz and colleagues showed that lethally irradiated mice and guinea pigs were protected by the administration of syngeneic marrow after irradiation, thereby demonstrating the therapeutic efficacy of allogeneic and xenogeneic marrow suspensions.⁴ These investigators and others considered that chemicals and/or components from the shielded spleen or infused marrow stimulated endogenous hematopoietic cell recovery after total-body irradiation (TBI).^{5–7} In 1954, Barnes and Loutit showed that if mice were immunized against marrow cells from mice of another strain and then lethally irradiated, no protection was observed by the injection of marrow cells from the strain to which they were immunized. However, if nonimmunized mice were lethally irradiated and injected with the same marrow cells, normal protection was seen and all mice survived more than 60 days. This experiment supported the cellular hypothesis of hematopoiesis and was the first to consider that hematopoietic recovery resulted from cellular repopulation and not from humoral factors.⁸

In 1956, Barnes and associates described the treatment of murine leukemia by supralethal irradiation and marrow grafting.⁹ Researchers pointed out that irradiation alone would not kill all leukemia cells, but that residual leukemia cells might be eliminated by transplanted cells through immunologic mechanisms, and the term adoptive immune therapy was coined. Their publication stimulated tremendous interest, and the period from 1956 to 1959 was characterized by an increasing appreciation of the potential application of marrow grafting to treat individuals exposed to lethal irradiation and to treat human leukemia. Thomas and colleagues began clinical studies in patients with terminal leukemias, and in 1957 described six patients treated with irradiation and intravenous infusion of marrow from healthy donors.¹⁰ Only two patients developed transient detectable donor hematopoietic engraftment, and none of the six survived beyond 100 days from the cell infusion. In 1959, Thomas and associates described a patient with terminal leukemia who received total body irradiation (TBI) and an intravenous infusion of marrow from an identical twin.¹¹ The patient showed prompt hematopoietic recovery and disappearance of the leukemia for 4 months, confirming for the first time that lethal irradiation followed by compatible marrow could have an antileukemic effect and restore normal marrow function. In the same year, Mathé and associates reported the infusion of marrow into six patients exposed to potentially lethal irradiation in a reactor accident in Belgrade, Serbia.¹² Five patients survived, yet there was no clear evidence of donor hematopoietic

TABLE 23–1. Key Historical Periods in Hematopoietic Cell Transplantation

Years	Event
1868–1906	Discovery that marrow was the source of the various blood cell types
1896–1900	Discovery of ABO system making blood transfusions possible
1939	First documented clinical marrow transplant
1949–1954	Development of preclinical models of marrow and organ transplantation
1956–1959	Early efforts of marrow grafting to treat human diseases
1960–1965	Development of the hierarchical stem/progenitor cell model of hematopoiesis
1960s	Period of pessimism for the clinical application of marrow grafting for the treatment of human diseases
1968–1969	First successful allogeneic HCT in patients with SCID
1975	First successful series of allogeneic HCT for leukemia
1978	First successful series of autologous HCT for leukemia
1988	Isolation of the murine HSC
1990	Nobel Prize in Physiology or Medicine awarded to Dr. E.D. Thomas
2008	More than 700,000 patients worldwide transplanted, more than 125,000 have survived 5 years or beyond after transplantation

HCT, hematopoietic cell transplantation; HSC, hematopoietic stem cell; SCID, severe combined immunodeficiency.

engraftment and thus no firm agreement over the contribution of marrow transplantation to patient recovery.

The first attempts at autologous marrow transplantation appeared during this time as well. In 1958, Kurnick and colleagues described two patients with metastatic cancer whose marrow was collected and stored by freezing.¹³ Following intensive radiation therapy, the marrow was thawed and infused intravenously. One patient died from transplantation complications, while the other showed hematopoietic recovery after a prolonged period of pancytopenia. In Philadelphia, an autologous marrow transplant was carried out after high-dose nitrogen mustard conditioning in a patient with malignant lymphoma who lived for more than 30 years after transplantation, the majority of that time in complete remission.¹⁴

Despite the many successful preclinical models of marrow transplantation and the predictive value of *in vitro* histocompatibility testing, the period of 1960 to 1967 was marked by increasing pessimism about allogeneic marrow grafting in humans. In a published compendium of 203 human allogeneic marrow grafts carried out throughout the 1950s and 1960s, none were considered successful.¹⁵ The first positive results came from studies of children with severe combined immunodeficiency (SCID). In 1968, Gatti and colleagues performed the first successful allogeneic marrow HCT in a child with SCID.¹⁶ The lymphoid elements of the donor graft corrected the immunodeficiency, and two similar

cases were reported shortly thereafter.^{17,18} These patients remained alive and well 25 years later.¹⁹

These successes stimulated a resurgence of enthusiasm for marrow transplantation, and by 1975 strikingly improved results were published by the Seattle team.²⁰ These investigators reported the outcomes of 37 patients with aplastic anemia and 73 patients with leukemia who had reached an advanced stage of their disease before transplantation. This study stressed the importance of histocompatibility and proper preparation of the patient before transplantation, detailed the technique of marrow transplantation, emphasized the role of posttransplant immunosuppression and supportive care, and raised the possibility of using unrelated donors. This report ushered in the modern era of allogeneic HCT. In 1977 and 1980, the first successful HCT procedures from unrelated marrow donors were reported.^{21,22} At the end of 1978, the first series of successful autologous HCT for lymphoma were reported.^{23,24} In 1990, the Nobel Prize in Physiology or Medicine was awarded to E. Donnall Thomas in recognition of his pioneering work in the field of marrow transplantation. By 2013, more than 700,000 patients worldwide had undergone transplantation during the previous 3 decades and more than 19,000 transplants were being performed annually.²⁵

● STEM CELL MODEL OF HEMATOPOIESIS

At the single-cell level, stem cells self-renew and give rise to progeny that differentiate into functional cells carrying out specific functions (Chap. 18).²⁶ Progenitor cells can be multipotent, oligopotent, or unipotent, but lack self-renewal capabilities. Hematopoietic stem cells (HSCs) are cells that give rise to more HSCs and form all elements of the blood. HSCs are entirely responsible for the development, maintenance, and regeneration of blood-forming tissues for life, and are the most important, if not the only, cells required for successful engraftment in hematopoietic transplantations.²⁶ In the adult mouse marrow, all HSC activity is contained in a population marked by the composite phenotype of $c\text{-kit}^+$, $\text{Thy-1.1}^{\text{lo}}$, lineage marker^{-/lo}, and Sca-1^+ (designated KTLS).^{27,28} When transplanted at the single-cell level into irradiated mice, KTLS HSCs gave rise to lifelong hematopoiesis, including a steady state of thousands of HSCs with more than 10^9 blood cells produced daily in the mouse.^{27–29} In humans, the combination of positive selection for CD34, Thy-1, and negative selection for lineage markers identified a homologous HSC population.³⁰

Following the success in rodent models, purified populations of human HSCs were tested in three separate clinical trials of patients with myeloma, non-Hodgkin lymphoma (NHL), and metastatic breast cancer.^{31–33} The goal of these trials was to purify HSC and thereby reduce the risk of occult malignant cells contaminating the autografts. These trials presented technical challenges primarily because of the rarity of HSC in marrow and granulocyte colony-stimulating factor (G-CSF)-mobilized blood. However, adequate numbers of HSC could be isolated that were tumor-free in the majority of patients. The times to neutrophil and platelet recovery following purified HSC infusion were comparable to those seen with unmanipulated marrow, but T-cell recovery (especially that of CD4+ T cells) was delayed by up to 6 months in almost all patients. A number of patients developed unusual infections (e.g., severe cases of influenza, respiratory syncytial virus, cytomegalovirus [CMV] and *Pneumocystis pneumonia*), thus raising concern over “pure” HSCs as the sole source of hematopoietic reconstitution in clinical transplantation. Although these studies were not powered to detect an impact of purified HSCs on relapse or overall survival, these outcomes

appeared favorable compared to historical controls.³⁴ Cotransplantation of antigen-specific mature T cells is being investigated as an approach to address the T-cell-specific immunodeficiency seen in patients receiving purified HSC autografts.³⁵

● TRAFFICKING AND HOMING OF HEMATOPOIETIC STEM CELLS

The ability of HSCs to migrate from marrow to blood and back has been conserved throughout evolution. Although the biologic role and physiologic significance of constitutive HSC circulation remains unclear, this capacity to traffic leads to hematopoietic cell reconstitution and is essential for the success of HCT in the treatment of hematologic and nonhematologic diseases.

The restoration of adequate hematopoiesis after transplantation requires a series of balanced interactions between the infused HSCs and the complex supporting marrow microenvironment (Chap. 5). Initially, infused HSCs must adhere to the marrow endothelium with sufficient strength to overcome the shear forces of blood flow.³⁶ Adhesion and arrest of HSCs are mediated primarily by the selectin ligand P-selectin glycoprotein ligand-1 (PSGL-1) and by the hematopoietic cell L- and E-selectin ligands, which interact principally with endothelial E-selectin.^{37,38} Other HSC surface adhesion molecules that mediate adherence to the marrow endothelium include members of the integrin superfamily, principally very late antigen-4, integrin $\alpha 4\beta 7$ and lymphocyte function antigen-1, that interact with endothelial immunoglobulin (Ig) superfamily receptors (e.g., vascular cell adhesion molecule [VCAM]-1), and the hyaluronate receptor CD44.^{39,40} HSCs that are null for the β integrins cannot migrate to their marrow niche even though they proliferate and differentiate in the fetal liver.⁴¹ Following firm adherence, the transendothelial movement and intraparenchymal homing to hematopoietic niches within the inner endosteal surface of the bone are predominantly regulated by a gradient of extracellular-matrix-bound stromal cell-derived factor-1 (also known as CXCL12).¹² Mice deficient in CXCR4 develop fetal liver hematopoiesis but die prenatally as a consequence of the lack of marrow hematopoiesis.⁴² The requirement for CXCR4 expression on HSCs for homing and engraftment is well-documented,⁴³ and has led to the development of CXCR4 antagonists such as plerixafor, which help mobilize marrow stem cells for clinical use.⁴⁴

Following successful homing, the initial adhesion of HSC within the hematopoietic niche appears to be regulated at least in part by annexin II.⁴⁵ The marrow niche is a complex biologic unit that includes potentially self-renewing mesenchymal stromal cells (MSCs), regulatory T cells (T_{reg}), and cells with the defined phenotype of parathyroid-hormone-receptor-bearing osteoblasts.^{46,47} MSCs promote engraftment when cotransplanted with HSCs.⁴⁸ Osteoblasts, possibly in conjunction with sinusoidal endothelial cells, also appear to play a pivotal role in the regulation of HSC engraftment by producing a number of molecules, such as annexin II, VCAM-1, intercellular adhesion molecule-1, CD44, CD164, and osteopontin, which promote engraftment.^{49,50} Stimulation of osteoblasts with parathyroid hormone results in expansion and mobilization of the HSC pool in animals,⁵¹ although a clinical trial in human cord-blood recipients did not demonstrate a benefit.⁵² In addition to the regulators of HSC adhesion and homing, the function of HSCs is further regulated by intrinsic genetic programs for quiescence, self-renewal, proliferation, differentiation, and apoptosis that are dependent on communication with a network of interacting cells in the marrow microenvironment, including various T-cell subpopulations, adipocytes, and fibroblasts. Given the complexity of HSC trafficking and control, it is surprising that clinical HCT has a relatively low rate of graft failure.

● SOURCES OF HEMATOPOIETIC CELLS

In humans, HSCs for transplantation can be collected from several sources, including directly from the marrow; from the blood after mobilization; and from umbilical cord blood (UCB) obtained at the time of delivery.

MARROW

Marrow has historically been the traditional source of HSCs for allogeneic and autologous transplantation. Marrow for transplantation is typically aspirated by repeated placement of large-bore needles into both sides of the posterior iliac crest, generally involving 50 to 100 aspirations per side, with the patient under regional or general anesthesia. The lowest cell dose which ensures stable long-term engraftment has not been defined with certainty; typical collections contain at least 2×10^8 total nucleated marrow cells per kg of recipient body weight. Current guidelines indicate that collection of up to 20 mL/kg of donor body weight is considered safe.

Marrow harvesting is considered a very safe procedure, and serious side effects are rare. A review of almost 10,000 healthy adult volunteer unrelated donors by the National Marrow Donor Program (NMDP) found that the risk of serious adverse events was 2.38 percent, most of which were mechanical or anesthesia-related and self-limited. Unexpected, life-threatening, or chronic complications occurred in 0.99 percent of donors.⁵³ Evaluation of pediatric marrow donor safety is more limited, but a safety review of 453 pediatric donors by the European Group for Blood & Marrow Transplantation (EBMT) found no serious adverse events; pain was the most common complaint but lasted a median of only 1 day after donation.⁵⁴ A survey of pediatric transplantation hematologists confirmed that 90 percent of centers were willing to perform a marrow harvest on children, even on those younger than 6 months old.⁵⁵

BLOOD

HSCs are normally present in the blood at very low levels. However, a number of different stimuli, including chemotherapy, hematopoietic growth factors, and inhibitors of certain chemokine receptors, result in the mobilization of HSC from marrow to blood. Once mobilized, HSC can be collected by apheresis; this product has been termed “peripheral blood progenitor cells (PBPCs)” to differentiate it from “blood stem cells,” a term that should be reserved for instances where the HSC population itself has been isolated. Agents used to mobilize HSCs include G-CSF, granulocyte-monocyte colony-stimulating factor (GM-CSF), interleukin (IL)-3, thrombopoietin, and the CXCR4 antagonist plerixafor.^{44,56,57}

Autologous PBPCs are most commonly mobilized with G-CSF, with or without additional chemotherapy. In contrast, PBPCs for allogeneic HCT are typically mobilized with G-CSF alone, so as to avoid exposing healthy donors to chemotherapy. PBPC mobilization and collection is very safe; a review of nearly 7000 healthy unrelated PBPC donors performed by the NMDP found that the rate of serious adverse events was 0.56 percent, making PBPC donation significantly safer than marrow donation.⁵³ The most common side effect of PBPC mobilization and collection is bone pain as a result of G-CSF administration. More serious side effects, such as splenic rupture or intracranial hemorrhage, have been described in case reports but are extremely rare.^{58,59}

Theoretical concern exists about the potential of short-term growth factor therapy to increase the risk of leukemia in normal donors. However, long-term followup of healthy adult PBPC donors has shown

no late effects of G-CSF administration or donation—in particular, no increased risk of cancer, autoimmune disease, or stroke.⁵³ Detailed white cell subset analysis by fluorescent-activated cell sorting of healthy donors at 1 year after donation shows no changes in B, T, and natural killer (NK) cells or monocytes and neutrophils compared with analysis before G-CSF administration.⁶⁰

The adequacy of PBPC products is generally measured through the absolute number of CD34+ cells per kg of recipient body weight. Most laboratories measure CD34+ cell content by fluorescent-activated cell sorting. A threshold of greater than 2×10^6 CD34+ cells/kg is often considered the minimum acceptable dose for PBPC products, although successful engraftment can occur with lower doses.⁶¹ Platelet recovery appears most impacted by low PBPC CD34+ cell dose. Higher CD34+ cell doses are associated with more rapid engraftment, and thus a dose of equal to or greater than 4×10^6 CD34+ cells/kg is considered optimal.⁶¹ The impact of very high CD34+ cells doses in allogeneic HCT is somewhat unclear; some studies have associated doses greater than 8×10^6 CD34+ cells/kg with a higher risk of extensive chronic graft-versus-host disease (GVHD) in matched-related-donor HCT, although this association was not confirmed in unrelated-donor allogeneic HCT. Because there is no evidence of benefit for CD34+ cell doses greater than 8×10^6 /kg in allogeneic HCT, this threshold is sometimes, although not universally, used as a maximum.⁶¹

Although inadequate mobilization of healthy donors is rare, patients with malignancies undergoing mobilization for autologous HCT often have difficulty collecting adequate numbers of CD34+ cells because of marrow damage from previous chemotherapy or radiation therapy. Approximately 10 to 20 percent of patients preparing for autologous HCT do not mobilize sufficient numbers of CD34+ cells using G-CSF alone or in combination with chemotherapy. Unfortunately, it has proven difficult to identify these individuals prospectively. For patients with NHL, Hodgkin lymphoma (HL), and myeloma who fail mobilization with G-CSF alone, the majority proceed to collect a transplantable dose of CD34+ cells ($>2 \times 10^6$ cells/kg) when remobilized with plerixafor plus G-CSF.⁶² Studies of allogeneic HCT using plerixafor-mobilized grafts have also confirmed prompt and stable donor cell engraftment.⁶³ Animal models suggest that plerixafor-mobilized PBPCs have a different phenotype and cytokine profile than G-CSF-mobilized PBPCs and may be associated with a higher risk of acute GVHD; however, the relevance of these findings to human allogeneic HCT is unclear.⁶⁴ For patients who are thought to be at high risk of poor mobilization, strategies include the upfront use of plerixafor and/or chemotherapy to supplement G-CSF mobilization, as well as large-volume leukapheresis.⁶¹ In 2014, the American Society for Blood & Marrow Transplantation (ASBMT) published guidelines on the mobilization and collection of PBPCs for autologous and allogeneic HCT.⁶¹

There is some evidence that circadian activity in the hypothalamus regulates the cyclic release of HSCs by altering the expression of CXCL12 in the marrow microenvironment, with the peak time for HSC release in humans in the evening.⁶⁵ Preliminary clinical data suggest that CD34+ yield is higher in donors collected in the later afternoon compared to the morning, and more abundant PBPC collections were reported from healthy donors when apheresis was performed at 8:00 PM as opposed to 8:00 AM.⁶⁶ Efforts to exploit this circadian rhythm dependence to increase HSC yield in PBPC products have thus far been inconclusive.⁶⁷

Mobilized Peripheral Blood Progenitor Cells versus Marrow

In the setting of autologous HCT, the superiority of PBPCs over marrow as a stem-cell source is clear. Randomized trials have shown that PBPC autografts in this setting are associated with more rapid engraftment, better quality of life, and lower costs compared to marrow autografts.^{68–70}

On the basis of these and other results, most transplantation centers use mobilized PBPCs for autologous HCT and have adopted a minimum CD34+ cell of 2×10^6 CD34+ cells/kg.⁶¹

In the allogeneic setting, the situation is considerably more complex. PBPC grafts contain approximately 10-fold more T cells compared to marrow grafts, leading to concern over a potentially increased incidence and severity of GVHD. At the same time, G-CSF can induce functional immune tolerance in healthy individuals, and T cells from G-CSF-mobilized PBPC grafts show a predominantly immune-tolerant profile with upregulation of genes related to T-cell helper type 2 (Th2) and T_{reg} cells, and downregulation of genes associated with Th1 cells, cytotoxicity, antigen presentation, and GVHD.⁷¹

A number of randomized clinical trials have compared PBPC and marrow grafts in the setting of allogeneic HCT.^{72–75} These studies have consistently reported similar or better overall and disease-free survival with PBPCs compared to marrow allografts. Most, although not all, of these randomized trials found a higher risk of chronic GVHD with PBPCs compared to marrow allografts, and one reported a longer duration of immunosuppression in patients receiving a PBPC graft.⁷³ PBPC allografts were also associated with faster engraftment and a lower risk of graft failure. Systematic reviews and meta-analyses have similarly reached varying conclusions.^{76–78} A 2014 systematic review performed by the Cochrane Library found that overall survival was similar with PBPC and marrow allografts, and that PBPC allografts were associated with faster engraftment but also a higher incidence of chronic GVHD. The effects of stem cell source on relapse and on acute GVHD were unclear.⁷⁶

Currently, the choice between PBPCs and marrow allografts is generally individualized and depends on patient, donor, and institutional considerations. Patients with advanced or high-risk hematologic malignancies may preferentially be given PBPC grafts to reduce their risk of relapse, a strategy with some support in the literature.⁷⁹ Conversely, patients with standard-risk malignancies are often given marrow allografts to reduce their risk of chronic GVHD. Likewise, patients transplanted for nonmalignant diseases such as aplastic anemia are typically given marrow allografts to reduce their risk of chronic GVHD, as they derive no benefit from T-cell-mediated graft-versus-malignancy effects. In settings where the risk of GVHD is particularly high—for example, with human leukocyte antigen (HLA)-mismatched unrelated donors—many institutions prefer to use marrow allografts to mitigate this risk. For patients receiving reduced-intensity conditioning (RIC), most centers use PBPC allografts exclusively, as engraftment in this setting is largely dependent on the presence of donor T cells in the allograft. Donor factors also play a role in the choice of allograft product, as some donors may specifically decline either marrow donation or PBPC mobilization and collection. Finally, with the recent predominance of PBPC as a graft source, institutional resources for and expertise in marrow collection have decreased, sometimes limiting the availability of marrow allograft products.

ALTERNATIVE SOURCES OF HEMATOPOIETIC STEM CELLS

One of the most significant advances in allogeneic HCT in the past 10 years is the increasing experience with alternative donors for patients who lack HLA-identical siblings or suitably HLA-matched unrelated donors. Each full sibling has a 25 percent chance of being HLA-identical with another, so the likelihood of finding an HLA-identical sibling donor is proportionate to the number of siblings available. HLA-matched unrelated donors can be identified for approximately 75 percent of patients of northern European ancestry, but the odds of finding a suitable unrelated donor are much lower for patients who belong to ethnic groups that are underrepresented in donor registries,

those of mixed ethnicity, and those with uncommon HLA haplotypes.⁸⁰ As a result, a substantial fraction of patients who would benefit from allogeneic HCT lack “conventional” related or unrelated donors. For such patients, there are two widely used alternative sources of HSC for allogeneic HCT: UCB and HLA-haploidentical family members.

Umbilical Cord Blood

UCB, collected from the umbilical vessels in the placenta at the time of delivery, is a rich source of HSCs. Because these cells are immunologically naïve, it is feasible to cross major histocompatibility barriers, thus extending the donor pool to individuals for whom finding suitably HLA-matched adult donors can be difficult or impossible.⁸¹ The first successful allogeneic HCT using UCB, in a child with Fanconi anemia, was reported by Gluckman and colleagues in 1989.⁸² Since then, hundreds of thousands of UCB units have been collected and stored; searchable registries have been established to facilitate identification of suitable UCB units for transplantation; and more than 20,000 allogeneic HCTs have been performed using UCB.⁸³ Cord blood units are fully HLA-typed before cryopreservation, and thus suitable units can be rapidly identified (as compared to unrelated-donor searches, which can take 2 to 6 months to complete).

Most UCB units are HLA-typed as HLA-A and HLA-B using low-resolution (serologic) methods, and as HLA-DRB1 using high-resolution (molecular) methods. UCB units matched at equal to or greater than 4/6 HLA loci are generally considered suitable for use, although UCB units matched at 5/6 or 6/6 HLA loci should be used if available because they are associated with lower transplant-related mortality.^{84,85} The role of HLA matching between UCB units in double UCB transplantation remains somewhat unclear, and unit-to-unit HLA matching does not appear to impact long-term engraftment rates or GVHD incidence.^{85,86}

A major limitation has been the relatively small number of HSC available in cord blood units relative to the size of the average adult recipient.⁸⁷ As a result, most UCB transplants in adults use two UCB units rather than one. The minimum acceptable cell doses for single-unit UCB transplantation are generally set at equal to or greater than 2.5×10^7 total nucleated cells or equal to or greater than 2×10^5 CD34+ cells/kg of recipient weight.^{84,88} It is difficult to locate units meeting these criteria for average-sized adult recipients, and thus most adult UCB transplants are performed using two UCB units. With double UCB transplantation, transient mixed donor chimerism from the two units is often observed, but ultimately one UCB unit dominates, eradicates the other unit, and is responsible for establishment of long-term hematopoiesis.⁸⁶ Despite extensive investigation, the factors determining which unit becomes dominant remain somewhat unclear,⁸⁹ although CD8+ T-cell responses against the nonengrafting unit have been implicated.⁹⁰ For recipients with a single suitable sized UCB unit, single-unit UCB transplantation is preferable to double UCB transplantation, because of better platelet recovery and a lower risk of GVHD.⁸⁸ For the majority of adult recipients, who lack a suitable single UCB unit, double UCB transplantation is typically used and produces equivalent overall survival.⁸⁹ For children, a single UCB unit appears superior to double UCB transplantation.⁸⁸ A major area of active research in UCB transplantation is the expansion of HSC or other hematopoietic progenitor cells in UCB products, with the goal of improving engraftment rates, shortening the period of preengraftment neutropenia, and reducing the need for double-unit UCB transplantation. Several approaches have been described in the literature, including Notch-mediated or prostaglandin-mediated expansion of progenitor cells and *ex vivo* mesenchymal cell coculture.^{91–93}

Recipients of UCB allografts have a higher risk of opportunistic infections—particularly viral infection or reactivation—compared to

recipients of PBPC or marrow allografts. Presumably the immunologic naïveté of UCB, which allows its use across HLA barriers, also contributes to impaired antiviral immunity and immune reconstitution after allogeneic HCT.⁹⁴ CD8+ T-cell recovery is significantly delayed after UCB compared to marrow allotransplantation (median time to reach $>0.25 \times 10^9$ CD8+ T cells/L, 7.7 months vs. 2.8 months, respectively), whereas CD4+ T cell and NK cell recovery is similar with these two graft sources.⁹⁵ A novel syndrome of cord colitis has been described in UCB recipients and tentatively linked to *Bradyrhizobium enterica*, a newly identified bacterium,^{96,97} although other groups have questioned the existence of a distinct cord colitis syndrome and instead attributed the findings in question to conventional GVHD.^{98,99}

Human Leukocyte Antigen–Haploidentical Donors

Virtually all patients have HLA-haploidentical family members—including any parent, any child, and some siblings—available as donors. Haploidentical related donor HCT has been evaluated for more than 2 decades as an alternative source of HSCs. However, as a result of the substantial HLA disparity involved, early attempts at haploidentical HCT were associated with severe GVHD in T-cell-replete transplants and with graft rejection in T-cell-depleted transplants.^{100,101} Extensive *ex vivo* depletion of CD3+ and CD19+ lymphocytes, coupled with megadose CD34+ cells and antithymocyte globulin, can successfully overcome the barriers to engraftment.¹⁰² The extensive T-cell depletion used in these protocols to prevent GVHD would also be expected to result in weak or no graft-versus-malignancy effects. Yet despite the lack of T-cell-mediated alloreactivity and the unfavorable prognostic features at the time of transplantation, relapse rates with this approach remained at 18 to 30 percent in patients with acute leukemia transplanted in first complete remission (CRI).¹⁰³ The low rate of relapse was attributed to a strong antitumor effect mediated by donor NK cell alloreactivity. Transplantation from NK-cell-alloreactive donors was associated with a significantly lower leukemia relapse rate and improved overall survival, leading some authorities to recommend selection of haploidentical donors based on NK cell alloreactivity.¹⁰⁴ However, this approach to haploidentical HCT remains hampered by prolonged immune reconstitution and a high risk of serious infection.¹⁰⁵

More recently, the group at Johns Hopkins has pioneered the use of posttransplantation cyclophosphamide (CY) as GVHD prophylaxis in T-cell-replete haploidentical HCT.¹⁰⁶ In this approach, unmanipulated marrow from an HLA-haploidentical donor is infused after nonmyeloablative conditioning. A period of 48 to 72 hours elapses after infusion, during which alloreactive donor T-cell clones become activated and proliferate. CY is then administered on days +3 and +4 after allogeneic HCT, preferentially eradicating the activated alloreactive donor T-cell clones while leaving other, nonalloreactive clones relatively untouched.¹⁰⁷ This approach has been remarkably well-tolerated and results in very low rates of GVHD and transplant-related mortality (TRM).¹⁰⁸ Additionally, because this approach avoids indiscriminate T-cell depletion, immune reconstitution is relatively robust, and the typical complications of T-cell-depleted allotransplantation (such as posttransplantation lymphoproliferative disorder [PTLD]) are not seen.¹⁰⁹ The major limitation of this approach is a relatively high rate of relapse, perhaps driven by the eradication of the alloreactive donor T-cell clones which would mediate graft-versus-tumor (GVT) effects along with those mediating GVHD.¹⁰⁸

Retrospective studies have examined the question of selecting the optimal HLA-haploidentical donor when several such donors are available. Early evidence suggested that lower TRM was seen with HLA-haploidentical sibling donors compared to parental donors, while maternal donors were associated with less chronic GVHD and better

overall survival than paternal donors.^{110,111} In contrast, a 2014 paper reporting outcomes of HLA-haploidentical HCT in China found less GVHD and better overall survival with paternal compared to maternal donors.¹¹² As with previous studies, haploidentical siblings (particularly those disparate for noninherited maternal antigens) were associated with the best outcomes. There is some preclinical evidence that exposure to noninherited maternal antigens through breastfeeding may reduce the risk of GVHD in maternal-donor haploidentical HCT,¹¹³ and thus the disparate clinical results with maternal donors may be explained in part by variations in demographic patterns of breastfeeding. In view of the conflicting state of the existing literature, there is no universal standard approach to selecting an HLA-haploidentical donor; the decision is often guided by donor availability and health status, although the literature arguably contains weak support to prefer HLA-haploidentical siblings over parents, and mothers over fathers, as donors.

Comparison of Alternative Donor Options

Although both UCB and HLA-haploidentical HCT have been established as feasible and effective options for patients lacking conventional donors, the optimal alternative-donor source remains unclear. Given the lack of robust comparative data, the choice between UCB and haploidentical HCT is often guided by institutional experience, comfort level, and research priorities. To address the relative merits of these approaches, the United States Blood & Marrow Transplant Clinical Trials Network (BMT-CTN) conducted parallel multicenter phase II clinical trials of RIC followed by either UCB or haploidentical HCT (the latter using T-cell-replete marrow as a graft source and posttransplantation CY as GVHD prophylaxis). These trials reported similar overall and disease-free survival at 1 year with the two approaches.¹⁰⁸ UCB transplantation was associated with a higher risk of GVHD and nonrelapse mortality, while haploidentical HCT was associated with a higher risk of relapse. Based on these results, the BMT-CTN is currently conducting a national, multicenter phase III clinical trial randomizing participants between UCB and haploidentical HCT. In addition to clinical outcomes, this trial is designed to measure quality-of-life and cost differences between the two alternative-donor approaches in a comprehensive effort to clarify their relative advantages and disadvantages.

CONCEPTS OF CURATIVE THERAPY

AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION

The relationship between the dose of chemoradiotherapy administered and the number of tumor cells killed has been extensively studied *in vitro* and in preclinical animal models, and forms the rationale for myeloablative autologous HCT. For chemosensitive tumors (including most hematologic malignancies), a steeply rising dose–response curve is observed. The curative potential of autologous HCT is, therefore, derived from high-dose chemotherapy or chemoradiotherapy administered as transplant conditioning to enhance tumor cell kill and overcome drug resistance. This level of dose escalation is possible in autologous HCT because dose-limiting toxicities to the hematopoietic system are circumvented by the infusion of autologous HSCs, which rebuild hematopoiesis after high-dose conditioning.

Autologous HCT is associated with relatively low TRM. The use of mobilized PBPCs rather than marrow as a graft source has decreased the duration of neutropenia, and when combined with improved supportive care and patient selection has reduced the TRM associated with autologous HCT from approximately 8 to 10 percent in historical studies to 1 to 3 percent at most centers. In addition, the reduced risks and

faster engraftment times seen with PBPC have enabled many centers to pursue outpatient autologous HCT, further easing the logistical burden on patients as well as treatment costs.

Tumor Contamination in the Autograft

A consistent concern in autologous HCT is the possibility that residual tumor cells may contaminate the HSC product and contribute to relapse. The relative contributions of autograft contamination and residual disease in the patient are difficult, if not impossible, to distinguish. Several investigators have approached this question by marking the HSC product at the time of harvest and then assaying for the marker gene in malignant cells at the time of subsequent relapse. Studies using this approach have been performed in patients with leukemia, lymphoma, and myeloma, and have reached conflicting conclusions about the contribution of autograft contamination to relapse.^{114,115}

A number of *ex vivo* and *in vivo* purging strategies have been investigated in autologous HCT. These include administration of rituximab before autologous HSC collection in patients with CD20+ malignancies; *ex vivo* positive selection for CD34+ cells; chemotherapy-based purging using CY derivatives; and purging via oncolytic viruses.^{116–120} Single-arm or uncontrolled studies have suggested a possible benefit in some of these instances, but there is little or no evidence from randomized clinical trials at present to support the efficacy of autograft purging, and its use remains investigational. One of the few randomized clinical trials in the field concluded that *in vivo* purging with rituximab administered before autologous HSC collection was as effective, and likely safer, than *ex vivo* CD34+ selection.¹²¹ Another randomized clinical trial found that CD34+ selection significantly reduced autograft contamination with myeloma cells, but did not improve clinical outcomes.¹²² Purging strategies carry some potential for harm, as they deplete the autograft of mature T cells and increase the risk of infectious complications, particularly CMV or other viral reactivation, after autologous HCT.^{123,124} At present, given the lack of convincing evidence of clinical benefit, purging strategies are not widely used and most centers collect and infuse unmanipulated autologous HSC (although these cells are often mobilized with a regimen containing chemoimmunotherapy, which arguably represents a form of *in vivo* purging). Because relapse remains a major concern after autologous HCT, ongoing research is focused on identifying more efficient and clinically effective means of autograft purging.

ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION

Allogeneic HCT is a considerably more complicated procedure than autologous HCT. It involves more pretransplantation preparation, poses a greater risk of complications to the patient, is associated with a significantly higher rate of TRM, and requires at least temporary postgrafting immunosuppression to enable engraftment and prevent GVHD. The decision to pursue allogeneic HCT is based on diagnosis, prognosis, and remission status, as well as the availability of an appropriate donor and the psychosocial resources of the patient to cope with the demands of the process. Decisions about eligibility for allogeneic HCT are typically made on a center-by-center and case-by-case basis, with inherent elements of subjectivity and patient and physician judgment.

A major obstacle to successful allogeneic HCT is the immune competence of the recipient. The potential to reject infused donor cells is mediated predominantly through regimen-resistant host T and NK cells. Strategies to reduce host immunity and promote donor hematopoietic cell engraftment include pretransplantation conditioning (most often chemotherapy and/or radiation) and postgrafting immunosuppressive medications. Donor T cells in the allograft play a key role in hematopoietic engraftment, and depletion of T lymphocytes from the

allograft before transplantation is associated with a substantial increase in the occurrence of graft rejection.^{125,126} With modern conditioning regimens, rates of allograft rejection are low (typically <5 percent) for patients who have received previous chemotherapy, which weakens their immune response to the allograft. In contrast, graft rejection is seen more often in patients who have not received cytotoxic chemotherapy before allogeneic HCT (for instance, some patients with myeloproliferative neoplasms) or those with nonmalignant diseases such as aplastic anemia, thalassemia, or sickle cell disease, who are often highly sensitized against donor antigens by virtue of being heavily transfused before allogeneic HCT.

Graft-Versus-Tumor Effects

The dominant mechanism of cancer eradication following allogeneic HCT is the immunologic recognition and destruction of residual host tumor cells by donor-derived immune cells. This phenomenon, termed the GVT effect, has been conclusively demonstrated and represents one of the most significant biologic findings of the past half-century, with implications well beyond the transplantation setting. The existence of GVT effects is supported by the following lines of evidence:

- *Tumor relapse is lower after allogeneic than after syngeneic HCT:* The appreciation of alloreactive GVT effects stemmed from the observation that recipients of genotypically identical (syngeneic) grafts had significantly higher rates of disease relapse than did patients who received grafts from HLA-identical siblings.^{127,128}
- *Tumor relapse is higher in recipients of T-cell-depleted grafts:* Further support for the allogeneic GVT effect came from studies of T-cell depletion of the graft.¹²⁹ T-cell depletion was performed in the expectation that it would reduce the risk of GVHD. However, the later observation that these patients had a much higher risk of disease recurrence as well as graft rejection was unanticipated. These results linked GVHD with GVT effects, and supported the concept that patients who developed some degree of alloreactivity, as manifested by clinically apparent GVHD, had a reduced risk of disease relapse.
- *Donor lymphocyte infusions can induce remission:* Perhaps the most definitive evidence for the existence of GVT effects came from the application of donor lymphocyte infusions (DLIs). In the early 1990s, Kolb and others demonstrated that patients with relapsed malignancies after allogeneic HCT could, in some cases, be returned to complete remission by the simple infusion of donor-derived lymphocytes.^{130–132} With increasing experience, it became clear that some diseases (such as chronic myelogenous leukemia [CML]) respond very well to DLI whereas others (for instance, acute lymphoblastic leukemia [ALL]) are much less responsive. Long-term followup of patients successfully treated with DLIs revealed that responders had remarkably durable remissions and excellent outcomes.¹³² These observations definitively established the GVT effect as a biologic entity capable of controlling an otherwise lethal condition such as leukemia.

Targets and Effector Cells in Graft-Versus-Tumor Reactions

The biology of the GVT effect remains incompletely understood. A number of immunologic targets recognized by donor immune effector cells have been proposed, including alloantigens (such as major or minor histocompatibility antigens depending upon donor–recipient genetic differences), lineage-specific antigens, and malignancy-specific antigens such as products of chromosomal translocations. Donor T cells clearly play a key role in GVT, and there is emerging evidence that NK cells are also responsible for tumor cell control, especially in the setting of T-cell-depleted HLA-haploidentical HCT.¹³³ Humoral immunity has also been implicated as playing a role in the GVT effect.¹³⁴ Based

on preclinical models, the common effector cells that could potentially mediate a clinical GVT effect include (1) CD8+ cytotoxic T lymphocytes that recognize tumor-associated antigens in context of class I major histocompatibility complex (MHC) antigens; (2) CD4+ T cells that recognize tumor-associated antigens in context of class II MHC antigens and mediate their effects via Th1 cytokines such as interferon (IFN)- γ and IL-2, upregulating expression of class I MHC antigens and promoting expansion and activation of CD8+ cytotoxic T lymphocytes; and (3) NK cells that recognize stress ligands and cells lacking MHC expression.^{135–141} The impact of NK cells seems especially pronounced in HLA-haploidentical or mismatched allotransplantation.^{104,142}

A major question continues to be whether the subset of T cells that induce GVHD is the same population of T cells responsible for the GVT effect. One of the central aims of research in allogeneic HCT is to separate the beneficial GVT effects from deleterious GVHD. Clinical evidence suggests that, in principle, the two should be separable, as some patients experience an apparent GVT effect in the absence of apparent GVHD.¹⁴³ Although numerous approaches have succeeded in separating GVT effects from GVHD in preclinical and animal models, none of these approaches have yet been translated successfully to widespread clinical use. One approach supported by preclinical models involves the use of T_{reg},¹⁴⁴ and recent studies in the HLA-haploidentical setting are supportive of this concept.^{145,146}

TRANSPLANT PREPARATIVE REGIMENS

The transplant preparative regimens used in HCT must accomplish two goals. Because the majority of autologous and allogeneic HCT are performed in individuals with cancer, these regimens were designed, at least initially, to maximize tumor cytoreduction and disease eradication. In the case of allogeneic HCT, the regimen must be sufficiently immunosuppressive to overcome host rejection of the graft. In autologous HCT, where efficacy depends on exploiting the dose–response curve, high-dose conditioning regimens are universally used. In contrast, in allogeneic HCT much or all of the clinical benefit derives from donor alloimmunity, enabling the use of RIC designed to facilitate donor engraftment with minimal toxicity.

TOTAL-BODY IRRADIATION

TBI has been a primary component of many autologous and allogeneic HCT preparative regimens since the inception of the field. TBI has excellent activity against a variety of hematolymphoid malignancies, has pronounced immunosuppressive properties, and is able to treat sanctuary sites like the testicles and the central nervous system. Aside from one very early study of high-dose TBI alone, most preparative regimens combine TBI with cytotoxic agents such as CY. Dose-finding studies suggest that higher TBI doses are associated with a lower risk of relapse with dose escalation as high as 15.75 Gy, but doses above 12 Gy are associated with higher risks of GVHD and TRM, which offset the reduced risk of relapse.¹⁴⁷ Currently, most high-dose TBI-based conditioning regimens use a dose between 12 and 13.2 Gy. Long-term concerns with TBI-based regimens include the development of cataracts and hypothyroidism, impairment of growth and development in children, and secondary malignancies.^{148–150}

Hyperfractionated TBI, in which relatively small dose fractions are given two to three times a day over a few days, minimizes leukemia regrowth and reduces lung and gastrointestinal toxicity, allowing higher TBI doses to be administered safely. Several clinical studies confirm decreased overall lung toxicity with fractionation.^{151,152} Excellent results are also reported with the combination of fractionated TBI and VP-16 (etoposide), particularly promising results in patients with ALL.^{153,154}

An alternate form of irradiation is radioimmunotherapy, which involves the use of antibodies to deliver locally acting radionucleotides to targeted sites. In theory, this strategy could provide excellent targeted antitumor effects without increased systemic toxicity. Clinical trials incorporating anti-CD45 monoclonal antibodies conjugated to radioactive iodine (^{131}I) or yttrium (^{90}Y) show promising early results in both the autologous and the allogeneic setting.^{155–158} One approach to further improving the targeting of radiation is the use of α -particle emitters. Alpha particles have a very short effective range but carry immense kinetic energy, making them an attractive option to maximize malignant cell killing while minimizing bystander damage. Preclinical studies using bismuth-213 (^{213}Bi) and astatine-211 (^{211}At) have demonstrated efficacy,^{159–162} and this approach is currently being translated into clinical trials.

CHEMOTHERAPY-ONLY REGIMENS

Autologous

Patients with NHL or HL have often received prior intensive local radiotherapy, often to the mediastinum, which results in a high incidence of fatal interstitial pneumonitis following TBI.¹⁶³ Therefore, non-TBI-containing conditioning regimens were developed. The choices of drugs include agents that can be significantly dose-escalated and have improved tumor cell killing at higher doses, yet have nonoverlapping toxicities; for example, a common preparative regimen for autologous HCT in lymphoma includes 1,3-bis(2-chloroethyl)-1-nitrosourea (carmustine or bis-chloroethylnitrosourea [BCNU]), VP-16, and CY.¹⁶⁴ The dose-limiting non-hematologic toxicity of BCNU affects the lungs; VP-16 affects the liver; and CY, the heart. Consequently, using these drugs below the maximally tolerated doses results in relatively low regimen-related toxicity but maximizes tumor cell kill to overcome drug resistance. Many other chemotherapy-only regimens have been developed for autologous HCT according to similar principles, including BCNU, etoposide, cytarabine, and melphalan (BEAM) (for lymphomas) and high-dose melphalan (for myeloma).

Allogeneic

A variety of chemotherapy-only conditioning regimens have been developed for allogeneic HCT. The most widely used combines oral busulfan (BU), at a total dose of 16 mg/kg given over 4 days, with CY at a total dose of 120 mg/kg given intravenously over 2 days (referred to as BU/CY).^{165,166} A randomized comparison between fractionated TBI plus CY (TBI/CY) and BU/CY in patients transplanted for CML demonstrated that the BU/CY regimen was better tolerated, but there was no significant difference in overall or event-free survival, TRM, or GVHD incidence.¹⁶⁷ The development of intravenous BU further improved the availability and tolerability of this regimen, although steady-state plasma concentrations remain variable after intravenous BU and therapeutic drug monitoring arguably remains necessary.^{168,169} Interestingly, pretreatment with BU may deplete hepatic glutathione and thus potentiate the toxicity of CY.^{170,171} Reversing the sequence of conditioning agents (from BU/CY to CY/BU) has been studied as a means of reducing regimen-related toxicity, and this alteration to the regimen has been associated with reduced exposure to toxic CY metabolites and a lower risk of hepatotoxicity.¹⁷²

Other high-dose chemotherapy-only conditioning regimens remain in use on an institution-, disease-, and patient-specific basis. The most common modification to BU/CY is the substitution of fludarabine (FLU) for CY (BU/FLU). This regimen has been proposed to avoid the hepatotoxicity of CY and to reduce regimen-related toxicity compared to BU/CY. However, two recent randomized clinical trials comparing BU/CY and BU/FLU have found increased risks of graft rejection and

pneumonitis, as well as decreased overall and disease-free survival, with BU/FLU, raising the concern that this regimen is inferior to BU/CY.^{173,174}

REDUCED-INTENSITY TRANSPLANTATION

The demonstration that immune-mediated mechanisms are critical in eradicating malignancy after allotransplant challenged the rationale for relatively toxic full-dose conditioning. A number of reduced-intensity regimens have been developed which have lower regimen-related toxicity but are sufficiently immunosuppressive to allow full donor engraftment, shifting the responsibility for tumor eradication largely or entirely to immunologic GVT effects. The development of RIC is one of the most transformative advances in the field of allogeneic HCT in the past several decades, as it has allowed the expansion of eligibility for allogeneic HCT to older and less medically fit patients who would otherwise be ineligible for high-dose conditioning. Additionally, patients with relatively indolent disease may not require the immediate cytoreductive capacity of an aggressive preparative regimen and may be particularly suitable candidates for transplantation using RIC. These regimens are also useful in patients with nonmalignant diseases where the goal is strictly the establishment of donor hematopoiesis; examples include genetic disorders, autoimmune diseases, and the induction of tolerance in combined solid-organ and same-donor marrow transplantation.

A variety of RIC regimens with differing dose intensities have been developed. One significant regimen came from detailed studies in a canine model using a backbone of low-dose 2 Gy TBI followed by postgrafting immunosuppression with mycophenolate mofetil (MMF) and cyclosporine (CSP).¹⁷⁵ This work was translated to patients with a variety of malignancies and resulted in reliable donor engraftment with the addition of intravenous FLU 90 mg/m².¹⁷⁶ This reduced-intensity regimen has been used successfully in more than 1000 patients with a wide variety of malignancies, especially in older patients and those with more indolent diseases such as follicular NHL or chronic lymphocytic leukemia (CLL).^{177–179} Another commonly used RIC regimen consists of intravenous FLU (between 90 and 150 mg/m²) and CY (between 900 and 2,000 mg/m²).¹⁸⁰ This regimen, combined with rituximab or ^{90}Y ibritumomab tiuxetan, has produced excellent long-term disease-free survival in patients with indolent lymphoma.¹⁸¹ A third common reduced-intensity regimen was developed in a rodent model using fractionated low-dose total lymphoid irradiation (TLI) combined with depletive T-cell antibodies (antithymocyte serum), which showed that recipients were protected from GVHD induction by donor-derived T cells.¹⁸² Rodents conditioned with this approach did not develop lethal acute GVHD despite the infusion of megadoses of donor T lymphocytes. TLI and antithymocyte serum altered residual host T-cell subsets to favor regulatory NK/T cells which suppress GVHD by polarizing the infused donor T cells toward secretion of noninflammatory cytokines such as IL-4, and by promoting expansion of donor CD4+CD25+FoxP3+ T_{regs}.¹⁸³ This approach was successfully translated to clinical transplantation; patients conditioned with TLI and antithymocyte globulin (ATG) developed sustained donor-derived hematopoiesis with very low incidences of acute GVHD and TRM.^{184,185} The relative merits of RIC versus high-dose conditioning continue to be studied; a national multicenter prospective randomized trial comparing high-dose to RIC in patients with acute myeloid leukemia (AML) or myelodysplastic syndrome (MDS) is ongoing under the auspices of the BMT-CTN.

Mixed Chimerism Following Reduced-Intensity Conditioning

A feature common to all RIC protocols is the incomplete eradication, at least initially, of host hematopoietic elements. As a consequence, a significant percentage of patients have mixed donor–recipient chimerism for months after transplantation before fully converting, if ever, to

complete donor type. Most reports suggest that persistent mixed chimerism is a significant risk factor for disease relapse.^{185,186} Interventions such as withdrawal of immunosuppressive medications, CD34-selected donor cell boost, and DLI have been used to convert mixed chimerism to complete donor type, although these interventions are not without risk and can precipitate GVHD. A significant percentage of patients who received alemtuzumab-containing conditioning regimens required DLI to promote donor engraftment and protect against immune-mediated graft rejection, but the risk of developing post-DLI GVHD was significant.¹⁸⁷ Mixed chimerism is not unique to RIC; prior to the addition of ATG, almost 60 percent of patients who received high-dose conditioning and allogeneic HCT for severe aplastic anemia had mixed chimerism, of whom two-thirds eventually converted to complete donor hematopoiesis while the remainder experienced late graft failure.¹⁸⁸

Persistent mixed chimerism may have a role in allogeneic transplantation for noncancer patients. In organ transplantation, tolerance, defined as immunosuppressive drug withdrawal without graft rejection, was achieved in kidney transplant recipients who received the same donor marrow when sustained mixed chimerism was established, and not in recipients who experienced donor hematopoietic graft loss.¹⁸⁹

EVALUATION AND SELECTION OF CANDIDATES FOR TRANSPLANTATION

Most transplantation candidates are referred by hematologists or oncologists to the tertiary center where HCT will be performed. Patients considered for transplantation require in-depth evaluation and counseling by experienced transplantation physicians, nurses, and social workers. A detailed review of initial diagnostic studies, previous drug and radiation treatments, and responses to these interventions, as well as a psychosocial assessment of the patient and their caregivers, are of the utmost importance. Table 23–2 highlights the issues and topics that should be addressed during counseling meetings with transplantation candidates and their caregivers.¹⁹⁰ Important factors which consistently impact outcomes following HCT include, but are not limited to, disease status at transplantation, type and compatibility of donor, recipient age, and comorbid medical conditions. Early referral for transplantation consultation is critical, particularly if allogeneic HCT is under consideration, because of the time required to identify a suitable donor.

DISEASE STATUS AT THE TIME OF TRANSPLANTATION

Disease status at the time of transplantation is perhaps the most powerful predictor of long-term disease-free survival following allogeneic and autologous HCT. Early studies of allogeneic HCT were performed using predominantly patients with refractory and progressive disease.¹⁹¹ Although a small percentage of these patients were salvaged, transplantation was unsuccessful in the majority of patients due to progressive malignancy. Patients with acute leukemias transplanted in complete remission (CR) have substantially better outcomes compared to those transplanted with active disease.¹⁹² Even very minimal amounts of residual disease are associated with significantly higher relapse risk in patients undergoing allogeneic HCT for AML, regardless of conditioning intensity,^{193–195} underscoring the importance of disease status at transplant as a prognostic factor. Likewise, disease status as determined by positron emission tomography (PET) prior to transplant is an important predictor of progression-free survival for patients with diffuse large B-cell lymphoma and HL undergoing autologous HCT.^{196–199} These scenarios highlight a truism: patients who have advanced poorly controlled disease at the start of transplant conditioning have significantly inferior

GVHD, graft-versus-host disease; RIC, reduced-intensity conditioning.

outcomes compared to patients transplanted earlier in the course of their disease and to those who have achieved good, albeit temporary, control of their disease. On the other hand, attempts to salvage patients with advanced disease who have failed multiple therapies are rarely successful, and transplantation is often best considered early in the course of therapy. These discussions are complex, as earlier transplantation, especially allogeneic, carries significant risks to the patient. A number of other disease-specific considerations are important in determining the appropriate timing for transplantation, including the presence and/or persistence of cytogenetic and molecular abnormalities, the immune phenotype, and evidence of extramedullary or extranodal disease. Advanced genetic characterization of leukemia and lymphoma may provide improved insight into cohorts of patients for which HCT should be performed earlier in the course of disease.

AGE

Historically, older age was a significant barrier to allogeneic HCT, since older patients suffered severe and often prohibitive toxicity after high-dose conditioning regimens.²⁰⁰ However, the impact of older age is mitigated by the increasing use of RIC for allogeneic HCT.²⁰¹ High-dose conditioning and allogeneic HCT is generally reserved for patients 60 years of age or younger, whereas allotransplantation with RIC has been performed successfully in patients into their eighth decade of life. Most centers in the United States do not have a stringent age cutoff for allogeneic HCT, although careful screening for comorbid medical conditions,

such as heart, lung, kidney, and liver disease, is particularly important in older patients, and allotransplantation in patients 70 years of age and older remains somewhat controversial. Existing data suggest that allogeneic HCT can be safely performed in selected patients age 60 to 75 years, with a 5-year overall survival of 35 percent.^{202,203} Some investigators have proposed that age is a poor and imprecise prognostic marker, and instead advocate the use of comorbidity assessment and scoring to determine eligibility for allogeneic HCT.²⁰⁴ However, caution is warranted since this approach has not been prospectively validated; retrospective cohort studies necessarily suffer severely from patient selection bias, as they include only those older patients who were deemed appropriate candidates to proceed to allogeneic HCT. Outcomes for this selected group of older patients cannot be generalized to the population of older adults as a whole.

In contrast to allogeneic HCT, autologous HCT relies on high-dose conditioning for its antitumor efficacy. Thus, there is no way to reduce conditioning intensity without sacrificing some degree of efficacy. As a result, age limitations are often stricter for autologous HCT than for allogeneic HCT, as candidates for the former must be able to tolerate intensive, high-dose chemotherapy. It is unusual for autologous HCT to be offered to patients older than 75 years of age.^{205,206}

COMORBID MEDICAL CONDITIONS

Comorbid medical conditions have a significant impact on transplantation outcomes. Routine screening of heart and lung function to detect occult abnormalities is of critical importance, especially in older patients. Evaluation of liver and kidney function, as well as exposure to potential pathogens such as CMV, hepatitis B and C, herpes viruses, and HIV are routine and should be performed in all patients. Another major factor is the nutritional status of the patient, as extremes such as cachexia or obesity require special considerations and adversely impact TRM.^{207,208}

Several scoring instruments have been devised to allow quantification and comparison of pretransplantation comorbidities. The most widely used of these are the EBMT Risk Score,²⁰⁹ the Pretransplant Assessment of Mortality (PAM) score,²¹⁰ and the HCT-specific Comorbidity Index (HCT-CI; later modified to incorporate age).^{204,211} A number of efforts have been made to validate, revise, or combine these scores in diverse populations, with variable success.^{212–216} Several caveats are important when considering quantitative scoring of pretransplantation comorbidities. First, because these scoring instruments were derived from retrospective cohorts of patients, they suffer from an inescapable selection bias, as only patients who were deemed fit for transplantation were included in their derivation. This selection bias limits the ability to generalize their use to unselected patient populations. Second, transplantation outcomes have not remained stable over time; instead, TRM has steadily decreased over time with the availability of better supportive care and other refinements.^{217,218} Thus, it is conceivable that the relative impacts of specific comorbidities on transplantation outcomes are not fixed, but may vary over time. Efforts are currently underway to prospectively validate these comorbidity scoring instruments.

Every effort should be made to encourage potential patients to maintain good health practices, including discontinuation of alcohol use, tobacco smoking, and illicit drug use (if applicable). Centers vary in their approach to abstinence, but it is common to require that patients cease all tobacco use permanently as a condition of proceeding to autologous or, especially, allogeneic HCT. The risk of pulmonary complications from chemotherapy (e.g., BCNU) or from chronic GVHD involving the lung is potentiated by smoking, as is the risk of secondary cancers of the lung and other organs. A special situation deserving consideration is the use of marijuana, which is increasingly legal,

available, and widely used by cancer patients to combat chemotherapy-related nausea and anorexia. Anecdotally, an increasing number of patients referred for transplantation consultation are actively using marijuana to control these symptoms during their pretransplantation chemotherapy. Cases of severe or fatal pulmonary aspergillosis from inhaled spores have been reported in immunosuppressed patients using marijuana.^{219,220} Transplant center policies regarding medical marijuana use and abstinence have lagged behind the rapidly changing legal status of marijuana in the United States, creating a challenge in assessing and counseling patients.

DISEASES TREATED WITH TRANSPLANTATION

Numerous malignant and nonmalignant hematologic disorders, as well as selected solid tumors, may be treated with HCT. The results obtained with transplantation are reviewed in detail in the disease-specific chapters of this book, and are discussed only briefly here.

In general terms, autologous HCT is recommended for patients whose malignancy exhibits chemosensitivity to conventional dose therapy and does not extensively involve the marrow; included are most lymphomas, germ cell tumors, and other selected pediatric tumors. In these instances, tumor eradication is a result of dose escalation of cytotoxic therapy in the conditioning regimen, and the autograft serves as hematopoietic cell rescue. In contrast, allogeneic transplantation is generally pursued for hematologic malignancies and disorders that primarily originate in the marrow, such as acute and chronic leukemias, aplastic anemia, MDSs, and myeloproliferative neoplasms. For some diseases with extensive marrow involvement, such as the low-grade lymphomas and myeloma, the decision to pursue autologous versus allogeneic HCT is more complex. In these settings, allogeneic transplantation has generally been more successful in controlling disease recurrence and reducing relapse risk. However, the associated risks, including GVHD and prolonged immunosuppression, result in a higher TRM compared to autologous HCT. Thus, the decision to pursue an allogeneic or autologous HCT for patients with these diseases depends on the combination of patient characteristics such as comorbidities and age, availability of a suitable donor, disease-specific characteristics, and often patient preference. For some hematologic conditions, such as MDSs, myeloproliferative neoplasms, and aplastic anemia, only allogeneic transplants are generally appropriate.

In addition, patients with selected solid tumors, such as testicular cancer, neuroblastoma, and other pediatric tumors, have had successful outcomes with autologous HCT.^{221–224} Extensive studies in women with breast and ovarian carcinoma, and more limited studies in patients with renal cell carcinoma and small cell lung cancer, have failed to demonstrate a role for HCT.^{225,226} Outside of the investigational setting, there are no currently accepted indications for allogeneic HCT to treat non-hematologic solid tumors.

A variety of congenital and acquired nonmalignant disorders can be successfully treated with HCT. The most well-established nonmalignant indication is for allogeneic HCT in patients with severe aplastic anemia, where outstanding results have been achieved, particularly for younger patients with HLA-matched sibling donors, where long-term disease-free survival rates of 88 to 100 percent have been reported.^{227,228} Hematopoietic cell transplantation for patients with clinically significant hemoglobin disorders, such as thalassemia major, has been very successful, especially in patients without significant liver disease.^{229,230} Likewise, allogeneic HCT is considered a treatment option for young patients with severe forms of sickle cell disease.^{231,232} Guidelines for patient selection and management of patients with thalassemia or sickle

cell disease were published in 2014 by EBMT.²³³ In patients with hemoglobin disorders, transplantation serves as a form of gene therapy, using allogeneic hematopoietic cells as vectors for genes essential for normal hematopoiesis. Eventually the vector may well be autologous stem cells transformed by the insertion of normal genes.²³⁴

For patients with SCID syndrome and other congenital immunodeficiencies, allogeneic HCT remains the treatment of choice.^{235,236} The role of allogeneic HCT for patients with storage diseases, a diverse group of disorders that typically involve a single gene defect in a lysosomal hydrolytic enzyme or peroxisomal function, is evolving and it appears that subsets of mucopolysaccharidoses derive the most benefit.²³⁷

SELECTED RESULTS OF HEMATOPOIETIC CELL TRANSPLANTATION

A comprehensive discussion of transplantation outcomes is beyond the scope of this chapter; please refer to other disease-focused chapters of this text for more complete information. A brief overview of transplantation-related outcomes in a number of diseases is presented here.

Acute Myeloid Leukemia

Allogeneic HCT has a major role in the management of patients with AML. For patients in CR1, the decision to proceed to allogeneic HCT as opposed to chemotherapy-based consolidation is predicated on prognostic markers and donor availability, as well as patient preference. For patients beyond CR1, allogeneic HCT often offers the only potentially curative treatment option.

First Complete Remission A question of significant practical importance is how best to treat a younger AML patient who achieves a CR1 following induction chemotherapy. Several large prospective trials have been conducted using so-called genetic randomization: that is, patients in CR1 with an HLA-identical sibling received allogeneic HCT, while those without an HLA-identical sibling received chemotherapy-based consolidation or autologous HCT.^{238,239} Two meta-analyses have focused on the comparative outcomes of allogeneic HCT versus chemotherapy, both of which found that allogeneic HCT in CR1 yielded better overall and disease-free survival for patients with intermediate- and poor-risk cytogenetics, but not for those with favorable-risk cytogenetics.^{240,241} For patients with poor-risk cytogenetics, there is little dispute that allogeneic HCT is the preferred postremission therapy for medically fit patients with available donors. Conversely, patients younger than 60 years of age with favorable-risk cytogenetics who promptly achieve CR1 with induction chemotherapy are generally not considered for allogeneic HCT, and instead should receive chemotherapy-based consolidation. For younger patients with intermediate-risk cytogenetics, allogeneic HCT in CR1 from an HLA-identical sibling donor is the best available postremission therapy, but its advantage over other approaches is not as substantial as in the setting of poor-risk cytogenetics. One caveat is that the studies demonstrating the superiority of allogeneic HCT were performed using genetic randomization, and thus the results are, strictly speaking, only applicable to patients with HLA-identical sibling donors. That said, single-center and registry data suggest that outcomes with HLA-matched unrelated donor allotransplantation for AML in CR1 are similar to those with HLA-identical sibling donors,^{242,243} so it is reasonable to extrapolate the results of the genetic-randomization studies to patients with HLA-matched unrelated donors.

Patients older than 60 years of age typically have substantially higher relapse rates with chemotherapy alone (60 to 80+ percent)^{244,245} and have poorer outcomes than younger patients with equivalent cytogenetics, suggesting that older adults may benefit from allogeneic HCT

in CR1. There are no prospective, genetically randomized trials in older adults with AML comparing allogeneic HCT to chemotherapy in CR1, but retrospective comparisons suggest that allogeneic HCT can reduce relapse risk and improve outcomes in this demographic.^{244,245} The decision to proceed to allogeneic HCT in older adults is often based less on disease risk factors and more on medical comorbidities and the estimated risk of TRM, which may be prohibitive.

In the genomic era of AML risk stratification, patients with intermediate-risk disease are often categorized based on the results of molecular testing for mutations of *FLT3*, *NPM1*, and *CEBPA*. Patients with intermediate-risk cytogenetics and biallelic *CEBPA* mutations or *NPM1* mutations in the absence of *FLT3* mutations have good-risk disease and are often not considered for allogeneic HCT in CR1.²⁴⁶ In contrast, patients with internal tandem duplications in *FLT3* have poorer prognoses and are often considered for allogeneic HCT in CR1.

Detailed guidelines have been published by the European LeukemiaNet AML Working Party to guide the use of allogeneic HCT in AML patients in CR.²⁴⁷ Based on existing data, many experts would recommend allogeneic HCT for all medically fit patients younger than 60 years old with AML in CR1 *except* for those with favorable-risk disease (including those with intermediate-risk cytogenetics and favorable molecular markers) who achieve CR1 with their first cycle of induction and have no evidence of minimal residual disease. For all other younger CR1 patients—including those with intermediate-risk cytogenetics and negative molecular markers, and those in any cytogenetic risk group who do not promptly achieve CR with induction or who have minimal residual disease—allogeneic HCT should be strongly considered as the best postremission option.²⁴⁸ For older adults with AML in CR1, allogeneic HCT should be considered for all medically fit patients except those with favorable-risk disease, although there are fewer data to support this recommendation and medical comorbidities play an increasingly important role in decision making as patients age.

The role of consolidation chemotherapy before allotransplantation in patients in CR1 is unclear. Many transplant physicians recommend at least 1 to 2 cycles of consolidation, especially for patients slated to receive RIC, in order to maximize pretransplantation cytoreduction. However, two recent retrospective studies have questioned the benefit of consolidation chemotherapy, and instead favored moving forward to allogeneic HCT as soon as a suitable donor is available.^{249,250} Consolidation chemotherapy is to maintain remission during prolonged donor searches, but its benefit is less clear in patients who have a donor identified.

AML Beyond First Complete Remission For patients with AML who relapse after attaining a CR1, allogeneic HCT is the treatment of choice. While no prospective randomized trials have compared allogeneic HCT to salvage chemotherapy alone in this setting, retrospective data strongly support the use of allogeneic HCT.²⁵¹ Autologous HCT has been used historically in patients who lacked suitable allogeneic donors,²⁵² but with the advent of improved alternative-donor options the use of autologous HCT for AML has become rare except in developing countries without the capability to perform allogeneic HCT. Patients with AML beyond CR1 who lack suitably HLA-matched donors are candidates for HLA-haploidentical or UCB allotransplantation, as retrospective studies have associated these approaches with equivalent overall and disease-free survival compared to allotransplantation from conventional donor sources.^{253,254}

The likelihood of long-term survival is very low in AML patients whose disease fails to achieve CR1 following induction therapy (primary induction failure) and in those whose disease is chemorefractory at relapse. Allogeneic HCT with myeloablative conditioning has been reported to cure approximately 19 to 30 percent of such patients in retrospective analyses.^{192,255} These retrospective reports undoubtedly

suffer from substantial selection bias; presumably patients with relapsed or refractory AML were not transplanted indiscriminately, but only if their physicians felt they had an above-average chance of responding. These success rates are therefore very unlikely to pertain to the overall population of adults with relapsed or refractory AML. Attempts have been made to construct prognostic tools to identify the subset of patients most likely to benefit from allogeneic HCT,¹⁹² and some authorities have argued that allogeneic HCT is underused in this population.²⁴⁸ Currently there is no single standard of care for treatment of patients with AML in refractory relapse or primary induction failure; reasonable options include additional salvage chemotherapy to induce remission; enrollment on a clinical trial; allogeneic HCT (in carefully selected patients); and palliative care, and the optimal choice must be individualized based on patient characteristics and donor availability.

Acute Lymphoblastic Leukemia

Allogeneic HCT is widely used in adult patients with ALL, especially those patients with high-risk features (most often defined as white blood cell count at diagnosis >30,000 [or >100,000 in T-cell ALL], adverse cytogenetics, progenitor B-cell immunophenotype, age >60 years, or failure to achieve CR within 4 weeks of induction chemotherapy).²⁵⁶ Patients with none of these features are considered to have standard-risk disease; there is no clear “favorable-risk” population in adult ALL. While the advisability of allogeneic HCT is uncontroversial as postremission therapy for adults with high-risk ALL, it is also the treatment of choice for eligible adults with standard-risk ALL in CR1. Several large genetically randomized prospective trials have demonstrated a survival benefit for allogeneic HCT in CR1 for adults with standard-risk ALL.^{257,258} A 2013 meta-analysis confirmed the benefit of upfront allogeneic HCT for adults 35 years of age or younger; for older adults, the benefit was more difficult to demonstrate owing to increasing TRM.²⁵⁹ As with all genetically randomized clinical trial data, these findings apply only to patients with HLA-identical sibling donors, strictly speaking, although many authorities extrapolate the observed benefit to HLA-matched unrelated donors and possibly even alternative donors on the basis of generally equivalent outcomes.

On the basis of existing data, we believe that myeloablative allogeneic HCT is the optimal therapy for all eligible adults with ALL in CR1 and available HLA-identical sibling donors—a recommendation supported by a recent Cochrane Library systematic review.²⁶⁰ Allogeneic HCT is likely also the optimal therapy for those with HLA-matched unrelated donors, although this recommendation relies more on extrapolation from data in the HLA-identical sibling setting. The decision to proceed with alternative-donor allogeneic HCT in a patient with standard-risk ALL in CR1 is less clear-cut and depends on patient preference and institutional comfort level. In any case, we believe that all adults with ALL should be referred for transplantation consultation early in their course to assist in determining the optimal treatment approach.

Conditioning-regimen intensity appears to play a major role in the success of allogeneic HCT for ALL. Results with nonmyeloablative allogeneic HCT for Philadelphia chromosome–negative (Ph–) ALL beyond CR1 have been poor, with virtually no survivors.²⁶¹ For older adults with Ph– ALL who are not candidates for intensive conditioning, the optimal approach remains unclear, particularly for those beyond CR1.

Philadelphia Chromosome–Positive Acute Lymphoblastic Leukemia The postremission management of patients with Philadelphia chromosome–positive (Ph+) ALL deserves special attention. Historically, Ph+ ALL carried a very poor prognosis with conventional chemotherapy, and this chromosomal abnormality was considered a high-risk feature. High-dose TBI-based conditioning and allotransplant has historically been the standard of care for postremission therapy of Ph+ ALL in adults, and resulted in 10-year overall survivals of

54 percent and 29 percent for patients transplanted in CR1 and beyond CR1, respectively, in the pre–tyrosine kinase inhibitor (TKI) era.²⁶²

The development of TKIs targeting *bcr/abl* has markedly improved the prognosis of Ph+ ALL. With the incorporation of TKI therapy into pretransplant induction and posttransplant maintenance, Ph+ ALL now carries one of the best prognoses of all forms of adult ALL, even with nonmyeloablative conditioning.^{261,263} Most authorities continue to recommend allogeneic HCT as postremission therapy for adults with ALL in the TKI era. The pediatric literature suggests that it may be safe to forgo allotransplantation in favor of TKI-based chemotherapy alone in Ph+ ALL,²⁶⁴ but these data cannot be extrapolated to the adult setting because of the very different clinical behavior of adult versus pediatric ALL. For adults with Ph+ ALL who are not candidates for allotransplantation, TKI-containing chemotherapy regimens coupled with close monitoring of minimal residual disease may be an alternative, but this approach has not been tested in clinical trials.

Myeloma

Autologous HCT is not curative in myeloma, but a number of randomized clinical trials have demonstrated prolongation of event-free survival by a median of approximately 1 year when single or double autologous HCT is incorporated into the treatment program.^{265–267} Some of these trials also reported improved overall survival with autologous HCT. In addition, early autologous HCT is associated with an improved quality of life in patients with myeloma, likely because it is associated with a shorter period of chemotherapy.²⁶⁸ However, these studies were performed before the introduction of modern highly active antimyeloma therapies such as thalidomide, lenalidomide, and bortezomib. In 2014, results were published from a randomized trial comparing upfront tandem autologous HCT to lenalidomide-based maintenance therapy after induction with lenalidomide and dexamethasone.²⁶⁹ Patients randomized to upfront autologous HCT had significantly improved 4-year overall survival compared to those randomized to the nontransplant arm (81.6 percent vs. 65.3 percent, $p = 0.02$; Fig. 23–1).²⁶⁹ Patients randomized to the nontransplantation arm remained eligible for autologous HCT at the time of myeloma progression, but only 62.8 percent actually received autologous HCT, suggesting that delayed autologous HCT is not feasible for many patients as a result of rapid clinical deterioration following relapse. These results support the continued role of upfront autologous HCT as the standard of care for medically fit patients with myeloma in the modern era, although several caveats apply. First, the maintenance regimen in the nontransplantation arm consisted of low-dose melphalan in combination with lenalidomide and dexamethasone, and it is unclear whether these findings can be generalized to other, more commonly used maintenance regimens. Second, patients randomized to upfront autologous HCT received planned tandem autologous HCT with intravenous melphalan 200 mg/m² conditioning for each transplant. This approach is relatively uncommon, as tandem autologous HCT has fallen out of favor based on evidence that it does not improve overall survival.²⁷⁰ In current practice, second autologous HCT is usually reserved for patients who fail to achieve at least a very good partial remission after first autologous HCT,²⁷¹ and is often performed using a lower dose of intravenous melphalan (140 mg/m²) as conditioning. As a result, it is unclear whether the benefit observed in this trial extends to the setting of single autologous HCT. Nonetheless, upfront autologous HCT continues to be widely used in myeloma, and the recent trial adds support for this approach, particularly since nearly 40 percent of patients intended to undergo transplantation never received the intervention.

Allogeneic HCT remains the only therapy thought to be potentially curative in myeloma, and has been widely studied, most often as part of a tandem autologous/allogeneic double-transplant approach.

Comparisons of tandem autologous/autologous versus tandem autologous/RIC allogeneic HCT have yielded conflicting results. Improved overall survival with allotransplantation was seen in an Italian randomized study of 162 patients and in long-term followup of the EBMT-NMAM2000 trial involving 257 patients,²⁷²⁻²⁷⁴ although the relapse rate remained high at 60 percent even after allografting.²⁷³ In contrast, three other large randomized trials failed to demonstrate an overall survival advantage with allografting.²⁷⁵⁻²⁷⁷ The largest trial addressing this question was completed by the BMT-CTN and enrolled 710 myeloma patients randomized between auto-auto and auto-allo approaches.²⁷⁸ This trial found no benefit in overall or progression-free survival with allografting. These results, along with a 2013 meta-analysis of randomized trials which similarly found no benefit to allotransplantation,²⁷⁹ have led to a loss of enthusiasm for allogeneic HCT in myeloma. Some authors have argued that survival improvements with allogeneic HCT require longer followup.²⁷³ Nonetheless, given existing data, allogeneic HCT in myeloma is typically reserved for younger patients with very high-risk disease or those who have failed autologous HCT, and is ideally performed in the context of a clinical trial.

Non-Hodgkin Lymphoma and Hodgkin Lymphoma

Patients with chemosensitive aggressive and highly aggressive lymphomas beyond CR1 have an improved overall survival with high-dose therapy followed by autologous HCT compared to best-of-care salvage chemotherapy.^{280,281} The benefit of autologous HCT appears restricted to patients with chemosensitive disease. Patients with negative 18-fluorodeoxyglucose (FDG)-PET imaging prior to transplantation have significantly better outcomes than patients with residual FDG-avid disease at the time of transplant.^{197,282,283} Historically, autologous HCT produced long-term disease-free survival in approximately 50 percent of patients with chemosensitive relapsed lymphoma.²⁸⁴ More recent studies have paradoxically demonstrated poorer cure rates (approximately 20 percent) with autologous HCT for relapsed B-cell NHL in the rituximab era.²⁸⁵ One possibility is that rituximab-containing first-line chemotherapy is successful in curing a greater number of patients, but also selects for patients with particularly resistant disease in the setting of relapse.

Autologous HCT is sometimes used as consolidation for high-risk lymphomas in CR1, especially in mantle cell lymphoma, where autologous HCT in CR1 has been shown to extend progression-free survival in a phase III randomized trial.²⁸⁶ Autologous HCT in mantle cell lymphoma is most effective when performed early in the disease course,^{287,288} and thus eligible patients with mantle cell lymphoma should be referred for transplant consultation during their induction course to discuss the risks and benefits of consolidative autologous HCT. Outside the setting of mantle cell lymphoma, there are few B-cell lymphomas where data clearly support consolidative autologous HCT in CR1. Nevertheless, patients with so-called “double-hit” lymphomas (those mutated at both *c-MYC* and either *bcl-2* or *bcl-6*) are viewed as particularly high-risk and sometimes treated with autologous HCT in CR1. However, two recent studies have questioned the need for this approach; in both, patients with double-hit lymphomas who achieved PET-negative CR with induction therapy had excellent overall survival (75 to 83 percent), and autologous HCT in CR1 was not considered beneficial.^{289,290} Autologous HCT is also often advocated as consolidation for patients with T-cell lymphomas in CR1, with the exception of anaplastic lymphoma kinase-positive (ALK+) large cell lymphoma. Definitive data supporting this practice are not available, but this approach appears reasonable in view of the very high relapse rate associated with these lymphomas.

Allogeneic HCT is highly active and potentially curative for NHL, particularly indolent NHL. Excellent disease-free survival has been reported with both early and late allogeneic HCT in indolent NHL, even in heavily pretreated patients and those with active disease at

allotransplantation.^{179,181} The optimal timing of allogeneic HCT in indolent NHL remains to be determined, particularly as indolent NHL can often be treated effectively with conventional chemotherapy for years or even decades. For more aggressive relapsed NHL or for relapsed HL after failed autografting, allogeneic HCT remains the only potentially curative salvage option. However, with these more aggressive malignancies, it is essential that patients be chemoresponsive and, ideally, in a PET-negative CR in order to proceed to allotransplantation, as otherwise relapse is nearly universal before GVT effects can become established.^{291,292}

● COMPLICATIONS OF HEMATOPOIETIC CELL TRANSPLANTATION

Table 23-3 lists the complications associated with HCT; the most common are discussed below. The first 100 days following transplantation are the time of greatest risk for recipients of autologous and allogeneic HCT. Care by physicians skilled in the management of patients undergoing these procedures is of critical importance.

GRAFT FAILURE

Graft failure is defined as the lack of donor hematopoietic cell engraftment following autologous and allogeneic HCT. Criteria are predominantly operational, and graft failure is divided into primary (early) and secondary (late) phases. The consequences of graft failure are significant, and include high risks of death from infection, hemorrhage, or relapsed malignancy.

Primary (Early) and Secondary (Late) Graft Failure

Myeloid engraftment has commonly been defined as the first of three consecutive days on which the absolute neutrophil count exceeds $5 \times 10^8/L$. Myeloid engraftment typically occurs within 21 days of the graft infusion, irrespective of graft source. Platelet recovery is more variably defined, often as the first day of a platelet count of at least 20, 50, or $100 \times 10^9/L$, sustained without transfusion for 7 days. Platelet recovery may be substantially delayed compared with myeloid recovery, particularly with lower CD34+ cell doses or UCB allografts. A hemoglobin level of at least 8 g/dL without transfusion support is an accepted threshold for red cell engraftment. These criteria were derived from the predictable kinetics seen after myeloablative conditioning. With RIC, many patients never develop severe cytopenias, and thus engraftment in these settings is usually defined, at least in part, by assessment of donor chimerism in the blood or marrow. In these settings, graft loss is typically defined by donor chimerism of less than 5 percent in blood CD3+ cells.

Primary graft failure is defined as failure to achieve these threshold counts or donor chimerism levels at any point beyond day +28. Isolated cytopenias does not necessarily herald graft failure, as they may be transitory phenomena related to infection, medications, lineage-specific immune-mediated cytopenias, or GVHD. Secondary (late) graft failure occurs in patients who initially meet criteria for engraftment but subsequently lose graft function in at least two cell lines. Late graft failure is more often associated with allogeneic HCT than with autologous transplantation; possible causes include graft rejection related to residual host immunity, persistent or progressive malignancy, low donor cell yield, medication side effects, infection, or GVHD.

Graft Rejection and Poor Graft Function

Graft rejection is a subset of primary or secondary graft failure caused by immune-mediated rejection of donor cells by residual host effector cells. A diagnosis of graft rejection requires analysis of blood or marrow for donor hematopoietic chimerism; graft rejection is defined as

TABLE 23-3. Complications of Hematopoietic Cell Transplantation

Vascular access complications
Graft failure

GVHD, graft-versus-host disease; HHV, human herpes virus subtypes.

the inability to detect a meaningful percentage (usually >5 percent) of donor hematopoietic elements. In contrast, *poor graft function* describes the failure to achieve adequate blood counts following allogeneic HCT in the presence of substantive donor hematopoietic cell chimerism.

Graft Failure Following Reduced-Intensity Conditioning

Allogeneic HCT following RIC is associated with incomplete eradication of host hematopoiesis. As a consequence, a significant percentage of patients have mixed donor/host hematopoietic chimerism for several months after transplantation before converting to complete donor type.^{186,293} Primary engraftment following reduced-intensity allogeneic HCT is defined by neutrophil, platelet, and hemoglobin count recovery as outlined above as well as stable donor T-cell chimerism. As described above, graft failure is said to have occurred when blood donor T-cell

chimerism is less than 5 percent at any point after reduced-intensity allogeneic HCT. Donor T-cell chimerism levels greater than 5 percent but less than 95 percent are generally termed “mixed chimerism,” while full donor chimerism is defined by blood donor T-cell chimerism of 95 percent or greater.

Incidence of Graft Failure

The incidence of graft failure varies widely in published reports. To estimate the incidence of graft failure following autologous HCT, consider that in most centers the TRM associated with autologous HCT is less than 5 percent, of which only a small subset can be attributed to graft failure. Another surrogate marker for estimating the incidence of graft failure following autologous HCT is the requirement for hematopoietic cell rescue using a backup autograft product. A study of 300 patients who underwent autologous HCT revealed that 4.7 percent required their backup product.²⁹⁴ Thus, it is reasonable to estimate that the incidence of graft failure following autologous HCT is somewhere between 1 and 5 percent.

Graft failure following allogeneic HCT is more complex, because of confounding factors such as histocompatibility, ABO matching, graft-versus-host and host-versus-graft reactions, and the use of postgrafting immunosuppression. The overall incidence of graft failure after allogeneic HCT is approximately 5 to 6 percent.²⁹⁵ In general, graft failure is uncommon after high-dose conditioning and in patients who are heavily pretreated with cytotoxic chemotherapy before coming to allogeneic HCT. Even in the myeloablative setting, though, the incidence of graft failure varies with conditioning regimen, as illustrated in a randomized trial where graft failure occurred in zero of 64 (0 percent) of patients receiving BU/CY but in five of 62 (8 percent) of patients receiving BU/FLU.¹⁷⁴ The risk of graft rejection is highest in patients who are heavily presensitized or who have autoimmunity directed at hematopoietic cells (as in aplastic anemia), those who receive low CD34+ cell doses,^{295,296} and those with diseases such as myelofibrosis where the marrow micro-environment is significantly perturbed.

The consequences of graft failure, and its optimal treatment, depend in large part upon the likelihood of autologous hematopoietic recovery. In patients who have received high-dose conditioning, autologous marrow recovery is likely to be severely delayed if not absent, and graft failure is associated with high mortality rates as a consequence of prolonged cytopenias. Second-salvage allogeneic HCT has been used successfully to treat graft failure in this setting; reported outcomes vary from dismal to encouraging,^{297,298} and likely depend substantially on patient selection. There is no consensus on whether to use the same or a different donor for salvage allogeneic HCT for graft rejection, and the decision often depends on donor availability. The time needed to identify and collect a second allograft product are often prohibitive for patients with graft rejection and pancytopenia, and thus readily available HSC sources such as UCB and HLA-haploidentical family members have sometimes been used.

For patients with graft failure after RIC, autologous hematopoietic recovery is more likely. For these patients, the optimal strategy often involves withdrawing postgrafting immunosuppression and awaiting autologous count recovery. However, for patients with malignant disease, the risk of relapse is substantially elevated in the setting of graft failure,²⁹⁵ presumably as a result of a loss of GVT effects.

REGIMEN-RELATED ORGAN TOXICITIES

The severity of organ toxicities associated with HCT is a function of the intensity of conditioning therapy, the amount of prior therapy received, patient comorbidities before transplantation, and posttransplantation factors such as immunosuppressive medication and antimicrobial agents.

Mucositis

Mucositis occurs in more than 90 percent of patients receiving high-dose regimens and is often regarded as the most difficult issue from the patient's perspective.²⁹⁹ Current management is supportive and includes frequent rinsing with saline solutions and antimicrobials, cryotherapy, pain control (often with continuous intravenous infusions of opioids), and parenteral nutrition when needed. Improvement typically occurs within 10 to 21 days of transplantation, around the time of engraftment. Fully ablative regimens, TBI-based conditioning, and the administration of posttransplantation methotrexate (MTX) for GVHD prevention are associated with more severe mucositis.³⁰⁰ Severe mucositis may result in significant tissue edema, upper airway obstruction, and/or aspiration pneumonitis, although fortunately these complications are rare. Regimen-related gastroenteritis results in nausea, vomiting, and diarrhea, which may persist for weeks after the transplant. Breaches in the mucosal lining predispose to bacterial translocation from the gastrointestinal tract, with increased risk of bacteremia and sepsis. Palifermin (keratinocyte growth factor) can reduce patient-controlled anesthesia (PCA) and total parenteral nutrition (TPN) usage because of mucositis, predominantly in patients receiving TBI-based conditioning,³⁰¹ but at a cost of \$5500 to \$14,000 per day.³⁰² Initial hopes that this agent would prevent GVHD after allogeneic HCT have not been realized,^{303,304} and the benefits of palifermin appear limited to ameliorating mucositis.

Sinusoidal Obstructive Syndrome

Sinusoidal obstructive syndrome (SOS) is a clinical syndrome of regimen-related hepatotoxicity characterized by tender hepatomegaly, fluid retention, weight gain, and elevated serum bilirubin following autologous or allogeneic HCT. This syndrome was formerly called venoocclusive disease (VOD), but this term is no longer used as it inaccurately describes the underlying pathobiology: the liver injury is initiated by damage to hepatic sinusoidal epithelium, and obstruction of hepatic venules is not essential to the development of the syndrome.³⁰⁵ The incidence of SOS varies significantly with the intensity of conditioning and with the stringency of diagnostic criteria, from less than 10 percent to as high as 30 to 40 percent. CY is a key culprit in the development of SOS, and large interpatient variability in CY metabolism may account for the syndrome's unpredictability.^{306,307} Other contributing factors include the preadministration of BU in the BU/CY regimen, which potentiates CY hepatotoxicity¹⁷²; preexisting hepatic fibrosis, as in patients with cirrhosis or with hepatic extramedullary hematopoiesis as in myelofibrosis³⁰⁸; and pretreatment with higher doses of gemtuzumab ozogamicin.^{309,310} The incidence of SOS appears to be decreasing over time,³¹¹ likely a result of the prevalence of RIC regimens and the prophylactic use of ursodiol, which prevents SOS and other forms of hepatic injury during allogeneic HCT.^{312,313}

SOS is generally is classified as mild (clinically apparent yet resolves without treatment), moderate (requiring diuretics and pain medication for abdominal discomfort yet completely resolves before day +100), or severe (not resolving before day +100 or death).³¹⁴ Severe SOS has a tendency to progress to multiorgan failure and is associated with a mortality rate of greater than 80 percent.³¹⁵ Therapy for SOS is supportive and includes management of sodium and water balance with diuretics, preservation of renal blood flow, and paracentesis for ascites associated with significant discomfort or pulmonary compromise. Patients with a poor prognosis can be recognized early after SOS onset by steep rises in serum bilirubin, body weight, and other liver enzymes; hepatic venous pressure measurement greater than 20 torr; development of portal vein thrombosis; and multiorgan failure requiring mechanical ventilation or renal dialysis.³¹⁶

There are few satisfactory therapies for severe SOS; the most commonly used is intravenous defibrotide, a mixture of single-stranded

porcine oligodeoxyribonucleotides which induces antithrombotic and fibrinolytic effects in preclinical models.³¹⁷ Its mechanism of action against SOS remains unknown. A randomized phase II dose-finding trial involving 149 patients with severe SOS reported day +100 survival of 42 percent with few adverse events, and a dose of 25 mg/kg/day was selected for ongoing randomized phase III trials.³¹⁸ However, defibrotide is not yet approved by the FDA and remains available only on an investigational or compassionate-use basis in the United States.

Pulmonary Complications

Noncardiogenic and noninfectious diffuse lung injury, also referred to as idiopathic pneumonia syndrome (IPS), remains a significant problem following autologous or allogeneic HCT, occurring in 10 to 15 percent of transplant recipients.³¹⁹ Risk factors for idiopathic IPS include high-dose conditioning, TBI, GVHD, older recipient age, prior history of cigarette smoking, prior thoracic/mediastinal irradiation, and abnormal gas exchange as measured by pretransplant pulmonary function testing.³²⁰ Preclinical models suggest that donor T cells play a key role in the development of IPS, indicating that it may be a form of graft-versus-host reaction.³¹⁹ In a small subset of patients, diffuse alveolar hemorrhage (DAH) develops, characterized by progressive shortness of breath, cough, and hypoxemia. Classically, DAH is defined by the demonstration of progressively bloodier aliquots in bronchoalveolar lavage fluid. Mortality from this complication is high (often >75 percent) despite aggressive treatment. Another subset of patients with IPS develop periengraftment respiratory distress without a bloody bronchoalveolar lavage. In the autologous setting, the IPS often responds promptly to glucocorticoids, whereas in the allogeneic setting response rates are lower, indicating that perhaps some cases may be complicated by GVHD.

The management of suspected IPS begins with bronchoscopy to rule out infectious etiologies and to evaluate for DAH. Care is supportive and aimed at maximizing respiratory function and preventing volume overload or multiorgan failure. Patients are typically treated with high-dose glucocorticoids (methylprednisolone at 2 mg/kg/day or higher), along with broad-spectrum antimicrobials and intensive supportive care. Retrospective studies have suggested that tumor necrosis factor (TNF) blockade with etanercept may be effective as an adjunct to high-dose glucocorticoids,³²¹ but a prospective randomized study failed to find an additive benefit,³²² and thus etanercept cannot be routinely recommended at this time. Patients with IPS who progress to require mechanical ventilation have a very poor prognosis, and a frank discussion of the goals of care is indicated in this setting, particularly in the presence of multiorgan failure.³²³

Lung inflammation following the administration of BCNU is a separate form of noninfectious lung injury seen in HCT recipients who receive this agent as part of their conditioning regimens. BCNU-induced pneumonitis is often characterized by a nonproductive cough with increasing dyspnea and bilateral pulmonary infiltrates on chest radiography, with or without fevers, and often occurs 1 to 2 months after transplantation.³²⁴ Pulmonary function tests reveal a restrictive pattern of lung injury and a decrease in diffusing capacity compared to pretransplant values. Prompt treatment with glucocorticoids reduces mortality and morbidity and is crucial to a successful outcome. If untreated or recognized late, significant pulmonary fibrosis may develop.

INFECTIONS

Susceptibility to infection is a significant challenge in the clinical management of transplant recipients. The essential principles are prevention, judicious monitoring, and expeditious treatment of all bacterial, fungal, and viral infections. These basic principles are widely accepted, yet the day-to-day strategy for implementing them varies widely among

transplant physicians and centers. Two universally important measures for reducing infections in immunocompromised transplant recipients are effective handwashing policies and a strategy for preventing transmission of respiratory viruses, including metapneumovirus, respiratory syncytial virus, parainfluenza, and influenza.

The duration of neutropenia and severity of oral and gastrointestinal mucosal damage from the conditioning regimen are risk factors for infection before neutrophil recovery has occurred. Following neutrophil recovery, deficiencies of B- and T-cell-mediated immunity persist and increase susceptibility to opportunistic infections. Immune recovery following autologous HCT is relatively rapid compared to after allogeneic transplantation. Most autologous transplant recipients recover T-cell immunity specific for herpes viruses, including CMV, by 3 months after transplantation.³²⁵ The degree and duration of immunodeficiency following allogeneic HCT are influenced, in part, by the type of immunosuppressive therapy and severity of GVHD. Chronic GVHD is associated with chronic B- and T-cell immune deficiencies that may persist for years, and Ig production and reticuloendothelial function may also be impaired.^{326–328}

Bacterial Infections

Bacterial infections are common during the period of immediate neutropenia that follows the preparative transplantation regimen, and can be caused by both Gram-positive and Gram-negative organisms.³²⁹ The increased risk of bacterial infections is not only caused by neutropenia, but also from loss of epithelial integrity from regimen-related injury, bacterial translocation, and the presence of indwelling intravenous catheters. Some centers institute preventive measures in addition to rigorous hand washing, such as gowning and masking, although there is little evidence that these actions reduce infection risk. Removal of venous catheters is sometimes required for patients who do not respond promptly to treatment. Chapter 24 reviews specific strategies and regimens for treating bacterial infections in neutropenic patients.

Patients who require ongoing immunosuppressive therapy for the control of chronic GVHD are at risk for recurrent bacteremia with encapsulated bacteria and sinopulmonary infections. Preventive strategies differ from institution to institution, although some form of antibiotic prophylaxis is often used in these patients. Infrequent bacterial pathogens which should also be considered, especially in the presence of pulmonary infiltrates or nodules, are *Legionella*, *Nocardia*, *Mycobacterium tuberculosis*, and atypical mycobacteria.

Fungal Infections

Fungal infections are serious and potentially fatal complications following HCT, and are seen most commonly in allogeneic HCT recipients as a result of the requirement for postgrafting immunosuppressive medication. The incidence of fungal infection varies considerably among transplantation centers because of a variety of factors, including geographic location, nearby construction, and prophylactic regimens. *Candida* and *Aspergillus* are the most common fungal pathogens; however, other organisms can also cause life-threatening infections. Chapter 24 discusses the treatment and prophylaxis of fungal infections.

Fluconazole prophylaxis decreases the incidence of invasive and superficial *Candida albicans* infections and may decrease the 100-day mortality in allogeneic HCT recipients.³³⁰ Fluconazole has limited activity against *Candida krusei*, *Torulopsis glabrata*, and *Aspergillus* species, and some centers reported an increased incidence of resistant *Candida* infections in patients receiving prophylactic fluconazole.³³¹ More aggressive prophylaxis with mold-active agents such as voriconazole or itraconazole can prevent invasive mold infections, including aspergillosis, but these agents are associated with a higher risk of adverse events and no clear benefit to mortality.^{332,333}

Viral Infections

Infection with herpesviruses can cause significant morbidity and mortality in HCT recipients. Most infections are a result of viral reactivation and follow a relatively predictable temporal pattern in the absence of prophylaxis: *Herpes simplex* virus (HSV) causes clinically apparent disease at approximately 2 to 3 weeks after HCT, CMV disease usually occurs during the second to third month, and varicella-zoster virus (VZV) recurrences present at a median of 5 months after HCT.³³⁴

CMV is an important viral pathogen in HCT recipients. Infection occurs from reactivation of latent virus or is newly acquired from the donor graft or blood transfusions. Reactivation is a common problem in allogeneic HCT, but is relatively rare after autologous HCT except in the setting of CD34+ selection and T-cell depletion.¹²³ Before effective prevention strategies were introduced, CMV infection developed in 70 percent of CMV-seropositive transplant recipients and 32 percent of CMV-seronegative recipients and was a frequent cause of TRM.³³⁵ Currently, all allogeneic HCT recipients at risk for CMV infection (those who are CMV-seropositive or who have a CMV-seropositive donor) require monitoring with preemptive therapy for CMV reactivation; this approach has markedly reduced the risk of progression to frank CMV disease such as enteritis or pneumonitis.³³⁶ Prophylactic antiviral therapy against CMV is used by some centers, particularly in high-risk situations such as UCB recipients. More commonly, allogeneic HCT recipients are monitored with plasma CMV polymerase chain reaction (PCR) assays at least weekly through at least day +100 after HCT, and are treated preemptively if these studies yield values which exceed institutionally established thresholds.³³⁴ The preemptive approach avoids the toxicity of universal antiviral prophylaxis, reduces the risk of acquired antiviral resistance, and limits overtreatment of CMV while preventing development of tissue disease. However, CMV tissue disease such as enteritis or pneumonitis can, rarely, develop despite negative plasma CMV PCR, and CMV enteritis or pneumonitis cannot be definitively ruled out by blood tests alone.

Prophylaxis with acyclovir or, more potently, valacyclovir can reduce the risk of CMV reactivation after allogeneic HCT, but does not obviate the need for CMV surveillance.^{337,338} Intravenous ganciclovir is typically the first-line treatment for CMV reactivation or tissue disease, although oral valganciclovir may be equally effective as preemptive therapy.^{339,340} The most common adverse effect of these antiviral drugs is myelosuppression, which often requires growth-factor support. Intravenous foscarnet is as effective as ganciclovir in CMV prevention and treatment,³⁴¹ and does not cause myelosuppression. However, foscarnet is nephrotoxic and requires cumbersome pre- and posthydration, and is thus most often used as second-line therapy in patients who cannot tolerate ganciclovir because of myelosuppression. Patients with CMV reactivation are typically treated with an induction dose of anti-CMV therapy (ganciclovir, valganciclovir, or foscarnet) for at least 2 weeks, followed by maintenance antiviral therapy until CMV assays are persistently negative. It is not uncommon for patients to experience additional late reactivations after antiviral therapy is discontinued, and these patients require ongoing monitoring beyond day +100.

Investigational approaches to CMV prevention and treatment include CMX-001, an oral prodrug that is converted to cidofovir intracellularly and lacks renal toxicity. A placebo-controlled randomized trial of CMX-001 as CMV prophylaxis in allogeneic HCT found that this agent reduced the incidence of CMV activation from 37 percent to 10 percent.³⁴² Diarrhea was the most common adverse effect; myelosuppression and nephrotoxicity were not observed. Letermovir, a novel terminase inhibitor, has also shown efficacy in preventing CMV reactivation in allogeneic HCT in randomized, placebo-controlled clinical trials.³⁴³ Maribavir, another antiviral agent with a novel mechanism of action, was effective in preventing CMV in a randomized dose-finding

study,³⁴⁴ but failed to demonstrate a benefit in a randomized phase III clinical trial.³⁴⁵ Donor-derived CMV-specific cytotoxic lymphocytes have also been used investigational with some success.³⁴⁶

HSV and VZV are two other members of the herpesvirus family that cause significant morbidity in the posttransplantation setting. These viruses share the characteristics of latency, reactivation, and neurotropism. Virtually all HSV disease occurring after HCT is a result of reactivation, and the serologic status of the transplant recipient determines the risk for disease and the requirement for prophylaxis. Oral mucositis, cutaneous infections, esophagitis, genital herpes, and pneumonia are the most common clinical manifestations. Acyclovir is highly effective for the prevention and treatment of HSV and should be administered to all HSV-seropositive transplant recipients, beginning before or during conditioning. Acyclovir prophylaxis is often continued for at least 1 year after HCT (or longer if patients remain on immunosuppressive therapy), as this approach reduces the risk of late HSV recurrence.³⁴⁷ Acyclovir is well tolerated immediately after transplantation with no effect on the recovery of neutrophil counts. Valacyclovir is an acceptable alternative. Patients do not require concomitant acyclovir prophylaxis while receiving maribavir, foscarnet, valganciclovir, ganciclovir, or cidofovir for treatment of another virus, because these agents have adequate anti-HSV activity. Acyclovir resistance is rare in HSV and can be treated using foscarnet.³⁴⁸

Recurrent VZV disease can occur after both allogeneic and autologous HCT. The initial manifestations of recurrence are localized in approximately half of patients. Treatment with acyclovir within 24 to 48 hours of the onset of herpes zoster prevents dissemination and shortens the course of cutaneous disease. The failure of VZV infections to resolve quickly or their recurrence shortly after acyclovir therapy is discontinued is usually a function of the limited host immune response and is generally not a result of acyclovir resistance. For the rare cases of acyclovir-resistant VZV, foscarnet is the most commonly used alternate therapy.³⁴⁸ Acyclovir, given for at least 1 year after HCT, is highly effective in preventing VZV recurrence.³⁴⁹ Pilot studies of vaccination with live attenuated VZV in allogeneic HCT recipients suggest that this approach is safe and effective in selected patients (median of 4 years posttransplantation, off systemic immunosuppression, blood CD4+ cell count >200/ μ L),³⁵⁰ but larger studies are required before vaccination can be widely recommended. Heat-inactivated VZV vaccination has also been reported as efficacious in recipients of autologous HCT.³⁵¹

ACUTE GRAFT-VERSUS-HOST DISEASE

Acute GVHD remains one of the most serious and challenging complications of allogeneic HCT. The requirements for the development of acute GVHD were described more than 40 years ago: the graft must contain immunologically competent cells, the recipient must express tissue antigens not found in the donor, and the recipient must be immunologically suppressed such that an effective response against transplanted cells cannot occur.³⁵² HLA disparities are potent triggers of GVHD, but in the setting of HLA-matched donor/recipient pairs GVHD is mediated by minor histocompatibility antigen disparities which provoke a donor T-cell response.^{353,354} There are two primary classes of MHC antigens in humans: HLA class I antigens have a broad distribution and are expressed on nearly all cells, whereas HLA class II antigen expression is restricted to macrophages, dendritic cells, B cells, and activated T cells. Minor histocompatibility antigens are endogenous cellular proteins which are subject to significant genetic polymorphism and are presented to donor T cells as small peptides bound in the grooves of the major histocompatibility antigens.³⁵⁵ Some minor histocompatibility antigens associated with GVHD include CD31, HA-1, and the male-specific *DBY* gene.^{356,357} There are likely hundreds if not thousands

of minor histocompatibility antigens relevant to allogeneic HCT, of which only a handful have been identified to date. Efforts are underway to utilize genome-wide association studies to broaden our knowledge of these determinants of GVT effects and GVHD.³⁵⁸

The most important risk factor for the development of acute GVHD is the degree of HLA disparity between donor and recipient. The increased incidence of acute GVHD with fully HLA-matched unrelated donors compared to HLA-identical sibling donors is likely related to increased disparity in minor histocompatibility antigens or unrecognized disparities in the phenotypically matched major histocompatibility loci.³⁵⁹ Other risk factors for acute GVHD development include conditioning intensity, use of TBI, and possibly graft source (although the effect of graft source on acute GVHD incidence is not consistently observed).^{72,359}

Classically, acute GVHD was defined temporally by its occurrence before day +100 after allogeneic HCT. With RIC, acute GVHD can occur beyond day +100, and the distinction between acute and chronic GVHD is now based on organ involvement and histology rather than time of onset.³⁶⁰ Acute GVHD affects the skin, gastrointestinal (GI) tract, and liver (although liver involvement is increasingly rare, for reasons which are not entirely clear).²¹⁸ The overall incidence of acute GVHD after allogeneic HCT is 40 to 60 percent,³⁵⁹ although the incidence may vary widely in specific settings depending on conditioning regimen, HLA matching, and graft source.

Skin involvement manifests as a rash, which may be localized and maculopapular or diffusely erythematous with bullae and desquamation in very severe cases. Definitive diagnosis requires skin biopsy and interpretation by an experienced pathologist.³⁶¹ However, skin biopsies are often inconclusive, and the diagnosis is often made on clinical grounds in patients with a skin rash consistent with acute GVHD arising during the appropriate timeframe after allogeneic HCT. Decision analysis supports the concept that the diagnosis of skin GVHD can be made clinically and does not require skin biopsy in patients with a pretest likelihood of acute GVHD of 30 percent or greater (the majority of allogeneic HCT recipients).³⁶²

GI manifestations of acute GVHD can affect the upper GI tract (presenting as nausea, emesis, anorexia, and weight loss), the lower GI tract (presenting as diarrhea with or without abdominal cramping and hematochezia), or both. Upper-GI involvement with acute GVHD is likely underdiagnosed, since the symptoms may be mild and post-transplant anorexia and nausea are often nonspecific and multifactorial. Diagnosis requires upper endoscopy and endoscopic biopsy, with interpretation by an experienced pathologist. The diagnosis of upper-GI acute GVHD is clinically important, because this syndrome often responds dramatically to even low-dose treatment and, if left untreated, can cause significant nutritional compromise.

Lower-GI involvement with acute GVHD is a more serious and feared complication of allogeneic HCT. These patients present with substantial diarrhea, often several liters per day, accompanied by pain and bleeding. The diarrhea of acute GVHD is secretory, related to epithelial injury, and typically persists around the clock. Abdominal computed tomography (CT) findings, particularly bowel-wall thickening, are common in acute GVHD,³⁶³ but CT findings alone are insufficient for diagnosis. Patients with suspected lower-GI GVHD should undergo endoscopic evaluation and biopsy as soon as feasible, although in the setting of myeloablative conditioning it is often difficult to differentiate regimen-related GI injury from acute GVHD endoscopically or histologically before day +20. Flexible sigmoidoscopy is viewed as a sufficient diagnostic test in most cases,^{364,365} and is far easier to perform than full colonoscopy as it does not require an aggressive preparatory regimen. Visual inspection of the gut mucosa is often sufficient to advance a diagnosis of acute GVHD and initiate treatment,³⁶⁶ particularly if

the endoscopist has experience in evaluating allogeneic HCT recipients, but biopsies remain essential to rule out CMV enteritis and other etiologies.³⁶⁵ Mucosal denudation is a particularly concerning endoscopic finding,³⁶⁶ and is associated with a grim prognosis.

Hepatic GVHD presents with abnormal liver function tests, most commonly elevated bilirubin and alkaline phosphatase. Liver biopsy is required for definitive diagnosis, but is rarely performed because of the low pretest likelihood of hepatic GVHD in the modern era and because of procedural risk. When biopsies are performed, the most common finding associated with hepatic GVHD is bile-duct injury and loss resulting in cholestasis.³⁶⁷ Numerous other etiologies can cause abnormal liver function tests in allogeneic HCT recipients, including SOS, viral hepatitis, regimen-related hepatotoxicity, and medication-related hepatotoxicity (particularly with triazoles and CSP). Hepatic GVHD is relatively uncommon except in the setting of severe multisystem acute GVHD.

Pathophysiology

The current model of acute GVHD requires three steps. In step 1, the transplantation conditioning regimen damages host tissue, leading to increased secretion of inflammatory cytokines such as TNF- α and IL-1. These cytokines enhance alloreactivity of donor T cells by upregulating the expression of major and minor host tissue histocompatibility antigens and also affect other molecules on host antigen-presenting cells (APCs). Regimen-related damage to the GI tract results in leakage of endotoxins such as lipopolysaccharides into the systemic circulation, where they serve as additional inflammatory stimuli.³⁵³ In step 2, resting donor T cells become activated in secondary lymphoid organs by host or donor APCs, which present alloantigens to the T-cell receptor in the context of MHC. Costimulatory signals are required for full T-cell activation. Donor T-cell activation is characterized by cellular proliferation and predominance of Th1 cells and the secretion of IL-2 and IFN- γ . In step 3, cellular effectors mediate tissue injury and destruction in the target organs, resulting in the clinical manifestations of acute GVHD. This step involves the continued release of inflammatory cytokines that direct specific antihost donor-derived T cells to migrate to the target tissues of acute GVHD, namely, skin, liver, and gut. Neutrophils and mononuclear phagocytes contribute to local tissue injury by amplifying the proinflammatory response.

Prevention

Without some form of GVHD prophylaxis, virtually all patients undergoing allogeneic HCT would develop severe or fatal acute GVHD. Immunosuppressive drugs are the mainstay of acute GVHD prevention, and all patients undergoing allogeneic HCT with a T-cell-replete graft require prophylaxis. On the basis of randomized clinical trials published in the 1980s, the most commonly used regimen in myeloablative allogeneic HCT is the combination of a calcineurin inhibitor (CSP or tacrolimus [TAC]) with a short course of MTX, generally given on days +1, +3, +6, and +11 after allotransplantation.^{368,369} The addition of prednisone to this backbone paradoxically increased the risk of acute GVHD in a randomized clinical trial, and thus glucocorticoids are rarely used for GVHD prophylaxis.³⁷⁰ Two randomized studies demonstrated that TAC was superior to CSP in preventing acute GVHD after myeloablative allogeneic HCT,^{371,372} and thus TAC has largely supplanted CSP in this setting. A recent randomized clinical trial conducted by the BMT-CTN compared TAC/sirolimus (TAC/SRL) to the standard TAC/MTX regimen as GVHD prophylaxis after myeloablative allogeneic HCT. The primary endpoint (day +114 survival free of acute GVHD grades II to IV) was not significantly different in the two arms, nor were overall or progression-free survival.³⁰⁰ The toxicity profiles of the two regimens

differed somewhat, but did not impact TRM. Interestingly, there was a strong trend toward a higher incidence of chronic GVHD in the SRL-containing arm (53 percent vs. 45 percent, $p = 0.06$).

Donor T-cell depletion has been explored as a means of GVHD prevention, using either mechanical *ex vivo* T-cell depletion or *in vivo* T-cell depletion in the form of ATG or alemtuzumab. T-cell-depletion strategies have generally been successful in reducing GVHD, but in many instances the reduction in donor T cells contributes to an increased incidence of graft rejection, infection, and relapse which may negate the advantage of GVHD prevention. A recent randomized clinical trial of ATG versus placebo added to standard CSP/MTX GVHD prophylaxis reported lower rates of acute and chronic GVHD in the ATG arm, although TRM and overall survival were not improved.³⁷³ Longer followup from this study confirmed a significantly lower rate of chronic GVHD in the ATG arm (45 percent vs. 12 percent, $p < 0.0001$).³⁷⁴ However, ATG was associated with an increased risk of PTLT, a complication that is virtually nonexistent after T-cell-replete allogeneic HCT. In fact, there were 4 deaths from PTLT in the ATG arm (versus none in the placebo arm). Perhaps as a result, the study did not show improvements in TRM or overall survival with ATG. A subsequent randomized clinical trial aimed at replicating and extending these results with ATG has been completed in the United States.

In the setting of reduced-intensity allotransplantation, a number of immunosuppressive regimens have been used, the most common being CSP plus MMF.^{177,185} Posttransplant CY has demonstrated impressive efficacy in the setting of HLA-haploidentical HCT, and has been studied in the setting of HLA-matched allotransplantation as well.^{375,376} The combination of TLI and ATG is associated with very low rates of acute and chronic GVHD even with standard CSP/MMF postgrafting immunosuppression,^{184,185} suggesting that protective conditioning can play a significant role in GVHD prevention.

Several laboratories have reported that naive (CD62L+) T cells induce experimental acute GVHD, whereas effector memory (CD62L-) T cells do not.^{377,378} Based on this insight, depletion of naive donor T cells has been investigated as a means of preventing acute GVHD in humans.³⁷⁹ Murine models of marrow transplantation show that simultaneous infusions of T_{reg} limited the proliferation and clonal expansion of activated donor T cells and protected against acute GVHD development in murine models.¹⁴⁴ Pilot studies of T_{reg} infusions in humans have demonstrated safety and some efficacy in preventing GVHD,^{145,146,380} although larger trials are required to confirm these preliminary findings. Importantly, relapse rates did not appear to be increased by the addition of T_{reg}, consistent with murine models.^{144,146}

Another investigational avenue in GVHD prevention involves inhibition of lymphocyte trafficking through CCR5 blockade. A recent trial combining the CCR5 antagonist maraviroc with standard GVHD prophylaxis demonstrated low rates of acute GVHD, particularly GI GVHD.³⁸¹ The BMT-CTN is currently conducting a three-arm randomized clinical trial comparing novel approaches to GVHD prophylaxis: posttransplant CY; maraviroc; and bortezomib-based immunosuppression.

Treatment

The standard first-line therapy for acute GVHD requiring systemic treatment is methylprednisolone or prednisone, at a dose of 1 to 2 mg/kg/day with subsequent tapering once disease activity resolves. Higher doses of methylprednisolone (10 mg/kg per day) do not prevent evolution to grades III to IV acute GVHD or improve survival.³⁸² Patients with acute GVHD grade II or less can be safely treated with a starting dose of 1 mg/kg/day of methylprednisolone, an approach that reduces overall glucocorticoid exposure and toxicity.³⁸³ Complete resolution of acute GVHD is reported in less than 50 percent of patients after first-line

treatment with glucocorticoids, and the likelihood for long-term survival is low among individuals who develop glucocorticoid-refractory acute GVHD.³⁸⁴ Various approaches, including third-party mesenchymal stem cells, MMF, and TNF blockade, have been combined with glucocorticoids in upfront treatment of acute GVHD, but none has proven superior to glucocorticoids alone.^{385,386}

There is no standard second-line therapy for patients with glucocorticoid-refractory acute GVHD. Practices vary widely, although groups such as the ASBMT have published guidelines in an effort to codify and standardize treatment.³⁸⁷ Even though many agents have been used in this setting, none has proven superior or even reliably effective. Options include enrollment on a clinical trial, treatment with a second-line agent of choice, and palliative care. Agents that have been studied include daclizumab, SRL, MMF, ABX-CBL (a CD147-specific monoclonal antibody), anti-TNF agents, visilizumab, ruxolitinib,^{388,389} and ATG, among others. In the absence of comparative clinical trial data, the choice of second-line agent is often guided by institutional experience, physician preference, and side-effect profiles. Outcomes with second-line therapy remain poor, and novel treatments for glucocorticoid-refractory acute GVHD are needed.

CHRONIC GRAFT-VERSUS-HOST DISEASE

Chronic GVHD is the major determinant of quality of life in long-term survivors of allogeneic HCT.^{390,391} Despite its impact, however, it remains poorly understood and treatment options remain limited and largely empiric. Historically, any form of GVHD occurring beyond day +100 after allogeneic HCT was defined as chronic GVHD. However, with an increasing appreciation of the biologic differences between acute and chronic GVHD and the recognition that late acute GVHD occurs beyond day +100 with RIC, chronic GVHD was redefined on the basis of pathognomonic clinical and histologic criteria by a National Institutes of Health (NIH) consensus conference in 2005.³⁶⁰ The NIH consensus criteria include global and organ-specific scoring to evaluate the severity of chronic GVHD, and these staging tools have been validated to correlate with clinical severity and outcomes.^{392,393} The Center for International Blood and Marrow Transplant Research (CIBMTR) has also developed a chronic GVHD risk-stratification algorithm that identifies age, donor–recipient gender mismatch, serum bilirubin, platelet count, donor type, and performance status, among other factors, as predictors of outcome in patients with chronic GVHD.³⁹⁴ The presence of chronic GVHD is consistently associated with more potent GVT effects and a lower risk of posttransplantation relapse,^{177,395} although the negative impact of chronic GVHD on TRM may outweigh the benefit against relapse.¹⁷⁷

In contrast to acute GVHD, which is limited to the skin, gut, and liver, chronic GVHD has diverse manifestations which can affect nearly any organ system and which overlap considerably with those of autoimmune disorders such as scleroderma, lichen planus, Sjögren syndrome, and dermatomyositis. The most common clinical features of chronic GVHD include lichenoid skin lesions that may progress to generalized scleroderma, keratoconjunctivitis sicca, lichenoid oral lesions, esophageal and vaginal strictures, intestinal abnormalities, chronic liver disease, and bronchiolitis obliterans. Comprehensive assessment of chronic GVHD requires a detailed history and physical examination, but can be performed in the clinic in less than 20 minutes.³⁹⁶ Instructional videos and training tools demonstrating clinical assessment of chronic GVHD are available.³⁹⁷

The pathophysiology of chronic GVHD remains poorly understood. In contrast to acute GVHD, where there is a track record of translation from relevant animal models to humans, existing murine models of chronic GVHD suffer from serious shortcomings,³⁹⁸ limiting

the understanding of its pathobiology and restricting the study of novel therapies. Efforts continue to develop more relevant murine models,³⁹⁹ although translational success remains elusive.

Although chronic GVHD is frequently preceded by acute GVHD, progress in reducing the incidence of acute GVHD has generally not translated into a reduction in the incidence of chronic GVHD. If anything, the incidence of chronic GVHD is likely increasing, as a result of the increasing use of PBPC as a graft source and the increasing at-risk pool of long-term survivors of allogeneic HCT. The only approaches proven to prevent chronic GVHD are the use of marrow as a graft source rather than PBPC,⁷² and the use of *ex vivo* or *in vivo* T-cell depletion (which carries increased risks of infection, PTL, and relapse).^{373,400} It has been suggested that posttransplant CY may prevent chronic GVHD, as low rates have been reported in single-arm studies,^{375,376} but this comparison is confounded by graft source (predominantly marrow in trials of posttransplant CY) and requires confirmation in randomized clinical trials. Recipient statin use has been associated with a significantly reduced risk of chronic GVHD, but a higher risk of relapse, in patients receiving CSP-based GVHD prophylaxis regimens.⁴⁰¹ Rituximab has been studied as a prophylactic agent because of the demonstrated role of B cells in the genesis of chronic GVHD. Results have been mixed; a clinical trial performed at Stanford University demonstrated that rituximab potentially abrogated B-cell alloimmunity, but did not lead to a statistically significant reduction in chronic GVHD incidence.⁴⁰² A nonrandomized study from the Dana-Farber Cancer Institute reported that rituximab decreased glucocorticoid-requiring chronic GVHD (but not overall chronic GVHD incidence) in comparison with a concurrent control cohort,⁴⁰³ a finding which requires confirmation in randomized clinical trials.

Despite decades of investigation of novel therapies, the standard of care for initial systemic treatment of chronic GVHD remains prednisone 1 mg/kg/day, with or without a calcineurin inhibitor.⁴⁰⁴ Numerous investigational agents have demonstrated promise in uncontrolled phase II clinical trials. However, these agents have uniformly proven disappointing when subjected to randomized phase III studies. At least six large randomized trials conducted over the past 20 years testing various alternate regimens, including azathioprine, thalidomide, MMF, and hydroxychloroquine, have failed to demonstrate the efficacy of any novel regimen for treatment of established chronic GVHD.^{405–410}

Patients with chronic GVHD typically require prolonged courses of immunosuppressive therapy. The median time to discontinuation of all systemic immunosuppression in patients with chronic GVHD resolution is approximately 2 years.⁴¹¹ Approximately half of patients with chronic GVHD will fail to respond to glucocorticoids and require second-line therapy.⁴¹² As with acute GVHD, there is no single standard of care for glucocorticoid-refractory chronic GVHD, and enrollment on a clinical trial should be strongly considered. Treatment choice depends on patient and physician preference, side-effect profile, and institutional priorities, as there are no data to guide a more systematic approach. Typical second-line agents include extracorporeal photopheresis (ECP), SRL, thalidomide, pentostatin, rituximab, and imatinib, among others.⁴¹² ECP is logistically cumbersome but can be effective and causes relatively few adverse effects⁴¹³; this approach is currently being studied in a randomized clinical trial conducted by the BMT-CTN. Low-dose IL-2 has been reported to facilitate T_{reg} expansion and homeostasis in a small single-center study of patients with chronic GVHD,^{414,415} although the degree of T_{reg} expansion was not significantly associated with clinical response.⁴¹⁴ Nonetheless, therapies targeting T_{regs} are under active investigation in the treatment of chronic GVHD, as is the Bruton tyrosine kinase inhibitor ibrutinib.⁴¹⁶ More effective prevention and treatment of chronic GVHD remains a crucial research need in allogeneic HCT.

RELAPSED MALIGNANCY AFTER HCT

Relapse following autologous or allogeneic HCT is an ominous clinical event. Every effort should be made to verify relapse pathologically, as it is common for patients to have residual radiographic abnormalities following transplantation, especially in patients with lymphoma. Patients with myeloma have gradual reductions in biochemical markers of disease which may take several months after autologous HCT to reach maximal response. Following RIC, the allogeneic GVT effect may take weeks to months to result in tumor eradication, and it may be difficult to distinguish persistent yet slowly regressing disease from slowly progressive disease, particularly with indolent NHL or CLL.

Relapse after Autologous Hematopoietic Cell Transplantation

Disease relapse remains the most common cause of treatment failure after autologous HCT. Relapse often occurs at sites of previous disease, suggesting that residual disease within the patient rather than autograft contamination is responsible.⁴¹⁷ Additional cytotoxic chemotherapy alone is highly unlikely to be curative in patients relapsing after autologous HCT, as the disease has already survived supralethal doses of chemotherapy. Treatment options for patients with relapse after autologous HCT include irradiation, immunomodulators, and/or targeted therapies. For selected patients, salvage allogeneic HCT may be feasible using RIC. Strategies to reduce the risk of relapse in high-risk patients undergoing autologous HCT include consolidative involved-field radiotherapy, antitumor vaccination,⁴¹⁸ maintenance therapy with targeted agents,^{269,419,420} and planned tandem allogeneic HCT.⁴²¹

Relapse after Allogeneic Hematopoietic Cell Transplantation

Treatment of disease relapse following allogeneic HCT is generally unsuccessful. In particular, patients with high-risk malignancies and early relapse (<100 days after allogeneic HCT) have a dismal prognosis, with 2-year overall survival of less than 5 percent.⁴²² Salvage chemotherapy can result in disease responses, but they are unlikely to be durable. Performing a second myeloablative transplantation procedure has largely been unsuccessful because of excessive toxicity and TRM of greater than 50 percent. More recently, selected patients have been treated with a second allogeneic HCT using RIC. Treatment-related toxicity with this approach is not prohibitive and successful disease eradication has been reported, although relapse remains the major cause of death.⁴²³ There is no consensus on whether to use the same donor or a different donor for second-salvage allogeneic HCT in the setting of relapse. More importantly, the majority of patients with relapse after allogeneic HCT are ineligible for second allotransplant because their diseases cannot be adequately controlled or cytoreduced. Experimental therapies with chimeric antigen receptor-bearing autologous T cells or other investigational approaches warrant consideration in these cases. In our view, palliative care is a reasonable option, particularly in the setting of early or chemorefractory relapse after allogeneic HCT, and should be presented to patients.

In the setting of retained donor T-cell chimerism, posttransplantation relapse has sometimes been treated by rapidly tapering immunosuppressive medications to stimulate a GVT effect. Although this approach is occasionally successful in patients with indolent malignancies such as low-grade NHL or CLL, it is rarely effective against more aggressive diseases such as acute leukemias, and carries a high risk of precipitating severe GVHD.

In patients who are off immunosuppression without evidence of GVHD at the time of relapse, DLI has been used to augment GVT. The mechanism by which DLI works is unclear; it may normalize the T-cell repertoire or reverse so-called T-cell “exhaustion.”^{424,425} Historically, the best outcomes for DLI have been reported for CML, although TKIs have

supplanted DLI for the most part in this setting.⁴²⁶ DLI alone is typically insufficient to control aggressive hematologic malignancies,⁴²⁷ and thus patients are often treated with reinduction chemotherapy or other cytoreduction before receiving DLI as consolidation.

The major potential adverse effects of DLI are GVHD and marrow aplasia. The risk of GVHD after DLI is at least 20 percent and likely as high as 50 to 70 percent.^{428,429} Marrow aplasia typically occurs in the setting of residual host hematopoiesis; when host HSC are eradicated by DLI, there may be too few donor HSC to support hematopoietic recovery and prolonged aplasia (>6 weeks) can ensue.⁴³⁰ Thus, chimerism should be evaluated before DLI, and DLI should be used with caution in patients with significant residual host hematopoiesis. There are limited data on the optimal cell dose of DLI. In a retrospective analysis, doses greater than 1×10^8 CD3+ cells/kg were associated with a high risk of GVHD (55 percent) without a corresponding benefit in disease control, while doses of 1×10^7 CD3+ cells/kg or less were associated with the lowest rates of GVHD (21 percent).⁴²⁸ Modifications of DLI, including selection of CD8+ effector lymphocytes or production of cytokine-induced killer cells,¹⁴¹ are under investigation to improve the safety and efficacy of this approach.

FUTURE DIRECTIONS

In recent years, research in HCT has helped to establish alternative-donor allotransplantation, improve outcomes through better supportive care,²¹⁸ and expand transplant eligibility to previously ineligible populations using RIC,²⁰² among other advancements. Current research directions in HCT are diverse; two avenues among many are briefly summarized here.

The past several years have seen an explosion of research interest in the microbiome and the role of host/microbiome interaction in regulating immunity. The relevance of this field to allogeneic HCT is immediately obvious, as the gut and skin are key targets of GVHD. Preclinical evidence suggests that gut microbiota play a critical role in the development of GI GVHD.^{431,432} In humans, preliminary evidence links changes in the microbiome to respiratory complications,⁴³³ GI GVHD,^{432,434} bacteremia,⁴³⁵ and mortality after allogeneic HCT.⁴³⁶ While our understanding of these interactions is still in its infancy and the clinical implications of these findings remain unclear, studies are underway revisiting older strategies, such as total gut decontamination, as well as more modern efforts to tailor the microbiome to optimize transplant outcomes.⁴³⁷

Allogeneic HCT is also under investigation as a platform to promote tolerance of solid-organ allografts. Solid-organ transplants typically require lifelong immunosuppression to maintain graft function, but investigators in the 1990s noted that renal allotransplantation could be accomplished without immunosuppressive therapy in recipients of allogeneic HCT, provided that the kidney allograft was obtained from the original marrow donor.^{438,439} The development of reduced-intensity regimens has spurred research in this field, as these regimens are less toxic and often produce mixed rather than complete donor chimerism—a desirable characteristic in this setting since mixed chimerism reduces the risk of GVHD.

Investigators at Northwestern University described a cohort of 15 HLA-mismatched living-donor kidney transplant recipients given RIC and an infusion of donor marrow enriched with facilitator cells. Six of the 15 patients developed sustained chimerism and were completely withdrawn from immunosuppressive medication without renal allograft rejection.^{440,441} Investigators in Boston reported that four of 10 HLA-haplotype matched living-donor kidney transplant recipients were able to discontinue immunosuppression for up to 11.4 years without subsequent graft dysfunction after establishment of transient mixed chimerism.⁴⁴²

Stanford investigators used TLI-ATG conditioning in 16 living-donor kidney transplant recipients from HLA-matched siblings treated with infusion of CD34-selected hematopoietic progenitor cells and a defined dose of T cells. Fifteen patients developed multilineage mixed chimerism without GVHD, and eight were withdrawn from antirejection medications without subsequent rejection episodes. Four additional chimeric patients were in the midst of drug withdrawal, and only four patients were not withdrawn because of the return of the underlying disease or rejection episodes.^{189,443} Case reports have also described the use of allogeneic HCT as a tolerance-induction platform in lung transplantation.⁴⁴⁴

CHAPTER 24

TREATMENT OF INFECTIONS IN THE IMMUNOCOMPROMISED HOST

Lisa Beutler and Jennifer Babik

SUMMARY

Infection is a major cause of morbidity and mortality in patients with severe inherited or acquired neutropenia or aplastic anemia, qualitative disorders of neutrophils, and, notably, those persons receiving chemotherapy for treatment of hematologic neoplasms. Severe neutropenia and monocytopenia often result from the combined effects of replacement of marrow with malignant cells and superimposed intense chemotherapy. The severity and duration of the neutropenia determine the risk of infection. Bacterial infections may result in rapid clinical deterioration and even death. Fungal, viral, and parasitic infections also may result in potentially lethal complications during or after chemotherapy. This chapter considers methods of diagnosis of bacterial, fungal, viral, and protozoal infection and describes treatment regimens. Because prevention of infection during periods of neutropenia should reduce morbidity and improve outcome, attention is focused on prophylaxis against bacterial, parasitic, viral, and/or fungal infections.

RISK FACTORS AND INFECTING ORGANISMS

SEVERITY OF NEUTROPENIA

Bacterial, fungal, viral, and parasitic organisms may cause infection in neutropenic patients.¹ Bacterial infections are the most frequent and usually the most serious. The risk for bacterial infection increases when the neutrophil count falls to less than $0.5 \times 10^9/L$ and becomes especially pronounced at neutrophil counts less than $0.1 \times 10^9/L$.¹ The rate of decline and duration of neutropenia are important in determining the risk of bacterial infection. Disruption of mucosal barriers, especially in the oral cavity, esophagus, and bowel, further favors the development of infection by providing portals of entry.

Acronyms and Abbreviations: CMV, cytomegalovirus; CT, computed tomography; ESBL, extended-spectrum β -lactamase; Ig, immunoglobulin; IVIG, intravenous immunoglobulin; LFT, liver function test; MRSA, methicillin-resistant *Staphylococcus aureus*; PCP, *Pneumocystis jiroveci* pneumonia; RSV, respiratory syncytial virus; VRE, vancomycin-resistant *Enterococcus*.

BACTERIAL PATHOGENS

Historically, Gram-negative bacilli have been the most commonly isolated pathogens. These organisms include *Klebsiella*, *Escherichia coli*, *Pseudomonas*, and *Proteus*. These bacteria are responsible for a variety of infections, including pneumonia, soft-tissue infections, perirectal infections, and bacteremia. Urinary tract infections are less frequent unless a urinary catheter is present or urinary tract obstruction has developed. Meningitis is uncommon.

At present, roughly half of all documented infections in neutropenic patients are caused by Gram-positive pathogens. This likely results from the popularity of semipermanent venous catheters and from the use of prophylactic regimens that are active against Gram-negative rods. Staphylococcal species and *Enterococcus* are now the pathogens most frequently isolated from neutropenic patients.² Several reports document the increasing frequency of viridans group streptococci as a major pathogen in neutropenic patients, especially in those receiving a hematopoietic stem cell transplant, perhaps because these patients have a higher incidence of mucositis.³ Among infections caused by both Gram-negative and Gram-positive organisms, antibiotic resistance is a growing problem and is discussed under “Bacterial Infections” below. Anaerobic infections are less common unless periodontal or gastrointestinal pathology coexists.

Patients with Hodgkin lymphoma, other lymphomas, or chronic lymphocytic leukemia primarily suffer from impaired cell-mediated immunity and diminished antibody production.⁴ Consequently, the spectrum of infections in these patients differs from that found in neutropenic patients. Bacterial infections, when they occur, tend to result from encapsulated organisms such as *Pneumococcus* or *Haemophilus*. *Listeria* and *Nocardia* infections also are seen more frequently in this group of patients.⁵

FUNGAL PATHOGENS

Fungal infections are common during periods of prolonged neutropenia and in patients with lymphomas or chronic lymphocytic leukemia who have impaired cell-mediated immunity. *Candida* species are most frequently isolated. Historically, *Candida albicans* had been the most common isolate; however, in recent years the number of non-*albicans* *Candida* infections has increased, partly as a consequence of widespread prophylaxis against *C. albicans*.⁶ The gastrointestinal tract serves as a reservoir for *Candida*, and erosive esophagitis may develop. *Candida* may also enter the bloodstream via indwelling catheters.

Aspergillus and fungi that cause mucormycosis also may cause invasive disease. The use of mold-active prophylaxis may be associated with an increased incidence of mucormycosis.⁷ These organisms tend to colonize and infect the sinuses and bronchopulmonary tree.

Infections with *Cryptococcus*, *Aspergillus*, *Coccidioides*, *Histoplasma*, and *Candida* are more common in patients with leukemia or lymphoma who require chronic glucocorticoid treatment. *Coccidioides* and *Histoplasma* are endemic mycoses. *Coccidioides* is endemic in the southwestern United States, in particular in Arizona and the San Joaquin Valley in California. *Histoplasma* is endemic in the Ohio and Mississippi River Valleys. Emerging fungal infections with organisms such as *Scedosporium* have become more common with increased use of mold-active prophylaxis.⁸

Pneumocystis jiroveci is a ubiquitous, endogenous fungus that may cause pneumonia in neutropenic patients and in those with defective cell-mediated immunity.

VIRAL PATHOGENS

Viral infections are especially frequent in patients with impaired cell-mediated immunity. Among viruses that cause infections in

immunocompromised hosts, herpes simplex, varicella zoster, cytomegalovirus (CMV), and adenoviruses are the most important. Cutaneous lesions and mucositis often are caused by herpes simplex. Herpes zoster infections may be especially severe and have a propensity for dissemination. Left untreated, primary varicella infections are associated with a high mortality rate. CMV may cause febrile illnesses associated with pneumonia, hepatitis, and/or gastrointestinal tract ulcerations. Respiratory syncytial virus (RSV) and influenza virus are important pathogens causing respiratory illness in stem cell transplant recipients in the winter months.⁹ Virus-associated hemorrhagic cystitis caused by BK virus and adenovirus is common among hematopoietic stem cell transplant recipients.¹⁰

MYCOBACTERIAL PATHOGENS

The association between lymphoid malignancies and tuberculosis, particularly among patients born outside the United States, has been recognized for more than a century. It threatens to become a more frequent, serious problem with the resurgence of tuberculosis and the increased prevalence of drug-resistant strains.^{11,12} Nontuberculous mycobacterial infections are common in HIV-positive patients, but are less common in patients receiving chemotherapy.¹³

● RECOGNITION AND DIAGNOSIS OF INFECTION

The development of an infection in a neutropenic patient may be accompanied by dramatic clinical manifestations or by none at all. Any fever that develops is very suggestive of infection. However, hypothermia, declining mental status, myalgia, or lethargy also may indicate infection in these patients. The usual local signs of infection, such as pus formation, may be absent or delayed because they are mediated by neutrophils.¹⁴

A careful physical examination should be performed when such a change in condition is observed. Special attention should be paid to the mouth and teeth for evidence of thrush, ulcerations, or periodontal disease. The skin should be examined in detail. Innocuous-appearing skin lesions may be septic emboli or evidence of disseminated fungal infection. Ordinarily trivial injuries inflicted by venipuncture or intravenous catheters may become infected and result in sepsis. An increased incidence of perianal and perirectal infection is observed in neutropenic patients.¹⁵ Examination of the rectum and perineum may provide a clue to the source of fever in patients without other clinical findings. Although such examinations should not be performed unnecessarily on an immunocompromised patient, rectal or pelvic examination should not be deferred when searching for a cause of fever.

Chest radiographic films should be obtained initially and may need to be repeated, although this practice has been questioned in patients without respiratory complaints.¹⁶ Chest computed tomography (CT) may reveal lesions not detected on routine radiograms.¹⁷ Additional imaging should be guided by clinical presentation.

Blood cultures should be collected prior to initiation of antibiotic therapy, and periodically thereafter if fever persists. If an indwelling venous catheter is present, a blood culture as well as cultures from each lumen of the catheter should be obtained for bacterial and fungal pathogens. Differential time to positivity of central and peripheral cultures may be helpful in diagnosing catheter-associated infections.¹⁸ Sending two or three cultures improves the likelihood of recovering fastidious organisms. If differential time to positivity cannot be performed, potentially infected intravenous lines should be cultured upon removal.

Other cultures should be obtained based on presenting symptoms and risk factors. Urine cultures should be sent in patients with

an indwelling urinary catheter, those whose urinalysis is suspicious for infection, and those who have urinary symptoms. Sputum cultures may be helpful in patients with respiratory symptoms or findings on chest radiographs, but must be interpreted with caution, because the results may reflect the flora colonizing the oropharynx rather than the pathogens infecting the lung. Pulmonary fungal and viral infections, which may be difficult to document using conventional culture techniques, may be diagnosed by polymerase chain reaction and antigen detection sent from nasal washes or bronchoalveolar lavage samples.^{19,20} Skin lesions of a suspicious nature should be biopsied and cultured. Stool should be cultured as well as examined for ova and parasites, and *Clostridium difficile* in patients with diarrhea. In some patients, testing for rotavirus, norovirus, and adenovirus also may be appropriate.

Patients with findings on chest CT that are consistent with pneumonia who do not respond to initial therapy and in whom initial microbiologic testing is negative may benefit from transbronchial biopsy or CT-guided biopsy of affected tissue.²¹

● TREATMENT AND PREVENTION

INITIAL TREATMENT

Bacterial Infections

Many different regimens have been evaluated and found to be acceptable for empiric therapy in febrile patients with neutropenia. Current recommendations support single-drug therapy with an antipseudomonal β -lactam as initial empiric therapy in febrile neutropenic patients.²² Piperacillin-tazobactam,²³ imipenem,²⁴ meropenem,²⁵ ceftazidime,²⁶ and ceftazidime²⁷ have each been studied as a single agent. These drugs are active against most of the virulent pathogens infecting neutropenic patients. Doripenem, another carbapenem with antipseudomonal activity has not been studied in a prospective randomized control trial in febrile neutropenia. Ertapenem, a carbapenem that is attractive for its daily dosing schedule, lacks activity against pseudomonas and should not be used as empiric therapy.²⁸ Differences in institutional sensitivity patterns should guide initial antibiotic selection, which should subsequently be tailored to culture results.

Although Gram-negative coverage with a single agent is associated with improved outcomes,²⁹ among patients who are unstable or in whom antibiotic resistance is suspected, it is reasonable to add a second antibiotic active against Gram-negative organisms. Aminoglycosides may provide synergy against Gram-negative bacilli and further broaden the spectrum of antimicrobial activity, but they increase the risk of nephrotoxicity. No good evidence supports the simultaneous use of two β -lactam drugs. Fluoroquinolones in conjunction with another antibiotic are effective in patients who have not received quinolone prophylaxis.³⁰

Patients with catheters, patients presenting with sepsis, patients with evidence of skin or soft-tissue infection, and other high-risk patients should be treated empirically for Gram-positive infections with vancomycin. Among patients without these risk factors, Gram-positive coverage should be added if fever persists for more than 3 to 5 days after Gram-negative treatment is initiated.²²

The emergence of multidrug-resistant organisms has influenced the approach to empiric therapy. Approximately 60 percent of the hospital-acquired strains of *Staphylococcus aureus* now are methicillin-resistant *S. aureus* (MRSA), as are a growing number of community-acquired strains.³¹ Vancomycin, quinupristin/dalfopristin,³² linezolid,³³ daptomycin,³⁴ ceftaroline,³⁵ and tigecycline³⁶ are active against MRSA. However, it should be noted that daptomycin should not be used in pneumonia because of inactivation by surfactant. Tigecycline should be avoided in bloodstream infections because of inadequate serum levels, and the drug now carries a black box warning because of increased

mortality seen with this agent. Dalbavancin, a second-generation glycopeptide that can be administered once per week, has been approved for treatment of MRSA skin and soft-tissue infections.³⁷ Ceftobiprole is a broad-spectrum cephalosporin that is also active against MRSA, but is not yet approved in the United States.³⁸

The emergence of vancomycin-resistant *S. aureus* strains may limit the use of vancomycin in the treatment of *S. aureus* infections in the future, although, fortunately, these isolates are currently quite rare.³⁹ Toxicities of anti-MRSA agents as well as a comprehensive list of antibiotics with activity against MRSA still in development are reviewed in Ref. 40. Linezolid is a commonly used alternative to vancomycin, but causes thrombocytopenia and therefore must be used with caution in patients who are receiving chemotherapy.⁴¹ Daptomycin is a good alternative to vancomycin for bloodstream infections.

Vancomycin-resistant *Enterococcus* (VRE) is being isolated with increasing frequency and presents a major challenge, particularly among neutropenic patients.^{42,43} Cefepime and ceftazidime lack activity against enterococcus. Linezolid,⁴⁴ daptomycin,⁴⁵ and quinupristin/dalfopristin,³² are the best agents currently available for treatment of serious VRE infections. Tigecycline also has activity against VRE,³⁶ but should not be used in bloodstream infections because of inadequate serum levels. Quinupristin/dalfopristin is not active against *Enterococcus faecalis*. The minimum inhibitory concentration of the organism should be checked before initiating daptomycin because VRE isolates can have daptomycin resistance, even in the absence of prior daptomycin usage.⁴⁶

Drug resistance among Gram-negative pathogens is also of great clinical concern in neutropenic patients. As a result of the rising prevalence of multidrug resistant Gram-negative organisms, older drugs, such as colistin, have been reintroduced into practice.⁴⁷ Enteric pathogens, particularly *Klebsiella* and *E. coli* which produce extended-spectrum β -lactamases are a large and growing clinical problem. In up to 25 percent of cases of Gram-negative rod bacteremia in neutropenic patients, cultures ultimately grow extended-spectrum β -lactamase (ESBL)-producing pathogens.⁴⁸ These organisms are resistant to all cephalosporins and exhibit varying and unpredictable degrees of sensitivity to aminoglycosides and quinolones. The carbapenems (imipenem, meropenem, doripenem, ertapenem) are active against these pathogens. Carbapenemase-producing organisms, currently relatively rare, may become an important clinical problem in the future. Data regarding treatment of infections caused by carbapenemase-producing organisms are limited to retrospective and noncontrolled, nonrandomized prospective studies but suggest that combination therapy with a carbapenem plus colistin, aminoglycoside, or tigecycline may be more effective than monotherapy.^{49,50}

Fungal Infections

Systemic fungal infections are relatively common in neutropenic patients, and empiric antifungal therapy should be considered in febrile patients if empiric antibiotic therapy is not effective within 5 to 7 days.⁵¹ Historically, amphotericin B deoxycholate had been the drug of choice for the majority of fungal infections that develop in neutropenic hosts, although its position has been largely supplanted by the introduction of liposomal formulations of amphotericin in most centers, newer azole drugs, and echinocandins.^{52,53}

There are three lipid-associated formulations of amphotericin currently available in the United States. AmBisome (liposomal amphotericin B); Abelcet (amphotericin B lipid complex); and Amphotec/Amphocil (amphotericin B colloidal dispersion). These three agents are not interchangeable. These formulations, particularly AmBisome, are less nephrotoxic, and appear to be at least as efficacious as nonlipid formulations. Infusion-related symptoms are not consistently less common with these

preparations, but are generally manageable.⁵⁴ Serum creatinine, potassium, and magnesium levels should be monitored closely while giving these medications. Amphotericin products remain the first-line agent in treatment of mucormycosis, although they are frequently used in combination with echinocandins.⁵⁵

Although there are limited data to support its efficacy, it is common practice to give intravenous fluids prior to and sometimes after amphotericin infusion to mitigate nephrotoxicity.⁵⁶ Fever and chills associated with administration of amphotericin may be treated or prevented with diphenhydramine hydrochloride, acetaminophen, or hydrocortisone.⁵⁷

Fluconazole, an azole drug that can be administered orally or intravenously, is approved for treatment of *C. albicans*, *Cryptococcus neoformans*, and *Coccidioides immitis*. It is less active against non-*albicans Candida* species and is completely inactive against *Candida krusei*. It also lacks activity against *Aspergillus*.⁵⁸

In contrast to fluconazole, itraconazole has modest activity against *Aspergillus*. It is less active than voriconazole but may have a role in milder infections or when voriconazole is not tolerated.⁵⁹

Voriconazole is another azole drug, which is also available in intravenous and oral formulations. A large study concluded that voriconazole is as effective as liposomal amphotericin B as empiric therapy for neutropenic patients who are febrile, but these results are controversial.^{52,60} Oral voriconazole may be a good alternative to the intravenous formulation in neutropenic patients with uncomplicated persistent fever.⁶¹ It is the first-line therapy against *Aspergillus*.⁶² Side effects of voriconazole, which may limit its use in some patients, include visual abnormalities, hallucinations, and liver function test (LFT) abnormalities. Recent data suggest that voriconazole use in transplant recipients is associated with an increased rate of nonmelanoma skin cancers. The mechanism by which this occurs is currently unknown.⁶³ Neurologic side effects may be related to blood levels of the drug, which vary widely depending upon a large number of factors including CYP2C19 genotype. There is mounting evidence that therapeutic drug monitoring improves safety and efficacy of voriconazole in the treatment of invasive fungal infections.^{64,65}

Posaconazole is the newest approved azole. It is now available in intravenous and oral formulations. Its primary use has been prophylactic; however, it has shown promise as salvage therapy for invasive aspergillosis.⁶⁶ Unlike the older triazoles, posaconazole is active against many species that cause mucormycosis, and it has been used successfully when other therapy has failed; however, there is no clinical trial data available at this time.⁶⁷

Isavuconazole is an investigational broad-spectrum azole available in oral and intravenous formulations. It is currently in phase III trials comparing it to voriconazole for treatment of *Aspergillus*. It also has some activity against species that cause mucormycosis.⁶⁸

The echinocandins, which include caspofungin, micafungin, and anidulafungin, are a class of intravenous drugs that has activity against a wide variety of *Candida* species as well as *Aspergillus*. They are generally well tolerated, and may become especially important as the prevalence of non-*albicans Candida* infections rises.⁶⁹ Currently, only caspofungin is approved for first-line empirical use in febrile neutropenia.⁷⁰ Caspofungin is also the only echinocandin approved as salvage therapy for aspergillosis; however, mounting evidences suggests that micafungin is also effective in the treatment of invasive *Aspergillus* infections.⁷¹ The echinocandins may have synergy with other antifungal agents against *Aspergillus* species and in treating mucormycosis.^{55,72} A randomized controlled trial evaluating echinocandins as part of combination therapy in *Aspergillus* treatment has been performed and results are expected soon. Anidulafungin, the newest approved echinocandin, has shown excellent efficacy in the treatment of candidiasis.⁷³

P. jiroveci pneumonia may be treated with trimethoprim-sulfamethoxazole. Pentamidine or primaquine-clindamycin should be used for moderate to severe infections in patients who are allergic to or otherwise intolerant of trimethoprim-sulfamethoxazole, although data for alternative regimens is much more robust in the HIV-positive patient population.⁷⁴ Other alternative regimens include dapsone-trimethoprim and atovaquone, although these are best used for mild PCP. Glucocorticoids are commonly given as adjunctive treatment in severe PCP, though the data for this among non-HIV-infected patients are conflicting.⁷⁵

Empiric therapy with antifungal agents is currently the standard of care in high-risk neutropenic patients with persistent fever. However, preemptive antifungal treatment is being evaluated as a possible alternative to empiric therapy in select patients. With preemptive strategies, microbiologic, molecular, and radiologic monitoring is used to detect early evidence of invasive fungal infections and prompt initiation of therapy.⁷⁶ Data from studies comparing empiric therapy with preemptive strategies are mixed.⁷⁷⁻⁷⁹ Surveillance with fungal cell wall components 1,3- β -D-glucan⁸⁰ and galactomannan⁸¹ in the blood plays a role in preemptive therapy. Real-time polymerase chain reaction of fungal gene products is another technique that appears to have high sensitivity and specificity for detecting candidemia, although it will require standardization before widespread use is possible.⁸²

Although currently not as large a problem as drug-resistant bacteria, the development of drug-resistant fungal organisms is a potential clinical threat. Prophylactic use of antifungals likely contributes to breakthrough infection with innately resistant species.⁸³ Cross-resistance within and between classes of antifungals is another potentially important problem, which is deserving of clinical study.⁸⁴

Viral Infections

A limited number of options are available for treatment of viral infections. Acyclovir is active against herpes simplex and, at higher doses, against varicella zoster. Other agents, such as famciclovir and valacyclovir, are as effective in treating herpes simplex and zoster infections, and may be administered less frequently, but are not available for intravenous administration.⁸⁵

Ganciclovir, valganciclovir, and foscarnet have efficacy in treatment of CMV disease and are also active against herpes simplex.⁸⁶ They are most effective when they are used early in the course of the infection. Hence, frequent screening for CMV and early preemptive treatment in high-risk patients, such as transplant recipients, may allow for improved outcomes.⁸⁷ Ganciclovir or valganciclovir is usually the first-line therapy against CMV, but results in marrow suppression in a significant percentage of patients who receive them. Foscarnet, a second-line agent, may be complicated by azotemia and electrolyte abnormalities.

Ribavirin plus an adjunctive immunomodulator such as RSV immunoglobulin (Ig) or intravenous immunoglobulin (IVIG) are used to treat RSV pneumonia in immunocompromised patients. Ribavirin can also be used to treat RSV upper respiratory tract infections, and may prevent spread to the lower respiratory tract as well as decrease mortality; however, prospective studies are needed.⁸⁸ The optimal route of ribavirin administration (oral versus inhaled) is not yet known. Oseltamivir or zanamivir should be used if influenza A is suspected.⁸⁹

Mycobacterial Infections

Rates of *Mycobacterium tuberculosis* infection are high among patients with hematologic malignancy worldwide, and tuberculosis should be ruled out in neutropenic patients with lung infiltrates who have tuberculosis risk factors. First-line therapy for tuberculosis includes rifampin, isoniazid, pyrazinamide, and ethambutol.⁹⁰

Infections with multidrug-resistant tuberculosis, defined as microbes resistant to rifampin and isoniazid, are difficult to treat and

are associated with poor prognoses. The prevalence of multidrug-resistant tuberculosis varies tremendously by country.⁹¹ Drugs used to treat multidrug-resistant tuberculosis include fluoroquinolones, amikacin, capreomycin, and kanamycin. Extensively drug-resistant *M. tuberculosis*, which is defined as being resistant to rifampin, isoniazid, fluoroquinolones, and at least one injectable second-line agent, is a potentially a huge clinical problem.⁹²

Although relatively uncommon, nontuberculous mycobacterial infections also occur in patients with hematologic malignancy. *Mycobacterium avium-intracellulare* complex is treated with clarithromycin, rifabutin, and ethambutol. Treatment of infections with rapidly growing mycobacteria is complicated and should be guided by an infectious disease specialist.¹³

Table 24-1 lists the drugs used as empiric therapy in neutropenic patients.

ADJUSTING THERAPY

Adjustment or modification of the initial antimicrobial regimen may be necessary for several reasons. Results of cultures may suggest another regimen would be more active or less toxic. All cultures may remain negative while the patient fails to respond to the regimen. Fever may recur following an initial response to therapy, raising the possibility of a second infection.

Adjusting therapy based on a culture report usually is straightforward, but the other two situations may pose dilemmas. In these circumstances, resistant organisms or noninfectious causes of fever, such as drug fever or recurrence of malignancy, must be considered. Repeat cultures and careful clinical reappraisal may prove helpful.

DURATION OF THERAPY

Antibiotic therapy for a specific infection is commonly continued for a defined minimum period of time *and* until the granulocyte count reaches $0.5 \times 10^9/L$. Although this strategy reduces the number of relapsing infections, it may increase the risk of superinfection and antibiotic toxicity. In low-risk patients whose fever resolves without a documented source of infection, empiric intravenous therapy can usually be stopped and replaced by an oral regimen until counts recover. Alternatively, there is some evidence that returning to a prophylactic regimen in select patients before the absolute neutrophil count reaches $0.5 \times 10^9/L$ is also a reasonable approach.⁹³ If antibiotics are discontinued or deescalated, close observation is required, and therapy should be reinstated at any suggestion of recurrent infection.

FEVER FOLLOWING RECOVERY FROM CHEMOTHERAPY

Fevers occasionally persist or even begin after the granulocyte count has returned to normal levels. Drug fever and engraftment syndrome are considerations in this setting, although a deep-seated infection must be excluded.⁹⁴ Hepatosplenic candidiasis is one important consideration in these patients, although its incidence has likely decreased in the setting of widespread antifungal prophylaxis discussed under "Fungal Infections" below.⁹⁵ Elevated serum alkaline phosphatase levels and the presence of multiple "punched-out" lesions in the liver on CT are common findings with hepatic involvement. Blood cultures are frequently negative so biopsy may be required to establish a microbiologic diagnosis.⁹⁶ Hepatosplenic candidiasis requires prolonged therapy. Several regimens have been proposed, including fluconazole,⁹⁷ caspofungin,⁹⁸ and liposomal amphotericin B,⁹⁹ but there are no randomized trial data. Persistent symptoms despite treatment may be a result of immune reconstitution inflammatory syndrome and may be relieved by adjuvant treatment

TABLE 24-1. Coverage and Side Effects of Drugs Used as Empiric Therapy

Drug Category	Drug	Brand Name	Activity	Toxicity
Antipseudomonal penicillins	Piperacillin-tazobactam	Zosyn	Methicillin-sensitive <i>Staphylococcus</i> , <i>Streptococcus</i> , <i>Enterococcus faecalis</i> , anaerobes, <i>Pseudomonas aeruginosa</i> , enteric Gram-negative rods	Hypokalemia, antiplatelet effect
Antipseudomonal cephalosporins	Ceftazidime	Fortaz	<i>P. aeruginosa</i> , enteric Gram-negative rods, methicillin-sensitive <i>Staphylococcus</i> *	
	Cefepime	Maxipime	<i>P. aeruginosa</i> , enteric Gram-negative rods, methicillin-sensitive <i>Staphylococcus</i>	Cefepime-induced neurotoxicity
Aminoglycosides	Amikacin	Amikin	Enteric Gram-negative rods, <i>P. aeruginosa</i>	Nephrotoxicity, ototoxicity
	Tobramycin	Nebcin		
	Gentamicin	Garamycin		
Glycopeptide	Vancomycin	Vancocin	<i>Staphylococcus</i> (including MRSA), <i>Streptococcus</i> , <i>E. faecalis</i> , <i>Corynebacterium</i>	Ototoxicity, red-man syndrome with rapid infusion
Carbapenem	Imipenem	Primaxin	Gram-negative rods, <i>Pseudomonas aeruginosa</i> (except for ertapenem), methicillin-sensitive <i>Staphylococcus</i> , <i>Streptococci</i> , <i>Enterococcus</i> (imipenem), anaerobes	Nausea, seizures (imipenem)
	Meropenem	Merrem		
	Ertapenem	Invanz		
	Doripenem	Doribax		
Monobactam	Aztreonam	Azactam	Gram-negative rods, <i>P. aeruginosa</i>	
Sulfonamides	Trimethoprim-sulfamethoxazole	Bactrim; Septra	<i>Pneumocystis jiroveci</i> , some Gram-negative rods, <i>Staphylococcus</i> , <i>Nocardia</i>	Sulfa allergy, increased creatinine, nausea, rash
Fluoroquinolones	Ciprofloxacin	Cipro	Gram-negative rods, <i>P. aeruginosa</i> , viridans streptococci	Nausea. Rare Achilles tendon rupture
	Levofloxacin	Levaquin	Gram-negative rods, <i>P. aeruginosa</i> , viridans streptococci [†]	
Nucleosides	Acyclovir	Zovirax	HSV, VZV	Crystalluria
	Valacyclovir	Valtrex	HSV, VZV	
	Famciclovir	Famvir	HSV, VZV	
	Ganciclovir	Cytovene	CMV	Marrow suppression
	Valganciclovir	Valcyte	CMV	Marrow suppression
Phosphonoformate	Foscarnet	Foscavir	CMV	Renal failure, electrolyte abnormalities
Polyene antifungals	Amphotericin B	Fungizone	<i>Candida</i> , <i>Aspergillus</i> , other fungi including mucormycosis	Fever, chills, nausea, vomiting, renal failure hypokalemia, hypomagnesemia
	Ampho-B lipid complex	Abelcet	<i>Candida</i> , <i>Aspergillus</i> , other fungi including mucormycosis	Fever, chills, nausea, vomiting, increased creatinine
	Ampho-B cholesteryl sulfate complex	Amphotec	<i>Candida</i> , <i>Aspergillus</i> , other fungi including mucormycosis	Fever, chills, nausea, vomiting, increased creatinine
	Liposomal ampho-B	AmBisome	<i>Candida</i> , <i>Aspergillus</i> , other fungi including mucormycosis	Fever, chills, nausea, vomiting, increased creatinine
Azole	Fluconazole	Diflucan	<i>Candida</i> , <i>Cryptococcus</i> , <i>Coccidioides immitis</i>	LFT abnormality
	Itraconazole	Sporonox	<i>Candida</i> , <i>Aspergillus</i> , <i>Histoplasma</i>	CHF; drug–drug interactions
	Voriconazole	Vfend	<i>Aspergillus</i> , <i>Coccidioides</i> , <i>Histoplasma</i>	Loss of vision with intravenous prep
	Posaconazole	Noxafil	<i>Aspergillus</i> , <i>Coccidioides</i> , <i>Histoplasma</i> , mucormycosis	Nausea, diarrhea, LFT abnormality

(continued)

TABLE 24-1. Coverage and Side Effects of Drugs Used as Empiric Therapy (Continued)

Drug Category	Drug	Brand Name	Activity	Toxicity
Echinocandin	Caspofungin	Cancidas	<i>Aspergillus</i> , <i>Candida</i> , mucormycosis [‡]	
	Micafungin	Mycamine	<i>Aspergillus</i> , <i>Candida</i> , mucormycosis [‡]	
	Anidulafungin	Eraxis	<i>Aspergillus</i> , <i>Candida</i> , mucormycosis [‡]	
Oxazolidinone	Linezolid	Zyvox	Staphylococci (including MRSA), <i>Enterococcus</i> (including VRE), streptococci	Thrombocytopenia, anemia, small risk of serotonin syndrome with concomitant SSRIs, mitochondrial side effects with prolonged use
Lipopeptide	Daptomycin	Cubicin	Staphylococci (including MRSA), <i>Enterococcus</i> (including VRE), streptococci	Creatinine kinase elevation

Ampho-B, amphotericin B; CHF, congestive heart failure; CMV, cytomegalovirus; HSV, herpes simplex virus; LFT, liver function test; SSRI, selective serotonin reuptake inhibitor; VRE, vancomycin-resistant *Enterococcus*; VZV, varicella-zoster virus.

*Ceftazidime has less activity than cefepime against methicillin-sensitive *Staphylococcus aureus* and viridans streptococci.

[‡]Levofloxacin has more reliable activity against viridans streptococci than ciprofloxacin.

[‡]Echinocandins are commonly used in combination with amphotericin in the treatment of mucormycosis, but are not used as monotherapy.

with glucocorticoids.¹⁰⁰ Cure is difficult to achieve regardless of the regimen used and mortality is high.¹⁰¹

Indwelling catheter infections are another important consideration in persistent fever after hematologic recovery. Diagnosing catheter infections remains a major challenge, and the use of catheter-sparing diagnostic techniques should be considered, as the need to remove catheters is patient and organism dependent. Coagulase-negative *Staphylococcus* spp. are most commonly isolated and are generally amenable to catheter-sparing treatment. If the catheter is to be retained, a 10- to 14-day course of antibiotics is recommended.¹⁰² If a tunnel infection is present, successful therapy is less likely without catheter removal.

Gram-negative,¹⁰³ *S. aureus*,¹⁰⁴ and fungal¹⁰⁵ infections of the catheter usually necessitate its removal. This may be followed, if necessary, by insertion of a new catheter at a different site once blood cultures have cleared. Antibiotic therapy for at least 14 days is recommended. Chlorhexidine and silver-impregnated central venous catheters may prevent bloodstream infections in neutropenic patients.¹⁰⁶ Catheter infections and their management are reviewed in detail elsewhere.¹⁰²

OUTPATIENT THERAPY

Twenty years ago, treatment of the febrile neutropenic patient outside of the hospital would have been unthinkable. Economic pressures, coupled with the widespread availability of home infusion services and more potent oral antibiotics, have made outpatient therapy an option for some of these patients.¹⁰⁷

Outcomes among patients with neutropenic fever treated as outpatients seem to be comparable to those observed in hospitalized patients, provided the patients are selected properly and appropriate monitoring can be ensured. Suitable candidates for home therapy include patients who are expected to have a short duration of neutropenia and who have few comorbidities.^{108,109} Individuals who remain febrile, who require multiple antibiotics, or who are unreliable are not candidates for home therapy. Rigorous family education is crucial for a successful outcome.

PREVENTION OF INFECTIONS

Bacterial Infections

In view of the high mortality rate associated with infections in neutropenic patients, preventive measures remain a priority. Careful attention to sterile technique and personal hygiene is of the utmost importance

in the prevention of bacterial infection during neutropenia. Instrumentation should be avoided whenever possible. Intravenous access sites should be carefully maintained. In addition, systemic antibiotics are currently widely used as prophylaxis against Gram-negative infections in neutropenic patients.

The use of prophylactic antibiotics reduces the number of Gram-negative infections and all-cause mortality in high-risk patients who are expected to have prolonged, severe neutropenia and is recommended in these patients.¹¹⁰ By contrast, the use of antibiotic prophylaxis in lower-risk patients expected to have a shorter duration of neutropenia is of much less certain benefit, and is not recommended in most cases.¹¹¹ Several studies show a reduction in mortality in high-risk patients given prophylactic antibiotics, but the contribution of this practice to the emergence of drug-resistant pathogens must be taken into account when deciding whether to employ it.^{112,113} Furthermore, although the agents used for this purpose are generally safe, the risk of drug toxicity must also be taken into consideration. Adverse events associated with antibiotic prophylaxis include drug fever, rash, and worsening of cytopenias. Infection with *C. difficile* is a potentially serious risk of prophylaxis.¹¹⁴ Incidence of *C. difficile* infection is high in stem cell transplant recipients, and patients who receive high-risk antibiotics including fluoroquinolones more frequently acquire infection with this organism.¹¹⁵ This potential complication deserves strong consideration, as drug-resistant, hypervirulent strains of this organism have become more prevalent over the last several years.¹¹⁶

The fluoroquinolones, particularly ciprofloxacin and levofloxacin, have received considerable attention for their ability to prevent Gram-negative infections in neutropenic patients.¹¹⁰ Ciprofloxacin has more activity against *Pseudomonas*, whereas levofloxacin is more active against Gram-positive organisms. Unfortunately, indiscriminate use of these agents in the community, as well as prophylactic use, has led to a greatly increased prevalence of quinolone-resistant Gram-negative organisms. Up to 85 percent of Gram-negative isolates from patients with febrile neutropenia are resistant to quinolones,¹¹⁷ and quinolone prophylaxis has resulted in an increased incidence of quinolone-resistant viridans streptococci.¹¹⁸ Prophylactic use also eliminates these agents from therapeutic use in the same patient.¹¹⁹ For these reasons, some centers abandoned the use of prophylactic quinolones in certain patients.¹²⁰⁻¹²² These studies consistently showed a decrease in fluoroquinolone resistance in isolates from neutropenic patients. While some studies have

failed to show an increase in the incidence of bacteremia with discontinuation of prophylaxis,¹²⁰ in at least two cases, institutional cessation of quinolone prophylaxis resulted in an increased incidence of bacteremia caused by Gram-negative organisms, which was reversed by reinstitution of fluoroquinolone prophylaxis.^{121,122} In summary, there is, at present, a clear role for quinolone prophylaxis in some patients. However, because of increasing resistance to these drugs, it is important to continuously monitor their efficacy and discourage their unnecessary use.

The use of granulocyte-macrophage colony-stimulating factor and granulocyte colony-stimulating factor to raise the absolute neutrophil count has been shown to decrease the incidence of fever in patients on high risk chemotherapy regimens, elderly patients, and patients with certain comorbid conditions.^{123,124} However, there is no definitive evidence that prophylaxis with these agents reduces infection-related mortality or overall survival.¹²⁵

Low-bacteria diets are often recommended to patients expected to experience neutropenia, but their effectiveness at preventing infection has not been shown.¹²⁶ Similarly, the efficacy of reverse isolation, though often employed as a prophylactic measure, has not been demonstrated.¹²⁷

Viral Infections

Acyclovir and its prodrug valacyclovir are effective at preventing recurrent herpes simplex infections in patients receiving chemotherapy.¹²⁸ Long-term treatment with acyclovir also prevents reactivation of varicella-zoster virus in hematopoietic stem cell transplant recipients,¹²⁹ as well as in patients undergoing chemotherapy for multiple myeloma.¹³⁰ Varicella-zoster immunoglobulin is recommended as postexposure prophylaxis for high-risk, nonimmune patients.¹³¹

Hematopoietic stem cell transplant recipients have a high risk of CMV infection. Patients at particular risk include those who are seropositive before transplantation, seronegative patients who receive transplants from seropositive donors, and those who receive highly immunosuppressive conditioning regimens prior to transplantation.^{132,133} The use of CMV seronegative blood components can markedly decrease the transmission of CMV to seronegative patients; leukocyte reduction similarly prevents transmission.¹³⁴ Ganciclovir,¹³⁵ oral valganciclovir,¹³⁶ and CMV immune globulin infusions have been used to prevent CMV infection in transplant recipients. Ganciclovir and valganciclovir frequently cause myelosuppression, which may complicate the management of neutropenic patients on these medications.¹³⁷ In addition, the emergence of CMV antiviral resistance has been reported in association with preventive treatment.¹³⁸ CMV prophylaxis among patients receiving conventional chemotherapy has not been as widely studied, but currently there is no evidence supporting its use in this population.¹³⁹ Many centers take a preemptive approach, screening patients regularly for CMV viremia and initiating therapy only when CMV is detected. Prophylactic immunotherapy may have benefit in patients unable to tolerate the potential myelotoxicity of antiviral therapy.¹⁴⁰ Recent randomized controlled trials have suggested that novel anti-CMV agents letermovir and brincidofovir may be effective at preventing CMV replication in stem cell transplant recipients.^{141,142}

Immunizations with killed vaccines such as influenza are recommended. Live-attenuated vaccines, such as measles and zoster, should be avoided during immunosuppression.¹⁴³

Fungal Infections

The high mortality rate of invasive fungal infections in neutropenic patients makes their prevention extremely important. Antifungal prophylaxis in these patients has been studied for more than 2 decades, yet there is still a great deal of controversy surrounding its efficacy.¹⁴⁴ Studies on prevention of fungal infections in neutropenic patients are difficult to evaluate. Results of the various studies have been conflicting,

partly because different definitions and outcomes were applied, different doses of antifungal agents were administered, and the numbers of study patients have often been small.

As with antibacterial prophylaxis, the clearest benefit of antifungal prophylaxis is seen in patients expected to have severe, prolonged neutropenia, particularly allogeneic transplant recipients. Antifungal prophylaxis is not indicated in patients who are undergoing chemotherapy with low levels of myelotoxicity.²² When deciding whether to treat prophylactically, drug toxicity must be taken into account. In addition, prophylactic use of antifungal agents may select for more resistant strains of fungus and lead to breakthrough infection with organisms inherently resistant to the agent used for prophylaxis. For example, certain prophylactic regimens active against *Candida* may actually increase the incidence of *Aspergillus* infections.¹⁴⁵ The ability of antifungal agents to prevent systemic infection in high-risk patients has been shown in several studies, but their ability to reduce all-cause mortality has not been definitively established.¹⁴⁶

Several azole drugs have been studied as prophylactic agents. A number of studies document a statistically significant reduction in superficial and invasive fungal infections when fluconazole is used prophylactically.¹⁴⁷ However, breakthrough infection with *Aspergillus*, *Candida glabrata*, and *Candida krusei* have occurred with fluconazole prophylaxis.⁸³ Itraconazole and voriconazole¹⁴⁸ have a broader spectrum of activity, are more effective at preventing *Aspergillus* infection, and are generally well tolerated.¹⁴⁹ Prophylaxis with posaconazole is associated with a reduced risk of *Aspergillus* infection, and a trend toward lower mortality.¹⁵⁰

Echinocandins have become popular antifungal prophylactic agents. Caspofungin has been shown to be as effective as itraconazole in preventing *Aspergillus* and *Candida* infections.¹⁵¹ Micafungin was shown to be superior to fluconazole at preventing systemic fungal infections in hematopoietic stem cell transplant recipients.¹⁵² Anidulafungin, the newest echinocandin, remains to be studied as a prophylactic agent.

P. jiroveci pneumonia can be prevented with trimethoprim-sulfamethoxazole.¹⁵³ Dapsone and atovaquone have each been used as a second-line prophylactic agent in hematopoietic stem cell transplant recipients, and in some cases may be preferred based on the risk of marrow suppression from trimethoprim-sulfamethoxazole.^{154,155} Although *P. jiroveci* is a ubiquitous organism, institutional variability in the incidence of infection is observed; therefore, the need for prophylaxis varies.

● INFECTIONS IN HEMATOPOIETIC STEM CELL TRANSPLANTATION RECIPIENTS

Patients receiving hematopoietic stem cell transplants are at risk for the same infections occurring in patients rendered neutropenic by chemotherapy. Graft-versus-host disease and the immunosuppressive agents used to treat it result in a particularly high incidence of infection in this group of patients. CMV and varicella zoster virus, are especially troublesome. Infection in stem cell transplant patients has been reviewed¹⁵⁶ and is discussed in Chap. 23.

CHAPTER 25

ANTITHROMBOTIC THERAPY

Gregory C. Connolly and Charles W. Francis

SUMMARY

Antithrombotic drugs are among the most commonly used drugs in medicine and are generally separated into anticoagulants, fibrinolytic agents, and platelet inhibitors based on their primary mechanism of action. For many decades, warfarin, which acts by inhibiting vitamin K action, was the only oral anticoagulant available. Vitamin K antagonists have a prolonged effect, unpredictable pharmacokinetics, and require monitoring, but warfarin was widely used for prevention and treatment. The introduction of novel targeted oral anticoagulants has changed the landscape of anticoagulation. Rivaroxaban, apixaban, and edoxaban are novel oral inhibitors of factor Xa, whereas dabigatran is an orally available inhibitor of thrombin. Unfractionated heparin and the low-molecular-weight heparins are the most commonly used rapidly acting parenteral anticoagulants; they inhibit activated serine proteases through antithrombin. One synthetic agent in this class, fondaparinux, is specific for inhibition of factor Xa, and is effective for prevention and treatment of venous thromboembolism. Several parenteral direct thrombin inhibitors have excellent anticoagulant action and offer an alternative to heparins. A number of fibrinolytic agents are available, all of which convert plasminogen to plasmin to accelerate clot lysis. Differences among them include their degree of fibrin specificity, half-life, and antigenicity. Antiplatelet agents play an important role in prevention and treatment of arterial thrombosis. Aspirin is a cyclooxygenase-1 inhibitor that is effective and widely used in the prevention of stroke and myocardial infarction. Drugs that modulate cyclic adenosine monophosphate levels include dipyridamole, pentoxifylline, and cilostazol, and are primarily used in treatment of peripheral vascular disease. Adenosine diphosphate receptor blockers such as ticlopidine, clopidogrel, and prasugrel are effective in treatment of coronary and peripheral arterial disease. Examples of inhibitors of fibrinogen interaction with $\alpha_{IIb}\beta_3$ are abciximab, tirofiban, and eptifibatid. These drugs are highly effective in treatment of patients with acute coronary syndromes.

Acronyms and Abbreviations: ACT, activated clotting time; ADP, adenosine diphosphate; aPTT, activated partial thromboplastin time; cAMP, cyclic adenosine monophosphate; COX, cyclooxygenase; CYP, cytochrome P450; DVT, deep vein thrombosis; FFP, fresh-frozen plasma; Gla, γ -carboxyglutamic acid; HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; ISI, international sensitivity index; LMWH, low-molecular-weight heparin; MI, myocardial infarction; NSAID, nonsteroidal antiinflammatory drug; PE, pulmonary embolism; PG, prostaglandin; PGI₂, prostacyclin; PRP, platelet-rich plasma; PT, prothrombin time; TNK, tenecteplase; t-PA, tissue-type plasminogen activator; VTE, venous thromboembolism.

Antithrombotic agents are highly effective and are among the most commonly used drugs in medicine because thrombotic diseases are the leading cause of mortality and morbidity in Western countries. Antithrombotic agents are characterized separately as anticoagulants, antiplatelet agents, or fibrinolytic drugs, depending on their primary mechanism, although there is overlap in their activities and clinical indications (Table 25-1). Their greatest use is in prevention of thrombosis in patients at high risk, but they also have important applications for treating acute thrombosis. For many agents, the risk-to-benefit ratio is narrow, with the result that bleeding complications occur, and bleeding is the most common adverse effect. Consequently, the clinician should carefully weigh the risks and benefits for each patient when selecting treatment. Generally, these drugs do not cause bleeding by themselves; instead, they exacerbate preexisting bleeding or predispose to bleeding from pathologic lesions that may be found in the gastrointestinal or genitourinary tracts or central nervous system. A careful review of comorbid conditions that may increase bleeding risk is important when deciding on therapy.

Anticoagulant therapy acts to decrease fibrin formation by inhibiting the formation and action of thrombin, and its most common uses are in preventing systemic embolization in patients with atrial fibrillation and for secondary prevention of venous thromboembolism. Anticoagulant therapy is sometimes monitored using coagulation testing because of marked biologic variation in effect with some agents. Antiplatelet agents act to inhibit platelet function, and their primary uses are in preventing thrombotic complications of cerebrovascular and coronary artery disease. They also have a role in treatment of acute myocardial infarction and some effect in preventing venous thrombosis. Fibrinolytic agents accelerate lysis of thrombi by increasing conversion of plasminogen to plasmin, and are primarily used in the acute management of myocardial infarction, in clearing occluded catheters and also in selected patients with stroke or venous thromboembolism. Fibrinolytic therapy is associated with a higher risk of bleeding complications than treatment with either anticoagulants or antiplatelet agents. Treatment of acute thrombosis often involves combinations of agents with multiple actions for maximum effect.

Antithrombotic therapy has changed considerably with the introduction of several novel target-specific oral anticoagulants. These drugs offer more predictable pharmacokinetics and fewer drug interactions than warfarin, thus eliminating the need for frequent monitoring. These agents have been studied in numerous phase III randomized clinical trials that have compared these agents to standard anticoagulation therapies. In most cases, the new anticoagulants are equivalent to conventional anticoagulation in reducing thrombotic events, while in many cases they are associated with lower rates of major bleeding complications.

VITAMIN K ANTAGONISTS

The development of vitamin K antagonists as oral anticoagulants began in the 1920s with investigation of a hemorrhagic disease in cattle, the cause of which was eventually traced to ingestion of moldy hay leading to hypoprothrombinemia.¹ A coumarin that inhibited vitamin K was purified and eventually introduced into clinical practice in the 1940s. Several coumarin derivatives with differing pharmacologic properties are now available as anticoagulants worldwide, and are collectively referred to as vitamin K antagonists, but warfarin is nearly universally used in North America. These agents are widely used to prevent or treat common thrombotic diseases and represent the most commonly used oral anticoagulant currently available.²

TABLE 25-1. Types and Function of Antithrombotic Agents

Anticoagulants—decrease fibrin formation by inhibiting thrombin or thrombin formation

Agents

Oral—warfarin and other vitamin K antagonists, dabigatran (direct thrombin inhibitor) and oral direct X_a inhibitors (rivaroxaban, apixaban, edoxaban)

Parenteral—heparin, low-molecular-weight heparins, fondaparinux, direct thrombin inhibitors (argatroban, desirudin, bivalirudin)

Antiplatelet agents—inhibit platelet function

Agents

Aspirin, clopidogrel, prasugrel, dipyridamole, abciximab, eptifibatide, tirofiban, vorapaxar

Fibrinolytic agents—plasminogen activators and accelerate clot lysis

Agents

Streptokinase, urokinase, alteplase, reteplase, tenecteplase

PHARMACOLOGY

The coumarins are competitive inhibitors of vitamin K. They inhibit γ -carboxylation reactions required for synthesis of several coagulation proteins, including factors II, VII, IX, and X, as well as proteins C and S, which are involved in inhibitory regulation of hemostasis. The synthesis of these proteins requires a posttranslational modification of several glutamic acid residues, converting them to γ -carboxylated glutamic acid (Gla), which is required for proper membrane interaction and biologic activity (Chap. 115).^{3,4} The carboxylation reaction requires reduced vitamin K, which is converted to vitamin K epoxide in the reaction. Vitamin K epoxide subsequently undergoes reduction by an enzyme that is inhibited by warfarin.⁵⁻⁷ Therefore, treatment with warfarin causes reduced γ -carboxylation, leading to synthesis of molecules with impaired activity.⁸⁻¹⁰

Warfarin preparations consist of a racemic mixture of S and R enantiomers in approximately equal proportion in an oral formulation with high bioavailability. Warfarin is water soluble and rapidly absorbed after oral administration, reaching a peak concentration after 60 to 90 minutes. An intravenous preparation is also available for patients who cannot take oral medications or who have malabsorption. It is tightly bound to plasma proteins with a half-life of 35 to 45 hours, with only the free, nonbound form having biologic activity. Warfarin is metabolized through the cytochrome P450 (CYP) system, the activity of which is influenced by environmental factors and also by genetic polymorphisms that alter the structure of common enzymes. Other vitamin K antagonists have similar activities but exhibit differences in absorption and elimination.

Because warfarin is a vitamin K antagonist, its action is influenced by the vitamin K content of the diet. Naturally occurring vitamin K is found in a variety of vegetables, and changes in diet can affect the vitamin K availability and warfarin effect.¹¹ This may be seen particularly in patients receiving warfarin who are on strict weight-reduction diets or in those with little oral intake because of illness. Also, diarrhea can affect vitamin K availability, as can administration of broad-spectrum antibiotics leading to marked warfarin sensitivity in hospitalized patients. Ingestion of vitamin K in dietary supplements or vitamins also affects sensitivity to warfarin. Liver disease can increase sensitivity to warfarin because of impaired synthesis of coagulation factors, and hyper-

TABLE 25-2. Effect of Drugs on Warfarin Response

POTENTIATE EFFECT	
α -Methyldopa	Indomethacin
Acetaminophen	Isoniazid
Acetohexamide	Mefenamic acid
Allopurinol	Methimazole
Androgenic and anabolic steroids	Methotrexate
Antibiotics that disrupt intestinal flora (tetracyclines, streptomycin, erythromycin, kanamycin, nalidixic acid, neomycin)	Methylphenidate
	Nalidixic acid
	Nortriptyline
	Oxyphenbutazone
Cephaloridine	<i>p</i> -Aminosalicylic acid
Chloral hydrate	Paromomycin
Chloramphenicol	Phenylbutazone
Chlorpromazine	Phenylramidol
Chlorpropamide	Phenytoin
Cimetidine	Propylthiouracil
Clofibrate	Quinidine
Diazoxide	Salicylate
Disulfiram	Sulfinpyrazone
Ethacrynic acid	Sulfonamides
Glucagon	Thyroid hormone
Guanethidine	Tolbutamide
DEPRESS EFFECT	
Antipyrine	Glutethimide
Azathioprine	Griseofulvin
Barbiturates	Haloperidol
Carbamazepine	Phenobarbital
Digitalis	Prednisone
Ethanol	Rifampin
Ethchlorvynol	Vitamin K

hypometabolic states may also alter sensitivity. Hereditary resistance to warfarin has been described and related to specific mutations in vitamin K epoxide reductase.¹² Many drug interactions can influence the pharmacodynamics of warfarin by altering synthesis or clearance of vitamin K–dependent coagulation factors or interfering with warfarin metabolism, and patients should be advised to consult their physician or pharmacist about effects on anticoagulation when changing drug therapy or starting new medications (Table 25-2).¹¹ Other commonly used drugs affecting hemostasis, such as aspirin, nonsteroidal anti-inflammatory agents, heparins, and other anticoagulants can add to the antihemostatic effects of warfarin and can lead to bleeding.

ADMINISTRATION AND MONITORING

The anticoagulant effect of warfarin is the result of decreased levels of vitamin K–dependent coagulation factors, and their concentration represents a balance of synthesis and metabolism. Warfarin administration

impairs synthesis, and levels of vitamin K–dependent factors fall in relation to their metabolism. This is short for factor VII, with a half-life of approximately 5 hours, but longer for factors X and IX ($t_{1/2} = 24$ hours) and longest for factor II (prothrombin) with a half-life of approximately 72 hours. The desired anticoagulant effect results from a balanced reduction of all factors and requires several days to achieve. Imbalances in reduction of coagulation factors may occur during initiation of therapy as factor VII level falls rapidly, whereas others, especially factor II, decline more slowly. The initial rapid fall in factor VII level may lead to an early elevation in the prothrombin time (PT) expressed as international normalized ratio (INR) without reflecting the desired anticoagulant effect. Because protein C is a natural inhibitor of coagulation with a short half-life (approximately 8 hours), its level may fall rapidly, theoretically inducing a procoagulant state during initiation of therapy.

As a result of the delayed anticoagulant effect of warfarin, therapy is initiated with a rapidly acting agent, such as heparin or low-molecular-weight heparin (LMWH), if immediate anticoagulation is needed. For example, patients with venous thromboembolism are typically given heparin or an LMWH for rapid effect, and warfarin is also administered within the first 24 hours. After a period of 5 or more days, the necessary anticoagulant effect of warfarin is achieved, and the parenteral anticoagulant can be stopped. Anticoagulation is initiated with a dose close to the expected daily maintenance requirement, which is usually between 5 and 10 mg.^{13–15} There is, however, great variability in the doses required, and smaller amounts should be used for frail, elderly, or poorly nourished patients, or those with an increased bleeding risk. In patients with a low level of protein C or protein S as a result of an inherited deficiency, initiation of warfarin therapy without concomitant heparin or other immediately acting anticoagulant can lead to very low levels of these natural anticoagulants with ensuing thrombosis such as skin necrosis.

The anticoagulant effect of the vitamin K antagonists is monitored using the PT, which is sensitive to decreases in vitamin K–dependent factors and is progressively lengthened as the vitamin K–dependent factors reach lower levels. A critical component of the PT is the thromboplastin reagent that is used. Variability in thromboplastin composition leads to variation in results. The widespread introduction of the INR has improved standardization of results.¹⁶ Manufacturers determine the potency of thromboplastins by measuring the international sensitivity index (ISI), and this is used as a correction factor for the responsiveness of the thromboplastin in the PT. The INR represents the ratio of the patient PT to control PT corrected by the ISI. By this method, INR values obtained in different laboratories can be reliably compared for therapeutic monitoring.

During initiation of therapy, the INR is checked every 2 to 3 days for 1 to 2 weeks until a stable therapeutic effect is achieved. The target INR for most indications is 2.5 with a desirable therapeutic range from 2 to 3. A higher INR is recommended for patients with mechanical heart valve replacement and for those who failed anticoagulant therapy despite well-documented INR values in the 2 to 3 range. During chronic therapy, the INR should be monitored regularly, depending on stability of the response, and minor dose adjustments are frequently needed. A recent randomized trial in patients on chronic warfarin therapy with a stable dose for 6 months demonstrated that INR monitoring every 12 weeks was noninferior to monitoring every 4 weeks with regards to time in therapeutic range (74.1 vs. 71.6 percent).¹⁷ Monitoring can also be performed using portable instruments that are suitable for home use, enabling selected patients to learn to modify their warfarin doses in response to their INR value.¹⁸ A nonblinded randomized study compared home monitoring to INR monitoring in a specialized coagulation clinic in a cohort of patients on chronic warfarin and capable of conducting home monitoring.¹⁹ In this trial, rates of the primary composite end

point (thrombosis, major bleeding or death) were equivalent, but home monitoring was associated with significant improvement in patient satisfaction, quality of life and time in therapeutic range. Specialized clinics devoted to monitoring warfarin typically achieve better results in maintaining patients within the therapeutic range, resulting in fewer bleeding complications.^{20,21} Problems with keeping patients within the therapeutic range often result from failure of compliance, changes in diet, medication or alcohol intake, or intercurrent illnesses.

Warfarin sensitivity is affected by polymorphisms in CYP and vitamin K epoxide reductase complex (VKORC), and pharmacogenomics may become important in dosing. The clearance of warfarin is the result of hepatic metabolism and CYP2C9 is the most important enzyme mediating its clearance.²² A number of polymorphisms have been identified, but the most important are CYP2C9*2 and CYP2C9*3, which are found in approximately 11 percent and 7 percent of patients and result in reductions of enzymatic activity of approximately 30 percent and 80 percent, respectively.^{23–25} This reduced metabolic clearance leads to increased drug levels and an increased anticoagulant effect. VKORC1 converts oxidized vitamin K to the active reduced form as required for posttranslational carboxylation. VKORC1 is the target of warfarin, which functions as a competitive inhibitor. Numerous coding polymorphisms have been identified that can affect the response to warfarin.^{26,27} Common haplotypes can be separated into low-dose (A) and high-dose (B) groups with different sensitivities to warfarin.

Evidence is clear that polymorphisms in either CYP2C9 or VKORC1 affect warfarin sensitivity. Retrospective studies have shown that patients with at least one variant allele have an increased risk of INRs over the desired range and the variant groups also require more time to achieve stable dosing compared to patient with wild type allele.^{28,29} Additional prospective observational studies indicate that CYP2C9 and VKORC1 genotype affect warfarin sensitivity.^{30–32} Several prospective studies have incorporated genotyping for CYP2C9 and VKORC1 into algorithms that typically include clinical variables such as age, gender, and drug interactions in an attempt to use genetic information to improve warfarin dosing. The results of these trials are conflicting possibly as a consequence of different trial design and patient populations. Incorporation of CYP2C9 and VKORC1 polymorphisms into a dosing algorithm in one randomized study more accurately predicted warfarin dose and reduced dose modifications, but did not improve time in therapeutic range.³³ Another randomized study compared dosing based on genotype and clinical variables to clinical variable alone in almost 1000 patients starting warfarin. This showed no difference in time in therapeutic range, bleeding, or thromboembolism.³⁴ Genotype-based dosing resulted in significantly decreased time in the therapeutic range for black patients in this study suggesting such an approach is detrimental for this subgroup. A third study conducted in Europe reported a significant improvement in time in therapeutic range (67.4 vs. 60.3 percent), episodes of excessive anticoagulation (INR >4), and median time to reach a therapeutic INR (21 vs. 29 days) with genotype-based dosing.³⁵ A similarly designed study by the same European group in patients starting acenocoumarol or phenprocoumon showed no improvement in these same measures with genotype based dosing.³⁶ Further research is needed before genetic testing becomes part of standard care for patients receiving warfarin.

COMPLICATIONS

The most serious and common complication of warfarin is bleeding, and its risk is related primarily to patient characteristics, the degree of the anticoagulation, and the duration of therapy. The rate of major bleeding with 3 to 6 months of warfarin treatment in recent clinical trials of patients with venous thromboembolism was 1.2 to 2.2 percent.^{37–39}

TABLE 25-3. HAS-BLED Score for Predicting Bleeding Risk on Coumadin

Variable	Points
Hypertension (uncontrolled, systolic >160 torr)	1 point
Abnormal renal or liver function	1 point each, max 2 points
Stroke (prior history)	1 point
Bleeding history of predisposition	1 point
Labile INR (<60% time in therapeutic range)	1 point
Elderly (>65 years old)	1 point
Drugs/alcohol use (nonsteroidal antiinflammatory drugs, aspirin, antiplatelet agents)	1 point for each, max 2 points

INR, international normalized ratio.

Bleeding rate: 0 points = 0.8%, 1 point = 1.3%, 2 points = 2.2%, ≥3 points = 7.8%

Several risk models have been developed to predict bleeding risk in patients on warfarin. The HAS-BLED score was derived and validated in a prospective cohort of more than 6000 patients on warfarin for atrial fibrillation (Table 25-3).⁴⁰ Variables in this model include hypertension, abnormal renal or liver function, stroke, prior bleeding complications, labile INR, age older than 65 years, and drug or alcohol abuse. The intensity of anticoagulation as reflected by the INR is the most important predictor of bleeding risk, which is low in the therapeutic range but increases as the INR prolongs further. The cumulative risk of bleeding increases with a longer duration of treatment, whereas the absolute risk is greatest early, possibly caused by pathologic lesions present at the time therapy is started.

A rare complication of warfarin therapy is skin necrosis, which if it occurs usually presents early in the course of anticoagulation.⁴¹ Thrombosis in dermal and subdermal venules is the underlying cause, and this may be caused by disproportionately rapid reduction in proteins C and S. Skin necrosis typically begins with burning and tingling at the affected site, which usually involves a region with a large amount of subcutaneous tissue, such as the breast, buttock, or thigh. Painful hemorrhagic full-thickness skin infarction may develop, and frequently will require skin grafting. Other complications from warfarin are rare. Occasional patients report alopecia; hypersensitivity reactions are rare and are almost uniformly caused by the dye used in the pill rather than by the warfarin itself.

Warfarin use in patients with heparin-induced thrombocytopenia (HIT) may be complicated by limb gangrene caused by occlusive venous thrombosis; this effect is likely a result of a combination of inadequate parenteral anticoagulant effect and reduced levels of protein C, in concert with relatively preserved levels of factors II and X that are seen early after the initiation of warfarin administration.⁴² This complication highlights the need for parenteral anticoagulants to be continued in patients with HIT until the coagulopathy has largely resolved, as indicated by a return of the platelet count to normal or near normal levels.

Oral anticoagulation should be avoided in pregnancy because warfarin crosses the placenta, and exposure during organogenesis in the first trimester can lead to fetal embryopathy with significant cranial bone malformations.⁴³ Anticoagulation during pregnancy increases bleeding complications, especially later in pregnancy. Warfarin may be

considered during the second trimester, but heparin or an LMWH is a preferable alternative in most situations. Vitamin K antagonists are safe during lactation.⁴⁴

REVERSAL OF ANTICOAGULATION

Anticoagulation must be reversed for episodes of bleeding, surgery, trauma, or overdosage. Appropriate interventions for patients with excessively prolonged INRs without bleeding include holding warfarin doses, administering low doses of vitamin K (0.5 to 1.0 mg), and increasing the frequency of monitoring (Table 25-4).⁴⁵ Serious bleeding and major warfarin overdosage requires factor replacement and larger vitamin K doses that may need to be given intravenously. Four-factor concentrates have been developed and tested for reversal of warfarin. A large, open-label, prospective phase IIIB noninferiority study in nonsurgical patients on warfarin requiring reversal for major bleeding compared fresh-frozen plasma (FFP) to four-factor prothrombin complex concentrate (PCC) (factors II, VII, IX, X, protein C, and protein S).⁴⁶ Four-factor PCC was as effective in achieving hemostasis as plasma (72.4 percent with four-factor PCC vs. 65.4 percent with plasma; absolute difference, 7.1 percent [95 percent confidence interval, -5.8 to 19.9]) and superior to FFP with regards to INR correction within 0.5 hours of infusion (62.2 percent receiving four-factor PCC vs. 9.6 percent receiving FFP; absolute difference, 52.6 percent [95 percent confidence interval, 39.4 to 65.9]). The rate of adverse events, such as death and thromboembolism, was similar between groups.

Anticoagulated patients who need invasive procedures represent management problems, and decisions about periprocedural anticoagulation should be based on balancing the risk of thromboembolism with that of bleeding from the procedure. Evidence-based guidelines for bridging therapy are available,⁴⁵ and the topic has been reviewed.⁴⁷ The goal is to reduce the intensity of anticoagulation during and immediately after surgery, while avoiding thromboembolism caused by the underlying disease. Generally, the risk of recurrence is greatest in the period shortly after an episode of acute thrombosis and declines progressively over time. If possible, elective surgery and other invasive

TABLE 25-4. Reversing Warfarin Therapy

Indication	Action
INR <6	Lower the dose, consider withholding 1 or more doses Recheck in 3–7 days
INR 6–10	Lower the dose and withhold 1–3 doses Consider administering vitamin K, 1–2 mg orally Recheck INR in 24–48 hours
INR >10	Withhold doses until INR in desired range and cause of elevation ascertained Give vitamin K, 2–4 mg orally Recheck INR in 24 hours
Serious bleeding and major overdose	Administer four-factor prothrombin complex concentrate if available for rapid reversal. If four-factor prothrombin complex concentrate not available administer fresh-frozen plasma. Also give 5–10 mg vitamin K intravenously

INR, international normalized ratio.

procedures associated with a high bleeding risk should be postponed during the first several months following acute thrombosis. The bleeding risk is usually highest during surgery and decreases rapidly to baseline after approximately 7 to 10 days. Most surgery can be done with a minimal bleeding risk in patients receiving warfarin and an INR of 1.5 or less. A recent cohort study of 1496 patients on chronic anticoagulation undergoing periprocedural bridging therapy showed that bleeding occurred in 5.1 percent of patients, and risk factors for bleeding included mitral mechanical valve, active cancer, prior bleeding history, and reinitiation of anticoagulation within 24 hours of procedure.⁴⁸ A randomized study of anticoagulated patients undergoing defibrillator placement showed that bridging therapy was associated with a significant increase in device-pocket hematoma (16 percent vs. 3.5 percent) without a reducing thromboembolic complications.⁴⁹ Patients at moderate or high risk of thrombotic recurrence should receive heparin or LMWH “bridging therapy” when their INR becomes subtherapeutic. Postprocedural bridging therapy should be undertaken only in patients in whom the risks of this therapy (principally bleeding) are less than the perceived benefits (a reduced risk of thromboembolism).

● HEPARIN

PHARMACOLOGY

Heparin (and the related LMWHs) is the most widely used, rapidly acting, parenteral anticoagulant. Heparin is a heterogeneous mixture of sulfated glycosaminoglycan molecules with varying chain lengths (molecular mass [Mr] 5000 to 30,000 daltons). Heparin has no direct anticoagulant effect, but serves to activate plasma antithrombin (AT), a serine protease inhibitor. Only about one-third of heparin molecules contain the necessary unique pentasaccharide sequence required to interact with AT and thus display anticoagulant activity.⁵⁰ AT inhibits thrombin, factor Xa, and other coagulation serine proteases in a reaction that is slow by itself, but is accelerated approximately 1000-fold in the presence of heparin.⁵¹ To inhibit thrombin, heparin binds to both the active enzyme and AT, forming a ternary complex. The inhibition of factor Xa, however, occurs through binding to heparin-AT complex without the requirement for heparin binding directly also to factor Xa. The requirement for a ternary heparin-AT-thrombin complex requires heparin molecules with 19 or more saccharide units, whereas smaller heparin molecules are effective in promoting factor Xa inactivation. Thrombin and factor Xa are relatively protected from inhibition by the heparin-AT complex when they are surface immobilized within thrombi or on cells.⁵²

ADMINISTRATION AND MONITORING

Heparin is not absorbed after oral ingestion, so must be given either subcutaneously or intravenously. The pharmacokinetics of unfractionated heparin is complex, a result of extensive protein binding, with a dose-dependent half-life in the range of 1 to 2.5 hours.⁵³ A common protocol uses an initial intravenous bolus of 5000 units or 75 U/kg, followed by a maintenance infusion of 1250 to 1660 U/h or 18 U/kg per hour. The anticoagulant effect is immediate, but laboratory monitoring is needed because of the variability in response among patients. Monitoring is most convenient with the activated partial thromboplastin time (aPTT), which is sensitive to plasma heparin concentrations of 0.1 U/mL or higher. Because different reagents and measuring systems have differing sensitivities to heparin, it is recommended that the therapeutic range be established for each laboratory by calibrating the aPTT to a plasma heparin concentration of 0.2 to 0.4 units by protamine sulfate titration, or 0.3 to 0.7 U/mL using an anti-factor Xa assay.⁵⁴ The usual aPTT range for heparin therapy is between 1.5 and 2.5 times the

mean of the normal range. Clinically useful nomograms are available for adjusting the heparin dose using either fixed- or weight-based dosing.⁵⁵ Alternatively, monitoring can be performed using anti-Xa levels, which is a useful approach when the aPTT is unreliable, as in patients with baseline prolongation of the aPTT as a consequence of expressing a lupus anticoagulant. Rapid achievement of a therapeutic level, as assessed by the aPTT or anti-Xa level, is important in ensuring an adequate anticoagulant effect.

Some patients fail to display an adequately prolonged aPTT following treatment with unfractionated heparin, despite apparently adequate or even supratherapeutic doses of the drug. This phenomenon is termed *heparin resistance* and is usually caused by an acute-phase response that results in high levels of procoagulant proteins, including factor VIII. The antithrombotic effect of heparin correlates best with plasma heparin levels, which may be adequate in these circumstances despite a subtherapeutic aPTT.⁵⁶ For patients who require heparin doses of greater than 35,000 U/day to increase the aPTT into the therapeutic range, consideration should be given to using heparin levels determined by an anti-Xa assay. Substitution of LMWH for unfractionated heparin is another consideration. Although AT deficiency may cause heparin resistance, most AT-deficient patients can be adequately anticoagulated with heparin in usual doses. No monitoring is recommended when low doses of heparin are used for prophylaxis of venous thromboembolic disease, although minimal prolongation of the aPTT may occur. Care is required in very light weight and frail elderly who may be anticoagulated with usual “prophylactic” doses of unfractionated heparin; aPTT monitoring might be considered in such patients.

A large study demonstrated that patients with acute venous thromboembolism can be safely treated with fixed, weight-adjusted heparin doses without aPTT monitoring.⁵⁷ In this study, 708 patients were allocated randomly to receive either unfractionated heparin with a subcutaneous bolus dose of 333 U/kg followed by a twice-daily dose of 250 U/kg, or LMWH over 3 months of follow up. Recurrent venous thromboembolism occurred in 13 patients who were allocated to unfractionated heparin and in 12 who were allocated to LMWH. Major bleeding occurred in four and five patients, respectively. This study calls into question the need for routine aPTT monitoring of therapeutic dose, weight-adjusted unfractionated heparin and warrants validation.

REVERSAL

Heparin has a short half-life, and its anticoagulant effect disappears several hours after discontinuation of an intravenous infusion. Therefore, stopping the infusion and local measures are usually adequate to control bleeding. However, in major or life-threatening bleeding, the anticoagulant effect can be neutralized with protamine sulfate, which is a basic polypeptide that binds tightly to the acidic heparin molecule. The usual dose of protamine required is 1 mg to neutralize 100 units of heparin. The dose to be administered is based on the amount of heparin remaining in the circulation. Protamine is routinely used to neutralize heparin after cardiopulmonary bypass using standard formulas and activated clotting time monitoring.

ADVERSE EFFECTS

The most frequent complication of heparin administration is bleeding, which is related to the dose and intensity of treatment, as well as to patient characteristics. HIT is an immune-mediated platelet consumption caused by an antibody directed against a complex of heparin and platelet factor 4 (Chap. 118). Despite thrombocytopenia, HIT is more commonly associated with thrombotic complications than bleeding, and it occurs in approximately 3 percent of patients, depending on the

type of heparin, the dose and route of administration, and the indication for heparin anticoagulation (e.g., more common in “surgical patients” than in “medical patients”). The “4T” score is a clinical prediction tool with good negative predictive value.⁵⁸ Platelet counts should be monitored during treatment and heparin discontinued if thrombocytopenia occurs, and an alternative anticoagulant that does not interact with the heparin-platelet factor 4 complexes should be administered. Vitamin K antagonists should be given only after the platelet count has risen to greater than 150,000/ μ L. Long-term heparin therapy can also cause osteoporosis, and radiographic evidence of bone loss occurs in approximately 15 percent of women who receive prolonged treatment during pregnancy, with symptomatic vertebrae fractures in approximately 2 percent. The bone loss may resolve after heparin is discontinued.

LOW-MOLECULAR-WEIGHT HEPARIN

Limitations of unfractionated heparin led to studies correlating structural and functional relationships of heparin, and this eventually resulted in the development of LMWHs, several of which are available. LMWH preparations are produced by treating heparin chemically or enzymatically to decrease the size of the polysaccharide chains, yielding products with restricted molecular weight distributions with a mean of approximately 4000 to 5000 daltons.⁵⁹ Like heparin, LMWHs exert antithrombotic effects through interaction with AT. In the presence of LMWH, AT inactivates factor Xa in the same way as unfractionated heparin, but it is less able to inactivate thrombin because the shorter polysaccharide length does not allow formation of the necessary ternary complex. Consequently, LMWHs have a greater proportion of anti-factor Xa than AT activity.

LMWHs also have different pharmacokinetic properties than unfractionated heparin.⁵⁴ Following subcutaneous administration, LMWHs are nearly completely absorbed, a clear benefit over unfractionated heparin, which exhibits variable and dose-dependent absorption. LMWHs also exhibit less binding to plasma proteins and cells than unfractionated heparin, resulting in more predictable blood levels and anticoagulant effects. LMWHs have a longer plasma half-life than unfractionated heparins, allowing once- or twice-daily subcutaneous administration.

LMWHs have significant renal clearance, and high levels can accumulate in patients with renal insufficiency. Care must be taken in dosing LMWHs in patients with reduced renal function as bleeding risks are increased,⁶⁰ and monitoring with anti-factor Xa levels may be needed. Similarly, monitoring may be necessary to achieve appropriate levels in very obese patients, although weight-based dosing probably achieves better anticoagulation. Protamine sulfate does not completely reverse the anticoagulant effect of LMWH but is partially effective and can be useful in patients with serious hemorrhage.⁶¹ Several LMWH preparations are available and approved for both prophylaxis and treatment of venous and arterial thrombotic diseases. Each preparation differs slightly and is pharmacologically unique, although the agents are likely similarly effective for the treatment and prevention of venous thrombosis.

Similar to unfractionated heparin, the most common adverse effect is bleeding, which occurs at approximately the same frequency and severity when used in similar patient groups for the same indication. HIT is much less common than with unfractionated heparin,⁶² occurring only in 0.3 to 0.45 percent of patients. However, cross-reactivity of the antibody occurs, and LMWH is not an acceptable choice for continued anticoagulation in patients with HIT induced by treatment with unfractionated heparin. Animal studies suggest that osteoporosis may be less common with LMWH, and this is reported by several small clinical trials.⁶³

CHOICE OF HEPARIN OR LOW-MOLECULAR-WEIGHT HEPARIN

The factors governing the choice of heparin or LMWH concern effectiveness, safety, convenience, and cost. For treatment of venous thromboembolic disease, the safety and efficacy of heparin and LMWH are comparable. A meta-analysis of 14 studies comparing unfractionated heparin to LMWH in 4754 patients showed that LMWH-treated patients had less recurrent venous thromboembolic complications (4.3 percent vs. 5.6 percent, odds ratio [OR] 0.76, 95 percent confidence interval 0.57 to 1.01) and fewer major bleeding events (1.3 percent vs. 2.1 percent, OR 0.6, 95 percent confidence interval 0.39 to 0.93).⁶⁴ LMWH also offers better convenience because subcutaneous administration permits outpatient treatment. However, LMWHs may be difficult to use in patients with renal insufficiency because of decreased clearance, and intravenous heparin may offer advantages in such patients. LMWHs are incompletely reversed by protamine sulfate, making them more difficult to use for cardiac bypass surgery. Unfractionated heparin may be preferable in patients who require an invasive procedure on an urgent basis because of its shorter half-life. LMWHs may offer some advantages for patients with acute coronary syndromes.

DANAPAROID

Danaparoid is a mixture of glycosaminoglycans and is composed of approximately 84 percent heparan sulfate, 12 percent dermatan sulfate, and 4 percent chondroitin sulfate. It is an AT-dependent anticoagulant with predominant anti-factor Xa activity. The plasma half-life is approximately 24 hours with predominant renal clearance. Danaparoid is not reversed by protamine sulfate. Danaparoid differs structurally from heparin and it has been used successfully to treat patients with HIT. Although there is *in vitro* cross-reactivity of 10 to 20 percent of heparin antibodies with danaparoid, this is of uncertain clinical relevance. Danaparoid is administered subcutaneously, and levels may be monitored with anti-factor Xa assays performed using a danaparoid standard curve. At the time of writing danaparoid has not been approved in the United States, and availability elsewhere was limited.

FONDAPARINUX

Fondaparinux is a unique heparin-like anticoagulant with highly selective AT-dependent anti-factor Xa activity.⁵⁴ It is a completely synthetic pentasaccharide whose structure is based on the heparin sequence that interacts with AT. It binds reversibly and with high affinity to AT, resulting in a conformational change that renders it effective in inhibiting factor Xa, but because of its small size, does not inhibit thrombin. Whereas unfractionated heparin and all LMWHs are derived from animal sources, fondaparinux is synthesized in a structurally homogenous form containing no animal products. Consequently, fondaparinux does not induce allergic responses. Because it inhibits factor Xa but has no direct action on thrombin, its mechanism of action depends on reducing thrombin generation.

Pharmacologic studies show that maximum plasma levels are reached approximately 2 hours after subcutaneous administration with an elimination half-life of approximately 17 hours independent of the dose.⁶⁵ Bioavailability is nearly complete after subcutaneous or intravenous administration. There is a low intra- and intersubject variability with little accumulation after multiple daily doses. Because elimination is primarily renal and the agent is excreted unchanged in the urine, fondaparinux is contraindicated in patients with severe renal impairment. Fondaparinux plasma levels can be measured with the anti-factor Xa assay, but there is no effect on other coagulation assays including the activated clotting time (ACT), aPTT, or thrombin clotting time.

Clinical studies have evaluated the use of fondaparinux in several conditions, and it is approved by the FDA for prevention of venous thromboembolism (VTE) in patients undergoing major orthopedic surgery or with hip fracture, prophylaxis after abdominal surgery, and treatment of deep venous thrombosis (DVT) or pulmonary embolism (PE). For prophylaxis it is administered subcutaneously in a dose of 2.5 mg once daily, whereas a weight-adjusted dose is used for treatment of VTE. The principal adverse effect is bleeding, and its frequency and severity have been comparable to those observed with LMWH. Elevated levels may occur in patients with renal insufficiency, and caution should be exercised in using fondaparinux in patients with renal compromise. Fondaparinux is a good choice for an anticoagulant in patients with HIT as there is no cross-reactivity.⁶⁶

BIVALIRUDIN

Bivalirudin, a direct thrombin inhibitor, is a recombinant protein based on the structure of hirudin, is composed of a dodecapeptide analogue of the carboxyterminal region of hirudin linked by a four-glycine residue to a structure directed to the active site of thrombin.⁶⁷ Pharmacokinetic studies show that plasma clearance is rapid (4.6 mL/min/kg) in patients with normal renal function with a volume of distribution of 0.2 L/kg and elimination half-life of approximately 30 minutes.⁵⁴ There is dose-dependent prolongation of the ACT and aPTT that correlates with plasma concentrations. The drug is eliminated by both renal and hepatic clearance, and consequently, dose modification is recommended for patients with moderate-to-severe functional liver or kidney disease.

Bivalirudin is effective when used with aspirin in patients with unstable angina or postinfarction angina undergoing angioplasty, and it is approved for this use.⁶⁸ It is also approved for patients with HIT undergoing percutaneous coronary intervention. In some clinical trials, bivalirudin also shows efficacy in preventing restenosis after coronary angioplasty, as an adjunct to streptokinase in acute myocardial infarction, and in preventing venous thrombosis after orthopedic surgery and in patients with HIT. However, these indications have not been approved by the FDA. The most common adverse effect is bleeding, and no specific antidote is available. The infusion should be discontinued in patients with bleeding complications and blood levels monitored with the aPTT or other coagulation parameters. Antibivalirudin antibodies have not been detected following therapy.

ARGATROBAN

Argatroban is a small-molecule arginine derivative that reversibly and directly inhibits thrombin by binding to the active catalytic site of the enzyme with a K_i of 3.9×10^{-8} mol/L.⁵⁴ Because of its small size, argatroban is an effective inhibitor of thrombin, both bound to surfaces and in solution.⁶⁹ The anticoagulant effect can be assessed with either the aPTT or ACT, and both correlate with plasma concentrations of the drug. Argatroban is approximately 50 percent protein bound and has a volume of distribution of 0.2 L/kg and an elimination half-life of 39 to 51 minutes.⁷⁰ Metabolism is primarily hepatic, and the clearance and half-life are prolonged in patients with hepatic functional abnormalities requiring dose reduction. Renal function has less effect on argatroban pharmacokinetics.

Argatroban is approved for treatment and prophylaxis of HIT and for percutaneous interventions in patients with HIT. It also shows some benefit in patients with thrombotic stroke in clinical trials. For treatment of HIT, argatroban is administered at 2 mcg/kg per hour and adjusted to maintain the aPTT at 1.5 to 3 times baseline. For patients with HIT who are undergoing percutaneous coronary interventions, the drug is administered as a bolus of 350 mcg/kg followed by a continuous infusion of 15 to 400 mcg/kg per minute for a target ACT of 300 to 450

seconds. As with other direct thrombin inhibitors, the main side effect is bleeding, and no specific agent is available to reverse its action. The anticoagulant effect may be prolonged in patients with hepatic impairment. If overdosage or excess bleeding occurs, the infusion should be discontinued and the aPTT and other coagulation parameters monitored.

The transition from argatroban to warfarin in patients requiring long-term anticoagulation is complicated because argatroban has a significant effect on both the PT and the aPTT. In patients transitioning to warfarin an INR should be measured; if it is greater than 4.0, the argatroban should be stopped for several hours and the INR remeasured. If the INR is still greater than 2.0, the argatroban can be discontinued; if it is less than 2.0, the argatroban should be reinstated and the same procedure followed on the next day.

LEPIRUDIN

Lepirudin is closely related to hirudin, a natural anticoagulant found in the salivary glands of the leech. The half-life is 1 to 3 hours in normal volunteers with predominantly renal catabolism, but it may be as long as 2 days in dialysis-dependent patients.⁷¹ Lepirudin prolongs the aPTT in a concentration-dependent manner.⁷² The manufacturer discontinued marketing of this product and it is no longer available.

DABIGATRAN ETEXILATE

Dabigatran etexilate, one of the novel oral anticoagulants, is a direct thrombin inhibitor prodrug with a bioavailability of approximately 6 percent after oral administration. The absorbed drug is rapidly converted by esterases to dabigatran. Peak levels occur 1 to 2 hours after an oral dose; the half-life is approximately 12 hours. Dabigatran does not require a cofactor and reversibly inhibits the active site of thrombin. Dabigatran does not interfere with drugs that are metabolized by the CYP enzyme system and it produces a predictable anticoagulant response, which allows therapy without the need for monitoring.⁷³ Dabigatran prolongs several coagulation assays. The PT, aPTT, and ACT lack sensitivity for therapeutic drug levels, while the dilute thrombin time and ecarin clotting time appear to correlate well across a broad range of drug levels.⁷⁴ None of these tests have been shown to predict clinical outcomes such as thrombosis or bleeding.

The major side effect of dabigatran is hemorrhage. No specific antidote is currently available, although such antidotes are in development.⁷⁵ Consequently, bleeding complications are managed symptomatically. Although not well studied, there are published case reports showing that dialysis or hemoperfusion likely removes this compound from the circulation.⁷⁶ In animal models the administration of various coagulation factor concentrates or recombinant activated factor VII (factor VIIa) improved prolonged bleeding times, although these agents did not cause correlative changes in anticoagulation tests.⁷⁷

Dabigatran etexilate, and the other novel oral anticoagulants, are effective in various clinical settings (Table 25-5). Dabigatran is now FDA approved for management of VTE and prevention of stroke and systemic embolism in nonvalvular atrial fibrillation. In the RE-LY trial, patients with nonvalvular atrial fibrillation and a risk of stroke were randomized to dabigatran etexilate (110 mg BID or 150 mg BID) or dose-adjusted warfarin.⁷⁸ In this noninferiority trial, rates of stroke or systemic embolism were 1.69 percent per year with warfarin, 1.53 percent per year with dabigatran etexilate 110 mg (relative risk [RR] 0.91, $p < 0.001$ for noninferiority) and 1.11 percent per year with dabigatran etexilate 150 mg (RR 0.66, $p < 0.001$ for superiority). The rates of major bleeding in the RE-LY trial were similar between higher dose dabigatran and warfarin, but significantly lower for low-dose dabigatran compared to warfarin. The rate of intracranial bleeding was lower for both doses of dabigatran compared to warfarin. The RE-COVER trial was a randomized double-blind

TABLE 25-5. Studies with Novel Targeted Oral Anticoagulants

Anticoagulant	Indication	Study	Efficacy	Safety
Dabigatran	Nonvalvular atrial fibrillation	RE-LY ⁷⁸	Dabigatran (150 mg BID dose) superior to warfarin at stroke reduction	Similar rates of major bleeding and lower rates of intracranial bleeding with dabigatran
	VTE	RECOVER ³⁷	Dabigatran (150 mg BID dose) noninferior to warfarin for prevention of recurrent VTE	Similar rates of major bleeding and decreased rates of total bleeding events with dabigatran
	Mechanical heart valves	RE-ALIGN ⁸⁰	Trial stopped early because of increased rates of thrombosis and bleeding in patients receiving dabigatran	
	Hip arthroplasty	RE-NOVATE ¹⁴⁰	Dabigatran (220 mg once daily or 150 mg once daily for 28–35 days) were noninferior to enoxaparin (40 mg once daily for 28–35 days) at prevention of total VTE or death	Major bleeding occurred in 1.4% of the dabigatran group and 0.9% of the enoxaparin group (p = 0.40)
	Hip arthroplasty	RE-NOVATEII ¹⁴¹	Dabigatran (220 mg once daily for 28–35 days) was noninferior to enoxaparin (40 mg once daily for 28–35 days) at prevention of total VTE or death (7.7% vs. 8.8%). Major VTE plus death was less common in dabigatran group (2.2% vs. 4.2%)	Major bleeding rates were similar (1.4% vs. 0.9%)
	Knee arthroplasty	RE-MODEL ¹⁴²	Dabigatran (220 mg once daily or 150 mg once daily for 6–10 days) were noninferior to enoxaparin (40 mg once daily for 6–10 days) at prevention of total VTE or death	The incidence of major bleeding did not differ between the three groups
Rivaroxaban	Nonvalvular atrial fibrillation	ROCKET-AF ⁸³	Rivaroxaban noninferior to warfarin at stroke reduction	Similar rates of overall bleeding, but significantly fewer intracranial bleeds with rivaroxaban (0.5% vs. 0.7%)
	Acute coronary syndrome	ATLAS ACS ¹⁴³	Rivaroxaban (2.5 or 5 mg BID) significantly reduced the combined end point of cardiovascular death, MI or stroke compared to placebo	Rivaroxaban increased the rates of major bleeding (2.1% vs. 0.6%) and intracranial hemorrhage (0.6% vs. 0.2%) without a significant increase in fatal bleeding (0.3% vs. 0.2%)
	PE	EINSTEIN-PE ³⁹	Rivaroxaban was noninferior to warfarin for treatment of acute PE	Similar overall bleeding rates but significantly fewer major bleeds with rivaroxaban (1.1% vs. 2.1%)
	DVT	EINSTEIN-DVT ³⁸	Rivaroxaban was noninferior to warfarin for treatment of acute DVT	Similar bleeding rates
	Hip arthroplasty	RECORD1 ⁸⁴	Extended duration rivaroxaban (10 mg daily 31–39 days) was superior to Lovenox (40 mg daily 31–39 days) for prevention of major VTE (0.2% vs. 2.0%)	Similar rates of major bleeding (0.3% vs. 0.1%)
	Hip arthroplasty	RECORD2 ¹⁴⁴	Extended duration rivaroxaban (10 mg daily 31–39 days) was superior to short duration Lovenox (40 mg daily 10–14 days) at prevention of any DVT, nonfatal PE or death (2.0% vs. 9.3%)	Similar rates of bleeding (5.5% vs. 6.6%)
	Knee arthroplasty	RECORD3 ⁸⁵	Short duration rivaroxaban (10 mg daily 10–14 days) was superior to short duration Lovenox (40 mg daily 10–14 days) at prevention of any DVT, nonfatal PE or death (9.2% vs. 18.9%)	Similar rates of major bleeding (0.5% vs. 0.6%)
	VTE prophylaxis in medically ill patients	MAGELLAN ⁸⁶	The rate of any proximal DVT or symptomatic VTE with extended duration rivaroxaban (10 mg daily for 31–39 days) was noninferior at 10 days (2.7% vs. 2.7%) and superior at 35 days (4.4% vs. 5.7%) when compared to standard prophylaxis (Lovenox 40 mg daily for 10–14 days)	The composite of major or clinically relevant nonmajor bleeding occurred more often in patients receiving extended duration rivaroxaban at day 10 (2.8% vs. 1.2%) and at day 35 (4.1% vs. 1.7%)

(Continued)

TABLE 25-5. Studies with Novel Targeted Oral Anticoagulants (Continued)

Anticoagulant	Indication	Study	Efficacy	Safety
Apixaban	Nonvalvular atrial fibrillation	ARISTOTLE ⁹³	Apixaban was superior to warfarin for stroke prevention (1.3% vs. 1.6%)	Significantly fewer major bleeds with apixaban (2.1% vs. 3.1%)
	Nonvalvular atrial fibrillation not suitable for warfarin	AVERROES ⁹⁴	Apixaban superior to aspirin for stroke prevention (1.6% vs. 3.7%)	Similar bleeding rates with apixaban and aspirin
	Acute coronary syndrome	APPRAISE-2 ¹⁴⁵	The trial was terminated prematurely because of an increase in major bleeding events without a reduction in cardiovascular ischemic events	
	VTE	AMPLIFY ⁹⁵	Apixaban was noninferior to warfarin for treatment of acute VTE	Significantly fewer major bleeding events with apixaban (0.6% vs. 1.8%)
	VTE extended treatment	AMPLIFY-EXT ⁹⁶	Apixaban was superior to placebo for prevention of recurrent VTE (1.7% vs. 8.8%)	Apixaban was not associated with increased major bleeding
	Knee arthroplasty	ADVANCE1 ⁹⁸	Apixaban (2.5 mg BID for 10–14 days) did not meet prespecified criteria for noninferiority in prevention of the composite end point including any DVT, nonfatal PE and death when compared to Lovenox (30 mg BID for 10–14 days)	Apixaban was associated with significantly fewer major and clinically relevant nonmajor bleeding events (2.9% vs. 4.3%)
	Knee arthroplasty	ADVANCE2 ⁹⁹	Apixaban (2.5 mg BID for 10–14 days) was superior to Lovenox (40 mg once daily 10–14 days) for prevention of the composite endpoint including any DVT, nonfatal PE and death (15% vs. 24%)	Similar rates of major and clinically relevant nonmajor bleeding events (4% vs. 5%)
	Hip arthroplasty	ADVANCE3 ⁹⁷	Apixaban (2.5 mg BID for 35 days) was superior to Lovenox (40 mg once daily 35 days) for prevention of the composite endpoint including any DVT, nonfatal PE and death (1.4% vs. 3.9%)	Similar rates of major and clinically relevant nonmajor bleeding events (4.8% vs. 5.0%)
VTE prophylaxis in medically ill patients	ADOPT ¹⁴⁶	The rate of any DVT, symptomatic PE, or death at 60 days with extended duration apixaban (2.5 mg BID for 30 days) was not superior to standard duration Lovenox (40 mg once daily 6–14 days) (2.7% vs. 3.1%)	Major bleeding was significantly more common in patients receiving apixaban (0.5% vs. 0.2%)	
Edoxaban	Nonvalvular atrial fibrillation	ENGAGE-AF ¹⁰¹	Edoxaban was noninferior to warfarin for stroke prevention	Significantly fewer major bleeding events with edoxaban (1.6% vs. 3.4%)
	VTE	HOKUSAI-VTE ¹⁰²	Edoxaban noninferior to warfarin for treatment of acute VTE	Significantly fewer overall bleeding events with edoxaban (8.2% vs. 10.3%)

DVT, deep vein thrombosis; MI, myocardial infarction; PE, pulmonary embolism; VTE, venous thromboembolism.

noninferiority trial comparing dabigatran etexilate (150 mg BID) to dose-adjusted warfarin in patients with acute VTE who received initial parenteral anticoagulation for a median of 9 days.³⁷ The rates of recurrent VTE were similar (2.4 vs. 2.1 percent, $P < 0.001$ for noninferiority). In a meta-analysis of three large randomized trials, dabigatran was as effective as LMWH for prevention of VTE and VTE-related mortality after hip and knee replacement, and had a similar bleeding risk.⁷⁹ Dabigatran does not appear to be safe or effective in prevention of thromboembolic complications following heart valve replacement. The RE-ALIGN study randomized patients to dabigatran or warfarin following valve replacement and was terminated early because of excess thrombotic and bleeding complications in dabigatran-treated patients.⁸⁰

RIVAROXABAN

Rivaroxaban is a direct factor Xa inhibitor that is administered orally and produces its anticoagulant effect through reversible binding with

factor Xa. Rivaroxaban can inhibit both free and thrombus-associated factor Xa. Like dabigatran, it is dependent on renal excretion, and bioaccumulation may occur in patients with renal insufficiency.

Rivaroxaban produces its peak anticoagulant effect within 4 hours of oral administration and has a terminal elimination half-life of 5.7 to 9.2 hours. PT is more accurate than the aPTT in measuring rivaroxaban effects; however, the sensitivity varies by specific reagent and is not good at lower therapeutic drug levels.⁸¹ A rivaroxaban calibrated anti-Xa assay appears to be the most accurate test as it correlates well with drug level across a broad therapeutic range.⁸²

Rivaroxaban is effective in a number of clinical settings. In the EINSTEIN-PE³⁹ and EINSTEIN-DVT³⁸ randomized clinical trials treatment with rivaroxaban (15 mg BID for 3 weeks followed by 20 mg once daily) was noninferior to standard anticoagulation (LMWH followed by warfarin) in preventing recurrent thrombosis in patients with acute VTE. In a large randomized trial of patients with nonvalvular atrial fibrillation, rivaroxaban was noninferior to warfarin for prevention of

stroke or systemic embolism.⁸³ Prophylactic rivaroxaban (10 mg once daily) significantly reduced rates of postoperative VTE compared to the LMWH Lovenox (40 mg once daily) following hip arthroplasty (1.1 percent vs. 3.7 percent, $p < 0.001$)⁸⁴ and knee arthroplasty (9.6 percent vs. 18.9 percent),⁸⁵ and in hospitalized acutely medically ill patients was noninferior to Lovenox for standard 10-day thromboprophylaxis.⁸⁶

The principal side effect of rivaroxaban therapy is bleeding. In a pooled analysis of the EINSTEIN studies, major bleeding was less common in patients receiving rivaroxaban compared to standard anticoagulation (1.0 percent vs. 1.7 percent, $p = 0.002$), and this includes a significant reduction in intracranial bleeding.⁸⁷ In another meta-analysis of phase III trials comparing rivaroxaban to standard anticoagulation, rivaroxaban was associated with a reduced risk of fatal bleeding complications.⁸⁸ There is no antidote for the anticoagulant effect of rivaroxaban. Prothrombin complex concentrates partially reverse prolonged coagulation times in healthy volunteers receiving rivaroxaban,⁸⁹ and PCC and recombinant activated factor VIIa improved bleeding times after rivaroxaban treatment in animal studies.⁹⁰ However, these agents have not been proven effective in managing rivaroxaban treated patients with bleeding complications.

APIXABAN

Apixaban is an orally administered direct inhibitor of factor Xa which is metabolized primarily by the hepatic cytochrome CYP3A4 enzyme. The onset of action and half-life are 3 hours and 12 hours respectively, and approximately 25 percent is excreted by the kidney. Apixaban affects standard anticoagulation assays less than rivaroxaban, and the effect is variable for different reagents within an assay group. In general the PT is more sensitive than aPTT, and chromogenic apixaban specific anti-Xa assays display the most accurate linear correlation across a therapeutic dose range.⁹¹ There is no antidote for reversal of apixaban. In animal studies recombinant activated factor VIIa but not PCCs reduced bleeding times in apixaban-treated animals.⁹²

Apixaban, like rivaroxaban and dabigatran, has been studied in several clinical settings. Two large phase III randomized clinical trials with slightly different designs led to the approval of apixaban for management of nonvalvular atrial fibrillation. In the ARISTOTLE trial, patients with nonvalvular atrial fibrillation and a risk for stroke were randomized to apixaban (5 mg BID) or dose-adjusted warfarin. Apixaban was superior to warfarin in reducing the rate of embolic or hemorrhagic stroke and systemic embolism (1.27 percent vs. 1.6 percent per year, $p = 0.01$), and fewer patients experienced major bleeding complications (2.13 percent vs. 3.09 percent, $p < 0.001$).⁹³ The AVERROES trial was terminated early because of a clear reduction in stroke and systemic embolism in patients with nonvalvular atrial fibrillation deemed unsuitable or unwilling to take vitamin K antagonists randomized to apixaban versus aspirin (1.6 percent vs. 3.7 percent, $p < 0.001$).⁹⁴ Interestingly, there was no difference in major bleeding or intracranial bleeding between apixaban and aspirin. Apixaban (10 mg BID for 7 days then 5 mg BID) has also been shown to be noninferior to standard anticoagulation (LMWH then dose-adjusted warfarin) in initial management of acute VTE,⁹⁵ and effective for secondary VTE prevention in patients treated for an extended time following acute VTE.⁹⁶ Major bleeding rates were significantly lower with apixaban compared to standard anticoagulation in the initial period after acute VTE (0.6 percent vs. 1.8 percent, $p < 0.001$), and rates of major bleeding were equivalent in patients receiving extended thromboprophylactic dosing of apixaban compared to placebo (0.1 percent in the 5-mg apixaban group, 0.2 percent in the 2.5-mg apixaban group, 0.5 percent in the placebo group). Prophylactic apixaban (2.5 mg BID) is better than Lovenox (40 mg daily) at preventing postoperative VTE following hip replacement.⁹⁷

Following total knee replacement apixaban did not meet prespecified noninferiority criteria in ADVANCE-1, where VTE rates were similar in patients receiving apixaban (2.5 mg BID) and twice daily Lovenox (30 mg BID) (9.0 percent vs. 8.8 percent),⁹⁸ however in ADVANCE-2 apixaban was proven to be noninferior to once daily Lovenox in prevention of postoperative VTE following knee replacement.⁹⁹

EDOXABAN

Edoxaban is a direct oral factor Xa inhibitor with peak onset approximately 1 to 2 hours after administration and a half-life of approximately 8 hours.¹⁰⁰ Like other direct Xa inhibitors, edoxaban is renally excreted. Multiple coagulation tests can be affected by edoxaban, but partial thromboplastin time (PTT) and anti-Xa assay show the best correlation with drug levels.

Edoxaban is effective in management of atrial fibrillation and acute venous thromboembolism, and in the prevention of VTE following hip or knee arthroplasty. In the ENGAGE AF-TIMI trial, the annualized rate of stroke or systemic embolism in patients with nonvalvular atrial fibrillation and moderate to high risk of thrombosis was 1.50 percent with warfarin, 1.18 percent with high-dose edoxaban ($P < 0.001$ for noninferiority), and 1.61 percent with low-dose edoxaban ($P = 0.005$ for noninferiority).¹⁰¹ Edoxaban-treated patients experienced significantly fewer major bleeding events (3.43 percent with warfarin vs. 2.75 percent with high-dose edoxaban and 1.61 percent with low-dose edoxaban). In the Hokusai-VTE study, edoxaban was noninferior to warfarin in preventing recurrent VTE in patients with acute PE or DVT (3.2 percent vs. 3.4 percent), and bleeding complications were reduced in the edoxaban treated group (8.5 percent vs. 10.3 percent).¹⁰²

FIBRINOLYTIC THERAPY

Fibrinolytic therapy is administered by infusing high doses of a plasminogen activator to accelerate the conversion of plasminogen to the active fibrinolytic enzyme plasmin, which proteolytically degrades fibrin (Chap. 135). The specific biochemical and pharmacologic properties of different agents are important determinants of the administration regimen, the efficacy of clot lysis, and the nature of adverse effects. For example, some fibrinolytic drugs are bacterial products that are antigenic and can cause allergic responses, whereas others are recombinant human proteins. Some agents activate plasminogen prominently, both in blood and at the clot surface, and induce a systemic fibrinolytic state in addition to accelerating clot lysis. In contrast, the activity of other agents is more specifically limited to the clot surface with fewer systemic effects. Fibrinolytic therapy is used for treatment of both venous and arterial thrombosis and represents standard treatment for many patients presenting with acute myocardial infarction because it accelerates reperfusion, decreases mortality, and reduces morbidity (Chap. 135). Thrombolytic therapy has also become standard for many patients presenting with thrombosis of peripheral arteries, bypass grafts, and catheters.¹⁰³ It is used for treatment of selected patients with thrombotic stroke. Fibrinolytic therapy improves outcome in selected patients with large pulmonary emboli (Chap. 135).

STREPTOKINASE

Streptokinase was the first plasminogen activator used clinically. It is derived from β -hemolytic streptococci and has a unique indirect mechanism of action. By itself, streptokinase has no enzymatic activity, but it combines with plasminogen to form an equimolar streptokinase-plasminogen complex that can then convert other plasminogen molecules to plasmin. Additionally, the streptokinase-plasminogen complex can undergo proteolytic cleavage itself, resulting in activation. When

administered in therapeutic doses, streptokinase is an effective thrombolytic agent. The streptokinase–plasmin(ogen) complex can bind to fibrin through the “kringle” domains of plasmin and activate clot-bound plasminogen to accelerate clot lysis (Chap. 135), but can also act on plasminogen in the blood to produce plasmin, giving rise to systemic proteolysis termed the *lytic state*. This results in consumption of plasminogen and α_2 -antiplasmin, degradation of fibrinogen, factor V, and factor VIII, proteolysis of platelet membrane proteins by plasmin, and platelet activation. Streptokinase has a rapid plasma clearance with a half-life of approximately 20 minutes, but the duration of the proteolytic effect is more prolonged.¹⁰⁴

Streptokinase can be used to treat either venous or arterial thrombosis. Higher doses given over a shorter time are typically used for arterial disease. For either venous or arterial thrombosis, a sufficient dose must be administered to overcome circulating neutralizing antibodies, which are common because of the frequency of streptococcal infections in the population. Occasionally, individuals have a high titer of antibodies that neutralize this amount of streptokinase, resulting in resistance. Streptokinase is antigenic, and high-titer antibodies develop 1 to 2 weeks after use, precluding retreatment until the titer declines. High titers can also cause febrile or hypotensive reactions. The first large study to demonstrate the utility of coronary reperfusion employed streptokinase.¹⁰⁵ Although not widely used in North America, streptokinase is still extensively used given its low cost, widespread availability, and familiarity.

TISSUE-TYPE PLASMINOGEN ACTIVATOR AND RECOMBINANT TISSUE PLASMINOGEN ACTIVATOR (ALTEPLASE)

Tissue-type plasminogen activator (t-PA) is a naturally occurring plasminogen activator that is structurally and immunologically distinct from urokinase. t-PA is synthesized by endothelial cells as a single-chain polypeptide and was originally produced from cell culture for pharmacologic use, but is now synthesized by recombinant techniques (alteplase). t-PA directly converts plasminogen to plasmin in a reaction that is accelerated several-hundred-fold in the presence of fibrin. In the absence of fibrin, t-PA has much less activity, and this property accounts for the relative “fibrin specificity” of t-PA observed physiologically. However, when administered pharmacologically in a high dose, significant proteolysis of plasma fibrinogen often occurs, but this is typically less prominent than observed with treatment using either streptokinase or urokinase. The half-life of t-PA following intravenous administration is approximately 5 minutes, which requires a constant infusion to maintain therapeutic plasma levels. t-PA is not antigenic because it is a physiologic enzyme.¹⁰⁴

t-PA has been evaluated in treatment of VTE, myocardial infarction, stroke, catheter thrombosis, and peripheral arterial occlusion. In patients with PE, a regimen of 100 mg intravenously over 2 hours results in a high rate of clot lysis and hemodynamic improvement. t-PA has been evaluated in many large studies for acute myocardial infarction and administration results in improved mortality and morbidity. t-PA has also been evaluated in treatment of stroke and results in significant benefit in highly selected patients who are treated within hours of symptom onset (Chap. 135). In the CaVenT study,¹⁰⁶ use of alteplase in catheter-directed thrombolysis of iliofemoral DVT resulted in an 18 percent reduction in postthrombotic syndrome.

RETEPLASE

Recombinant technology has been used to engineer many t-PA mutants in an attempt to improve pharmacologic properties. The structural

modifications in reteplase include removal of the finger, kringle 1, and EGF (epidermal growth factor) receptor domains. These changes result in enhanced fibrin specificity and a significantly longer half-life of 15 minutes compared to 4 minutes with t-PA, so it can be administered as an intravenous bolus rather than a continuous infusion. Its mode of administration (two 10-U IV boluses given over 2 minutes, 30 minutes apart) make it particularly useful for prehospital administration in remote areas, or areas with limited access to primary percutaneous coronary interventions.¹²⁹

TENECTEPLASE

Tenecteplase (TNK) is another bioengineered variant of t-PA with a longer half-life, increased resistance to inactivation by plasminogen activator inhibitor-1, and improved fibrin specificity. Advantages include a longer half-life, greater fibrin specificity, ease and rapidity of administration, and similar clinical efficacy as t-PA for treatment of acute myocardial infarction. It has a half-life of more than 30 minutes and can be administered as a single IV bolus. Large studies in patients with ST elevation myocardial infarction have shown it to be equivalently effective as other t-PA derivatives.¹⁰⁴ The PEITHO study examined the use of heparin with TNK or placebo in hemodynamically stable patients with large pulmonary emboli associated with right ventricular dysfunction. Thrombolysis resulted in a reduction in the primary end point of death or hemodynamic decompensation at 7 days following randomization (6 percent vs. 3 percent). The administration of thrombolytic agents was associated with increased bleeding complications, which was more prominent in elderly patients.

● ANTIPLATELET DRUGS

Platelets play an important role in hemostasis and thrombosis and inhibitors of platelet function are important therapeutic agents (Chap. 134). Platelets adhere to exposed subendothelium, become activated, release contents of their dense and α granules, and form aggregates. Additional platelets from the circulating blood are then recruited by adenosine diphosphate (ADP), which is released from dense granules, and also by thromboxane A_2 synthesized by activated platelets in the aggregate. Simultaneous with the initial platelet adhesion and aggregation, thrombin generation is initiated. The activated platelet phospholipid membrane is an effective surface for binding of coagulation factors to enhance the rate of thrombin generation. As thrombin is formed it activates additional platelets and also cleaves fibrinopeptides from fibrinogen to form fibrin in and around the platelet plug, consolidating it. The role of platelets in initiating thrombosis is greater in the arterial circulation than in the venous circulation because higher shear forces present in arteries activate platelets. Consequently, antiplatelet drugs are more effective in arterial than in venous thrombosis. Table 25–6 summarizes the types of drug, their use in clinical settings, their mechanism of action, and their dosages.

CYCLOOXYGENASE-1 INHIBITORS

Cyclooxygenase (COX)-1 is an enzyme that is present in most cells. It converts arachidonic acid released from membrane phospholipids by phospholipase A_2 or phospholipase C and diacylglycerol to prostaglandin (PG) G_2 (Chap. 112). A peroxidase converts PGG_2 to PGH_2 , which is then converted by thromboxane synthase in platelets to thromboxane A_2 . Thromboxane A_2 is a potent activator of platelets. In endothelial cells, PGH_2 is converted to prostacyclin, a potent inhibitor of platelet function, through an increase in intraplatelet cyclic adenosine monophosphate (cAMP).

TABLE 25–6. Antiplatelet Agents by Mechanism of Action and Clinical Use

Agent and Indications		Dosages
Cyclooxygenase inhibitors		
Aspirin	Coronary and cerebrovascular disease	75–650 mg daily
	VTE secondary prevention	
Agents that increase cAMP		
Dipyridamole	Coronary, cerebrovascular, peripheral arterial disease	75–100 mg QID
Pentoxifylline	Peripheral arterial disease	400 mg BID
Cilostazol	Peripheral arterial disease	100 mg BID
ADP receptor blockers		
Ticlopidine	Cerebrovascular disease	250 mg BID
Clopidogrel	Coronary, cerebrovascular disease, PCI	75 mg daily, loading dose 300 mg
Prasugrel	ACS, PCI	10 mg daily, 60-mg loading dose
Ticagrelor	ACS	90 mg BID, 180-mg loading dose
ADP mimetic		
Cangrelor	Not approved in United States at time of this writing	
$\alpha_{IIb}\beta_3$ inhibitors		
Abciximab	ACS, PCI	0.25 mg/kg, then 10 mcg/kg/min
Eptifibatide	ACS, PCI	ACS 180 mcg/kg, then 2 mcg/kg/min PCI 180 mcg/kg, then 2 mcg/kg/min with 180 mcg/kg at 10 min
Tirofiban	ACS, PCI	0.4 mcg/kg/min \times 30 min, then 0.1 mcg/kg/min
Thrombin receptor blocker		
Vorapaxar	Coronary disease, peripheral arterial disease	2.08 mg daily

ACS, acute coronary syndrome; ADP, adenosine diphosphate; cAMP, cyclic adenosine monophosphate; PCI, percutaneous coronary intervention; VTE, venous thromboembolism.

Aspirin (acetylsalicylic acid) was recognized as an inhibitor of platelet function in the 1960s, although the mechanism of its action was unknown at that time. It prolonged the bleeding time in normal subjects slightly, although usually not out of the normal range, and its effect

lasted for several days. It was demonstrated that acetylation of COX is important in platelet inhibition by aspirin. Because platelets cannot synthesize new COX, irreversible enzyme inhibition by aspirin means that inhibition persists for the life span of the platelet. Most cells have two forms of COX, known as COX-1 and COX-2. COX-1 is synthesized constitutively, whereas COX-2 is only synthesized under stress conditions. Both COX-1 and COX-2 are inhibited by aspirin and most nonsteroidal antiinflammatory drugs (NSAIDs), with aspirin acetylating both forms. The nonaspirin COX inhibitors are reversible inhibitors, so they are active only while in the circulation. It was thought initially that only COX-1 is found in platelets, but COX-2 has been detected in platelets and its effect is particularly apparent when there was a rapid platelet turnover. Because COX-1 is the major COX in platelets, COX-2-specific inhibitors have minimal effect on platelet function.

Aspirin and several of the commonly used NSAIDs (e.g., indomethacin, ibuprofen, and naproxen) have similar *in vitro* effects on platelet function. Platelet aggregometry demonstrates that the second wave of aggregation induced by ADP or epinephrine in citrated platelet-rich plasma (PRP) is abolished after aspirin ingestion and that aggregation induced by low concentrations of collagen is markedly decreased. Arachidonic acid–induced aggregation is abolished after aspirin ingestion. Additionally, secretion of dense granule components (ADP, ATP, and serotonin) and of α -granule proteins by ADP, epinephrine, collagen, and arachidonic acid is inhibited in PRP after aspirin ingestion or with addition of indomethacin to PRP. Because of these *in vitro* effects of aspirin, the drug has been used extensively as an inhibitor of platelet function *in vivo*, with beneficial effects in primary and secondary prevention and in treatment of myocardial infarction (Chap. 135). Aspirin is also beneficial in stroke prevention with carotid artery disease and embolic stroke, although anticoagulation with warfarin or its analogues is generally more effective than aspirin in embolic stroke in most patients with a cardiac embolic source.¹⁰⁷ Aspirin is less often used to prevent venous thrombosis, although two recent large randomized studies showed significant benefit for secondary prevention of recurrent VTE compared to placebo.^{108,109} Other drugs that inhibit COX-1 are not used to prevent either arterial or venous thrombosis.

A daily dose of 81 to 325 mg is recommended for most indications, as lower-dose aspirin appears as effective and may be associated with a lower risk of gastrointestinal bleeding than higher doses.^{110,111} Broadly, aspirin is currently recommended for primary and secondary prevention of a wide variety of atherosclerotic outcomes including stroke, myocardial infarction, and peripheral vascular disease.

DRUGS THAT MODULATE CYCLIC ADENOSINE MONOPHOSPHATE LEVELS

cAMP in platelets is formed from ATP by the action of adenylate cyclase and degraded by cAMP phosphodiesterase, and basal levels of cAMP in platelets are low. Elevated levels of intraplatelet cAMP are induced by inhibition of cAMP phosphodiesterase, or by stimulation of adenylate cyclase activity, resulting in inhibition of platelet activation through several pathways: (1) modulation of phosphorylation of specific proteins; (2) inhibition of several steps in metabolism of phosphoinositol phosphates; and (3) lowering of intracellular Ca^{2+} , and accumulation of Ca^{2+} by platelet microsomes. Agents that inhibit the cAMP phosphodiesterase include theophylline, papaverine, and dipyridamole, as well as pentoxifylline and cilostazol. Several prostaglandins stimulate adenylate cyclase, including PGE_1 , PGD_2 , and PGI_2 (prostacyclin). Drugs that elevate cAMP levels are dipyridamole, pentoxifylline, and cilostazol. Dipyridamole can be used alone or in combination with aspirin. A very large study of dipyridamole in combination with low-dose aspirin (25 mg) found the combination equivalently effective to clopidogrel for

the secondary prevention of noncardioembolic stroke.¹¹² Recent systematic reviews have also suggested that the combination of dipyridamole and aspirin is superior to aspirin alone for the prevention of cerebrovascular events.¹¹³

The other two phosphodiesterase inhibitors (pentoxifylline and cilostazol) are used primarily in patients with peripheral vascular disease. In addition to their inhibitory effect on platelets they may exert a beneficial effect on blood rheology and the microcirculation by increasing red cell deformability, thereby reducing blood viscosity. Cilostazol increases vascular endothelial growth factor levels, which may lead to an increase in collateral circulation. It has been shown to reduce risk of stroke in Asian populations,^{114,115} and increases walking distance in patients with peripheral vascular disease.¹¹⁶ Pentoxifylline inhibits vascular smooth-muscle cell proliferation and collagen synthesis, which may enhance vasodilation. Pentoxifylline probably is an effective treatment for ulcers associated with peripheral vascular disease; however, it is only modestly effective for treatment of peripheral vascular disease.¹¹⁷

ADENOSINE DIPHOSPHATE RECEPTOR BLOCKERS

The third class of platelet inhibitors is the ADP receptor blockers, which include thienopyridines (ticlopidine, clopidogrel, and prasugrel) and nonthienopyridines (ticagrelor and cangrelor). There are three ADP receptors on platelet membranes (Chap. 112), with the thienopyridines inhibiting one of them, the P2Y₁₂ receptor. The inhibition of binding of ADP to the P2Y₁₂ receptor results in inhibition of adenylate cyclase.

Ticlopidine was available for clinical use before clopidogrel. The Canadian American Ticlopidine Study was a randomized, placebo-controlled, double-blind study showing a 30 percent risk reduction for recurrent cardiovascular events with ticlopidine.¹¹⁸ A review of four trials of ticlopidine plus aspirin versus oral anticoagulants for coronary stenting showed benefit to the combination in terms of reduced risk of nonfatal myocardial infarction and revascularization at 30 days, combined negative events (mortality, myocardial infarction, revascularization at 30 days), and major bleeding, but increased the risk of thrombocytopenia and neutropenia.¹¹⁹

In clinical practice fear of toxicity has largely led ticlopidine to be abandoned in favor of clopidogrel. In a direct comparison of ticlopidine and clopidogrel in patients undergoing coronary stenting (CLASSICS trial), clopidogrel was associated with a significantly lower rate of major adverse events (4.6 percent vs. 9.1 percent).¹²⁰ The first clinical trial of clopidogrel was the Clopidogrel Versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial, a large randomized, blinded trial of clopidogrel versus aspirin in 19,000 patients at risk of ischemic events.¹²¹ Patients were enrolled after recent myocardial infarction (MI) or stroke, or if they had symptomatic peripheral arterial disease. The primary outcome was the occurrence of ischemic stroke, MI, or vascular death. With a mean followup of 1.91 years, there was a relative risk reduction of 8.7 percent in the clopidogrel group ($p = 0.043$). No major differences were noted in terms of safety. Clopidogrel is also used in acute coronary syndromes, based on studies like the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) study, which showed a significant reduction in the combined end point of cardiovascular death, nonfatal MI, or stroke with clopidogrel and aspirin versus aspirin alone.¹²² Several studies have demonstrated the effectiveness of clopidogrel in patients undergoing percutaneous coronary intervention, and a recent meta-analysis of several large studies showed that clopidogrel treatment prior to intervention is associated with decreased incidence of major cardiac events (MI, stroke, urgent revascularization) compared to treatment after intervention.¹²³ The degree of platelet inhibition after clopidogrel therapy varies. Larger loading doses of clopidogrel appear to

reduce variability in response; the safety and efficacy of such doses are being compared in ongoing studies.¹²⁴

Prasugrel is a “third-generation” P2Y₁₂ blocking agent. Unlike clopidogrel it can be converted to its active metabolite via esterases present in either the liver or the gut. Like clopidogrel it irreversibly blocks the P2Y₁₂ receptor.¹⁴⁴ Evidence for the use of prasugrel comes predominantly from one large study of prasugrel compared with clopidogrel. This study randomized 13,608 patients with moderate-to-high-risk acute coronary syndromes and who were scheduled to undergo percutaneous coronary intervention to receive prasugrel (a 60-mg loading dose and a 10-mg daily maintenance dose) or clopidogrel (a 300-mg loading dose and a 75-mg daily maintenance dose) for up to 15 months.¹²⁵ Although prasugrel significantly reduced death from cardiovascular causes, nonfatal MI, and nonfatal stroke, it significantly increased all forms of bleeding, including major and fatal hemorrhage.

Ticagrelor is a member of the cyclopentyltriazolopyrimidines chemical class, a group of agents that reversibly inhibit the P2Y₁₂ platelet receptor. Ticagrelor does not require hepatic activation and has a more rapid onset of action than clopidogrel. The PLATO trial was a large phase III randomized study comparing ticagrelor and aspirin (180 mg loading dose followed by 90 mg twice daily) to clopidogrel (300 to 600 mg dose followed by 75 mg daily) and aspirin for treatment of acute coronary syndrome.¹²⁶ Patients receiving ticagrelor experienced the composite primary end point (death from vascular causes, MI, or stroke) less often than patients receiving clopidogrel (9.8 percent vs. 11.7 percent, hazard ratio [HR] 0.84) without a significant difference in the rates of major bleeding (11.6 percent vs. 11.2 percent).

Cangrelor, the first parenteral ADP receptor blocker, is not currently available for clinical use, but has been tested in three large randomized clinical trials of patients undergoing intracoronary stent implantation procedures. Advantages of this agent include parenteral administration, very rapid onset, and short half-life. The CHAMPION studies (PLATFORM,¹²⁷ PCI,¹²⁸ and PHOENIX¹²⁹) compared cangrelor to clopidogrel or placebo in patients undergoing coronary interventions. Although only the PHOENIX trial showed a significant reduction (4.7 percent vs. 5.9 percent) in the 48-hour composite end point (death, MI, ischemia-driven revascularization, or stent thrombosis), in a pooled analysis of patient level data from the three CHAMPION trials cangrelor use was associated with a significant reduction in the primary efficacy end point compared to control (3.8 percent vs. 4.7 percent, OR 0.81).¹³⁰

$\alpha_{IIb}\beta_3$ BLOCKERS

Fibrinogen binds specifically and saturably to the surface of activated platelets, and the $\alpha_{IIb}\beta_3$ complex is the fibrinogen receptor. This complex mediates platelet aggregation induced by all physiologic agonists. Fibrinogen binds only to the activated conformation of the receptor $\alpha_{IIb}\beta_3$. Monoclonal antibodies have been developed against $\alpha_{IIb}\beta_3$ complex on resting or activated platelets, which prevent aggregation by blocking ligand binding. *Abciximab*, is the Fab’₂ fragment of a chimeric mouse–human antibody. Initial human pharmacodynamic studies were performed in patients with unstable angina and in patients undergoing high-risk coronary angioplasty, and dose-related inhibition of platelet function was found. No spontaneous bleeding was observed, despite prolongation of the template bleeding time. Because of the mouse component of abciximab, it may induce antimouse antibodies, preventing repeated use in patients.

The first large clinical trial of abciximab was the Evaluation of c7E3 for the Prevention of Ischemic Complications (EPIC) trial,¹³¹ published in 1994, in which the drug was used in patients with high-risk coronary angioplasty. Abciximab reduced ischemic events after angioplasty when given together with heparin and aspirin, but it also increased the

risk of bleeding. Subsequent studies of patients undergoing percutaneous coronary intervention, the Evaluation in PTCA to Improve Long-term Outcome with Abciximab GP IIb/IIIa ($\alpha_{IIb}\beta_3$) Blockade (EPILOG) study¹³² and EPISTENT trial,¹³³ demonstrated efficacy in both low-risk and high-risk patients without any increase in major bleeding. Abciximab has also been tested in patients with acute ischemic stroke, but resulted in significant increase intracranial hemorrhage without any clinical efficacy so it has not been further pursued for this clinical indication.¹³⁴

Other types of inhibitors of fibrinogen binding to platelets have also been developed. Those in clinical use are eptifibatide, a cyclic heptapeptide based on a rattlesnake venom peptide, and tirofiban, a nonpeptide derivative of tyrosine. Pharmacokinetic and pharmacodynamic studies in animals and humans showed a rapid onset of action, short plasma half-life, and rapid reversibility of action. The pharmacodynamics of eptifibatide are substantially altered by anticoagulants that chelate calcium, and pharmacokinetic modeling suggests that optimal dosing is obtained by giving a second bolus 10 minutes after the first bolus. Eptifibatide is not immunogenic.

The first major clinical trial of eptifibatide was the Integrilin to Minimize Platelet Aggregation and Coronary Thrombosis (IMPACT) II trial in patients undergoing any kind of coronary intervention.¹³⁵ There was a highly significant reduction in the composite end point of death, MI, coronary artery bypass grafting, repeat urgent or emergent coronary intervention, or stent placement for abrupt closure at 24 hours with both eptifibatide dosing arms. There was no increase in major bleeding. The effect was no longer significant at 30 days on intention-to-treat analysis.

Animal studies with tirofiban were performed in dogs. Dose-dependent inhibition of *ex vivo* platelet aggregation was achieved, with rapid reversibility at the end of the infusion. Electrically induced coronary artery thrombosis was markedly reduced by tirofiban infusion, without significant extension of the bleeding time. Pharmacokinetic and pharmacodynamic studies in humans showed that tirofiban provided a well-tolerated reversible means of inhibiting platelet function. Bleeding time was prolonged, and ADP-induced aggregation was blocked by at least 80 percent in normal volunteers. The plasma half-life was 1.6 hours. ADP- and collagen-induced platelet aggregation in normal volunteers returned to 55 percent and 89 percent of baseline, respectively, by 3 hours after the end of infusion. Similar results were found in a dose-ranging study in patients undergoing coronary angioplasty. Based on these results tirofiban has been extensively studied as an adjunct to therapies for patients with, or at risk of, acute coronary syndromes. Clinical results for patients treated with tirofiban have been reviewed.¹³⁶

THROMBIN RECEPTOR BLOCKERS

Platelet activation occurs through a variety of cell surface receptors including the thrombin receptor, a potent platelet activator mediated by its binding to and cleaving the protease-activated receptor (PAR)-1. Vorapaxar is an irreversible PAR-1 thrombin receptor antagonist, which has been studied in two large phase III randomized studies. In the TRACER study 12,944 patients with non-ST elevation acute coronary syndromes were randomized to vorapaxar or placebo plus standard care.¹³⁷ Vorapaxar use was associated with a significant reduction in death from cardiovascular causes (14.7 percent vs. 16.4 percent), but was also associated with a significant increase in major bleeding events, including intracranial hemorrhage (1.1 percent vs. 0.2 percent). The TRA 2P-TIMI 50 study randomized 26,449 patients with prior MI, stroke, or peripheral artery disease to vorapaxar versus placebo.¹³⁸ This phase III study also demonstrated clinical efficacy with a reduction in death from cardiovascular cause (11.2 percent vs. 12.4 percent), but it was at the expense of increased major bleeding complications. Efforts are underway to identify subgroups that may have the greatest net

benefit from vorapaxar. Atopaxar is a low-molecular-weight inhibitor of PAR-1, which has been studied in phase II trials of patients with acute coronary syndrome or high-risk coronary artery disease.¹³⁹ These studies showed an increase in minimal bleeding events (16.4 percent vs. 4.5 percent) but no difference in clinically significant bleeding.

CHAPTER 26

IMMUNE CELL THERAPY

Carolina Berger and Stanley R. Riddell

SUMMARY

T cells represent an important component of the host response to pathogens and tumors. Adoptive T-cell therapy, in which T cells are isolated or engineered to be specific for molecules expressed on diseased cells and administered to patients, has shown efficacy in infections and malignancy. Clinical applications of T-cell therapy have been facilitated by identification of target antigens expressed by viruses and tumors, improvement in strategies for the isolation and genetic engineering of antigen-specific T cells with intrinsic qualities that enable their persistence *in vivo*, and recognition that transferring T cells into a lymphopenic environment improves the efficiency of cell transfer and treatment efficacy. Insights into the obstacles to routinely achieving an effective antitumor response either by T-cell therapy or vaccination have been derived from careful analysis of clinical trials, and further development of immune cell therapy combined with interventions that target specific regulatory or inhibitory pathways that are present in tumor microenvironments and impede effective immunity represent promising areas for future applications.

Acronyms and Abbreviations: ALL, acute lymphatic leukemia; BCMA, B-cell maturation antigen; CAR, chimeric antigen receptor; cDNA, complementary DNA; CDR3, complementarity determining region 3; CEA, carcinoembryonic antigen; CLL, chronic lymphatic leukemia; CMV, cytomegalovirus; CRS, cytokine release syndrome; CTL, cytotoxic T lymphocyte; DLI, donor lymphocyte infusion; E, early viral protein; EBV, Epstein-Barr virus; EGFR, epidermal growth factor receptor; ERBB2IP, erbb2 interacting protein; GD2, disialoganglioside; GVHD, graft-versus-host disease; GVL, graft-versus-leukemia; HHV-6, human herpes virus-6; HLA, human leukocyte antigen; HSCT, hematopoietic stem cell transplantation; HSV, herpes simplex virus; HSV-TK, herpes simplex virus thymidine kinase; iCasp9, inducible caspase-9; IE, immediate early viral protein; IFN- γ , interferon- γ ; IL, interleukin; L1CAM, L1-cell adhesion molecule; LCL, lymphoblastoid cell line; LPD, lymphoproliferative disease; mAbs, monoclonal antibodies; mHAGs, minor histocompatibility antigens; MHC, major histocompatibility complex; PBMC, peripheral blood mononuclear cell; PD-1 receptor, programmed death-1 receptor; PML-RAR α , promyelocytic leukemia-retinoic acid receptor α protein; scFv, single-chain variable fragment; SNP, single nucleotide polymorphism; T_{CM}, central memory T cell; TCR, T-cell receptor; T_E, effector T cell; T_{EM}, effector memory T cell; Th, T helper; TIL, tumor-infiltrating lymphocyte; T_{REG}, regulatory T cell; T_{SCM}, T memory stem cell; WT-1, Wilms tumor antigen-1.

ADOPTIVE CELLULAR THERAPY OF VIRAL DISEASES

Two broad subsets of antigen-specific T cells cooperate to terminate acute viral infections and control reactivation of latent viruses. CD8+ cytotoxic T lymphocytes (CTLs) recognize viral peptides presented by major histocompatibility complex (MHC) class I molecules and lyse infected cells, and produce inflammatory cytokines. CD4+ T-helper (Th) cells recognize viral peptides presented by class II MHC molecules and produce cytokines that amplify T-cell responses and promote B-cell proliferation and antibody production. A deficiency of CD8+ and CD4+ Th cells occurs after allogeneic hematopoietic stem cell transplantation (HSCT) as a consequence of the administration of intensive chemoradiotherapy, anti-T-cell monoclonal antibodies (mAbs), and/or immunosuppressive drugs, and these patients are at risk for life-threatening viral infections.¹⁻⁵ Clinical trials have shown that adoptive T-cell therapy has antiviral activity against cytomegalovirus (CMV), Epstein-Barr virus (EBV), and adenovirus infection in immunocompromised allogeneic HSCT recipients.^{6,7}

T-CELL THERAPY OF CYTOMEGALOVIRUS INFECTION

The first application of adoptive T-cell therapy with antigen-specific T cells in humans was to treat CMV infection after allogeneic HSCT. CMV is a DNA virus that infects hematopoietic progenitors, monocytes, and endothelial cells.⁸ To evade complete elimination by host immunity, CMV encodes proteins that interfere with antigen presentation in cells that contain replicating virus, and establishes latency.⁹ Normal CMV+ individuals maintain high levels of CD8+ and CD4+ T cells that are specific for CMV antigens, and these responses are essential to control infection.¹⁰⁻¹² CMV frequently reactivates in individuals with a T-cell immunodeficiency, such as after allogeneic HSCT and solid-organ transplantation, and contributes to morbidity and mortality. Lymphocytopenia and a deficiency of functional CMV-specific T cells persist for several months in many HSCT recipients, including cord blood transplant recipients, and CMV reactivation is frequent.¹³⁻¹⁵ Antiviral drugs are used to suppress CMV,¹⁶⁻¹⁸ but often provide only temporary control of reactivation, and restoration of immune function is essential to contain CMV infection.^{13,19-21}

Target Antigens for Cytomegalovirus-Specific T Cells

Studies of the specificity of CMV-specific T cells isolated from immunocompetent CMV seropositive individuals identified antigens to target in T-cell therapy.^{15,21} A majority of CD8+ CTLs elicited by *in vitro* stimulation with autologous CMV-infected cells recognize virion proteins, including the pp65 and pp150 matrix proteins that are introduced into the cytoplasm of cells immediately following viral entry and processed and presented for T-cell recognition. Although virion proteins are important targets for CD8+ T cells, stimulation of peripheral blood mononuclear cells (PBMCs) from normal CMV+ donors with panels of CMV peptides, or with cells infected with a CMV strain in which the immune evasion genes had been deleted, identified significant CD8+ T-cell responses to intermediate-early (IE) or early (E) viral proteins.^{10,11} IE and E are not efficiently presented to T cells *in vitro* by cells replicating wild-type CMV, but evidence from animal models suggests that IE-specific T cells recognize cells that are reactivating CMV from latency.²² Thus, reconstitution of responses both to virion and IE or E antigens may be necessary to restore control of both the latent and replicating pools of virus in immune-deficient hosts.²³

CD4+ Th cells are required for optimal CD8+ CTL responses and may eliminate CMV-infected cells that express class II MHC *in vivo*. Studies using recombinant CMV proteins or peptide panels have identified CD4+ T-cell responses to pp65, IE-1, glycoprotein B, and the major capsid protein (UL86) in normal CMV+ individuals.^{10,24,25}

Techniques for Adoptive Transfer and Tracking of Cytomegalovirus-Specific T Cells

The application of T-cell therapy for CMV in allogeneic HSCT recipients required the development of approaches to reliably isolate CMV-specific T cells from the stem cell donor, and to remove potentially alloreactive T cells that could cause graft-versus-host disease (GVHD). The first clinical trial of T-cell therapy employed CD8+ CMV-specific T-cell clones that were isolated and expanded by *in vitro* culture of donor lymphocytes with autologous CMV-infected fibroblasts.²⁶ The donor-derived T-cell clones were screened to exclude alloreactivity with noninfected recipient cells prior to adoptive transfer, to minimize the risk of causing serious GVHD. In a phase I study, 14 allogeneic HSCT recipients received four escalating weekly intravenous doses (3.3×10^7 to 1×10^9 /m²) of CD8+ CMV-specific CTL clones as prophylaxis for CMV disease. The treatment did not cause toxicity or exacerbate GVHD, CMV-specific cytolytic activity was increased after therapy to levels equivalent to those in the donor, and transferred CTLs persisted for more than 12 weeks.²⁷ None of the 14 patients developed CMV viremia or disease, which in the absence of antiviral drug therapy was expected to occur in approximately 50 percent or 40 percent of these patients, respectively.²⁷

The results of the initial trials with CMV-specific T-cell clones suggested this approach can provide an alternative to antiviral drugs

for controlling CMV infection after HSCT. However, the isolation and propagation of antigen-specific T-cell clones requires specific expertise and is time-consuming. Culture methods for enrichment of polyclonal CMV-specific T cells circumvent prolonged *ex vivo* manipulation and T-cell expansion and enabled broader application of this approach (Fig. 26-1).^{28,29} Clinical trials with polyclonal CD4+ and/or CD8+ T-cell lines generated by short-term culture confirmed the efficacy of adoptive therapy for CMV and suggested that low cell doses (as low as 10^5 /kg) of polyclonal T cells can be therapeutically effective.^{28,30-32}

A key requirement for T-cell therapy for rapidly progressing and/or life-threatening CMV infections is to further reduce the time needed to generate the CMV-specific T cells for adoptive transfer and to improve the feasibility of this approach (see Fig. 26-1). Techniques have been developed for rapidly isolating antigen-specific T cells directly from the blood using conventional human leukocyte antigen (HLA) multimers or reversible streptamers that are comprised of soluble HLA molecules folded with the viral cognate peptide and bind T cells based on T-cell receptor (TCR) specificity.³³⁻³⁶ Alternatively, mAbs and immunomagnetic bead-selection strategies have been developed to capture T cells that produce interferon (IFN)- γ or have upregulated activation markers in response to antigen stimulation.³⁷⁻³⁹ A pilot study in 18 patients showed that CMV-specific T cells (mean cell dose 2.1×10^4 /kg) isolated by IFN- γ capture techniques and transferred after brief *ex vivo* culture had a clinical effect.⁴⁰ CMV-specific T cells were also purified from the blood of HSCT donors using HLA-peptide tetramers or reversible streptamers, transferred directly to the patients at low cell doses, and mediated antiviral activity.^{35,36}

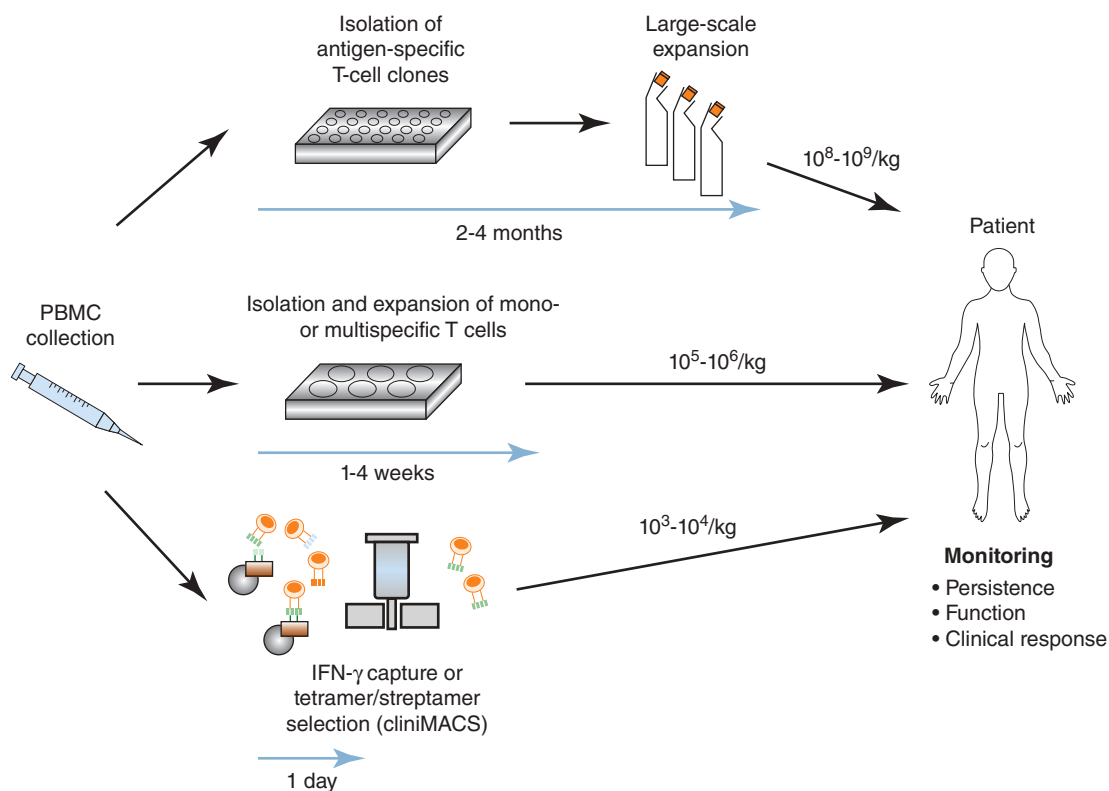

Figure 26-1. Scheme for adoptive T-cell therapy with antigen-specific T cells. Antigen-specific T cells can be isolated by *in vitro* culture, expanded in long- or short-term culture, and then transferred in large numbers to patients. Alternatively, antigen-specific T cells can be isolated using direct methods and transferred immediately to the patient at low numbers. Patients are monitored after each cell infusion for toxicity, T-cell persistence, and efficacy.

Transferred T cells must persist as functional memory T cells and migrate to sites of virus replication to be effective. Therefore, it was essential to verify the presence of the transferred T cells in the blood based on functional or structural properties. In the initial studies of adoptive therapy with CD8+ CMV-specific T-cell clones, assays of cytolytic activity provided an indirect semiquantitative functional measure for the presence of the transferred immune effectors.²⁷ New approaches that use flow cytometric analysis of blood samples have been developed, such as staining with HLA multimers or intracellular staining, to detect cytokines produced after antigen stimulation. These techniques are being employed to enumerate and analyze the function of cells on a single-cell level.^{11,34} The unique DNA sequences of the rearranged TCR V α or V β genes have also been used to evaluate survival of transferred T cells in the first trial of CMV-specific T-cell therapy.²⁷ Quantitative real-time polymerase chain reaction with TCR-specific primers that flank the unique complementarity determining region 3 (CDR3) sequence can provide precise quantitation of transferred T cells in blood samples. Advances in high-throughput sequencing and computational analysis of the TCR sequences have now enabled much more sensitive analysis and sequencing of the CDR3 and detection of unique sequences in transferred T cells.^{36,41,42}

Selection of Defined Subsets of Cytomegalovirus-Specific T cells for Adoptive Therapy

The pool of memory T cells contains both CD45RO+CD62L+ central memory (T_{CM}), and CD62L- effector memory (T_{EM}) subsets that differ in phenotype, function, and migration.⁴³⁻⁴⁵ Studies in animal models have revealed profound differences in the ability of adoptively transferred T cells from distinct subsets to persist *in vivo* and revert to the memory pool. The transfer of effector cells derived from CD8+CD62L+ T_{CM} or a rare subset of CD62L+ cells termed *memory stem cells* (T_{SCM}) that share cell-surface markers of both naïve T cell (T_N) and T_{CM} cells, displayed superior survival *in vivo*, and/or mediated superior antitumor activity compared with more differentiated T_{EM}.⁴⁶⁻⁴⁹ Studies in mice provide increasing evidence for a progressive differentiation model of T-cell subsets. Fate mapping studies and single-cell transfer experiments show that naïve T cells differentiate into memory and effector subsets (Fig. 26-2), and demonstrated that the stem cell-like properties of self-renewal and differentiation are present in CD62L+ T_{CM} cells.⁵⁰⁻⁵² It is uncertain whether the intermediate phenotype T_{SCM} has self-renewal capability or represents a cell that is of sufficient frequency to be reliably isolated for immunotherapy. Nevertheless, these findings suggest that selecting less differentiated memory subsets as a starting population for clinical adoptive T-cell therapy can allow very low numbers of T cells to be effective, and this concept has been validated in animal models and patients with CMV infection.⁵³ Given the considerable potential of this approach, methods are now being developed for clinically applicable serial selection strategies for human T_{CM} subsets.⁵⁴

Figure 26-2. Linear differentiation of T-cell subsets. The phenotype of naïve, memory, and effector subsets is shown and the linear pathway of differentiation from a naïve T cell is based on recent data from fate mapping studies in murine models.^{50,51}

T-CELL THERAPY OF EPSTEIN-BARR VIRUS INFECTION

EBV is a ubiquitous γ -herpesvirus (Chap. 82) that persists in immunocompetent hosts lifelong without causing disease. Some latently infected B cells express only the EBNA-1 protein, which has glycine-alanine repeats that inhibit its translation and processing for presentation to CD8+ T cells.⁵⁵ Infected B cells may activate the latency III program of viral genes that includes EBNA-1, EBNA-2, EBNA-3A, EBNA-3B, EBNA-3C, LMP-1, LMP-2A, and LMP-2B, and induces cell proliferation.⁵⁶ In normal hosts, both the CD8+ CTL and CD4+ Th cell response to EBV infection is mainly directed against lytic viral proteins and the EBNA-3A, -3B, and -3C latency proteins.^{57,58} The CD4+ Th cell response may also contribute to eliminating class II MHC+ EBV-infected cells *in vivo*⁵⁸ and EBV-specific CD8+ and CD4+ T cells cooperate to prevent the outgrowth of EBV+ B cells in immunocompetent hosts.^{59,60} Thus, tumors comprised of proliferating EBV+ B cells can arise in individuals with a T-cell deficiency, such as solid-organ or HSCT patients receiving intense immunosuppression, especially if T-cell depletion is used as part of the conditioning regimen.^{61,62} Historically, patients with EBV-induced lymphoproliferative disease (EBV-LPD) had a grave prognosis, responding poorly to antiviral drugs or chemotherapy, although early detection of EBV reactivation and treatment with mAbs specific for CD20 have improved outcomes.⁶³ Ultimately, restoration of EBV-specific T cells is necessary for control of the virus.

Techniques for Isolation and Adoptive Transfer of Epstein-Barr Virus-Specific T Cells

The efficacy of T-cell therapy for EBV-LPD was first demonstrated in a study in which a low dose of unselected donor lymphocytes was administered to five patients with EBV-LPD after T-cell-depleted allogeneic HSCT. Complete resolution of EBV-LPD was achieved in all patients,⁶⁴ but this was complicated by GVHD and two patients developed a fatal respiratory failure, demonstrating the importance of selecting EBV-specific T cells for therapy.⁶⁴ The adoptive transfer of donor EBV-specific T-cell lines derived by *in vitro* culture with EBV-transformed lymphoblastoid cell lines (LCLs) was effective in 2 of 3 HSCT recipients with established EBV-LPD without causing GVHD.⁶⁵ One patient had progressive LPD with a mutation in the EBNA-3B gene that eliminated the region encoding the epitopes targeted by the CTL line.⁶⁶ To diminish the probability of escape variants, subsequent studies administered donor EBV-specific T-cell lines prophylactically to a cohort of patients at risk for EBV-LPD after T-cell-depleted allogeneic HSCT.⁶⁷ No GVHD was observed, and there were no cases of LPD, although this was expected to occur in 14 percent of the patients.⁶⁷ A 9-year followup report summarized the results in a total of 114 HSCT recipients, 101 of which safely received prophylactic infusions of EBV-specific CTLs.⁶⁸ None of the 101 patients progressed to EBV-LPD and 11 of 13 patients with LPD achieved sustained complete remissions.⁶⁸ Thus, transfer of

EBV-specific T cells safely reconstituted immunity, mediated antiviral activity, and protected the majority of patients from EBV-LPD.

MULTISPECIFIC T-CELL THERAPY OF VIRAL INFECTIONS

Severe infections with a broad array of viruses remain a serious problem for immunocompromised patients.^{2-5,7,69} In addition to CMV and EBV, infections with adenovirus, BK virus, human herpes virus-6 (HHV-6), herpes simplex virus (HSV), and/or varicella-zoster virus can pose a serious problem. Antiviral drugs may benefit a subset of patients, but the effects are often limited and accompanied by toxicities.⁷⁰ There is inferential evidence that restoration of T-cell immunity is also critical for protection against these infections, suggesting that multivirus-specific T-cell products would have greater utility.⁷¹ EBV-LCLs that had been transfected with a recombinant adenovirus that encoded CMVpp65 were used to stimulate donor-derived PBMC and simultaneously expand T cells specific for adenovirus, CMV, and EBV.^{31,72,73} The infusion of such multispecific T cells into HSCT recipients augmented T-cell responses to all three viruses and promoted virus clearance. These initial reports of adoptive T-cell therapy with “broad-spectrum” T cells to treat the multiplicity of distinct viral infections that may complicate the clinical outcome of HSCT are encouraging. Studies have further extended this work and demonstrated the feasibility and clinical utility of rapidly generated T-cell lines that recognize 12 immunogenic antigens from five viruses, including CMV, EBV, adenovirus, BK virus, and HHV-6. Adoptive transfer of these T cells to 11 allogeneic transplant recipients produced a greater than 90 percent sustained virologic and clinical response.⁷⁴

ADOPTIVE CELLULAR THERAPY OF MALIGNANCY

There is evidence from murine models that the host immune system has a dynamic relationship with a developing tumor and can recognize, control, and even eliminate cancer.⁷⁵⁻⁷⁷ Immunogenic proteins in human tumors have now been identified by screening of tumor complementary DNA (cDNA) libraries with tumor-specific T cells isolated from the blood or tumor environment,⁷⁸ or by screening of patient sera for antibody responses to tumor-associated proteins.⁷⁹ Distinct categories of tumor antigens have been uncovered, and several are being investigated as targets for T-cell therapy or vaccination (Table 26-1). However, the clinical translation of adoptive T-cell therapy and other immunotherapeutic modalities for human cancers has proven to be more challenging than for opportunistic viral infections. This reflects many issues, including the difficulty isolating highly avid tumor-specific T cells from cancer patients, and evasion mechanisms that tumors employ to avoid immune elimination including the local recruitment of regulatory T cells (T_{REG}) or myeloid-derived suppressor cells, loss of antigen or HLA expression, and expression or secretion of inhibitory molecules or cytokines.⁸⁰⁻⁸³ Additionally, a problem distinct from the results of T-cell therapy for viruses is that transferred tumor-reactive T cells persisted only transiently in most early clinical trials, even if high-dose interleukin (IL)-2 was given to support their survival.⁸⁴⁻⁸⁸

The development of immune cell therapy for malignancy has focused on melanoma because target antigens have been identified and this tumor has responded to nonspecific immune therapy with IL-2,⁸⁹ and on amplifying the graft-versus-leukemia (GVL) effect after allogeneic HSCT because of the evidence that donor T cells mediate tumor eradication in this setting.⁹⁰⁻⁹² The ability to engineer T cells to have tumor specificity by introducing TCR genes that recognize

TABLE 26-1. Categories of Tumor Antigens

A. Classes of antigens for MHC-restricted T cells

- Antigens arising from mutations or gene rearrangements (e.g., CDK-4, BCR/ABL)
- Tissue-specific differentiation antigens (e.g., Tyrosinase, gp100)
- Cancer-testes antigens (e.g., MAGE-1, NY-ESO-1)
- Nonmutated overexpressed self-proteins (e.g., Her2/neu, WT-1)
- Oncofetal antigens (e.g., CEA)
- Viral proteins in virus associated malignancies (e.g., HPV E6 and E7, EBV LMP-1)

B. Classes of tumor cell surface molecules for chimeric antigen receptor-modified T cells

- B-cell differentiation molecules (e.g., CD19, CD20, CD22)
- Myeloid differentiation molecules (e.g., CD123)
- Adhesion molecules (e.g., CD44v6, GD2, L1 CAM, mesothelin)
- Oncofetal antigens (e.g., ROR1)
- Signaling molecules (e.g., Her-2)
- Hypoxia induced (e.g., CAIX)

tumor-associated antigens,⁹³ or chimeric antigen receptor (CAR) genes that encodes a single chain mAb domain linked to the CD3 ζ chain of the TCR, and confers recognition of a tumor-associated, cell-surface molecule, is facilitating the broader application of T-cell therapy for both human hematologic malignancies and common epithelial cancers.⁹⁴⁻⁹⁷

CELLULAR THERAPY OF MELANOMA

Early studies demonstrated that the adoptive transfer of autologous polyclonal tumor-infiltrating lymphocytes (TILs), isolated and expanded from resected melanoma specimens, combined with the administration of high-dose IL-2 resulted in a 31 percent response rate in patients with advanced melanoma.⁹⁸ Most of the responses were transient, but these results validated the potential to eradicate a human solid tumor with immunotherapy. These results also encouraged efforts to define the antigens recognized by TILs in responding patients, and to refine the approaches to augmenting T-cell responses to tumor antigens.

Target Antigens for Melanoma-Specific T Cells

Melanoma has served as a model for the discovery of human tumor antigens because T cells specific for melanoma cells can often be detected in the blood or the tumor microenvironment. A landmark in cancer immunotherapy was the identification by cDNA expression cloning of MAGE-1, which is a member of the cancer-testes antigen class of tumor associated antigens.⁷⁸ Several additional shared tumor/self-melanocyte differentiation antigens recognized by CD8+ and/or CD4+ T cells have been discovered, including differentiation proteins that function in normal melanocyte physiology such as tyrosinase, gp100, and MART-1; and other cancer testis antigens such as NY-ESO-1.^{78,99,100} Melanosome antigens are also expressed in normal tissues (skin, retina), and toxicity because of autoimmunity is a concern. Mutated proteins that arise as a consequence of the genetic instability of tumors are being identified as critical targets of immune recognition, and these offer the greatest promise for selectively targeting tumor cells without recognition of normal cells.¹⁰¹

Techniques for Isolation and Adoptive Transfer of Melanoma-Specific T Cells

The adoptive transfer of tumor-specific T-cell clones or oligoclonal populations of T cells expanded *ex vivo* can, in principle, allow control over the magnitude and function of the tumor-reactive T-cell response in the patient. If the tumor is easily accessible, tumor-reactive T cells can sometimes be isolated directly from the tumor biopsies by culture in high-dose IL-2.¹⁰² Melanoma-reactive T cells can also be isolated using autologous dendritic cells pulsed with synthetic peptide antigen, but this approach can enrich low-avidity T cells that have a limited capacity to persist and function *in vivo*.¹⁰³

Initial clinical trials of T-cell therapy for melanoma employed CD8+ T-cell clones specific for MART-1 or gp100; or clonal or polyclonal melanoma-reactive T cells derived and expanded from TILs.^{84,104,105} The transferred T-cell clones given with low-dose IL-2 mediated transient antitumor activity in some patients with advanced disease, but did not persist for long term.¹⁰⁴ The response rate was higher in patients treated with polyclonal TILs and high-dose IL-2.¹⁰⁵ T-cell persistence was highly variable and only rarely sustained despite the infusion of large T-cell numbers (up to 10¹¹).^{84,104} The inability of T cells to persist *in vivo* could reflect an inadequate antigen-specific CD4+ Th response, terminal differentiation of T cells during expansion, activation-induced T-cell death at the tumor site, or cell death as a consequence of IL-2 withdrawal.^{84,106}

A major advance in the field was the demonstration that the transferred human T-cell persistence and therapeutic efficacy could be improved by pretreatment of the patient with a lymphodepleting regimen containing cyclophosphamide and fludarabine.^{107,108} In these studies, high-dose IL-2 was administered daily after TIL transfer until toxicity required it be discontinued. A subset of the patients achieved prolonged high-level engraftment of one or a few tumor-reactive CD8+ T-cell clonotypes present in the infused polyclonal T-cell product.¹⁰⁷⁻¹¹⁰ In a followup analysis of a large cohort of patients, the overall and complete response rates were approximately 50 percent and 20 percent, respectively.^{108,111} The antitumor activity correlated with the persistence of high levels of transferred tumor-reactive CD8+ T cells. Several mechanisms make the lymphopenic environment favorable for T-cell transfer, including less competition for homeostatic cytokines such as IL-15 and IL-7 that promote lymphocyte survival,^{112,113} and the elimination of CD4+CD25+ T_{REG} cells.¹¹⁴ Studies in murine models have confirmed that severe lymphodepletion can be exploited to improve the antitumor efficacy of the transferred T cells.¹¹⁵ The addition of 2 Gy or 12 Gy of total-body irradiation to the lymphodepleting treatment with cyclophosphamide and fludarabine before TIL transfer increased the response rate to 52 percent and 72 percent, respectively.¹¹⁶ The results of TIL therapy in a metastatic tumor that is unresponsive to conventional therapy were achieved with moderate toxicity, demonstrating the encouraging potential of this therapy.

Studies of the mechanisms of tumor eradication in melanoma are providing insights for treatment of other cancers with T-cell therapy. Exome sequencing of melanoma has shown that the frequency of mutational events is high,^{101,117} and detailed analysis of the specificity of TILs showed that in addition to T cells specific for shared tumor/self-melanocyte differentiation antigens,¹¹⁸ such mutated gene products encoded neoepitopes that were often targets of immune recognition.^{101,108,119} The identification of neoepitope T cells in nonmelanoma cancers is of considerable interest because mutations in other tumors may be similarly targeted. In one example, TIL therapy was used to successfully treat a patient with metastatic cholangiocarcinoma.¹²⁰ Whole-exome sequencing of the tumor identified a mutation within the *erbb2* interacting protein (ERBB2IP) that was recognized by a subset of CD4+ T cells in the TIL product. Treatment with a greater than 95 percent pure population of mutation-reactive T cells resulted in dramatic

and durable tumor regression in this patient.¹²⁰ These results illustrate the potential of patient specific T-cell therapy targeting immunogenic mutations present in their tumor and highlight the need to apply advanced genomic technologies to the discovery of targets for immune therapy in cancer.^{108,120}

Collectively, significant progress has been made in cellular therapy for melanoma, but additional studies are necessary to define the optimal and safest regimens for adoptive therapy with tumor-reactive T cells. Advances in our understanding of the role of individual cytokines in T-cell survival *in vitro* and *in vivo*, or the regulation of T-cell activation and homeostasis will provide new opportunities for improving the persistence of *in vitro* expanded T cells after transfer, perhaps obviating use of toxic chemoradiotherapy to deplete lymphocytes before T-cell infusions. Most of the initial efforts have focused on the CD8+ T-cell response to tumor antigens, but newer data highlights the potential of tumor-specific CD4+ T cells. Combining T-cell therapy with targeted depletion of T_{REG}, checkpoint inhibitors, and vaccines is also under investigation, and may help overcome mechanisms by which tumors evade elimination by limiting the quantity and quality of the host response.

CELLULAR THERAPY OF LEUKEMIA

Allogeneic donor T cells contained in or derived from the stem cell graft can mount a GVL effect that can contribute to the eradication of hematologic cancers, including leukemia.⁹⁰ This is underscored by studies on the antitumor effects of infusions of unselected donor lymphocytes (DLI) given to patients who relapse after allogeneic HSCT. DLI can have potent antitumor effects in patients with relapsed chronic myeloid leukemia, but has been less effective in acute leukemias, and often complicated by the development of acute and chronic GVHD.⁹¹ The identification of leukemia-associated antigens that can be targeted to selectively promote a GVL effect without causing GVHD remains an important goal.^{92,121}

Target Antigens for Leukemia-Specific T Cells

GVHD and GVL effects usually coexist, but a GVL effect can be observed after HSCT in the absence of GVHD.⁹⁰ Thus, it is presumed there are antigens that are expressed by leukemia cells that can be targeted by allogeneic T cells. Several categories of such antigens have been identified. These include (1) minor histocompatibility antigens (mHAGs) that are selectively expressed in hematopoietic cells including leukemic cells, (2) tumor-specific proteins resulting from chromosome translocations or mutations, and (3) normal proteins that are overexpressed in leukemic cells. Proteins in the latter two classes could be targets both in the transplantation and nontransplantation setting, whereas mHAGs are only relevant after allogeneic HSCT.

Minor Histocompatibility Antigens

The increased potency of the GVL effect after allogeneic HSCT compared with syngeneic HSCT emphasizes the importance of disparity in major HLA and mHAGs for immune-mediated eradication of malignancy.^{90,122} Class I and class II molecules on recipient T cells display mHAGs, which are peptides derived from proteins that differ between the donor and recipient as a result of genetic polymorphism.^{92,123} In murine models, the adoptive transfer of T cells specific for a single mHAG eradicated leukemia without causing GVHD.¹²⁴ In humans, donor T cells reactive with recipient mHAGs can be isolated after transplantation from most allogeneic HSCT recipients.¹²⁵ Analysis of the specificity of such T-cell clones shows that many mHAGs are expressed preferentially in hematopoietic cells, including leukemic blasts, and might permit the separation of GVL from GVHD.¹²⁵ mHAG-specific CD8+ CTLs prevent

engraftment of human leukemia in nonobese diabetic/severe combined immunodeficiency mice, providing evidence that the leukemic stem cell can be recognized by allogeneic T cells.¹²⁶

Most mHAGs result from nonsynonymous single nucleotide polymorphisms (SNPs) in the coding sequence of donor and recipient genes that alter the HLA binding or TCR contact of HLA-bound peptides. There are several million SNPs with an allele frequency of greater than 5 percent in the human genome, including approximately 50,000 SNPs that lead to amino acid changes in proteins.¹²⁷ Identification of the polymorphic genes that encode mHAGs is facilitated by the data on genetic variation from the human HapMap project, which has enabled the use of whole-genome association analysis for mHAG discovery in addition to conventional techniques for antigen discovery.¹²³ Identifying the subset of mHAGs that will be the most useful to target to augment the GVL effect requires consideration of several factors, including the allele frequency of the mHAG encoding gene, the HLA restricting allele that presents the mHAG, and the expression and presentation of the mHAG in leukemia cells and nonhematopoietic tissues.¹²⁸ Most mHAG discovery efforts have focused on CD8+ T cells, but CD4+ T cells are likely to play a key role either as direct effector cells in the GVL response, or to support the function and persistence of CD8+ T cells, and efforts to define class II MHC-restricted mHAGs remain an important area of investigation.

Autosome-encoded mHAGs that could be targets for therapy of leukemia after allogeneic HSCT include HA-1 and HA-2, which are encoded by *KIAA0023* and *MYO1G*, respectively, and presented by HLA-A2; peptides encoded by *BCL2A1*, which encodes two mHAGs presented by HLA-A24 and HLA-B44, respectively; LRH-1, encoded by the *P2X5* gene and presented by HLA-B7; SP110, which is derived by a novel peptide-splicing mechanism and presented by HLA-A3; and PANE-1, which is presented by HLA-A3 and selectively expressed on B-lymphoid malignancies.^{123,128,129} Additionally, the HLA-A2-restricted and hematopoietic-specific mHAG UTA2-1 has been described.¹³⁰ Direct evidence for a role of these mHAGs in the GVL effect is provided by studies using HLA-A/peptide tetramers to detect expansion of mHAG-reactive T cells in patients who responded to treatment with DLI for treatment of relapse following transplantation.^{131,132}

There is also evidence for a role of Y-chromosome-encoded mHAGs in the GVL effect. Male recipients of allogeneic HSCT from female donors have a higher risk of GVHD but exhibit a lower risk of leukemia relapse than do other donor/recipient gender combinations, even after controlling for GVHD.¹³³ Several H-Y antigens are ubiquitously expressed in tissues, providing an explanation for the increased GVHD. Identifying mHAGs encoded by the Y chromosome that are selectively expressed on leukemia cells has been more challenging. A *UTY* epitope presented by HLA-B8 is preferentially presented in hematopoietic cells including acute myeloid leukemia, but the gene is expressed in other tissues and it is not clear if targeting this antigen could avoid GVHD.¹³⁴

Leukemia-Associated Proteins

Leukemia-associated proteins that could be targets for cellular therapy have been identified.¹²¹ These include mutated proteins, such as p21/Ras, or the products of chromosome translocations, such as BCR/ABL, and the promyelocytic leukemia-retinoic acid receptor α protein (PML-RAR α), which can provide unique peptides that represent potential tumor-specific targets.^{135,136} Nonpolymorphic proteins, such as proteinase 3, Wilms tumor antigen-1 (WT-1), or cyclin A1, which are overexpressed in some leukemias or the leukemic stem cells, also represent potential targets for T-cell therapy.¹³⁷⁻¹⁴² T cells specific for WT-1, which is expressed at high levels in myeloid leukemias but at low levels in normal hematopoietic cells, have been isolated from normal donors by *in vitro* stimulation of PBMCs with synthetic peptides.¹⁴³ WT-1-specific

CTL selectively lysed leukemic blasts and prevented engraftment of leukemia in immunodeficient mice, suggesting that these T cells may mediate an antileukemic effect without affecting normal hematopoiesis *in vivo*.^{140,144} Recent work has identified WT-1-specific T cells after HLA-identical sibling HSCT and correlated these cells with a GVL effect.¹⁴⁵ In a recent pilot trial, 11 high-risk leukemia patients received infusions of WT-1-specific T cells.¹⁴⁶ In four of these patients, the infused T cells were generated in the presence of IL-21, which modulates the differentiation of T cells in culture. The transferred T cells exhibited evidence of leukemic activity, and CTL that were generated with IL-21 had superior antileukemic activity and survived long-term as memory T cells.¹⁴⁶ Additional study in a larger number of patients is needed, but these results offer a potential safe and effective treatment for patients with limited treatment options.

GENETIC RETARGETING OF T CELLS

Extending cellular therapy to patients from whom tumor-reactive T cells cannot be isolated and to other malignancies can be accomplished by using gene transfer approaches to retarget patient T cells to recognize tumor antigens (Fig. 26-3). Two approaches that have already been translated to the clinic are discussed below. The first is the use of retroviral or lentiviral vectors to transfer of TCR α - and β -chain genes isolated from tumor-reactive T cells into T cells obtained from the patient, and the second is the expression of non-MHC-restricted synthetic CARs that target a tumor cell-surface molecule.

Genetic Retargeting of T Cells with T-Cell Receptor Genes

Antigen specificity is conferred by the TCR, therefore the transfer of TCR α - and β -chain genes from a T cell of defined specificity into any T cell, will transfer antigen recognition. This strategy can impart specificity to viral antigens, tumor-associated antigens, or mHAGs,^{93,147,148} and can confer potent tumor recognition. However, TCRs are MHC-restricted and a given TCR construct can only be used to treat patients with tumors expressing the target molecule and also express the MHC

Figure 26-3. Engineering tumor-reactive T cells by insertion of genes that encode tumor-specific T-cell receptors (TCRs) or chimeric antigen receptors (CARs). After isolation of T cells from the desired T-cell subset, the tumor targeting receptor is introduced in the T cells by gene transfer, and the engineered redirected T cells are expanded for reinfusion to the patient.

restricting allele. Moreover, it can be difficult to achieve the same surface level of TCR expression in transduced T cells as observed in the parental T-cell clone from which the TCR genes were isolated. This problem was apparent in the first clinical trial in which MART-1 TCR-engineered T cells were used to treat melanoma and the low TCR expression likely contributed in part to the limited antitumor activity of the TCR-modified T cells.¹⁴⁹ Another problem is that the TCR transfer endows T cells with additional rearranged TCR chains, leading to T cells that could potentially express four different TCR molecules on the cell surface: the natural endogenous TCR, the exogenously introduced TCR, and two mixed heterodimers consisting of endogenous and exogenous TCR chains. Such mismatched TCRs could result in potentially deleterious self-reactive specificities.¹⁵⁰ This problem can be mitigated by the introduction of cysteine residues into the extracellular constant region of the introduced α and β TCR chains to provide for disulfide bond formation^{151,152} or by using murine constant domains in place of the human constant regions,¹⁵³ both of which promote preferential pairing of the introduced chains. More recently, strategies to knock out or silence the endogenous TCR have been developed.^{154,155} These modifications provide for more stable pairing during assembly and export, and better competition for limiting components of the TCR complex.¹⁵⁶

Strategies to enhance the potency of the TCR, such as by enhancing TCR affinity, may increase the risk of toxicity, particularly if self-antigens are targeted.^{157–161} In a clinical trial, autologous T cells were modified to express optimized high-affinity MART-1 or gp100 TCR transgenes and transferred to 36 melanoma patients. Nine of the patients exhibited clinical antitumor responses, but “on-target” toxicities to normal melanocytes in the skin, eye, and ear that required local glucocorticoid treatment were observed in a significant fraction of patients that received the high-avidity TCR.¹⁵⁷ In a separate trial, autologous T cells modified to express a high-affinity TCR specific for the carcinoembryonic antigen (CEA) were transferred to three patients with colorectal cancer. The serum CEA levels decreased in all three patients and there was some regression of metastatic disease. However, the clinical trial was closed early when all three patients developed severe colitis, putatively from recognition of normal epithelial cells that express CEA.¹⁶¹ Toxicity was also observed in a study in which nine cancer patients were treated with autologous T cells modified to express an anti-MAGE-A3 TCR. Five patients experienced cancer regression, but three patients experienced serious and/or fatal neurologic toxicity. This occurred because of previously unrecognized expression of MAGE-A12, which encodes the identical epitope, in the human brain that resulted in neuronal cell destruction.¹⁶⁰ Additional safety concerns of targeting MAGE-A3 using an affinity-enhanced TCR construct were identified after an unexpected fatal cardiac toxicity. Detailed analysis showed cross-reactivity of the engineered MAGE-A3 TCR-modified T cells with a titin-derived peptide.^{158,159}

Such serious “on-target and off-target” toxicities of TCR gene transfer suggested that targeting antigens with restricted expression on tumor cells such as mutant epitopes or cancer testes antigens is preferable. NY-ESO-1 is expressed in many human cancers, but not in normal tissues, except testis. A TCR specific for an HLA-A2-restricted NY-ESO-1 epitope was used for the treatment of melanoma and synovial sarcoma.¹⁶² Toxicity was not observed, and encouraging results showed that the TCR-engineered T cells mediated objective responses in four of six patients with synovial cell carcinoma and five of 11 melanoma patients.

Genetic Retargeting of T Cells with Chimeric Antigen Receptors

A notable advance in T-cell therapy has been the development of CARs that link recognition domains of antibodies to molecules involved in

Figure 26–4. Structure of a chimeric antigen receptor (CAR). The CAR is typically composed of a recognition module that is fused in tandem to nonsignaling extracellular and transmembrane domains and intracellular signaling elements. The recognition module, spacer domain, and signaling modules of the CAR can be modified to optimize tumor cell recognition and T-cell function.

signaling T-cell effector function.^{94–96,163,164} CARs typically consist of a single-chain variable fragment (scFV) derived from the V_H and V_L sequences of a mAb specific for a tumor cell-surface molecule, fused to a *trans*-membrane domain, as well as the CD3 ζ -signaling domain alone, or in combination with one or more costimulatory signaling modules, such as CD28, 4-1BB, OX40, or CD27 (Fig. 26–4).^{94–96,165,166} CARs can be introduced into T cells by gene transfer to target surface molecules expressed on tumors. Unlike conventional TCRs, CARs are not MHC-restricted and have the advantage that a single construct can be used to treat all patients expressing the tumor antigen.

A large number of CARs targeting a variety of molecules expressed on hematologic malignancies have been developed.^{96,167,168} Examples for candidate targets for the treatment of hematologic malignancies include CD19,⁹⁶ CD20,¹⁶⁹ and the orphan tyrosine kinase receptor ROR1^{170–172} expressed on B-cell lymphomas and leukemias; Lewis Y,¹⁷³ CD44v6,¹⁷⁴ CD33 and/or CD123 expressed on acute myeloid leukemia^{168,175–177}; and NKG2D ligands¹⁷⁸ or the B-cell maturation antigen (BCMA)¹⁷⁹ expressed on myeloma.

Efficient methods for T-cell activation, gene transfer, and expansion of T cells for therapy have been developed and the results of pilot clinical trials of T cells modified to express CARs specific for CD19, CD20, ERBB2, the disialoganglioside GD2, and mesothelin have been reported and provided evidence of *in vivo* antitumor activity.^{180–187} However, serious toxicity has also been observed including a fatal toxicity shortly after infusion of a single high dose of ERBB2-specific CAR-T cells that contained both CD28 and 4-1BB costimulatory domains, and was attributed to cytokine release and recognition of normal lung epithelium that expresses low amounts of ERBB2.¹⁸⁸ Toxicity to normal tissues was also observed in patients receiving CAIX CAR-engineered T cells for the treatment of metastatic renal cell carcinoma.^{189,190}

The most encouraging results with CAR-T cells have been obtained targeting the B-cell lineage-restricted CD19 molecule that is expressed on B-cell leukemias and lymphomas. Dramatic and durable remissions in patients with chronic lymphatic leukemia (CLL) and acute lymphatic leukemia (ALL) have been reported after infusion of autologous T cells transduced with CD19-specific CARs that contained either a CD28 or a 4-1BB costimulatory domain.^{182,183,191,192} In these studies, infused T cells were shown to expand *in vivo*, induce tumor lysis and a deficiency of normal CD19+ B cells, and persist long-term in some patients. The complete response rate appears to be higher in patients with ALL than those with CLL or lymphoma for reasons that have not been elucidated. Tumor regression is often associated with a cytokine release syndrome (CRS) initiated by activation of CAR-T cells *in vivo*, associated with elevated levels of IFN- γ , IL-6, and tumor necrosis factor, and resulting in high fever, hypotension, and neurologic abnormalities.^{183,193} CRS is more severe in patients with high tumor burden and can require

intensive supportive care, and treatment with glucocorticoids and/or anti IL-6 receptor antibodies. CAR-T cells often do not persist long term, although prolonged B-cell aplasia has been observed in a subset of patients.

The finding that durable responses can be achieved in some patients with advanced B-cell malignancies illustrates the potency of CAR-T cells, and suggests that future work to define optimal design of the CD19 CAR constructs and to identify the optimal subset(s) of T cells to modify may further improve outcomes, particularly in CLL and lymphoma where response rates and durability are lower. The demonstration of the superior engraftment properties of effector T (T_E) cells derived from T_{CM} would suggest that selection or enrichment of T_{CM} prior to gene insertion may provide a superior T-cell product for adoptive therapy.^{48,194} This hypothesis is being examined prospectively in clinical trials of CAR-T-cell therapy. Moreover, integrating T-cell therapy earlier after diagnosis or after autologous HSCT, in which marked tumor cytoreduction can be achieved by intensive conditioning, may further improve outcome and reduce the toxicity resulting from CAR-mediated tumor lysis.

CAR-modified T cells also may have applications in the treatment of solid tumors. Candidate surface molecules on solid tumors that are being actively pursued as targets include GD2,¹⁸⁶ mesothelin,¹⁸⁷ L1-cell adhesion molecule (L1CAM),⁸⁵ ROR1,^{170,171} prostate stem cell antigen,¹⁹⁵ folate receptor,¹⁹⁶ and the fibroblast activation protein.¹⁹⁷ Significant antitumor activity without toxicity has been reported in patients with neuroblastoma treated with T cells modified with a first-generation GD2 CAR.¹⁸⁶ The persistence of the transferred cells was relatively short in that study, however, perhaps owing to the lack of costimulation in the CAR. GD2 is expressed on normal peripheral nerves, and on-target toxicity from a sustained T-cell response will need to be monitored if more potent CARs are being examined. Suitable animal models for preclinical toxicity studies are urgently needed and are being developed.¹⁹⁷⁻¹⁹⁹ It will also be important to address the multiple evasion mechanisms that tumors employ to avoid immune elimination.⁹⁶ For example, the programmed death-1 (PD-1) receptor is a negative regulator of T_E mechanisms that limits immune responses against cancer, and the combination of checkpoint blockade and T-cell therapy is of future interest.²⁰⁰⁻²⁰²

Suicide Genes for Conditional Ablation

The results of clinical trials of T-cell therapy have revealed toxicity to normal tissues in some patients. The introduction of a suicide gene into the T cells that could be activated if toxicity occurred has long been the subject of research. The HSV-thymidine kinase (*HSV-TK*) gene has been used in gene therapy trials in the clinic and was effective in reversing GVHD after DLI.²⁰³ However, the viral thymidine kinase is immunogenic and can result in premature elimination of transferred T cells that do not cause toxicity.²⁰⁴ Novel suicide genes based on inducing conditional cell death through activation of CD95 (Fas) or caspases using a chemical dimerizer such as AP1903 to activate an engineered chimeric human CD95 or caspase transgene product may circumvent the problem of immunogenicity.²⁰⁵⁻²⁰⁷ Recently, 10 patients undergoing haploidentical HSCT for relapsed acute leukemia were treated with donor T cells modified to express an inducible *caspase9* gene (*iCasp9*). The *iCasp9* T cells engrafted and conferred protection against infectious diseases. A subset of the patients developed GVHD. A single dose of the dimerizing drug, given to those patients who developed GVHD ablated more than 90 percent of the *iCasp9*-modified T cells rapidly and eliminated the GVHD without recurrence or adverse events.^{208,209} A truncated epidermal growth factor receptor (EGFR) marker/suicide gene that could be targeted *in vivo* using a clinical grade anti-EGFR antibody

(Erbix) has been developed, but its efficacy for ablating transferred T cells in patients has not been established.

FUTURE DIRECTIONS IN T-CELL THERAPY

The field of adoptive T-cell therapy is now emerging as a viable and effective therapeutic approach for treating human infections and cancer. Advances in the understanding of cell intrinsic properties of T-cell subsets, discovery of target antigens that distinguish tumor cells from normal cells, and improvements in the methodology for introducing genes into T cells have combined to make it feasible to treat patients with certain malignancies using highly effective T-cell products. Several challenges remain. For most common human tumors, target antigens have not yet been defined, and tumor heterogeneity and other mechanisms that tumors use to evade T-cell recognition represent barriers to effective therapy. Thus, additional research to identify and validate a larger number of target molecules for TCR- and CAR-recognition is essential to broaden therapeutic applications, and improve efficacy. Combination therapies with T cells and checkpoint inhibitors are promising for overcoming local and systemic evasion mechanisms that limit antitumor immunity. Finally, it would be ideal if expression of the tumor targeting receptors or the survival of transferred T cells were under regulatory control by small molecules that could be administered to the patient to reduce toxicity.

CHAPTER 27

VACCINE THERAPY

Katayoun Rezvani and Jeffrey J. Mollidrem*

SUMMARY

Vaccines are biologic substances that are designed to stimulate the host immune system to elicit a neutralizing response against clinically relevant targets, including pathogens and tumors. Active immunotherapy with vaccines has been extremely effective as prevention against infectious pathogens. However, effective vaccine therapy of chronic infectious diseases or cancer, in the therapeutic setting, remains a promising but largely unrealized goal. Hematologic malignancies are an excellent model system for vaccine therapies, in part because of accessibility to the hematopoietic and lymphatic space and susceptibility to immune effector mechanisms and availability of tumor cells for mechanistic studies.

ADVANTAGES OF CANCER VACCINE THERAPY

Immunity elicited by therapeutic cancer vaccines offers several advantages over passive immunotherapy using monoclonal antibodies. In active immune therapy, all components of the effector immune response are host derived without murine or xenogeneic components that could cause indirect toxicity. The lack of foreign components also allows the host response to be sustained. Also, if the vaccine contains more than a single determinant of the target antigen, the immune response could be broad in scope, recognizing more than a single epitope in the antigen (polyclonal). This feature might be of particular importance for cancer immunotherapy, as mutation of individual peptide epitopes is a possible mechanism of immune evasion by tumors. In addition to inducing antibodies, which can recognize intact proteins on the surface of tumor cells, vaccines activate T cells that can recognize peptide fragments derived from proteins that may be endogenously processed and presented on the surface of tumor cells. Such T cells have various effector mechanisms capable of neutralizing tumor cells, including lysis of the tumor cell by cell-to-cell contact and the local production of cytokines that might directly neutralize tumor cells (e.g., interferon- γ).

Acronyms and Abbreviations: cDNA, complementary DNA; CTLA-4, cytotoxic T-lymphocyte antigen-4; GM-CSF, granulocyte-macrophage colony-stimulating factor; HLA, human leukocyte antigen; IL, interleukin; KLH, keyhole limpet hemocyanin; PD-1, programmed cell death protein-1; PD-L, programmed death ligand.

*This chapter was written by Sattva S. Neelpu and Larry W. Kwak in the eighth edition and portions of that text have been retained.

COMPONENTS OF THERAPEUTIC CANCER VACCINES

Most therapeutic cancer vaccines that are being tested in clinical trials have at least three components: antigenic material derived from the tumor, a carrier, and an adjuvant. The antigenic material is usually a protein or peptide derived from the tumor that is either uniquely expressed or is overexpressed in the tumor, compared with normal tissues. A unique tumor antigen or the overexpression of the antigen to prevent the tumor is necessary to prevent the induction of an unwanted autoimmune response against normal tissues following vaccination. The carrier is necessary for delivery of the tumor antigen to antigen-presenting cells, such as dendritic cells, so as to induce the immune response against the tumor antigen. The third component of a cancer vaccine, the adjuvant, is usually a cytokine or other nonspecific immune stimulant to facilitate an enhanced immune response against the tumor antigen.

ANTIGEN DISCOVERY

Both conventional and novel technologies used to define cancer-associated antigens, such as serologic analysis by recombinant expression cloning (SEREX), serial analysis of gene expression (SAGE), screening tumor complementary DNA (cDNA) libraries with tumor-reactive T cells, and characterization of peptides eluted from tumor-derived human leukocyte antigen (HLA) molecules, have resulted in a rapidly growing list of candidate tumor antigens for various hematologic malignancies (Table 27-1). The majority of these candidate antigens have been identified since 1998. Furthermore, the application of genomic and proteomic techniques, combined with the feasibility of isolating sufficient quantities of clonogenic tumor cells from individual patients, should identify additional targets that are differentially expressed in tumors as compared with normal tissues.

Desirable characteristics for candidate target antigens for immune therapy include antigens that are selectively or aberrantly expressed by the tumor or that are required to maintain the malignant cell phenotype or cell survival. Even though the adaptive immune response is comprised of both humoral and cellular components, most efforts at tumor vaccination have focused on eliciting T-cell responses because of their central role in regulating and mediating the overall adaptive response (Chap. 76). Host T-cell recognition of such antigens requires that they are naturally processed and presented by tumor cells into peptides that bind host HLA molecules. Optimally, the candidate antigen should contain both CD4+ and CD8+ T-cell epitopes. Antigens recognized by humoral immune responses must be expressed on the tumor cell surface, and the relevant epitopes must be accessible to antibody molecules. Immunogenic tumor antigens should provoke a strong effector response and not induce tolerance.

Vaccine therapy does not necessarily require a completely defined tumor antigen. Vaccines can consist of whole tumor cells or subcellular components containing putative antigens. For example, autologous tumor cells engineered to overexpress cytokines such as granulocyte-macrophage colony-stimulating factor (GM-CSF)^{15,16} or activated *ex vivo* by CD40 receptor engagement,¹⁷ can be effective at inducing tumor-specific T cells with as yet undefined antigen specificity. Similarly, transfer of the gene encoding CD40-ligand into chronic lymphocytic leukemia cells induced CD4+ and CD8+ T-cell responses in human patients.¹⁸ Vaccination with membrane proteins extracted from tumor cells and incorporated into liposomes along with interleukin (IL)-2 is another strategy that is in clinical testing.¹⁹

TABLE 27-1. Examples of Candidate Human Tumor Antigens for Hematologic Cancers

Antigen	Reference
Minor histocompatibility antigens (HA-1, HA-2)	1
Proteinase-3	2
Wilms tumor antigen-1	3
B-cell receptor (immunoglobulin idiotype)	4
Anaplastic lymphoma kinase	5
Sperm protein 17	6
Sperm protein associated with the nucleus on X chromosome (SPAN-X)	7
CML-66	8
Survivin	9
HM1.24	10
Immature laminin receptor protein	11
BCR-ABL fusion protein	12
Aurora kinase	13
Fibromodulin	14

VACCINE DELIVERY

Effective delivery of the target antigen to the immune system is critical for the successful induction of immunity. For most tumor antigens, this is a daunting challenge, as most antigens (with the exception of viral antigens associated with cancers) are weakly immunogenic, self, or tissue-differentiation antigens.

Many vaccine-delivery strategies use dendritic cells. These key antigen-presenting cells are principally responsible for initiating a host immune response.²⁰ The cells, represented in minute quantities, have the powerful capacity to take up antigens, and once activated, to present processed peptides to T cells. Accordingly, optimizing the delivery of tumor antigens to specialized antigen-presenting cells is critical. Such efforts have included isolation of dendritic cells from blood, followed by physical loading with protein or peptide antigens, or introducing the genes for candidate antigens by transfection with cDNA or messenger RNA, or by fusion with whole tumor cells. Loaded dendritic cells have been administered to patients as vaccines.²¹

An alternative strategy is to target the delivery of antigens to dendritic cells *in vivo*. Traditional approaches focused on attempts to make the antigen look foreign to the host immune system; for example, by chemical linkage to larger, highly immunogenic proteins (carriers) or incorporation into liposomes. Rational approaches to increase the efficiency of antigen delivery to dendritic cells have included genetic fusion of the gene encoding the antigen to one encoding biologically active molecules that has the ability to target cell-surface receptors on antigen-presenting cells. Such targeting molecules have included cytokines, chemokines, antibody Fc or Fab fragments, transferrin, CD40, and mannose, which serve as ligands for specific receptors on antigen-presenting cells.²² Such molecular vaccines can be administered as naked DNA or as fusion proteins. Other promising approaches to target dendritic cells *in vivo* are represented by recombinant viral or bacterial vectors or virus-like particles.^{23,24}

IMMUNOSTIMULANTS TO ENHANCE VACCINE EFFICACY

Traditionally, immunologic adjuvants, described by the late Charles Janeway as “immunology’s dirty little secret,” such as alum and oil-in-water emulsions (e.g., incomplete Freund adjuvant), provide a physical depot for slow release of antigen. Adjuvants also serve as general immune stimulants by providing a danger signal to activate antigen-presenting cells. This feature describes classical adjuvant components, such as bacterial cell wall extracts, as well as unmethylated CpG DNA sequences, which deliver maturation signals to dendritic cells through toll-like receptors (Chap. 20).²⁵ The incorporation of either recombinant cytokines or their genes into vaccine formulations may increase vaccine potency by broadly enhancing the function of either antigen-presenting cells or T cells. Consequently, cytokines, such as interferon- γ , IL-2, and IL-15, may be useful as components of vaccines.²⁶ Such cytokines also can help direct the type of immune response elicited. For example, IL-12 elicits primarily T-helper (Th) type 1 cell responses, whereas the inclusion of IL-4 or IL-10 generally induces predominantly Th2 cell responses (Chap. 76). Some cytokines, such as GM-CSF, which can induce dendritic cell differentiation, can also function as an adjuvant by recruiting antigen-presenting cells to local vaccination sites.²⁷

CLINICAL TRIAL DESIGN

Cancer vaccine trials might not fit into the paradigm developed for chemotherapeutic agents, which have direct effects on tumor and normal host cells. For example, studies in heavily pretreated patients with terminal disease might be inappropriate for vaccines, which generally require an intact host immune system. For this reason, even safety cannot be evaluated completely in patients who cannot make an immune response, because any toxicity will likely be indirect, resulting from the immune response elicited. In addition, animal models show that the immune system may be more effective at clearing minimal residual disease than at clearing advanced tumor cell burdens. Accordingly, several late-stage clinical trials of cancer vaccines are testing this approach in the setting of clinical remission, after primary surgery or chemotherapy.

Although conventional clinical trials generally test one experimental agent at a time, vaccine formulations may contain several components. The simultaneous optimization of multiple variables (e.g., vaccine and adjuvant dose and schedule, and routes of administration) in a single clinical study often requires the application of novel, more flexible clinical trial design.²⁸

ASSAYS OF VACCINE EFFICACY

The development of surrogate measures of vaccine efficacy has potential value for answering the scientific question of whether it is even possible to vaccinate human patients against a candidate antigen. Traditional assays of immune response, including simple lymphoproliferation and cytotoxicity assays, requiring prolonged periods of prior stimulation, are being replaced by quantitative assays that can measure effector function of T cells directly sampled from blood (e.g., enzyme-linked immunospot assay) and by sensitive tetramer binding assays (Table 27-2).²⁹ In some cases, tetramer-binding assays have been combined with intracellular cytokine production to provide both quantitative and functional analyses of antigen-specific T cells.³⁰ An important aim of clinical trials is to determine which, if any, of these measures of immune response are valid surrogates for vaccine efficacy.

TABLE 27-2. Monitoring of Human Immune Responses

Type of Response	Representative Assay
CD4+ T cells	Cytokine induction
	Cytokine ELISPOT (IFN- γ)
	Intracellular cytokine
CD8+ T cells	Proliferation
	Cytotoxicity
	Limiting dilution analysis
	Tetramer
Antibody	Cytokine ELISPOT (IFN- γ)
	Intracellular cytokine
	ELISA
Multiple	Flow cytometry
	ELISPOT
	Microarray
	Cytokine mRNA by RT-PCR
	T-cell spectratyping

ELISA, enzyme-linked immunosorbent assay; ELISPOT, enzyme-linked immunospot assay; IFN, interferon; mRNA, messenger RNA; RT-PCR, reverse transcriptase polymerase chain reaction.

CLINICAL TRIALS OF PEPTIDE VACCINATION IN MYELOID LEUKEMIAS

Peptide vaccines derived from primary granule proteins, including proteinase 3, the Wilms tumor 1 protein (WT1), and the fusion sequence of the BCR-ABL protein of chronic myelogenous leukemia, show promising results in early trials of patients with myeloid leukemias.²⁷⁻³¹ Both WT1 and PR1 vaccines (a 9 amino acid peptide derived from proteinase 3) induce peptide-specific cytotoxic CD8+ T cells, which are associated with a fall in WT1 expression, and have induced complete and partial remissions in patients with myeloid leukemia who have relapsed. Other vaccines, such as BCR-ABL peptides and heat-shock protein 70 peptide complexes, have also been administered to patients with chronic myelogenous leukemia on conventional treatment with imatinib or interferon- α . Vaccination was associated with a reduction in BCR-ABL transcripts and cytogenetic or molecular responses in some patients.³¹ These preliminary trials show that peptide vaccines that target patients with myeloid malignancies are safe and can induce responses in a subset of patients.

B-CELL ANTIGEN-RECEPTOR VACCINES AS SCIENTIFIC PROOF OF PRINCIPLE

B cells are clonally restricted to express surface immunoglobulin receptors that have unique epitopes present in the antibody variable region termed idiotypes (Chap. 75). Idiotypes expressed by B-cell malignancies are clonally distributed and thus can serve as tumor-specific target antigen for specific immunotherapy. Idiotypes were initially validated as tumor-rejection antigens in mouse models of myeloma and lymphoma,^{31,32} and the first clinical trial testing this approach in human patients with lymphoma was reported in 1992.^{33,34} Customized idiotypic proteins were isolated by heterohybridoma fusion, conjugated chemically to keyhole limpet hemocyanin (KLH), which functioned as a

Figure 27-1. Granulocyte-monocyte colony-stimulating factor (GM-CSF) enhances lymphoma vaccine potency. Mice were vaccinated subcutaneously with idiotypic keyhole limpet hemocyanin (KLH) protein, together with or without various doses of GM-CSF and challenged with a lethal dose of syngeneic lymphoma cells. The use of 10,000 units of GM-CSF plus idiotypic KLH conjugate on days 1 to 4 (closed dots) resulted in a significantly longer survival after tumor challenge than did idiotypic KLH conjugate vaccination alone.

carrier, and emulsified in a simple oil-in-water emulsion. These vaccines elicited predominantly antibody responses.

Subsequently, guided by additional data from murine lymphoma models (Fig. 27-1), recombinant GM-CSF protein was substituted as the immunologic adjuvant. Soluble GM-CSF, initially mixed with the vaccine and then administered for three additional daily doses subcutaneously as close as possible to the original site of immunization, significantly enhanced vaccine potency, consistent with previous gene therapy studies.³⁵ The cellular mechanism of this effect required CD8+ and CD4+ T cells.³⁶

A phase II study was designed to test these vaccines in the setting of minimal residual disease, defined as first remission after chemotherapy in follicular lymphoma patients.⁴ Previously untreated patients first received treatment with uniform chemotherapy to achieve complete remission. After a 6-month break to allow for immune reconstitution, idiotypic proteins conjugated with KLH plus GM-CSF vaccines were administered in five monthly doses. Surrogate assays for vaccine efficacy were developed that used autologous lymphoma cells as targets for both B- and T-cell responses. In 19 patients (86 percent), vaccination elicited CD8+ cytotoxic T-lymphocyte cells reactive with the lymphoma cell (Fig. 27-2). More than half of the patients remain in continuous first complete remission, even after a median followup of more than 7 years. A randomized, controlled phase III trial testing this vaccine formulation in follicular lymphoma patients in first remission was reported to improve disease-free survival as compared with controls, suggesting that therapeutic cancer vaccines could induce meaningful clinical benefit in cancer patients.³⁷

IMPEDIMENTS TO VACCINE THERAPY

Despite the success of the idiotypic vaccine phase III trial in follicular lymphoma, most other phase III trials of cancer vaccines have been disappointing and objective clinical response rates have been low. Potential reasons for the failure despite the high immunogenicity of vaccines³⁸ may be categorized into factors affecting the afferent or priming phase

Figure 27-2. T-cell–mediated lysis of human autologous lymphoma cells after vaccination with idiotype keyhole limpet hemocyanin (KLH) protein plus granulocyte–monocyte colony-stimulating factor (GM-CSF). Representative results are shown from six individual patients, designated by unique patient number (UPN). (Adapted with permission from Bendandi M, Gocke CD, Kobrin CB, et al: Complete molecular remissions induced by patient-specific vaccination plus granulocyte–monocyte colony-stimulating factor against lymphoma. *Nat Med* 5(10):1171–1177, 1999.)

of the immune response and factors influencing the efferent or effector phase of the immune response. For instance, during the afferent phase of the immune response, it is possible that the magnitude of the T-cell response or the avidity of the induced T-cells was not high enough following vaccination. During the effector phase of the immune response, it is possible that the antitumor T-cells may not have trafficked to the tumor site or, if they trafficked, they may not have been able to overcome newly recognized immunosuppressive mechanisms present in the tumor microenvironment. Several immunosuppressive mechanisms were shown to impair the function of tumor-specific effector T cells in the tumor microenvironment in several animal models and in some human cancers.³⁹ Important negative regulatory pathways that inhibit T-cell function include extrinsic suppression by regulatory T-cells; direct inhibition through inhibitory ligands such as cytotoxic T-lymphocyte antigen-4 (CTLA-4), programmed death-ligand (PD-L) 1, PD-L2, and B7-H4; soluble factors such as transforming growth factor β and IL-10; and metabolic dysregulation of essential amino acids such as tryptophan.³⁹ Therapeutic monoclonal antibodies such as ipilimumab and pembrolizumab that block the immune checkpoint pathways mediated by CTLA-4 and programmed cell death protein-1 (PD-1), respectively, prevent downregulation of T-cell responses and enhance anti-tumor immunity⁴⁰ and are effective in the treatment of nonhematopoietic tumors. Such immune checkpoint inhibitors offer a novel therapeutic approach that might be highly relevant for hematopoietic tumors.

FUTURE DIRECTIONS

Advances in understanding of immune tolerance and tumor-induced immunosuppression have now provided several novel agents to augment both the afferent and efferent phases of the immune responses in combination strategies with therapeutic vaccines. It is, therefore, an appropriate time to consider the best way in which leukemia vaccines might be incorporated into the overall treatment strategy for that cancer.

One strategy is to vaccinate patients after chemotherapy, when a state of minimal residual disease has been achieved. Moreover, lymphopenia induced by chemotherapy can also enhance antitumor immunity by promoting expansion of vaccine-induced effector T cells and minimizing tumor-induced immune suppression.³³ In this setting, the profound lymphopenia from chemotherapy results in release of cytokines, such as IL-15, providing a powerful proliferative drive to lymphocytes, which could be exploited to increase specific lymphocyte responses to the vaccine. Moreover, this strategy can eradicate cells that suppress antitumor responses such as regulatory T cells, and may overcome inherent defects in T-cell signaling, processing, or presentation.³³ In addition, the afferent phase of the immune response could be enhanced by using more potent vaccines with novel adjuvants such as toll-like receptor ligands, or by vaccinating donors of transplant recipients who have a healthy immune system as opposed to patients who may be immunocompromised either from the cancer or from therapy.⁴¹ Alternatively, vaccines could be used in combination with agents that inhibit immunosuppressive mechanisms, such as immune checkpoint receptors/ligands⁴² and/or deplete regulatory T cells,⁴³ to augment the afferent and/or effector phase of the immune response. The use of these agents in combination with therapeutic cancer vaccines may lead to enhanced antitumor immunity and improved clinical outcome.

CHAPTER 28

THERAPEUTIC APHERESIS: INDICATIONS, EFFICACY, AND COMPLICATIONS

Robert Weinstein

SUMMARY

Therapeutic apheresis refers to several blood processing methods that are used in the treatment of diverse clinical conditions. In most cases, the disorders so treated are characterized by a specific qualitative or quantitative abnormality of the blood. In hematologic practice, apheresis procedures are used to mitigate hyperviscosity in monoclonal protein disorders or remove pathologic autoantibodies and replete important plasma proteins. Red cell apheresis is used to improve the ratio of normal to abnormal red cells in hemoglobinopathies and protozoan disease, and to remove excess red cells, red cell-associated toxins, or excess iron from the body. Leukocyte apheresis is used to reduce the circulating blast count in acute leukemias with hyperleukocytosis and platelet apheresis is used to lower a very elevated platelet count in patients with myeloproliferative neoplasms. Photopheresis is used in the treatment of cutaneous T-cell lymphoma and chronic graft-versus-host disease. Adverse effects of apheresis with current technologies are typically mild and, usually, do not prevent completion of therapy.

DEFINITION AND HISTORY

The term *apheresis* emerged in 1914 when John J. Abel, of the Johns Hopkins University Pharmacological Laboratory, demonstrated how large quantities of plasma could be removed from dogs by a process he called “plasmapheresis” (from the Greek *apairesos* or Roman *aphaeresis*, meaning take away by force).¹ The treatment, by manual plasmapheresis, of hyperviscosity syndrome in patients with Waldenström macroglobulinemia during the 1950s supported the concept that a disease state causally related to a substance in the plasma can be effectively treated by removal of plasma.^{2,3} Today, a number of automated apheresis, or blood processing, techniques are used in the treatment of a growing list of clinical disorders. The American Society for Apheresis

Abbreviations and Acronyms: ADAMTS-13, von Willebrand factor cleaving metalloprotease; ARDS, acute respiratory distress syndrome; ASFA, American Society for Apheresis; CDC, United States Centers for Disease Control and Prevention; ECP, extracorporeal photochemotherapy; FCR, fraction of cells remaining; GRADE, Grading of Recommendations Assessment, Development and Evaluation; HUS, hemolytic uremic syndrome; MHC, major histocompatibility complex; 8-MOP, 8-methoxypsoralen; PUVA, psoralen plus ultraviolet A; TPE, therapeutic plasma exchange; TTP, thrombotic thrombocytopenic purpura; UVA, ultraviolet A light; VR, volume of red blood cells to be removed.

(ASFA) categorizes the indications for apheresis (Table 28–1) according to where apheresis fits into the management strategy for the condition under consideration.⁴ In addition, ASFA evaluates the individual indications (clinical entities) and issues recommendations regarding the use of apheresis in their treatment according to the GRADE (Grading of Recommendations Assessment, Development and Evaluation) system.^{4,5} Table 28–2 lists the covered indications most relevant to the practice of hematology. This chapter considers the various apheresis approaches to hematologic disorders.

THERAPEUTIC PLASMA EXCHANGE

Therapeutic plasma exchange (TPE) is the most commonly performed therapeutic apheresis procedure in the United States and Medicare claims for TPE have doubled over the past 10 years.⁶ The term *plasmapheresis* refers to the removal of plasma from the circulation by manual or automated methods; the term *plasma exchange* refers to a therapeutic procedure in which plasmapheresis is combined with replacement of the removed plasma by a substitute colloid fluid, most commonly a mixture of 5 percent human serum albumin and 0.9 percent saline.^{4,7} The efficient extraction of the plasma from whole blood, and its replacement with a substitute colloid fluid, is predicated on the hypothesis that the plasma substance targeted for removal (usually an immunoglobulin or other large molecule) does not escape to the extracellular space during the time it takes to perform the plasma exchange procedure.⁷ This hypothesis underlies the “one compartment model” that forms the basis for our understanding of the physiology of plasma exchange and the depletion of plasma constituents (Fig. 28–1).

If the “one compartment model” applies, then the intravascular mass of a substance to be removed is a function of its concentration in the plasma (y) and the patient’s plasma volume. Its clearance from the plasma by plasmapheresis depends on the fraction of that plasma volume that is removed per unit of time during the exchange. The fraction of the targeted substance remaining in the intravascular space at any time (t) during the exchange procedure can be expressed as

$$y_t = y_0 e^{-x}$$

where y_t is the concentration of targeted substance remaining in the intravascular space at time t , y_0 is the concentration of targeted substance at the start of the procedure (time zero), e is the natural logarithm base (a constant valued at approximately 2.718282) and x represents multiples of the patient’s plasma volume processed by time t . Figure 28–2 is a plot based on this formula that generates an asymptotic curve that predicts the disappearance of the intravascular target substance as a function of plasma volumes processed (i.e., multiples of the patient’s plasma volume). The curve is initially steep, and the processing of one plasma volume removes approximately two-thirds of the substance of interest. Processing of another half plasma volume lowers the remaining substance of interest to approximately 22 percent of its initial level in the blood. But the curve then rapidly flattens, with much less removal of the substance of interest per volume of plasma processed. Thus the “sweet spot” for plasma exchange procedures is the processing of between 1.0 and 1.5 plasma volumes.⁷ The “one compartment model” is particularly relevant to the removal of large molecules, such as immunoglobulins, that have a predictable rate of synthesis and volume of distribution within the intravascular space. Smaller molecules, that are synthesized and/or metabolized in a less-predictable fashion, or are distributed within total body water, are less predictably removed according to the model.⁷

As shown in Table 28–2, most indications for plasma exchange in hematologic disorders are weakly recommended based on low-quality evidence. These indications are reviewed in detail elsewhere.^{8,9} The discussion herein is restricted to situations where plasma exchange has an important impact on hematologic practice.

TABLE 28–1. Indication Categories for Therapeutic Apheresis According to the American Society for Apheresis

Category	Definition of Category
I	Apheresis is an accepted first-line therapy for these disorders.
II	Apheresis is an accepted second-line therapy for these disorders.
III	Individualize decision making. The optimal role of apheresis has not been conclusively determined in these disorders.
IV	Published evidence indicates that apheresis is ineffective or harmful in these disorders. Seek institutional review board approval if apheresis is planned.

Adapted with permission from Schwartz J, Winters JL, Padmanabhan A: et al: Guidelines on the use of therapeutic apheresis in clinical practice-evidence-based approach from the Writing Committee of the American Society for Apheresis: the sixth special issue. *J Clin Apher* 28(3):145–284, 2013.

HYPERVISCOSITY IN MONOCLONAL GAMMOPATHIES

Hyperviscosity syndrome in the monoclonal gammopathies (Chaps. 106, 107, and 109) is caused by impaired blood flow from an increase in viscosity of blood as a result of immunoglobulin–red cell interactions.^{10–12} It is most common in Waldenström macroglobulinemia because of the highly red-cell-aggregating properties of immunoglobulin (Ig) M and, less often, in IgG or IgA myeloma.^{13–15} Symptoms typically emerge when serum viscosity rises above 4.0 relative viscosity units (normal being 1.4 to 1.8).^{12,16} Although the relevant variable is blood viscosity, the measurement of serum viscosity is relatively simple and can be used as an indicator of risk of symptomatic hyperviscosity. Specific symptoms may include headache, dizziness, vertigo, nystagmus, hearing loss, visual impairment, somnolence or coma and seizures. In addition, congestive heart failure, impaired respiration, coagulation abnormalities, anemia or peripheral neuropathy may be seen.¹³ Plasma exchange rapidly relieves symptoms of hyperviscosity by lowering the plasma content of the responsible paraprotein.^{2,3,16,17}

The relationship between monoclonal protein level and serum viscosity is nonlinear, therefore a relatively small (20 percent) decrease in plasma protein can affect a major change in viscosity.^{10,17} This is noteworthy in that whereas the removal of plasma proteins during plasma exchange from patients without monoclonal proteinemia closely follows the predictions of the “one compartment model” (i.e., $y_t = y_0 e^{-0.94x}$), removal of plasma proteins from patients with monoclonal proteinemia deviates from the model by as much as 50 percent (i.e., $y_t = y_0 e^{-0.5x}$).¹⁸ The difference likely relates to the underestimated expansion in plasma volume that occurs in monoclonal proteinemias.⁷ But despite this compromised removal of plasma protein, the nonlinear relationship between serum monoclonal protein level and serum viscosity results in plasma exchange remaining highly effective in alleviating clinical manifestations of hyperviscosity.¹⁹

OTHER PLASMA PROTEIN-ASSOCIATED CONDITIONS

Cryoglobulinemia

Cryoglobulins are immunoglobulins or complexes of immunoglobulins that reversibly precipitate when exposed to temperatures below

37°C. They can be isolated monoclonal immunoglobulins (type I), a mixture of immunoglobulins including a monoclonal component that exhibits antibody activity toward polyclonal IgG (type II) or mixed polyclonal immunoglobulins of one or more classes (type III). Whereas type I cryoglobulinemia is largely associated with lymphoproliferative disorders, and type III with chronic infections or autoimmune disorders, type II is almost always associated with infection with hepatitis C. Clinical sequelae may include purpura, arthralgia and arthritis, Raynaud phenomenon, peripheral sensory or sensorimotor neuropathy, nephropathy, skin ulcers, or widespread vasculitis.^{20,21} The removal of cryoglobulins by plasma exchange can be effective in treating the renal, vasomotor, vasculitic, and neurologic manifestations of cryoglobulinemia,^{22–24} but medical treatment of the underlying disorder with which the cryoglobulinemia is associated is also necessary for a persistent good result.

Myeloma Cast Nephropathy

Myeloma cast nephropathy (“myeloma kidney”) results from combination of free light chains with Tamm-Horsfall mucoprotein in the distal nephron and the resultant precipitation of obstructing casts.²⁵ A number of early case reports and small clinical trials suggested that combining plasma exchange with chemotherapy improved the likelihood of recovering renal function in patients with myeloma and renal failure.^{26–30} The largest trial to date (104 participants) was unable to demonstrate a difference in primary outcome based on the composite measure of death, dialysis dependence, or glomerular filtration rate below 30 mL/min/1.73 m² at 6 months.³¹ The effectiveness and rapidity of modern chemotherapy may have subsumed a salutary effect of plasma exchange.³² Plasma exchange is not currently considered to be part of first-line treatment for myeloma with cast nephropathy, but may be a reasonable option when renal function does not rapidly improve with chemotherapy.⁴

THROMBOTIC MICROANGIOPATHIES

Idiopathic Thrombotic Thrombocytopenic Purpura

Idiopathic thrombotic thrombocytopenic purpura (TTP) is a medical emergency that presents with microangiopathic hemolytic anemia and thrombocytopenia (Chap. 132). It is typically characterized by central nervous system, cardiac, renal, or other organ impairment as a result of microvascular obstruction by aggregates of platelets and von Willebrand factor.^{33,34} It results from inadequate processing of ultralarge von Willebrand factor multimers by the enzyme ADAMTS-13.^{35,36} In acquired, idiopathic TTP, this enzymatic defect is caused by an autoantibody inhibitor of ADAMTS-13 that results in severe deficiency of the enzyme.^{35,36} An inherited, relapsing form of TTP results from mutations in the ADAMTS-13 gene.³⁷ TPE, using human plasma as the colloid exchange fluid, is the only therapy for TTP that has been demonstrated highly effective in a randomized clinical trial.^{38,39} It has improved the survival rate of TTP from approximately 20 percent to upward of 90 percent, but with a relapse rate over 30 percent.⁸ TPE should be initiated for a patient who presents with unexplained microangiopathic hemolytic anemia and thrombocytopenia while awaiting the result of an assay for ADAMTS-13 level and activity.⁴⁰ Of note, hemolytic uremic syndrome (HUS), a thrombotic microangiopathy with acute oliguric or anuric renal failure, is rarely associated with severe deficiency of ADAMTS-13. Shiga toxin-associated HUS does not respond to TPE; atypical HUS (i.e., with defects in regulation of the complement system) has shown only limited responses to TPE and is more appropriately treated with eculizumab.⁴⁰

Drug-Associated Thrombotic Microangiopathy

Several drugs are implicated in thrombotic microangiopathies and a TTP-like syndrome (see Table 28–2). The two most common drugs reported to the FDA as associated with TTP are the antiplatelet

TABLE 28–2. Indications for Apheresis in Hematology: Indication Category Assignments and Recommendation Grades

Clinical Disorder	Apheresis Procedure*	Indication Category [†]	Grade [‡] of Recommendation
Amyloidosis, systemic	TPE	IV	2C

Thrombotic thrombocytopenic purpura			

*Apheresis procedures: ECP, extracorporeal photochemotherapy (photopheresis); IA, immunoadsorption apheresis; MCP, monocyte chemoattractant protein; Str., streptococcal. TPE, therapeutic plasma exchange. NOTE: Leukocytapheresis, erythrocytapheresis, thrombocytapheresis refer to removal of white cells, red cells or platelets respectively by apheresis. RBC (red blood cell) exchange refers to apheresis removal of red blood cells and simultaneous replacement of removed red cells with donor red blood cells.

[†]Indication categories: see Table 28-1 for definitions.

[‡]Grade of recommendation: 1 = strong recommendation (i.e., “we recommend”); 2 = weak recommendation (i.e., “we suggest”). A = recommendation based on high-quality published evidence; B = based on moderate-quality published evidence; C = based on low-quality published evidence.

Adapted with permission from Schwartz J, Winters JL, Padmanabhan A: et al: Guidelines on the use of therapeutic apheresis in clinical practice—evidence-based approach from the Writing Committee of the American Society for Apheresis: the sixth special issue. *J Clin Apher* 28(3): 145–284, 2013.

Figure 28-1. Illustration of the “one compartment model” depicting the interaction between intra- and extravascular compartments as relates to plasma exchange. A soluble substance enters the intravascular compartment at synthetic rate (S) and is removed at its fraction catabolic rate (FCR). Movement of the substance of interest between the intravascular and (larger) extravascular compartment takes place by the mechanisms shown. The plasma exchange procedure only removes soluble substances directly from the intravascular compartment. S , FCR , and the intracompartamental movement of soluble substances are in a balanced steady state and proceed much more slowly than the rate of plasma extraction by the apheresis instrument. Thus, for the purpose of the plasma exchange procedure, the intravascular compartment can be considered to be an isolated system which can be depleted of soluble substances by exchanging the plasma for a replacement fluid.

Figure 28–2. Depletion of soluble substances from the intravascular compartment by plasma exchange according to the One Compartment Model. With each incremental volume of plasma removed (and replaced) from the intravascular compartment, a fixed proportion of the remaining intravascular content of a soluble substance of interest is removed. The processing of 1.0 plasma volume depletes the intravascular substance of interest by approximately two thirds. Processing of the next half plasma volume furthers the depletion to almost 80 percent.

thienopyridine derivatives ticlopidine and clopidogrel.⁴¹ Autoantibodies to ADAMTS-13 are seen in ticlopidine-associated TTP, and the contribution of TPE to the survivability of ticlopidine-associated TTP is similar to what is seen in acquired idiopathic TTP.^{41,42} Patients with clopidogrel-associated TTP do not appear to benefit from plasma exchange.⁴¹

ADVERSE EFFECTS OF THERAPEUTIC PLASMA EXCHANGE

Two large studies identified adverse effects in 40 percent of patients but only 12 percent of plasma exchange procedures and in 49 percent of patients but only 17 percent of plasma exchange procedures, respectively.^{43,44} This indicates that although a plurality of patients may experience an adverse effect during a course of plasma exchange, they will not necessarily experience them in every procedure during the prescribed course. In both studies, most adverse effects were classified as mild or moderate and did not prevent the successful completion of the procedure. The majority of adverse effects consisted of muscle cramps or paresthesias, transient hypotension, mild nausea, or, in patients receiving plasma as the colloid exchange fluid, fever, chills or urticaria. Muscle cramps, paresthesias, and mild nausea can be attributed to hypocalcemic toxicity that occurs when plasma ionized calcium decreases as a result of the rapid infusion of calcium-free pharmaceutical albumin and, in part, to the use of calcium chelating agents as anticoagulants in plasma exchange procedures.^{45,46} A large national survey reported similar findings but with a lower rate of adverse effects during plasma exchange (3.3 percent of procedures without plasma as the colloid replacement fluid, 7.8 percent of procedures with plasma as the colloid replacement fluid) because adverse effects that did not compromise the completion of the procedure were not included.⁴⁷ Very few adverse effects are seen as caused by complications of peripheral venous access⁴⁷; however, adverse effects of central venous access placement, although relatively rare, can be severe.^{45,47}

RED CELL APHERESIS

Red cell exchange refers to the removal of a patient's red cells in exchange for donor red cells. When red cells are removed for therapeutic purposes, but not replaced with donor red cells, the process is referred to as *erythrocytapheresis*. Red cell exchange is employed in settings where a clinical disorder is caused by an abnormality (inherited or acquired) of the patient's red blood cells, and erythrocytapheresis may be employed in situations characterized by an untoward elevation in circulating red cell volume or in iron-overload states.⁴⁸

RED CELL EXCHANGE

Therapeutic red cell exchange can be performed manually (i.e., "exchange transfusion") or by apheresis using automated programmable blood-processing equipment.^{49–51} This discussion focuses on automated red cell exchange. The programming functions of automated apheresis instruments are used to determine the parameters of red cell exchange procedures. Data that include the patient's gender, height, and weight are used to calculate the patient's total blood volume.⁵² Also programmed into the machine are the patient's starting hematocrit, the desired ending hematocrit, the average hematocrit of the replacement red cell units, and the desired fluid balance (typically 100 percent). The desired fraction of the patient's own red cells remaining in the circulation at the end of the procedure (fraction of cells remaining [FCR]) is also programmed into the instrument. The instrument's computer can thus determine how many units of red cells are to be used to obtain the desired hematocrit and FCR. The desired FCR is calculated based on the therapeutic end point targets of the red cell exchange procedure^{49,53–55}:

FCR (as %) = 100

$$\times \left(\frac{\text{starting hematocrit}}{\text{desired ending hematocrit}} \times \frac{\text{desired end point parameter}}{\text{starting parameter}} \right)$$

where the specified starting and end point parameters may be the percent hemoglobin S, the percent parasitized red cells counted on the blood film, etc.

Red Cell Exchange in Sickle Cell Disease

Chapter 49 discusses sickle cell anemia and related abnormalities in greater detail.

In general, clinical studies of the role of transfusion therapy in sickle cell disease have focused mostly on simple transfusion or manual exchange transfusion (reviewed in Ref. 56). Manual versus automated red cell exchange have not been directly compared in a clinical trial, although automated red cell exchange can be completed more efficiently and quickly than manual exchange transfusion.⁴⁹ Automated red cell exchange mitigates the accumulation of iron while maintaining a low level of hemoglobin S in patients receiving chronic treatment and, thus, has entered into routine use where available.^{57–59} Manual or automated red cell exchange can be initiated using isotonic saline, rather than packed red cells, as the replacement fluid during the early part of the procedure in order to maximize the removal of hemoglobin S-containing red cells and avoid the gratuitous removal of normal red cells.^{57,59,60} As shown in Table 28–2, red cell exchange is indicated as first-line therapy in acute vasoocclusive stroke, and may be used in acute chest syndrome refractory to standard management or in prophylaxis (primary or secondary) for vasoocclusive stroke.⁵⁶ In the latter two instances, red cell exchange may not be superior to simple transfusion.^{56,61} In addition, red cell exchange may not be superior to simple transfusion, as needed,

in the management of acute multiorgan failure syndrome, preparation for general anesthesia, complications of pregnancy, or frequent pain episodes.^{48,56}

Red Cell Exchange in Protozoan Disease

Chapter 53 discusses infections with microorganisms in greater detail.

Malaria The World Health Organization has suggested that exchange transfusion be considered for nonimmune (i.e., not previously exposed) patients with *falciparum* malaria who have any of the following characteristics: greater than 30 percent parasitemia in the absence of clinical complications, greater than 10 percent parasitemia in the presence of severe⁶² disease, greater than 10 percent parasitemia and failure to respond to optimal chemotherapy after 12 to 24 hours, or greater than 10 percent parasitemia and poor prognostic factors (elderly, late-stage parasites [schizonts] in the blood).⁶³ The Centers for Disease Control and Prevention (CDC) previously recommended strong consideration of exchange transfusion or red cell exchange in severely affected patients.⁶⁴ Subsequently, the CDC has rescinded this recommendation based on a literature review and an analysis of the U.S. national malaria surveillance system (patients reported 1985 to 2010) that found no evidence for efficacy of exchange transfusion as adjunctive therapy in severe malaria when rapidly acting antimalarials (specifically artemisinins) were available.⁶⁵ It is not certain whether the emergence of artemisinin-resistant *Plasmodium falciparum* will affect their position.⁶⁶⁻⁶⁸

Babesiosis Infection with intraerythrocytic protozoan *Babesia microti* is most commonly acquired through the bite of the tick *Ixodes scapularis* and presents with clinical manifestations that range from asymptomatic infection or influenza-like illness to organ failure and death.⁶⁹ Complications may include acute respiratory distress syndrome (ARDS), disseminated intravascular coagulopathy, renal failure, or hemolytic anemia. Immunocompromised, elderly, or asplenic individuals are most at risk for severe manifestations.^{70,71} Between 2009 and 2013 babesiosis was the most frequent cause of transfusion-transmitted infectious death reported to the FDA.⁷² In the United States, the occurrence of babesiosis in Connecticut, Massachusetts, Minnesota, New Jersey, New York, Rhode Island, and Wisconsin accounted for 97 percent of 1124 cases of babesiosis reported to the CDC in 2011.⁷³ Because the parasite is completely intraerythrocytic, and, despite the lack of clinical trials, observational evidence indicates that the parasite can be efficiently removed using automated red cell exchange.^{4,74} Red cell exchange is recommended⁴ for patients with severe manifestations, high parasite burdens (>10 percent) or who are at high risk.

Miscellaneous Uses of Red Cell Exchange

Red cell exchange has been successfully used, in conjunction with Rh immunoglobulin, to prevent Rh sensitization of an Rh-negative woman who received emergency transfusion with Rh-positive red blood cells.⁷⁵ The macrolide immunosuppressant tacrolimus is highly erythrocyte-bound and overdoses are not responsive to plasma exchange,⁷⁶ but can be mitigated using red cell exchange.⁷⁷ Red cell exchange can successfully treat refractory methemoglobinemia in patients with glucose-6-phosphate dehydrogenase deficiency or after ingestion of strong oxidants.⁷⁸

RED BLOOD CELL DEPLETION (ERYTHROCYTAPHERESIS)

Although therapeutic phlebotomy is a mainstay of management of polycythemia vera and hereditary hemochromatosis,⁷⁹⁻⁸² ASFA now considers these clinical entities to be category I (first-line) indications for automated erythrocytapheresis.⁴ The role of automated erythrocytapheresis in secondary erythrocytosis is less certain,⁸³ but it may be

useful when circumstances require isovolemic procedures.⁸⁴ The volume of red cells to be removed (VR) during an automated erythrocytapheresis procedure in order to achieve a desired hematocrit can be calculated as⁸⁵:

$$VR = \frac{(\text{starting hematocrit} - \text{desired hematocrit})}{79} \times [\text{blood volume (ml/kg)}] \times [\text{body weight (kg)}]$$

This formula also estimates the volume of replacement fluid (colloid or crystalloid) needed to maintain isovolemic fluid balance.⁸³

Polycythemia Vera

Chapter 84 provides a more detailed discussion.

A retrospective case series described 69 patients with polycythemia vera who underwent 206 isovolemic erythrocytapheresis procedures using 4 percent albumin as replacement fluid.^{83,85} Hematocrit was reduced from 56.8 ± 5.6 percent to 41.9 ± 6.6 percent after removal of 1410 ± 418 mL of red blood cells with a hematocrit of 79.7 ± 9.3 percent. Close followup data were provided for a subset of 21 patients whose hematocrits were reduced from 58 ± 5.7 percent to 41.5 ± 4.9 percent by a single erythrocytapheresis procedure and were maintained at less than 50 percent for a median of 6 months.⁸⁵ The durability of response to a single procedure was associated with a median 70 percent inhibition of *in vitro* erythropoietin-independent burst-forming unit-erythroid (BFU-E) growth that the authors attributed to iron removal during the apheresis procedure.⁸⁶ This claim has not been confirmed. Automated erythrocytapheresis may be useful in polycythemia vera for the rapid induction of hematocrit lowering, followed by maintenance therapeutic phlebotomy, for emergent isovolemic hematocrit lowering in patients with acute thrombotic or microvascular complications, or to avoid perioperative thrombohemorrhagic complications in a patient with an uncontrolled hematocrit who requires urgent surgery.^{56,85}

Hereditary Hemochromatosis

Chapter 43 provides a more detailed discussion.

Early observational studies from Europe⁸⁷⁻⁹¹ suggested that automated erythrocytapheresis could deplete iron from patients with hereditary hemochromatosis more efficiently and quickly than could conventional therapeutic phlebotomy. A prospective, randomized trial from the Netherlands involving 38 patients with newly diagnosed C282Y-homozygous hemochromatosis compared automated erythrocytapheresis to conventional therapeutic phlebotomy.⁹² Study subjects were evenly randomized to either treatment arm. The primary outcome measure was the number of procedures needed to reach a serum ferritin target of 50 mcg/L or less. This was reached in a mean (range) of nine (4 to 20) procedures over 19.6 (7 to 37) weeks in the erythrocytapheresis arm and 27 (11 to 58) procedures over 33.7 (12 to 79) weeks in the phlebotomy arm. Erythrocytapheresis removed 427 (294 to 545) mg of iron with each procedure compared to 205 (136 to 230) mg with each phlebotomy. Secondary outcomes were total duration of treatment, side effects, change in iron status and liver function, quality of life (related to health) and costs. Adverse effects, including hypocalcemia, vasovagal syncope, and mild dizziness, occurred in 3 of 19 patients in the erythrocytapheresis group and in 5 of 19 patients in the phlebotomy group. The 3.5-fold higher cost of performing erythrocytapheresis versus therapeutic phlebotomy was fully counterbalanced by greater time off from work and lost productivity among the phlebotomy group. The investigators were careful to point out that the cost structure of apheresis treatments versus phlebotomy in the Netherlands may not apply to other countries.

ADVERSE EFFECTS OF RED CELL EXCHANGE AND ERYTHROCYTAPHERESIS

Red cell exchange conveys risks related to red cell transfusion including febrile, allergic and hemolytic transfusion reactions, acute lung injury, vasovagal reactions, and transfusion-transmitted disease. Hypocalcemic toxicity resulting from the use of citrate-based anticoagulants in the apheresis circuit and in the red cell replacement units may also occur. Erythrocytapheresis conveys similar risks but not the risks associated with red cell transfusions.⁴⁸

THERAPEUTIC LEUKOCYTAPHERESIS

ASFA has designated hyperleukocytosis (white blood cell count $>100,000/\mu\text{L}$ in acute myeloid leukemias [Chaps. 83 and 88], white cell count $>400,000/\mu\text{L}$ in acute lymphoblastic leukemia [Chap. 91] with leukostasis as a category I indication for therapeutic leukocytapheresis.⁴ Asymptomatic hyperleukocytosis is designated a category III indication, reflecting limited and conflicting published evidence regarding the utility of leukocytapheresis as prophylaxis.⁴ Hyperleukocytosis, which occurs in 5 to 13 percent of newly presenting cases of adult acute myelogenous leukemia and 12 to 25 percent of pediatric acute myelogenous leukemia is a risk factor for early mortality, often from leukostasis and pulmonary and/or central nervous system hemorrhage.⁹³⁻⁹⁷ The processing of 1.5 to 2.0 blood volumes, using crystalloid or colloid fluids to maintain fluid balance, with or without a sedimentation agent such as 6 percent hydroxyethyl starch to enhance separation of white cells from red cells, can reduce the circulating white cell count by upward of 60 percent,^{4,98} but without a clear effect on the rate of early mortality in patients with acute myeloid leukemia and hyperleukocytosis with or without leukostasis.^{99,100} In any case, leukocytapheresis is not undertaken without initiating measures to mitigate the risk of tumor lysis syndrome, including intravenous hydration, lowering of plasma uric acid using allopurinol or urate oxidase, and, if urate oxidase is not used, intravenous sodium bicarbonate to alkalize the urine.¹⁰¹ Leukapheresis would ordinarily not be considered primary therapy in patients who present with high blast counts but without symptoms of leukostasis.^{4,100}

THERAPEUTIC THROMBOCYTAPHERESIS

Thrombocytapheresis refers to the selective removal of platelets from a patient, for therapeutic purposes using a blood processing (apheresis) device. ASFA lists symptomatic thrombocytosis in patients with myeloproliferative neoplasms (Chaps. 83 and 85) as a category II indication for thrombocytapheresis.⁴ Thrombocytapheresis for prophylaxis in asymptomatic patients or to lower the platelet count in cases of secondary or reactive thrombocytosis¹⁰² is listed as a category III (see Table 28-1) indication because the available data do not firmly establish a role for thrombocytapheresis in these circumstances and decision making should be highly individualized. Secondary thrombocytosis per se does not convey a risk of thromboembolic morbidity absent confounding factors such as malignancy or major surgery.¹⁰³⁻¹⁰⁵ Rapid lowering of an elevated platelet count, using apheresis and/or chemotherapy, is indicated for patients with myeloproliferative neoplasms who present with clinical syndromes of thrombocytosis with microvascular thrombosis such as digital or cerebral ischemia.¹⁰⁶ Several case series and case reports have reported successful, rapid lowering of the platelet count in symptomatic patients in whom chemotherapy was either not an immediate option or was judged to have an insufficiently rapid

effect.¹⁰⁷⁻¹¹³ Procedures in which 1.5 to 2.0 blood volumes are processed, and crystalloid replacement fluids are used to manage fluid balance, can lower the platelet count by 30 to 60 percent^{108,112,113}; however, thrombocytapheresis without concomitant chemotherapy is ordinarily not a practical means for controlling the platelet count beyond the acute setting. Weekly thrombocytapheresis, beginning in the fifth gestational week, has been used in the management of a high-risk pregnant patient with essential thrombocythemia.¹¹³ Thrombocytapheresis has been reported as effective acute therapy in the case of a patient with immune thrombocytopenic purpura, treated with romiplostim, who developed platelet counts as high as $2 \times 10^6/\mu\text{L}$ and acute neurologic symptoms in the days following splenectomy,¹¹⁴ and can be used to prepare acutely symptomatic patients with poorly controlled severe thrombocytosis for cardiovascular surgery.¹¹⁵

EXTRACORPOREAL PHOTOCHEMOTHERAPY (PHOTOPHERESIS)

Extracorporeal photochemotherapy (ECP) is a treatment process in which a patient's mononuclear white blood cells are manipulated outside of the body such that their reinfusion into the patient results in down regulation of cytotoxic T-cell activity.¹¹⁶ This procedure involves collection of circulating mononuclear cells by centrifugal apheresis, exposing them to 8-methoxyypsoralen (8-MOP, a photoactivating agent) and then to ultraviolet A light (UVA), and then reinfusing the treated cells into the patient.⁵⁶ ECP was originally approved for Medicare reimbursement in 1998 for palliative treatment of skin manifestations of cutaneous T-cell lymphoma (Chap. 103) unresponsive to other therapy and was further found "reasonable and necessary" for treatment of acute cardiac allograft rejection and chronic graft-versus-host disease (Chap. 23) unresponsive to standard treatments in 2006.¹¹⁷ It was developed based on an earlier treatment called PUVA (psoralen plus ultraviolet A) in which a patient would take an oral dose of 8-MOP and then stand in a UVA light box thus exposing affected skin to treatment. With ECP, only the white cells collected by apheresis are exposed to 8-MOP and UVA, thus only approximately 0.25 percent of the oral dose equivalent of 8-MOP is used.¹¹⁶ The precise mechanism of action of ECP is still under investigation, but likely involves a process of immunomodulation.¹¹⁸ UVA-activated 8-MOP intercalates within nuclear DNA of normal and malignant T lymphocytes and causes the treated T cells, but not treated monocytes, to undergo apoptosis by 24 hours after treatment.^{119,120} Immunologic consequences of phagocytosis of reinfused apoptotic cells include induction of major histocompatibility complex (MHC) class I-restricted CD8+ cytotoxic T lymphocytes through the antigen-presenting activity of human dendritic cells and the elaboration by monocytes and macrophages of immunosuppressive cytokines including interleukin (IL)-10 and IL-1 receptor antagonist.¹²¹ Furthermore, ECP results in an increase in CD83+, CD86+ plasmacytoid (DC2) dendritic cells with a concordant diminution in CD80+, CD123+ monocytoid (DC1) dendritic cells. The DC2 cells stimulate T-helper type 2 (Th2) cells to secrete inhibitory cytokines (e.g., IL-4, IL-10, IL-13) while inhibiting stimulation of T-helper type 1 (Th1) cells that secrete proinflammatory cytokines (e.g., IL-2, interferon- γ) and thus inhibiting Th1-mediated alloreactivity.¹²² ECP also appears to result in an increase in a population of circulating CD4+, CD25+, CD69- CTLA-4+ regulatory T cells (T_{REG}) that are immunosuppressive and are involved in transplant tolerance.¹²³ Such induced immunologic responses to ECP are presumed to explain observed clinical benefit in diverse conditions such as cutaneous T-cell lymphoma, chronic graft-versus-host disease, and cardiac transplant rejection.¹²⁴⁻¹²⁶

ADVERSE EFFECTS OF EXTRACORPOREAL PHOTOCHEMOTHERAPY

Adverse effects are largely related to volume shifts that result in hypotension, which can be managed by pausing the procedure and/or administering fluids. Transient fevers to 38°C to 39°C have been observed 6 to 8 hours after reinfusion of the treated mononuclear cells.¹²⁷

CHAPTER 29

GENE THERAPY FOR HEMATOLOGIC DISEASES

Hua Fung and Stanton Gerson

SUMMARY

The term *gene therapy* describes treatment resulting from expression of a transferred gene (or transgene) in diseased or other cells by engineered vectors. Once within the cell, the transgene can direct synthesis of a therapeutic protein that can complement a genetic deficiency or confer upon the cell a desired phenotype or function. Many clinical trials have involved gene therapy for patients with various gene-deficient hematologic diseases, such as severe combined immunodeficiency, hemophilia, Wiskott-Aldrich syndrome, chronic granulomatous disease, aplastic anemia, hemoglobinopathies, HIV infection, and leukemia. Results from some clinical trials indicate that gene therapy can cure or improve many inherited or acquired hematologic disorders. This chapter reviews the basic principles of gene transfer and the results of selected preclinical and clinical studies.

DEFINITION AND HISTORY

Gene therapy is a promising treatment for several inherited or acquired hematologic disorders. Gene therapy involves the introduction of a functional gene to replace a mutated gene or a therapeutic gene to provide a missing or defective protein to the organism. In some cases, the patient's blood cells are removed and special, targeted cells such as hematopoietic stem cells (HSCs) are selected for engineering. The therapeutic genes are introduced into a vector and delivered into the targeted cells. These targeted, gene-modified cells are reinfused back into the patient. Because this method modifies cells outside the patient's body, it is called *ex vivo* gene therapy (Fig. 29-1A). By contrast *in vivo*

Acronyms and Abbreviations: AAV, adeno-associated virus; ADA-SCID, adenosine deaminase deficiency severe combined immunodeficiency; ARSA, arylsulfatase A; BCNU, 1,3-bis-(2-chloroethyl)-1-nitrosourea; CAR, chimeric antigen receptor; CCR5, chemokine (C-C motif) receptor 5 gene; CGD, chronic granulomatous disease; CLL, chronic lymphocytic leukemia; CRISPR, clustered, regularly interspaced, short palindromic repeats; DSB, double-stranded break; FA, Fanconi anemia; FVIII, factor VIII; FIX, factor IX; GCV, ganciclovir; GVHD, graft-versus-host disease; Hgb, hemoglobin; HR, homologous recombination; HSC, hematopoietic stem cell; HSV, herpes simplex virus; HSV-TK, herpes simplex virus thymidine kinase; iCasp9, inducible caspase 9 protein; IL2RG, interleukin-2 receptor gene; LTRs, the long terminal repeats; MGMT, O⁶-methylguanine-DNA methyltransferase; MLD, metachromatic leukodystrophy; SIN, self-inactivating; siRNA, small interfering RNA; TALEN, transcription activator-like effector nuclease; TMZ, temozolomide; WAS, Wiskott-Aldrich syndrome; X-ALD, X-linked adrenoleukodystrophy; X-SCID, X-linked severe combined immunodeficiency; ZFN, zinc-finger nuclease.

gene therapy describes the therapeutic gene-containing vectors being directly injected into the patient (Fig. 29-1B). In the *in vivo* case, the gene is expressed, producing a therapeutic protein for treatment. Theoretically, if the gene-modified cells are long-lived and able to expand inside the body, a single gene therapy can be sufficient to provide a life-long therapeutic effect. Current gene therapy technologies have reached the point that many types of single-gene hematologic deficiency diseases can be permanently corrected, for example, X-linked severe combined immunodeficiency (X-SCID) and adenosine deaminase deficiency severe combined immunodeficiency (ADA-SCID).

Gene therapy has improved significantly in effectiveness since the mid-1980s when the first experiment using stem cell gene transfer was successful. Scientists initially encountered several serious obstacles. First, there was difficulty in delivering a modified gene into HSCs because of their lack of cell-surface receptors and their quiescent state.¹ Second, early X-SCID gene therapy was interrupted because 20 percent of patients developed a T-cell type of leukemia within 3 to 6 years after therapy. This event was caused by gene therapy-related viral vector insertional mutagenesis; the vector contained powerful enhancer elements within its long terminal repeats (LTRs) that inserted close to, and activated the *LMO2* protooncogene.² Over 3 decades, these problems have been (for the most part) resolved. With an array of cytokine stimulation cocktails to improve HSC receptivity to engineering, and improved lentiviral vectors, the HSC transduction rate in humans can reach 80 to 100 percent.^{3,4} In addition, myeloablative conditioning regimens (e.g., busulfan, melphalan and 1,3-bis-[2-chloroethyl]-1-nitrosourea [BCNU; aka carmustine]) that decrease the number of endogenous stem cells prior to infusion of the engineered HSCs has proven to be an effective method to increase engraftment rates (average: 1 to 2 copies of gene marking/cell).^{3,4} High-level stem cell engraftment is a critical factor for the gene therapy of chronic granulomatous disease, X-linked adrenoleukodystrophy (X-ALD) and metachromatic leukodystrophy.³⁻⁶ Moreover, newer, safer self-inactivating (SIN) viral vectors have been developed in which viral LTR enhancers are completely removed. Using these newer vectors, no patient has developed therapy-related malignancy in several clinical trials, some of which have followed patients for as long as 8 years.^{3,4} Gene therapy is no longer a hypothetical form of therapy; some trials have achieved clinical correction for as long as 12 years. Gene therapy has, thus, undergone a renaissance. This chapter discusses two critical technical factors in gene therapy: targeted cells and delivered vectors; briefly reviews the gene therapy of several common hematopoietic genetic deficient diseases; and describes new strategies of *in vivo* selection and insertion site-targeted gene therapy.

GENE THERAPY TARGETED CELLS

HEMATOPOIETIC STEM CELLS

HSCs are the cell of choice for many gene therapy applications for several reasons. First, many blood cell disorders originate at the stem cell level and, therefore, gene-corrected HSCs are the best candidate for replacement. Second, HSCs are a long-lived and self-renewing population and may reduce or eliminate the need for repeated administration of gene therapy. HSCs are readily obtained in the blood, marrow, or umbilical cord blood. They are also easily selected and manipulated in the laboratory and can be returned to patients relatively easily. Third, engineered HSCs are able to correct defects in all hematopoietic lineages. Fourth, HSCs migrate to several tissues in the body—primarily the marrow, but also the liver, spleen, and lymph nodes. These may be strategic locations for localized delivery of therapeutic agents for disorders unrelated to the hematopoietic system, such as for patients with liver diseases.

Figure 29-1. **A.** *Ex vivo* gene therapy involves 4 steps: 1. Obtain patient's blood (HSCs or T cells); 2. transduce the cells in the laboratory by engineering the virus that contains a transgene; 3. infuse the transduced cells into the patient; and 4. the infused transduced cells produce therapeutic proteins. **B.** *In vivo* gene therapy is done by directly injecting viral particles into the patient.

T LYMPHOCYTES

The use of hematopoietic progenitor or precursor cells for gene therapy theoretically would require repeat application. However, for some inherited and acquired diseases involving T cells (e.g., severe combined immunodeficiency [SCID] and AIDS), the use of T-cell precursors is capable of long-term correction of the T-cell deficiency. The underlying mechanism is still not clear, but some types of T cells, such as memory T cells, are long-lived. The memory T-cell compartment has three subsets: T-memory stem cells, central memory T cells, and effector memory T cells.⁷ Memory T cells and central memory T cells can expand to large numbers of effector T cells when activated. T-cell gene therapy is effective in some forms of cancer therapy. Long-term effects could be related to memory T stem cells. For example, T effector cells can directly eradicate malignant cells. However, cancer cells are often "invisible" to T cells. For this reason, modified T cells have been created by adding a chimeric antigen receptors (CARs) expressing gene, engineering the T cells to recognize cancer-specific antigens such as CD19 on chronic lymphocytic leukemia (CLL) cells.^{8,9} Once the CAR-modified T cells are transfused into the patient, they can attack and eradicate the targeted malignant cells. In clinical trials, anti-CD19 CAR T cells profoundly decreased the level of cancer cells in three patients with end-stage CLL.^{8,9}

An advantage of using gene-modified T cells is that the procedure does not disturb the otherwise normal hematopoietic system. However, this is also a limitation of using T cells in gene therapy. For example, when using T cells to correct X-SCID, although T cells recover to near normal levels, the other affected cell types (e.g., B cells, natural killer [NK] cells) are not corrected. In this approach, the patient would require immunoglobulin replacement and the NK cell deficiency would persist. A study compared the outcomes of several clinical trials of HIV therapy comparing CD4+ T-cell treatment to HSC-based treatment. These trials found that overall, the results from HSCs were better than that of CD4+ T cells.¹⁰ One reason offered for this result is that without stimulation, T cells proliferate at a very low rate, estimated at approximately one division every 3.5 years for naïve T cells, and one division every 22 weeks for memory T cells.¹¹

GENE THERAPY VECTORS

The majority of gene therapy studies thus far have employed viral vectors, because of their high efficiency of transgene delivery into the human nucleus. For a long-term effect, genome-integrating retroviral/lentiviral vectors have been employed. However, DNA integration causing critical gene mutagenesis has raised concern about long-term safety. This concern has led to the development of persisting but nonintegrating viral vectors.

NON-GENOME-INTEGRATING VIRAL VECTORS

Adenoviral Vector

Adenoviral vectors do not integrate into the genome, but are highly effective in gene therapy because of their ability to efficiently transduce both dividing and nondividing cells, and to persist relatively well in long-lived targeted cells. Adenoviral vectors also have capacity to hold large segments of DNA (e.g., 7.5 kbp); they are easily manipulated with recombinant DNA techniques and have the ability to produce high titers.^{12,13} However, adenoviral vector infection enlists a variety of humoral and cellular immune responses.¹⁴ Therefore, adenoviral vector therapy may result in acute toxicity and autoimmunity, and which clears transgene-expressing cells, reducing the efficacy of therapy.¹³ Of interest, this autoimmunity can be targeting to adenovirus-infected cancer cells, and thus used as an oncolytic agent.¹⁵

ADENO-ASSOCIATED VIRAL VECTORS

The adeno-associated viral vector (AAV) has the abilities to infect both nondividing and dividing cells and to persist without vector integration.^{16,17} Upon entering host cells, wild-type AAV DNA becomes episomal or integrates into the genome; in contrast, current, modified AAV vectors are designed to lose their integrating ability.¹⁸ AAV can carry a transgene up to 4.7 kbp. The AAV genome is single-stranded DNA and vector preparations are composed of a mixture of vector particles having one of the two strands of the virus. Upon transduction, the

required annealing of the two strands delays gene expression. This limitation can be overcome by using a self-complementary design in which the two strands of the transgene are on a single hairpin genome in an inverted orientation, which allows quick assembly into a transcription unit following transduction.¹⁹

GENOME-INTEGRATING VIRAL VECTORS

Retroviral Vectors

A feature of retroviral vectors is that they have the ability to stably incorporate their viral DNA into the host genome, which can result in long-term expression of the transgene. Most retroviral vectors are γ -retroviral or lentiviral vectors. Lentiviral vectors are usually HIV-1 based, or may also contain elements of simian immunodeficiency virus, and have at least three advantages over γ -retroviral vectors; first, the lentiviral vector preintegration complex is able to cross the nuclear membrane in host cells even in the absence of mitosis and, therefore, is able to transduce nondividing cells, such as HSCs.²⁰ Second, the lentiviral vector preintegration complex is more stable and persists longer, which improves the likelihood of integration.²⁰ Third, γ -retroviral vectors prefer to integrate near gene transcription start sites, such as the CpG islands and conserved noncoding sequences and conserved transcriptional factor binding sites, whereas lentiviral vectors are more evenly distributed, reducing the likelihood of driving the expression of a deleterious gene(s).²² Lentiviral vectors have thus emerged as an important advance for gene therapy in the hematologic disorders.

GENE THERAPY FOR HEMATOLOGIC DISEASES

X-LINKED SEVERE COMBINED IMMUNODEFICIENCY

X-SCID is a single-gene-deficient disease caused by mutations in the gene of the interleukin-2 receptor, γ IL2RG (Chap. 80).²³ Lack of functional γ IL2RG results in a lack of T and NK cells and poorly functional B cells. X-SCID is a fatal disease, and without medical interventions, patients often die within the first 2 years of life.²³ During 1999 to 2006, 20 X-SCID children were treated in two gene therapy trials.^{24,25} Because patients lacked a human leukocyte antigen (HLA)-identical donor, precluding stem cell transplantation as a curative therapy, all 20 patients were given a single γ -retroviral vector-mediated gene therapy in which a wild-type γ IL2RG gene was delivered into patients' T cells. From 5 to 12 years of observation after the gene transfer procedure, 17 of the 20 treated participants are alive and display nearly full correction of the T-cell deficiency by genetically modified T cells.^{24,25}

ADENOSINE DEAMINASE DEFICIENCY SEVERE COMBINED IMMUNODEFICIENCY

Adenosine deaminase (ADA) deficiency is an autosomal-recessive inherited disorder caused by mutation of *ADA* gene on chromosome 20 (Chap. 80). ADA deficiency leads to inhibition of DNA synthesis, which is particularly toxic to lymphocytes because they are some of the most mitotically active cells. This condition ultimately causes SCID. ADA-SCID is almost always fatal by 2 years of age. Gene therapy with a normal *ADA* gene expressed in autologous HSC is a potentially curative treatment. However, early attempts at gene therapy did not show any clinical benefit. In the late 1990s, when improved retroviral vector and preinfusion chemotherapy conditioning were instituted, success occurred. Since 2000, 40 patients have been treated in Italy,

Great Britain, and the United States.²⁶⁻²⁸ In these studies HSCs were transduced with a γ -retroviral vector encoding the *ADA* enzyme. Low-intensity conditioning with either busulfan or melphalan was used to increase engraftment of stem cells. In some patients the corrected *ADA* gene can be detected in blood mononuclear cells for more than 9 years, and the ADA enzyme remains at a normal level.²⁷

WISKOTT-ALDRICH SYNDROME

Wiskott-Aldrich syndrome (WAS) is the result of a mutation in the gene encoding the WAS protein (*WASp*).²⁸ The gene is located on the short arm of the X chromosome and WAS is an X-linked recessive genetic disorder. WASP activates actin polymerization in almost all blood cells. Hereditary deficiency in WASP is associated with microthrombocytopenia, recurrent infections, eczema, high incidence of autoimmunity and hematopoietic malignancy (lymphoma or leukemia).²⁹ In 2010, three patients in Italy were administered a lentiviral vector engineered to express *WASp* following busulfan conditioning. All three WAS patients showed excellent multilineage engraftment with an average of 0.4 to 0.9 correct gene copy per genome persisting to 30 months. Symptoms of WAS improved substantially. Pretreatment eczema resolved between 6 and 12 months after therapy. The frequency and severity of infections progressively decreased, and cytomegalovirus replication was controlled, allowing withdrawal of anti-infectious prophylaxis in two patients. Improvement of platelet count resulted in discontinuation of platelet transfusions.³

LEUKODYSTROPHIES, X-LINKED ADRENOLEUKODYSTROPHY, AND METACHROMATIC LEUKODYSTROPHY

There are two major leukodystrophies, X-ALD and metachromatic leukodystrophy (MLD); both have been successfully treated with gene therapy.^{4,6} X-ALD is a severe genetic demyelinating disease caused by mutations in the *ABCD1* gene on the X chromosome that encodes the adrenoleukodystrophy (ALD) protein, an adenosine triphosphate binding cassette transporter. ALD deficiency leads to the accumulation of very-long-chain fatty acids and progressive demyelination in the central nervous system. In 2009, two French children were reported to have autologous HSC gene therapy with a lentiviral vector encoding wild-type *ABCD1*.⁶ The patients were given myeloablative regimen conditioning with cyclophosphamide and busulfan. ALD protein was expressed in 23 and 25 percent of blood mononuclear cells in the two patients. Over 3 years of followup, corrected *ABCD1* was found in 7 to 14 percent of granulocytes, monocytes, and T and B lymphocytes. Cerebral demyelination was arrested.⁶

MLD is an autosomal recessive disorder caused by mutations in *ARSA* gene in chromosome 22 that encodes arylsulfatase A (ARSA). Deficiency in ARSA leads to sulfatide accumulation, eventually destroying the myelin sheath of the nervous system. In 2013, three children with the disease received autologous HSC gene therapy with a lentiviral vector encoding wild-type *ARSA*.⁴ After myeloablative conditioning with busulfan, engraftment was excellent with 45 to 80 percent gene marking levels. ARSA activity was restored to above normal values in the hematopoietic lineages and the cerebrospinal fluid.⁴ There was a clear therapeutic benefit. In X-ALD and MLD gene therapies, corrected cells did not have an obvious selective advantage. However, in both cases the gene marking levels were high (>10 percent) for as long as 2 years.^{4,6} These results indicate that successful gene therapy can be achieved with very high viral transduction rates, even absent a transduced cell selection mechanism.

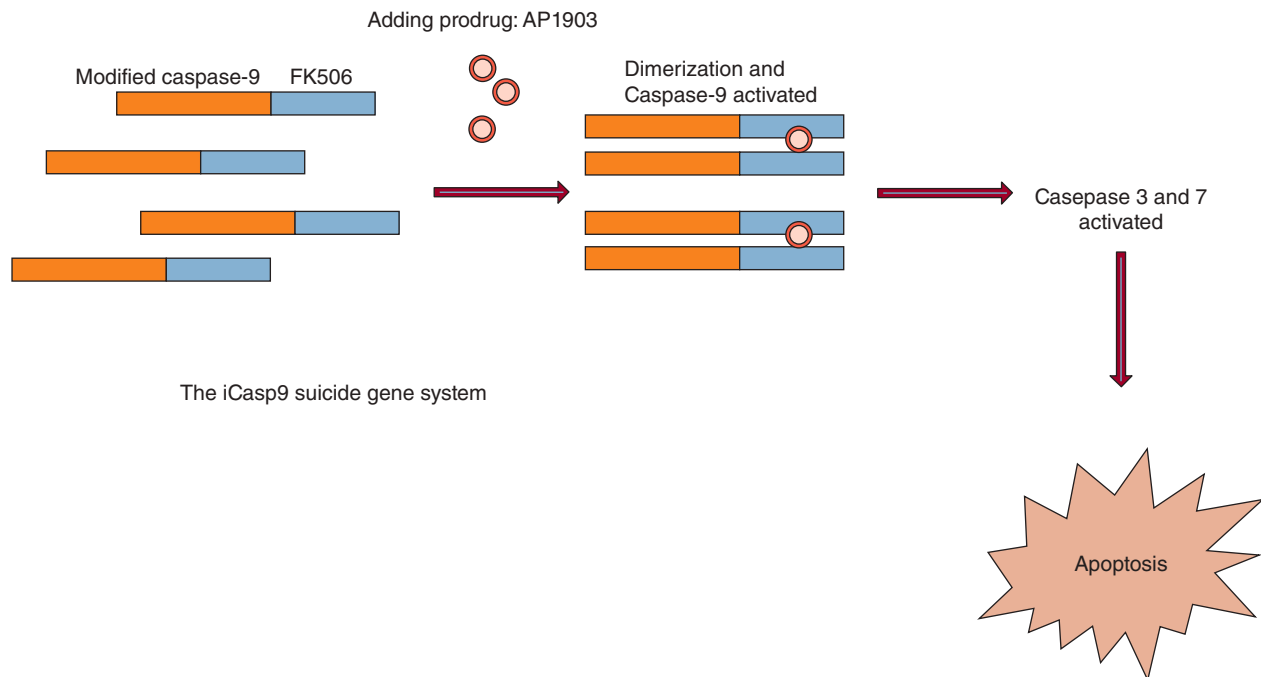

Figure 29–2. Inducible caspase-9 protein (iCasp9) suicide gene therapy system. A fusion protein contains a mutated FK506 protein linked to the modified caspase 9 (deleted for activation and recruitment domains). The prodrug AP1903 interacts with the FK506 domain and triggers the fusion protein dimerization, which activates caspase-9. Activated caspase-9 initiates the cell caspase cascade (caspases 3 and 7) and induces cell death by apoptosis.

Avoiding Graft-versus-Host Disease

Gene therapy can lead to graft-versus-host disease (GVHD), especially after an allogeneic stem cell transplantation. To prevent GVHD, a suicide gene is introduced in the transferred cells; in the event of GVHD, a prodrug is given to activate the suicide gene to kill the transduced cell. This “safety mechanism” can also guard against uncontrolled proliferation of targeted cells. Traditionally, the suicide gene is herpes simplex virus thymidine kinase (*HSV-TK*), which can be made “suicidal” in the presence of ganciclovir (GCV). Once GCV is phosphorylated by *HSV-TK*, it turns to a nucleotide analogue that inhibits DNA synthesis and kills the cell.³⁰ Another new suicide gene system was developed by an inducible caspase-9 protein (iCasp9), which activates the mitochondrial apoptotic pathway. Its use is based on caspase-9 dimerization to an active form. The catalytic domain of caspase-9 is fused to a modified FK506-binding domain that can be homodimerized by a chemical inducer, such as AP1903 (Fig. 29–2). In a clinical trial, four patients who had undergone stem cell transplantation for relapsed acute leukemia were treated with the modified T cells. A single dose of AP1903 was given when GVHD developed, which eliminated more than 90 percent of the modified T cells within 30 minutes and eliminated the clinical signs of GVHD.³¹ In comparison to *HSV-TK*, iCasp9 offers several advantages. It induces cell death faster, does not rely on cell proliferation, which makes it ideal for cancer stem cell killing; and, because caspase-9 is downstream of the mitochondria, the sensitivity of cells to its activation should be independent of the antiapoptotic BCL-2 family of proteins, which is often upregulated in hematologic malignancies.

HUMAN IMMUNODEFICIENCY VIRAL INFECTION

The HIV infects helper T cells, such as CD4+ T cells, macrophages, and dendritic cells. The infection kills CD4+ T cells and cripples cell-mediated immunity (Chap. 81). Without treatment, average survival

time after infection with HIV is estimated to be 9 to 11 years. In 2007, a gene therapy trial demonstrated that AIDS can be cured. A patient with an HIV infection and acute myeloid leukemia was given allogeneic stem cell transplantation from a selected donor, whose two copies of the chemokine (C-C motif) receptor 5 gene (*CCR5*) were lost because of mutations.³² *CCR5* is the major cellular coreceptor used by HIV to infect CD4+ T cells. The patient has since remained off anti-HIV drugs for 7 years. This case generated enormous interest in gene therapy approaches to cure HIV by blocking *CCR5* expression. One of the most promising methods is to create loss of function mutations of *CCR5* with zinc-finger nucleases (ZFNs). ZFNs are artificial restriction enzymes generated by fusing zinc fingers to a nonspecific double-strand DNA cleavage protein, a truncated Fox1.³³ A zinc finger can be engineered to a target 18 to 24 bp sequences in *CCR5* DNA. ZFNs can repeatedly cut the DNA at a targeted site and eventually mutate *CCR5* when repair errors occur. In a 12-patient clinical trial, the patient’s CD4+ T cells were infected *ex vivo* with a ZFN-expressing adenoviral vector to disrupt *CCR5*.³⁴ The modified cells were then reintroduced. CD4 T cells lacking *CCR5* are resistant to HIV infection. Ultimately, the *CCR5*-mutated cells replace those vulnerable *CCR5* wild-type cells. The infusion immediately increased the circulating CD4+ T cell count from a median of $488 \times 10^9/L$ to $1517 \times 10^9/L$ in the first week. The modified cells were also found in T-cell-rich gut-associated lymphoid tissues. Patients were off antiviral drugs for 84 days during which time the circulating CD4+ T cells dropped while viral load spiked. Antiviral treatment had to be reinstated.³⁴ The *CCR5*-mutated CD4+ T-cell count remained stable even during the drug-off period, consistent with their resistance to HIV killing. However, *CCR5*-mutated CD4+ T cells apparently did not expand quickly, which may explain why in this trial the modified cell infusion alone was insufficient to control the HIV infection. Another trial used a lentiviral anti-HIV small interfering RNA (siRNA) expression vector to modify HSCs.³⁵ Although long-term (18 months) expression of siRNA in multiple blood cell lineages was observed, modified

cell levels were less than 0.4 percent. The fact that both modified HSCs and T cells failed to repopulate indicated that the *in vivo* selection of modified HIV-resistant cells may be weak or the modified T cells do not have a proliferative reaction to HIV infection. In both cases, the engraftment rate was very poor (T cell <10 percent and HSC <0.2 percent), which could indicate that the modified cells do not have a sufficient starting number for repopulation. New trials are underway with an improved lentiviral vector, engraftment protocols and a methylguanine DNA methyltransferase (MGMT) *in vivo* selection mechanism.³⁶ The cure for HIV by gene therapy has shown promise, but some clinical obstacles have to be overcome to achieve success.

DISORDERS OF HEMOGLOBIN

Thalassemia and sickle cell disease represent the most common single-gene defect diseases worldwide (Chaps. 48 and 49). β -Thalassemia is caused by a mutation in the β -globin gene, resulting in reduced adult hemoglobin A (HgbA) and severe anemia.³⁷ Therefore, gene therapy is used to express a normal β -globin gene. Many efforts have been made to use stem cell gene therapy. However, success has been very limited.³⁷ Although a weak survival advantage for corrected red cells at an early mature stage was observed, the *in vivo* selection alone appears insufficient to achieve a sustained correction.³⁸ It is predicated that it would require 20 percent of the primitive hematopoietic cells to be genetically modified, and the gene expressed at near normal levels in those cells, to achieve a definitive therapeutic benefit. Even higher levels of corrected cells (approximately 100 percent) might be required to cure the disease.³⁸ The first successful clinical trial was reported in 2007.³⁹ An 18-year-old patient with severe β -thalassemia dependent on monthly red cell transfusion since age 3 years, received HSC lentiviral β -globin gene therapy. The viral transduction rate was approximately 30 percent. The patient continued receiving transfusions for 16 months after the transplantation, at that point the therapeutic HgbA was sufficient and maintained at a sufficient level until 33 months (Fig. 29-3). During the final 21 months, 100 percent of HgbA was from modified cells and the patient was transfusion-free. However, the therapy effect was later found to be from a dominant clone (>60 percent of all viral insertion sites in nucleated blood cells at 24 months), in which the viral insertion causes transcriptional activation of *HMGA2* in erythroid cells.³⁹ Nevertheless,

the patient remained with a good quality life with a stable Hgb of 9 to 10 g/dL, transfusion-free, and cancer-free for up to 7 years.⁴⁰ The dominant clone might indicate a strong *in vivo* selection, however, the level of gene modified cells in this patient has been never greater than 21 percent, and the highest level noted in blood was 10.9 percent and in erythroblasts was 3.3 percent, which is below that predicted. The dominant clone remained stable over time. However, *HMGA2* overexpression was detected in erythroid cells, which could enhance *in vivo* selection and proliferation of the corrected cells. Nevertheless, this is but a single case; whether the *in vivo* selection of the dominant clone had a significant role is not clear. More trials are needed.

HEMOPHILIA

Hemophilia is an X-linked single-gene defect, of which 70 percent of affected patients display inheritance and 30 percent develop from *de novo* somatic mutations (Chap. 124). There are two major forms of hemophilia: hemophilia A, caused by loss-of-function mutations of the gene encoding clotting factor VIII (FVIII), and hemophilia B, the result of mutations in the gene encoding clotting factor IX (FIX). Hemophilia A accounts for 80 percent of patients and hemophilia B for 20 percent.⁴¹ The absence of either FVIII or FIX severely impairs the ability to generate thrombin and, subsequently, fibrin, leading to spontaneous bleeding when the factor levels fall below approximately 5 percent of normal. Theoretically, gene therapy using a lentiviral vector that permanently expresses a normal *FVIII* or *FIX* gene in the patient could cure either disease. However, after 2 decades of intense research, gene therapy has been very difficult. FVIII and FIX are produced in hepatocytes, not in derivatives of HSCs.⁴² Therefore, hemophilia is not a circumstance for HSC-based gene therapy. The emerging approach to gene therapy for hemophilia is by using *in vivo* gene therapy (see Fig. 29-1). In this approach, viral particles are injected into a patient's vein, muscle, hepatic artery, or omentum.⁴³ Initially, five clinical trials with retroviral, adenoviral, or AAV vectors failed to achieve long-term expression of the coagulation factor and no measurable clinical benefit was observed.⁴³ However, a trial by a British-American team reported in 2011 showed exceptional results.¹⁵ This group focused on hemophilia B. The *FIX* gene, unlike the *FVIII* gene, is small and easy to insert into an AAV vector, and 1 to 2 percent of the normal blood levels of FIX

Figure 29-3. A typical successful gene therapy outcome. In this case a β -thalassemia patient was given a lentiviral vector that contains a HgbA^{T87Q} transgene. After infusion of modified HSCs 16 months (red arrow), HgbA^{T87Q} (red) completely replaced HgbA (blue) that was from prior transfusions. At this point, the patient had become transfusion-independent. (Adapted with permission from Cavazzana-Calvo M, Payen E, Negre O, et al: *Transfusion independence and HMGA2 activation after gene therapy of human β -thalassaemia*. *Nature* 16;467(7313):318–322, 2010.)

is sufficient to markedly reduce the bleeding risk.⁴³ A new improved AAV vector (AAV8) was used. This vector has a self-complementary genome to improve transduction efficiency, and was designed to produce fivefold higher levels of capsid protein to reduce a potential cytotoxic T-cell response and increase liver tropism. The AAV vector is not genome-integrating and maintains itself as an intracellular episome. Its gene expression in growing cells is transient because episomes may be lost with each cell division. But in quiescent tissues the AAV vector is capable of mediating long-term gene expression as episomal chromatin.⁴⁴ A single intravenous infusion of the vector was given to six adult male hemophilia B patients who had been treated with recombinant FIX for many years. No notable acute or chronic toxicities were observed. All six patients displayed stable FIX expression at 2 to 11 percent of normal blood levels for 3 years. Four of these patients discontinued recombinant FIX treatment and remained free of spontaneous hemorrhage.^{15,43,45} The same research team is attempting a similar approach for hemophilia A gene therapy; however, *FVIII* gene expression has been inefficient. One reason is gene size. The *FVIII* coding sequence is 7 kb, which far exceeds the normal packaging capacity of AAV vectors. By modifying the B domain, the *FVIII* size was reduced to a 5.2-kb AAV expression cassette, which is more efficiently packaged. Also, a hybrid liver-specific promoter was introduced into the vector. The resulting new AAV vector has shown high (15 percent of normal) FVIII expression for 20 to 45 weeks in four macaques.⁴⁶ This AAV vector will be used in a trial of hemophilia A gene therapy in the near future.

FANCONI ANEMIA

Fanconi anemia (FA) is caused by mutations in *Fanconi* genes, which encode the DNA repair proteins that form a function complex (Chap. 35). FA cells are hypersensitive to DNA crosslinking agents.⁴⁷ Sixteen *Fanconi* genes have been described. A defect in one of them will lead to FA. The disease is characterized by a high risk of developing marrow failure and later myelodysplasia, acute leukemia, or cancers of other tissues.⁴⁷ More than half of patients with FA are the result of *FANCA* gene mutations; therefore current gene therapy has focused on *FANCA* insufficiency. Gene therapy for FA is particularly challenging because of the low numbers of HSCs in the stage of marrow failure, and FA cells are extremely sensitive to DNA damage when exposed to myelosuppressive drugs used to condition the patient for stem cell transplantation. In a rare case, two identical twins had inherited *FANCA* mutations but with normal DNA repair in their blood stem cells. Functional *FANCA* in blood cells was found to be restored by a spontaneous intrauterine self-correcting somatic mutation in a single HSC. The fact that a single HSC was sufficient to restore a fully normal blood system indicates that *FANCA* gene therapy may require transduction of only a few HSCs.⁴⁸

In 2011, an international working group was established to facilitate the development of gene therapy for FA.⁴⁹ The initial protocol included delivery of a normal *FANCA* gene by a third-generation lentiviral vector into HSC and increasing HSC number by *in vitro* HSC expansion using a combination of HOXB4 and DELTA-1 proteins.⁵⁰

GENE THERAPY FOR CANCER

Gene therapy for cancer has been widely exploited. A review was published detailing the new developments in this field.⁵¹ This chapter has described a few significant new approaches.

One of the most creative new approaches to cancer-targeted gene therapy is the use of CAR for CLL, in which patient's T cells were modified to target their own cancers (Chap. 92).^{7,8} Another strategy is to

enhance conventional chemotherapy by protecting the marrow cells through gene transfer. Chemotherapy has a limited therapeutic window because of its severe toxic effect on marrow cells, and its leukemogenic potential. Because the lethal effect of chemotherapy is mainly DNA damage, especially methylating O⁶-guanine, to overcome the side effects, a strong chemoresistant DNA repair gene, a mutant (P140K) of MGMT was introduced into brain tumor patients' autologous HSC by a γ -retroviral vector, thus the patient's transduced marrow progenitor cells could be protected by the modified MGMT, permitting them to tolerate more cycles of chemotherapy. A phase I clinical trial demonstrated that intensification of chemotherapy was feasible, and there was an improvement in therapy outcome and patient survival in these small studies.^{52,53} A similar result was also observed in a recent clinical trial with a lentiviral vector (reported at the ASH meeting 2014).

NEW TECHNOLOGIES USED IN GENE THERAPY

IN VIVO SELECTION AND O⁶-METHYLGUANINE-DNA METHYLTRANSFERASE SELECTIVE METHOD

Whether stem cell gene therapy can cure a disease is dependent on the functionality of the gene-corrected cell. In the early successful gene therapy trials for X-SCID and ADA-SCID, a low (0.1 to 1.0 percent) engraftment rate was sufficient for long-term gene correction, and the single most important factor was that the transgene conferred a selective survival advantage on the transgene-bearing cell.³⁸ In contrast, a main reason for poor responses in other gene therapy trials has been that the gene-corrected cells have no, or only a weak selective advantage, such that the gene-transduced cell levels are insufficient to provide a clinical meaningful benefit. Therefore, *in vivo* selection is a key element in the success of clinical gene therapy.

The gene-corrected cells in the majority of hematologic genetic diseases have no *in vivo* selection advantage.³⁸ To overcome this problem, a second, selectable gene can be used to be coexpressed with the gene that corrected the defect. The second gene turns the cells into selectable cells.³⁸ The selectable gene can be cloned into a vector along with correcting gene driven by a single or separate promoter. Experiments have identified several selectable genes including multidrug resistance protein, dihydrofolate reductase, and MGMT.³⁸ MGMT shows the most promising results in large animal and humans trials. MGMT encodes a DNA repair enzyme O⁶-alkylguanine-DNA-alkyl-transferase, which confers resistance to the cytotoxicity of chemotherapy, such as BCNU and temozolomide (TMZ).⁵⁴ A MGMT mutant, P140K-MGMT, has at least a 50-fold stronger effect on drug resistance.⁵⁵ P140K-MGMT-expressed cells can be exposed to BCNU and TMZ selection pressure (Fig. 29-4). Clinical trials have demonstrated that P140K-MGMT protects the gene-modified cells from TMZ-induced toxicity.⁵² This strategy has also been used in a mouse model of HIV gene therapy.³⁶

Successful gene therapy with satisfactory gene marking levels (approximately 30 percent) are dependent on three factors: a high HSC transduction rate, a high engraftment rate, and *in vivo* selection.³⁸ Other trials indicate that if there are excellent transduction rates (80 to 90 percent) and excellent engraftment rates (gene copy marking/genome >0.5), these two factors can be sufficient to achieve a sustained gene correction, even without an *in vivo* selection mechanism.⁴ Nevertheless, if there is a low transduction rate and low engraftment rate, MGMT-mediated *in vivo* selection will be a very valuable tool to improve the likelihood of successful gene therapy.

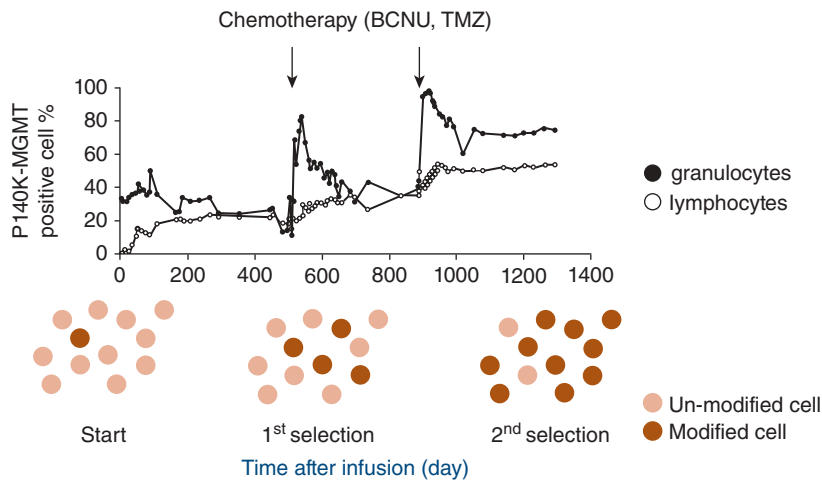

Figure 29-4. An example of P140K-MGMT (O⁶-methyl-guanine-DNA methyltransferase) *in vivo* selection. Studies in a monkey. The P140K-MGMT-modified cells continued to increase after each chemotherapy administration (selective pressures). BCNU, 1,3-bis-(2-chloroethyl)-1-nitrosourea; TMZ, temozolomide. (Adapted with permission from Beard BC, Trobridge GD, Ironside C, et al: Efficient and stable MGMT-mediated selection of long-term repopulating stem cells in nonhuman primates. *J Clin Invest* 120(7):2345–2354, 2010.)

OVERCOMING GENOTOXICITY BY TARGETED-INSERTION GENE THERAPY

To achieve sustained gene correction, some gene therapy approaches have used integrated vectors such as γ -retroviral or lentiviral vectors. Gene therapy for X-SCID,⁵⁶ WAS,⁵⁷ and chronic granulomatous disease (CGD)⁵⁸ has found that γ -retroviral insertion in the vicinity of protooncogenes is associated with the development of lymphoproliferative and myeloproliferative neoplasms. Improved lentiviral vectors have added safety features, such as no preference for integration near promoters, removal of viral promoter-enhancers, and self-inactivation. However, even with these new features, lentiviral vector-induced clonal dominance in human⁶ and murine leukemia have been reported.⁵⁹ DNA insertion is the most important factor to determine whether a therapy-related cancer will occur, especially as 80 to 90 percent of lentiviral vector insertions are within gene regions.²¹ Gene therapy with

viral vector insertion, in which the insertion site is uncontrollable, raises the risk of a secondary clonal disease. The FDA has not approved a single-gene therapy in the United States, largely because of the risk of uncontrollable insertional mutagenesis.

One way to reduce this risk is to select preferred sites of DNA insertion. Gene-targeting and gene-editing technologies could make this possible. Gene editing describes insertion of DNA at a desired location.³³ It starts with artificially engineered nucleases, such as ZFNs, which can create a double-stranded break (DSB) at a targeted DNA sequence anywhere in the human genome. The DSBs is repaired by homologous recombination (HR) repair or nonhomologous end-joining repair. The ZFNs can be cotransfected with another plasmid (donor DNA plasmid), in which a desired DNA sequence, such as a transgene has been inserted within a sequence that is homologous to the flanking sequences of the DSB. When this DNA sequence is used as a template by HR, it would result in insertion at a targeted location (Fig. 29-5).

Figure 29-5. Targeted transgene insertion. A targeted nuclease, such as zinc finger nuclease first generates a double-strand break (DSB). Thereafter, the DSB is repaired by homologous recombination repair using donor DNA with a transgene inserted within two homologous arms. When repair is finished, the transgene is inserted at the targeted site.

Using ZFN, a DNA (up to 9.6 kb)⁶⁰ can be inserted precisely into a selected location of the human genome. There are several known “safe harbors” in the human genome. For example, the *PPP1R12C* gene on chromosome 19 (*AAVSI* locus) is frequently integrated by an AAV and such an AAV-based integration is not associated with any subsequent pathologic events.⁶¹ Several genes have been inserted into the *AAVSI* site in human cells, including stem cells, using ZFN gene-targeting methods.^{60,62} The gene correction rate of gene editing is still very low (approximately 1 percent).⁶³ Fortunately, gene targeting is a fast-growing field. Many new technologies have developed in recent years. The transcription activator-like effector nuclease (TALEN)⁶⁴ and the clustered, regularly interspaced, short palindromic repeats (CRISPR)⁶⁵ technology show promise. Both TALEN and CRISPR are much easier and faster to use than the ZFN approach. These new gene-targeted technologies together may solve the retroviral insertion mutagenesis safety problems.

CHAPTER 30

REGENERATIVE MEDICINE: MULTIPOTENTIAL CELL THERAPY FOR TISSUE REPAIR

Jakub Tolar, Mark J Osborn, Randy Daughters, Anannya Banga, and John Wagner

SUMMARY

Regenerative medicine is a complex and rapidly advancing field that holds tremendous promise in treating, and even curing, many diseases. The understanding and control of tissue repair is one of the most urgent challenges in medicine today. Regenerative medicine seeks to either recruit the patient's reparative cells or to replace the malfunctioning tissue altogether to restore the deficient organ to adequate function. The common link among all types of regenerative therapies is the stem cell, which gives all tissues the capacity to regenerate. The mechanisms underlying the ability of a progenitor cell to differentiate have been challenging to elucidate, with recent experimentation focused on editing the genome itself. It has been even more difficult to determine how a differentiated cell can be instructed to revert to an immature state and undergo a re-specification to another differentiated cellular phenotype or an asymmetrical division to generate more immature cells. Our ability to modify genomes, harness stem cells, and transplant autologous or allogeneic tissues has transformed biomedical inquiry and offers hope to patients with diseases spanning all organ systems, including cardiac, lung, central nervous system, and liver and pancreatic diseases.

Acronyms and Abbreviations: ALS, amyotrophic lateral sclerosis; AMI, acute myocardial infarction; ATI or ATII, alveolar epithelial cells type I or II; BASCs, bronchiolar alveolar stem cells; BDNF, bone-derived neurotrophic factor; BM-derived, marrow-derived; CAR, chimeric antigen receptor; CDCs, cardiac-derived stem cells; COPD, chronic obstructive pulmonary disease; CRISPRs, clustered regularly interspaced short palindromic repeats; dmP-GE_{2,16,16}-dimethyl-prostaglandin E₂; DPSCs, dental pulp stem cells; DSB, double-strand break; EC, embryonic carcinoma; ESCs, embryonic stem cells; EPCs, epithelial progenitor cells; FAH, fumarylacetoacetate hydrolase; GVHD, graft-versus-host disease; HCT, hematopoietic cell transplantation; hESC, human embryonic stem cell; HR, homologous recombination; IDLV, integrase-deficient lentiviral; iPSCs, induced pluripotent stem cells; MN, meganuclease; MNCs, mononuclear cells; MSCs, mesenchymal stromal/stem cells; NHEJ, nonhomologous end-joining; NSC, neural stem cell; OPCs, oligodendrocyte progenitor cells; OT, off target; PD, Parkinson disease; SCID-X1, X-linked severe combined immunodeficiency; SCNT, somatic cell nuclear transfer; TALEN, transcription activator-like effector nuclease; TCR, T-cell receptor; TGF- β , transforming growth factor- β ; UBCs, umbilical cord blood cells; VEGF, vascular endothelial growth factor; ZFN, zinc finger nuclease.

INTRODUCTION

Regenerative medicine is a concept that evolved from knowledge in genome regulation and modification, from understanding of embryonic development and “stemness” of cells, and from 50 years of experience in human transplant biology. Therefore, a narrow view of any of these disciplines is not sufficient for illuminating the mechanisms of action underlying the already accomplished successes and for guiding the potential of novel basic biology discoveries into clinically meaningful regenerative medicine (Fig. 30–1).

Accordingly, this chapter spans major organ systems (marrow, liver, pancreas, brain, and spinal cord) to demonstrate their connectivity and shared biologic responses deployed at the times of acute and chronic injury. Furthermore, the goals of regenerative therapies are different than those of commonly used drugs. Medications are typically aimed at amelioration of symptoms, while regenerative medicine seeks to either recruit the patient's reparative cells or to replace the malfunctioning tissue altogether to restore the deficient organ to adequate function.

Regenerative medicine harnesses the body's own repair mechanisms to replace, restore, or regenerate damaged or malfunctioning cells and tissues in conditions as diverse as diabetes, heart disease, spinal cord injury, and types of blindness. Some regenerative medicine therapies are already in use, for example using unrelated hematopoietic cell transplant to regenerate a patient's immune system after their marrow has been destroyed by chemotherapy or radiation. There are some therapies that are in the early stages of clinical trials, for example using a patient's cells seeded onto a biomesh scaffolding to grow a new trachea, ear, or nose. Some therapies are on the cusp of progressing into clinical trials, such as differentiating human embryonic stem cells into beta cells that could produce insulin in diabetic patients. And some therapies, such as growing new lungs from patient cells and repairing a spinal cord injury with a cellular bridge, remain tantalizingly out of reach.

The zygote has the ability to give rise to a complete organism. Any cellular genome in the organism has the ability to code for any protein in the body. Although we know this, the mechanisms underlying the ability of a progenitor cell to differentiate have been challenging to elucidate. For the earliest critical steps in this long and complex process, we must look at developmental biology. Nuclear transfers in amphibians done by Briggs, King, and Gurdon^{1–3} established that bidirectionality of cellular fate determination is possible. It was, established by McGrath and Solter that this process is driven by a multitude of factors of such temporal and spatial complexity that it would make reprogramming of mammalian cells by nuclear transfer impossible.^{4,5} Recent experimentation has focused on editing the genome itself, finding success in both mouse and human DNA models. Much work remains to bring this technology into human therapies, but in the foreseeable future, cells and organisms will no longer be seen as being given sealed orders at birth, but rather the instructions contained in their developmental program can be thought of as “software” that can be rewritten and used to reprogram the genomic “hardware” of a cell.

It has been even more difficult to imagine and later define the possibility that a differentiated cell could be instructed to revert to an immature state and undergo a re-specification to another differentiated cellular phenotype or an asymmetrical division to generate more immature cells. Yamanaka's experimental proof reduced this perceived complexity to a four-factor recipe sufficient to restore skin fibroblasts to induced pluripotent stem cells (iPSCs).^{6,7,8}

This chapter gives a broad overview of the state of regenerative medicine as it stands today, a complex and rapidly advancing field that holds tremendous promise in treating, and even curing, many of the disorders that cause pain and suffering.

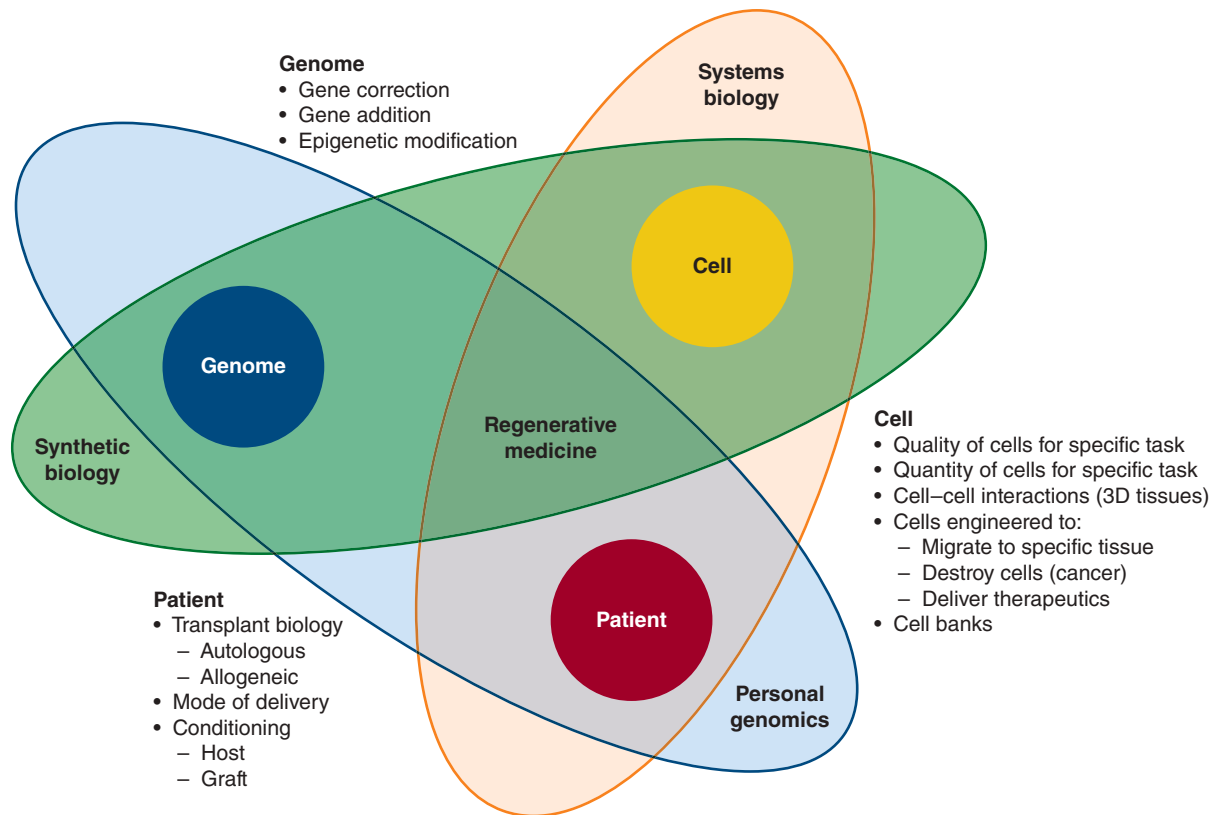

Figure 30-1. The three-body problem of regenerative medicine. The three factors—cell, genome, and patient—influence each other in complex and sometimes unexpected ways. These three separate scientific foci of regenerative medicine must be developed in the context of one another to have meaningful impact.

MULTIPOTENTIAL CELLS

EMBRYONIC STEM CELLS

Four to 5 days after fertilization, an egg becomes a blastocyst, a ball of approximately 100 to 150 cells. A small group of inner cells within the blastocyst are pluripotent and have the potential to replicate indefinitely and to become any of the differentiated types of tissue in the body. These pluripotent cells are called embryonic stem cells (ESCs). ESCs have the dual ability to self-renew (copy themselves) and differentiate (produce more specialized types of cells of the body).

ESCs were first isolated from mice when embryonic carcinoma (EC) cells⁹ were shown to proliferate indefinitely like stem cells and were used to generate a chimeric mouse. Further development of the culture conditions for EC cells that used feeder (supporting) cells, along with discovery of cell-surface antigens, like SSEA-1 and F-9 antigen on EC cells, led to the isolation of the first ESCs from a mouse embryo in 1981.¹⁰ In 1995, Thomson isolated ESC lines from a non-human primate,¹¹ followed by the first successful isolation of human embryonic stem cell (hESC) lines in 1998.¹² The use of human ESCs in research, however, has been severely limited because of the social and religious concerns that the blastocyst is destroyed when the ESC lines are generated.

hESC lines can be cultured on feeder cells where they divide infinitely. They can also be grown without feeder cells, where they develop into clusters known as embryoid bodies. Using cells from a human blastocyst in clinical therapy has been difficult, so the 2006 discovery by Yamanaka and Takahashi that pluripotent stem cells could

be created from skin cells⁶ revolutionized the stem cell research. Their pioneering work showed that inducing skin cells with four genes (*Oct4*, *SOX2*, *Klf4*, and *c-Myc*) would generate pluripotent embryonic stem-like cells *in vitro*. These cells, known as iPSCs, have the basic properties of hESCs while being derived from somatic cells rather than blastocysts.

An alternative approach for obtaining pluripotent stem cells is somatic cell nuclear transfer (SCNT).¹³ In this process, the nucleus of an adult human cell is placed in an egg cell that has had its nucleus removed. As this cell divides it can be a source of pluripotent stem cells. A recent study verified that the SCNT pluripotent stem cells are more similar to ESCs than are iPSCs.¹⁴ Although much research remains to be done, SCNT pluripotent stem cells appear to have potential in regenerative medicine.

There are many disorders and defects that arise from errors in the complex process of embryonic development. Research over the past decade advanced our understanding of the critical steps in the embryonic development of mice; however, information about the embryonic development of humans remains limited. Although there is overlap with what has been learned from studying mouse embryos, human embryonic growth is different and unique. However, by growing hESCs in the laboratory the multitude of regulatory factors that control the different stages of cell, tissue, and organ system development can be studied and can also provide insights into how our adult tissues are maintained and repaired and allows identification of the causes of birth defects by discovering what interferes with the normal path of cell fate acquisition. The hESCs are also used to produce laboratory disease models in specialized cells like nerve, heart, or beta cells and can also be used for development of new drug therapies.

Despite the much-anticipated potential of hESCs to differentiate and replace malfunctioning cells in the body, progress toward clinical use has been hindered by the possibility of teratoma formation or the immune rejection of the allogeneic transplanted cells and production issues.

INDUCED PLURIPOTENT STEM CELLS

Generation of iPSCs has connected several previous observations into a coherent outline. For example, the ability of transcription factor MyoD to change fibroblasts to myoblasts¹⁵ and of transcription factor Antennapedia to change development of antennae into legs in *Drosophilla*,¹⁶ uncovered potential of a differentiated cell to assume an alternative cell fate as a result of defined, externally provided signals.

The understanding of induced pluripotency has become more refined as additional reprogramming factors are identified,¹⁷ the critical role of epigenetic regulation is uncovered,¹⁸ and with the dynamics of iPSC generation (from initially random event to deterministic process) more fully developed.¹⁹

The reprogramming technology applied to human cells iPSCs allows for modeling various, typically genetic, disorders.^{20,21} Furthermore, organoid cultures derived from the patients themselves allow for high throughput drug testing that would be impossible without the supply of differentiated cells from patient-specific iPSCs.

The first preclinical example of iPSC technology conceptually applied to human disease has been amelioration of the sickle cell anemia phenotype in a murine model.²² At the time of this writing, the first iPSC-based clinical trial opened in Japan for individuals with exudative age-related macular degeneration.²³

New knowledge derived from the rapidly expanding iPSC field has also reenergized the technology of direct reprogramming, whereby one differentiated cellular phenotype (such as a dermal fibroblast) can be induced to convert into another somatic cell (such as a neuron) without the intermediate iPSC stage. In contrast to the expandable iPSC-based generation of differentiated cells, the process of direct reprogramming makes it more challenging to produce the large numbers of cells needed for therapeutic intervention.

An example of this strategy has been *in vivo trans*-differentiation of exocrine pancreatic cells or biliary epithelial cells into insulin-producing endocrine cells in rodent models.^{24,25} A conceptually different concept to solve the same clinical challenge has been blastocyst complementation whereby rat iPSCs were injected into blastocysts that had been derived from mice deficient in pancreatic organogenesis, which resulted in the development of a functional rat pancreas in mice.²⁶ In addition to reducing the cell numbers needed to create a physiologically meaningful effect, the efficacy of both strategies may be enhanced by targeting them into a permissive cellular niche.

HEMATOPOIETIC STEM CELLS

The earliest advances with clinical potential will most likely arise from understanding reprogramming in hematopoietic stem cells. Not only was hematopoietic cell transplantation the first stem cell therapy, developed close to half a century ago, but reports of using defined factors to turn committed blood progenitor cells into transplantable hematopoietic cells^{27,28} suggest that robust generation of clinical-grade, patient-specific autologous grafts for transplantation is possible.

Equally important has been combination of pluripotentiality of ESCs and iPSCs with their commitment to specific lineages, such as hemogenic differentiation program. Derivation of hematopoietic stem cells from murine ESC and their genetic correction has been used in murine severe combined immune deficiency²⁹; similarly in a model

of sickle cell anemia, hematopoietic stem cells derived from gene-corrected murine iPSCs²² have established preclinical proof-of-concept for combined gene correction and stem cell engineering. Furthermore, insights from murine embryogenesis were applied to *in vitro* induction of mesoderm and ESC differentiation to blood cells via coculture with feeder cells or generation of embryoid bodies. These seemingly straightforward concepts, however, have proven challenging to mimic in human ESCs and iPSCs. Despite many attempts, current technology appears to lead only to low hematopoietic chimerism after transplantation of hematopoietic stem cells derived from pluripotent human cells.^{30,31} An alternative to generation of transplantable human hematopoietic stem cells is direct conversion of fibroblasts to hematopoietic stem cells without the iPSC intermediate. This is done by using forced expression of OCT4³² and differentiation of human pluripotent progenitor cells by forced expression of GATA-1, ETV2, and TAL-1 into hemoendothelial cells.³³

The replacement of hematopoiesis by marrow transplantation is the prototype of regenerative medicine. While the initial experimentation with marrow transfers on both sides of the Atlantic was almost immediately recognized as a pioneering effort in hematology, it was only later understood as a turning point in the larger field of regenerative medicine. The critical evidence was the ability of a relatively small number of donor cells to repopulate the host and reconstitute its full lymphohematopoietic system. Although initially applied to leukemia and lymphoma therapy in an effort to replace the malignant lymphohematopoiesis with a healthy wild-type system, it later became clear that the immune elimination of the tumor (graft-versus-leukemia, graft-versus-lymphoma) is the dominant mechanism behind successful therapy in many cases.

This remarkable regenerative capacity of hematopoietic stem cells established marrow, and later cord blood, transplantation as the blueprint for other stem cell therapies.

MESENCHYMAL STROMAL CELLS

Originally defined by how they were identified—they adhered to the surface of a culture dish³⁴—marrow-derived mesenchymal stromal/stem cells (MSCs) were then identified as key support cells in the cellular niche. Evidence from different sources (e.g., marrow, umbilical cord blood, and adipose tissue) suggests that MSCs have different functions in various organs (e.g., as pericytes in adventitia of blood vessels, or as supporting cells in marrow periosteal and endovascular hematopoietic niches).^{35–37} In addition to this developmental heterogeneity, cultured MSCs display various levels of “stemness,” and the cellular products used in therapeutic applications may be more a cell culture artifact than a counterpart to physiologic functionally integrated MSCs. This is not necessarily a disadvantage, as the culture process enables both amplification of cell numbers and defined release criteria for clinical use.

The most striking application of MSCs in medicine to date relies not on the regenerative capacity of MSCs alone but on the immunosuppressive potential of MSC cultures in the setting of severe graft-versus-host disease (GVHD),^{38–40} a serious complication of allogeneic hematopoietic cell transplantation (HCT).⁴¹ The treatment options for individuals with glucocorticoid-resistant severe GVHD have been inadequate, and mortality in this subgroup remains high. In a paradigm-changing study, it was demonstrated that culture-expanded MSCs can ameliorate severe GVHD.^{38,42} The induction and maintenance of MSC-driven regulation of immune and inflammatory reactions⁴³ has made it possible to assess their role in autoimmune and inflammatory disorders such as Crohn disease, arthritis, diabetes, organ rejection, and bridge therapy before solid-organ transplantation.^{44–46}

The regenerative potential of MSCs has long been sought as a tool to rebuild and replace tissues damaged by acute or chronic injury whereby injected cultured MSCs activate endogenous repair mechanisms and disappear in the process.⁴⁷ In this capacity, MSCs in preclinical models have been shown to alleviate ischemic injury in the heart, brain, and kidneys; toxic insults to lung and liver; and degenerative damage to joints; and it is possible that in some settings allogeneic MSCs may be even more effective than autologous MSCs.⁴⁸

Lastly, MSCs are relatively easy to gene-modify and thus can be used as cellular vectors for delivering gene therapeutic agents in both inborn genetic disorders and acquired conditions, such as in anticancer therapy or for trophic factor support after surgery.

● REGENERATIVE MEDICINE

CARDIAC REPAIR

Cardiovascular disease is a leading cause of death in the world, leading to an estimated 17 million deaths per year.⁴⁹ As life expectancy in the developed world rises, so too do risk factors associated with chronic heart disease. It is estimated that there are approximately 800,000 new cases of acute myocardial infarction (AMI)⁵⁰ annually. Heart failure occurs when there is significant deprivation of oxygen to cardiac tissue, which results in decreased cardiac output and function as a result of loss of cardiomyocytes, scar formation, and tissue remodeling.⁵⁰ Identifying ways to regenerate or repair heart tissue will be key to developing effective treatment options for heart failure.

Since the mid-1990s, scientists have been investigating the potential of adult progenitor cells for use in heart regeneration. These early studies were triggered by the discovery that certain adult tissue-specific stem cells could be differentiated *in vitro* to become cardiac-like cells.⁵¹ This discovery led to many preclinical studies that assessed the ability of adult stem cells to repair or enhance cardiac function after various types of injury.

The cells reported to differentiate *in vitro* to cardiac-like cells *in vivo* are satellite cells, which are undifferentiated skeletal muscle myoblasts,⁵² which led to studies using autologous skeletal myoblasts surgically implanted into the heart muscle.⁵³ Although these cells survived for short periods of time, they retained their intrinsic contractile properties and did not fully integrate into the cardiac tissue,⁵⁴ which led to arrhythmias and gave little long-term significant benefit in overall heart function.

Some marrow-derived cell populations (lin⁻; c-kit⁺) were capable of differentiating to myocytes expressing cardiomyocyte markers such as Nkx2.5, Gata4, and MEF.⁵⁵ These marrow-derived cells were shown to survive in infarcted hearts and were capable of differentiating into smooth muscle and endothelial cells but not cardiomyocytes *in vivo*.⁵⁶ Additional studies demonstrated that other marrow-derived progenitor cell populations (endothelial progenitors, angioblasts, or CD34⁺ cells) were able to contribute to angiogenesis and neovascularization of the infarcted myocardium.⁵⁷ This differed from more immature marrow progenitor populations, called *side-population cells* (Lin⁻ c-kit⁺ Sca-1⁺), that not only contribute to neovascularization but also regenerate myocardium.⁵⁸ These marrow-derived side-population cells homed to the border zone of infarction and resulted in improved left ventricular function.⁵⁸ The cardiac regeneration capacity of the marrow-derived progenitor cells facilitated large-scale clinical studies using heterogeneous populations of bone mononuclear cells (MNCs), also called *epithelial progenitor cells* (EPCs), for cardiac repair in patients with AMI^{59,60} or ischemic cardiomyopathy.⁶¹ These studies showed only moderate improvements, and therefore led to further refinement of the selection criteria for marrow-derived cells (CD34⁺/CD133⁺) and changes in the route of administration (intracoronary injection) in the Regeneration

by Intracoronary Infusion of Selected Population of Stem Cells in Acute Myocardial Infarction (REGENT) study, which still only showed modest success.⁶²

The moderate success of marrow-derived MNCs spurred the investigation of other populations of adult progenitor cells, as well as new routes of administration. The investigations led to the discovery of MSCs, as well as endogenous cardiac-derived stem cells, that could differentiate into cardiomyocytes and endothelial cells in animal models.⁶³ These findings led to clinical studies comparing marrow-derived MNCs versus the new MSCs used for intracoronary injection into patients with ischemic cardiomyopathy.⁶⁴ These tests showed significant improvement in left ventricle ejection fraction in response to MSC treatment.

To date, the clinical success of cell therapy approaches for cardiac regeneration has been mixed. This is in contrast to the promising early preclinical studies that showed significant improvement in many different measures of cardiac function. This difference has been attributed to the differences between rodent cardiac injury models and human clinical pathology, the cell population administration route, the origin of the cell populations, and the limited number of cells injected.

ESCs, because of their pluripotency and unlimited ability to proliferate, have been the subject of extensive preclinical investigation for many tissues, particularly cardiac tissue repair.^{65,66} However, there has been less enthusiasm for hESC-derived cardiomyocytes for human cell therapy because their allogeneic nature requires concomitant immunosuppressive therapy and because ethical issues surround their derivation. Despite these challenges, clinical studies have begun to collect ESCs for cardiac differentiation with the intent of being used in a trial for AMI patients. However, as about any somatic cell can be used to generate embryonic stem-like iPSCs,⁶⁷ with the capability to differentiate into cardiomyocytes, endothelial cells, and smooth muscle cells.⁶⁸ Initial preclinical studies of murine iPSC-derived cardiomyocytes, injected into ischemic myocardium, led to rejection of transplanted cells by immune reaction as well as continuous proliferation that led to teratoma formation.⁶⁹ Although iPSCs are attractive for their allogeneic potential they have potential disadvantages for human cell therapy based on their oncogenic nature, epigenetic memory, and maintenance of potency for other cells types.

Growing tissues *in vitro* for use in regenerative therapies has been investigated as another delivery method of cells for heart repair. This tissue engineering approach involves seeding cells onto scaffolds and growing them for later engraftment or for the generation of whole organs.⁷⁰ In these systems, cells are transplanted with the scaffolding to the cardiac wall, which provides structural support and a better micro-environment for the migration of cells into the damaged myocardium.⁷¹

A common theme in most preclinical and clinical cell therapy-based studies is the demonstration of improvements in cardiac function that is not correlated to number of cells injected or their longevity after administration. This observation has led investigators to speculate that transplanted cells improve cardiac function through paracrine rather than structural effects. This model suggests that observed improvements in myocardial regeneration or vasculogenesis are a result of transplanted cells secreting molecules that are known to improve cardiovascular function after injury.⁷² The effects of paracrine factors include decreased inflammation, increased angiogenesis, induction of proliferation of cardiomyocytes or protection of existing ones, and activation of endogenous stem cells.⁷³ Ischemic hearts subjected to secreted factors showed an increase in the expression of genes involved in cardiogenesis and a downregulation of cell-death markers, effects that contribute to survival of ischemic cardiomyocytes.⁷⁴ The advantage of the paracrine model is the potential for the commercial development of paracrine factors that have proven potential for cardiac repair.

LUNG REPAIR

The prevalence of lung diseases, like the chronic obstructive pulmonary diseases (COPDs) that include asthma and emphysema, has increased dramatically over the last 50 years. Lung disease is expected to become the third leading cause of disease-related death in the world by 2020. New therapeutic approaches from regenerative medicine are being developed ranging from stem cell therapies to bioengineering of entire tissues of the respiratory system for transplantation. These approaches are based on initial observations that endothelial progenitor cells and mesenchymal stem cells can differentiate *in vitro* to cells expressing lung epithelial markers and contribute to mature functional bioengineered tissues.

Throughout the pulmonary tract there exist many different niche environments containing distinct epithelial cell types that contribute to the complexity of the lung. Identification of a true endogenous stem cell population that is responsible for maintaining lung tissue under steady state and injury has been challenging and has been a source of controversy.⁷⁵ Evidence from rodent models and human lungs suggests that the adult endogenous airway, alveolar epithelial cells, lung stroma, and pulmonary vasculature all contain putative stem cell populations that can repair damaged tissue.^{76,77} These studies suggest the lung has a regional hierarchy of stem and progenitor cells that are specific for proximal versus distal airways as well as alveoli.

Identifying endogenous lung stem cells is complex because many different subpopulations of basal epithelial cells exhibit restricted patterns or roles in self-renewal for steady-state maintenance or after injury.^{78,79} In the distal airway, putative progenitor cells have been identified in the neuroepithelial body,⁸⁰ bronchoalveolar duct junction,⁸¹ by specific markers of self-renewing lung epithelial cells,^{82,83} and by function as bronchiolar alveolar stem cells (BASCs). This is in contrast to alveolar epithelial repair thought to be regulated by type 2 alveolar epithelial cells (A2IE) because they have been shown to be precursors to type 1 (A1IE) cells.^{84,85} Identification of regionally specific stem cell populations is further complicated by the demonstration that isolated distal airway progenitors (BASCs, CK5+/p63+) can differentiate into A2IE and A1IE cells.^{86,87} Regardless, all of these cells show unique functions in repair after injury, reside in different locations in the distal airway and alveolar epithelium, and play different roles as endogenous lung epithelial progenitors.

Many preclinical studies have shown that EPCs can increase function in pulmonary lung injury models.^{88–90} This improvement in function could be because of contributions to structure, paracrine effects, modulation of immune responses, or a combination of these.⁹⁰ EPCs have also been demonstrated to preferentially home to sites of injury in the lung after systemic administration⁹¹; consequently, autologous EPCs have been used clinically in pulmonary hypertension patients and showed improved cardiopulmonary outcomes.^{92,93}

Marrow MSCs are known for their immunomodulatory effects in a wide range of diseases.^{94,95} The beneficial effect of MSCs results from secretion of soluble mediators and microsomal particles that influence lung progenitor cells directly or indirectly through mediation of inflammatory cells that subsequently promote repair.^{96,97} Both preclinical and clinical studies have shown efficacy in either systemic or intratracheal administration of MSCs in acute lung injury models, asthma, COPD, and a host of other inflammation-related lung injuries or diseases.^{75,98} Although different studies have shown varying degrees of efficacy, there are still significant gaps in our understanding of the mechanisms of MSC action on ameliorating disease symptoms and of the specific subtype of MSCs used. This is important, as studies have demonstrated that certain MSCs can have negative effects in some lung disease models, such as pulmonary fibrosis.^{99,100}

Although there has been significant preclinical investigation into using EPC and MSC therapy approaches to lung repair, clinical studies have been slow to develop. However, there are a growing number of clinical trials in development focused on using MSCs for chronic lung diseases where preclinical data show the most promise. The most recent is the PROCHYMAL phase II trial looking at systemic administration of marrow MSCs for moderate to severe COPD,¹⁰¹ which showed the safety of using MSCs and also preliminary evidence for decrease in markers of inflammation.

BRAIN AND SPINAL CORD REPAIR

Stem cell-based therapy is rapidly developing as a way to improve outcomes following brain and spinal cord injury or disease. The human CNS is composed of more than 100 billion nerve cells connected in a complex network that must work seamlessly throughout our lives. Conditions affecting the CNS—such as stroke, brain, spinal cord injury, and neurodegenerative diseases—affect millions of people worldwide. Challenges for therapeutic intervention include the complex pathology of these conditions, as well as the specialized anatomical structures of the CNS that prevent easy access from systemic administration of therapies (e.g., the blood–brain barrier).

As with other areas of regenerative medicine, much effort has been spent on the identification of cell types with the best potential for CNS repair. Although it was initially thought that the adult CNS did not contain progenitor cells for repair, it is now recognized that the human CNS does retain an endogenous neural stem cell (NSC) population that retains some capacity for repair, although only in select regions and of a limited nature. Isolated adult and fetal NSCs can be expanded and differentiated into neurons, astrocytes, and oligodendrocytes, the three main CNS cell types. Adult NSCs are retained throughout life, and are found in the striatal subventricular zone and the dentate gyrus of the hippocampus. In preclinical studies, endogenous NSCs have shown to provide the most significant improvement in functional recovery in rodent stroke models.¹⁰² Isolated human fetal NSCs (CD133+),¹⁰³ are currently being investigated in a number of clinical studies.^{104,105} In addition, multiple NSC-based cell therapy trials are being conducted to determine the safety and efficacy in patients with amyotrophic lateral sclerosis (ALS, sometimes called Lou Gehrig disease).^{106,107} Although all trials to date have confirmed the safety of using these cells, any benefit from them has yet to be reported.

Although other adult stem cell types (endothelial progenitor cells, umbilical cord blood cells [UBCs], dental pulp stem cells [DPSCs]) have been investigated preclinically, only MSCs have been shown to have the same level of efficacy as NSCs. Marrow-derived MSCs have been the primary focus of preclinical and clinical studies because of their relative abundance and potential for autologous cell transplantation.^{108,109} Administration of MSCs, regardless of route, have been shown to improve outcome measures in rodent models of injury and disease.^{106,110} Based on these findings, there have been a number of early phase clinical trials initiated to study the effects of MSC transplantation following CNS injury^{111,112} or disease.^{113,114} In both cases, MSCs have been shown to be both safe and a feasible approach. Although not designed to test efficacy, many trials have observed improvements in functional outcomes.¹¹⁵

From studies of the efficacy of adult stem cells for therapy in preclinical models of CNS injury or disease over the past 20 years, there is strong evidence that transplanted adult stem cells can migrate to the site of injury and promote functional improvement. The mechanism of action, however, remains controversial.¹¹⁶ There is speculation that the benefits of cell-based therapy arise from multiple factors. From the host of preclinical studies on MSCs for treatment of stroke, improvements in

function have been attributed to increased angiogenesis, neurogenesis, prosurvival signals, and mitigation of immune responses.^{117,118} These mechanisms are potentially mediated by various soluble factors that act through a paracrine mechanism secreted by transplanted stem cells that benefit the local environment. Many of these secreted factors have begun to be identified and are well-known mediators of neurogenesis (bone-derived neurotrophic factor [BDNF]), angiogenesis (vascular endothelial growth factor [VEGF]), and immune regulation (transforming growth factor- β , [TGF- β]).^{117,119}

The use of pluripotent cell types (ESCs, iPSCs) holds significant potential as a therapeutic approach for CNS repair. Clinical application of ESCs/iPSCs is limited because of the inability to isolate pure differentiated populations of neuronal cell types.^{120,121} Despite this limitation, considerable progress has been made in preclinical studies for remyelination following spinal cord injury.^{122,123} These studies and others have demonstrated that ESCs/iPSCs can be differentiated to oligodendrocyte progenitor cells (OPCs), migrate within the spinal cord, and produce myelin. Again, the efficacy and mechanism of recovery remain controversial.^{124–127} In 2010, the Geron Company began recruitment of patients for a phase I clinical trial for treatment of spinal cord injury with ESC-derived OPCs. Despite significant enthusiasm from the patient population, and report of no adverse events on a small cohort of treated patients ($n = 4$), significant methodologic¹²⁸ and economic obstacles forced the early discontinuation of the trial.

LIVER AND PANCREAS REPAIR

The liver is an essential organ that coordinates glycogen storage, drug detoxification, production of various serum proteins, and secretion of bile, which plays a critical role in food digestion and metabolism. It is interspersed with small microscopic canals known as canaliculi through which the bile drains to the gall bladder. The numerous bile canaliculi join together into many larger bile ducts, which join to become a branched structure that forms the common hepatic duct. The part of the common hepatic duct that is outside the liver is called the extra hepatic bile duct, which joins the cystic duct from the gall bladder to form the common bile duct and connect to the exocrine pancreas. This whole branched structure forms the biliary tree.¹²⁹ Liver, biliary tree, and pancreas originate from the anterior definitive endoderm and have been found to share stem cell populations during the early stages of development.¹³⁰

The normal liver has extraordinary potential to regenerate following partial removal of the liver or liver injury. The hepatocytes and cholangiocytes (biliary epithelial cells) are normally quiescent, but in response to liver injury, these cells proliferate and contribute to regeneration.¹³¹ Average liver turnover is maintained by differentiation and proliferation of parenchymal or nonparenchymal cells. However, in chronic liver disease, when the liver cannot be repaired by self-duplication of existing hepatocytes, small bipotential progenitor cells are activated that have the ability to differentiate into either hepatocytes or cholangiocytes.¹³² Severe injury in alcoholic liver disease has been found to stimulate increased proliferation of hepatic stem/progenitor cells in humans¹³³ and oval cells in rodents.¹³⁴ Some experiments have suggested that stem progenitor cells are not only activated in the injured liver, but that the normal adult human liver contains a large number of liver progenitor cells that may contribute to liver homeostasis.

Liver transplantation is currently the only option in acute liver failure. Two small clinical trials conducted with hepatocyte transplantation resulted in limited restored enzyme function in one patient, but it was not enough for survival and the patient eventually needed a liver transplant.¹³⁵ It remains unknown if hepatocytes can contribute to long-term rescue in patients. Additionally, hepatocytes are difficult to produce in

clinically sufficient numbers, as they lose their viability and function when cultured *in vitro*.

Transplanted human ESC/iPSC-derived mature hepatocytes can express liver-specific enzymes such as albumin, antitrypsin, and cytochrome P450, which can improve liver function.^{136,137} Furthermore, a functional liver organ bud generated from iPSCs was found to be engrafted and integrated within the host organism, even including development of blood vessels.¹³⁸ When iPSCs are injected into the blastocysts of fumarylacetoacetate hydrolase (FAH)-deficient mice, iPSC-derived hepatocytes can repopulate the damaged liver efficiently and restore liver function.¹³⁹

The liver and pancreas both harbor a niche of stem cells, collectively known as the hepatic stem/progenitor cells.^{140,141} The fetal biliary tree, arising from the ductal plate cells during development and consisting of the intrahepatic and extrahepatic ducts, has been shown to harbor a rich source of stem/progenitor cells.¹⁴² These stem/progenitor cells are quite distinctive from hepatoblasts, which contribute toward the hepatocytes or cholangiocytes during development.¹⁴³ These stem/progenitor cells present in the biliary tree differ from hepatoblasts by their ability to self-renew and differentiate into hepatocytes, cholangiocytes, or pancreatic islets, depending on the microenvironment. Sox9 expression is detected throughout the pancreatic ducts, intra- and extrahepatic ducts, and in the intestinal crypt connected through the major duodenal papilla, forming a contiguous Sox9+ zone.^{144,145} Remarkably, when an adenovirus contacting three pancreatic transcription factors (Pdx1, Ngn3, and MafA) was delivered into the liver, it was able to reprogram the Sox9+ population of cells within the bile ducts into functional insulin-secreting, beta-like cells.²⁵ When both *Ad-PNM* and a peroxisome proliferator-activated receptor (PPAR) agonist, WY14643, were given in animals, it resulted in injury to the liver, led to an increase in the cell division rate of Sox9+ cells lining bile ducts, and contributed toward making more insulin-positive beta cells.¹⁴⁶ In an injured liver, the Wnt signaling pathway is activated, which stimulates discrete subsets of progenitor cell populations, which, in turn, engage in liver regeneration.¹⁴⁷ Isolation of stem/progenitor cell populations based on their surface markers like Lgr5 or EpCAM has identified the possibility of differentiating them toward a hepatocyte- or beta-like cell fate.^{145,148}

The pancreas plays an important role in digestion, as well as in maintaining blood glucose homeostasis. It is composed of ducts, with the main duct (pancreatic duct) running the length of the pancreas. The pancreatic duct merges with the bile duct to form the major duodenal ampulla, which drains the pancreatic fluid into the first portion of the small intestine, the duodenum. The pancreas is composed of exocrine and endocrine parts. The exocrine component plays an integral part in digestion. The endocrine component contains the islets of Langerhans that produce and secrete hormones into the bloodstream. The pancreatic hormones, insulin and glucagon, work together to maintain proper sugar levels in the blood.

Diabetes mellitus is a metabolic syndrome caused by having an insufficient number of insulin-producing beta cells. In type 1 diabetes, beta cells are destroyed by the body's own immune system. In type 2 diabetes, although the pancreas has functioning beta cells, insulin resistance causes the liver to release too much sugar into the bloodstream, and the beta cells cannot secrete enough insulin to maintain normal glucose homeostasis. The American Diabetes Association estimated in 2012 that approximately 9.3 percent of the United States population is living with diabetes.¹⁴⁹ Beta-cell therapy holds promise for treating type 1 diabetes by replenishing beta cells in the body; however, donor pancreases are in short supply and the demand for transplantable beta cells cannot be met.

In addition, beta-like cells have been successfully generated from hESCs and iPSCs using overexpression of transcription factors,

chemicals, or growth factors.¹⁵⁰ Current protocols for differentiation of pluripotent stem cells to beta cells follow a five-stage procedure that recapitulates the embryonic stages of development.¹⁵¹ Only the first four stages have been carried out successfully *in vitro*. The fifth stage—which involves maturation to glucose-responsive, insulin-secreting beta cells and other islet cells—until recently could only be carried out by implantation *in vivo*.¹⁵² A long-awaited directed differentiation of insulin-producing cells from hESCs has been accomplished; this fully defined *ex vivo* technology is immediately relevant.¹⁵³

Also nonendocrine cells within the pancreas have been found to transdifferentiate or reprogram to a beta cell fate²⁴ upon their being induced with the three-pancreatic-gene cocktail (Pdx1, Ngn3, and MafA). Another source for adult cell reprogramming to beta cells has been described from glucagon-producing alpha cells. A study showed that overexpression of *Pax4* (a gene responsible for specifying endocrine fate) in the alpha cells was able to force them to become beta-like cells.¹⁵⁴ In another study, it was observed that near-complete ablation of beta cells forced regeneration of beta cells from former alpha cells.¹⁵⁵ However such *in vivo* studies have not been established in humans or other primates.

● GENE EDITED MULTIPOTENTIAL CELLS

The ability to correct defective cells or give them enhanced properties (e.g., antitumor effects) represents a novel approach to transplantation medicine and sets the stage for individualized therapies. Two options exist for this strategy: provision of functional copies of a gene delivered by a viral or nonviral gene transfer system or *in situ* correction of the disease-causing sequence. Several major studies have used clinically employed viral transgenesis of hematopoietic stem cells (HSCs). In 2010, a γ -retroviral vector was used to deliver the complementary DNA for the *IL2RG* gene to CD34+ progenitors from patients with X-linked severe combined immunodeficiency (SCID-X1). Normalization of the immune system occurred in most patients; however, four patients developed acute T-cell leukemia from promiscuous LMO2 oncogene activation by the viral vector.¹⁵⁶ To mitigate the potential for viral elements to dysregulate endogenous gene expression, investigators have used self-inactivating lentiviral vectors for the gene therapy of X-linked adrenoleukodystrophy,¹⁵⁷ metachromatic leukodystrophy,¹⁵⁸ and Wiskott-Aldrich syndrome,¹⁵⁹ in gene therapy trials using hematopoietic progenitors.

Despite this, the integrating nature of viral vectors, with a preference for transcriptionally active areas, makes more precise gene targeting a highly desirable goal. Such precision can be achieved with genome editing nucleases that are rationally designed and with engineered proteins that have the unifying characteristic of recognizing and contacting a unique sequence of DNA. Most studies have tethered these proteins to nuclease domains or used their inherent ability to cut DNA. Once the DNA is broken, two predominant repair pathways have been used for therapeutic genome engineering: nonhomologous end-joining (NHEJ) and homologous recombination (HR). NHEJ is an error-prone pathway that, in the absence of a donor template, repairs the DNA break in a way that can cause small insertions or deletions (“indels”) that can permanently disrupt coding DNA sequences. Gene repair relies on the error-free HR pathway. In gene repair, the inclusion of an exogenous single- or double-stranded DNA donor template that contains homologous sequences to the target site avoids disruption. In response to a double-strand break (DSB), the donor template acts as the template for repair and allows for the precise and permanent insertion of user-defined sequences at the target locus. Both repair pathways can be used therapeutically. The major candidates employed for DNA cleavage are the meganucleases (MNs), zinc finger nucleases (ZFNs), transcription

activator-like effector nucleases (TALENs), and clustered regularly interspaced short palindromic repeats (CRISPRs)/Cas9 system.

Each class of reagent has been used for stem and progenitor cell genome modification with ZFNs, which is, to date, the first to enter clinical application. Human ESC engineering with ZFNs was first used to target the HUES-3 and HUES-1 cell lines with ZFNs designed for inactivation of the *CCR5* gene, a coreceptor for HIV entry to a cell.¹⁶⁰ ZFNs and a donor sequence containing green fluorescent protein (GFP) were introduced into exon 3 of the *CCR5* gene and approximately 5 percent rates of targeted integration were observed. Importantly, the cells maintained their pluripotency and ability to self-renew.¹⁶⁰ This study established a precedent for inserting genes of interest into a specified spot in the ESC genome via HR. Others extended this to allow for gene addition, a placement of an inducible expression cassette at the so-called safe harbor locus *AAVS1*. Using ZFNs for the first exon of the *PPP1R12C* gene on chromosome 19, a “standalone” expression cassette was introduced containing a promoter, puromycin gene, and a polyadenylation signal (or gene trap targeting vector) containing a splice acceptor-2A-puromycin gene that relied on proper targeting and splicing with the first exon of the *PPP1R12C* gene.¹⁶¹ As such, gene targeting at the *AAV* locus allows for placement of a gene with a promoter that drives the desired level of expression or is controlled by the native *PPP1R12C* promoter that is constitutively active.¹⁶² In another study, employing the safe harbor strategy did not appear to alter the pluripotent nature of ESCs.^{161–163} The ability to modify genes in pluripotent target cells is important to disease modeling *in vitro*, which has become a new foundation for the acceleration of translational research. Although these studies established the ability to modify ESCs at a site-specific and “safe harbor” locus, widespread use is limited by the relatively small number of approved ESC lines and the even smaller number of disease-specific ones.

As an elegant solution to address the potential paucity of disease-specific stem cells and to remove the potential for variability between stem cell lines, ZFNs have been used to generate isogenic control and Parkinson disease (PD) cell lines.¹⁶⁴ This work centered on engineering the A53T or E46K PD mutations into disease-free ESCs or repairing the mutation in PD patient-derived iPSCs.¹⁶⁴ In this way they mitigated the effects of the numerous genetic differences and modifiers that exist between individuals and ESC and iPSC clones.

Toward realizing the therapeutic potential of stem cells, investigators derived a fibroblast cell line from a humanized mouse model of sickle cell anemia; reprogrammed these cells into iPSCs; performed gene correction using a plasmid donor; differentiated the cells into hematopoietic progenitor cells; and transplanted them into sickle cell mice to reconstitute normal erythropoiesis.²² Proof of principle for a similar strategy using human cells was demonstrated using ZFNs to correct the sickle cell mutation in iPSCs that were subsequently differentiated into cells of the erythroid lineage.¹⁶⁵ Numerous studies using ZFNs, TALENs, and CRISPR/Cas9 have shown the ability to correct disease-causing mutations in iPSCs or in primary cells that are subsequently differentiated into iPSCs. A major limitation for these strategies for hematologic disorders is the poor and/or absent ability of iPSCs to form from true blood progenitors *ex vivo* that are capable of reconstituting a functional circulatory system. However, the most streamlined path to translational use is likely to be direct modification of a patient's own HSCs. To date only two reports document the ability to mediate HR in HSCs. In 2007, maximal rates of 0.11 percent gene targeting at the *CCR5* locus utilizing ZFNs and a donor containing GFP or a puromycin resistance gene were reached.¹⁶⁰ Subsequently, optimized conditions involving ZFNs delivered as mRNA and the donor construct delivered on an integrase-deficient lentiviral (IDLV) cassette were used to correct the *IL2RG* gene from an individual with SCID-X1 and observed multilineage repopulation in transplanted mice.¹⁶⁶ This specialized

delivery methodology in conjunction with the use of the StemRegenin 1 aryl hydrocarbon receptor antagonist¹⁶⁷ and/or 16,16-dimethyl-prostaglandin E₂ (dmPGE₂)^{168,169} allowed for HR in HSCs that normally preferentially employ NHEJ. These data provide a strong platform for first-in-human studies.

The NHEJ arm of DNA repair also holds potential for therapeutic use. A promising avenue of investigation to use NHEJ to permanently disrupt genes has been employed clinically in T cells from HIV patients.¹⁷⁰ However, because of the ability of HIV to infect non-T-cell subsets,¹⁷¹ studies have also investigated *CCR5* disruption in a preclinical humanized mouse model and showed that the modified cells are resistant to HIV-1 infection.^{172,173} These data are especially relevant due to the recent treatment of patients using HCT of grafts with homozygous *CCR5Δ32* mutations that disrupt cellular entry of the HIV particles.¹⁷⁴ This treatment protocol was initiated for an individual with HIV/AIDS who developed acute myeloid leukemia (the “Berlin patient”) in an attempt to cure both the malignancy and the HIV infection.^{174,175} Because of the paucity of *CCR5Δ32/CCR5Δ32* donors, ZFN-modified HSCs are thought to be an ideal strategy for widespread implementation of this regimen. However, a 2013 evaluation of this individual showed reinfection, possibly with an HIV strain different from the initial one, indicating that *CCR5* loss alone may not result in full HIV resistance. The CXCR4 receptor is a coreceptor for HIV cellular entry, and a significant number of HIV patients harbor the CXCR4-using HIV strain.¹⁷⁶ A recent combinatorial ZFN approach has been investigated in the laboratory using CXCR4 and *CCR5* adenoviral-borne ZFNs, with a demonstrated ability to remove both HIV coreceptors simultaneously in human T cells.¹⁷⁷ A potential clinical limitation of this approach is the fact that CXCR4 is a critical homing molecule for HSCs¹⁷⁷ and its disruption may perturb normal HSC homeostasis.

A joint approach using nuclease-induced gene disruption with chimeric antigen receptor (CAR) expression has mitigated the potential for cell-mediated alloreactivity and maximized the antitumor cellular effects. When the T-cell receptor (TCR) α and β chains were disrupted and paired with a Wilms tumor CAR, a potent tumoricidal activity without GVHD resulted.¹⁷⁸ A therapeutic success employing T cells transduced with a CD19-specific CAR have been achieved in patients with chronic lymphoid leukemia.¹⁷⁹ Scientists have extended these findings to include CAR expression with TCR- α disruption via ZFNs.¹⁸⁰ Future improvements to this technology will include more tumor-specific antigen recognition and/or temporizing CAR expression in order to minimize B-cell aplasia and tumor lysis syndrome.¹⁷⁹

Their blood lineage plasticity and their expansive clinical application makes HSCs a desirable cell type for genome engineering with designer nucleases; however, their limited ability to form extrahematopoietic tissue limits their wide use in comprehensive disease modeling and in regenerative medicine outside the lymphohematopoietic system. ESCs and iPSCs are powerful tools for filling this void and performing nuclease genome modification of multilineage stem cells. Collectively, the convergence of stem cell technology and precision genome engineering holds tremendous potential to increase the therapeutic benefit of cell-based therapies while minimizing allogeneic transplant-associated risks. Crucial to the realization of their clinical potential will be rigorous safety assessments for each platform.

Both nucleases and pluripotent stem cells have potentially deleterious aspects that could limit their effectiveness. For pluripotent stem cells this relates to the presence or accumulation of genetic and epigenetic modifications prior to or during reprogramming. Both ESCs and iPSCs are subject to these modifications *in vitro*, which may manifest in the same line or even within the same culture vessel during propagation.¹⁸¹ Aneuploidy has been reported in iPSCs, their parental cellular precursors, and ESCs. Studies by the International Stem Cell Initiative

suggest that karyotypic abnormalities may occur in as many as one of every three cell lines.¹⁸² Trisomy 12 is the most common abnormality in human ESCs and iPSCs, and chromosome 17 trisomy occurs frequently in murine ESCs.^{182,183}

By definition, engineered nucleases are designed to recognize a specific DNA sequence; however, they may also exhibit off-target (OT) effects due to overlapping or low-complexity sequence recognition between the primary target and the OT site. Unbiased genome-level screens are a powerful way to assess putative OT sites, and ZFN, TALEN, and CRISPR/Cas9 have shown excellent safety profiles to date^{184,185}; however, this high-resolution methodology will need to be performed for each gene target candidate. In summary, engineered nucleases allow for unparalleled specificity and flexibility that complement the attributes of progenitor cells. The ability to precisely manipulate the genome will support individualized *ex vivo* therapies and will allow for more uniform disease modeling *in vitro*.

CHAPTER 31

STRUCTURE AND COMPOSITION OF THE ERYTHROCYTE

Narla Mohandas*

SUMMARY

Collectively, the erythroid progenitors, terminally differentiating erythroblasts (precursors), and adult red cells are termed the *erythron* to reinforce the idea that they function as an organ. The widely dispersed cells comprising this organ arise from pluripotential hematopoietic stem cells. Following commitment to the erythroid lineage (unipotential progenitor), further maturation gives rise to the erythroid progenitors, burst-forming unit–erythroid and, subsequently, colony-forming unit–erythroid (CFU-E), that can be identified by their development into representative clonal colonies of red cells *in vitro*. The CFU-E then undergoes terminal differentiation, progressing through four to five morphologic stages, each having characteristic light microscopic and ultrastructural features. During terminal erythroid differentiation there is an increasing amount of hemoglobin synthesis accompanied by nuclear chromatin condensation and at the final stage of differentiation there is nuclear extrusion to generate an anucleate polychromatophilic macrocyte (reticulocyte with supravital staining). The human polychromatophilic macrocyte (reticulocyte) matures over 2 to 3 days, first in the marrow and then in circulation into the discoid erythrocyte. During reticulocyte maturation, cytoplasmic inclusions including residual mitochondria and ribosomes are degraded and the reticulocyte loses surface area to achieve the mean cell volume and surface area of a discoid erythrocyte. Mature erythrocytes are approximately 7 to 8 μm in diameter and undergo extensive deformation to pass through 3- μm diameter capillaries and the 1- μm wide and 0.5- μm thick endothelial slits in the red pulp of the spleen. The ability of the red cell to undergo extensive reversible deformation is essential for both its function and its survival. Red cell deformability is a function of its geometry, the viscosity of the cytoplasm, largely determined by the concentration of hemoglobin. Decreased deformability is a feature of red

cells in various pathological states. The erythrocyte is unique among eukaryotic cells in that its principal physical structure is its cell membrane, which encloses a concentrated hemoglobin solution. Thus, all of the structural properties of this cell are in one way or another linked to the cell membrane. In contrast to other cells, the erythrocyte has no cytoplasmic structures or organelles. Only, red cells and platelets do not have a nucleus.

● ERYTHRON

The mass of circulating erythrocytes constitutes an organ responsible for the transport of oxygen to tissues and the removal of carbon dioxide from tissues for exhalation. Collectively, the progenitors, precursors, and adult red cells make up an organ termed the *erythron*, which arises from pluripotential hematopoietic stem cells. Following commitment to the erythroid lineage, unipotential progenitors mature into the erythroid progenitors, the burst-forming unit–erythroid (BFU-E) and, subsequently, the colony-forming unit–erythroid (CFU-E), which then undergoes further maturation to generate anucleate polychromatophilic macrocytes (reticulocytes on supravital staining). The BFU-E and CFU-E are identified by their development into morphologically identifiable clonal colonies of red cells *in vitro*. The reticulocyte further matures, first in the marrow for 2 to 3 days and, subsequently, in the circulation for approximately 1 day, to generate discoid erythrocytes.^{1–5} The proerythroblast, the first morphologically recognizable erythroid precursor cell in the marrow undergoes four to five mitoses prior to maturation to an orthochromatic erythroblast, which then undergoes nuclear extrusion. A feature of erythropoiesis is that following each cell division the daughter cells advance in their state of maturation as compared to the parent cell and, ultimately, become functional as mature erythrocytes.⁴ In this process, they acquire the human blood group antigens, transport proteins, and all components of the erythrocyte membrane.^{4,6}

In the adult stage of development, the total number of circulating erythrocytes is in a steady state, unless perturbed by a pathologic or environmental insult. This effect is not so during growth of the individual *in utero*, particularly in the early stages of embryonic development and also during neonatal development as the total blood volume increases markedly. Consequently, erythrocyte production in the embryo and fetus differs markedly from that in the adult.

THE EARLIEST ERYTHRON

In the very early stages of human growth and development, there are two forms of erythroid differentiation: primitive and definitive.^{7–10} Chapters 5 and 7 provide detailed descriptions of embryonic and fetal hematopoiesis. The primitive erythron supplies the embryo with oxygen during the phase of rapid growth before the definitive form of maturation has had a chance to develop and seed an appropriate niche. The hallmark of this primitive erythron is the release of nucleated erythroid precursors containing embryonic hemoglobin. Although primitive in the sense that the cells contain nuclei when released into the circulation, this form of maturation differs from avian and reptilian erythropoiesis in that the nucleus is eventually expelled from the mammalian cells as they circulate. The transient presence of a nucleus in the cells of the circulating primitive erythron can decrease the efficiency of gas exchange in the lungs and microvasculature because the nucleus prevents the red cell from behaving as a fluid droplet.¹¹ The definitive stage of maturation makes its appearance around week 5 of embryogenesis when multipotential stem cells develop and seed the liver which maintains the

*This chapter contains text written for previous editions of this book by Brian Bull, Paul Herrmann, and Ernest Beutler.

erythron for most of fetal life. In later fetal life, skeletal development provides marrow niches to which erythropoiesis relocates being sustained in the form of erythroblastic islands, a central macrophage with circumferential layers of developing erythroid cells.¹² The definitive stage of erythroid maturation predominates during the remainder of fetal development and is the only type of erythroid maturation present through childhood and adult life. All of normal human erythropoiesis occurs in the marrow in the form of erythroblastic islands.¹³

ERYTHROID PROGENITORS

Burst-Forming Unit–Erythroid

The earliest identifiable progenitor committed to the erythroid lineage is the BFU-E (see Chap. 32, Fig. 32–1). A BFU-E is defined *in vitro* by its ability to create a “burst” on semisolid medium—that is, a colony consisting of several hundred to thousands of cells by 10 to 14 days of growth, during which time smaller satellite clusters of cells form around a larger central group of erythroid cells, giving rise to the designation of a “burst.” The generation of BFU-E from hematopoietic stem cells requires interleukin (IL)-3, stem cell factor, and erythropoietin for differentiation, proliferation, prevention of apoptosis, and maturation (Chap. 18).^{5,13}

Colony-Forming Unit–Erythroid

As erythroid maturation progresses, a later progenitor, the CFU-E, derived from the BFU-E, can be defined *in vitro*. The CFU-E is dependent on erythropoietin for its development and can undergo only a few cell divisions.^{5,14} Thus, the CFU-E forms a smaller colony of morphologically recognizable erythroid cells in 5 to 7 days (see Chap. 32, Fig. 32–1). Adhesion between erythroid cells and macrophages occurs at the CFU-E stage of maturation.

Using cell-surface markers, IL-3 receptor, CD34, and CD36, highly purified populations of BFU-E and CFU-E can be isolated from human marrow.⁵ Gene expression profiling show distinctive changes in gene expression profiles in hematopoietic stem cells, BFU-E, and CFU-E.⁵ Some of the marrow failure syndromes are the result of defects in differentiation of stem cells into erythroid progenitors.

ERYTHROBLASTIC ISLAND

The anatomical unit of erythropoiesis in the normal adult is the erythroblastic island or islet.^{13,16,17} The erythroblastic island consists of a centrally located macrophage surrounded by maturing terminally

differentiating erythroid cells (Fig. 31–1A). A number of binding proteins are implicated in the cell–cell adhesions important to this process. These include $\alpha_v\beta_1$ integrin, erythroblast macrophage protein (EMP), and intercellular adhesion molecule-4 (ICAM-4) on the erythroblasts and vascular cell adhesion molecule (VCAM-1), EMP, α_v integrin on macrophages.¹⁶ Additional macrophage receptors include CD69 (sialoadhesin) and CD163, but the counterreceptors for these on erythroblasts remains to be defined.¹⁶ Phase-contrast microcinematography reveals that the macrophage is far from passive or immobile. Evidence suggests that either the erythroblastic islands migrate or that erythroid precursors move from island to island, as islands near sinusoids are composed of more mature erythroblasts while islands more distant from the sinusoids are composed of proerythroblasts.¹⁸ The macrophage’s pseudopodium-like cytoplasmic extensions move rapidly over cell surfaces of the surrounding wreath of erythroblasts. On phase contrast micrographs, the central macrophage of the erythroblastic island appears sponge-like, with surface invaginations in which the erythroblasts lie (Fig. 31–1B). As the erythroblast matures, it moves along a cytoplasmic extension of the macrophage away from the main body. When the erythroblast is sufficiently mature for nuclear expulsion, the erythroblast makes contact with an endothelial cell, passes through a pore in the cytoplasm of the endothelial cell and enters the circulation as a polychromatophilic macrocyte (reticulocyte).^{19–21} The nucleus is ejected prior to egress from the marrow, phagocytized, and degraded by marrow macrophages.²² In addition to the unique cytologic features described above, the macrophage of the erythroblastic island is also molecularly distinct as demonstrated by a unique immunophenotypic signature.²³ In addition, the macrophage of the erythroblastic island appears to play a stimulatory role in erythropoiesis independent of erythropoietin. The anemia of chronic inflammation and of the myelodysplastic syndrome (MDS) may result, at least in part, from inadequate stimulation of erythropoiesis by these macrophages (Chap. 5).

Despite the central role of erythroid islands in erythropoiesis *in vivo*, morphologically normal development of erythroid cells can be recapitulated *in vitro* without these structures as long as developing cells are provided with supraphysiologic concentrations of appropriate cytokines and growth factors. Such growth, however, occurs at a much slower rate than that observed *in vivo*, when erythroblasts form erythroblastic islands.²⁴ The erythroblastic island is a fragile structure. It is usually disrupted in the process of obtaining a marrow specimen by needle aspiration but can be seen in marrow biopsies.

Figure 31–1. Erythroblastic island. **A.** Erythroblastic island as seen in Wright-Giemsa–stained marrow. Note central macrophage surrounded by a cohort of attached erythroblasts. **B.** Erythroblastic island in the living state examined by phase-contrast microscopy. The macrophage shows dynamic movement in relation to its surrounding erythroblasts. (A, reproduced with permission from Lichtman’s Atlas of Hematology, www.accessmedicine.com.)

Macrophages in erythroblastic islands not only affect erythroid differentiation and/or proliferation, but also perform other functions, including rapid phagocytosis (<10 min) of extruded nuclei as a result of exposure of phosphatidylserine on the surface of the membrane surrounding the nucleus.²² This phagocytosis is the reason for the inability to find extruded nuclei in marrow aspirates in spite of the fact that 2 million nuclei are extruded every second during steady-state erythropoiesis. A protective macrophage function linked to efficient phagocytosis has been described. In normal mice, DNase II in macrophages degrades the ingested nuclear DNA but in DNase II knockout mice the inability to degrade DNA results in macrophage toxicity with resultant decrease in number of marrow macrophages and in conjunction with severe anemia.²⁵ Macrophages can play both positive and negative regulatory roles in human erythropoiesis but the mechanistic basis for these regulatory processes are not completely understood.^{16,24} These processes may play a role in the ineffective erythropoiesis in disorders such as MDS, thalassemia, and malarial anemia.

Another potentially important role originally proposed for the central macrophage is direct transfer of iron to developing erythroblasts mediated by ferritin exchange between macrophages and erythroblasts (Chap. 42).¹³ Although this is an interesting concept, there is no definitive evidence for this exchange.

ERYTHROID PROGENITORS AND PRECURSORS

Early Progenitors

A “progenitor” in the hematopoietic system is defined as a marrow cell that is a derivative of the pluripotent hematopoietic stem cell through

the process of differentiation and is antecedent to a “precursor” cell, the latter being identifiable by light microscopy by its morphologic characteristics (see Chap. 83, Fig. 83–2). In erythropoiesis, the earliest precursor is the proerythroblast. Erythroid progenitor cells are identified as marrow cells capable of forming erythroid colonies in semisolid medium *in vitro* under conditions in which the appropriate growth factors are present. Progenitor cells also may be identified by characteristic profiles of surface CD antigens using flow cytometry. Numerically, erythroid progenitors, BFU-E and CFU-E represent only a minute proportion of human marrow cells. BFU-E range from 300 to 1700 × 10⁶ mononuclear cells and CFU-E range from 1500 to 5000 × 10⁶ mononuclear cells.⁵ *In vitro* cultures using CD34+ cells from blood, cord blood, and marrow as the starting material have identified the critical cytokines required for erythroid differentiation and maturation and enabled the identification and isolation of pure cohorts of erythroid progenitors and erythroblasts at all stages of terminal erythroid maturation.^{4,5}

Precursors

Figure 31–2 shows the sequence of precursors as seen in marrow films. Figure 31–3 shows the marrow precursors as isolated by flow cytometry.

Proerythroblasts On stained films, the proerythroblast appears as a large cell, irregularly rounded or slightly oval.¹³ The nucleus occupies approximately 80 percent of the cell area and contains fine chromatin delicately distributed in small clumps. One or several well-defined nucleoli are present. The high concentration of polyribosomes gives the cytoplasm of these cells its characteristic intense basophilia. At very high magnification, ferritin molecules are seen dispersed singly throughout the cytoplasm and lining the clathrin-coated pits on the cell

Figure 31–2. Human erythrocyte precursors. Light microscopic appearance. Marrow films stained with Wright stain. There are five stages of erythroblast development recognizable by light microscopy. **A.** Proerythroblasts. Two are present in this field. They are the largest red cell precursor, with a fine nuclear chromatin pattern, nucleoli, basophilic cytoplasm, and often a clear area at the site of the Golgi apparatus. **B.** Basophilic erythroblast. The cell is smaller than the proerythroblast, the nuclear chromatin is slightly more condensed and cytoplasm is basophilic. **C.** Polychromatophilic erythroblasts. The cell is smaller on average than its precursors. The nuclear chromatin is more condensed with a checkerboard pattern developing. Nucleoli are not apparent, usually. The cytoplasm is gray, reflecting the staining modulation induced by hemoglobin synthesis, which adds cytoplasmic content that takes an eosinophilic stain, admixed with the residual basophilia of the fading protein synthetic apparatus. **D.** Orthochromic normoblast. Smaller on average than its precursor, increased condensation of nuclear chromatin, with homogeneous cytoplasmic coloration approaching that of a red cell. **E.** Late orthochromic erythroblasts (*asterisks*). The orthochromic erythroblast to the right is undergoing apparent enucleation. The other three mononuclear cells are lymphocytes. A degenerating four-lobed neutrophil is also present. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

Figure 31-3. Human erythroblast precursors as isolated by cell flow cytometry. Images of populations of human erythroblast precursors at stages of erythroid maturation when sorted from human marrow by flow cytometry. **A** and **B**. membrane (see Figs. 31-2 and 31-4) Diffuse cytoplasmic density on sections stained for peroxidase indicates hemoglobin is already present. Dispersed glycogen particles are present in the cytoplasm.

Basophilic Erythroblasts Basophilic erythroblasts are smaller than proerythroblasts. The nucleus occupies three-fourths of the cell area and is composed of characteristic dark violet heterochromatin interspersed with pink-staining clumps of euchromatin linked by irregular strands.¹³ The whole arrangement often resembles wheel

spokes or a clock face. The cytoplasm stains deep blue, leaving a perinuclear halo that expands into a juxtannuclear clear zone around the Golgi apparatus. Cytoplasmic basophilia at this stage results from the continued presence of polyribosomes (see Figs. 31-2 and 31-5).

Polychromatophilic Erythroblasts Following the mitotic division of the basophilic erythroblast, the cytoplasm changes from deep blue to gray, as hemoglobin dilutes the polyribosome content. Cells at this stage are smaller than basophilic erythroblasts. The nucleus occupies less than half of the cell area. The heterochromatin is located in well-defined clumps spaced regularly about the nucleus, producing a

Figure 31-4. Proerythroblast. Phase-contrast micrograph (*inset*) of a proerythroblast showing the immature nucleus with nucleoli and finely dispersed nuclear chromatin. The centrosome (juxtannuclear clear zone) is apparent with its dense accumulation of mitochondria. Electron microscopic section of the proerythroblast shows nucleoli (*n*) in contact with the nuclear membrane. Chromatin is finely dispersed and forms small aggregates in the fixed nuclear membrane. The perinuclear canal is narrow but well defined. Polyribosome groups, many in helical configuration, are dispersed throughout the cytoplasm. The Golgi apparatus (*g*) is well developed, and regions of endoplasmic reticulum (*arrows*) are seen.

Figure 31-5. Basophilic erythroblast. Phase-contrast photomicrograph (*inset*) shows increased clumping of the nuclear chromatin and further rounding of the cell, with aggregation of the mitochondria and centrosome into the regions of nuclear indentation. Electron microscopic section shows clumping of the nuclear chromatin, nuclear pores (*p*), organization of the nucleoli, increased density of polyribosomes (*pr*), well-developed Golgi apparatus (*g*), and a decrease in smooth endoplasmic reticulum.

Figure 31-6. Polychromatophilic erythroblast. Phase-contrast micrograph (*inset*) demonstrates diminished size of this cell compared with its precursor. Further clumping of nuclear chromatin gives the nucleus a checkerboard appearance. The centrosome is condensed, and a perinuclear halo has developed. Electron microscopic section demonstrates relative reduction of the density of polyribosomes and dilution by the moderately osmiophilic hemoglobin in the cytoplasm. Nuclear chromatin shows a marked increase in clumping, and nuclear pores (*P*) are enlarged.

checkerboard pattern. The nucleolus is lost, but the perinuclear halo persists.¹³ It is at this point that erythroblasts lose their mitotic potential. Electron microscopy of the polychromatophilic erythroblast reveals increased aggregation of nuclear heterochromatin.¹³ Active ferritin transport across the cell membrane is always evident, and siderosomes along with dispersed ferritin molecules can be identified within the cytoplasm (see Figs. 31-2 and 31-6).

Orthochromic (syn. Orthochromatic) Erythroblasts After the final mitotic division of the erythropoietic series, the concentration of hemoglobin increases within the erythroblast. Under the light microscope, the nucleus appears almost completely dense and featureless. It is measurably decreased in size. This cell is the smallest of the erythroblastic series.¹³ The nucleus occupies approximately one-fourth of the cell area and is eccentric. Cell movement can be appreciated under the phase-contrast microscope. Round projections appear suddenly in different parts of the cell periphery and are just as quickly retracted.¹³ The movements probably are made in preparation for ejection of the nucleus. The cell ultrastructure is characterized by irregular borders, reflecting its motile state. The heterochromatin forms large masses. Mitochondria are reduced in number and size (see Figs. 31-2, 31-7, and 31-8).

Normal Sideroblasts All normal erythroblasts are sideroblasts in that they contain iron in structures called *siderosomes*, as evident by transmission electron microscopy. These structures are essential for the transfer of iron for heme (hemoglobin) synthesis. By light microscopy, under the usual conditions of Prussian blue staining for iron, a minority of normal erythroblasts (approximately 15 to 20 percent) can be

Figure 31-7. Orthochromic erythroblast. Phase-contrast appearance of this cell in the living state (*inset*) shows the irregular borders indicative of its characteristic motility, the eccentric nucleus making contact with the plasmalemma, further pyknosis of the nuclear chromatin, and condensation of the centrosome. Electron microscopic section shows further dilution of polyribosomes, some of which appear to be disintegrating into monoribosomes, by the increasing hemoglobin. The number of mitochondria is decreased, and some mitochondria are degenerating. Nuclear chromatin is clumped into large masses, and a perinuclear canal (*pnc*) is seen.

identified as containing siderosomes and those that can be so identified have very few (one to four) small Prussian blue–positive granules.

Pathologic Sideroblasts A heterogeneous group of erythrocyte disorders is accompanied by ineffective erythropoiesis, abnormal erythroblast morphology and hyperferremia. These disorders include acquired megaloblastic anemia (Chap. 41), congenital dyserythropoietic anemias (Chap. 39), thalassemias (Chap. 48), the inherited and acquired sideroblastic anemias, pyridoxine-responsive anemia, alcohol-induced sideroblastic anemia, and lead intoxication (Chaps. 52 and 59). Some of these conditions are characterized by the presence of pathologic sideroblasts. Pathologic sideroblasts are of two types. One type is an erythroblast that has an increase in number and size of Prussian blue-stained siderotic granules throughout the cytoplasm. Another type is the erythroblast that shows iron-containing granules that are arranged in an arc or a complete ring around the nucleus (Fig. 31-8). These pathologic sideroblasts are referred to as *ring* or *ringed sideroblasts*.^{26,27} Electron microscopic studies show that granules in ringed sideroblasts are iron-loaded mitochondria. In cells with iron-loaded mitochondria, many ferritin molecules are deposited between adjacent erythroblast membranes.

RETICULOCYTE

Birth

Prior to enucleation at the late orthochromatic erythroblasts stage, intermediate filaments and the marginal band of microtubules disappear. Enucleation is a highly dynamic process that involves coordinated

Figure 31-8. Pathologic sideroblast is an erythroblast characterized by the presence of mitochondrial deposits of iron-containing ferruginous micelles (arrows) between the cristae.

action of multiple mechanisms.²⁸⁻³⁰ Tubulin and actin become concentrated at the point where the nucleus will exit. These changes, accompanied by microtubular rearrangements and actin polymerization, play a role in nuclear expulsion. Expulsion of the nucleus *in vitro* is not an instantaneous phenomenon; it requires a period of 6 to 8 minutes. The process begins with several vigorous contractions around the midportion of the cell, followed by a division of the cell into unequal portions.

The smaller portion consists of the expelled nucleus surrounded by a thin ring of hemoglobin and plasma membrane (Fig. 31-9). *In vivo*, expulsion of the nucleus may occur while the erythroblast is still part of an erythroblastic island or the nucleus may be lost during passage through the wall of a marrow sinus as the nucleus, which cannot traverse the small opening, remains in the marrow. The outer leaflet of the bilaminar membrane surrounding the expelled nucleus is high in phosphatidylserine, a signal for macrophage ingestion (Fig. 31-10).²² It is not clear what fraction of the expelled nuclei is ingested by the macrophage of the erythroblastic island or by other macrophages resident in marrow. Two hypotheses have been proposed to explain how the reticulocyte exits the marrow.¹⁹⁻²¹ The reticulocyte may actively traverse the sinus epithelium to enter the lumen. More likely, however, the reticulocyte may be driven across by a pressure differential because it appears incapable of directed amoeboid motion. The precise mechanism is yet to be defined.

Maturation

Following nuclear extrusion, the reticulocyte retains mitochondria, small numbers of ribosomes, the centriole, and remnants of the Golgi apparatus. It contains no endoplasmic reticulum. Supravital staining with brilliant cresyl blue or new methylene blue produces aggregates of ribosomes, mitochondria, and other cytoplasmic organelles. These aggregates stain deep blue and, arranged in reticular strands, give the reticulocyte its name. Maturation of the reticulocyte requires 48 to 72 hours. During this period, approximately 20 percent of the membrane surface area is lost and cell volume decreases by 10 to 15 percent and the final assembly of the membrane skeleton is completed.³¹⁻³³ Living reticulocytes observed by phase-contrast microscopy are irregularly shaped cells with a characteristically puckered exterior and a motile membrane. Examined by electron microscopy, reticulocytes are irregularly shaped and contain many remnant organelles.¹³ The organelles, small smooth vesicles, and an occasional centriole are grouped in the region of the cell where the nucleus is expelled. In “young” reticulocytes, the vast majority of ribosomes dispersed throughout the cytoplasm are in the form of polyribosomes. As protein synthesis diminishes during maturation, the polyribosomes gradually transform into monoribosomes. During reticulocyte maturation there is significant remodeling of the membrane, including loss of membrane proteins that include transferrin receptors, Na-K adenosine triphosphatase (ATPase), and adhesion molecules, as well as loss of tubulin and cytoplasmic actin.³³ During the remodeling

process the membrane becomes more elastic and acquires increased membrane mechanical stability.³²

Macroreticulocytes

“Stress” reticulocytes are released into the circulation during an intense erythropoietin response to acute anemia or experimentally in response to large doses of exogenously administered erythropoietin.³⁴ These cells

may be twice the normal volume, with a corresponding increase in mean cell hemoglobin (MCH) content. Whether the increase results from one less mitotic division during maturation or from some other process such as changes in cell cycle is not clear. It is interesting to note that mice do not have the ability to produce stress reticulocytes with increased mean cell volume (MCV) and MCH. In contrast, even under moderate erythropoietic stress, some reticulocytes in the marrow pool shift to the circulating pool. These “shift” reticulocytes with normal MCH contain a higher-than-normal RNA content and now can be quantified. Quantification is commonly performed by applying a fluorescent stain to tag RNA and then dividing reticulocytes into high-, medium-, and low-fluorescence categories using a fluorescence-sensitive flow cytometer. The “stress” reticulocytes of the older literature likely fall in the high- and medium-fluorescence categories. Unfortunately, at present little attention is being paid to discriminate stress and shift reticulocytes.

Pathology of the Reticulocyte

The reticulocyte may show pathologic alterations in size or staining properties. The reticulocyte may contain inclusions visible by light microscopy or identifiable only on ultrastructural analysis. Most pathologic inclusions usually attributed to erythrocytes are actually found within reticulocytes and are nuclear or cytoplasmic remnants derived from late-stage erythroblasts. In splenectomized patients, they may also be found in mature erythrocytes.

RED CELL INCLUSIONS

See Fig. 31–11 for images of red cell inclusions.

Howell-Jolly Bodies

Howell-Jolly bodies are small nuclear remnants that have the color of a pyknotic nucleus on Wright-stained films and give a positive Feulgen reaction for DNA.^{35,36} They are spherically shaped, randomly distributed

Figure 31–11. Red cell inclusions. Blood films. **A.** Red cells with Howell-Jolly bodies (*arrows*) postsplenectomy. The crisp circular border, dark blue color, and peripheral location are characteristic. **B.** Basophilic stippling. These basophilic inclusions may be fine or coarse. In this case, the cell contains coarse stippling seen in lead poisoning (*arrow*). **C.** Siderocyte. These cells contain purple granules when stained with Wright stain (Pappenheimer bodies). Compared to basophilic stippling, siderotic granules are usually fewer in number and sometimes clustered. These Prussian blue–stained cells confirm that the granules contain iron (blue reaction product). *Arrow* points to two siderocytes. **D.** Cabot ring. Rare red cell inclusion (*arrow*). See text for further description. **E.** Heinz bodies. These cells from a patient with glucose-6-phosphate dehydrogenase deficiency were incubated with a supravital dye, which stains the denatured globin precipitates. **F.** Red cells from a patient with hemoglobin H disease (α -thalassemia). The hemoglobin precipitates are stained with brilliant cresyl blue. (Reproduced with permission from Lichtman’s Atlas of Hematology, www.accessmedicine.com.)

in the red cell and usually no larger than $0.5\ \mu\text{m}$ in diameter. Howell-Jolly bodies may be numerous, although generally only one is present. In pathologic situations, they appear to represent chromosomes that have separated from the mitotic spindle during abnormal mitosis, and contain a high proportion of centromeric material along with heterochromatin. More commonly, during normal maturation they arise from nuclear fragmentation or incomplete expulsion of the nucleus. Howell-Jolly bodies are pitted from the reticulocytes during their transit through the interendothelial slits of the splenic sinus. They are characteristically present in the blood of splenectomized persons and in patients suffering from megaloblastic anemia, and hyposplenic states.

Pocked (or Pitted) Red Cells

When viewed by interference-phase microscopy, pocked red cells appear to have surface membrane “pits” or craters.^{37–39} The vesicles or indentations characterizing these cells represent autophagic vacuoles adjacent to the cell membrane. The vacuoles appear to be instrumental in disposal of cellular debris as the erythrocyte passes through the microcirculation of the spleen. Within 1 week following splenectomy, pocked red cell counts begin to rise, reaching a plateau at 2 to 3 months. Pocked red blood cell counts sometimes are used as a surrogate test for splenic function.

Cabot Rings

The ring-like or figure-of-eight structures sometimes seen in megaloblastic anemia within reticulocytes and in an occasional, heavily stippled, late-intermediate megaloblast are designated *Cabot rings*.^{40,41} Their composition is nuclear. Some investigators have suggested that Cabot rings originate from spindle material that was mishandled during abnormal mitosis. Others have found no indication of DNA or spindle filaments but have shown the rings are associated with adherent granular material containing arginine-rich histone and nonhemoglobin iron.

Basophilic Stippling

Basophilic stippling consists of granulations of variable size and number that stain deep blue with Wright stain. Electron microscopic studies have shown that *punctate basophilia* represents aggregated ribosomes.⁴² Clumps form during the course of drying and postvital staining of the cells, much as “reticulum” in reticulocytes precipitates from ribosomes during supravital staining. The clumped ribosomes may include degenerating mitochondria and siderosomes. In conditions such as lead intoxication (Chap. 52), pyrimidine 5'-nucleotidase deficiency (Chap. 47), and thalassemia (Chap. 48), the altered reticulocyte ribosomes have a greater propensity to aggregate. As a result, basophilic granulation appears larger and is referred to as coarse basophilic stippling.

Heinz Bodies

Heinz bodies are composed of denatured proteins, primarily hemoglobin, that form in red cells as a result of chemical insult; in hereditary defects of the hexose monophosphate shunt; in the thalassemias (Chap. 48); and in unstable hemoglobin syndromes (Chap. 49).⁴³ Heinz bodies are not seen on ordinary Wright- or Giemsa-stained blood films. Heinz bodies are readily visible in red cells stained supravivally with brilliant cresyl blue or crystal violet and are eliminated as red cells traverse the endothelial slits of the splenic sinus.

Hemoglobin H Inclusions

Hemoglobin H is composed of β_4 tetramers, indicating that β chains are present in excess as a result of impaired α -chain production (Chap. 48). Exposure to redox dyes such as brilliant cresyl blue, methylene blue, or new methylene blue, results in denaturation and precipitation of abnormal hemoglobin.^{44–46} Brilliant cresyl blue causes the formation of a large number of small membrane-bound inclusions, giving the

cell a characteristic “golf ball–like” appearance when viewed by light microscopy. Methylene blue and new methylene blue generate a smaller number of variably sized membrane-bound and floating inclusions. These changes are seen most frequently in α -thalassemia but also can be found in patients with unstable hemoglobin (Chap. 49) and in rare patients with primary myelofibrosis who develop acquired hemoglobin H disease.

Siderosomes and Pappenheimer Bodies

Normal or pathologic red cells in blood containing siderosomes (“iron bodies”) usually are reticulocytes. The iron granulations are larger and more numerous in the pathologic state (Chap. 59). Electron microscopy shows that many of these bodies are mitochondria containing ferruginous micelles rather than the ferritin aggregates characterizing normal siderocytes.⁴⁷ Siderosomes usually are found in the cell periphery, whereas basophilic stippling tends to be distributed homogeneously throughout the cell. Pappenheimer bodies are siderosomes that stain with Wright stain. Electron microscopy of Pappenheimer bodies shows that the iron often is contained within a lysosome, as confirmed by the presence of acid phosphatase. Siderosomes may contain degenerating mitochondria, ribosomes, and other cellular remnants.

STRUCTURE AND SHAPE OF ERYTHROCYTES

The normal resting shape of the erythrocyte is a biconcave disc (Fig. 31–12). Variations in the shape and dimensions of the red cell are useful

Figure 31–12. Scanning electron micrographs of distinct red cell morphologies. Discoid normal red cells (*top left panel*). Elliptocytes and fragmented red cells (*top right panel*). Oxygenated sickle red cells (*middle left panel*) and deoxygenated sickle red cells (*middle right panel*). Stomatocytic red cells (*bottom left panel*). Acanthocyte (*bottom right panel*).

in the differential diagnosis of anemias. Normal human red cells have a diameter of 7 to 8 μm , and the diameter decreases slightly with cell age. The size decrease likely results from loss of membrane surface area during erythrocyte life span by spleen-facilitated vesiculation. The cells have an average volume of approximately 90 fL and a surface area of approximately 140 μm^2 . The membrane is present in sufficient excess to allow the cell to swell to a sphere of approximately 150 fL or to deform so as to enter a capillary with a diameter of 2.8 μm . The normal erythrocyte stains reddish-brown with Wright-stained blood films and pink with Giemsa stain. The central third of the cell appears relatively pale compared with the periphery, reflecting its biconcave shape. Many artifacts can be produced in the preparation of the blood film. They may result from contamination of the glass slide or coverslip with traces of fat, detergent, or other impurities. Friction and surface tension involved in the preparation of the blood film produce fragmentation, “doughnut cells” or anulocytes, and crescent-shaped cells. Observed under the phase-contrast or interference microscope, the red cell shows a characteristic internal scintillation known as red cell flicker.⁴⁸ The scintillation results from thermally excited undulations of the red cell membrane. Frequency analysis of the surface undulations has provided an estimate of the membrane curvature elastic constant and of changes in this constant resulting from alcohol, cholesterol loading, and exposure to cross-linking agents.

RED CELL SHAPE AND SURVIVAL IN CIRCULATION

The red cell spends most of its circulatory life within the capillary channels of the microcirculation. During its 100- to 120-day life span, the red cell travels approximately 250 km and loses approximately 15 to 20 percent of its cell surface area. The long survival of the red cell is at least partially a result of the unique capacity of its membrane to “tank tread”—that is, to rotate around the red cell contents and thereby facilitate more efficient oxygen delivery. The physical arrangement of membrane skeletal proteins in a uniform shell of highly folded hexagonal spectrin lattice permits this unusual behavior.^{49–51} The arrangement also is responsible for the characteristic biconcave shape of the resting cell. Red cells must also be able to withstand large shear forces and must be able to undergo extensive reversible deformation during transit through the microvasculature and in transiting from the splenic red cell pulp back into circulation. The resiliency and fluidity of the membrane to deformation is regulated by the spectrin-based membrane skeleton.⁴⁹ A deficiency in the amount of spectrin or the presence of mutant spectrin in the submembrane skeleton results in abnormally shaped cells in hereditary spherocytosis, elliptocytosis, and pyropoikilocytosis (Chap. 46).⁴⁹ In regions of circulatory standstill or very slow flow, red cells travel in aggregates of two to 12 cells, forming rouleaux. Within large vessels, increased shear forces disrupt this aggregation.

RED CELL COMPOSITION

The erythrocyte is a complex cell. The membrane is composed of lipids and proteins, and the interior of the cell contains metabolic machinery designed to sustain the cell through its 120-day life span and maintain the integrity of hemoglobin function. Each component of red blood cells may be expressed as a function of red cell volume, grams of hemoglobin, or square centimeters of cell surface. These expressions are usually interchangeable, but under certain circumstances each may have specific advantages. However, because disease may produce changes in the average red cell size, hemoglobin content, or surface area, the use of any of these measurements individually may, at times, be misleading. For convenience and uniformity, data in the accompanying tables (Tables 31–1 through 31–6) are expressed in terms of cell constituent per milliliter of red cell and per gram of hemoglobin. In many instances, this

TABLE 31–1. Human Erythrocyte Protein and Water Content

process required recalculation of published data. These recalculations assume a hematocrit value of 45 percent and 33 g of hemoglobin per deciliter of red cells. To obtain concentration per gram of hemoglobin, the concentration per milliliter red blood cell can be multiplied by 3.03. The tables list only some of the most commonly referred to constituents of the erythrocyte. The reference on which each value is based is the first number presented in the last column of each table. Where applicable, additional confirmatory references are given. In some instances, only the percentage of the total of the type of constituent present is given. Chapter 46 discusses the detailed protein composition of the red cell membrane and its various protein constituents.

ERYTHROCYTE DEFORMABILITY

During its 120-day life span, the erythrocyte must undergo extensive passive deformation and must be mechanically stable to resist fragmentation and cellular deformability is an important determinant of red cell survival in the circulation. Red cell deformability is influenced by three

distinct cellular components: (1) cell shape or cell geometry, which determines the ratio of cell surface area to cell volume (SA:V); higher values of SA:V facilitate deformation; (2) cytoplasmic viscosity, which is primarily regulated by the mean corpuscular hemoglobin concentration (MCHC) and is therefore influenced by alterations in cell volume; and (3) membrane deformability and mechanical stability, which are regulated by multiple membrane properties, which include elastic shear modulus, bending modulus, and yield stress.⁵²⁻⁵⁵ Either directly or indirectly, membrane components and their organization play an important role in regulating each of the factors that influence cellular deformability.

The biconcave disc shape of the normal red cell creates an advantageous SA:V relationship, allowing the red cell to undergo marked deformation while maintaining a constant surface area. The normal human adult red cell has a volume of 90 fL and a surface area of 140 μm^2 . If the red cell were a sphere of identical volume, it would have a surface area of only 98 μm^2 . Thus, the discoid shape provides approximately 40 μm^2 of excess surface area, or an extra 43 percent, that enables the red cell to undergo extensive deformation. Most deformations occurring *in vivo* and *in vitro* involve no increase in surface area. This is important because the normal red cell can undergo large linear extensions of up to 230 percent of its original dimension while maintaining its surface area, but an increase of even 3 to 4 percent in surface area results in cell lysis. Either membrane loss, leading to a reduction in surface area, or an increase in cell water content, leading to an increase in cell volume, will create a more spherical shape with less redundant surface area. This loss of surface area redundancy results in reduced cellular deformability, compromised red cell function, and diminished survival as a result of splenic sequestration of spherocytic red cells. A 17-percent reduction in surface area results in rapid removal of red cells by the human spleen.⁵⁶

Cytoplasmic viscosity, another regulatory component of red cell deformability, is largely determined by the MCHC, which is determined

in large part by cell water content. As the hemoglobin concentration rises from 27 to 35 g/dL (the normal range for red blood cells), the viscosity of hemoglobin solution increases from 5 to 15 centipoise (cP), 5 to 15 times that of water. At these levels, the contribution of cytoplasmic viscosity to cellular deformability is negligible. However, viscosity increases exponentially at hemoglobin concentrations greater than 37 g/dL, reaching 45 cP at 40 g/dL, 170 cP at 45 g/dL, and 650 cP at 50 g/dL. At these levels, cytoplasmic viscosity may become the primary determinant of cellular deformability. Thus, cellular dehydration, usually caused by the failure of normal volume homeostasis mechanisms, can severely impair cellular deformability and thus decrease optimal oxygen delivery by impairing the ability of red cells to undergo rapid deformation necessary for passage through the microvasculature. As examples, cellular dehydration reduces red cell deformability in hereditary xerocytosis, sickle cell anemia, hemoglobin CC, and β -thalassemia.^{55,57,58} However, changes in cellular dehydration by itself have little influence on red cell survival.

The property of membrane deformability determines the extent of membrane deformation that can be induced by a defined level of applied force. The more deformable the membrane, the less the force required for the cell to pass through the capillaries and other narrow openings, such as fenestrations in the splenic cords. The property of membrane mechanical stability is defined as the maximum extent of deformation that a membrane can undergo, beyond which it cannot completely

recover its initial shape. This is the point at which the membrane fails. Normal membrane stability allows human red cells to circulate for 100 to 120 days without fragmenting, while decreased stability leads to cell fragmentation under normal circulating stresses. Both membrane deformability and membrane mechanical stability are regulated by structural organization of membrane proteins.⁵⁴ While decreased membrane deformability can reduce effective tissue oxygen delivery it appears to have little effect on red cell survival since Southeast Asian ovalocytes with marked reductions in membrane deformability have near-normal red cell survival. Loss of membrane mechanical stability leading to membrane fragmentation and consequent reduction in SA:V

ratio on the other hand compromises red cell survival as in hemolytic hereditary elliptocytosis.⁴⁹

RED CELL SENEESCENCE

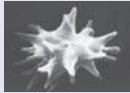

The reticulocyte loses membrane as it matures into a discocyte and membrane loss by vesiculation continues throughout the erythrocyte life span. The notion that erythrocyte aging is synonymous with membrane loss, increasing MCHC, and decreasing deformability largely results from studies on density-separated cells and the equating of dense cells with aged cells (Chap. 33). Although it is clear that loss of membrane surface area and decreased cell volume is a feature of normal red cell senescence and that cell density increases with cell age, there is no direct relationship between cell age and cell density since there is a large heterogeneity in cell densities of reticulocytes as they enter circulation. What is clear is that the densest 1 percent of circulating red cells are

TABLE 31-7. Nomenclature of Red Cell Shapes and Associated Disease States

Terminology (Greek Meaning)	Old Terms, Synonyms	Description	Micrograph	Associated Disease States
Discocyte (disc)	Biconcave disc	Biconcave disc form of RBC		
Echinocyte (I-III) (sea urchin)	"Burr cell," crenated cell, "berry cell"	Spiculated RBC with short, equally spaced projections over entire surface; progressing from the "crenated disc" (echinocyte I) to the crenated sphere (echinocyte IV—not shown) with nearly complete loss of spicules	  	Uremia, liver disease Low-potassium red cells Immediately posttransfusion with aged or metabolically depleted blood Carcinoma of stomach and bleeding peptic ulcers
Acanthocyte (spike)	"Spur cell," acanthoid cell, acanthocyte	Irregularly spiculated RBC with projections of varying length and position		Abetalipoproteinemia Alcoholic liver disease Postsplenectomy state Malabsorptive states
Stomatocyte (I-III) (mouth)	Mouth cell, cup form, mushroom cap, uniconcave disc, microspherocyte	Bowled-shaped RBC with single concavity; progressing from shallow bowl (I) to near sphere with small dimple (seen as mouth-shaped form in peripheral film)	 	Hereditary spherocytosis Hereditary stomatocytosis Alcoholism, cirrhosis, obstructive liver disease Erythrocyte sodium-pump defect
Spherostomatocyte (sphere)	Spherocyte, prelytic sphere, microspherocyte	Spherical RBC with dense hemoglobin content; scanning electron microscopy shows a persistent minimal dimple		Hereditary spherocytosis (cells actually spherostomatocytes) Immune hemolytic anemia Posttransfusion Heinz body hemolytic anemia Water-dilution hemolysis Fragmentation hemolysis
Schizocyte (cut)	Schistocyte, helmet cell, fragmented cell	Split RBC, often showing half-disc shape with two or three pointed extremities; may be small, irregular fragment		Microangiopathic hemolytic anemia (TTP, DIC, vasculitis, glomerulonephritis, renal graft rejection) Carcinomatosis Heart-valve hemolysis (prosthetic or pathologic valves) Severe burns March hemoglobinuria
Elliptocyte (oval)	Ovalocyte	Oval to elongated ellipsoid RBC (with polarization of hemoglobin)		Hereditary elliptocytosis Thalassemia Iron deficiency Myelophthitic anemias Megaloblastic anemias

TABLE 31–7. Nomenclature of Red Cell Shapes and Associated Disease States (*Continued*)

Terminology (Greek Meaning)	Old Terms, Synonyms	Description	Micrograph	Associated Disease States
Drepanocyte (sickle)	Sickle cell	RBC containing polymerized hemoglobin S; showing varying shapes from bipolar, spiculated forms to holly-leaf and irregularly spiculated forms	 	Sickle cell disorders (SS, S trait, SC, SD, S thalassemia, etc.) Hemoglobin C-Harlem Hemoglobin Memphis/S
Codocyte (bell)	Target cell	Bell-shaped RBC that assumes a target shape on dried films of blood	 	Obstructive liver disease Hemoglobinopathies (S, C) Thalassemia Iron deficiency Postsplenectomy state Lecithin cholesterol acetyltransferase deficiency
Dacryocyte (tear)	Teardrop cell	RBC with a single elongated or pointed extremity		Primary myelofibrosis Myelophthitic anemias Thalassemia
Leptocyte (thin)	Thin cell, wafer cell	Thin, flat RBC with hemoglobin at periphery		Thalassemia Obstructive liver disease (± iron deficiency)
Keratocyte (horn)	Horn cell	RBC with spicules resulting from ruptured vacuole; cell appears half-moon shaped or spindle shaped		DIC or vascular prosthesis

DIC, disseminated intravascular coagulation; RBC, red blood cell; TTP, thrombotic thrombocytopenic purpura.

the most aged—they have the highest levels of glycated hemoglobin (HbA_{1c}), a very good marker of cell age. The loss of membrane surface area of the senescent red cells appears to be a result of membrane oxidation-induced band 3 clustering and consequent membrane vesiculation and the resultant critical decrease in SA:V ratio leads to their removal from circulation^{59,60}

PATHOPHYSIOLOGY OF ERYTHROCYTE SHAPES

Chapter 46 discusses erythrocytes in greater detail.

See [Table 31–7](#) and [Fig. 31–13](#) for scanning and blood film appearance of pathologically shaped red cells.

Spherocytes and Stomatocytes

Spherocytes (Chap. 46) represent red cells, with the most decreased SA:V ratio seen in hereditary spherocytosis, immune hemolytic anemia, stored blood, Heinz body hemolytic anemia, and caused by cell fragmentation.^{49,61} Stomatocytes are seen in hereditary stomatocytosis, as well as in hereditary spherocytosis, alcoholism, cirrhosis, obstructive liver disease, and erythrocyte sodium pump defects.^{49,62,63} Red cells sensitized with antibodies, complement, or immune complexes lose cholesterol and surface area. As a result, they are less deformable and more osmotically fragile. Heinz body formation leads to membrane depletion

by fragmentation, with spherocyte formation. A spherogenic mechanism common to Heinz body hemolytic anemias and immune hemolysis is partial phagocytosis of portions of the cell containing aggregates of denatured hemoglobin and portions of the sensitized membrane, respectively.

Stomatocytosis appear to be an intermediate form in the generation of spherocytosis with varying extents of decreased SA:V ratio as a result of loss of membrane surface area or increased cell volume. Stomatocytosis is a feature of hereditary hydrocytosis caused by increased cell volume and consequent decrease in SA:V ratio. A spectrum of abnormal cells varying from normal discocytes to stomatocytes, spherostomatocytes, and dense microspherocytes is seen in hereditary spherocytosis.

Elliptocytes

Elliptocytes are seen in hereditary elliptocytosis (Chap. 46) as well as in thalassemia (Chap. 48), iron deficiency (Chap. 43), and megaloblastic anemia (Chap. 41).⁴⁹ In blood films of normal subjects, elliptical or oval cells usually constitute less than 1 percent of the erythrocytes. In various pathologic situations, with or without anemia (thalassemia trait, folate, and iron deficiency), the number of elliptocytes can increase to 10 percent. Exceptionally, as in dyserythropoiesis, the proportion can be as high as 50 percent. In hereditary elliptocytosis, the number of elliptical

Figure 31-13. **A.** Normal blood. *Arrow* points to a normochromic-normocytic discocyte. **B.** Stomatocytes. The *double arrow* points to the two morphologic types of stomatocyte: upper cell with a slit-shaped pale area and lower cell with a small central circular pale area. **C.** Echinocytes. The field has several such cells. The *arrow* points to one example with evenly distributed, blunt, short, circumferentially positioned, projections. **D.** Acanthocytes. The *arrow* points to one example with a few spike-shaped projections, unevenly distributed and of varying lengths. **E.** Spherocytes. Small, circular, densely-staining (hyperchromic) cells which, when fully developed, show no central pallor. **F.** Schizocytes (schistocytes, helmet cells, fragmented red cells). These microcytic cell fragments may assume varied shapes. The *arrow* points to a triangular shape, but two others of different shape are also present in the field. Despite being damaged and very small, they frequently maintain a biconcave appearance as witnessed by their central pallor. **G.** Sickle cells (Drepanocytes). Numerous sickle cells are shown. Two are in the classic shape of the blade on the agricultural sickle (*arrow*). Many red cells that have undergone the transformation to a “sickle” cell take the slightly less extreme form of elliptical cells with a very narrow diameter with condensed hemoglobin in the center (para-crystallization). About eight such cells are in the field. **H.** Elliptocytes and ovalocytes. The *lower arrow* points to an elliptocyte (cigar-shaped). The *upper arrow* points to an ovalocyte (football-shaped). Because both forms may be seen together in a case of inherited disease (same gene mutation resulting in both shapes), as shown here, it has been proposed that all such shapes be called elliptocytes with a Roman numeral to designate the severity of the shape change toward the elliptical, that is, elliptocytes I, II, and III. **I.** Target cells (Codocytes). The *arrow* points to one characteristic example among several in the field. The hemoglobin concentration corralled by membrane recurvature in the center of the cell gives it the appearance of an archery target. **J.** Tear-drop-shaped cells (Dacryocytes). Three dacryocytes are in this field. One example is indicated by the *arrow*. **K.** Horn cell (Keratocyte). Several examples are in the field. The *arrow* points to a typical such cell with two sharp projections. (Reproduced with permission from Lichtman’s Atlas of Hematology, www.accessmedicine.com.)

erythrocytes varies greatly, from 1 to 98 percent. Qualitative and quantitative anomalies of spectrin and protein 4.1, the major proteins of the membrane skeleton, are associated with hereditary elliptocytosis.^{49,64} Severe hemolytic anemia is seen only in the homozygous or compound heterozygotes form of the disease (hereditary pyropoikilocytosis) where extensive cell fragmentation produces *pyropoikilocytes* with marked decreases in SA:V ratio.

Acanthocytes

The acanthocyte (Chap. 46) is irregularly shaped, with two to 10 hemispherically tipped spicules of variable length and diameter. The bases of the spicules on the acanthocyte are of varying girth, unlike the spicules on echinocytes, which have remarkably uniform dimensions. Acanthocytes are seen in neuroacanthocytosis and in abetalipoproteinemia.⁶⁵ The lack of anemia in these conditions suggests that these cells have near normal life span in circulation.

Target Cells (Codocytes)

A relative excess of membrane surface area or decreased cell volume leading to increased SA:V ratio results in target cells.⁶⁶ Target cells may be seen in obstructive liver disease, hemoglobinopathies (S and C), thalassemia, iron deficiency, postsplenectomy, and lecithin cholesterol acetyltransferase deficiency. In patients with obstructive liver disease, lecithin cholesterol acetyltransferase activity is depressed. This increases the cholesterol-to-phospholipid ratio and produces an absolute increase in the surface area of the red cell membrane. In contrast, membrane excess is only relative in patients with iron-deficiency anemia and thalassemia because of the reduced cell volume. In contrast to spherocytes which exhibit increased osmotic fragility, target red cells are osmotically resistant.

Sickle Cells (Drepanocytes)

The sickle cell (Chap. 49) displays a characteristic variation of form on stained blood films. The fusiform cell in the crescent shape with two pointed extremities is encountered most commonly in deoxygenated blood samples as a result of polymerization of sickle hemoglobin. If sickle cell formation is observed by phase-contrast microscopy, the earliest change with deoxygenation is loss of flicker, followed by slight deformation at the discocyte border with displacement of the hemoglobin to one region of the cell. The cell then elongates and becomes rigid as a result of polymerization of hemoglobin S. Upon reoxygenation, the sickle cell resumes the discocyte form and, in so doing, loses membrane by microspherulation and fragmentation during retraction of long spicules.⁶⁷ Evidence suggests that the more typical sickle-shaped cells form under slow deoxygenation. With each sickling-unsickling cycle, membrane damage accumulates resulting in the formation of irreversibly sickled cells (ISCs).^{68,69} These cells are incapable of reversion to the biconcave disc shape, even when fully oxygenated. They have an increased hemoglobin concentration, increased cation permeability, decreased potassium, and increased sodium.

Fragmented Cells (Schistocytes)

Schistocytes (Chap. 51) are seen in microangiopathic hemolytic anemias (thrombotic thrombocytopenic purpura [TTP], disseminated intravascular coagulation [DIC], vasculitis, glomerulonephritis, renal graft rejection), carcinomatosis, heart valve hemolysis (prosthetic or pathologic valves), severe burns, and march hemoglobinuria (Chap. 51). Fibrin strands in damaged blood vessels can be arrayed so that they sieve the passing red cells. If a passing red cell folds over or otherwise attaches to the strand, the bloodstream pulls on the arrested cell, stretches it, and eventually fragments it.⁷⁰ The spleen rapidly removes the schistocytes with a low relative SA:V ratio; the remainder may circulate for many days.

CHAPTER 32

ERYTHROPOIESIS

Josef T. Prchal and Perumal Thiagarajan

SUMMARY

Production of red cells or *erythropoiesis*, is a tightly regulated process by which hematopoietic stem cells differentiate into erythroid progenitors and then mature into red cells. Erythropoiesis generates approximately 2×10^{11} new erythrocytes to replace the 2×10^{11} red cells (approximately 1 percent of the total red cell mass) removed from the circulation each day. Red cell production increases several fold after blood loss or hemolysis. When one of the progeny of the multipotential hematopoietic stem becomes committed to the erythroid lineage, this early erythroid progenitor undergoes a series of divisions and concurrent maturation that eventually result in morphologically recognizable erythroblasts. After expulsion of the nucleus, a macrocyte (polychromatophilic when stained by Wright stain, or a reticulocyte if stained with new methylene blue) leaves the marrow. During the first 24 hours in the circulation, reticulocytes lose their residual organelles (mitochondria and ribosomes) through an autophagic process and undergoes reconditioning of the membrane to become mature red blood cells with a morphology of a biconcave disc. Erythropoiesis is controlled by transcription factors and cytokines, the principal ones being GATA 1 and erythropoietin (EPO), which influence the rate of lineage commitment, proliferation, apoptosis, differentiation, and number of divisions from the earliest progenitor to late erythroblasts. The number of red cells produced varies in response to tissue oxygenation that determines the level of

Acronyms and Abbreviations: BCL11A, a critical switching factor for silencing γ -globin; Bcl-x, an antiapoptotic factor; BFU-E, burst-forming units–erythroid; CBP, a coactivator of a transcription factor; CFU-E, colony-forming units–erythroid; CFU-Ec-Kit, growth factor receptor also a protooncogene; CIS, a signal transduction protein that downregulates activity of erythropoietin receptor; CPM, counts per minute; EKLF, erythroid Kruppel-like factor; Emp, erythroblast-macrophage protein; EPO, erythropoietin; EPOR, EPO receptor; FOG, “friend of GATA,” a GATA-1 interacting protein; Gas6, growth arrest-specific 6; GATA-1, transcription factor; HCP, hematopoietic cell phosphatase; Hct, hematocrit; HIF, hypoxia-inducible transcription factor; ICSH, International Committee on Standardization in Hematology; JAK2, a tyrosine kinase that interacts with erythropoietin receptor; KAP1, KRAB-associated protein-1 is a transcriptional cofactor; KRAB-ZFP, one of the 400 human zinc finger protein-based transcription factors; mDia2, a protein that regulates actin and focal adhesion dynamics; miRNAs, microRNAs are small noncoding RNA molecules; NFE-2, a transcription factor, one of the principal regulator of hematopoiesis; Nix, a protein that is expressed during erythropoiesis and regulates mitochondrial apoptosis (autophagy); OS-9, osteosarcoma protein 9; PU.1, a transcription factor; RACK1, receptor of activated protein kinase C; RCM, red cell mass; SCL/TAL1, stem cell leukemia/T-cell acute lymphoblastic leukemia 1 factor; SOCS3, a signal transduction protein (also known as CIS3) that downregulates activity of erythropoietin receptor; VHL, von Hippel-Lindau protein.

the transcription factors, hypoxia-inducible factors (HIF), HIF-1 and HIF-2, the principal regulators of the response to hypoxia. HIFs modulate erythropoiesis by regulation of EPO production, by direct EPO-independent mechanism(s) and facilitating iron availability.

HISTORY

Erythrocytes evolved largely for the purpose of transporting oxygen to tissues. Thus, the size of the red cell mass and the rate of red cell production must be closely related to supply and demand for oxygen in the tissues. Toward the end of the 19th century, French mountaineers and physiologists established that a low tissue tension of oxygen stimulates red cell production.¹ In 1906, Paul Carnot, a professor at the Sorbonne, and Mademoiselle DeFlandre, his associate, suggested that hypoxia generates a humoral factor capable of stimulating red cell production.² Based on questionable experimental data, an influential biochemist Friederich Miescher³ erroneously proposed that marrow hypoxia directly stimulates red cell production. Finally, in 1950, in an ingenious study on parabiotic rats, Kurt Reissmann⁴ provided evidence for the existence of an indirect humoral mechanism. This work, and work of Erslev and colleagues^{5,6} who demonstrated that the plasma from anemic rabbits and primates contains an erythrocyte-stimulating factor, provided a strong basis for an existence of the factor appropriately named erythropoietin (EPO). In 1957, Jacobson and coworkers⁷ reported that EPO was produced by the kidney, a finding that raised the possibility that EPO isolated in adequate amounts might be of therapeutic benefit to uremic patients. After EPO cloning and production of recombinant EPO in therapeutic quantities, EPO has proved to have not only indications for therapy of anemia, but also has extraerythroid effects that are yet to be fully elucidated, such as its effect on cell growth. Widespread use of EPO for the treatment of anemia has surpassed original expectations.

PHYLOGENY OF RED CELL PRODUCTION

HEMOGLOBIN AND RED CELLS

Hemoglobin is present in the most primitive animal forms, such as *Paramecium* and *Tetrahymena*. Some crustaceans, such as *Daphnia*, are capable of developing an oxygen transport system without circulating red cells.⁸ One interesting exception is an Antarctic ice fish (*Chaenoccephalus aceratus*) lacking hemoglobin.⁹ These ice fish compensate for the absence of hemoglobin by their unusual nitric oxide metabolism.^{10–12} They have very large hearts and unusually large diameter capillaries. This permits a large volume of blood to circulate at high flow rate and at low vascular pressure because of decreased peripheral resistance. This permits their survival in the very high oxygen content of Antarctic waters.¹²

An erythroid cell that can synthesize, carry, and protect hemoglobin from oxidation was found only with the development of a circulatory system. Circulating nucleated erythrocytes first appear in the worms of the phylum Nemertina and in the sessile marine creatures of the phylum Phoronida. Erythropoiesis in these primitive invertebrates takes place near or on the peritoneal surface, derived from endothelial cells.¹³ Nonnucleated red cells are observed for the first time in the

more advanced phylum Annelida. However, the evolutionary advantage derived from enucleation appears to be slight. Nucleated red cells are observed in more advanced animals, such as reptiles and birds.¹⁴ All mammalian erythrocytes are nonnucleated and in most species are disc shaped, but are oval in some species.¹⁵ Enucleation decreases the workload of heart as it reduces one third of the cell weight.

In nonmammalian species, the spleen is the fundamental erythropoietic organ. However, in some fish, the kidneys also are involved in red cell production.^{16,17} In vertebrates, an evolutionary shift occurred from the spleen to the liver and from the liver to the bones cavities.¹⁸ The homeostatic regulation of blood or hemoglobin production has been studied in *Daphnia*,⁸ where a balance exists between oxygen need and hemoglobin production. In higher animals, this relationship is maintained by adjusting red cell production. Studies of birds,¹⁹ fish,²⁰ and mammals²¹ indicate that red cell production is controlled by EPO, which is capable of adjusting red cell production to the demands for oxygen in the tissues. EPO of mammals has considerable biologic similarity and genetic homology.²²

● ONTOGENY OF RED CELL PRODUCTION

EMBRYONIC AND FETAL ERYTHROPOIESIS

The environment within the bone apparently is optimal for cellular proliferation and maturation. However, bone cavities do not develop until the fifth fetal month. Other, presumably less favorable, sites are responsible for red cell production during early embryonic life (Chap. 7). In the human, large nucleated blood cells are first formed in the yolk sac,²³ and some enucleate.²⁴ They cluster in blood islands that become enveloped by endothelial cells forming the vascular plexus of the yolk sac.²⁵ This is referred to as primitive erythropoiesis, and is contrasted with definitive erythropoiesis, which occurs in the fetal liver and in the marrow. During the second gestational month, erythropoiesis moves to fetal liver, wherein smaller, but still macrocytic, nonnucleated cells are produced.^{26,27} At birth, the hepatic phase of blood cell production

ceases, and erythropoiesis moves to the marrow (Chaps. 7 and 48 provide details of developmental switching of embryonic, fetal, and adult globin expression).

During the neonatal period, the volume of available marrow space is almost the same as the total volume of hematopoietic cells and marrow vasculature.²⁸ This process continues for a few years until the growth of bones and bone cavities exceeds the growth of hematopoietic mass. However, whenever the demand on erythropoiesis increases (blood loss, hypoxia, ineffective erythropoiesis, or hemolysis), the lack of reserve space in neonates and small children reactivates extramedullary erythropoiesis in the liver and spleen.²⁹ In adults, expansion of marrow space continues, and the amount of fatty tissue gradually increases in all bone cavities. Because of the abundant marrow space, compensatory reactivation of extramedullary sites rarely occurs in later life. Extramedullary hematopoiesis during adult years indicates pathologic rather than compensatory blood formation, such as seen in primary myelofibrosis (Chap. 86) wherein the stem cells have abnormal interaction with the extracellular matrix.³⁰ During fetal life, EPO production is primarily hepatic.³¹ At birth, a gradual switch to renal production of EPO occurs. In the adult, the kidney is responsible for approximately 85 percent of total production.^{32,33}

● CELLULAR COMPONENTS OF ERYTHROPOIESIS

PROGENITOR CELLS

Our ability to evaluate early erythropoiesis rests on functional assays of hematopoietic progenitors. The developmentally earliest progenitor committed to the erythroid lineage is the burst-forming unit–erythroid (BFU-E). It was initially termed a burst because it contains cells still capable of migration. These cells form smaller clusters around a larger central colony, giving the appearance of a sunburst with satellite colonies (Fig. 32–1). However, all the cells in the colony and its satellites are derived from a single BFU-E and, thus, are clonal. BFU-E takes longer

Figure 32–1. Burst-forming unit–erythroid (BFU-E) and colony-forming unit–erythroid (CFU-E). Erythroid colony growth in methylcellulose medium in presence of erythropoietin. Normal human marrow. The colonies are stained for hemoglobin. **A.** BFU-E. This colony grows from a single marrow erythroid progenitor cell (BFU-E). It was photographed at 14 days in culture. The BFU-E is a differentiated cell, committed to the erythroid lineage. The BFU-E is a more primitive progenitor in the erythroid maturation pathway than the CFU-E. The colony it forms is large, compared to the CFU-E, has spreading margins, and often satellite colonies. **B.** CFU-E. This colony was photographed at day 7 in culture. The CFU-E originates from a more mature single progenitor cell than the BFU-E. The CFU-E is smaller and grows typically in a tight, dense colony, compared to the BFU-E. The sequence established in the erythroid lineage is BFU-E, CFU-E, erythrocyte precursors (proerythroblast, etc.). (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

than more mature erythroid progenitors to form a colony of erythroblasts (10 to 14 days) and form a large colony approximately 2000 to 3000 cells. BFU-E express low levels of EPO receptors (EPORs). BFU-E mature into colony-forming unit–erythroid (CFU-E), the more mature erythroid progenitor. A CFU-E is identified through more differentiated erythroid progenitor that *in vitro* form smaller colonies (50 to 200 cells) that mature in 3 to 5 days with EPOR density and EPO dependency increase gradually as progenitor cells mature, culminating at the level of the CFU-E.^{34,35} BFU-E and CFU-E cannot be identified by microscopy (Chap. 31), but they can be studied *in vitro* by their ability to generate microscopically recognizable hemoglobinized precursors (i.e., erythroblasts) by so-called clonogenic assays on semisolid media.

PRECURSOR CELLS

In contrast, cells that constitute the latter stages of erythropoiesis can be identified by light microscopy (Chap. 31). The earliest morphologically recognizable erythroid precursor in the adult marrow is the pronormoblast. Pronormoblasts are conspicuously large and they have large undense nuclei and deep basophilic cytoplasm as a result of the presence of numerous RNA-containing polyribosomes. Pronormoblast has a volume of 900 fL, 10 times the volume of the mature red blood cell. With each successive division, the precursor cells give rise to daughter cells of half their volume. Furthermore, with each division there is an increase in hemoglobin synthesis and condensation of nucleus. Thus, when the pronormoblasts divide to become basophilic normoblasts, the daughter cells have less blue cytoplasm because of hemoglobin synthesis and also a greater condensation of the nucleus. When the basophilic normoblasts divide further, they give rise to mature cells with more cytoplasmic hemoglobin that is stainable with both acid and basic dyes resulting in muddy-colored cytoplasm. These cells are called polychromatophilic normoblasts. The offspring of polychromatophilic normoblasts are called orthochromic normoblasts. Their nuclear chromatin is completely condensed and cytoplasm is pink from complete hemoglobinization. These cells do not divide further. Following extrusion of the nucleus, the enucleated cells derived from orthochromic orthochromic erythroblasts are termed *reticulocytes*, named after the cytoplasmic remnants of the endoplasmic reticulum and the persistence of a few mitochondria and strings of ribosomes seen when stained with supravital dyes. Reticulocytes remain in the marrow for 48 to 72 hours before being released to the blood. The reticulocytes have an irregular polylobated shape and various membrane-bound organelles.³⁶ In the blood, immature erythrocytes (reticulocytes) undergo further maturation with the removal of vestiges of organelles and reconditioning of the membrane to become mature red blood cells with the morphology of a biconcave disk.³⁷

The number of erythroid precursor cells determines to a great extent the number of red cells produced. The proerythroblasts also contain EPORs that, in the presence of higher than normal levels of EPO, may accelerate their entry into their first mitotic division. This process may lead to a shortened marrow transit time of erythroblasts³⁸ and result in release of still immature erythrocytes (polychromatophilic macrocytes), so-called stress reticulocytes (Fig. 32-2).³⁹ Creation of a normal sized and shaped red cells, devoid of organelles, is the end result of an orderly transformation of a proerythroblast with a large nucleus and a volume of approximately 900 fL to a hemoglobinized anucleate disc-shaped cell with a volume of approximately 90 fL. Although cytoplasmic maturation is continuous, the interposed mitotic divisions cause a stepwise reduction in cytoplasmic and nuclear volumes, enabling recognition of proerythroblasts, erythroblasts, and polychromatophilic macrocytes (reticulocytes) with light microscopy (Chap. 31). Direct measurements of the number of

marrow erythroblasts and reticulocytes have shown approximately 50 erythroblasts and approximately 124 reticulocytes for each proerythroblast (Table 32-1).^{40,41} This distribution conforms to the number of cells in a theoretic erythroid pyramid (Table 32-1, Fig. 32-3). In the pyramid, each erythroblast undergoes five mitotic divisions over 5 days before the orthochromic erythroblast loses its nucleus and as an immature erythrocyte enters a 2- to 3-day period of maturation before its release from the marrow. The size and shape of these erythroid pyramids undoubtedly vary, but such variations play a role in the physiologic control of red cell production. When production is suppressed, as in low EPO as seen in anemia of chronic renal disease, the distribution of erythroblasts appears normal, with no morphologic or ferrokinetic evidence of ineffective erythropoiesis but the number of erythroid progenitors is decreased.³⁸ When production is increased, as in severe hemolytic anemia, the pyramid of erythroid precursors also appear normal, with no evidence of additional mitotic divisions but the number of erythroid progenitors is increased. Consequently, the rate of red cell production largely depends on the number of erythroid progenitors formed.

As the erythroblast matures, its synthetic activities increase rapidly, producing all proteins characteristic of mature red blood cells, particularly globin. Eventually 95 percent of all protein in the red cell is hemoglobin, almost all hemoglobin A ($\alpha_2\beta_2$) in adults, with only small amounts of hemoglobin F ($\alpha_2\gamma_2$) and hemoglobin A₂ ($\alpha_2\delta_2$). Hemoglobin F is unequally distributed and is present only in some erythrocytes, designated as F cells (Chaps. 48 and 49).

EPOR density declines sharply on early erythroblasts, and EPORs are absent from the more mature erythroblast forms while the number of receptors for transferrin increases, reflecting the increased demands for iron for heme synthesis.

ERYTHROBLAST ENUCLEATION

The microenvironment may be important for proliferation and maturation of erythroblasts. However, *in situ* secreted or circulating growth factors and cytokines appear to be less important for precursor cells than for progenitor cells. Intercellular adhesion molecules secure the structural integrity of the marrow, and fibronectin is of special importance for erythroblasts.⁴² Loss of fibronectin receptors heralds the translocation of polychromatophilic macrocytes (reticulocytes) into blood, but some newly emerging erythrocytes remain sticky even after release and are temporarily sequestered by the spleen (Chap. 6). Because erythroid colonies developed *in vitro* consist principally of nucleated red cells, enucleation may primarily be induced by marrow stromal cells (Chaps. 5 and 31).

The extrusion of the spent pyknotic nuclei at terminal erythroid maturation is unique to mammals. This process results in the formation of pliable biconcave disc from rigid spheroidal cells. Enucleation decreases workload of the heart as it reduces one-third of the erythrocyte weight. The retinoblastoma protein and its effector, E2f-2, are critical for erythroid cells to exit the cell cycle for enucleation to take place.⁴³ During terminal differentiation, the plasma membrane forms an envelope around the nucleus, followed by the formation of the contractile actin ring on the plasma membrane to move the nucleus for disposal.⁴⁴ Rac guanosine triphosphatases (GTPases) and their effector mDia2 are required for the contractile actin ring movement in the release of the nucleus.⁴⁵ After separation from the cell, the expelled nucleus displays phosphatidylserine and is recognized and engulfed by macrophages.⁴⁶ Emp, an erythroblast–macrophage protein initially identified as a mediator of erythroblast–macrophage interactions, also plays a role in the enucleation.⁴⁷ Emp associates with F-actin, an interaction important for the normal distribution of F-actin in both

Figure 32-2. Stress reticulocytes. **A.** Blood film. Hemolytic anemia. The polychromatophilic macrocyte with puckering evident by the clover-leaf-shaped clear areas (folds) is a characteristic stress erythrocyte, so named because they are prematurely released from the marrow by high levels of erythropoietin, usually as a result of a hemolytic anemia. They are large, intensely polychromatophilic, and often have evidence of excess surface area as evident by folds. **B.** Phase-contrast microscopy of the blood cells in suspension from a case of hemolytic anemia. The arrows point to two macrocytes with pucker (folded) surfaces, characteristic of stress reticulocytes. **C.** A scanning electron micrograph of a stress reticulocyte. Note the markedly increased surface area to volume relationship for a red cell. **D.** Scanning electron micrograph of a marrow sinus of a mouse. *L* denotes the sinus lumen. The asterisk is the edge of the endothelial lining of the sinus, torn in preparation for microscopy. The arrow points to two anucleate red cells folded amidst the reticular cell extensions that make up the stroma of marrow. Note the severe folding of reticulocytes *in situ*. Note similarity between folds of the cell to the scanning image in **(C)**. Just below the asterisk is an enucleated red cell (reticulocyte) half in the hematopoietic space and half in the lumen, presumptively in egress. Note the surface folding required when traversing the narrow pore in endothelium. **E.** A marrow sinus with an anucleate red cell emerging into the lumen. Note the folding required to negotiate the narrow pore through which the cell is exiting. (Chapter 3 provides details of erythrocyte egress.) (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

erythroblasts and macrophages. Emp null mice do not extrude their nuclei from erythroid cells. Thus, Emp appears to be required for erythroblast enucleation.⁴⁸

Microscopic determination of marrow cellularity and proportion of erythroblasts permits semiquantitative evaluation of erythropoiesis.

TABLE 32-1. Erythroid Pools

Cell Type	Cell Number × 10 ⁸ per kg/Body Weight	
	Observed*	Theoretic Model (Fig. 31-3)
Proerythroblasts	1	1
Erythroblasts	49	58
Marrow reticulocytes	82	64
Blood reticulocytes	31	32
Mature red cells	3300	3800

Data from Donohue DM, Reiff RH, Hanson ML, et al.: Quantitative measurement of the erythrocytic and granulocytic cells of the marrow and blood. *J Clin Invest* 37(11):1571-1576, 1958 and Finch CA, Harker LA and Cook JD: Kinetics of the formed elements of human blood. *Blood* 50(4):699-707, 1977.

However, the presence of ineffective erythropoiesis in disease states, such as iron deficiency, anemia of chronic disease, megaloblastic anemias, and thalassemias, makes the morphologic approach misleading (Chaps. 37, 41, 42, and 48). Red cell production can be accurately estimated by ferrokinetic studies using ⁵⁹Fe. Similarly, the amount of the final product of erythropoiesis, the red cell mass, can also be accurately measured. Unfortunately, the ever-increasing regulation of even minute amounts of radioisotopes used *in vivo* makes these methods available in only a few specialized centers.

Chapters 7, 30, 47, and 48 discuss developmental control of erythropoiesis, differential use of enzyme and globin genes, and the crucial differences between embryonic yolk sac and fetal/adult definite erythropoiesis. This chapter focuses mainly on adult erythropoiesis.

REGULATION OF ERYTHROPOIESIS

Erythropoiesis is a tightly regulated system, but the details are still not fully elucidated. Much remains to be learned from uncovering the molecular basis of many congenital and acquired mutations that disrupt the control of erythropoiesis. Two competing hypothesis have been proposed to explain the differentiation of the hematopoietic progenitor cells toward erythroid lineage.

Figure 32-3. Theoretical model of proliferation of erythroid-committed marrow cells, including their most important receptors. BFU-E, burst-forming units–erythroid; CFU-E, colony-forming units–erythroid; EPO, erythropoietin; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin.

DETERMINISTIC MODEL OF LINEAGE COMMITMENT

According to the deterministic model of lineage commitment, specific extracellular signals, such as cytokines, play an instructive role in lineage specification.

Multipotential progenitors (Chap. 18) and erythroid unipotential progenitors, the BFU-E, require stem cell factor, interleukin-3, granulocyte-macrophage colony-stimulating factor, and/or thrombopoietin for growth and survival (Fig. 32-4).

STOCHASTIC MODEL OF ERYTHROID DIFFERENTIATION

In contrast, the stochastic model proposes that spontaneous formation of a set of transcription factors, independently of extrinsic signals, mediates lineage commitment. These transcription factors activate a unique set of genes for a particular lineage and repress the action of alternative transcription factors and cytokines play only a permissive role. Most of evidence based on gene targeting studies and *in vitro* culture studies support the stochastic model of differentiation. Several transcription factors, such as GATA-1, FOG1, erythroid Kruppel-like factor (EKLF), PU.1, and SCL/TAL1 (stem cell leukemia/T-cell acute lymphoblastic leukemia 1 factor) have been characterized that are involved in erythroid differentiation.

The GATA family of zinc-finger transcription factors was first identified as the nuclear factors that bind to the GATA sequence in the

Figure 32-4. A. Cytokine influence on hematopoiesis. CFU-GEMM, colony-forming unit–growing granulocyte, erythrocyte, megakaryocyte, and macrophage precursors; G-CSF, granulocyte colony-stimulating factor; IL3, interleukin-3; SCF, stem cell factor; TPO, thrombopoietin. **B.** Regulation of erythropoiesis by hypoxia. HIF-1 hypoxia inducible factor-1; VEGF, vascular endothelial growth factor 1.

enhancer region of the globin genes.^{49,50} GATA-1 protein is expressed during erythroid differentiation, with highest expression in CFU-Es and pronormoblasts. GATA-1 promotes erythroid differentiation by activating several erythroid-specific genes and represses transcription of Kit receptor and GATA-2. GATA-1 deficient mice die at embryonic day 10.5 with severe anemia from maturation arrest at the stage of pronormoblasts.⁵¹ *In vitro*, GATA-1 null the embryonic stem cells fail to mature beyond pronormoblast and undergo apoptosis. GATA-1 and its cofactor CBP are essential for the formation of an erythroid-specific histone acetylation pattern of histones at the active globin genes and the β -globin locus control region.⁵² GATA-1, along with EPO, induces expression of the antiapoptotic protein Bcl-x_L⁵³ and interacts with multiple proteins, including FOG-1 and PU.1,⁵⁴ and FOG-1 acts as a cofactor for GATA-1.⁵⁵ GATA-1 interaction with PU.1 appears to counteract erythropoiesis by inducing differentiation of pluripotent stem cell to myeloid and B lymphopoiesis and inhibition of erythropoiesis.^{54,56,57} Whereas PU.1 absence appears to be required for completion of terminal erythroid differentiation, low levels of PU.1 expression are essential for fetal erythropoiesis and for proper augmentation of adult erythropoiesis at times of stress.⁵⁸

Friends of GATA

FOG-1, a member of friend of GATA family of zinc finger proteins, act as cofactors for GATA-1. It was first identified in a yeast two-hybrid

screen for GATA-1 interacting proteins.⁵⁵ It binds to the amino zinc finger of GATA-1. FOG-1^{-/-} mice die during embryonic days 10.5 to 11.5 from severe anemia with arrest in erythroid maturation at a stage similar to that observed in the GATA-1⁻ mice.⁵⁹ FOG-1 physically interacts with GATA-1 to augment or inhibit its transcriptional activity depending on the promoter context.

GATA-2 was initially cloned as a GATA motif-binding factor is present in all erythroid cells; and, targeted deletion of GATA-2 resulted in embryonic lethality at day 10.5 from ablation of blood cell development.⁶⁰ GATA-1 and GATA-2 directly regulate GATA-2 transcription in a reciprocal fashion during erythroid differentiation.^{61,62} GATA-2 autoregulates its transcription by binding to its own regulatory elements in the promoter region. This autoregulation is abolished by the displacement of GATA-2 by GATA-1 (GATA-2/GATA-1 switch), an interaction facilitated by FOG-1.⁶³ Chromatin immunoprecipitation studies indicate that FOG-1 facilitates occupancy by GATA-1 at selected *cis*-regulatory chromatin elements. Double knockout of GATA-1 and GATA-2 results in embryonic lethality with complete absence of primitive erythropoiesis.⁶⁴ The severity of this phenotype compared to either single GATA-1 or GATA-2 knockout suggests overlapping functions of these two transcription factors in primitive erythropoiesis.

Kruppel-like Factor

EKLF is a zinc finger protein identified by subtractive hybridization of the mRNA of erythroid cells with common messages in a myeloid cell line.⁶⁵ It interacts with CACCC sequence in the β -globin promoter, where it modifies chromatin structure permitting β -globin gene transcription. EKLF-deficient mice die at embryonic day 14.5 to 15 from severe anemia from defective definitive erythropoiesis.⁶⁶ There is a marked decrease in β -globin mRNA and protein levels in EKLF-deficient erythroid cells. Large amounts of iron accumulate in the reticuloendothelial system of EKLF-deficient mice, consistent with an ineffective erythropoiesis.

STEM CELL LEUKEMIA/T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA 1

SCL/TAL1 is a member of basic helix-loop-helix transcription factors essential for maturation of the erythroid and megakaryocytic lineages.⁶⁷ Knockout of SCL/TAL1 leads to failure of hematopoiesis.⁶⁸ Selective rescue of SCL/TAL1 null embryonic stem cells under the control of stem cell enhancer revealed differentiation blocks in erythroid and megakaryocytic maturation.⁶⁹ Conditional knockout studies have revealed that erythroid and megakaryocytic precursors do not develop in the marrow of mice upon deletion of SCL/TAL1.⁷⁰ Heterodimerization of SCL with other transcription factors, such as E2A, is a prerequisite for its functions.⁷¹

BCL11A, a transcription factor initially identified in lymphoid cells, regulates erythroid differentiation, especially in switching from fetal to adult hemoglobin.⁷¹ Fetal hemoglobin (HbF) levels decline after birth and are then replaced by adult hemoglobin A. The molecular mechanisms responsible for this switch are not completely known. Genome-wide association findings have provided a major breakthrough in understanding this phenomenon.⁷² There is an inverse correlation between BCL11A and HbF expression in erythroid cells. BCL11A occupies several discrete sites in the β -globin gene cluster and likely plays an important role in hemoglobin switching during erythroid differentiation.

GROWTH ARREST-SPECIFIC 6 PROTEIN

Growth arrest-specific 6 (Gas6) protein is a secreted vitamin K-dependent protein that interacts with cell membranes and leads to intracellular

signaling (via its receptor tyrosine kinases). Gas6 receptors are expressed in hematopoietic tissue, megakaryocytes, myelomonocytic precursors, and marrow stromal cells. Gas6 amplifies the erythropoietic response to EPO using a mouse model of Gas6 knockout.⁷³ Gas6 is known to downregulate the expression of inflammatory cytokines such as tumor necrosis factor- α by macrophages.⁷⁴

Figure 32-5 outlines the interrogation of the molecular mechanisms that regulate lineage-specific differentiation and commitment reveals the existence of separate megakaryocytic/erythroid progenitors versus both myeloid and lymphoid lineages.⁷⁵

ERYTHROPOIETIN, OXYGEN SENSING, AND HYPOXIA-INDUCIBLE FACTOR

Erythropoietin

The principal hormone regulating erythropoiesis is EPO, which is produced principally in the kidney.⁷ Erythroid progenitors express their own EPO.⁷⁶ Different levels of kidney-produced EPO are optimal for various stages of erythroid maturation.⁷⁷ Purification of EPO provided a partial protein sequence that led to cloning of the gene and permitted mass production of the recombinant protein.⁷⁸ EPO and its recombinant form are heavily glycosylated α -globulins with a molecular mass of 34,000 daltons and a specific activity of approximately 200,000 IU/mg.^{79,80} Sixty percent of the molecular weight of the recombinant protein is contributed by amino acids; the remaining 40 percent is composed of carbohydrate. Using molecular probes for EPO, mRNA enabled the localization of the synthesis of EPO to renal cortical interstitial cells^{81,82} of endothelial or fibroblastic lineage. The cells appear to function in an all-or-none fashion, with the overall production of mRNA dependent on the number of cells activated.⁸³

Certain 5' sequences located 6000 to 12,000 bp upstream also affect EPO gene transcription.⁸⁴ These sequences are not hypoxia sensitive but appear necessary for tissue and cellular specificity.⁸⁴ Hepatic production is contributed primarily by hepatocytes but is a much less important source than is the kidney.⁸⁵ During fetal life, however, hepatic EPO production is of major importance for red cell production (Chap. 7).^{86,87} EPO production is regulated exclusively at the level of its transcription by hypoxia at the transcription level. The transcriptional activation of the EPO gene is controlled by a specific sequence located in the 3' flanking region termed *hypoxia-responsive element*.⁸⁸⁻⁹⁰ The core of the enhancer is constituted by the sequence CACGTGCT and mutations in this core sequence abolish hypoxia responsiveness.

EPO is not stored; it is secreted immediately.⁸¹⁻⁸³ Circulating recombinant EPO and presumably native EPO have a half-life ($T_{1/2}$) of 4 to 12 hours, with a volume of distribution slightly larger than that of the plasma volume.⁹¹ EPO is degraded after it binds to EPOR (see "Erythropoietin Receptor" below).⁹²

Erythropoietin Receptor

Interaction of EPO with its receptor EPOR results in (1) stimulation of erythroid cell division, (2) erythroid differentiation by induction of erythroid-specific protein expression, and (3) prevention of erythroid progenitor apoptosis.⁹³ Earlier models of this interaction were based on the ligand (EPO)-induced homodimerization of EPOR. In reality, EPOR is a preformed homodimer that undergoes a major conformational change upon binding,⁹⁴ which initiates the EPO-specific erythroid signal transduction cascade (Fig. 32-6). The cytoplasmic portion of EPOR contains a positive regulatory domain that interacts with Janus kinase 2 (JAK2).⁹⁵ Immediately after EPO binding, JAK2 cross-phosphorylates the EPOR itself, and other proteins such as STAT5 (signal transducer and activator of transcription 5), thus initiating a cascade of erythroid-specific signaling.⁹⁶ JAK2/STAT5

Figure 32-5. Schematic outline of emerging hierarchy of hematopoiesis outlining a separate progenitor for erythroid/megakaryocytic lineage (MEP). RUNX-1, Scl1/Tal1, Lmo1, Mll/Tel, PU-1, GATA-1, GATA-2, gf-1, C/EBP α , FOG1, EKLF, Ikaros, E2A, EBF, PAX-5, BCL 11A, NOTCH, TCF-1 are transcription factors. CLP, common lymphoid progenitor; CMP, common myeloid progenitor; GMP, granulocyte/macrophage progenitor; LT-HSC, long-term hematopoietic stem cell; MEP, megakaryocyte/erythroid progenitors; RBCs, red blood cells; ST-HSC, short-term hematopoietic stem cell. (Reproduced with permission from Orkin SH1, Zon LI: Hematopoiesis: an evolving paradigm for stem cell biology. *Cell* 22;132(4):631–644, 2008.)

signaling plays an essential role in EPO-EPOR-mediated regulation of erythropoiesis (see Fig. 32-6).⁹⁷ Deficiency of EPO-EPOR is lethal by abrogating fetal liver erythropoiesis (but not the “primitive” yolk sac erythropoiesis). However, in these *EPO* or *EPOR* knockout mice, differentiation of pluripotent stem cells to BFU-E occurs, but not the subsequent erythroid differentiation. This occurrence demonstrates the crucial role of EPO in terminal erythroid maturation.^{35,98,99} The C-terminal cytoplasmic portion of EPOR also possesses a domain essential for prevention of apoptosis (see Fig. 32-6) by inducing expression of Bcl-x_L via phosphoinositide 3'-kinase (PI3K).⁵³ However, the cytoplasmic portion of EPOR also contains a negative regulatory domain¹⁰⁰ that interacts with hematopoietic cell phosphatase (HCP, also known as SHP1) and down-modulates signal transduction.¹⁰¹ Once recruited by EPOR tyrosine (Y)429, HCP attaches to the cytoplasmic EPOR domain and dephosphorylates JAK2. Inactivation of the HCP binding site leads to prolonged phosphorylation of JAK2/STAT5.^{101,102} CIS3 (also known as SOCS3), another negative regulator of erythropoiesis, binds to the cytoplasmic portion of the EPOR Y401 and suppresses EPO-dependent JAK2/STAT5 signaling.^{103,104} Thus, deletion of the distal C-terminal cytoplasmic portion of EPOR results in a truncated EPOR, abolishes

negative regulatory elements, and results in increased proliferation of erythroid progenitor cells. Gain-of-function mutations resulting from deletion of the negative regulatory domain of the *EPOR* gene (Chap. 57) have been demonstrated in a small proportion of individuals with primary familial and congenital polycythemia, but are rarely found in erythroleukemia¹⁰⁵; however, the rearranged EPOR has also been identified in a subtype of high-risk B-progenitor acute lymphoblastic leukemia.¹⁰⁶

Because the activation signal after EPO binding to its receptor is rapidly downregulated and EPO briskly disappears after binding to EPOR, EPO-EPOR internalization is one mechanism of downregulation of EPO signaling.⁹² After EPO binds to the receptor, EPO-EPOR complexes are ubiquitinated, rapidly internalized, and targeted for degradation. This process involves two proteolytic systems, the proteasomes that remove part of the intracellular domain of EPOR at the cell surface and the lysosomes that degrade the EPO-EPOR complex in the cytoplasm.¹⁰⁷

Another incompletely understood mechanism of erythropoiesis regulation is the presence of several EPOR isoforms, some of which may have an inhibitory function on erythropoiesis.^{108–110}

Figure 32-6. Outline of erythropoietin–erythropoietin receptor (EPO–EPOR) signaling. Activation of Janus kinase 2 (JAK2) and signal transducer and activator of transcription 5 (STAT5) represents erythropoiesis-promoting signals. Interaction of CIS, a signal transduction protein that downregulates activity of erythropoietin receptor, and hematopoietic cell phosphatase (HCP) inhibit erythropoiesis. Phosphatidylinositolide 3′-kinase (PI3K) activation of Bcl-x_L inhibits apoptosis of erythroid progenitors.

Nonerythroid Effect of Erythropoietin Signaling

Soon after the erythroid effects of recombinant EPO were described, nonerythroid effects were identified.¹¹¹ Some of these effects are beneficial, including roles in neural, cardiovascular, and retinal tissues, and in immune function and in tissue repair. It has been claimed that the hormone also exerts beneficial effects on athletic performance and improved neurocognition, but these are not convincingly substantiated. The effects of EPO in nonerythroid tissues are the result of EPO binding to EPOR, and, as in erythroid cells, the EPO–EPOR interaction initiates a signal transduction process that regulates the survival, growth and differentiation of the involved tissue.¹¹² EPO and EPOR

play a physiologic role in many nonerythroid cells including endothelial cells,¹¹³ megakaryocytes, and cells of the brain, heart, uterus, breast, and testis. However, in some tissues (e.g., brain, heart, and kidney) the signaling mechanism may be different because EPO can interact with EPOR and CD131 heterodimers.^{114,115}

Detrimental EPO effects include a poorly understood increased cancer mortality,^{95,116,117} increased blood pressure, and thrombosis.¹¹⁴

Hypoxia-Inducible Factors

Under normal conditions, EPO production is mediated by decreased oxygen saturation of hemoglobin, that is, hypoxemia.⁷⁷ Hypoxia is an important factor in development, energy metabolism, vasculogenesis, iron metabolism, tumor promotion and is the principal regulator of erythropoiesis. The response to hypoxia is controlled by transcriptional factors termed *hypoxia-inducible factors* (HIFs).^{118,119} Adaptive physiologic responses to hypoxia serve to (1) increase O₂ delivery to cells, (2) allow cells to survive under reduced O₂ by activating glycolysis, and (3) reduce the formation of reactive oxygen species.¹²⁰ HIFs are heterodimeric transcription factors composed of a highly-regulated α subunit and a constitutively expressed β subunit that belongs to the basic helix-loop-helix containing the PER-ARNT-SIM (PAS)-domain family of transcription factors. The first HIF to be discovered, HIF-1, is induced in hypoxic cells and binds to a *cis*-acting nucleotide sequence of hypoxia-controlled genes referred to as the *hypoxia-responsive element*, first identified in the 3′-flanking region of the human *EPO* gene.¹²¹ Two other HIF homologues, HIF-2 and HIF-3, have been identified. HIF-2 has more limited tissue expression than HIF-1 but it is the principal regulator of EPO expression.^{118,119} Many hypoxia-inducible genes are directly regulated by HIF-1. Approximately 3 percent of all genes expressed in endothelial tissue are HIF-1 regulated.¹²² The half-life of HIF-1 α in the cell is minutes under normoxic conditions. HIF-1 and HIF-2 α subunits are rapidly degraded by the von Hippel-Lindau (VHL) protein–ubiquitin–proteasome pathway.¹²³ The targeting and subsequent polyubiquitination of HIF α subunits requires VHL, iron, O₂, and proline hydroxylase activity, and this complex constitutes the oxygen sensor (Fig. 32-7).^{124,125}

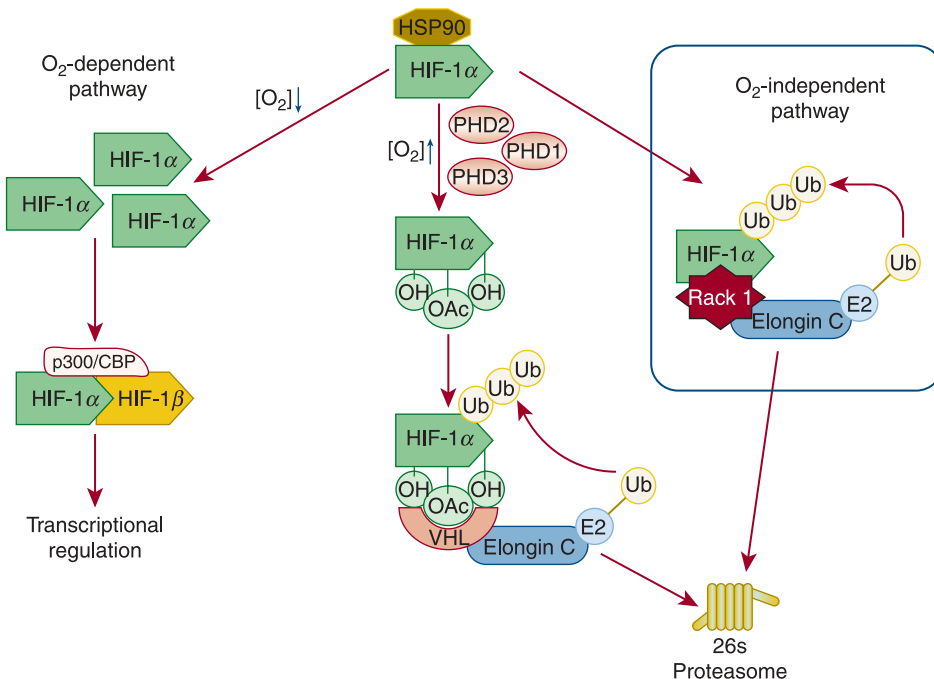

Figure 32-7. Schematic outline of regulation of HIF-2 and HIF-2 α subunits by hypoxic and nonhypoxic pathways. HIF, hypoxia-inducible factor; HSP90, heat shock protein 90; PHDs, proline hydroxylases; p300 and CBP, cofactors of hypoxia response transcription with HIF-1; RACK1, receptor of activated protein kinase C; ub, ubiquitin residues; VHL, von Hippel-Lindau protein.

This degradation of HIFs α subunits is initiated by a posttranslational hydroxylation event at residue proline 564 (P564) that is mediated by one of several iron-containing proline hydroxylases (PHDs). The hydroxylation of HIFs α subunits facilitates binding to the VHL protein and subsequent ubiquitination and proteasomal degradation. Osteosarcoma protein 9 (OS-9) binds to both HIF-1 α and PHD2 and is required for efficient prolyl hydroxylation.¹²⁶ Under hypoxic conditions, HIF-1 and HIF-2 α proteins are not degraded and are translocated to the cell nucleus where they dimerize with HIF- β to form the HIF heterodimer that activates transcription through binding to specific hypoxia-responsive elements on target genes. Another regulatory step involves O₂-dependent asparaginyl-hydroxylation of asparagine (N) 803 in HIF-1 α that requires the enzyme HIF-3, also known as FIH-1 (factor inhibiting HIF-1). Hydroxylation of N803 during normoxia blocks the binding of transcription factors p300 and CBP to HIF-1, resulting in inhibition of HIF-1-mediated gene transcription. Under hypoxic conditions, HIF α subunits are not hydroxylated. The unmodified protein escapes VHL-binding, ubiquitination, and degradation (see Fig. 32-7). When N803 of HIF-1 α is not asparaginyl-hydroxylated, p300 and CBP can bind to the HIF-1 heterodimer, allowing transcriptional activation of HIF-1 target genes.

HIF-2 Transcription Factor HIF-1 α and HIF-2 α exhibit a high degree sequence homology but have differing mRNA expression patterns: HIF-1 α is expressed ubiquitously, whereas HIF-2 α expression is restricted to certain tissues.^{118,127} The kidney is the main site of EPO production (i.e., renal interstitial cells), and HIF-2 and, to a lesser degree, HIF-1 are the principal regulator of EPO transcription in the kidney.^{118,127} In other tissues, such as brain¹²⁸ and liver⁸⁷ (which generates approximately 15 percent of circulating EPO), EPO gene transcription is HIF-2-dependent.¹²⁷ The discovery of an iron-responsive element in the 5' untranslated region of HIF-2 α reveals a novel regulatory link between iron availability and HIF-2 α expression¹²⁹ that may also influence control of erythropoiesis. The importance of HIF-2 α in regulation of EPO gene was demonstrated by a gain-of-function HIF-2 α mutation causing erythrocytosis.¹³⁰

Hypoxia-Independent Regulation of Hypoxia-Inducible Factor While O₂-dependent regulation of the HIF-1 α subunit is mediated by prolyl hydroxylases, VHL protein, and the proteasomal complex, hypoxia-independent regulation of HIF-1 α has been uncovered. This novel mechanism involves the receptor of activated protein kinase C (RACK1) as a HIF-1 α -interacting protein that promotes prolyl hydroxylase/VHL-independent proteasomal degradation of HIF-1 α . RACK1 competes with heat shock protein 90 (HSP90) for binding to the PAS-A domain of HIF-1 α . HIF-1 α degradation is abolished by loss-of-function RACK1. RACK1 binds to the proteasomal subunit, elongin-C, and promotes ubiquitination of HIF-1 α (see Fig. 32-7). Therefore, RACK1 and HSP90 are the essential components of an O₂/PHD/VHL-independent mechanism for regulating HIF-1 α .¹³¹

The rapid degradation of HIF is complex and tightly regulated, and mutations affecting the genes that encode the regulatory factors may underlie some of the unexplained congenital polycythemias.

This complex (Chaps. 34 and 57) constitutes the oxygen sensor (see Fig. 32-7).^{124,125,132}

INSULIN-LIKE GROWTH FACTOR-1, RENIN-ANGIOTENSIN SYSTEM, AND HEMATOPOIESIS

Although *in vitro* studies of erythropoiesis have provided crucial information about the regulation of erythropoiesis, many experiments were performed in the presence of serum and serum-component proteins capable of stimulating and inhibiting erythropoiesis.^{133,134} Using serum-free conditions, insulin-like growth factor-1 (IGF-1) can partially

substitute for EPO in BFU-E cultures. Furthermore, anephric, nonanemic patients with no detectable EPO have elevated levels of IGF-1.¹³⁵

REMOVAL OF ERYTHROCYTE ORGANELLES

NIX-DEPENDENT CLEARANCE OF MITOCHONDRIA BY AUTOPHAGY

During terminal erythroid differentiation, erythroid cells discard all their internal organelles including mitochondria. Autophagy has been suggested to play an important role in this process based on early morphologic studies.^{136,137} This is confirmed by studies using chemical inhibitors of autophagy and small interfering ribonucleic acid (siRNA) knockdown of essential autophagy associated genes.^{138,139} At the initial stage of autophagy, a double-membrane structure is formed to sequester cytoplasmic components in autophagosomes. Autophagosomes then fuse with lysosomes and become autophagolysosomes to degrade the sequestered components. Mice deficient in a bcl-2 family member, Nix, a protein that is expressed during erythropoiesis and regulates mitochondrial apoptosis (autophagy), display defects in the clearance of mitochondria. Interestingly, the formation of autophagosomes in reticulocytes is normal in the absence of Nix, suggesting that Nix is not required for the initiation of autophagy or the formation of autophagosomes. Instead, mitochondria remain clustered outside of autophagosomes in Nix-/- reticulocytes.¹³⁸ This indicates that Nix is required for the sequestration of mitochondria by autophagosomes. Another study using virally transformed Nix-/- erythroid cells also reported defective inclusion of mitochondria by autophagosomes.¹⁴⁰ Therefore, Nix deficiency leads to a specific defect in mitochondrial removal without causing a general block in autophagy or erythroid maturation. Nix-/- reticulocytes are defective in the loss of mitochondrial membrane potential during *in vitro* maturation.¹³⁸

DOWNREGULATION OF CELL SURFACE PROTEINS AND OTHER ORGANELLES

During erythroid maturation, reticulocytes release small vesicles containing cellular proteins. These vehicles are exosomes that are involved in the clearance of cell-surface proteins, such as acetyl cholinesterase, CD71 transferrin receptor and integrin $\alpha_v\beta_1$.^{141,142} The enrichment of these surface molecules in exosomes suggests that the exosomal pathway plays a major role in the clearance of these surface molecules. Other cellular components, such as lysosomes, endoplasmic reticulum, Golgi apparatus, ribosomes, and RNA, are also cleared during erythroid maturation. The precise mechanisms for the removal of these components are unclear. In Nix-deficient mice, the loss of CD71 and ribosomes are normal during erythroid maturation, suggesting that exosomal pathways play a major role in the clearance of CD71 or ribosomes.¹³⁸

MICRORNAS IN ERYTHROPOIESIS

MicroRNAs (miRNAs) are small 18- to 22-nucleotide noncoding RNAs that regulate gene expression by inhibiting protein translation or by destabilizing target mRNAs; they are important regulators of hematopoiesis. The role of miRNAs in regulation of erythropoiesis is being actively defined. Some miRNAs are mainly expressed in early stages of erythropoiesis, others in late stages, and some have biphasic expression during erythroid differentiation. Some appear to have erythroid specific expression.¹⁴³ The critical role of miRNAs and their relationship to the essential transcription factors regulating erythropoiesis is outlined

by the report that the pivotal transcription factors for erythropoiesis, GATA-1 and NFE-2, directly regulate and control differentiation via miRNA-199b-5p. This miRNA then targets c-Kit, an important receptor on early erythroid cells.¹⁴⁴ Some miRNAs likely play a role in the commitment to erythroid versus megakaryocytic differentiation. Thus, miRNA-18a was reported to be upregulated during erythropoiesis and downregulated during megakaryopoiesis, while miRNA-145 was upregulated in megakaryopoiesis and downregulated in erythropoiesis. Their mRNA targets and their functional significance are being defined.¹⁴⁵ LIN28B and its targeted let-7 have regulated expression during the fetal-to-adult erythroid cell transition.¹⁴⁶ Another important erythroid development and function is regulated by miRNA-351. A complex regulatory transcriptional repressor system controlling heterochromatin formation exists composed of KRAB-ZFP-mediated repression that include cofactor KAP1 (KRAB-associated protein-1). Deletion of KAP1 in mice upregulates miRNA-351 and several other microRNAs, which then downregulate Nix and mitochondrial autophagy (see “Neocytolysis” in Chap. 33), resulting in expansion of mitochondria in erythroid progenitors and severe hypoproliferative anemia phenotype.¹⁴⁷

MEASUREMENTS OF RED CELL MASS

The red cell mass is maintained and regulated by the kidney and marrow, which, under steady-state conditions, precisely replaces cells lost by senescence. Red cell mass defines pathogenesis of anemia and polycythemia. The kinetics of red cell production and destruction helps establish their pathogenesis. A number of tests have been developed to measure the three main components of red cell kinetics: red cell mass, rate of red cell production, and rate of red cell destruction. Some of these tests are simple but indirect and only semiquantitative, such as hematocrit, reticulocyte count, haptoglobin, lactic dehydrogenase, and unconjugated bilirubin concentration. Examination of the marrow allows assessment of total cellularity and relative erythroid contribution but is limited in that the kinetics of cell production cannot be inferred from a single static image, obtained from a very small fraction of the whole marrow. These tests are very useful in the aggregate but can be supplemented by more complex but direct quantitation; however, most require use of radioisotopes.

HEMATOCRIT

Packed red cell volume is commonly referred as the *hematocrit* (Hct). It is measured as the percentage of the volume of whole blood that is made up by red blood cells. Historically, it was measured by centrifugation but modern counters measure Hct indirectly based on red cell count and the mean red cell volume (MCV). Total-body Hct is the volume of red cells in the body divided by the total blood volume. Blood Hct is the simplest and most widely used test for estimating the size of red cell mass. In most anemic patients, blood Hct gives an excellent approximation of total red cell mass and a functional estimation of the oxygen-carrying capacity and whole-blood viscosity. Its main drawback is that it is an indirect measure that is influenced by changes in plasma volume and may not reflect the size of the red cell mass in dehydrated patients. Dehydration usually is clinically apparent and in most cases can be taken into account when evaluating the significance of a specific Hct determination. Only direct measurement of red cell mass can differentiate between relative and absolute polycythemia. However, when the Hct is greater than 60 percent, almost all patients have an increase in total red cell mass.¹⁴⁸ The extent of the increase cannot be estimated accurately from a Hct measurement alone (Fig. 32–8).

Figure 32–8. Iron clearance and iron utilization in normal subjects, patients with decreased effective red cell production (erythroid hypoplasia), and patients with ineffective red cell production. CPM, counts per minute; RBC, red blood cell.

RED CELL MASS AND PLASMA VOLUME

A more direct and accurate estimate of the size of the red cell mass is obtained from labeling a known volume of red cells and determining the dilution of this label in blood. Radioactive iron is an excellent label of red cells because it is biosynthetically incorporated into hemoglobin *in vivo*. In experimental animals, radioactive iron can be given to a donor animal and the donor's cells transfused into the animal whose red cell volume is being assessed. However, the radiation exposure to the donor and the hazards of transfusing allogeneic cells preclude its use in humans. Thus, almost all current clinical methods use labeling of autologous red cells *in vitro* by any one of a number of isotopes or biotin (Chap. 33). If studies must be performed in radiation-sensitive individuals, such as pregnant women, red cell labeling can be performed by nonradioactive chromium-123 or by biotin, which is detected with streptavidin coupled to a fluorochrome.¹⁴⁹ Among the isotopes available, chromium-51 (⁵¹Cr) is the most widely used label, although technetium-99m (^{99m}Tc) is convenient and accurate.¹⁵⁰ Chromium in the form of the chromate ion (CrO_2^-) readily enters the red cell and binds to globin chains. Excess isotope in the incubation mixture can be removed by washing or by using ascorbic acid to reduce the chromate ion to a nonpermeant chromic ion. Approximately 15 minutes after injection of a known amount of labeled cells, a sample of blood is obtained; its volume, Hct, and radioactivity are determined; and the total red cell volume is calculated from the equation:

$$\text{Red cell mass (mL)} = \frac{\text{CPM of isotope injected}}{\text{CPM of red cells in sample}}$$

where CPM = counts per minute. Sampling time is generally 15 minutes. Chromium also labels white cells; thus, one should centrifuge and remove the buffy coat before labeling if the white cell count is elevated ($>25 \times 10^9/\text{L}$).

No theoretical objection exists to measuring the red cell mass using labeled cells. It is independent of the Hct of the blood used to measure radioactivity, and replicate determination can be made with a coefficient of variation of approximately 1.5 percent.¹²⁶ The principal problem lies in reporting the measured red cell mass. The total red cell mass can be expressed as a volume related to body surface (mL/m^2) or as a volume related to body weight (mL/kg). A committee of the International Committee on Standardization in Hematology (ICSH) has

extensively examined existing data and concluded that the most reproducible expressions of red cell mass are related to body surface area estimated from height and weight¹⁵¹:

$$\text{RCM}_{\text{Males}} = (1486 \times S) - 285 \text{ RCM}_{\text{Females}} = (822 \times S) + (1.06 \times \text{Age})$$

where RCM = red cell mass, S = body surface area in square meters, and Age = age in years. The calculated values, ± 25 percent, included 98 percent of the measured male values and 99 percent of the measured female values.¹³

Despite the ICSH recommendation, the most common method is to report red cell mass values in terms of milliliters per kilogram. However, this method of expression gives erroneously low values in obese individuals because fat is hypovascular. A better method might be to express the red cell mass in terms of lean weight. In general, lean weight is 20 percent less than actual weight in normal males and 25 percent less in normal females.¹⁵⁰ However, estimation of lean weight in obese individuals is inaccurate. From a practical point of view, RCM probably is best reported in terms of actual weight, with mental adjustments made based on body configuration. In general, the RCM of normal females ranges from 23 to 29 mL/kg of body weight and of normal males ranges from 26 to 32 mL/kg of body weight.¹⁵¹

PLASMA LABELS

RCM also can be estimated from plasma volume. Radioactive iodine (¹²⁵I) is used to label albumin and measure its distribution volume.¹⁵² Other radioactive isotopes of iodine other than ^{99m}Tc have been used, but ¹²⁵I has virtually supplanted all other plasma labels. Albumin labeled with radioactive iodine is commercially available, and a known amount is injected intravenously. Several blood samples are obtained within the first 15 minutes and centrifuged. CPM per milliliter of plasma is measured, plotted on semilogarithmic paper, and extrapolated to zero time. This procedure is necessary because, in contradistinction to labeled red cells, labeled albumin is removed gradually, beginning immediately after injection. Plasma volume is calculated according to the equation:

$$\text{Plasma volume (mL)} = \frac{\text{CPM of labeled albumin injected}}{\text{CPM mL plasma at 0 hour}}$$

The continuous exchange of intravascular with extravascular albumin is the major problem encountered when plasma volume is measured with labeled albumin. Even with extrapolation to 0 hour, plasma volume is somewhat larger than that measured with a strictly intravascular protein such as fibrinogen.¹⁵³ Consequently, if measurement of the plasma volume is used to calculate the size of the total red cell mass, it is a less-reliable measure than determining red cell mass directly with tagged red cells. This inaccuracy is further augmented by the fact that the venous Hct used to calculate red cell mass from measured plasma volume does not reflect accurately the distribution of plasma and red cells in the body. However, from a practical point of view, the results of estimating RCM from plasma volume are surprisingly accurate and have been advocated based on simplicity and low cost.¹⁵²

TOTAL-BODY HEMATOCRIT

When total RCM is measured with labeled red cells, the value is approximately 10 percent lower than that calculated from plasma volume and the Hct of blood. In fact, the mean Hct of blood in all of the vessels (total-body Hct) clearly is somewhat lower than the Hct measured from blood obtained from large vessels; these differences are a result of varying proportions of plasma in different size vessels.

Generally, the ratio of total-body Hct as estimated by direct measurements of red cell volume and plasma volume to the large-vessel Hct ranges from 0.89 to 0.92.¹⁵⁴ Consequently, when using the determined plasma volume to calculate RCM and total blood volume, a correction factor is necessary, and a value of 0.90 is generally used:

$$\text{Corrected red cell mass} = \frac{\text{Hct} \times \text{plasma volume} \times 0.90}{100 - \text{Hct}}$$

Recommended procedures for determination and evaluation of blood volume are outlined by the ICSH.¹⁵⁵

MEASUREMENTS OF RED CELL PRODUCTION

Under normal circumstances, most human red cells produced in the marrow live, or have the potential to live, a normal life span. Under certain conditions, however, a fraction of red cell production is ineffective; with destruction of nonviable red cells either within the marrow or shortly after the cells reach the blood.³⁸

EFFECTIVE RED CELL PRODUCTION

Effective erythropoiesis is most simply estimated by determining the reticulocyte count. Most modern automated counters measure reticulocytes by nucleic acid binding dyes such as thiazole orange using flow cytometry. These are fast reliable assays. This count usually is expressed as the percentage of red cells that are reticulocytes, but it also can be expressed as the total number of circulating reticulocytes per unit of blood (absolute reticulocyte count and corrected reticulocyte counts; equation 1 below).

Equation 1

$$\text{Absolute reticulocyte count} = \frac{\% \text{ reticulocytes} \times \text{red cell count}}{100}$$

A simple clinical method to estimate effective erythropoiesis uses the reticulocyte count to calculate the reticulocyte index (see equation 2 below).¹⁵⁶ This measurement depends on several assumptions: (1) the human red cell life span is approximately 100 days (actually approximately 115); (2) the life span is finite and, thus, the oldest 1 of 100 or 1 percent of red cells is removed (and replaced) each day; (3) the reticulocyte is identifiable as such in the blood for 1 day using supravital stain; and (4) the reticulocyte count of 1 percent in a person with a normal Hct represents normal red cell production and thus "1" is the basal reticulocyte index.

In anemic patients, two calculations are needed to measure the reticulocyte index and compare it to the normal of 1 in the basal state. To correct the reticulocyte percentage for the lower red cell count in anemic subjects, the reticulocyte percent is multiplied by the ratio of the patient's Hct over the normal mean Hct, providing a corrected reticulocyte percent.

Conversion of the reticulocyte count (see equation 1 above) to the reticulocyte index (equation 2 below) is achieved by taking into account the estimated life span of reticulocytes. The life span of reticulocytes in blood in a normal individual is approximately 1 day. However, when red cell production is increased under conditions of erythropoietic stress, for example, in severe anemia, reticulocytes are released prematurely and circulate as reticulocytes for 2 to 4 days, except in situations with low EPO levels, as in renal insufficiency. These appear as polychromatophilic erythrocytes on Wright-stained blood film and are called stress or shift reticulocytes.

Equation 2

$$\text{Reticulocyte index} = \frac{\text{corrected reticulocyte \%}}{\text{correction factor (usually 2)}}$$

Accordingly, the corrected reticulocyte percent may give an erroneous impression of the actual rate of daily red cell production. To take this situation into account when estimating the rate of red cell production in anemic patients with high reticulocyte counts, dividing the corrected reticulocyte percent by a factor may provide a more accurate estimate of red cell production.¹⁵⁶ For simplicity, an average factor of 2 often is used; however, the factor depends on the degree of anemia: 1.5 in mild cases, 2.5 in moderate cases, and 3.0 in severe cases.

An example follows: A patient with autoimmune hemolytic anemia has a Hct of 10 and reticulocyte count of 70 percent. The marrow cannot increase production by 70-fold. To measure the approximate true increase, we calculate the reticulocyte index as follows: corrected reticulocyte percent = $70 \times 10/45 = 15$, and the reticulocyte index = $15/3 = 5 \times$ basal. Thus, marrow erythroid production in response to this severe anemia has increased fivefold, a plausible response to this severity of hemolytic anemia.

INEFFECTIVE RED CELL PRODUCTION

Ineffective erythropoiesis is suspected when the reticulocyte count is normal or only slightly increased despite erythroid hyperplasia of the marrow. Ineffective erythropoiesis was first recognized as an entity from the study of isotope incorporation into fecal urobilin following administration of labeled glycine, a precursor of heme.¹⁵⁷ Two peaks were observed: an early peak at 3 to 5 days and a late peak at 100 to 120 days. One of the sources of the early labeled peak was suggested to be the hemoglobin of red cells that had never completed their development, having been destroyed either in the marrow or shortly after reaching the blood. Subsequent studies revealed that in certain disorders, such as pernicious anemia, thalassemia, and sideroblastic anemia, ineffective erythropoiesis is a major component of total erythropoiesis. This component can be quantitated by measuring ¹⁵N-labeled glycine incorporation into the early bilirubin peaks¹⁵⁷ or ferrokinetics.³⁸ Calculated from bilirubin peaks and turnover, ineffective erythropoiesis under normal conditions amounts to approximately 4 to 12 percent of total erythropoiesis. Using ferrokinetic methods, ineffective erythropoiesis is calculated as the difference between total plasma iron turnover and erythrocyte iron turnover plus storage iron turnover (see "Ferrokinetics"). The values estimated from such studies in normal subjects are higher, ranging from 14 to 34 percent.³⁸ However, the results, both high and low, probably are misleading because none of the methods actually measures cell death, only the turnover of heme and iron. It is possible that little premature death of cells occurs in normal subjects, but much of the early release of bilirubin and iron is derived from the rim of hemoglobin extruded during enucleation of erythroblasts (Chap. 31).

TOTAL ERYTHROPOIESIS

Total erythropoiesis, which is the sum of effective and ineffective red cell production, can be estimated from a marrow examination. Films or sections from marrow aspirates and biopsies are first examined for relative content of fat and hematopoietic tissue. This examination gives an estimate of overall hematopoietic activity within the marrow space. A differential count then is performed, determining the ratio between granulocytic and erythroid precursors (M:E ratio). In a normal adult, the ratio is approximately 3:1 to 5:1. The ratio can be used to estimate whether erythropoiesis is normal, increased, or decreased (Chap. 3).

The ratio is only an approximation of total erythroid activity because the ratio can be altered by changing the myeloid and erythroid components, and an aspirate or biopsy of a small segment of the marrow may not always reflect total marrow activity. These assumptions are valid as long as the marrow reflects the steady-state, if the marrow is recovering from aplasia, or is developing aplasia, it will not accurately reflect output of mature red cells. However, when used in conjunction with determination of red blood cell count and reticulocyte count, under most circumstances the ratio provides qualitative information about the rate and effectiveness of red blood cell production. A more accurate quantitation of total erythropoiesis can be made by measuring the rate of production of red cells (ferrokinetics) or, in steady-state conditions, the rate of destruction of red cells (red cell life span, bilirubin production, carbon monoxide excretion).

FERROKINETICS

In 1950, Huff and associates¹⁵⁸ described a method for measuring the rate of red cell production utilizing a simple model of iron metabolism (Fig. 32-9; Chap. 42). In this method, radioactive iron is complexed to transferrin *in vitro* and injected intravenously. Alternatively, ⁵⁹Fe can be injected directly intravenously as the gluconate without preincubation with the patient's own plasma, providing enough unbound transferrin is available, because binding is almost instantaneous. The rate of clearance of the transferrin-bound iron from the plasma (⁵⁹Fe plasma T_{1/2}) and the subsequent uptake in the red cells are measured. From these two values and from determinations of plasma iron concentration and plasma volume, the rate of formation of red cells can be calculated.³⁸

The initial clearance of iron is exponential, and sampling during this period can be used to calculate T_{1/2}. In normal individuals, initial clearance averages approximately 90 minutes. Initial clearance is shorter in patients with hyperplasia of the erythropoietic tissue and longer in patients with marrow hypoplasia (see Fig. 32-9). However, the clearance rate is not a direct measurement of erythropoietic activity because it depends on the size of the pool of unlabeled, circulating iron. Consequently, calculation of the plasma iron turnover rate must include the plasma iron concentration. Clearance is expressed in milligrams of iron. The point of reference can be hemoglobin mass, blood volume,

Figure 32-9. Single dynamic pool model of iron metabolism. Radioactive iron injected into the plasma iron pool is cleared from the plasma as a single exponential, and approximately 80 percent is incorporated into circulating blood cells.

or weight, but a commonly used expression is micrograms of iron per deciliters of whole blood per day:

Plasma iron turnover rate (mg iron/dL blood/24 h)

$$= \frac{\text{plasma iron (mg dL)} \times (100 - \text{Hct})}{T_{1/2} (\text{min}) \times 100}$$

Under normal conditions, radioactive iron is incorporated into newly formed red cells after a few days and reaches a maximum approximately 10 to 14 days after injection (see Fig. 32–9). Normal utilization is 70 to 90 percent on day 10 to 14, a value that is so high that further increases have little significance. However, decreased utilization is an important finding and suggests immature red cells are destroyed in the marrow before they are released to the circulation (ineffective erythropoiesis) or that serum iron is diverted to nonerythropoietic tissues (marrow hypoplasia). The shape of the red cell utilization curve also is important. An early and steep rise (rapid marrow transit time) suggests a high EPO level. Finally, an early rise in utilization with a subsequent fall off suggests hemolysis.

When calculating utilization, the blood volume must be known:

Red cell iron utilization (%)

$$= \frac{\text{CPM of 1 mL blood} \times \text{blood volume} \times 100}{\text{CPM of } ^{59}\text{Fe injected}}$$

Using the plasma iron clearance and utilization of iron, the red cell turnover in milligrams per dL blood for 24-hours is calculated as follows:

Red cell iron turnover (mg iron/dL blood/24 h) = plasma iron turnover \times maximal red cell iron utilization

The normal value of red cell iron turnover is 0.30 to 0.70 mg/dL blood per 24 hours.³⁸ This range fits very well with a crude estimation of the iron used for maintaining the red cell mass in 1 dL of blood or 45 mL of packed red cells. The daily red cell production must equal the daily red cell destruction (45 mL/120 = 0.38 mL), assuming a red cell life span of 120 days. Because 1 mL of packed red cells contains approximately 1 mg of iron, a daily plasma iron turnover of 0.38 mg is needed by 1 dL of blood to maintain homeostasis.

Calculating red cell iron turnover has provided useful information about the total volume and effectiveness of erythroid tissue (Table 32–2). However, an elevated serum iron concentration gives

erroneous impressions of the state of erythropoiesis. Moreover, more prolonged sampling of plasma following an intravenous injection of ⁵⁹Fe has shown that clearance is not a single exponential, but must be represented by several exponential components.¹⁵⁹ This finding has led to the introduction of more complex models of iron kinetics with a single pool of plasma iron exchanging with a number of extravascular erythroid and nonerythroid pools. Careful analysis of such models has generated computer-supported methods calculating the degree and effectiveness of erythroid activity.¹⁶⁰ Although possibly more accurate than the conventional method of calculating iron turnover, the models appear to be too cumbersome for clinical use. Moreover, even these sophisticated methods may not give an accurate account of the state of erythropoiesis. Despite a constant rate of red cell production, the plasma iron turnover was found to increase with increasing plasma iron and transferrin saturation. This finding was first thought to result from increased nonerythroid iron uptake and led to the introduction of various correction factors in the calculation of red cell iron turnover.¹⁶⁰ However, the iron in plasma is present in two pools, a diferric and a monoferric transferrin pool (Chap. 42), and the erythroid and nonerythroid receptors have a four times greater avidity for diferric transferrin than for monoferric transferrin. Consequently, total plasma iron turnover depends on the degree of saturation and does not necessarily reflect the number of transferrin receptors, presumably a critical measure of erythropoietic capacity.¹⁶¹ To measure the number of transferrin receptors, adjusting the plasma iron turnover equations for both nonerythroid uptake and degree of transferrin saturation and expressing the plasma turnover in terms of transferrin rather than iron have been proposed.¹⁶² Normal erythroid uptake of transferrin is 60 \pm 12 μ mol/L of blood per day, a value that has appropriately decreased and increased in patients with hypoplastic and hyperplastic marrow.

TABLE 32–2. Plasma Radioactive Iron Clearance and Red Blood Cell Uptake

Condition	Plasma ⁵⁹ FE T _{1/2}	Red Blood Cell Uptake (%)
Normal	90 min	80–90
Increased erythropoiesis	Rapid (10–40 min)	80–90
Hemolytic anemia	Rapid	20–90*
Ineffective erythropoiesis	Normal to rapid	10–30
Iron-deficiency anemia	Normal to rapid	100
Decreased erythropoiesis	Slow (\geq 180 min)	0–20

*Variability a result of variability in intensity of hemolysis and size of iron stores.

CHAPTER 33

ERYTHROCYTE TURNOVER

Perumal Thiagarajan and Josef Prchal

SUMMARY

The survival of red cells in the circulation can be measured in a variety of ways: (1) by labeling with radioactive isotopes, particularly chromium-51 (^{51}Cr), and assessing the disappearance of the radioactive tag from the circulation over time; (2) by labeling the erythrocytes with biotin or a fluorescent dye and measuring this marker over time; (3) by determining the disappearance of transfused antigen-matched allogeneic erythrocytes using immunologic markers; and (4) by measuring the excretion of carbon monoxide, a product of heme catabolism.

Such studies show that normal human red cells have a finite life span averaging 120 days, with very little random destruction. The mitochondrial and ribosomal removal highlighting maturation of the reticulocyte is accompanied by increasing cell density, but after a few days of intravascular life span there is little further increase in density or other changes in the physical property of the red cells. Thus, cell density is not a good marker for aged red cells. This has made the senescent changes in the red cell that mark it for destruction difficult to study. Candidates for such changes include changes in membrane band 3 and exposure of phosphatidylserine on the membrane, which may be of major importance.

● RED CELL LIFE SPAN

Normal human red blood cells have a life span of approximately 120 days, after which they are engulfed by macrophages. This is an extremely efficient process as macrophages phagocytose approximately 5 million erythrocytes every second without a significant release of hemoglobin into the circulation. The precise molecular mechanism by which macrophages recognize senescent red blood cells for phagocytosis remains largely unknown. As red blood cells age, several physiologic changes occur that may serve as signals for recognition by macrophages.^{1,2} These include a decrease in the activity of enzymes,³ a progressive decrease of ATP content,⁴ a loss of lipid asymmetry with exposure of phosphatidylserine,⁵ an accumulation of lipid peroxidation products,⁶ a desialylation of membrane glycoprotein,⁷ an exposure of cryptic senescent antigens,⁸ aggregation of band 3 protein (Chap. 46),⁹ a decrease in deformability as the result of increased oxidative stress,¹⁰ and an increase

Acronyms and Abbreviations: ADP, adenosine diphosphate; AMP, adenosine monophosphate; BNIP3L, an hypoxic regulated gene that facilitates mitochondrial autophagy; C_3 , third component of complement; ^{14}C , radioactive carbon; CD44, cell differentiation antigen; CO, carbon monoxide; ^{50}Cr , chromium-50; ^{51}Cr , chromium-51; DFP, diisopropylfluorophosphate; ^{55}Fe or ^{59}Fe , radioactive iron; G6PD, glucose-6-phosphate dehydrogenase; HO, heme oxygenase; Ig, immunoglobulin; ^{111}In , indium-111; ^{15}N , nitrogen; PK, pyruvate kinase; $^{99\text{m}}\text{Tc}$, technetium-99m.

in cell surface-bound immunoglobulins and complement components (Chap. 54).^{11,12} All of these changes have been investigated as signals for recognition by the macrophages.

MEASUREMENT OF RED CELL DESTRUCTION

The original method for the measurement of the red cell life span consisted in the transfusion of cells that were compatible but identifiable immunologically—the Ashby technique; type O red cells were infused into individuals with type A or B cells. The differential agglutination technique used anti-A or anti-B antiserum to measure the life span of type O red cells that were transfused to type A or type B recipients and the recipients' own cells were removed using anti-A or anti-B serum.¹³ During World War II and shortly after, this method was used extensively, but in recent years, because of the hazards associated with the administration of allogeneic erythrocytes, it has been completely replaced by techniques based on labeling of autologous blood. Furthermore, this method could not be applied to autologous red cells.

In 1946, Shemin and Rittenberg demonstrated that the incorporation of nitrogen (^{15}N)-labeled glycine into heme could be used to measure the life span of the red cells.¹⁴ Since then a number of other isotopic methods have been developed. These can be divided into three groups: (1) those that label a cohort of cells, (2) those that label cells randomly, and (3) those that use indirect measurements such as the rate of production of red cells or the rate of heme breakdown. The first two methodologic approaches yield information about the nature of the shortening of the red cell life span, age-dependent or random. The methodology yields only mean life span.

COHORT METHODS

Cohort methods depend on the biosynthetic incorporation of the label into the developing red cells. In these methods, a group of cells of approximately the same age is labeled. The labels used are glycine-containing labeled ^{15}N ,¹⁴ radioactive carbon (^{14}C),¹⁵ or radioactive iron (either ^{55}Fe or ^{59}Fe).^{16–18} The main disadvantage of cohort labeling is the need for prolonged periods of sampling, especially if the life span is only moderately reduced (Fig. 33–1). In addition, radioiron from destroyed red cells may be reused, making it difficult to interpret results. Furthermore, the increasing restrictions on use of radiochemicals has drastically decreased availability of these two previously widely used nuclear medicine tests.

A simple double-labeling technique that allows nonradioactive cohort labeling was described using two distinct labeling steps separated by a defined time interval. Cells are subsequently evaluated by the relative proportions of these labels. The initial labeling step uses biotin that binds to all circulating cells (the red blood cells accounting for most of the label) the second administered labeling substance at later time digoxigenin then distinguishes erythrocyte subpopulation of known age.¹⁹

RANDOM-LABEL METHODS

The random-label methods are the Ashby differential agglutination technique,¹³ which uses an immunologic marker, and or the use of various red cell labels such as chromium-50 (^{50}Cr), chromium-51 (^{51}Cr), or chromium-53 (^{53}Cr),^{20–22} diisopropylfluorophosphate (DFP) labeled with phosphorus-32 (^{32}P),²³ ^{14}C ,²⁴ or ^{14}C cyanate,²⁵ a lipophilic dye,^{26,27} or biotin.^{28,29}

Chromium-51 Method

By far the most commonly used radioactive isotope for the measurement of the red cell life span is ^{51}Cr . As the chromate ion penetrates the red cell membrane it binds to the β and γ chains of globin. Unfortunately, these

Figure 33-1. Red cell life span measured by cohort labeling or random labeling. When red cells are labeled randomly with chromium-51 (^{51}Cr) there is a daily 1 percent elution that needs to be corrected for in the calculation of total red cell life span.

bonds are not covalent and there is a continuous elution of the isotope, varying from 0.5 to 2.9 percent per day.³⁰ DFP, on the other hand, is irreversibly bound to red cell cholinesterase. There is some elution of unbound DFP during the first 2 to 3 days of study, but after that, DFP disappearance closely matches red cell destruction.^{25,31} Nevertheless, because sample preparation is somewhat complicated, this label is not commonly used.

The life span is estimated by measuring the survival of randomly labeled red cells. Immediately following transfusion, the labeled red cells equilibrate with unlabeled red blood cells (RBCs). This takes normally approximately 5 minutes,³² but may be longer in patients with splenomegaly. Following equilibration, the cells that have been damaged by the labeling process will be removed from the circulation during the next 24 hours. RBCs that survive this period will usually have their expected long-term survival.³³

To accurately calculate red cell life span using a random label method requires steady-state conditions or that correction can be made for concurrent blood loss or blood transfusion. Fortunately, it is usually possible to gain an accurate estimate of red cell half-life by sampling three times a week for 1 to 2 weeks.

In the normal human the red cell, life span is finite with an average of approximately 120 days, with very little random destruction, that is, loss irrespective of cell age (0.06 to 0.4 percent per day). In some mammalian species the amount of random destruction is much greater.³⁴ The survival curve of randomly labeled human red cells should consequently be nearly linear from day 0 to day 120, with a half-life of 60 days. When ^{51}Cr is used as the label, approximately 1 percent of label elutes per day and the survival curve becomes exponential with a half-life of approximately 30 days (see Fig. 33-1). For clinical use, the red cell life span is usually expressed as chromium half-life ($T_{1/2}$) and compared to the normal value for the method of 30 days.

Because merely expressing the red cell life span measured by chromium as chromium $T_{1/2}$ will not give information as to the character of destruction, senescence versus random, it has been recommended that in addition a correction factor for chromium elution be used and the data recorded using linear coordinates.³⁵ If the data lie on a straight line, the destruction is by senescence and the life span can be calculated

as twice the half-life. If the data indicate exponential disappearance and it is necessary to use a semilogarithmic paper in order to depict the data on a straight line, the destruction is random and the life span is 1.44 times the half-life. One objection to this method is that the degree of chromium elution is not a constant but varies from day to day and is influenced by various disease states.³⁰ Furthermore, the best fit of data is rarely linear or exponential, but somewhere between. Although computer-assisted methods can resolve ambiguities, the inherent biologic and technical variations in measuring red cell life span are such that it is better to rely on chromium $T_{1/2}$ with intuitive adjustments based on clinical findings.

Biotin Method

A nonradioactive label has also been developed to label the RBCs in humans by covalent attachment of biotin to red cell membrane proteins and enumerating the survival by flow cytometry.³⁶ Biotin labeling estimates RBC survival comparable to that obtained with a concurrent ^{51}Cr label for both normal volunteers and patients with sickle-cell disease. In addition to being a nonradioactive probe, biotin labeling has other advantages. The transfused cells can be isolated from the patients on avidin substrates for further characterization. Biotin labeling has been used to demonstrate that sickle cells without fetal hemoglobin have a shorter *in vivo* survival compared to those with fetal hemoglobin,³⁷ and has been also instrumental in showing a role for phosphatidylserine exposure in the clearance of sickle cells.³⁸

INDIRECT METHODS

There are two approaches to the calculation of the red cell life span by indirect methods: from a measurement of the rate of production of red cells using radioactive iron and from a measurement of the rate of breakdown of heme to bilirubin,³⁹ that is, the release of carbon monoxide from catabolized heme.⁴⁰ Both of these compounds are derived almost exclusively from catabolized hemoglobin and measurements of their rate of production have provided useful information about the red cell life span. There are too many variables that affect the serum bilirubin level to make it a reliable, quantitative measurement of red cell destruction. The measurement of carbon monoxide (CO) production was formerly very tedious, requiring elaborate rebreathing apparatus. With the development of newer technologies,^{41,42} measuring CO levels has become more practical. An advantage of the measurement of blood CO as an indication of the rate of red cell destruction is that it gives the rate of destruction at a single point in time. An instrument by CoSense (Capnia Inc., Palo Alto, CA) obtained FDA 510(k) clearance in December 2013 and provides a substitute for the previous Natus end-tidal breath analyzer (Natus Medical, San Carlos, CA) that had not been available for about a decade. CoSense is compact and portable, and uses a sterile one-time-use single nasal cannula for quantifying end-tidal breath for CO quantification and also samples ambient CO, which is subtracted from the value in exhaled breath and is suitable for use in neonates. This device also counts the breath rate, analyzes CO in individual breaths, and provides CO measurements in parts per million in a matter of minutes.

● IN SITU LOCALIZATION OF RED CELL PRODUCTION AND DESTRUCTION

As part of routine erythrokinetic studies both radioactive iron and radioactive chromium may be used to localize red cell production and red cell destruction. This is accomplished by positioning probes for external counting over the sacrum, liver, spleen, and heart and measuring the distribution of radioactivity in the body.⁴³

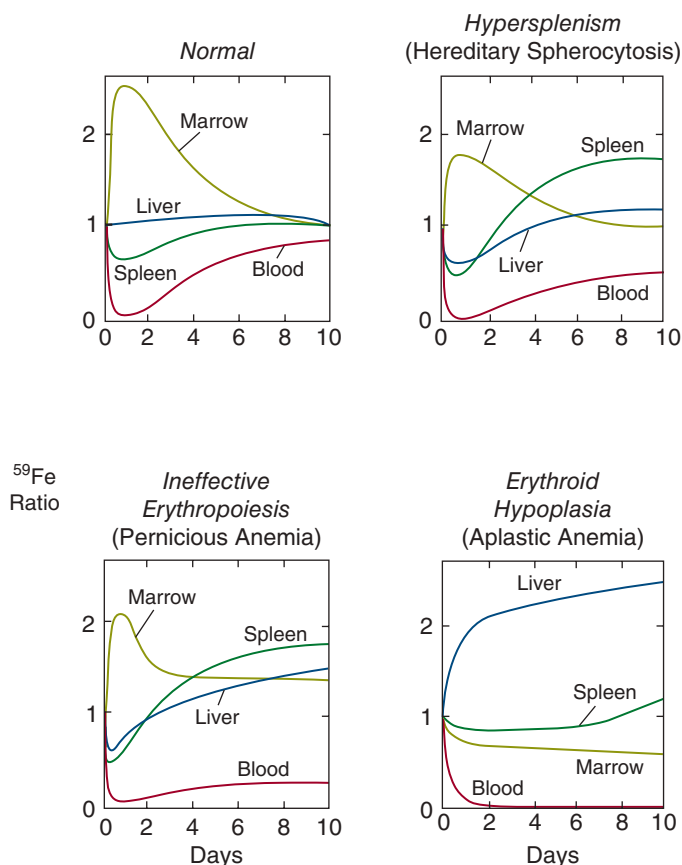

Figure 33-2. Tissue distribution of ^{59}Fe in normal subjects, hypersplenic patients, and anemic patients with ineffective and effective erythropoiesis. The radioactivity is expressed on the ordinate as a ratio relative to the radioactivity measured in the same organ 15 minutes after the intravenous administration of the isotope. (Redrawn with permission from Hillman RS and Finch CA: *Erythropoiesis: Normal and abnormal*. Semin Hematol (4):327–336, 1967.)

In a normal subject, ^{59}Fe injected intravenously is cleared rapidly from the plasma, and within 24 hours approximately 85 percent of the radioactivity can be accounted for in the marrow. The liver and the spleen divide the remaining 15 percent. Over the next 10 days the marrow radioactivity decreases gradually as a result of the release into circulating blood of red cells labeled with radioactive hemoglobin. Patterns showing different uptake and distribution of the radioactive iron have been found for various hematologic disorders.⁴⁴ In hypersplenism, the trapping and destruction of iron-labeled cells in the spleen increases splenic radioactivity rapidly, and in patients with erythroid hypoplasia the distribution of radioactive iron between liver and marrow is reversed (Fig. 33-2).

IMAGING MACROPHAGES IN THE MARROW, LIVER, AND SPLEEN

More effective methods demonstrating *in situ* erythropoiesis involve imaging the macrophages in the marrow, liver, and spleen with a technetium-99m (^{99m}Tc) sulfur colloid or indium-111 (^{111}In).⁴⁵ Although these isotopes label primarily the monocyte-macrophage system, their uptake is similar to that of ^{59}Fe and they can be used as surrogate markers to estimate the distribution of erythroid tissue.

SURFACE COUNTING FOR CHROMIUM-51

Surface counting for ^{51}Cr -labeled red cells provides a characteristic organ distribution of radioactivity and has been used to demonstrate the degree of red cell sequestration and destruction in an enlarged spleen (see Fig. 33-2).⁴⁶ This approach has been used to predict the results of elective splenectomy, but the utility of this method has been challenged.⁴⁷ The *in situ* localization of red cell sequestration or destruction can also be determined by following the tissue distribution of ^{59}Fe -labeled red cells, especially if the red cell life span is very short.

SENESCENCE OF NORMAL ERYTHROCYTES

Methodologic Considerations

Labeling a cohort of human erythrocytes with ^{59}Fe and centrifuging the cells in a density gradient demonstrates that reticulocytes and young red cells are less dense than mature red cells.^{48,49} However, at the end of the life span of the labeled cohort, radioactivity is fairly evenly distributed throughout red cells of all densities, with only a slight tendency of the radioactivity to be concentrated in the more dense cells. Unfortunately, many studies of the properties of senescent cells in the past have been based upon the characteristics of the most dense fraction of erythrocytes, using various fractionating techniques. In fact, the most dense fraction of red cells is only slightly enriched with old erythrocytes.^{50,51} A combination of density separation and elutriation seemed to provide results superior to density separation alone using hemoglobin A_{1c} content as a marker, but the degree of enrichment with older cells has not been documented using actual old red cells as separated by biotinylation or by the mouse hypertransfusion technique.⁵²

There are two animal models and one human disease model that provide cells that are truly aged. In mice, *in vivo* aged cells have been produced by serially transfusing mice, maintaining polycythemia to suppress virtually all erythropoiesis.⁵³ In other species, particularly the rabbit, red cells have been labeled with traces of biotin, which allows them to be recovered from the circulation.⁵⁴ The human model is transient erythroblastopenia of childhood (Chaps. 36 and 55), a disorder in which there is cessation of all erythropoiesis for several months; however, the density and deformability of the aged cells in erythroblastopenia of childhood is normal.⁵⁰ The use of the latter model has been criticized because this disorder is not fully understood and the red cells in the circulation may not be entirely normal.⁵⁵ However, the results that have been obtained are consistent with those obtained in animal models and are probably reliable (see “Properties of Aged Cells” below).

PROPERTIES OF AGED CELLS

Although the activities of a large number of enzymes, including hexokinase, glucose-6-phosphate dehydrogenase (G6PD), and pyruvate kinase (PK), are higher in reticulocytes than in mature erythrocytes, the activities of these enzymes do not normally continue to decline during the aging of the erythrocyte.^{54,56} Pyrimidine-5'-nucleotidase^{57,58} and adenosine monophosphate (AMP)-deaminase⁵⁹⁻⁶¹ appear to be exceptions to this rule in that there is continuing decline of enzyme activity throughout the life span of the red cell. The decrease in the activity of these enzymes is not linear with age but exponential.³ This stability of many of the red cell enzymes during the aging of normal erythrocytes contrasts to the circumstances that are brought about by mutations in enzymes such as G6PD and PK, where instability of the abnormal enzyme leads to accelerated decay in the amount of enzyme protein, a factor that surely plays an important role in the ultimate demise of the cell (Chap. 47). Fluorescent sorting of blood type NN erythrocytes transfused into humans shows that the most dense fractions are

only minimally enriched with old cells,⁶² and biotinylated aged cells of rabbits have been found to have only a modestly decreased surface area, volume, cell water, and density, and therefore slightly decreased deformability.^{51,63}

As they circulate red cells lose a substantial portion of their membrane and hemoglobin in the form of vesicles (reviewed in Ref. 64). The loss of membrane material in hemoglobin vesicles may play a role in the aging process.⁶⁵ In normal blood, a small number of red cell vesicles, approximately 190/ μ L blood, can be harvested. During storage of RBCs, the aggregates of vesicles are formed and may contribute to acute lung injury by interacting with neutrophils.⁶⁶

MECHANISM OF DESTRUCTION OF NORMAL, AGED CELLS

Several different mechanisms of senescent red cell destruction have been proposed. Determining the actual mechanism(s) is especially difficult because the cells that are marked for removal are bound to be present at very low concentrations or not at all in the circulating blood—they have been removed. Many of the earlier data are predicated upon the isolation of dense cells and the consideration that they are “old”; we now recognize that they are not (see “Methodologic Considerations” above). Moreover, it is likely that there is more than one mechanism that serves to remove effete red cells from the circulation; there is no known mutation that lengthens red cell life span.

Band 3 Clustering Models

It has been proposed that an altered membrane band 3 serves as a receptor for antibodies directed against a neoantigen, designated senescent-cell antigen, and that possibly after-binding complement marks the senescent cell for destruction. It is not known how clustering of band 3 occurs *in vivo* and recent work suggests peroxidation of cytoplasmic aspect of band 3 results in carbonylation. Methemoglobin binds to the cytoplasmic peroxidized domain of band 3 and induces cluster formation.⁶⁷ But much, if not all, of the evidence for these models depends upon the assumption that dense cells are old, and the uptake of cells by monocytes as a surrogate for their being marked for destruction.⁶⁸ However, immunoglobulin levels on aged, biotinylated rabbit cells are not increased,⁶⁹ and the fact that red cell life span has never been demonstrated to be prolonged in agammaglobulinemic patients casts serious doubt upon the concept that immunoglobulins mediate removal of senescent red cells.

Phosphatidylserine Exposure Models

In RBCs, as in most other cells, the anionic phospholipid phosphatidylserine is present exclusively in the inner cytoplasmic leaflet of the membrane bilayer.⁷⁰ The exposure of phosphatidylserine on the outer leaflet of the cell membrane is one of the signals that allows macrophages to recognize apoptotic cells. It is likely that this is, indeed, at least one of the signals by which macrophages recognize senescent erythrocytes.^{5,71,72} Data from a biotinylated rabbit erythrocyte model suggests that the average time during which phosphatidylserine is exposed is only 0.3 to 0.5 days, so that few cells with increased exposure of the phospholipid are in the circulation at any time.⁷¹ An increase of phosphatidylserine exposure has also been documented in humans descending from high altitudes.⁷³ The exposure of phosphatidylserine on the outer leaflet of the cell membrane is one of the signals. A proposed model for the destruction of newly formed cells was that endothelial cells might respond to changes in circulating erythropoietin by influencing the interaction of phagocytes with young red cells, targeting the cells by surface adhesion molecules.⁷⁴ A study in mice, using somewhat different methods, suggested that phosphatidylserine

exposure is greatest in young erythrocytes, and does not increase with aging.⁷⁵ It is not yet clear whether phosphatidylserine exposure is the only or even the primary signal that indicates that a cell has reached the end of its life span, but it is the only major difference between senescent and non-senescent erythrocytes that has been documented clearly.⁷²

Several proteins were described that bind to phosphatidylserine-expressing apoptotic cells including lactadherin,⁷⁶ gas-6,⁷⁷ Del-1,⁷⁸ and several complement components.⁷⁹ These proteins act as opsonins in promoting the clearance of phosphatidylserine-expressing cells by macrophages. Angiogenic endothelial cells also express several integrin associated with phagocytosis in macrophages and can engulf phosphatidylserine expressing “aged” erythrocytes and may play a role in clearance of senescent cells.⁸⁰

Eryptosis is defined as cell shrinkage and exposure of phosphatidylserine caused by entry of calcium ions followed by activation of a scramblase, an enzyme capable of randomizing the distribution of phospholipid in both membrane bilayers.⁷⁰ It may contribute to red cell clearance in diseased states,⁸¹ but its role in senescence associated clearance is not clear.⁸²

Another model that has been proposed is based upon a slight increase in green autofluorescence, believed to represent the result of oxidative damage, which has been observed in aging murine erythrocytes.⁸³ Interaction of erythrocyte cell surface antigen CD44 with hyaluronic acid may play a role in the clearance of aged erythrocytes from the circulation, but such clearance seems limited to primates, and a patient with CD44 deficiency manifested congenital dyserythropoietic anemia.⁸⁴

NEOCYTOLYSIS

Hypoxia increases RBCs by enhancing hypoxia-inducible factors (HIFs). Upon return to normoxia, the secondary polycythemia is overcorrected, as the accumulated, newly formed RBCs undergo preferential destruction, a process termed *neocytolysis*; however, its mechanism is unclear.⁷⁴ Neocytolysis was originally observed during space travel at zero gravity wherein the mechanism is even less clear. It has been suggested that on return to normoxia, there is excessive generation of reactive oxygen species from increased mitochondrial mass correlating with decreased hypoxia controlled gene BNIP3L transcripts,^{85,86} as BNIP3L mediates removal of reticulocyte mitochondria accompanied by reduced catalase activity.⁸⁷ Rapid changes in hematocrit in human newborns also suggest that neocytolysis also occurs after birth when a hypoxic fetus is polycythemic at birth, but the neonate rapidly overcorrects its increased red cell mass and becomes anemic in first 2 weeks of life.^{88,89}

MECHANISMS OF DESTRUCTION

“Senescence of Normal Erythrocytes,” above, enumerated some mechanisms that may be involved in normally terminating the life of the effete erythrocyte. It has sometimes been assumed that the mechanisms by which red cells are destroyed prematurely in disease states reflect these normal mechanisms. Although there may well be some overlap, the mechanisms of red cell destruction in disease states are likely different. The assumption that the mechanisms that bring around hemolytic anemia represent premature aging of the erythrocyte is no more logical than to suggest that an animal’s death through pneumonia, renal failure, or cancer represents premature aging.

INTRAVASCULAR DESTRUCTION

If the red cell membrane is breached in the circulation the red cell is destroyed. This mode of erythrocyte demise occurs at a low frequency, but may be the predominant mode of destruction in some hemolytic

disorders, for example, ABO-incompatible transfusions (Chap. 138) and paroxysmal nocturnal hemoglobinuria (Chap. 40), where the surface complement complex creates pores in the red cell membrane, and in cardiac valve hemolysis (Chap. 51) and microangiopathic hemolytic anemia (Chaps. 51 and 132), where the shear stress may be so strong as to break open the membrane.

EXTRAVASCULAR DESTRUCTION

Most commonly, the life of the red cell comes to an end when it is ingested by a macrophage. Clearly, signals that allow the macrophage to distinguish the younger normal red cell from a damaged or senescent cell must exist. Such signals may consist of decreased deformability and/or altered surface properties.

Decreased Deformability

The red cell does not circulate as the biconcave disc customarily observed under the microscope. Instead, it is normally greatly distorted by the shear stresses in the circulation and such distortion is an absolute requirement for the red cell to be able to negotiate the narrow slits that separate the splenic pulp from the sinuses (Chaps. 6 and 56). The deformability of the erythrocyte can be measured clinically using the ektacytometer, an instrument that displays the diffraction pattern of a red cell suspension under shear stress.^{90,91} The red cell membrane, a lipid bilayer, bends readily but has very little capacity to stretch. Thus, deformability is largely a function of the excess red cell membrane intrinsic to the biconcave disc shape of the cell, membrane composition, and to some extent, of the viscosity of the hemoglobin solution within the cell. As the red cell loses membrane it assumes a spherical shape and loses its ability to deform. Hereditary spherocytosis and hereditary elliptocytosis are prototypic of hemolytic anemias in which decreased deformability as a result of a decreased surface-to-volume ratio plays a key role in red cell destruction (Chap. 46). However, loss of membrane plays a role in many types of pathologic hemolysis, including autoimmune hemolytic anemia (Chap. 54). In sickle cell disease and hemoglobin C disease (Chap. 49), the internal viscosity of the cell is increased. Loss of water from the red cell, as may occur when the membrane is damaged and leaks potassium as in hereditary xerocytosis (Chap. 46), also markedly impairs the deformability of the cell.

Altered Surface Properties

The surface of the red cell membrane can be altered by binding of antibodies to surface antigens, by binding of complement components, and by chemical alterations, particularly oxidation of membrane components. Immunoglobulin (Ig) G-coated red cells⁹² and red cells coated by the third component of complement (C_3)^{93,94} are bound by Fc receptors on macrophages and undergo partial phagocytosis. This results in the formation of a spherocyte.

In vitro oxidation of red cells with phenylhydrazine or adenosine diphosphate (ADP) plus iron causes clustering of band 3 protein in the membrane. Although the physiologic significance of this is far from clear, it has been suggested that the clustered protein serves as a recognition site for the binding of IgG.⁹⁵ Oxidative damage to the membrane may play a role in the removal of sickle cells (Chap. 49) and thalassemic cells from the circulation (Chap. 48).

FATE OF DESTROYED RED CELLS

INTRAVASCULAR DESTRUCTION

Hemoglobin

When red cells are destroyed in the vascular compartment the hemoglobin escaping into the plasma is bound to haptoglobin. A dimeric

glycoprotein, each molecule of haptoglobin can bind two hemoglobin dimers. The binding of hemoglobin not only protects against its potential toxicity, it also triggers the second step of the scavenging process, that is, recognition by macrophage receptor CD163, and subsequent clearance of the entire complex by receptor-mediated endocytosis.⁹⁶ CD163 belongs to the scavenger receptor cysteine-rich family of proteins and the haptoglobin-hemoglobin complex is cleared from the plasma with a $T_{1/2}$ of 10 to 30 minutes. The heme of the hemoglobin is converted to iron and biliverdin by heme oxygenase and the biliverdin is further catabolized to bilirubin. CO is released (see "Indirect Methods," above, on measuring red cell life span) in the course of cleavage of heme by heme oxygenase.⁹⁷

Haptoglobin

Free haptoglobin, in contrast to the hemoglobin-haptoglobin complex, has a $T_{1/2}$ of 5 days, and when large amounts of the rapidly turned over haptoglobin-hemoglobin complex are formed, the haptoglobin content of the plasma is depleted. The haptoglobin content of the plasma is diminished not only in the plasma of patients undergoing frank intravascular hemolysis, but also from the plasma of patients who, like those with sickle cell disease, have accelerated red cell destruction occurring primarily within macrophages. Presumably there is either enough intravascular hemolysis in such hemolytic disorders to lower the plasma haptoglobin level or sufficient leakage from the phagocytic cells into the plasma to bind to haptoglobin. Thus the measurement of plasma haptoglobin levels has usefulness in diagnosing the presence of hemolysis, although it cannot, as previously suggested, serve to clearly distinguish extravascular from intravascular hemolysis.

Heme

Free heme that is released into the circulation is bound in a 1:1 ratio to the plasma glycoprotein hemopexin,⁹⁸ which is cleared from the plasma with a $T_{1/2}$ of 7 to 8 hours.^{99,100} The heme-hemopexin complex is taken up by a low-density lipoprotein-related receptor, CD91.¹⁰¹ Figure 33-3 illustrates the parallel functions of hemopexin and haptoglobin. When the capacity of hemopexin to bind heme is saturated, excess heme may bind to albumin to form methemalbumin.¹⁰² Excess heme is toxic to cells because of the ability of heme to catalyze the so-called Fenton reaction, generating hydroxyl radicals, a highly reactive oxygen species. To avoid the phenomenon and complement the negative feedback regulation of heme synthesis, the expression of heme oxygenase (HO)-1 is induced in response to an increased level of heme, which subsequently results in the degradation of excess heme not bound to proteins. In contrast to HO-1, HO-2 is constitutively expressed and participates in the regulation of a basal heme level.

EXTRAVASCULAR DESTRUCTION

Red cells that are engulfed by phagocytic cells are degraded within lysosomes into lipids, protein, and heme. The proteins and lipids are reprocessed in their respective catabolic pathways and the heme is cleaved by a microsomal HO.¹⁰³ HO catalyzes the oxygen-dependent degradation of heme to biliverdin with the release of CO and "free" iron. Biliverdin is converted into bilirubin by biliverdin reductase α ($BVR\alpha$), which is expressed ubiquitously in all tissues under basal conditions with high levels in macrophages in the spleen and liver.¹⁰⁴ The overall reduction of biliverdin to bilirubin is very efficient, and under physiologic circumstances, the concentration of serum biliverdin is low.

Bilirubin Excretion

Regardless of the site of destruction of hemoglobin, one of the final products is bilirubin. Bilirubin is very insoluble and transported in

Figure 33-3. Overview of the receptor pathways for endocytosis of extracellular heme and hemoglobin in complex with hemopexin and haptoglobin, respectively. LRP/CD91 and CD163 represent two pathways for uptake of extracellular heme incorporated in hemopexin–heme and haptoglobin–hemoglobin. Both receptors are highly expressed in phagocytic macrophages, which are known to metabolize heme into bilirubin, Fe, and CO. In addition to the expression in macrophages, LRP/CD91 is highly expressed in several other cell types including hepatocytes, neurons, and syncytiotrophoblasts. (Reproduced with permission from Hvidberg V, Maniecki MB, Jacobsen C, et al: Identification of the receptor scavenging hemopexin-heme complexes. *Blood* 106(7):2572–2579, 2005.)

plasma bound to albumin. Unconjugated bilirubin is taken up into hepatocytes by transporters of the organic anion-transporting polypeptide (OATP) family, followed by conjugation with glucuronic acid in the microsomes, and ATP-dependent transport into bile. This efflux across the canalicular membrane is mediated by multidrug resistance protein 2, which has high affinity for monoglucuronosyl bilirubin and bisglucuronosyl bilirubin.¹⁰⁵ In the gastrointestinal tract the bilirubin is converted to urobilinogens by bacterial reduction.¹⁰⁶ A small fraction of urobilinogen is reabsorbed and excreted into the urine. Thus, the fecal and urinary urobilinogen excretion have been used as an indicator of the rate of hemolysis, but are only uncommonly used for this purpose in modern practice because the collections are cumbersome and because alternative degradative pathways detract severely from the accuracy of the estimates of the rate of heme catabolism.

CHAPTER 34

CLINICAL MANIFESTATIONS AND CLASSIFICATION OF ERYTHROCYTE DISORDERS

Josef T. Prchal

SUMMARY

Anemias are characterized by a decrease and polycythemia by an increase of the red cell mass. In most clinical situations, changes in red cell mass are inferred from the hemoglobin concentration or hematocrit. Some red cell disorders are associated with compensated hemolysis without or with only slight anemia. Their clinical manifestations are evident not by the effects of anemia but by changes associated with catabolism of hemoglobin such as an increase in serum bilirubin and, if sustained, cholelithiasis, decreased haptoglobin, and usually chronic reticulocytosis. Some red cell disorders are only showcased by morphologic abnormalities as exemplified by hereditary elliptocytosis unaccompanied by hemolysis or anemia.

The anemias have their principal effect by decreasing the oxygen-carrying capacity of blood and their severity is best considered in terms of blood hemoglobin concentration. Anemia may cause symptoms because of tissue hypoxia (e.g., fatigue, dyspnea on exertion). Some manifestations are also caused by compensatory attempts to ameliorate hypoxia (e.g., hyperventilation, tachycardia, and increased cardiac output). These manifestations are a function of the severity and rapidity of onset of the anemia. Tissue hypoxia sensing is ubiquitous and is signaled by an increased level of hypoxia-inducible transcription factors (HIFs)-1 and -2. HIFs upregulate transcription of many genes, in addition to the principal erythropoietic factor erythropoietin (EPO), that are involved in erythropoiesis, but also in angiogenesis, energy metabolism, and iron balance. The classification of anemia should take into account new kinetic and molecular findings.

The polycythemias (erythrocytoses) are best expressed in terms of the packed red cell volume (hematocrit), as their clinical manifestations are primarily related to the expanded red cell mass and resulting increased viscosity of blood, and other specific features related to the pathophysiology stemming from a molecular causative defect (e.g., thrombosis in polycythemia vera, cyanosis in congenital methemoglobinemia). The polycythemias may be primary, caused by somatic or germline mutation(s) dysregulating expansion of

erythroid progenitors and, thus, red cell production, e.g., clonal expansion of a multipotential hematopoietic cell (polycythemia vera) or gain-of-function mutations of the EPO receptor (EPOR) on red cell progenitors—or secondary, caused by increased levels of circulating erythropoiesis-stimulating factors, usually EPO, as a result of tissue hypoxia (e.g., chronic pulmonary disease, high oxygen-affinity hemoglobin mutants, cobalt poisoning). Some polycythemias have hypersensitive erythroid progenitors, as well as increased levels of EPO, and thus share features of both primary and secondary polycythemia; these include Chuvash polycythemia and some other congenital disorders of hypoxia sensing. Persons with relative (spurious) polycythemia have an increased hematocrit as a result of a decreased plasma volume but a normal red cell mass.

ANEMIA

PATHOPHYSIOLOGY AND MANIFESTATIONS

Effects on Oxygen Transport

The clinical manifestations of anemia are a function of the degree of tissue hypoxia and the etiology and pathogenesis of the specific anemia (e.g., splenomegaly characteristic of hereditary spherocytosis, neurologic degeneration, or gastric atrophy of pernicious anemia). Decreased oxygen-carrying capacity mobilizes compensatory mechanisms designed to prevent or ameliorate tissue hypoxia. Red cells also transport carbon dioxide from tissues to the lungs and help distribute nitric oxide throughout the body (Chap. 50), but transport of these gases does not appear to be dependent on the concentration of red cells in the blood and is normal in anemic patients. Tissue hypoxia occurs when the pressure of oxygen in the capillaries is too low to provide cells with enough oxygen for cell metabolic needs. In an average person, the red cell mass must provide the total body tissues with approximately 250 mL/min of oxygen to support life. The oxygen-carrying capacity of normal blood is 1.34 mL per gram of hemoglobin (approximately 200 mL/L of normal blood) and cardiac output is approximately 5000 mL/min; thus, 1000 mL/min of oxygen is available at the tissue level. Extraction of one-fourth of this amount reduces the oxygen tension of 100 torr in the arterial end of the capillary to 40 torr in the venous end. This partial extraction ensures the presence of sufficient diffusion pressure throughout the capillaries to provide all cells with enough oxygen for the cell's metabolic needs (Fig. 34-1). In anemia, extraction of the same amount of oxygen leads to greater hemoglobin desaturation and lower oxygen tension at the venous end of the capillary. The resulting hypoxia in the immediate vicinity initiates a number of compensatory, and frequently symptomatic, adjustments in the supply of blood and oxygen.

Hypoxia-Inducible Transcription Factors Hypoxia-inducible transcription factor (HIF)-1 and its homologue with tissue-restricted expression, HIF-2, play a central role in the body's response to hypoxia (Chaps. 32 and 57). HIF-1 was first identified as a factor regulating the transcriptional activity of the erythropoietin (EPO) gene (Chap. 32).¹ The essential role of this transcriptional factor in global regulation of protection against hypoxia soon became clear. Its actions include respiratory control, transcriptional regulation of glycolytic enzyme genes, angiogenesis, and energy metabolism.²⁻⁴ The prediction that degradation of the hypoxia-regulated subunit of HIF-1 (HIF-1 α) is controlled by an enzyme sensitive to the presence or absence of oxygen⁵ proved to be prescient. Thus, HIF's downregulation is mediated by two principal negative regulators: von Hippel-Lindau tumor suppressor (VHL) and prolyl hydroxylase domain-containing protein 2 (PHD2). Chapter 32

Acronyms and Abbreviations: *EGLN1*, a gene encoding PHD2 protein; *EPAS1*, a gene encoding hypoxia-inducible factor-2 α ; EPO, erythropoietin; EPOR, erythropoietin receptor; HIF, hypoxia-inducible factor; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; PFCP, primary familial and congenital polycythemia; PHD2, prolyl hydroxylase domain-containing protein 2; *VHL*, a gene encoding von Hippel-Lindau tumor suppressor.

Figure 34-1. Theoretical tissue segment provided with oxygen from one capillary. With an arterial diffusion pressure of oxygen of 100 torr and partial oxygen extraction resulting in a venous oxygen pressure of 40 torr, one capillary can provide oxygen to cells within a truncated cone segment. With complete oxygen extraction, however, oxygen cannot be supplied to cells within a rim of tissue around the apex of the cone.

describes the current knowledge of hypoxia sensing in greater detail; however, it is now clear that HIF-2, not HIF-1, is the major regulator of EPO production (Chap. 32). Tissue-specific factors are responsible for tissue-specific mobilization of the compensatory mechanisms listed below that permit survival under hypoxic conditions. **Figure 34-2** outlines the regulation of some physiologic processes by hypoxia.

Decreased Oxygen Consumption Energy metabolism at the optimal oxygen supply is sustained by energy-efficient oxidative phosphorylation. In hypoxia, energy is produced by less-efficient glycolysis accomplished by upregulation of transcription of glycolytic enzyme genes⁴ and increased glucose transport, a process known as the *Pasteur effect*. The Pasteur effect and its exception in the metabolism observed in malignant tissue, referred to as the *Warburg effect*, are both explained at the molecular level by changes in HIF-1 levels.^{4,6-8}

Decreased Oxygen Affinity Efficient increase in tissue oxygen delivery is accomplished by decreasing the affinity of hemoglobin for

oxygen (right-shifted hemoglobin oxygen dissociation curve). This action permits increased oxygen extraction from the same amount of hemoglobin (Chap. 49).⁹ Acutely, a very small shift in pH produces a large effect on the dissociation curve because of the Bohr effect (described by Danish physician Christian Bohr in 1904: “hemoglobin’s oxygen binding affinity is inversely related both to acidity and to the concentration of carbon dioxide”).¹⁰ In chronic anemia, increased oxygen tissue delivery is accomplished by increased amounts of 2,3-bisphosphoglycerate (Chap. 47).⁹ The increased synthesis of 2,3-bisphosphoglycerate in anemia is accomplished by increasing the intracellular pH of red cells (Chap. 47) by respiratory alkalosis resulting from increased respiration. This effect is clearly demonstrated in individuals with high-altitude hypoxemia.¹¹

Increased Tissue Perfusion The effect of decreased oxygen-carrying capacity on the tissue tension of oxygen can be compensated acutely by increasing tissue perfusion locally via changing vasomotor

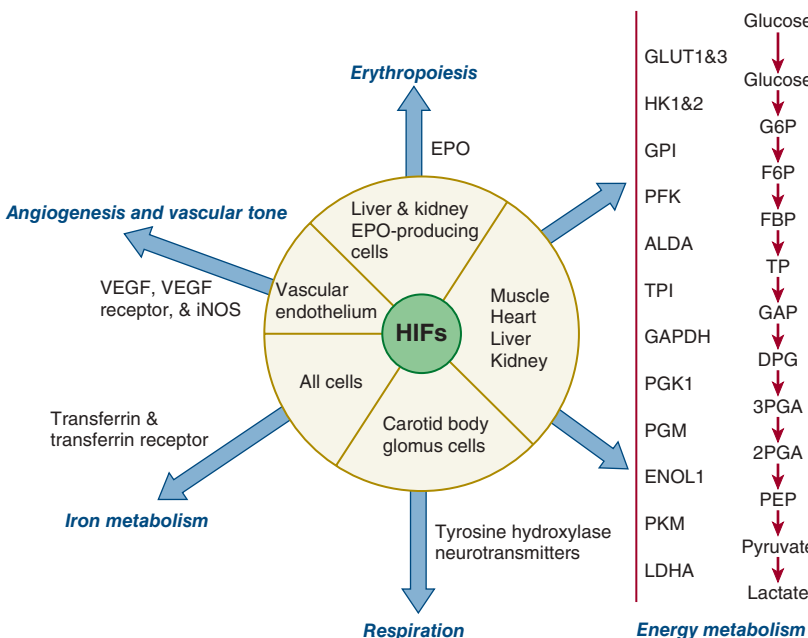

Figure 34-2. Regulation of erythropoiesis, angiogenesis, iron metabolism, respiration, and energy metabolism by hypoxia-inducible factors (HIFs) are examples of physiologic processes regulated by hypoxia. EPO, erythropoietin; iNOS, inducible nitrous oxide synthase; VEGF, vascular endothelial growth factor. *Right panel, left column (in order of listing):* GLUT1&3, glucose transporters 1 and 3; glycolytic enzymes: HK1&2, hexokinase 1 and 2; GPI, glucose phosphate isomerase; PFK, phosphofructokinase; ALDA, aldolase A; TPI, triosephosphate isomerase; GAPDH, glycerol phosphate dehydrogenase; PGK1, phosphoglycerate kinase; PGM, phosphoglycerate mutase; ENOL1, enolase 1; PKM, pyruvate kinase M isoform; LDHA, lactic dehydrogenase A isoform. *Right column:* Metabolic intermediates generated by the depicted enzymes.

Figure 34-3. Relationship between hematocrit and total blood volume in normal individuals and in patients with anemia and polycythemia. (Reproduced with permission from Huber H, Lewis SM and Szur L. *The Influence of Anaemia, Polycythaemia and Splenomegaly on the Relationship between Venous Haematocrit and Red-Cell Volume*. *Br J Haematol* 10:567–575,1964.)

activity and, in the long run, by enhanced tissue angiogenesis.² Because in chronic anemia the blood volume is not changed (Fig. 34-3),¹² increased tissue perfusion is organ selective, accomplished by shunting the blood from nonvital donor-tissue areas to oxygen-sensitive essential recipient organs. In acute anemia, the major donor areas for redistribution of blood are the mesenteric and iliac beds.¹³ In chronic anemia in humans, the donor areas are the cutaneous tissue¹⁴ and the kidneys.¹⁵ Vasoconstriction and oxygen deprivation in the skin cause the characteristic pallor of anemia. In the kidneys, the oxygen supply under normal conditions exceeds oxygen demands. The arteriovenous oxygen difference in the kidney is as low as 1.4 mL/dL (compared with the myocardium, where the difference can be as high as 20 mL/dL), indicating that even a severe reduction in kidney blood perfusion can be tolerated. Nevertheless, enough renal hypoxia must be present to activate HIF-2 and stimulate increased EPO production and erythropoiesis (Chap. 32). The effect on renal excretory mechanisms is slight because the reduction in renal blood flow is offset by a high plasmacrit. Even in severe anemia in which renal blood flow is reduced by almost 50 percent, the total renal plasma flow is only moderately reduced. Thus, organs with the most pressing need for oxygen, such as the myocardium and brain, are largely unimpeded by a moderate reduction in oxygen-carrying capacity, whereas in other tissues severe anemia leads to tissue hypoxia, with some tissue-specific consequences such as retinal hemorrhages.¹⁶

Increased Cardiac Output

Increased cardiac output is a metabolically expensive compensatory device.¹⁷ It decreases the fraction of oxygen that must be extracted during each circulation, thereby maintaining higher oxygen pressure. Because the viscosity of blood in anemia is decreased and selective vascular dilatation decreases peripheral resistance, high cardiac output can be maintained without any increase in blood pressure.¹⁸ In an otherwise healthy person, a measurable increase in resting cardiac output does not occur until hemoglobin concentration is less than 7 g/dL, and clinical signs of cardiac hyperactivity usually are not present until hemoglobin concentration reaches even lower levels.¹⁹

Signs of cardiac hyperactivity include tachycardia, increased arterial and capillary pulsation, and hemodynamic “flow” murmurs.²⁰

Murmurs usually are heard during systole. Murmurs and bruits have been described in many regions, such as over the jugular vein, the closed eye, and the parietal region of the skull, and may be sensed by the patient as roaring in the ears (tinnitus), especially at night. They disappear promptly after the hemoglobin concentration is restored to normal.²⁰ The myocardium tolerates a prolonged period of sustained hyperactivity. However, angina pectoris and high-output failure may supervene if anemia is so severe that it exceeds myocardial oxygen demands or if the patient has coronary artery disease. Cardiomegaly, pulmonary congestion, ascites, and edema have been observed, and they require prompt treatment with oxygen and transfusion of packed red cells.

Increased Pulmonary Function

Significant anemia leads to a compensatory increase in respiratory rate that decreases the oxygen gradient from ambient air to alveolar air and increases the amount of oxygen available to oxygenate a greater than normal cardiac output. Consequently, exertional dyspnea and orthopnea are characteristic clinical manifestations of moderate to severe anemia.^{19–22}

Increased Red Cell Production

The most appropriate response to anemia is a compensatory increase of red cell production, which may increase about twofold to threefold acutely and fourfold to sixfold chronically, and 10-fold in the most extreme case. The increase is mediated by increased production of EPO. The rate of EPO synthesis is inversely and logarithmically related to hemoglobin concentration (Chap. 32). EPO concentration can increase from approximately 10 mU/mL at normal hemoglobin concentrations to 10,000 mU/mL in severe anemia (Fig. 34-4).^{23,24} The change in EPO levels ensures that red cell production increases in response to hemolytic and other anemias or subacute blood loss. If the former is mild, the anemia may be compensated and, if iron is available, the blood loss will be repaired after it ceases. Augmented erythroid activity expands marrow space, which, if intense, can cause sternal tenderness and diffuse bone pains. The proportion and number of reticulocytes increase. Because erythroid transit time through the marrow is shortened, “stress reticulocytes” have increased cell volume and surface area (see Chap. 32, Fig. 32-2). They develop characteristic surface folds as a result of the increased surface-area-to-volume ratio that can be identified in the

Figure 34-4. Erythropoietin (EPO) levels in plasma of normal individuals and patients with anemia uncomplicated by renal or inflammatory disease. The lower limit of accuracy of the EPO assay is 3 mU/mL and is indicated by the *dashed line*. ■, Anemias; ▲, normals; Hgb, hemoglobin.

blood film. Nucleated red cells may be observed in the blood in severe anemia.²⁵

Administration of human recombinant EPO augments or replaces endogenous synthesis. In pharmacologic amounts, the effect on hemoglobin concentration is most noticeable if endogenous production is subnormal as a result of renal failure or systemic illnesses (Chap. 37). In severe anemia where endogenous EPO production (providing production is not impaired) has already increased red cell production maximally, administration of EPO rarely helps, and the patients require transfusion.²⁴

Uncorrected Tissue Hypoxia

A certain residual degree of tissue hypoxia remains despite mobilization of compensatory mechanisms. Hypoxia is essential for initiation of adequate cardiovascular and erythropoietic compensation mechanisms, but severe tissue hypoxia can cause the following symptoms: dyspnea on exertion or even at rest; angina; intermittent claudication; muscle cramps, typically at night; headache; light-headedness; and fatigue. A number of diffuse gastrointestinal symptoms are associated with anemia (e.g., abdominal cramps, nausea), but whether the symptoms should be attributed to tissue hypoxia, compensatory redistribution of blood, or the underlying cause of anemia is uncertain.

CLASSIFICATION

Based on determination of the red cell mass, anemia can be classified as either *relative* or *absolute*. Relative anemia is characterized by a normal total red cell mass in an increased plasma volume, resulting in a dilution anemia, a disturbance in plasma volume regulation. However, dilution anemia is of clinical and differential diagnostic importance for the hematologist.

Classification of the *absolute anemias* with decreased red cell mass is difficult because the classification has to consider kinetic, morphologic, and pathophysiologic interacting criteria. Anemia of acute hemorrhage is not a diagnostic problem and is usually a genitourinary or gastrointestinal matter, not a hematologic consideration. Initially, all anemias should be divided into anemias caused by decreased production and anemias caused by increased destruction of red cells. The differentiation is based largely on the reticulocyte count. Subsequent diagnostic breakdown can be based on either morphologic or pathophysiologic criteria.

Morphologic classification subdivides anemia into (1) macrocytic anemia, (2) normocytic anemia, and (3) microcytic hypochromic anemia. The main advantages of this classification are that the classification is simple, is based on readily available red cell indices, for example, mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC), and forces the physician to consider the most important types of curable anemia: vitamin B₁₂, folic acid, and iron-deficiency anemias. Such practical considerations have led to wide acceptance of this classification.

Pathophysiologic classification (Table 34-1) is best suited for relating disease processes to potential treatment. In addition, anemia resulting from vitamin or iron-deficiency states occurs in a significant proportion of patients with normal red cell indices.

This chapter presents a classification based on our present concepts of normal red cell production and red cell destruction. Figure 34-5 outlines the cascade of proliferation, differentiation, and maturation underlying the transformation of a multipotential stem cell, first to erythroid progenitor cells, then to erythroid precursor cells, and finally to mature red cells. Each of these steps can become impaired and cause anemia. Therapeutic intervention depends on identifying the defective step and instituting the specific therapy. The limitation of such a

classification is that, in most anemias, the pathogenesis involves several steps. For example, a decreased rate of production most often results in production of defective red cells with a shortened life span. Thus, the outline provided is a conceptual guide to our present understanding of the processes underlying the production and destruction of red cells.

POLYCYTHEMIA (ERYTHROCYTOSIS)

PATHOPHYSIOLOGY

The production and presence of an increased number of red cells are associated with general and specific effects generated by changes in blood viscosity and blood volume.

The viscosity of blood increases logarithmically with an increase in hematocrit (Fig. 34-6). At hematocrits above the normal range, the increase in blood viscosity impairs blood flow and increases cardiac workload. The resulting decrease in blood flow reduces the transport of oxygen, with average optimal values at hematocrit readings between 40 and 45 percent.^{26,27} In a study of red cells from a number of animal species, the optimal value of oxygen transport corresponded closely to their normal hematocrits,²⁸ which may explain the evolutionary determination of optimal hematocrit levels.²⁹ However, before concluding that polycythemia always is a suboptimal condition, consider that it may be inappropriate to correlate viscosity readings, derived from blood tested in a rigid glass viscometer (Ostwald) or even in a cone-plate viscometer, with those in flowing blood through tiny distensible vessels *in vivo*.³⁰ First, the flow through these narrow channels is rapid (high shear rate), which in a nonnewtonian fluid such as blood causes a marked decrease in viscosity. Second, blood flowing through narrow channels *in vivo* is axial, with a central core of packed red cells sliding over a peripheral layer of lubricating low-viscosity plasma. Finally, and most importantly, absolute polycythemia is not normovolemic but is accompanied by increased blood volume, which, in turn, enlarges the vascular bed and decreases peripheral resistance. Because blood pressure remains stable, the increased blood volume must be associated with increased cardiac output and increased oxygen transport (cardiac output times hemoglobin concentration). Using measurements of cardiac output in dogs³¹ and tissue oxygen tension in rats and mice,³⁰ construction of curves (Fig. 34-7) that relate oxygen transport to hematocrit in normovolemic and hypervolemic states is possible. These curves show that hypervolemia *per se* increases oxygen transport and that the optimum oxygen transport in these conditions occurs at higher hematocrit values than in normovolemic states. Consequently, despite the increased viscosity, a moderate increase in hematocrit is beneficial. The same may not be true of a more pronounced increase in hematocrit. Observations in humans³² and experimental animals³¹ indicate that high viscosity causes reduced blood flow to most tissues and may be responsible for the cerebral and cardiovascular impairment experienced occasionally by high-altitude dwellers,³³ patients with severe polycythemia,^{34,35} and athletes self-administering overdoses of EPO (Chap. 57).

MANIFESTATIONS

The rate of red cell production is increased in true polycythemias, but changes in erythroid marrow cellularity can be difficult to assess by microscopy means, although the marrow is hypercellular in a typical patient with polycythemia vera. Under normal conditions, the rate of red cell production is adjusted to maintain the red cell mass at approximately 30 mL per kilogram of body weight. Because the life span of red cells in polycythemia is normal, a doubling of the daily rate of red cell production is adequate to maintain a polycythemic red cell mass of 60 mL/kg. Consequently, the morphology and volume of the marrow are only moderately altered in polycythemia compared with the changes

TABLE 34-1. Classification of Anemia

- I. Absolute anemia (decreased red cell volume)
- A. Decreased red cell production
1. Acquired
 - a. Pluripotential hematopoietic stem cell failure
 - (1) Autoimmune (Aplastic anemia) (Chap. 35)
 - (a) Radiation-induced
 - (b) Drugs and chemicals (chloramphenicol, benzene, etc.)
 - (c) Viruses (non-A-G hepatitis, Epstein-Barr virus, etc.)
 - (d) Idiopathic
 - (2) Anemia of leukemia and of myelodysplastic syndromes (Chaps. 87, 88, and 91)
 - (3) Anemia associated with marrow infiltration (Chap. 45)
 - (4) Postchemotherapy (Chap. 22)
 - b. Erythroid progenitor cell failure
 - (1) Pure red cell aplasia (parvovirus B19 infection, drugs, associated with thymoma, autoantibodies, etc. [Chap. 36])
 - (2) Endocrine disorders (Chap. 38)
 - (3) Acquired sideroblastic anemia (drugs, copper deficiency, etc. [Chaps. 59 and 87])
 - c. Functional impairment of erythroid and other progenitors from nutritional and other causes
 - (1) Megaloblastic anemias (Chap. 41)
 - (a) Vitamin B₁₂ deficiency
 - (b) Folate deficiency
 - (c) Acute megaloblastic anemia because of nitrous oxide (N₂O)
 - (d) Drug-induced megaloblastic anemia (pemetrexed, methotrexate, phenytoin toxicity, etc.)
 - (2) Iron-deficiency anemia (Chap. 42)
 - (3) Anemia resulting from other nutritional deficiencies (Chap. 44)
 - (4) Anemia of chronic disease and inflammation (Chap. 37)
 - (5) Anemia of renal failure (Chap. 37)
 - (6) Anemia caused by chemical agents (lead toxicity [Chap. 52])
 - (7) Acquired thalassemias (seen in some clonal hematopoietic disorders [Chaps. 48 and 83])
 - (8) Erythropoietin antibodies (Chap. 36)

2. Hereditary

- a. Pluripotential hematopoietic stem cell failure (Chap. 35)
 - (1) Fanconi anemia
 - (2) Shwachman syndrome
 - (3) Dyskeratosis congenita
- b. Erythroid progenitor cell failure
 - (1) Diamond-Blackfan syndrome (Chap. 35)
 - (2) Congenital dyserythropoietic syndromes (Chap. 39)

c. Functional impairment of erythroid and other progenitors from nutritional and other causes

- (1) Megaloblastic anemias (Chap. 41)
 - (a) Selective malabsorption of vitamin B₁₂ (Imerslund-Gräsbeck disease)
 - (b) Congenital intrinsic factor deficiency
 - (c) Transcobalamin II deficiency
 - (d) Inborn errors of cobalamin metabolism (methylmalonic aciduria, homocystinuria, etc.)
 - (e) Inborn errors of folate metabolism (congenital folate malabsorption, dihydrofolate deficiency, methyltransferase deficiency, etc.)
- (2) Inborn purine and pyrimidine metabolism defects (Lesch-Nyhan syndrome, hereditary orotic aciduria, etc.)
- (3) Disorders of iron metabolism (Chap. 42)
 - (a) Hereditary atransferrinemia
 - (b) Hypochromic anemia caused by divalent metal transporter (DMT)-1 mutation
- (4) Hereditary sideroblastic anemia (Chap. 59)
- (5) Thalassemias (Chap. 48)

B. Increased red cell destruction

1. Acquired

- a. Mechanical
 - (1) Macroangiopathic (march hemoglobinuria, artificial heart valves [Chap. 51])
 - (2) Microangiopathic (disseminated intravascular coagulation [DIC]; thrombotic thrombocytopenic purpura [TTP]; vasculitis [Chaps. 51, 122, and 129])
 - (3) Parasites and microorganisms (malaria, bartonellosis, babesiosis, *Clostridium perfringens*, etc. [Chap. 53])
 - b. Antibody mediated
 - (1) Warm-type autoimmune hemolytic anemia (Chap. 54)
 - (2) Cryopathic syndromes (cold agglutinin disease, paroxysmal cold hemoglobinuria, cryoglobulinemia [Chap. 54])
 - (3) Transfusion reactions (immediate and delayed [Chaps. 54 and 136])
 - c. Hypersplenism (Chap. 56)
 - d. Red cell membrane disorders (Chap. 46)
 - (1) Spur cell hemolysis
 - (2) Acquired acanthocytosis and acquired stomatocytosis, etc.
 - e. Chemical injury and complex chemicals (arsenic, copper, chlorate, spider, scorpion, and snake venoms, etc. [Chap. 52])
 - f. Physical injury (heat, oxygen, radiation [Chap. 52])
2. Hereditary
- a. Hemoglobinopathies (Chap. 49)
 - (1) Sickle cell disease
 - (2) Unstable hemoglobins

observed in some types of hemolytic anemia, in which the rate of red cell production can be four to six times normal. In erythrocytosis, the number of red cells destroyed daily merely causes a slight increase in bilirubin levels. The presence of secondary gout and splenomegaly are usually signs of a myeloproliferative neoplasm rather than of erythrocytosis alone. Although considerable homology exists between EPO and

thrombopoietin,³⁶ there is no evidence that the two molecules cross-react at the level of their respective receptors.³⁷ EPO-driven erythrocytosis is generally not associated with increased platelet production.

The increased viscosity and expansion of vascular space are responsible for many of the signs and symptoms of polycythemia. The characteristic *rubor* in patients with polycythemia vera is caused by excessive deoxygenation of blood flowing sluggishly through dilated cutaneous vessels. Nonspecific symptoms such as headaches, dizziness, tinnitus, and a reported feeling of fullness of the face and head probably are caused by a combination of increased viscosity and vascular dilatation. In extreme polycythemia and some specific types of polycythemia (e.g., methemoglobinemia; Chap. 50), cyanosis can result from greater than 4 g/dL of deoxygenated hemoglobin (accomplished more easily at higher hemoglobin concentrations [see “blue bloaters” and “pink puffers” in Chap. 57]) or greater than 1.5 g/dL of methemoglobin.

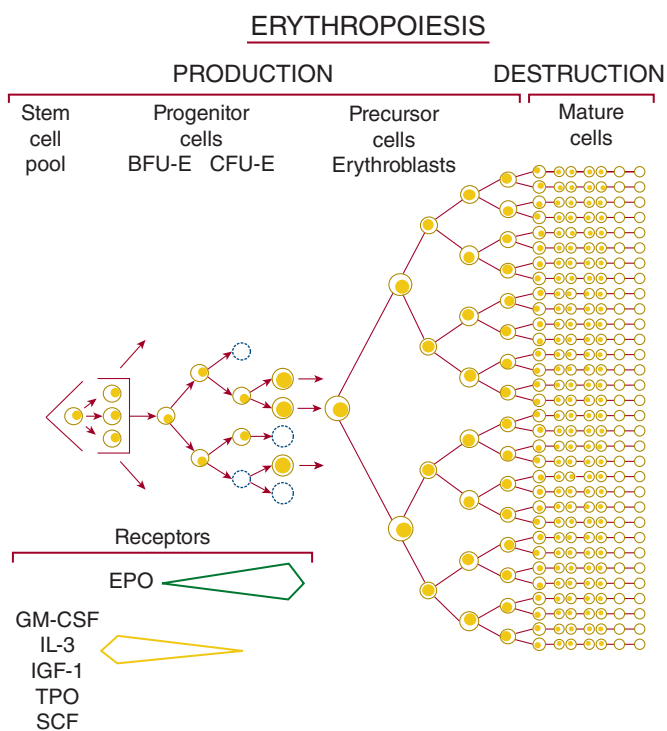

Figure 34-5. Outline of the process of differentiation, proliferation, and maturation underlying the production and destruction of red blood cells. Multipotential stem cells responding to a number of growth factors, including granulocyte-monocyte colony-stimulating factors (GM-CSF), interleukin 3 (IL-3), insulin growth factor 1 (IGF-1), thrombopoietin (TPO), and stem cell factor (SCF), differentiate to progenitor cells committed to erythroid development. Progenitor cells, burst-forming unit-erythroid (BFU-E), and colony-forming unit-erythroid (CFU-E) proliferate under the control of erythropoietin (EPO) and finally differentiate to precursor cells (erythroblasts). In the presence of adequate amounts of nutrients, such as vitamin B₁₂, folic acid, and iron, precursor cells proliferate and mature into nucleated red cells, reticulocytes, and mature red blood cells. After an average 120-day life span, these cells are destroyed.

Figure 34-6. Viscosity of heparinized normal human blood related to hematocrit (Hct). Viscosity is measured with an Ostwald viscosimeter at 37°C and expressed in relation to viscosity of saline solution. Oxygen transport is computed from Hct and O₂ flow (1/viscosity) and is recorded in arbitrary units.

Hemorrhage from the nose or stomach in patients with normal platelets and coagulation proteins can be attributed to capillary distention; however, circulatory stagnation causing ischemia and necrosis may contribute. Thrombosis are common in polycythemia vera, but are not seen at similar frequencies in other types of polycythemia (Chaps. 57 and 84). Coronary blood flow is decreased in polycythemia,³⁴ so the risk of coronary thrombosis in patients with a high hematocrit is assumed to be increased; however, statistical analyses have yielded equivocal evidence of such a relationship.^{35,38,39} Polycythemia reportedly does not pose a risk in surgical patients.⁴⁰ Although cerebral blood flow is materially reduced in patients with moderately elevated hematocrit,^{32,41} such reductions may have little practical significance. In polycythemia vera, however, it has been advocated that normalization of red cell mass should be accomplished before surgery; again, firm data supporting this practice are lacking (Chap. 84).

CLASSIFICATION

Polycythemia, or erythrocytosis, is a condition in which the hematocrit percentage is above the upper limits of normal: greater than 51 percent in men and greater than 48 percent in women. Polycythemia can be classified as: (1) relative, in which the red cell mass is normal but the

plasma volume is decreased, or (2) absolute, in which the red cell mass is increased above normal (Chap. 57). Table 34–2 outlines the polycythemic states.

Differentiation of absolute from relative polycythemia can be difficult at hematocrits of less than 60 percent. Designation of a measured red cell mass as normal is imprecise because the red cell mass depends on the patient’s age, sex, weight, height, and body frame, and because only increases above the mean of greater than 25 percent are considered abnormal.

Primary Polycythemias

Primary or secondary polycythemia are caused by either acquired (polycythemia vera) or inherited mutations (such as gain-of-function erythropoietin receptor [EPOR] causing primary familial and congenital polycythemia [PFCP]) expressed within hematopoietic progenitors, leading to increased production of red cells.

Secondary Polycythemias

Secondary polycythemia are caused by augmentation of erythropoiesis by circulating stimulatory factors such as EPO (polycythemia of high altitude), cobalt, or insulin-like growth factor 1 (Chap. 57).

Figure 34-7. Oxygen transport at various hematocrit levels in normovolemia, mild hypervolemia, and severe hypervolemia. Oxygen transport is estimated by multiplying hematocrit (Hct) by cardiac output. (1) Optimal oxygen transport for normovolemic subjects is at a hematocrit of approximately 45 percent, with a progressive increase in optimal hematocrit as blood volume increases. (2) Suboptimal hematocrit in a hypervolemic person (anemia of pregnancy) may be associated with higher oxygen transport than in a normovolemic person with normal hematocrit. (3) High hematocrit without an increase in blood volume may be associated with an absolute reduction in oxygen transport and tissue hypoxia. (4) Only high hematocrit coupled with high blood volume enhances oxygen transport to the tissues. (Data from Murray JF, Gold P and Johnson BL, Jr. *The circulatory effects of hematocrit variations in normovolemic and hypervolemic dogs.* *J Clin Invest.* 42:1150-9, 1963 and Thorling EB and Erslev AJ. *The "tissue" tension of oxygen and its relation to hematocrit and erythropoiesis.* *Blood* 31(3):332-343, 1968.)

Disorders of Hypoxia Sensing

Polycythemia from VHL Gene Mutation Chuvash polycythemia and some other disorders of hypoxia sensing, including several recessively inherited mutations of the *VHL* gene, have elevated or inappropriately normal EPO levels in relation to elevated hematocrit. This phenotype is different from other, more common *VHL* mutations encompassing *VHL* tumor predisposition syndrome, wherein dominantly inherited germline *VHL* mutations precede the acquired somatic mutations that eventually result in tumor genesis (hemangioblastoma, renal cell carcinoma, pheochromocytoma, pancreatic endocrine tumors, and endolymphatic sac tumors). Following the description of Chuvash polycythemia, other homozygous and compound heterozygous inherited *VHL* mutations causing polycythemia, but not tumors, have been described (Chap. 57). Some patients with tumor predisposition *VHL* syndrome also develop acquired polycythemia as a consequence of EPO production in tumor tissue.⁴²

Clinically, Chuvash polycythemia patients are prone to develop thrombosis, they have elevated pulmonary pressure and have increased mortality independent of the increase in hematocrit.⁴³

Polycythemia from HIF2 α and PHD2 Mutations Dominantly inherited gain-of-function HIF2 α (encoded by *EPAS1*) gene mutations have elevated or inappropriately normal EPO levels in relation to elevated hematocrits. All reported polycythemic heterozygotes for

loss-of-function PHD2 variants (encoded by *EGLN1* gene) have normal EPO levels.

Because of the rarity of *HIF2 α* and *PHD2* mutations, their non-erythroid phenotype is not well defined; however, some *HIF2 α* mutations, possibly associated with genetic mosaicism, are associated with congenital polycythemia and later development of pheochromocytoma/paraganglioma and somatostatinoma tumors. In these instances, in most patients, the *HIF2 α* mutation is present in the tumors, which frequently recur, but not in leukocytes.^{44,45}

CHAPTER 35

APLASTIC ANEMIA: ACQUIRED AND INHERITED

George B. Segel and Marshall A. Lichtman

SUMMARY

Acquired aplastic anemia is a clinical syndrome in which there is a deficiency of red cells, neutrophils, monocytes, and platelets in the blood, and fatty replacement of the marrow with a near absence of hematopoietic precursor cells. Reticulocytopenia is a constant feature. Neutropenia, monocytopenia, and thrombocytopenia, when severe, are life-threatening because of the risk of infection and bleeding, complicated by severe anemia. Most cases occur without an evident precipitating cause and are caused by autoreactive cytotoxic T lymphocytes that suppress or destroy primitive CD34+ multipotential hematopoietic cells. The disorder also can occur after (1) prolonged high-dose exposure to certain toxic chemicals (e.g., benzene), (2) after specific viral infections (e.g., Epstein-Barr virus), (3) as an idiosyncratic response to certain pharmaceuticals (e.g., ticlopidine, chloramphenicol), (4) as a feature of a connective tissue or autoimmune disorder (e.g., lupus erythematosus), or, (5) rarely, in association with pregnancy. The final common pathway may be through cytotoxic T-cell autoreactivity, whether idiopathic or associated with an inciting agent since they all respond in a similar fashion to immunosuppressive therapy. The differential diagnosis of acquired aplastic anemia includes a hypoplastic marrow that can accompany paroxysmal nocturnal hemoglobinuria or hypoplastic oligoblastic (myelodysplastic syndrome) or polyblastic myelogenous leukemia. Allogeneic hematopoietic stem cell transplantation is curative in approximately 80 percent of younger patients with high-resolution human leukocyte antigen–matched sibling donors, although the posttransplant period may be complicated by severe graft-versus-host disease. The disease may be significantly ameliorated or occasionally cured by immunotherapy, especially a regimen coupling antithymocyte globulin with cyclosporine. However, after successful treatment with immunosuppressive agents, the disease may relapse or evolve into a clonal myeloid disorder, such as paroxysmal nocturnal hemoglobinuria, a clonal cytopenia, or oligoblastic

or polyblastic myelogenous leukemia. Several uncommon inherited disorders, including Fanconi anemia, Shwachman-Diamond syndrome, dyskeratosis congenita and others have as a primary manifestation aplastic hematopoiesis.

ACQUIRED APLASTIC ANEMIA

DEFINITION AND HISTORY

Aplastic anemia is a clinical syndrome that results from a marked diminution of marrow blood cell production. The decrease in hematopoiesis results in reticulocytopenia, anemia, granulocytopenia, monocytopenia, and thrombocytopenia. The diagnosis usually requires the presence of pancytopenia with a neutrophil count fewer than $1500/\mu\text{L}$ ($1.5 \times 10^9/\text{L}$), a platelet count fewer than $50,000/\mu\text{L}$ ($50 \times 10^9/\text{L}$), a hemoglobin concentration less than 10 g/dL (100 g/L), and an absolute reticulocyte count fewer than $40,000/\mu\text{L}$ ($40 \times 10^9/\text{L}$), accompanied by a hypocellular marrow without abnormal or malignant cells or fibrosis.¹ For the purpose of therapeutic decision making, comparative clinical trials, and international sharing of data, the disease has been stratified into moderately severe, severe, and very severe acquired aplastic anemia based on the blood counts (especially the neutrophil count) and the degree of marrow hypocellularity (Table 35–1). Most cases of aplastic anemia are acquired; fewer cases are the result of an inherited disorder, such as Fanconi anemia, Shwachman-Diamond syndrome, and others (see “Hereditary Aplastic Anemia” below).

Aplastic anemia was first recognized by Paul Ehrlich in 1888.² He described a young, pregnant woman who died of severe anemia and neutropenia. Thrombocytopenia was difficult to measure and the role of blood dust (platelets) was controversial at that time. Autopsy examination revealed a fatty marrow with essentially no hematopoiesis. The name *aplastic anemia* was subsequently applied to this disease by Chauffard, a French hematologist, in 1904,³ and although an anachronistic term because the morbidity is the result of pancytopenia, especially neutropenia and thrombocytopenia, the designation is entrenched in medical usage. For the next 40 years, many conditions that caused pancytopenia were confused with aplastic anemia based on incomplete or inadequate histologic study of the patient’s marrow.⁴ The development of improved instruments for percutaneous marrow biopsy in the last half of the 20th century improved diagnostic precision. In 1972, Thomas and his colleagues established that marrow transplantation from a histocompatible sibling donor could cure the disease.⁵ The disease initially was thought to result from an atrophy or chemical injury of primitive marrow hematopoietic cells. The unexpected recovery of marrow recipients who were given immunosuppressive conditioning therapy but who did not engraft with donor stem cells raised the possibility that the disease may not be intrinsic to primitive hematopoietic cells but the result of a suppression of hematopoietic cells by immune cells, notably T lymphocytes.⁶ The requirement to treat the recipient of a marrow transplant from an identical twin with immunosuppressive conditioning therapy for optimal results of transplant, buttressed this concept.⁷ This supposition was confirmed by a clinical trial that established antilymphocyte globulin (ALG) capable of ameliorating the disease in the majority of patients.⁸ Since that time, compelling evidence for a cellular autoimmune mechanism has accumulated (see “Etiology and Pathogenesis” below).

EPIDEMIOLOGY

The International Aplastic Anemia and Agranulocytosis Study and a French study found the incidence of acquired aplastic anemia to be approximately 2 per 1,000,000 persons per year.^{1,9} This annual incidence

TABLE 35-1. Degree of Severity of Acquired Aplastic Anemia

Diagnostic Categories	Hemoglobin	Reticulocyte Concentration	Neutrophil Count	Platelet Count	Marrow Biopsy	Comments
Moderately severe	<100 g/L	<40 × 10 ⁹ /L	<1.5 × 10 ⁹ /L	<50 × 10 ⁹ /L	Marked decrease of hematopoietic cells.	At the time of diagnosis at least 2 of 3 blood counts should meet these criteria.
Severe	<90 g/L	<30.0 × 10 ⁹ /L	<0.5 × 10 ⁹ /L	<30.0 × 10 ⁹ /L	Marked decrease or absence of hematopoietic cells.	Search for a histocompatible sibling should be made if age permits.
Very severe	<80 g/L	<20.0 × 10 ⁹ /L	<0.2 × 10 ⁹ /L	<20.0 × 10 ⁹ /L	Marked decrease or absence of hematopoietic cells.	Search for a histocompatible sibling should be made if age permits.

NOTE: These values are approximations and must be considered in the context of an individual patient's situation. (In some clinical trials, the blood count thresholds for moderately severe aplastic anemia are higher, e.g., platelet count <100 × 10⁹/L and absolute reticulocyte count <60,000 × 10⁹/L.) The marrow biopsy may contain the usual number of lymphocytes and plasma cells; "hot spots," focal areas of erythroid cells, may be seen. No fibrosis, abnormal cells, or malignant cells should be evident in the marrow. Dysmorphic features of blood or marrow cells are not features of acquired aplastic anemia. Ethnic differences in the lower limit of the absolute neutrophil count should be considered (Chap. 64).

has been confirmed in studies in Spain (Barcelona),¹⁰ Brazil (State of Parana),¹¹ and Canada (British Columbia).¹² The highest frequency of aplastic anemia occurs in persons between the ages of 15 and 25 years; a second peak occurs between the ages of 65 and 69.¹ Aplastic anemia is more prevalent in the Far East where the incidence is approximately 7 per 1,000,000 in parts of China,¹³ approximately 4 per 1,000,000 in sections of Thailand,¹⁴ approximately 5 per 1,000,000 in areas of Malaysia,¹⁵ and approximately 7 per 1,000,000 among children of Asian descent living in Canada.¹² The explanation for a twofold or greater incidence in the Orient compared to the Occident may be multifactorial,¹⁶ but a predisposition gene or genes is a likely component.^{12,17} Studies have not established the use of chloramphenicol in Asia as a cause. Poorly regulated exposure of workers to benzene is a factor,¹⁸ but the attributable risk from benzene and other toxic exposures does not explain the magnitude of the difference in the incidence in Asia compared to that in Europe and South America.^{16,17} A relationship to impure water use in Thailand has led to speculation of an infectious etiology, although no agent, including seronegative hepatitis, a known association with the onset of acquired aplastic anemia,¹⁶ has been identified. Seronegative viral hepatitis is a forerunner of approximately 7 percent of cases of acquired aplastic anemia.^{17,19} The male-to-female incidence ratio of aplastic anemia in most studies is approximately one.¹⁷

ETIOLOGY AND PATHOGENESIS

Table 35-2 lists the conditions associated with aplastic anemia.

The final common pathway to the clinical disease is a decrease in blood cell formation in the marrow. The number of marrow CD34+ cells (multipotential hematopoietic progenitors) and their derivative colony-forming unit-granulocyte-macrophage (CFU-GM) and burst-forming unit-erythroid (BFU-E) are reduced markedly in patients with aplastic anemia.²⁰⁻²³ Long-term culture-initiating cells, an *in vitro* surrogate assay for hematopoietic stem cells, also are reduced to approximately 1 percent of normal values.²³ Potential mechanisms responsible for acquired marrow cell failure include (1) cellular or humoral immune suppression of the marrow multipotential cells, (2) progressive erosion of chromosome telomeres, (3) direct toxicity to hematopoietic multipotential or stem cells, (4) a defect in the stromal microenvironment of the marrow required for hematopoietic cell development, and (5) impaired

production or release of essential multilineage hematopoietic growth factors. There is little experimental evidence for a stromal microenvironmental defect or a deficit of critical hematopoietic growth factors or their receptors. Telomerase mutations with consequent telomere shortening may be involved in as many as 40 percent of patients.²⁵ A susceptibility to the development of aplastic anemia is present in persons with certain human leukocyte antigen (HLA) types, such as HLA-DR15.²⁵

Deficiencies in telomere repair could predispose to aplastic anemia by affecting the size of the multipotential hematopoietic cell compartment and by decreasing the multipotential cell's response to marrow injury, and could play a role in the evolution of aplastic anemia to a clonal myeloid disease by contributing to genomic instability.²⁴ Reduced hematopoiesis in most cases of aplastic anemia results from cytotoxic T-cell-mediated immune suppression of very early CD34+ hematopoietic multipotential progenitor or stem cells.²⁶ A small fraction of cases is initiated by a toxic exposure, drug exposure, or viral infection, and in these cases the pathogenesis also may relate to autoimmunity as there is evidence of immune dysfunction in seronegative hepatitis, after benzene exposure, and many such patients respond to anti-T-cell therapy.²⁶

Autoreactive Cytotoxic T Lymphocytes

In vitro and clinical observations have resulted in the identification of a cytotoxic T-cell-mediated attack on multipotential hematopoietic cells in the CD34+ cellular compartment as the basis for most cases of acquired aplastic anemia.²⁷ Cellular immune injury to the marrow after drug-, viral-, or toxin-initiated marrow aplasia could result from the induction of neoantigens that provoke a secondary T-cell-mediated attack on hematopoietic cells. This mechanism could explain the response to immunosuppressive treatment in cases that follow exposure to an exogenous agent. Spontaneous or mitogen-induced increases in mononuclear cell production of interferon- γ ,^{28,29} interleukin (IL)-2,²⁹ and tumor necrosis factor- α (TNF- α)^{30,31} occur. These factors are inhibitory to hematopoietic cell development. Elevated serum levels of interferon- γ are present in 30 percent of patients with aplastic anemia, and interferon- γ expression has been detected in the marrow of most patients with acquired aplastic anemia.³² Addition of antibodies to interferon- γ enhances *in vitro* colony growth of marrow cells from affected patients.³³ Long-term marrow cultures manipulated to elaborate exaggerated amounts of interferon- γ , markedly reduced the frequency of long-term culture-initiating cells.²⁶ These observations indicate that acquired aplastic anemia is the result of cellular immune-induced apoptosis of primitive CD34+ multipotential hematopoietic progenitors, mediated by cytotoxic T lymphocytes, in part, through the expression of T-helper type 1 (Th1) inhibitory cytokines, interferon- γ , and TNF- α (Fig. 35-1).³⁴ The secretion of interferon- γ is a result of the upregulation of the regulatory transcription factor T-bet,³⁵ and apoptosis of CD34+ cells is, in part, mediated through a FAS-dependent pathway.²⁶ Because HLA-DR2 is more prevalent in patients with aplastic anemia, antigen recognition may be a factor in those patients. A variety of other potential factors have been found in some patients, including nucleotide polymorphisms in cytokine genes, overexpression of perforin in marrow cells, and decreased expression of SLAM-associated protein (SAP), a modulator protein that inhibits interferon- γ secretion.²⁶

A decrease in regulatory T cells (CD4+CD25+FoxP3+) contributes to the expansion of an autoreactive CD8+CD28- T-cell population, which induces apoptosis of autologous hematopoietic multipotential hematopoietic cells.³⁶⁻³⁸ T-regulatory cells are a component of the immune system that suppress immune responses of other cells. They provide a "stop" for immune reactions that have achieved their purpose. They also play a role in preventing autoimmune reactions (Chap. 76). One mouse model of immune-related marrow failure, induced by infusion of parental lymph node cells into F1 hybrid

recipients, caused a fatal aplastic anemia. The aplasia could be prevented by immunotherapy or with monoclonal antibodies to interferon- γ and TNF- α .²⁶ Another mouse model of aplastic anemia induced by the infusion of lymph node cells histoincompatible for the minor H antigen, H60, resulted from the expansion of H60-specific CD8 T cells in recipient mice. The result was severe marrow aplasia. The effect of the CD8 T cells could be abrogated by either immunosuppressive agents or administration of CD4+CD25+ regulatory T cells,³⁹ providing additional experimental evidence for the role of regulatory T cells in the prevention of aplastic anemia.

Several putative target antigens on affected hematopoietic cells have been identified. Autoantibodies to one putative antigen, kinectin, have been found in patients with aplastic anemia. T cells, responsive to kinectin-derived peptides, suppress granulocyte-monocyte colony growth *in vitro*. However, in these studies cytotoxic T lymphocytes with that specificity were not isolated from patients.⁴⁰ Thus, the putative antigen(s) that is the target of the autoreactive T cells has not been identified.

Telomere Shortening

A relationship between acquired aplastic anemia and hereditary aplastic anemia (Fanconi anemia or dyskeratosis congenita) in some patients has been suggested because the defects in telomerase and telomere repair, characteristic of Fanconi anemia and dyskeratosis congenita are shared in some adult patients with aplastic anemia, but in these cases there is no family history of such a disorder and no phenotypic abnormalities that characterize the hereditary disorders (see "Fanconi Anemia" and "Dyskeratosis Congenita" below). Telomeres shorten physiologically with age as telomerase becomes less active. T-cell-mediated acquired aplastic anemia is associated with telomere shortening which could reflect an inherited defect in telomerase or a senescent erosion of activity. The telomerase mechanism consists of a telomerase reverse transcriptase (TERT); an RNA template for TERT, the telomerase RNA component (TERC), and other stabilizing proteins.^{41,41a} Cells with shortened telomeres normally undergo apoptosis unless DNA repair mechanisms are impaired allowing the development of aneuploidy and neoplastic transformation.

Drugs

Chloramphenicol is the most notorious drug documented to cause aplastic anemia. Although this drug is directly myelosuppressive at very high dose because of its effect on mitochondrial DNA, the occurrence of aplastic anemia appears to be idiosyncratic, perhaps related to an inherited sensitivity to the nitroso-containing toxic intermediates.⁴² This sensitivity may produce immunologic marrow suppression, as a substantial proportion of affected patients respond to treatment with immunosuppressive therapy.⁴³ The risk of developing aplastic anemia in patients treated with chloramphenicol is approximately 1 in 20,000, or 25 times that of the general population.⁴⁴ Although its use as an antibiotic has been largely abandoned in industrialized countries, global reports of fatal aplastic anemia continue to appear with topical or systemic use of the drug.

Epidemiologic evidence established that quinacrine (Atabrine) increased the risk of aplastic anemia.⁴⁵ This drug was administered to all U.S. troops in the South Pacific and Asiatic theaters of operations as prophylaxis for malaria during 1943 and 1944. The incidence of aplastic anemia was 7 to 28 cases per 1,000,000 personnel per year in the prophylaxis zones, whereas untreated soldiers had 1 to 2 cases per 1,000,000 personnel per year. The aplasia occurred during administration of the offending agent and was preceded by a characteristic rash in nearly half the cases. Many other drugs have been reported to increase the risk of aplastic anemia, but owing to incomplete reporting of information and

Figure 35-1. Immune pathogenesis of apoptosis of CD34 multipotential hematopoietic cells in acquired aplastic anemia. Antigens are presented to T lymphocytes by antigen-presenting cells (APCs). This triggers T cells to activate and proliferate. T-bet, a transcription factor, binds to the interferon- γ (IFN- γ) promoter region and induces gene expression. SLAM-associated protein (SAP) binds to Fyn and modulates the signaling lymphocyte activation molecule (SLAM) activity on IFN- γ expression, diminishing gene transcription. Patients with aplastic anemia show constitutive T-bet expression and low SAP levels. IFN- γ and tumor necrosis factor- α (TNF- α) upregulate both the T cell's cellular receptors and the Fas receptor. Increased production of interleukin-2 leads to polyclonal expansion of T cells. Activation of the Fas receptor by the Fas ligand leads to apoptosis of target cells. Some effects of IFN- γ are mediated through interferon regulatory factor 1 (IRF-1), which inhibits the transcription of cellular genes and entry into the cell cycle. IFN- γ is a potent inducer of many cellular genes, including inducible nitric oxide synthase (NOS), and production of the toxic gas, nitric oxide (NO), may further diffuse the toxic effects. These events ultimately lead to reduced cell cycling and cell death by apoptosis. (Reproduced with permission from Young NS, Calado RT, Scheinberg P: *Current concepts in the pathophysiology and treatment of aplastic anemia*. *Blood* 108(8):2509–2519, 2006.)

the infrequency of the association, the spectrum of drug-induced aplastic anemia may not be fully appreciated. Table 35-3 is a partial list of drugs that have been implicated.⁴⁶⁻⁵⁴

Many of these drugs are known to also induce selective cytopenias, such as agranulocytosis, which usually are reversible after discontinuation of the offending agent. These reversible reactions are not correlated with the risk of aplastic anemia, casting doubt on the effectiveness of routine monitoring of blood counts as a strategy to avoid aplastic anemia.

Because aplastic anemia is a rare event with drug use, it may occur because of an underlying metabolic or immunologic predisposition (gene polymorphism) in susceptible individuals. In the case of phenylbutazone-associated marrow aplasia, there is delayed oxidation and clearance of a related compound, acetanilide, as compared to either normal controls or those with aplastic anemia from other causes. This finding suggests excess accumulation of the drug as a potential mechanism for the aplasia. In some cases, drug interactions or synergy may be required to induce marrow aplasia. Cimetidine, a histamine H₂-receptor antagonist, is occasionally implicated in the onset of cytopenias and aplastic anemia, perhaps owing to a direct effect on early hematopoietic progenitor cells.⁵⁵ This drug accentuates the marrow-suppressive

effects of the chemotherapy drug carmustine.⁵⁶ In several instances, it has been reported as a possible cause of marrow aplasia when given with chloramphenicol.

There appears to be little difference in the age distribution, gender, response to immunotherapy, marrow transplantation, or survival, whether or not a drug exposure preceded the onset of the marrow aplasia.

Toxic Chemicals

Benzene was the first chemical linked to aplastic anemia, based on studies in factory workers before the 20th century.⁵⁷⁻⁵⁹ Benzene is used as a solvent and is employed in the manufacture of chemicals, drugs, dyes, and explosives. It has been a vital chemical in the manufacture of rubber and leather goods and has been used widely in the shoe industry, leading to an increased risk for aplastic anemia (and acute myelogenous leukemia) in workers exposed to a poorly regulated environment.⁵⁹ In studies in China, aplastic anemia among workers was sixfold higher than in the general population.¹⁸

The U.S. Occupational Safety and Health Administration has lowered the permissible atmospheric exposure limit of benzene to 1 part per million (ppm) (8-hour time-weighted average) and short-term

TABLE 35-3. Drugs Associated with Aplastic Anemia

Category	High Risk	Intermediate Risk	Low Risk
Analgesic			Phenacetin, aspirin, salicylamide
Antiarrhythmic			Quinidine, tocainide
Antiarthritic		Gold salts	Colchicine
Anticonvulsant		Carbamazepine, hydantoins, felbamate	Ethosuximide, phenacemide, primidone, trimethadione, sodium valproate
Antihistamine			Chlorpheniramine, pyrilamine, tripeleminamine
Antihypertensive			Captopril, methyldopa
Antiinflammatory		Penicillamine, phenylbutazone, oxyphenbutazone	Diclofenac, ibuprofen, indomethacin, naproxen, sulindac
Antimicrobial			
Antibacterial		Chloramphenicol	Dapsone, methicillin, penicillin, streptomycin, β -lactam antibiotics
Antifungal			Amphotericin, flucytosine
Antiprotozoal		Quinacrine	Chloroquine, mepacrine, pyrimethamine
Antineoplastic drugs			
Alkylating agent	Busulfan, cyclophosphamide, melphalan, nitrogen mustard		
Antimetabolite	Fluorouracil, mercaptopurine, methotrexate		
Cytotoxic antibiotic	Daunorubicin, doxorubicin, mitoxantrone		
Antiplatelet			Ticlopidine
Antithyroid			Carbimazole, methimazole, methylthiouracil, potassium perchlorate, propylthiouracil, sodium thiocyanate
Sedative and tranquilizer			Chlordiazepoxide, chlorpromazine (and other phenothiazines), lithium, meprobamate, methyprylon
Sulfa derivative		Sulfonamides	
Antibacterial			Numerous sulfonamides
Diuretic		Acetazolamide	Chlorothiazide, furosemide
Hypoglycemic			Chlorpropamide, tolbutamide
Miscellaneous			Allopurinol, interferon, pentoxifylline, penicillamine

NOTE: Drugs that invariably cause marrow aplasia with high doses are termed *high risk*; drugs with 30 or more reported cases are listed as moderate risk; others are less often associated with aplastic anemia (low risk).

SOURCE: This list was compiled from the AMA Registry,⁴⁶ publications of the International Agranulocytosis and Aplastic Anemia Study,⁴⁷⁻⁵¹ and other reviews and studies.^{26,52-54} An additional comprehensive source for potentially offending drugs can be found in *The Drug Etiology of Agranulocytosis and Aplastic Anemia*, Oxford, UK: Oxford University Press, 1991.

exposure to 5 ppm (15-minute time-weighted average). The National Institute for Occupational Safety and Health recommends limits of exposure of 0.1 ppm as the 8-hour weighted average and 1 ppm for 15-minute short-term exposure. Previous to that regulatory change, the frequency of aplastic anemia in workers exposed to greater than 100 ppm benzene was approximately 1 in 100 workers, which decreased to 1 in 1000 workers at 10 to 20 ppm exposure.⁵⁸

Organochlorine and organophosphate pesticide compounds have been suspected in the onset of aplastic anemia^{60,61} and several studies have indicated an increased relative risk, especially for agricultural exposures^{11,16,62,63} and household^{11,63} exposures. These relationships are suspect because dose-disease relationships and other important

factors have not been delineated, and several studies have not found an association with environmental exposures.^{12,64} DDT (dichlorodiphenyltrichloroethane), lindane, and chlordane are insecticides that also have been associated with cases of aplastic anemia.^{16,61} Occasional cases still occur following heavy exposure at industrial plants or after its use as a pesticide.⁶⁵ Lindane is metabolized in part to pentachlorophenol (PCP), another potentially toxic chlorinated hydrocarbon that is manufactured for use as a wood preservative. Cases of aplastic anemia and related blood disorders have been attributed to PCP over the past 25 years.^{61,66} Prolonged exposures to petroleum distillates in the form of Stoddard solvent⁶⁷ and acute exposure to toluene through the practice of glue sniffing^{68,69} also have been reported to cause marrow aplasia.

Trinitrotoluene (TNT), an explosive used extensively during World Wars I and II, is absorbed readily by inhalation and through the skin.⁷⁰ Fatal cases of aplastic anemia were observed in munitions workers exposed to TNT in Great Britain⁷¹ from 1940 to 1946. In most cases, these conclusions have not been derived from specific studies but from accumulation of case reports or from patient histories, making conclusions provisional, although the argument for minimizing exposures to potential toxins is logical in any case.

Viruses

Non-A, -B, -C, -D, -E, -G Hepatitis Virus A relationship between hepatitis and the subsequent development of aplastic anemia has been the subject of a number of case reports, and this association was emphasized by two major reviews in the 1970s.^{72,73} In the aggregate, these reports summarized findings in more than 200 cases. In many instances, the hepatitis was improving or had resolved when the aplastic anemia was noted 4 to 12 weeks later. Approximately 10 percent of cases occurred more than 1 year after the initial diagnosis of hepatitis. Most patients were young (ages 18 to 20 years); two-thirds were male, and their survival was short (10 weeks). Although hepatitis A and B have been implicated in aplastic anemia in a small number of cases, most cases are related to non-A, non-B, non-C hepatitis.⁷⁴⁻⁷⁶ Severe aplastic anemia developed in 9 of 31 patients who underwent liver transplantation for non-A, non-B, non-C hepatitis, but in none of 1463 patients transplanted for other indications.⁷⁷ Several lines of evidence indicate there is no causal association with hepatitis C virus, suggesting that an unknown viral agent is involved.^{16,78,79} Hepatitis virus B or C can be a secondary infection, if carefully screened blood products are not used for transfusion. In 15 patients with posthepatic aplastic anemia, no evidence was found for hepatitis A, B, C, D, E, or G, transfusion-transmitted virus, or parvovirus B19.⁸⁰ Several reports suggest a relationship of parvovirus B19 to aplastic anemia,^{81,82} whereas others have not.⁷⁹ This relationship has not been established (Chap. 36). The effect of seronegative hepatitis may be mediated through an autoimmune T-cell effect because of evidence of T-cell activation and cytokine elaboration.²⁶ These patients also have a similar response to combined immunotherapy as do those with idiopathic aplastic anemia^{83,84} (see "Treatment: Combination Immunotherapy" below).

Epstein-Barr Virus Epstein-Barr virus (EBV) has been implicated in the pathogenesis of aplastic anemia.^{85,86} The onset usually occurs within 4 to 6 weeks of infection. In some cases, infectious mononucleosis is subclinical, with a finding of reactive lymphocytes in the blood film and serologic results consistent with a recent infection (Chap. 82). EBV has been detected in marrow cells,⁸⁶ but it is uncertain whether marrow aplasia results from a direct effect or an immunologic response by the host. Patients have recovered following therapy with antithymocyte globulin.⁸⁶

Other Viruses HIV infection frequently is associated with varying degrees of cytopenia. The marrow is often cellular, but occasional cases of aplastic anemia have been noted.⁸⁷⁻⁸⁹ Marrow hypoplasia may result from viral suppression and from the drugs used to control viral replication in this disorder. Human herpes virus (HHV)-6 has caused severe marrow aplasia subsequent to marrow transplantation for other disorders.⁹⁰

Autoimmune Diseases

The incidence of severe aplastic anemia was sevenfold greater than expected in patients with rheumatoid arthritis.⁵² It is uncertain whether the aplastic anemia is related directly to rheumatoid arthritis or to the various drugs used to treat the condition (gold salts, D-penicillamine, and nonsteroidal antiinflammatory agents). Occasional cases of aplastic anemia are seen in conjunction with systemic lupus erythematosus.⁹¹ *In vitro* studies found either the presence of an antibody⁹² or suppressor

cell^{93,94} directed against hematopoietic progenitor cells. Patients have recovered after plasmapheresis,⁹² glucocorticoids,⁹⁴ or cyclophosphamide therapy,^{93,95} which is compatible with an immune etiology.

Eosinophilic fasciitis, an uncommon connective tissue disorder with painful swelling and induration of the skin and subcutaneous tissue, has been associated with aplastic anemia.^{96,97} Although it may be antibody-mediated in some cases, it has been largely unresponsive to therapy.⁹⁶ Nevertheless, (1) stem cell transplantation, (2) immunosuppressive therapy using cyclosporine, (3) immunosuppressive therapy using antithymocyte globulin (ATG), or (4) immunosuppressive therapy with ATG and cyclosporine has cured or significantly ameliorated the disease in a few patients.^{96,97}

Severe aplastic anemia also has been reported coincident with immune thyroid disease (Graves disease)⁹⁸⁻¹⁰² and the aplasia has been reversed with treatment of the hyperthyroidism. Aplastic anemia has occurred in association with thymoma.¹⁰²⁻¹⁰⁸ Autoimmune renal disease and aplastic anemia have occurred concurrently. The underlying relationship may be the role of cytotoxic T lymphocytes in the pathogenesis of several autoimmune diseases and in aplastic anemia.¹⁰⁹

Pregnancy

There are a number of reports of pregnancy-associated aplastic anemia, but the relationship between the two conditions is not always clear.¹¹⁰⁻¹¹⁵ In some patients, preexisting aplastic anemia is exacerbated with pregnancy, only to improve following termination of the pregnancy.^{110,111} In other cases, the aplasia develops during pregnancy with recurrences during subsequent pregnancies.^{111,112} Termination of pregnancy or delivery may improve the marrow function, but the disease may progress to a fatal outcome even after delivery.¹¹⁰⁻¹¹² Therapy may include elective termination of early pregnancy, supportive care, immunosuppressive therapy, or marrow transplantation after delivery. Pregnancy in women previously treated with immunosuppression for aplastic anemia can result in the birth of a normal newborn.¹¹⁵ In this latter study of 36 pregnancies, 22 were uncomplicated, 7 were complicated by a relapse of the marrow aplasia, and 5 without marrow aplasia required red cell transfusion during delivery.¹¹⁵ One death occurred from cerebral thrombosis in a patient with paroxysmal nocturnal hemoglobinuria (PNH) and marrow aplasia.

Iatrogenic Causes

Although marrow toxicity from cytotoxic chemotherapy or radiation produces direct damage to stem cells and more mature cells, resulting in marrow aplasia, most patients with acquired aplastic anemia cannot relate an exposure that would be responsible for marrow damage.

Chronic exposure to low doses of radiation or use of spinal radiation for ankylosing spondylitis is associated with an increased, but delayed, risk of developing aplastic anemia and acute leukemia.^{116,117} Patients who were given thorium dioxide (Thorotrast) as an intravenous contrast medium suffered numerous late complications, including malignant liver tumors, acute leukemia, and aplastic anemia.¹¹⁸ Chronic radium poisoning with osteitis of the jaw, osteogenic sarcoma, and aplastic anemia was seen in workers who painted watch dials with luminous paint when they moistened the brushes orally.¹¹⁹

Acute exposures to large doses of radiation are associated with the development of marrow aplasia and a gastrointestinal syndrome.^{120,121} Total-body exposure to between 1 and 2.5 Gy leads to gastrointestinal symptoms and depression of leukocyte counts, but most patients recover. A dose of 4.5 Gy leads to death in half the individuals (LD₅₀) owing to marrow failure. Higher doses in the range of 10 Gy are universally fatal unless the patient receives extensive supportive care followed by marrow transplantation. Aplastic anemia associated with nuclear accidents was seen after the disaster that occurred at the Chernobyl nuclear power station in the Ukraine in 1986.¹²²

Antineoplastic drugs such as alkylating agents, antimetabolites, and certain cytotoxic antibiotics have the potential for producing marrow aplasia. In general, this is transient, is an extension of their pharmacologic action, and resolves within several weeks of completing chemotherapy. Although unusual, severe marrow aplasia can follow use of the alkylating agent, busulfan, and may persist indefinitely. Patients may develop marrow aplasia 2 to 5 years after discontinuation of alkylating agent therapy. These cases often evolve into hypoplastic myelodysplastic syndromes.

Stromal Microenvironment and Growth Factors

Short-term clonal assays for marrow stromal cells have shown variable defects in stromal cell function in patients with aplastic anemia. Serum levels of stem cell factor (SCF) have been either moderately low or normal in several studies of aplastic anemia.^{123,124} Although SCF augments the growth of hematopoietic colonies from aplastic anemia patient's marrows, its use in patients has not led to clinical remissions. Another early acting growth factor, FLT-3 ligand, is 30- to 100-fold elevated in the serum of patients with aplastic anemia, although the pathobiologic effect of this change is unclear.¹²⁵ Fibroblasts grown from patients with severe aplastic anemia have subnormal cytokine production. However, serum levels of granulocyte colony-stimulating factor,¹²⁶ erythropoietin,¹²⁷ and thrombopoietin (TPO)¹²⁸ are usually high. Synthesis of IL-1, an early stimulator of hematopoiesis, is decreased in mononuclear cells from patients with aplastic anemia.¹²⁹ Studies of the microenvironment have shown relatively normal stromal cell proliferation and growth factor production.¹³⁰ These findings, coupled with the limited response of patients with aplastic anemia to growth factors, suggest that cytokine deficiency is not the etiologic problem in most cases. The most compelling argument is that most patients transplanted for aplastic anemia are cured with allogeneic donor stem cells and autologous stroma.¹³¹

A rare exception to the negligible pathogenetic role of hematopoietic growth factors in the etiology of aplastic anemia is the homozygous or mixed heterozygous mutation of the TPO receptor gene, *MPL*, which can cause amegakaryocytic thrombocytopenia that evolves, later, into aplastic anemia (Chap. 117). Furthermore, eltrombopag, a TPO receptor agonist, can stimulate mono, or in some patients, bilineage or trilineage recovery of blood counts that may be sustained off therapy (see "Treatment: Cytokines" below).

CLINICAL FEATURES

The onset of symptoms of aplastic anemia may be gradual with pallor, weakness, dyspnea, and fatigue as a result of the anemia. Dependent petechiae, bruising, epistaxis, vaginal bleeding, and unexpected bleeding at other sites secondary to thrombocytopenia are frequent presenting signs of the underlying marrow disorder. Rarely, it may be more dramatic with fever, chills, and pharyngitis or other sites of infection resulting from severe neutropenia and monocytopenia. Physical examination generally is unrevealing except for evidence of anemia (e.g., conjunctival and cutaneous pallor, resting tachycardia) or cutaneous bleeding (e.g., ecchymoses and petechiae), gingival bleeding and introral purpura. Lymphadenopathy and splenomegaly are not features of aplastic anemia; such findings suggest an alternative diagnosis such as a clonal myeloid or lymphoid disease.

LABORATORY FEATURES

Blood Findings

Patients with aplastic anemia have varying degrees of pancytopenia. Anemia is associated with a low reticulocyte index. The reticulocyte count is usually less than 1 percent and may be zero despite the high levels of erythropoietin. Absolute reticulocyte counts are usually fewer than

40,000/ μL ($40 \times 10^9/\text{L}$). Macrocytes may be present in the blood film and the mean cell volume (MCV) increased. The absolute neutrophil and monocyte count are low. An absolute neutrophil count fewer than 500/ μL ($0.5 \times 10^9/\text{L}$) along with a platelet count fewer than 30,000/ μL ($30 \times 10^9/\text{L}$) is indicative of severe disease, and a neutrophil count below 200/ μL ($0.2 \times 10^9/\text{L}$) denotes very severe disease (see Table 35-1). Lymphocyte production is thought to be normal, but patients may have mild lymphopenia. Platelets function normally. Significant qualitative changes of red cell, leukocyte, or platelet morphology on the blood film are not features of classical acquired aplastic anemia. On occasion, only one cell line is depressed initially, which may lead to an early diagnosis of pure red cell aplasia or amegakaryocytic thrombocytopenia. In such patients, other cell lines will fail shortly thereafter (days to weeks) and permit a definitive diagnosis. Table 35-4 is a plan for the initial laboratory investigation.

Plasma Findings

The plasma contains high levels of hematopoietic growth factors, including erythropoietin, TPO, and myeloid colony-stimulating factors. Growth factor levels need not be measured, however, for clinical care. Plasma iron values are usually high, and ⁵⁹Fe clearance is prolonged, with decreased incorporation into red cells.

Marrow Findings

Morphology The marrow aspirate typically contains numerous spicules with empty, fat-filled spaces, and relatively few hematopoietic cells. Lymphocytes, plasma cells, macrophages, and mast cells may be present. On occasion, occasional spicules are cellular or even hypercellular ("hot spots"), but megakaryocytes usually are reduced. These focal areas of residual hematopoiesis do not appear to be of prognostic significance. Residual granulocytic cells generally appear normal, but it is not unusual to see mild macronormoblastic erythropoiesis, presumably as a result of the high levels of erythropoietin. Marrow biopsy is essential to confirm the overall hypocellularity (Fig. 35-2), as a poor

TABLE 35-4. Approach to Diagnosis

History and Physical Examination

- Complete blood counts, reticulocyte count, and examination of the blood film
- Marrow aspiration and biopsy
- Marrow cell cytogenetics to evaluate clonal myeloid disease
- DNA stability test as a marker of Fanconi anemia
- Immunophenotyping of red and white cells, especially for CD55, CD59 to exclude PNH
- Direct and indirect antiglobulin (Coombs) test to rule out immune cytopenia
- Serum lactate dehydrogenase (LDH) and uric acid, which if increased may reflect neoplastic cell turnover
- Liver function tests to assess evidence of any recent viral hepatitis
- Screening tests for hepatitis viruses A, B, and C
- Screening tests for EBV, cytomegalovirus (CMV), and HIV
- Serum B₁₂ and red cell folic acid levels to rule out cryptic megaloblastic pancytopenia
- Serum iron, iron-binding capacity, and ferritin as a baseline prior to chronic transfusion therapy

Figure 35-2. Marrow biopsy in aplastic anemia. **A.** A normal marrow biopsy section of a young adult. **B.** The marrow biopsy section of a young adult with very severe aplastic anemia. The specimen is devoid of hematopoietic cells and contains only scattered lymphocytes and stromal cells. The hematopoietic space is replaced by reticular cells (pre-adipocytic fibroblasts) converted to adipocytes.

yield of spicules and cells occurs in marrow aspirates in other disorders, especially if fibrosis is present.

In severe aplastic anemia, as defined by the International Aplastic Anemia Study Group, less than 25 percent cellularity or less than 50 percent cellularity with less than 30 percent hematopoietic cells is seen in the marrow.

Progenitor Cell Growth *In vitro* CFU-GM and BFU-E colony assays reveal a marked reduction in progenitor cells.¹⁹⁻²²

Cytogenetic and Genetic Studies Cytogenetic analysis may be difficult to perform owing to low cellularity; thus, multiple aspirates may be required to provide sufficient cells for study. The results are normal in aplastic anemia. Clonal cytogenetic abnormalities in otherwise apparent aplastic anemia is indicative of an underlying hypoplastic clonal myeloid disease.¹³² The move to newer techniques such as microarray-based comparative genomic hybridization (CGH) permits detection of aneuploidies, deletions, duplications, and/or amplifications of any locus represented on an array. In addition, microarray-based CGH is an effective tool for the detection of submicroscopic chromosomal abnormalities. This approach would increase the sensitivity to detect chromosome abnormalities in very hypocellular marrow samples, compared to standard G-banding, despite dilution of scant hematopoietic cells with nonhematopoietic stromal cells (e.g., fibroblasts). Next-generation sequencing of targeted exons has uncovered 32 mutations associated with myeloid malignancies. These mutations occurred in nearly 20 percent (29 of 150 patients) of cases of aplastic anemia. These mutations include the genes *ASXL1*, *DNMT3A*, and *BCOR*, which are considered driver mutations in myelodysplastic syndrome and acute myelogenous leukemia. Seventeen of the 29 patients with one of these three mutations evolved to overt myelodysplasia.^{132a}

Imaging Studies Magnetic resonance imaging (MRI) can be used to distinguish between marrow fat and hematopoietic cells.¹³³ This approach may be a more useful overall estimate of marrow hematopoietic cell density than morphologic techniques and may help differentiate hypoplastic myelogenous leukemia from aplastic anemia.¹²⁸

DIFFERENTIAL DIAGNOSIS

Any disease that can present with pancytopenia may mimic aplastic anemia if only the blood counts are considered. Measurement of the reticulocyte count and an examination of the blood film and marrow biopsy are essential early steps to arrive at a diagnosis. A reticulocyte

percentage of 0.5 percent to zero is strongly indicative of aplastic erythropoiesis, and when coupled with leukopenia and thrombocytopenia, points to aplastic anemia. Absence of qualitative abnormalities of cells on the blood film and a markedly hypocellular marrow are characteristic of acquired aplastic anemia. The disorders most commonly confused with severe aplastic anemia include the approximately 5 to 10 percent of patients with myelodysplastic syndromes who present with a hypoplastic rather than a hypercellular marrow. Myelodysplasia should be considered if there is abnormal blood film morphology consistent with myelodysplasia (e.g., poikilocytosis, basophilic stippling, neutrophils with hypogranulation or the pseudo-Pelger-Huet anomaly). Marrow erythroid precursors in myelodysplasia may have dysmorphic features. Pathologic sideroblasts are inconsistent with aplastic anemia and a frequent feature of myelodysplasia. Granulocyte precursors may have reduced or abnormal granulation. Megakaryocytes may have abnormal nuclear lobulation (e.g., unilobular micromegakaryocytes; Chap. 87). If clonal cytogenetic abnormalities are found, a clonal myeloid disorder, especially myelodysplastic syndrome or hypocellular myelogenous leukemia is likely. MRI studies of bone may be useful in differentiating severe aplastic anemia from clonal myeloid syndromes. The former gives a fatty signal and the latter a diffuse cellular pattern.

A hypocellular marrow frequently is associated with PNH. PNH is characterized by an acquired mutation in the *PIG-A* gene that encodes an enzyme that is required to synthesize mannolipids. The gene mutation prevents the synthesis of the glycosylphosphatidylinositol anchor precursor. This moiety anchors several proteins, including inhibitors of the complement pathway to blood cell membranes, and its absence accounts for the complement-mediated hemolysis in PNH. As many as 50 percent of patients with otherwise typical aplastic anemia have evidence of glycosylphosphatidylinositol molecule defects and diminished phosphatidylinositol-anchored protein on leukocytes and red cells as judged by flow cytometry, analogous to that seen in PNH.¹³⁴ The decrease or absence of these membrane proteins may make the PNH clone of cells resistant to the acquired immune attack on normal marrow components, or the phosphatidylinositol-anchored protein(s) on normal cells provides an epitope that initiates an aberrant T-cell attack, leaving the PNH clone relatively resistant (Chap. 40).²⁶

Occasionally, apparent aplastic anemia may be the prodrome to childhood¹³⁵ or, less commonly, adult¹³⁶ acute lymphoblastic leukemia. Sometimes, careful examination of marrow cells by light microscopy

or flow cytometry will uncover a population of leukemic lymphoblasts. In other cases, the acute leukemia may appear later. Hairy-cell leukemia, Hodgkin disease, or another lymphoma subtype, rarely, may be preceded by a period of marrow hypoplasia. Immunophenotyping of marrow and blood cells by flow cytometry for CD25 may uncover the presence of hairy cells. Other clinical features may be distinctive (Chap. 93). Organomegaly such as lymphadenopathy, hepatomegaly, or splenomegaly are inconsistent with the atrophic (hypoproliferative) features of aplastic anemia. Large granular lymphocytic leukemia has also been associated with aplastic anemia. Rare cases of typical acquired aplastic anemia have been followed by t(9;22)-positive acute lymphocytic leukemia (ALL) or chronic myelogenous leukemia (CML).¹³⁶

RELATIONSHIP AMONG APLASTIC ANEMIA, PAROXYSMAL NOCTURNAL HEMOGLOBINURIA, AND CLONAL MYELOID DISEASES

In addition to the diagnostic difficulties occasionally presented by patients with hypoplastic myelodysplastic syndromes, hypoplastic acute myelogenous leukemia (AML), or PNH with hypocellular marrows, there may be a more fundamental relationship among these three diseases and aplastic anemia. The development of clonal cytogenetic abnormalities such as monosomy 7 or trisomy 8 in a patient with aplastic anemia portends the evolution of a myelodysplastic syndrome or acute leukemia. Occasionally, these cytogenetic markers have been transient, and in cases with disappearance of monosomy 7, hematologic improvement has occurred as well.¹³⁷ Persistent monosomy 7 carries a poor prognosis as compared to trisomy 8.^{138,139}

As many as 20 percent of patients with aplastic anemia have a 5-year probability of developing myelodysplasia.¹³⁷ If one excludes any transformation to a clonal myeloid disorder that occurs up to 6 months after treatment to avoid misdiagnosis among the hypoplastic clonal myeloid diseases, the frequency of a clonal disorder was nearly 15 times greater in patients treated with immunosuppression as compared to those treated with marrow transplantation after 39 months of observation.¹⁴⁰ This finding suggests either that immune suppression by anti-T-cell therapy enhances the evolution of a neoplastic clone or that it does not suppress the intrinsic tendency of aplastic anemia to evolve to a clonal disease, but provides the increased longevity of the patient required to express that potential. The latter interpretation is more likely as patients successfully treated solely with androgens develop clonal disease as frequently as those treated with immunosuppression.¹⁴¹ Transplantation may reduce the potential to clonal evolution in patients with aplastic anemia by reestablishing robust lymphohematopoiesis.

Telomere shortening also may play a pathogenetic role in the evolution of aplastic anemia into myelodysplasia. Patients with aplastic anemia have shorter telomere lengths than matched controls, and patients with aplastic anemia with persistent cytopenias had greater telomere shortening over time than matched controls. Three of five patients with telomere lengths less than 5 kb developed clonal cytogenetic changes, whereas patients with longer telomeres did not develop such diseases.^{23,142}

The findings of mutated genes considered driver mutations in myelodysplastic syndrome or AML (see “Marrow Findings: Cytogenetic and Genetic Studies” earlier) in nearly 20 percent of a population of patients with clinical aplastic anemia indicates that clonal hematopoiesis may develop or be present surreptitiously. The precise relationships to the aplastic anemia lesion is uncertain but could be caused the outgrowth of a clone of cells in the background of severally suppressed polyclonal hematopoietic stem cells. These findings were more common in patients with a long duration of disease and with shorter telomeres.^{132a}

The relationship of PNH to aplastic anemia remains enigmatic. Because hematopoietic stem cells lacking the phosphatidylinositol-anchored proteins are present in many or all normal persons in very small numbers,¹⁴³ it is not surprising that more than 50 percent of patients with aplastic anemia may have a PNH cell population as detected by immunophenotyping.¹³⁴ The probability of patients with aplastic anemia developing a clinical syndrome consistent with PNH is 10 to 20 percent, and this is not a consequence of immunosuppressive treatment.¹³⁷ Patients also may present with the hemolytic anemia of PNH and later develop progressive marrow failure so that any pathogenetic explanation should consider both types of development of aplastic marrows in PNH. The *PIG-A* mutation may confer either a proliferative or survival advantage to PNH cells.^{144,145} A survival advantage could result if the anchor protein or one of its ligands served as an epitope for the T-lymphocyte cytotoxicity, which induces the marrow aplasia. In this case, the presenting event could either reflect cytopenias or the sensitivity of red cells to complement lysis and hemolysis, depending on the intrinsic proliferative potential of the PNH clone.

Within our current state of knowledge, aplastic anemia is an autoimmune process, and any residual hematopoiesis is presumably polyclonal. This is a critical distinction from hypoplastic leukemia and PNH, which are clonal (neoplastic) diseases. The environment of the aplastic marrow, however, may favor the eventual evolution of a mutant (malignant) clone, especially if immunotherapy is used, whereas hematopoietic stem cell transplantation may either ablate threatening minor clones or establish more robust hematopoiesis, an environment less conducive to clonal evolution.

TREATMENT

Approach to Therapy

Severe anemia, bleeding from thrombocytopenia, and, uncommonly at the time of diagnosis, infection secondary to granulocytopenia and monocytopenia require prompt attention to remove potential life-threatening conditions and improve patient comfort (Table 35-5). More specific treatment of the marrow aplasia involves two principal options: (1) syngeneic or allogeneic hematopoietic stem cell transplantation or (2) combination immunosuppressive therapy with ATG and cyclosporine. The selection of the specific mode of treatment depends

TABLE 35-5. Initial Management of Aplastic Anemia

- Discontinue any potential offending drug and use an alternative class of agents if essential.
- Anemia: transfusion of leukocyte-depleted, irradiated red cells as required for very severe anemia.
- Very severe thrombocytopenia or thrombocytopenic bleeding: consider ϵ -aminocaproic acid; transfusion of platelets as required.
- Severe neutropenia; use infection precautions.
- Fever (suspected infection): microbial cultures; broad-spectrum antibiotics if specific organism not identified, granulocyte colony-stimulating factor (G-CSF) in dire cases. If child or small adult with profound infection (e.g., Gram-negative bacteria, fungus, persistent positive blood cultures) can consider neutrophil transfusion from a G-CSF pretreated donor.
- Immediate assessment for allogeneic stem cell transplantation: Histocompatibility testing of patient, parents, and siblings. Search databases for unrelated donor, if appropriate.

on several factors, including the patient's age and condition and the availability of a suitable allele-level HLA-matched hematopoietic stem cell donor. In general, transplantation is the preferred treatment for children and most otherwise healthy younger adults. Early histocompatibility testing of siblings is of particular importance because it establishes whether there is an optimal donor available to the patient for transplantation. The preferred stem cell source is a histocompatible sibling matched at the HLA-A, -B, -C, and -DR loci.

Supportive Care

The Use of Blood Products Although it has been recommended that red cell and platelet transfusions be used sparingly in potential transplant recipients to minimize sensitization to histocompatibility antigens, this has become less important since ATG and cyclophosphamide have been used as the preparative regimen for transplantation in aplastic anemia, as their use has markedly reduced the problem of graft rejection.¹⁴⁶

Cytomegalovirus (CMV)-reduced risk red cells and platelets should be given to a potential transplant recipient to minimize problems with CMV infections after transplantation. Once a patient is shown to be CMV-positive, this restriction is no longer necessary. Leukocyte-depletion filters or CMV serotesting are equivalent methods of decreasing the risk of transmitting CMV.

Red Cell Transfusion Packed red cells to alleviate symptoms of anemia usually are indicated at hemoglobin values below 8 g/dL (80 g/L), unless comorbid medical conditions require a higher hemoglobin concentration. These products should be leukocyte-depleted to lessen leukocyte and platelet sensitization and to reduce subsequent transfusion reactions and radiated to reduce the potential for a transfusion-related graft-versus-host reaction. It is important not to transfuse patients with red cells (or platelets) from family members if transplantation within the family is remotely possible, as this approach may sensitize patients to minor histocompatibility antigens, increasing the risk of graft rejection after marrow transplantation. Following a marrow transplant, or in those individuals in whom transplantation is not a consideration, family members may be ideal donors for platelet products. Because each unit of red cells adds approximately 200 mg of iron to the total body iron, over the long-term transfusion-induced iron overload may occur. This is not a major problem in patients who respond to transplantation or immunosuppressive therapy, but it is an issue in nonresponders who require continued transfusion support. In the latter case, consideration should be given to iron-chelation therapy. Newer oral agents make this procedure easier to effect (Chap. 48).¹⁴⁷

Platelet Transfusion It is important to assess the risk of bleeding in each patient. Most patients tolerate platelet counts of 10,000/ μ L (10×10^9 /L) without undue bruising or bleeding, unless a systemic infection is present or vascular integrity is impaired.^{148,149} A traumatic injury or surgery requires transfusion to greater than 50,000/ μ L or greater than 100,000/ μ L, respectively. Administration of ϵ -aminocaproic acid, 50 mg/kg per dose every 4 hours orally or intravenously, may reduce the bleeding tendency.¹⁵⁰ Pooled random-donor platelets may be used until sensitization ensues, although it is preferable to use single-donor platelets from the onset to minimize sensitization to HLA or platelet antigens. Subsequently, single-donor apheresis products or HLA-matched platelets may be required.

Platelet refractoriness is a major problem with long-term transfusion support.¹⁵¹ This may occur transiently, with fever or infection, or as a chronic problem secondary to HLA sensitization. In the past, this occurred in approximately 50 percent of patients after 8 to 10 weeks of transfusion support. Filtration of blood and platelet concentrates to remove leukocytes reduces this problem to approximately 15 percent of patients receiving chronic transfusions.^{151,152} Patients should also get

ABO-identical platelets because this enhances platelet survival and further decreases refractoriness to platelet transfusion. Single-donor HLA-matched apheresis-harvested platelets may be necessary in previously pregnant or transfused patients who are already allosensitized or who so become after treatment with leukoreduced platelets. The frequency of either of these events is less than 10 percent. Chapter 139 discusses approaches to chronic platelet transfusion.

Management of Neutropenia Neutropenic precautions should be applied to hospitalized patients with a severe depression of the neutrophil count. The level of neutrophils requiring precautions is fewer than 500/ μ L (0.5×10^9 /L). One approach is to use private rooms, with requirements for face masks and handwashing with antiseptic soap. Unwashed fresh fruits and vegetables should be avoided as they are sources of bacterial contamination. It is uncommon for patients with aplastic anemia to present with a significant infection. When patients with aplastic anemia become febrile, cultures should be obtained from the throat, sputum (if any), blood, urine, stool, and any suspicious lesions. Broad-spectrum bactericidal antibiotics should be initiated promptly, without awaiting culture results. The choice of antibiotics depends on the prevalence of organisms and their antibiotic sensitivity in the local setting. Organisms of concern usually include *Staphylococcus aureus* (notably methicillin- and oxacillin-resistant strains), *Staphylococcus epidermidis* (in patients with venous access devices), and Gram-negative organisms. Patients with persistent culture-negative fevers should be considered for antifungal treatment (Chap. 24).

In the past, leukocyte transfusions were used on a daily basis to reduce the short-term mortality from infections. It was unusual to detect more than 100 to 200 neutrophils per microliter for more than a few hours after transfusion. The yield of neutrophils can be increased by administering granulocyte colony-stimulating factor (G-CSF) to the donor,¹⁵³ but most physicians avoid using white cell products because present-day antibiotics are usually sufficient to treat a patient for an episode of sepsis. Notable exceptions include documented invasive aspergillosis unresponsive to amphotericin (particularly in the posttransplant setting), infections with organisms resistant to all known antibiotics, and when blood cultures remain positive in spite of antibiotic treatment. Leukocyte transfusion is more effective in children and adults with smaller body size, as transfused leukocytes have a smaller distribution space, which results in higher blood and tissue concentrations.

Specific Treatment

Hematopoietic Stem Cell Transplantation Prompt therapy usually is indicated for patients with severe aplastic anemia. The major curative approach is hematopoietic stem cell transplantation from a histocompatible sibling.^{154–156} Chapter 23 describes this treatment modality. Only 20 to 30 percent of patients in the United States have compatible sibling donors (related to average family size). In the unusual case of an identical twin donor, conditioning is required to obliterate the immune disease in the recipient, but it can be limited to cyclophosphamide. In this setting, an 80 to 90 percent survival is expected. Marrow stem cells seem to perform better than blood stem cells when used as a source for patients with aplastic anemia, although this is under continued study. The results of transplantation are best in patients younger than age 20 years (80 to 90 percent long-term survival) but decrease every decade of increasing age thereafter. Posttransplant mortality is increased and survival decreased with increasing age (Fig. 35–3). In patients older than age 40 years, survival in matched sibling transplant is reduced to approximately 50 percent.¹⁵⁷ There are still uncertainties about the optimal conditioning program in younger and older patients. ATG, cyclophosphamide, total-body radiation, fludarabine, and alemtuzumab are among the agents being studied.^{154,156–158} Alemtuzumab (Campath)-containing regimens appear to improve outcome by decreasing the

Figure 35-3. Allogeneic hematopoietic stem cell transplantation is the principal treatment for young patients with severe aplastic anemia and available HLA-matched sibling donor. Among the 2763 patients receiving HLA-matched sibling donor hematopoietic stem cell transplantation for severe aplastic anemia (SAA) between 2001 and 2011, the 3-year probabilities of survival were $88\% \pm 1\%$ for those younger than 20 years and $76\% \pm 1\%$ for those 20 years of age or older. Among the 1407 recipients of unrelated donor hematopoietic stem cell transplantation, the corresponding probabilities of survival were $70\% \pm 2\%$ and $63\% \pm 2\%$. (Reproduced with permission from MC Pasquini, Z Wang: Current use and outcome of hematopoietic stem cell transplantation: CIBMTR Summary Slides, 2013. Available at: <http://www.cibmtr.org>.)

frequency of chronic graft-versus-host disease, which could make it useful in older patients.¹⁵⁸

The longer the delay between diagnosis and transplantation, the less likely is a salutary outcome, probably as a result of a greater number of transfusions and a higher likelihood of pretransplantation infection. Acute and chronic graft-versus-host disease are serious complications, and therapy to prevent or ameliorate them is a standard part of post-transplantation treatment.^{154,157} Transplantations have been performed using stem cells from partially matched siblings or unrelated, histocompatible donors recruited through the National Marrow Donor Program or similar organizations in other countries.¹⁵⁹ Umbilical cord blood is an alternative source of stem cells from unrelated donors (or, rarely, siblings) for transplantation in children, but the results are optimal with matched sibling transplantation. Alternatively, the use of high-resolution, HLA typing of a matched, unrelated donor markedly improves the prognosis for transplantation.¹⁶⁰ High-resolution DNA matching at HLA-A, -B, -C, and -DRB1 (8 of 8 alleles) is considered the lowest level of matching consistent with the highest level of survival. If there is an HLA mismatch at one or more loci, especially HLA-A or -DRB1, the outcome is compromised,¹⁶⁰ and immunosuppression with combined therapy may be preferred initially, depending on patient age, CMV status, and disease severity. Older patients have a much lower favorable response with alternative, non-matched-sibling, donor transplantations. The use of hematopoietic stem cell transplantation can be considered for patients who do not respond or who no longer respond to immunotherapy.¹⁵⁷ If the patient in question is a candidate for stem cell transplantation based on all relevant factors, transplantation could be considered at any age for a patient with a syngeneic donor; transplantation could be considered as a first-choice therapy up to age 50 years for a patient with an HLA allele-level matched sibling donor; and transplantation could be considered a first-choice therapy if an allele-level HLA-matched unrelated donor is available for patients younger than

age 20 years.¹⁵⁷ These guidelines are subject to the unique or special circumstances of an individual case. For example, if patients with aplastic anemia undergo gene sequencing and a mutation known to be a driver mutation for myelodysplasia or AML is found, allogeneic hematopoietic stem cell transplantation may prove to be a preferred approach.

Components of Anti-T-Lymphocyte (Immunosuppressive) Therapy

Antilymphocyte Serum and Antithymocyte Globulin ATG and ALG act principally by reducing cytotoxic T cells. This involves ATG-induced apoptosis through both FAS and TNF pathways.¹⁶¹ Cathepsin B also plays a role in T-cell cytotoxicity at clinical concentrations of ATG, but may involve an independent apoptosis pathway.¹⁶² ATG and ALG also release hematopoietic growth factors from T cells.^{163,164} Horse and rabbit ATG are licensed in the United States. Skin tests against horse serum should be performed prior to administration.¹⁶⁵ If positive, the patient may be desensitized. ATG therapy is given daily for 4 to 10 days with doses of 15 to 40 mg/kg. Fever and chills are common during the first day of treatment. Concomitant treatment with glucocorticoids, such as methylprednisolone or dexamethasone lessens the reaction to ATG. Several studies have compared equine to rabbit ATG in the immunotherapy of aplastic anemia, contemporaneously or using historical comparisons. The consensus is that equine ATG is superior to rabbit and, if available, is recommended as the first line of therapy (Table 35-6).¹⁶⁶⁻¹⁷⁴ Nevertheless, rabbit ATG is effective and should be considered if equine ATG does not result in a satisfactory outcome (Fig. 35-4).

ATG treatment may accelerate platelet destruction, reduce the absolute neutrophil count, and cause a positive direct antiglobulin (Coombs) test. This effect may lead to an increase in transfusion requirements during the 4- to 10-day treatment interval. Serum sickness, characterized by spiking fevers, skin rashes, and arthralgias, occurs commonly 7 to 10 days from the first dose. The clinical manifestations of serum sickness can be diminished by increasing the glucocorticoid dose from day 10 to day 17 after treatment. Approximately one-third of patients no longer require transfusion support after treatment with ATG alone.¹⁷⁵⁻¹⁷⁷

Of 358 patients responding to immunosuppressive therapy, principally ATG alone, 74 (21 percent) relapsed after a mean of 2.1 years. The actuarial incidence of relapse was 35 percent at 10 years.¹⁷⁸ Similar results were observed when 227 patients were treated with immunosuppression, primarily ATG alone.¹⁷⁹ The actuarial survival at 15 years was 38 percent following immunosuppression.¹⁷⁸ However, a combination of immunosuppressive agents provides more effective therapy than ATG alone (see "Combination Immunotherapy" below).

Twenty-eight (22 percent) of 129 patients treated with ALG developed myelodysplasia, leukemia, PNH, or combined disorders.¹⁸⁰ This tendency to relapse and to develop clonal hematologic disorders was reviewed by the European Cooperative Group for Bone Marrow Transplantation in 468 patients, most of whom received ATG.¹⁸¹ The risk of a hematologic complication increased continuously and reached 57 percent at 8 years after immunosuppressive therapy. A further survey found 42 (5 percent) malignancies in 860 patients treated with immunosuppression, whereas only 9 (1 percent) malignancies were seen in 748 patients who received marrow transplants.¹⁸²

There are no predictors that auger the risk of clonal evolution in an individual patient, although shorter telomere length at diagnosis and poorer prognosis are associated.¹⁸³

Cyclosporine Administration of cyclosporine, a cyclic polypeptide that inhibits IL-2 production by T lymphocytes and prevents expansion of cytotoxic T cells in response to IL-2, is another approach to immunotherapy. After the initial report of its ability to induce remission in 1984,¹⁸⁴ several groups have used cyclosporine as

either (1) primary treatment,^{185–188} (2) in patients refractory to ATG or glucocorticoids,^{186–191} (3) in combination with G-CSFs,^{192,193} or (4) in varying combinations with other modes of therapy.¹⁹⁴ Cyclosporine is administered orally at 10 to 12 mg/kg per day for at least 4 to 6 months. Dosage adjustments may be required to maintain trough blood levels of 200 to 400 ng/mL. Renal impairment is common and may require increased hydration or dose adjustments to keep creatinine values below 2 mg/dL. Cyclosporine also may cause moderate hypertension, a variety of neurologic manifestations, and other side effects. Several drug classes interact with cyclosporine to either increase (e.g., some antibiotics and antifungals) or decrease (e.g., some anticonvulsants) blood levels. Responses usually are seen by 3 months and may range from achieving transfusion independence to complete remission. Approximately 25 percent of patients respond to this agent when used alone, but the response rate has ranged from 0 to 80 percent in various reports.¹⁹⁴

Although immunosuppression with ALG or ATG has been used the longest and has a seemingly better response rate, there are certain advantages to cyclosporine. This drug does not require hospitalization or use of a central venous catheter. Fewer platelet transfusions are required during the first few weeks of therapy compared to treatment with ALG or ATG. A French cooperative trial showed equal effectiveness of cyclosporine compared to ATG plus prednisone.¹⁹⁵ In this

crossover study of newly diagnosed patients, survival of approximately 65 percent was observed 12 months after diagnosis.

Combination Immunotherapy Combination treatment of severe aplastic anemia usually includes, for example, ATG, 40 mg/kg per day, for 4 days; cyclosporine, 10 to 12 mg/kg per day, for 6 months and methylprednisolone, 1 mg/kg per day, for 2 weeks.¹⁹⁶ The dose of cyclosporine is adjusted to maintain a trough level of 200 to 400 ng/mL. Prophylaxis for *Pneumocystis carinii* with daily trimethoprim-sulfamethoxazole or with monthly pentamidine inhalations should be considered for these patients as they receive immunosuppressive therapy.

The addition of cyclosporine to the combination of ALG and glucocorticoids improves response rates to approximately 70 percent of patients (Table 35–7).^{197,198} G-CSF added to the combined immunosuppressive therapy does not increase response rate or survival.¹⁹⁹ Response is usually defined as a significant improvement in red cells, white cells, and platelets to eliminate risk of infection and bleeding and the requirement for red cell transfusions.

The 5-year survival after completion of combination immunosuppressive therapy may approximate that after stem cell transplantation.²⁰⁰ Forty-eight children treated between 1983 and 1992 had a 10-year survival of approximately 75 percent for marrow transplantation and approximately 75 percent for combined immunosuppressive

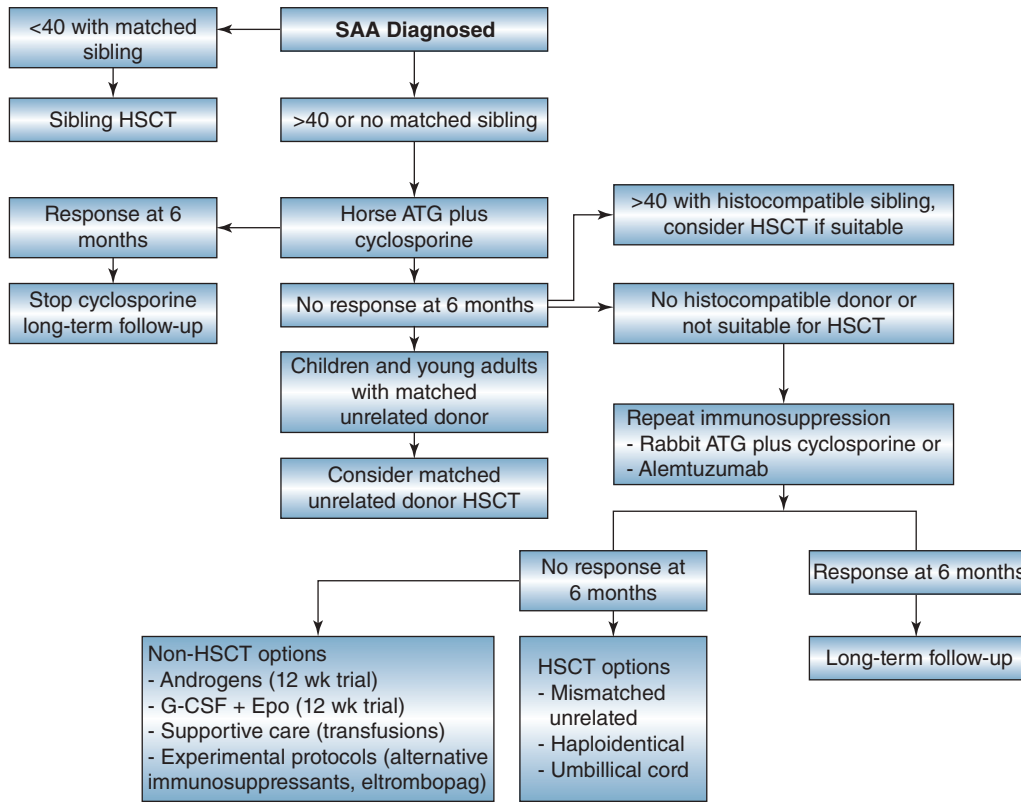

Figure 35-4. Flow chart with general guidelines for treatment. Response to horse ATG plus cyclosporine is followed for 6 months before deciding the patient has not responded adequately unless the patient is doing poorly and the neutrophil count remains less than $200 \times 10^9/L$. In that case, one can proceed to next suitable option. In general, transplantation options are reassessed at 6 months after immunotherapy and are dependent on donor availability and quality of match, patient age, comorbid conditions that would increase transplantation risk, and the severity of the depression in neutrophil count. In younger patients, a matched unrelated donor may be appropriate. In older patients, retreatment with immunotherapy would be favored unless the neutrophil count persists in the very-severe-risk category. After two unsuccessful attempts at immunotherapy, therapy is individualized and a high-risk transplantation procedure (slight mismatched-related, haploidentical, umbilical cord blood) may be considered, using the relevant variables (e.g., age, comorbidities, performance status, neutrophil count). The age of 40 years is an approximate guideline for considering an initial allogeneic hematopoietic stem cell transplant and may be modified upwards somewhat (e.g., 41 to 50 years) based on the clinical status and other features of the patient. therapy, although there were only half the number of severely affected patients in the immunosuppressive therapy group.²⁰¹ Thus, immunosuppression may be preferable for patients who are older than 30 years of age and in those who may experience a delay in finding a suitable donor. Marrow transplants are, however, curative for aplastic anemia, whereas more frequent sequelae have been found after immunosuppressive therapy,²⁰²⁻²⁰⁴ notably a substantial rate of evolution to a myelodysplastic syndrome or AML.

A National Institutes of Health protocol was designed to increase immune tolerance by specific deletion of activated T lymphocytes that target primitive hematopoietic progenitor cells.²⁶ Concurrent administration of cyclosporine with ATG may diminish the ATG effect so that in this program cyclosporine is introduced at a later time. The addition of new immunosuppressive agents, such as mycophenolate mofetil, rapamycin, or monoclonal antibodies, to the IL-2 receptor may be more effective in decreasing cytotoxic T cells, sparing the targeted hematopoietic stem cells.²⁶

For the 30 to 40 percent of patients who relapse after immunotherapy, retreatment with ATG and cyclosporine is effective in 50 to 60 percent of them.^{205,206} Alternatively, alemtuzumab, a monoclonal anti-CD52 antibody that targets that antigen on T lymphocytes, has been an effective immunosuppressive agent in relapsed and in refractory patients, and it may be administered with cyclosporine.²⁰⁷⁻²⁰⁹

High-Dose Glucocorticoid Treatment Marrow recovery can occur after very high doses of glucocorticoids.^{210,211} Methylprednisolone in the range of 500 to 1000 mg daily for 3 to 14 days has been successful, but the side effects, which include marked hyperglycemia and glycosuria, electrolyte disturbances, gastric irritation, psychosis, increased infections, and aseptic necrosis of the hips, can be severe. Glucocorticoids at lower doses commonly are used only as a component of combination therapy for aplastic anemia to ameliorate the toxic effects of ATG and in providing additional lymphocyte suppression.

High-Dose Cyclophosphamide Therapy High-dose cyclophosphamide has been used as a form of immunosuppression.²¹² Although it would seem inappropriate to administer high doses of chemotherapy to patients with severe marrow aplasia, this approach was based on observations of autologous recovery after preparative therapy for allogeneic transplants not followed by a transplantation.⁶ In an early study, 10 patients who received cyclophosphamide at 45 mg/kg per day intravenously for 4 days with or without cyclosporine for an additional 100 days had gradual neutrophil and platelet recovery over 3 months. Seven patients responded completely and remained in remission 11 years after treatment. High-dose cyclophosphamide treatment may spare hematopoietic stem cells, which have high levels of aldehyde dehydrogenase and are relatively resistant to cyclophosphamide.^{213,214} Thus, cyclophosphamide in this situation may be more immunosuppressive than myelotoxic. The most extensive trial of high-dose cyclophosphamide resulted in 65 percent of patients responding completely at 50 months.²¹⁵ However, the role of this regimen as initial therapy is not clear because of early toxicity that may exceed that of the ATG and cyclosporine combination.²¹⁶ The probability of a durable remission may be superior, but there are insufficient data (comparative clinical trials) to conclude whether high-dose cyclophosphamide provides better long-term results than ATG and cyclosporine. The latter approach is favored at this time.

Rituximab A case report of the successful use of the anti-CD20 humanized mouse antibody rituximab has provided preliminary evidence for its potential effectiveness in treating aplastic anemia.²¹⁷ Clinical trials have not examined its efficacy compared to standard immunotherapy (ATG and cyclosporine), in patients refractory to standard therapy, or as a third drug in an immunotherapy regimen. Whether B lymphocytes play a role in the pathogenesis of T-cell-mediated aplastic anemia has not been defined, so rituximab does not appear to have a

theoretical rationale for use at this time. However, a singular case of antibody-mediated aplastic anemia responded to rituximab, and the autoantibodies became undetectable.^{218,219}

Androgens Randomized trials have not shown efficacy when androgens were used as primary therapy for severe aplastic anemia.^{220,221} Androgens stimulate the production of erythropoietin, and their metabolites stimulate erythropoiesis when added to marrow cultures *in vitro*. High doses of androgens were beneficial in some patients with moderately severe aplasia.²²⁰ Series of patients were reported in which survival seemed improved as compared with historical controls, but this could have resulted from improved supportive care.¹⁴¹ Masculinization and other androgen side effects can be severe, especially in female patients. Long-term survivors after androgen therapy have essentially the same progression to clonal hematologic disorders as patients treated with immunosuppressive agents.¹⁴¹ These agents have been replaced by immunosuppression or allogeneic hematopoietic stem cell transplantation as a principal approach to treatment.

Cytokines Despite their effectiveness in accelerating recovery from chemotherapy, these agents have been far less effective in achieving long-term benefits in patients with severe aplastic anemia. Daily treatment with G-CSF²²² has improved marrow cellularity and increased neutrophil counts approximately 1.5- to 10-fold. Unfortunately, in nearly all patients, the blood counts return to baseline within several days of cessation of therapy. Although occasional patients show evidence of trilineage marrow recovery with long-term therapy, the vast majority do not respond. Therapy with myeloid growth factors is probably best reserved for episodes of severe infection or as a preventive measure prior to dental work or other procedures that would compromise mucosal barriers in patients who have not responded to stem cell transplant or immunotherapy. G-CSF in a dose of 5 mcg/kg by subcutaneous injection is easiest to administer and seems to be associated with the fewest side effects. The drug can be given daily or fewer times per week depending on the response. Newer pegylated preparations have a longer effect and usually are administered at less frequent, every-other-week intervals. The SAA Working Party of the European Group for Blood and Marrow Transplant reported that G-CSF added to ATG and cyclosporine reduces infection early in treatment, but does not affect survival or length of remission.²²³ Generally, prophylactic use of growth factors is not warranted.

IL-1, a potent stimulator of marrow stromal cell production of other cytokines, and IL-3 have been ineffective in small numbers of patients so treated with severe aplastic anemia.^{224,225} These disappointing results with cytokines are not unexpected, as previous work has found high serum levels of growth factors in patients with aplastic anemia. Moreover, the majority of patients have suppression of very primitive progenitors, which may be unresponsive to individual factors that act on more mature progenitor cells.

An exception to the poor response to cytokines is the use of eltrombopag, a TPO receptor agonist that binds to the transmembrane region of the TPO receptor and stimulates the Janus kinase (JAK)-signal transducer and activator of transcription (STAT) and mitogen-activated protein (MAP) kinase pathways. TPO may expand stem cell numbers and promote DNA repair.²²⁶⁻²²⁹ Use of this agent in 43 patients with acquired aplastic anemia who did not respond to immunotherapy resulted in improved hematopoiesis and cell counts in 17 (40 percent) with several having improved bi- or trilineage hematopoiesis and cell counts. Five patients had near normalization of all blood counts and had therapy stopped after 9 to 37 months with maintenance of their blood counts for 1 to 13 months of observation.²³⁰ Although many did not normalize their counts, several became red cell and platelet transfusion independent. Eight patients developed new cytogenetic abnormalities (5 of 8 patients developed -7 or del[7]), but none had progressed to AML.

Splenectomy Removal of the spleen does not increase hematopoiesis but may increase neutrophil and platelet counts two- to threefold and improve survival of transfused red cells or platelets in highly sensitized individuals.²³¹ The surgical morbidity and mortality in patients with few platelets and white cells makes this a questionable therapeutic procedure. Because there are more successful methods of therapy that attack the fundamental problem, this approach is not recommended.

Other Therapy High doses of intravenous γ -globulin have been given to small numbers of patients with severe aplastic anemia^{232,233} because of its success in treating certain cases of antibody-mediated pure red cell aplasia. Some improvement was noted in 4 of 6 patients treated. Another treatment that is occasionally successful is lymphocytapheresis to deplete T cells.^{234,235} Agents that target other T-cell functions, such as alefacept, a CD2-directed leukocyte function antigen-3 (LFA-3)/Fc fusion protein that consists of the extracellular CD2-binding portion of the human LFA-3 linked to the Fc (hinge, CH2 and CH3 domains) portion of human immunoglobulin (Ig) G₁ are being tested as immunosuppressive drugs in acquired aplastic anemia.²³⁶

Course and Prognosis

At diagnosis, the prognosis is largely related to the absolute neutrophil and platelet count. The absolute neutrophil count is the most important prognostic feature, with a count of fewer than 500/ μ L (0.5×10^9 /L) considered severe aplastic anemia and a count of fewer than 200/ μ L (0.2×10^9 /L) very severe aplastic anemia, the latter associated with a poor response to immunotherapy and usually a dire prognosis, if early successful allogeneic transplant is not available. In the past, the prognosis appeared worse when the disease followed hepatitis.^{72,73} But, more comprehensive results with immunosuppression²¹⁰ or hematopoietic stem cell transplantation²³⁷ show an equivalent response to that seen with idiopathic or drug-induced cases.

Before marrow transplantation and immunosuppressive therapy, more than 25 percent of the patients with severe aplastic anemia died within 4 months of diagnosis; half succumbed within 1 year.^{235,239} Marrow transplantation is curative for approximately 80 to 90 percent of patients younger than 20 years of age, approximately 70 percent if between the ages of 20 and 40 years, and approximately 50 percent if older than age 40 years.^{157,240} Unfortunately, as many as 40 percent of transplant survivors suffer the deleterious consequences of chronic graft-versus-host disease,¹⁵⁷ and the risk of subsequent cancer can be as high as 10 percent in older patients or after immunotherapy prior to hematopoietic stem cell transplantation.^{241,242} The best outcomes occur in those patients who have an allele-based HLA-matched sibling; have not been exposed to immunosuppressive therapy prior to transplantation; have not been exposed and sensitized to blood cell products; have had a marrow rather than a blood stem cell donor product; and have not been subjected to high-dose radiation in the conditioning regimen for transplantation.^{157,241,243,244}

Combination immunosuppressive therapy with ATG and cyclosporine leads to a marked improvement in approximately 70 percent of the patients; a higher initial absolute reticulocyte and lymphocyte counts are predictive of the response to therapy.²⁴⁵ Although some patients regain normal blood counts, many continue with moderate anemia or thrombocytopenia. In as many as 40 percent of patients initially responding to immunosuppressive therapy, their disease may relapse or progress to PNH, a myelodysplastic syndrome, or AML over 10 years of observation.^{178-186,214-216} Moreover, the beneficial effects of immunotherapy are often lost 10 years after treatment. In 168 transplanted patients the actuarial survival at 15 years was 69 percent, and in 227 patients receiving immunosuppressive therapy it was 38 percent.¹⁷⁸ The long-term survival in pediatric patients younger than age 18 years appears better, with approximately one-third relapsing at 10 years.²⁴⁶

Treatment with high-dose cyclophosphamide produces early results similar to that seen with the combination of ATG and cyclosporine.^{247,248} However, cyclophosphamide has greater early toxicity and slower hematologic recovery, but may generate more durable remissions. Its use has been too limited to reach a firm conclusion on its relative merits and it is rarely used as the first choice of immunotherapy.

HEREDITARY APLASTIC ANEMIA

FANCONI ANEMIA

Definition and History

Fanconi anemia is the most common form of constitutional aplastic anemia and was initially described in three brothers by Fanconi in 1927.²⁴⁹ It is inherited as an autosomal recessive condition that results from defects in genes that modulate the stability of DNA.

Epidemiology

Fanconi anemia is an uncommon disorder and is estimated to be present in 1 in 1 million individuals. It is far more frequent in Afrikaners of European descent.²⁵⁰ This unusually high frequency has been attributed to a founder effect.

Etiology and Pathogenesis

Sixteen complementation groups, defined by somatic cell hybridization, are associated with the development of Fanconi anemia (FA).^{251,252} A complementation group is a genetic subgroup. Identifying a complementation group requires adding a gene to the genome of a cell to correct (complement) the genetic defect. This procedure can be done by cell fusion studies. After fusing two cells together, thereby joining their genetic material, one can test the cells for the genetic defect. In the case of Fanconi anemia, this would be with the diepoxybutane test. In this test, diepoxybutane results in chromosome fragmentation in the cells of patients with Fanconi anemia. Hybrids in which the hypersensitivity to diepoxybutane is corrected (complemented) can be assumed to result from the fusion of cells from different genetic subgroups (complementation groups), whereas hybrids that still show the sensitivity are the result of fusion of cells from the same subgroup. Because one can determine the complementation group without knowing the gene involved, this approach is the first step in understanding the genetic basis of a disease. Once the genes are known, one does not need to use cell fusion studies; rather, retroviral vectors can be used to insert corrected genes into the cells.

The complementation groups have been designated FANCA, B, C, D1, D2, E, F, G, I, J, L, M, N, O, P, and Q. Table 35-8 lists the gene mutations corresponding to these complementation groups, and Fig. 35-5 summarizes the functions of the known Fanconi anemia proteins.²⁵² The great majority of patients have mutations of FANCA, FANCC, or FANCG.²⁵³ It has been proposed that the A and C gene products, which are cytoplasmic proteins, form an "FA core complex" with the products of genes B, E, F, G, L, and M, which are adaptors or phosphorylators.^{253,254} The complex translocates to the nucleus, where it is required for the ubiquitination of FANCD2 and protects the cell from DNA crosslinking and participates in DNA repair (Fig. 35-6). DNA damage initiates activation of the FA/BRCA pathway and ubiquitination of FANCD2, which is targeted to the altered DNA and facilitates repair by interacting with DNA repair proteins, BRCA1, FANCD1/BRCA2, FANCN/PALB2, and RAD51. In the presence of a mutant gene product, the normal protective and repair functions are disturbed leading to damaging effects in sensitive tissues, including hematopoietic cells. The genetic damage appears related to the adverse effects of reactive oxygen radicals, such as superoxide and hydrogen peroxide as well as

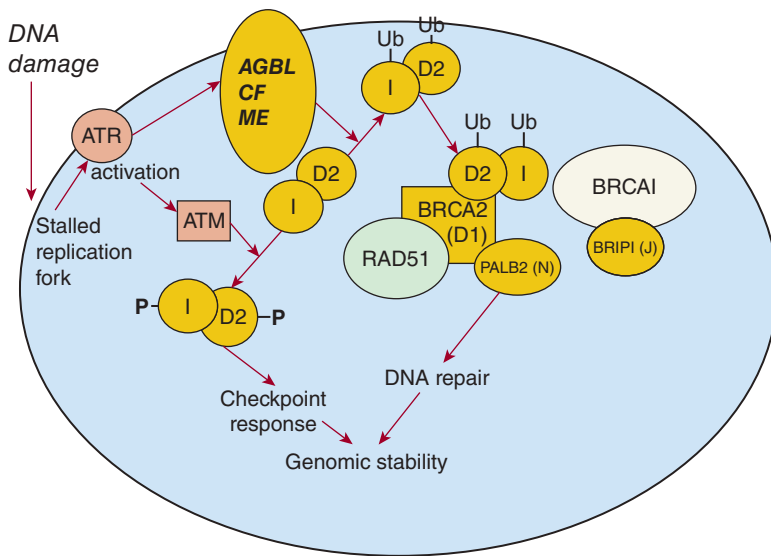

Figure 35-6. Representation of the “FA/BRCA pathway.” Following DNA damage when a replication fork encounters a DNA crosslink, ATR (ataxia telangiectasia and rad3-related protein) is activated. This leads to the activation of the Fanconi anemia (FA) pathway, as well as cell-cycle checkpoint activation via the ATM (ataxia telangiectasia mutated) protein. Activation of the FA pathway leads to the formation of the “FA core complex” (consisting of the FA proteins A, B, C, E, F, G, L, and M). This activated FA core complex leads to the monoubiquitination of FANCD2 (FANCD2-Ub) and FANCI (I-Ub). The I-Ub/FANCD2-Ub complex is then targeted to the chromatin containing the crosslink where it interacts with BRCA2 and possibly other DNA repair proteins (e.g., RAD51, J, N) leading to the repair of the DNA damage. Proteins mutated in the different FA subtypes are shown in yellow. (Reproduced with permission from Dokal I, Vulliamy T: *Inherited aplastic anaemias/bone marrow failure syndromes*. *Blood Rev* 22(3):141–153, 2008.)

Clinical Features

Growth retardation, resulting in short stature, and skeletal anomalies are common. Absent, misshapen, or supernumerary thumbs and dysplastic radii occur in half the patients. Hip and vertebral abnormalities also may occur. Septal heart defects, eye abnormalities, and absent, misshapen, or fused kidneys may be present. Females may have aplasia of the uterus and vagina, absent ovaries, infertility and late menarche and early menopause and males may have hypospermia. Thus, hypogonadism may be evident. Learning disability is frequent, and microcephaly and mental retardation may be a feature. The skin may be generally hyperpigmented or may have areas of abnormal skin pigmentation referred to as *café-au-lait* spots, which are flat, light brown, and from 1 to 12 centimeters in diameter. Hepatosplenomegaly is not a feature of the disease. Some patients have no or minor phenotypic abnormalities and may be diagnosed as a result of the onset of marrow failure or a cancer involving any of many sites as late as the fifth decade of life.

The onset of marrow failure is gradual and usually is evident during the last half of the first decade of life. The manifestations of anemia, including weakness, fatigue, and dyspnea on exertion, and of thrombocytopenia with epistaxis, purpura, or other unexpected bleeding, are the principal findings. Hematologic and visceral manifestations are combined eventually in more than a third of patients, but some may have cytopenias and inconspicuous somatic changes, whereas others may have somatic anomalies with no or a nominal disorder of blood cell formation for months or years. Some who carry the gene may be virtually unaffected.^{259–261} In a review of the more than 1300 patients in the literature, 100 patients, or fewer than 7 percent, without anomalies were identified by chromosome breakage studies (see “Laboratory Features” below) because of affected siblings.²²⁷ In the past, children in Fanconi families with an onset of aplastic anemia without congenital somatic abnormalities were thought to have a different disorder termed *Estren-Dameshek syndrome*.²⁶² However, these children, whose lymphocytes show sensitivity to diepoxybutane, are considered to have Fanconi anemia without skeletal abnormalities.

Laboratory Features

Blood counts and marrow cellularity are often normal until 5 to 10 years of age, when pancytopenia develops over an extended interval. Macrocytosis with anisocytosis and poikilocytosis may be present before any cytopenia occurs. Thrombocytopenia may precede the development of

granulocytopenia and anemia. The marrow becomes hypocellular, and *in vitro* colony assays reveal a decrease in CFU-GM and BFU-E.²⁶¹

Random chromatid breaks are present in myeloid cells, lymphocytes, and chorionic villus biopsy samples. This chromosome damage is intensified after exposure to DNA crosslinking agents such as mitomycin C or diepoxybutane. The hypersensitivity of the chromosomes of marrow cells or lymphocytes to the latter agent is used as a diagnostic test for this condition. Cell-cycle progression is prolonged at the G2-to-M transition, and the cells are more susceptible to oxygen toxicity when cultured *in vitro*. It is important to test the lymphocytes from pediatric patients with aplastic anemia for sensitivity to diepoxybutane, because therapy for Fanconi anemia differs from that used for acquired aplastic anemia.

In the near future, clinical laboratories will be able to genotype suspected patients. Determining the specific gene mutation responsible in a patient (see Table 35–8) is important because it confirms the diagnosis, identifies the genotype linked to BRCA2 that may predispose to a cancer (e.g., breast, ovary), and permits carrier detection.²⁶³

Differential Diagnosis

The differential diagnosis of Fanconi anemia includes other causes of aplastic anemia, particularly those familial syndromes associated with skeletal anomalies and other dysmorphic features. Other familial types of aplastic anemia have been reported with or without associated anomalies. In those instances in which no sensitivity to DNA damaging agents is observed, the syndrome does not represent Fanconi anemia. Several uncommon syndromes of this type are described below and are tabulated in Table 35–9.

Therapy and Course

Most patients with Fanconi anemia do not respond to ATG or cyclosporine but do improve with androgen preparations, often for as long as several years. Cytokines may provide some improvement in blood counts, but their effect may wane. Studies in a mouse model also suggest that cytokine effects may not be sustained.²⁶⁴ The cumulative median survival is approximately 20 years from progressive marrow failure, conversion to myelodysplastic syndrome, AML (approximately 10 percent of patients), or the development of a variety of other cancers, such as those involving the genitourinary system, digestive system (especially liver), or head and neck.²⁶⁵ Multiple cancers in an individual patient

TABLE 35–9. Other Rare Inherited Syndromes Associated with Aplastic Anemia

Disorder	Findings	Inheritance	Mutated Gene	References
Ataxia-pancytopenia (myelocerebellar disorder)	Cerebellar atrophy and ataxia; aplastic pancytopenia; \pm monosomy 7; increased risk of AML	AD	Unknown	315–317
Congenital amegakaryocytic thrombocytopenia	Thrombocytopenia; absent or markedly decreased marrow megakaryocytes; hemorrhagic propensity; elevated thrombopoietin; propensity to progress to aplastic pancytopenia; propensity to evolve to clonal myeloid disease	AR (compound heterozygotes)	<i>MPL</i>	305–307
DNA ligase IV deficiency	Pre- and postnatal growth delay; dysmorphic facies; aplastic pancytopenia	AR (compound heterozygotes)	<i>LIG4</i>	314, 318, 319
Dubowitz syndrome	Intrauterine and postpartum growth failure; short stature; microcephaly; mental retardation; distinct dysmorphic facies; aplastic pancytopenia; increased risk of AML and ALL	AR	Unknown	320, 321
Nijmegen breakage syndrome	Microcephaly; dystrophic facies; short stature; immunodeficiency; radiation sensitivity; aplastic pancytopenia; predisposition to lymphoid malignancy	AR	<i>NBS1</i>	322, 323
Reticular dysgenesis (type of severe immunodeficiency syndrome)	Lymphopenia; anemia and neutropenia; corrected by hematopoietic stem cell transplantation	XLR	Unknown	308, 309
Seckel syndrome	Intrauterine and post-partum growth failure; microcephaly; characteristic dysmorphic facies (bird-headed profile); aplastic pancytopenia; ? increased risk of AML	AR	<i>ATR</i> (and <i>RAD3</i> -related gene); <i>PCNT</i>	310–314
WT syndrome	Radial/ulnar abnormalities; aplastic pancytopenia; increased risk of AML	AD	Unknown	324

AD, autosomal dominant; ALL, acute lymphocytic leukemia; AML, acute myelogenous leukemia; AR, autosomal recessive; XLR, X-linked recessive. NOTE: The listed clinical findings in each syndrome are not comprehensive. The designated clinical findings may not be present in all cases of the syndrome. Isolated cases of familial aplastic anemia with or without associated anomalies that are not consistent with Fanconi anemia or other defined syndromes have been reported.²²⁷

also occur. Cancers may occur as late as the fifth decade of life and precede the diagnosis of Fanconi anemia in 25 percent of patients.²⁶⁵ The presence of a clonal cytogenetic abnormality or marrow morphology consistent with myelodysplasia markedly reduces the 5-year survival.²³² Allogeneic hematopoietic stem cell transplantation is curative for the marrow manifestations of Fanconi anemia.^{266–269} A marked reduction in dosage of the marrow-conditioning regimen of cyclophosphamide and radiation is necessary owing to the undue sensitivity of the tissues to DNA-damaging exposures. The risk of cancer is so high that, where practical, surveillance should be used; for example, frequent pelvic exams in females, hepatic ultrasonography to detect adenomas, and careful oropharyngeal examinations. Therapy of cancer in patients with Fanconi anemia needs to consider the marked sensitivity of their cells to DNA cross-linking agents and radiotherapy.

Normal complementary DNA has been transferred into cells from patients with restoration of resistance to DNA damaging agents.^{270,271} Difficulties in this approach include the paucity of stem cells in these patients, as well as the potential toxicity of the gene transfer methodology.

DYSKERATOSIS CONGENITA

Definition

This inherited disorder is characterized by cutaneous and mucous membrane abnormalities, progressive marrow insufficiency, and a predisposition to malignant transformation. It is much more common in

males than in females, and occurs in approximately 1 per 1,000,000 population.^{251,272}

Pathogenesis

Dyskeratosis usually is inherited as a recessive X-chromosome-linked disorder although rare cases can have autosomal dominant or autosomal recessive inheritance (Table 35–10). The disease is a reflection of telomere complex dysfunction,^{273–276} and it results from defective telomerase activity resulting from mutations in the telomerase-related genes (Fig. 35–7).^{274,278,279} The telomerase complex maintains the length of telomeres, which are nucleotide tandem repeat structures residing at the termini of eukaryotic chromosomes (e.g., 5'-TTAGGG-3'). Telomerase restores the guanine (G)-rich telomere repeats that are lost as a result of end-processing during normal cell division. Combined with protein, located at the ends of chromosomes, they maintain chromosome integrity by preventing end-to-end chromosome fusion, preventing chromosome degradation, and preventing chromosome instability. In dyskeratosis congenita, the telomeres are markedly shortened resulting in genomic instability and cell (including marrow cell) apoptosis, and the underlying gene defects may alter Box H/ACA small nucleolar RNAs, such as the telomerase RNA component, TERC, that is central to telomere maintenance.^{279a} Rapidly proliferating cells are at highest risk for dysfunction. Mutations of the *DKC1* gene are responsible for the X-linked recessive form. *DKC1* encodes dyskerin, which is a conserved multifunctional protein component of the telomerase complex. Mutations of the *TERT*, *TERC*, and *TINF2* genes are the

TABLE 35-10. Gene Mutations in Dyskeratosis Congenita

Gene	Chromosome Location	% of Patients	Inheritance	Protein Function
<i>DKC1</i>	Xq28	30	XLR	Essential part of snoRNPs and telomerase
<i>TERC</i>	3q26	5–10	AD	RNA 3' end processing and stability
<i>TERT</i>	5p15.33	5–10	AD, AR	Reverse transcriptase component of telomerase
<i>NOP10 (NOLA3)</i>	15q14-q15	<1	AR	RNA binding

<i>CTC1</i>	17p13.1	Rare	AR	Telomere maintenance component
<i>NHP2 (NOLA2)</i>	5q35.3	<1	AR	RNA binding protein; associates with NOP10 and <i>DKC1</i>
<i>WRAP53 (TCAB1, WDR79)</i>	17p13.1	Rare	AR	Trafficking of telomerase
<i>RTEL1 (NHL)</i>	20q13.33	Rare	AD, AR	Regulator of telomere elongation helicase 1
<i>C16orf57 (USB1)</i>	16q21	2	AR	Unknown; Patient telomeres were normal length
<i>hTR</i>	3q	5–10	AD	<i>hTR</i> is the RNA component of telomerase

AD, autosomal dominant; AR, autosomal recessive; XLR, X-linked recessive.

NOTE: Table prepared from data in references 251, 254, 273, 276 to 279 and OMIM (Online Mendelian Inheritance in Man). Percent of patients is approximate because of continuing identification of mutations.

principal abnormalities in the autosomal dominant form. *TERC* is the RNA component of the telomerase reverse transcriptase that *TERT*, the reverse transcriptase, uses to synthesize the 6-bp repeats on the 3' end of telomeric DNA. Mutations of *TINF2* have been described in patients with dyskeratosis congenital.²⁸⁰ *TINF2* is a component of the shelterin complex, which prevents end-to-end telomere fusion.²⁸⁰ It also permits the distinction of telomeres from sites of DNA damage, preventing their inappropriate processing. Recessive mutations in *NHP2* and in *NOP10*, which encode parts of small ribonucleoprotein components associated with the telomerase complex, also have been described in association with dyskeratosis.^{281,282} Homozygous recessive mutations in the *TERT* gene produce a severe variant of dyskeratosis, referred to as the Hoyeraal-Hreidarsson syndrome.²⁷²

Clinical Findings

The cutaneous findings usually appear after 5 years of age and include reticulated, tan to gray, hyperpigmented and hypopigmented cutaneous macules; alopecia of scalp, eyelashes, and eyebrows; adermatoglyphia

(loss of dermal ridges on fingers and toes); hyperkeratosis of palms and soles; mucosal leukoplakia in 75 percent of patients; and dystrophic nails in more than 85 percent of patients.^{251,272,273} Other mucosal sites, such as conjunctiva, lacrimal duct, esophagus, urethra, vagina, and anus, can be involved, sometimes with stenosis leading to dysphagia or dysuria. Pulmonary vascular involvement occurs in a significant minority of affected children. Aplastic anemia usually develops in late childhood or early adulthood and is evident in the classical blood and marrow findings described under acquired aplastic anemia. Female carriers of X-linked dyskeratosis congenital may have slight abnormalities such as a dystrophic nail, a single area of hypopigmentation, or slight leukoplakia.²⁷² The clinical manifestations exhibit disease anticipation, occurring earlier in subsequent generations, and this appears related to earlier shortening of the telomeres.²⁸³

Diagnosis

The diagnosis results from the combination of phenotypic findings and blood cell deficiencies. Genetic analysis for telomerase complex gene

Figure 35-7. Representation of the interaction between dyskerin and the other molecules (*GAR1*, *NHP2*, *NOP10*, *TERC*, and *TERT*) of the telomerase complex (and their association with different disease categories). Telomerase is an RNA-protein complex because *TERC* is an RNA molecule that is never translated. The other molecules (*dyskerin*, *GAR1*, *NHP2*, *NOP10*, and *TERT*) are proteins. The minimal active telomerase enzyme is composed of two molecules each of *TERT*, *TERC*, and *dyskerin*. *Dyskerin*, *GAR1*, *NHP2*, and *NOP10* are important for the stability of the telomerase complex. AA, aplastic anemia; AD-DC, autosomal dominant dyskeratosis congenita; AR-DC, autosomal recessive dyskeratosis congenita; AR-HH, autosomal recessive Hoyeraal-Hreidarsson syndrome; MDS, myelodysplasia; PF, pulmonary fibrosis; PNH, paroxysmal nocturnal hemoglobinuria; X-linked DC, X-linked dyskeratosis congenita; X-linked HH, X-linked Hoyeraal-Hreidarsson syndrome. (Reproduced with permission from Dokal I, Vulliamy T: Inherited aplastic anaemias/bone marrow failure syndromes. *Blood Rev* 22(3):141–153, 2008.)

mutations should be used to confirm the clinical conclusion. Shortened telomere length in leukocytes also can be assessed by flow cytometric fluorescence in situ hybridization studies.²⁸⁴

Management

Stem cell hematopoietic transplantation has had inconsistent results because of frequent and severe posttransplantation complications.²⁸⁵ Nonmyeloablative transplantation might improve results.^{286–288} Transplantation might improve the cytopenias, but not the abnormalities of other organs or the frequency of secondary nonhematopoietic cancer.

Course and Prognosis

The incidence of squamous cell carcinoma of mucosal sites is increased and the squamous cell carcinoma often originates in sites of leukoplakia in the skin, gastrointestinal, or genitourinary tracts.²⁸⁹ These carcinomas usually develop between the ages of 20 and 30 years. Mortality from neutropenic infection or thrombocytopenic hemorrhage occurs in about two-thirds of patients with aplastic anemia. Median survival is approximately 30 years.

SHWACHMAN-DIAMOND SYNDROME

Definition

This disease is an uncommon inherited disorder that is estimated to occur once in every 75,000 births,²⁹⁰ manifesting exocrine pancreatic insufficiency with secondary steatorrhea, blood cell deficiencies, and skeletal abnormalities. It was first described in 1964.^{291,292}

Pathogenesis

Shwachman-Diamond syndrome results from mutations in the *SBDS* gene on chromosome 7q11, which induces accelerated cellular apoptosis via the FAS pathway.²⁹³ The resulting hyperproliferation may account for the abnormal telomere shortening that has been documented in the leukocytes in this condition.²⁹⁴ The pathogenetic mechanism that (1) prevents development of pancreatic acinar cells, (2) results in abnormal bone morphogenesis, and (3) causes marrow impairment of blood cell production is not understood. *SBDS* knockdown in experimental animals affects expression of genes involved in brain, bone, and marrow development, and may be the result of the gene's role in RNA processing.^{295,296} The *SBDS* gene promotes the release of eukaryotic initiation factor 6 from the pre-60s ribosome.^{279a} This action is necessary for the formation of a mature 80s functional ribosome and production of appropriate ribosome joining. The mutations in *SBDS* also result in abnormalities in neutrophil motility and chemotaxis, but pus formation *in vivo* seems adequate.

Clinical Findings

Pancreatic insufficiency, steatorrhea, and neutropenia are present in most patients at the time of diagnosis.^{291,292,297} Pallor may reflect anemia and easy bruising; epistaxis or bleeding from other sites reflect thrombocytopenia. Neutropenia occurs in approximately 95 percent, anemia in approximately 50 percent, and thrombocytopenia in approximately 35 percent of patients.²⁹³ Thus, a substantial plurality of patients has bicytopenia or tricytopenia with an hypoplastic marrow. Fetal hemoglobin levels are elevated in approximately 75 percent of the patients, perhaps secondary to erythroid hypoplasia. Cytogenetic abnormalities involving chromosomes 7 and 20 have been described in marrow cells. Nutritional inadequacies related to intestinal malabsorption result in a failure to thrive. Short stature is characteristic. Skeletal abnormalities are present in most patients, notably osteopenia, but also syndactyly, supernumerary metatarsals, coxa vera deformity, and dental enamel defects and caries. Hepatic dysfunction as evidenced by elevated serum

aminotransaminase is seen in most young patients and appears to resolve with age.²⁹⁸ Delayed puberty is common. The neutropenia and chemotactic abnormality may result in recurrent infections, including sinusitis, otitis, pneumonia, osteomyelitis, and others. Pancreatic cell lipase production improves with age, and as many as half the patients may have improvement in lipid absorption in the small bowel with time.

Diagnosis

The diagnosis is based on the clinical findings of failure to thrive, steatorrhea, and neutropenia. Pancreatic insufficiency can be established by low serum trypsinogen in patients younger than 3 years of age. The marrow may be initially normal, but develops evidence of marrow failure and sometimes cytogenetic abnormalities, particularly of chromosome 7, as the child ages. The age of expression of clonal hematopoiesis (e.g., myelodysplastic syndrome or AML) is variable.²⁹⁹ The *SBDS* gene mutation is present in 90 percent of patients with Shwachman-Diamond syndrome.³⁰⁰ The remaining 10 percent have the clinical features of the syndrome, but the gene defects have not been defined.

Management

Supportive care, particularly with supplemental pancreatic enzymes, to provide proper nutrition, and appropriate and prompt treatment of bacterial infections with antibiotics is important. Many agents, including G-CSF, glucocorticoids, pancreatic extract, vitamins, have been tried to improve the neutropenia with unpredictable results. Some agents have potential risks, such as G-CSF fostering clonal evolution and glucocorticoids fostering immunodeficiency. Severe hematopoietic dysfunction and cytopenias can be corrected with allogeneic hematopoietic stem cell transplantation.³⁰¹

Course and Prognosis

Death from overwhelming sepsis is common. These patients, especially males, have a significant risk of progression to a myelodysplastic syndrome or AML.^{292,302,303} Cytogenetic abnormalities are common, and telomeres are shortened,³⁰⁴ as in other marrow failure syndromes. Survival is a function of the severity of the cytopenias. If the cytopenias are mild, survival is not uncommon into the fourth or fifth decade of life. It is not clear whether Shwachman-Diamond syndrome is associated with an increased incidence of solid tumors.

OTHER INHERITED APLASTIC ANEMIAS

Several other rare syndromes are associated with aplastic pancytopenia, and these are described in Table 35–9. Congenital (hereditary) amegakaryocytic thrombocytopenia (CAMT) results from mutations in the TPO receptor gene, *MPL*.^{305–307} The affected children can be divided into two groups: CAMT I with mutations leading to complete loss of function of the TPO receptor, resulting in more severe thrombocytopenia and a rapid progression to pancytopenia (aplastic anemia), and CAMT II, resulting from a variety of missense mutations, in which affected children have an increase in platelet count above $50 \times 10^9/L$ with time and much slower progression to and sometimes less-severe pancytopenia.³⁰⁶ Reticular dysgenesis results from a pluripotential stem cell defect as both lymphoid and granulocytic progenitors are affected.^{308,309} It is a rare autosomal recessive disorder caused by mutations in the adenylate kinase 2 gene (*AK2*) and characterized by bilateral sensorineural deafness, severe combined immunodeficiency, and agranulocytosis, which subjects infants to severe, often, life-threatening infections. The Seckel syndrome results from mutations in the *ATR* gene, and marrow cells exhibit heightened sister chromatid exchange.^{310–314} The ataxia-telangiectasia mutated and rad3-related (*ATR*) kinase mediates cellular responses to DNA damage and replication stress. Most of the eight syndromes delineated in Table 35–9 can be treated by marrow

transplantation, but this step, if successful, does not correct somatic abnormalities, only the hematopoietic and immunologic defect. The restoration of robust lymphohematopoiesis by transplantation may decrease their propensity to undergo clonal evolution to a clonal myeloid or, in some cases, lymphoid disorder.

CHAPTER 36

PURE RED CELL APLASIA

Neal S. Young

SUMMARY

Pure red cell aplasia is the diagnosis applied to isolated anemia secondary to failure of erythropoiesis. Cardinal findings are a low hemoglobin level combined with reticulocytopenia and absent or extremely infrequent marrow erythroid precursor. Historical names for pure red cell aplasia include *erythroblast hypoplasia*, *erythroblastopenia*, *red cell agenesis*, *hypoplastic anemia*, and *aregenerative anemia*. *Aplastic anemia* confers the same meaning, of course, but is applied to pancytopenia and an empty marrow (Chap. 35). Pure red cell aplasia was first separated from aplastic anemia by Kaznelson in 1922. The association of red cell aplasia and thymoma interested physicians in the 1930s and ultimately led to laboratory studies linking pure red cell aplasia to immune mechanisms, including the early identification of antierythroid precursor cell antibodies by Krantz and later characterization of T cells that inhibited erythropoiesis. Red cell aplasia as an acute and life-threatening complication of sickle cell disease and other hemolytic anemias was recognized in the 1940s, presaging the role of a specific virus in the etiology of both acute and chronic erythropoietic failure. Despite its infrequency, pure red cell aplasia has been a subject of much laboratory research because of its link to an immune mechanism of erythropoietic failure and as a manifestation of parvovirus B19 infection and viral destruction of red cell progenitors. However, because of its infrequency, pure red cell aplasia has not been the subject of large or controlled clinical trials; as a result, therapeutic recommendations are based on single cases or small series. Table 36–1 lists a practical classification of pure red cell aplasia.

● INHERITED PURE RED CELL APLASIA (DIAMOND-BLACKFAN ANEMIA)

DEFINITION AND HISTORY

Anemia in infancy and early childhood associated with absent reticulocytes in the blood and erythroid precursor cells in the marrow was described by Joseph¹ in 1936 as a “failure of erythropoiesis” and by Diamond and Blackfan² in 1938 as “congenital hypoplastic anemia.”

Acronyms and Abbreviations: B19, primate erythroparvovirus 1; BFU-E, burst-forming unit–erythroid; CD20, a cluster of differentiation molecule expressed on the surface of all mature B cells; CFU-E, colony-forming unit–erythroid; CLL, chronic lymphocytic leukemia; FA, Fanconi anemia; *GATA1* gene, globin transcription factor 1; HLA, human leukocyte antigen; Ig, immunoglobulin; IL, interleukin; LGL, large granular lymphocytic leukemia; *RPS14* and *RPS19* genes, ribosomal protein S14 and S19 genes; *STAT3* gene, signal transducer and activator of transcription 3 gene; T cell, thymus-derived lymphocyte.

Gasser³ first reported a response of a patient to glucocorticoids in 1951, and Diamond and associates⁴ presented a series of treated patients. Genetic linkage studies have identified etiologic mutations in ribosomal protein genes.^{5–9} Hundreds of cases have been reported, and many excellent reviews have been published.¹⁰ Although Joseph was the first to describe the disorder, the anemia invariably is referred to as either *Blackfan-Diamond* or *Diamond-Blackfan anemia*.

ETIOLOGY AND PATHOGENESIS

An annual incidence of 5 cases per 1 million livebirths has been estimated from registry data.¹¹ Well-characterized pedigrees are consistent with an autosomal dominant or, less often, recessive inheritance pattern. Sporadic cases are seen most frequently. Retrospective studies may reveal subtle hematologic or biochemical lesions, or an abnormal gene, in an affected parent or another relative without clinical anemia.¹²

Recent genetic studies have led to the characterization of Diamond-Blackfan anemia as a disease of ribosomal biogenesis.^{5–7,13,14} Linkage analyses of several dozen European families mapped to a site on chromosome 19q13¹⁵ and the finding of a translocation in one individual allowed cloning of the ribosomal protein S19 (*RPS19*) gene, which encodes a protein involved in ribosome assembly.^{5–9} Most mutations are whole gene deletions, translocations or truncations; this pattern suggests a mechanism of haploinsufficiency, and *RPS19* behaves as a dominant gene.¹⁶ (Disruption of both copies of the gene in the mouse prevents implantation.¹⁷) *RPS19* mutations occur in approximately 25 percent of patients with inherited red cell aplasia^{16,18}; and mutations subsequently have been identified in multiple other ribosomal biogenesis genes (*RPS10*, *RPS26* particularly) in other cases.^{16,19,20} More recently, a globin transcription factor 1 (*GATA1*) gene mutation was identified in a Diamond-Blackfan kindred, implicating a signal transduction pathway of erythroid differentiation as also causative of the syndrome.²¹ Experiments have implicated *RPS14* in one of the myelodysplastic syndromes characterized by loss of 5q.²²

Precisely how defects in ribosomal protein genes cause constitutional red cell aplasia is uncertain. Historically, Diamond-Blackfan anemia has been characterized by diminished erythroid progenitor cell numbers (colony forming unit–erythroid [CFU-E] and burst-forming unit–erythroid [BFU-E]).^{23,24} In cell culture, early, erythropoietin-independent erythropoiesis is relatively normal; the major defect is in the late stage of erythropoietin-dependent erythroid cell expansion and maturation.²⁵ A defect in late erythroid differentiation is compatible with the classic findings of macrocytosis and increased hemoglobin F expression in inherited red cell aplasia. Granulopoiesis in the colony-forming unit–granulocyte-macrophage assay and the earlier hematopoietic progenitors as measured *in vitro* by long-term culture-initiating cell assay (an assay for an early multipotential hematopoietic progenitor) frequently are abnormal, but to a lesser degree than are CFU-E and BFU-E.²⁶ In a zebrafish model, deficiency of *rps19* in early embryogenesis caused a decrease in erythrocytes and also physical anomalies.²⁷ In tissue culture experiments, silencing of *RPS19* profoundly affects erythropoietic differentiation and, to lesser degrees, myelopoiesis.^{28,29} Both *in vivo* and *in vitro* models have implicated accumulation in the cell of free ribosomal proteins, which modulates the inhibitory activity of regulators of tumor protein p53, leading to p53 stabilization and apoptosis.³⁰ The specificity of this molecular defect for the erythroid pathway may be a result of the extreme requirement of red cell progenitors and precursors for ribosome biogenesis.

Despite responsiveness of patients to glucocorticoids, there is little evidence of an immune mechanism, cellular or humoral, underlying inherited red cell aplasia.

CLINICAL FEATURES

Approximately one-third of patients are diagnosed at birth or within a few weeks of delivery, and almost all are identified within the first year of life.³¹ Considerable variations are noted with regard to severity of phenotype, ranging from hydrops fetalis^{32,33} to presentation in adulthood, when diagnosis is inferred from associated physical anomalies.^{5,34} No sex predominance exists. Increased rates of prematurity in patients and of miscarriages in families have been inferred from collected cases.³⁵ Symptoms of anemia in early childhood include pallor, apathy, poor appetite, and “failure to thrive.” Physical anomalies occur in about a third of cases; most frequent is craniofacial dysmorphism, the classic appearance described by Cathie³⁶ is “tow-colored hair, snub nose, wide set eyes, thick upper lips, and an intelligent expression.” Malformations of the thumbs and short stature are frequent, followed by abnormalities of the urogenital system, web neck, and skeletal and cardiac defects.^{11,31,37} These physical anomalies are less prevalent than the abnormalities seen in Fanconi anemia (FA).

LABORATORY FEATURES

The degree of anemia is highly variable at diagnosis. Erythrocytes may be macrocytic or normocytic. Reticulocytopenia is profound. The marrow, which usually is devoid of red blood cell precursors, may show small numbers of megaloblastoid early erythroid cells with apparent “maturation arrest.” Platelets are normal or elevated. Leukocytes may be normal or slightly decreased at presentation. Neutrophils often decline with age, and in adult survivors neutropenia occasionally is severe enough to predispose to fatal infection.³⁸

Erythrocyte adenosine deaminase level is elevated in approximately 75 percent of patients but also may be increased in other aregenerative anemias of childhood.³⁹ Serum erythropoietin level, serum iron level, and total iron-binding capacity are high. Ferritin level increases as patients receive multiple transfusions and develop iron overload if they are not treated with chelation therapy.

DIFFERENTIAL DIAGNOSIS

The characteristic triad consists of the clinical diagnostic features of anemia, reticulocytopenia, and a paucity or absence of erythroid precursors in the marrow. These findings may be supplemented by increased activity of red cell adenosine deaminase and ribosomal gene mutation analysis. FA can be excluded by cytogenetic analyses under clastogenic stress and determination of FA gene mutations (Chap. 35). Transient erythroblastopenia of childhood, which unusually occurs in the first year of life, is established by spontaneous recovery. When presentation occurs at older ages, the distinction between inherited and acquired aplastic anemia can be difficult⁴⁰; family history, physical anomalies, and characteristic cytogenetic enzymatic, or genetic findings implicate and indicate an inherited disorder.

THERAPY, COURSE, AND PROGNOSIS

Untreated inherited pure red cell aplasia is fatal; death results from severe anemia and congestive heart failure. Transfusions, glucocorticoids, and allogeneic stem cell transplantation are of proven efficacy.^{9,41} Predictors of glucocorticoid administration in glucocorticoid responsive patients include older age at presentation, a family history, and a normal platelet count. Younger age at presentation and premature birth correlate with continued red cell transfusion dependence.⁴² Supportive care consists of red cell transfusions. To avoid transfusional hemosiderosis, chelation with desferrioxamine should be initiated early (Chap. 43). Injury to visceral organs from iron overload has been a major cause of death in the past.

Red cell transfusions should be leukocyte depleted to avoid alloimmunization (see Chap. 138). Erythrocytes are administered with the goal of eliminating symptoms and permitting normal growth and sexual development, usually achieved by maintaining hemoglobin levels between 7 and 9 g/dL (70 to 90 g/L).

Glucocorticoids are effective in many patients.⁴³ Although the mechanism of action of glucocorticoids in this disease is not understood, their toxicities are substantial, and a response is not predictable. Once the diagnosis is established, prednisone is administered orally at 2 mg/kg daily in three or four divided doses.^{35,44,45} A reticulocyte response is seen in the majority of patients 1 to 4 weeks later, followed by a rise in hemoglobin level. Once the hemoglobin level reaches 9 to 10 g/dL (90 to 100 g/L), very slow reduction of the glucocorticoid dose is undertaken by decreasing the number of daily doses. When a single daily dose is achieved, an alternate-day schedule is adopted. In general, severe anemia can be avoided with continued glucocorticoid administration. The maintenance dose may be low (1 to 2 mg/day). Some patients may tolerate complete withdrawal of prednisone, but relapse is frequent and most responders become glucocorticoid dependent. A variety of patterns of response have been described, ranging from prompt recovery and apparent cure to refractoriness after a long period of responsiveness.³⁵ Conversely, a second trial of glucocorticoids years after an apparent therapeutic failure may be successful. In a series of 76 patients followed for many years, 59 were treated with prednisone; 31 initially responded, and two of the 25 who initially failed later responded.⁴⁴ Glucocorticoid responsiveness is strongly associated with better survival, and patients who require low doses of prednisone, or those few who spontaneously remit, may have normal life expectancies. Long-term use of high-dose prednisone results in significant toxicity, including some combination of growth retardation, cushingoid facies, buffalo hump, osteoporosis, aseptic necrosis of the hip and fractures, diabetes, hypertension, and cataracts. Red cell transfusions with iron chelation may be preferable to such an outcome.

Allogeneic stem cell marrow transplantation, when successful, is curative (Chap. 23), but the procedure has not been widely applied to children responding to medical measures. The median life expectancy of patients requiring transfusions and iron chelation is 30 to 40 years. A less-favorable outcome is related to poor compliance and cardiac and hepatic disease from iron overload.⁴⁶ Because of the morbidity and mortality associated with allogeneic stem cell transplant, most patients have been transplanted late in their disease course, after large numbers of transfusions, accumulation of heavy iron loads, and alloimmunization. Despite the poor predictive factors, 15 of 19 patients of the first published series of cases survived 5 months to many years posttransplant.³⁷ Comparable survival rates have been reported from European⁴⁷ and Japanese registries.⁴⁸ Stem cell transplantation from unrelated stem cell donors or use of cord blood stem cells^{47,49} has been less successful. Recurrent red cell aplasia despite full engraftment was reported in one child after transplantation.⁵⁰

Other therapies have not gained wide acceptance despite promising pilot studies, including interleukin-3 (IL-3),⁵¹ high-dose methylprednisolone,⁵² cyclosporine and other immunosuppressive agents,^{53,54} and prolactin induction by metoclopramide.⁵⁵ Leucine, which is effective in animal models,⁵⁶ is in clinical trials.

With better survival, the risk of late development of leukemia has become apparent.^{14,43} Four of 76 patients followed at Children's Hospital in Boston died of acute myelogenous leukemia, with a calculated relative risk of greater than 200 times expected.⁴⁴

Gene transfer *in vitro* has functionally corrected cells defective in *RSP19*,⁵⁷ and in animal models corrected cells show improved erythropoiesis and a survival advantage *in vivo*⁵⁸ offering the possibility of gene therapy.

TRANSIENT APLASTIC CRISIS AND TRANSIENT ERYTHROBLASTOPENIA OF CHILDHOOD

DEFINITION AND HISTORY

Temporary failure of erythropoiesis is clinically identical to pure red cell aplasia except for spontaneous resolution of symptoms and of the laboratory findings of normocytic and normochromic anemia and marrow erythroid hypoplasia, usually over the course of a few weeks. Erythrocyte production is halted: (1) by acute primate erythroparvovirus 1 (B19 parvovirus) infection, typically in the context of underlying hemolytic disease (called transient aplastic crisis); (2) in normal children, usually after an infection by another [unknown] childhood virus (transient erythroblastopenia of childhood); or (3) as a transient reaction to a drug.

An anemic crisis was described in the 1940s first by Lyngar⁵⁹ and then by Owren,⁶⁰ Gasser,³ and Dameshek and Bloom⁶¹ in kindreds with hereditary spherocytosis. Several children within a family suffered anemic crises and exhibited low, rather than the usually high, reticulocyte numbers. Transient aplastic crisis also was noted as a complication of sickle cell disease.^{62,63} Marrow examination showed decrease or absence of erythroid precursor cells, and often giant erythroblasts.^{60,61} An infectious etiology was suspected from the history of a preceding febrile illness in families and its simultaneous occurrence in siblings. After the serendipitous discovery of B19 parvovirus in a normal blood donor, Pattison and colleagues screened large numbers of stored sera for evidence of recent infection. Immunoglobulin (Ig) M antibody or viral antigen was found in the blood of Jamaican children in London, all of whom had transient aplastic crisis of sickle cell disease.⁶⁴ B19 parvovirus later was established as the agent also responsible for fifth disease.⁶⁵ In the large cohort of sickle cell patients in Jamaica reported by Serjeant and colleagues,^{66,67} virtually all episodes of transient aplastic crisis could be linked to B19 parvovirus. In retrospect, red cell aplasias blamed on kwashiorkor, vitamin deficiency, bacterial infections, and chemical exposures likely represented parvovirus infection.

Gasser³ described erythroblastopenia in normal children who ultimately recovered⁶⁰; the disease was recognized as an entity by Wranne⁶⁸ in the 1970s. Transient erythroblastopenia of childhood has an unclear etiology but may represent a postviral immune-mediated syndrome. The syndrome is rare and may be declining in incidence.⁶⁹

ETIOLOGY AND PATHOGENESIS

B19 parvovirus, a small DNA virus, commonly infects humans. Most of the adult population has IgG antibodies specific to B19.⁶⁵ The virus is

tropic for erythroid progenitor cells,⁷⁰ mainly because of their P antigen or globoside, the receptor for entry of B19 into the cell^{71,72} (Fig. 36–1). Infection lyses the target cell and abrogates erythropoiesis *in vitro* and *in vivo*. Reticulocytopenia probably accompanies B19 parvovirus infection in all infected persons.⁷³ Anemia only manifests if red cell survival is decreased. Infection ordinarily is terminated by production of neutralizing antibodies to the virus (when such antibodies are absent, persistence of the virus produces chronic pure red cell aplasia). B19 parvovirus may appear in epidemics of fifth disease in the normal population and of transient aplastic crisis, for example, in hematology clinics specializing in sickle cell disease.^{74,75} In fifth disease, IgM antibody is present in the blood, and virus levels are either low or are not detectable. Symptoms and signs of a typical “slapped cheek” cutaneous eruption and arthralgia or arthritis are secondary to antibody–virus immune complex deposition.

In contrast, in transient aplastic crisis, high concentrations of virus are present in the circulation, and patients do not develop fifth disease. In children with sickle cell disease, the incidence of B19 parvovirus infection was estimated at approximately 11 percent, and 75 percent of patients were infected by age 20 years.⁷⁶ In this setting, parvovirus infection was associated with transient aplastic crisis, a higher frequency of fever, pain, acute chest syndrome, and acute splenic sequestration syndrome.⁷⁶ As in normal individuals, parvovirus infection can be asymptomatic in sickle cell disease.⁷⁷

The origins of transient erythroblastopenia of childhood are poorly understood. An apparent viral prodrome is typical,⁷⁸ and temporal and seasonal clustering of cases may occur.^{79–81} With rare exception,⁸² B19 parvovirus is not the etiology,^{83,84} and no other virus has been consistently implicated.⁷⁸ Erythroid colony numbers (Chap. 32) usually are low.⁸⁵ An immune pathophysiology has been inferred from *in vitro* experiments in which IgG from sera of patients inhibited erythropoiesis⁸⁶ in the majority of cases.⁸⁷ Cell-mediated mechanisms also may play a causal role. In one report, T-cell depletion led to a dramatic increase in CFU-E formation.⁸⁸ A possible relationship between transient erythroblastopenia of childhood and inherited red cell aplasia has been suggested by the clustering of polymorphic alleles in familial transient erythroblastopenia.⁸⁹

The same drugs implicated in chronic pure red cell aplasia apply to transient erythropoietic failure.⁹⁰ Laboratory investigations of red cell aplasia secondary to diphenylhydantoin⁹¹ and rifampicin⁹² are consistent with a hapten mechanism, in which serum antibody affects erythroid progenitor cells only in the presence of drug.

CLINICAL FEATURES

Transient aplastic crisis typically occurs in younger patients who are chronically anemic as a result of hereditary spherocytosis, sickle cell

Figure 36–1. **A** and **B.** Giant early erythroblast precursors in the marrow aspirate of a patient with chronic pure red cell aplasia secondary to persistent B19 parvovirus infection. Note the nuclear inclusions (darker nuclear shading) representing parvovirus infection. **C.** Marrow biopsy section. The arrows point to binucleate erythroid precursor cell with nuclear inclusions representing parvovirus infection. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

disease, or another hemolytic anemia. The decrease in erythropoiesis results in more evident pallor, fatigue on exertion or at rest, lassitude, and dyspnea on exertion. Gastrointestinal complaints or headache may be associated.⁹³ Parvovirus infection can unmask previously undiagnosed underlying hemolytic anemia. Physical examination may reveal signs of anemia, such as pallor, tachycardia, and a flow murmur. No rash or joint swelling is seen. Elevated serum bilirubin or overt icterus may be a clue to underlying hemolysis.

Transient erythroblastopenia of childhood presents as an acute anemia in a previously well child. The syndrome has an estimated incidence rate of 4 to 5 cases per 1 million children.^{94–96} Transient erythroblastopenia is a frequent diagnosis in children with severe anemia,^{95,97} and is the most common cause of acquired red cell aplasia in pediatric patients.^{94,98} Most patients are 1 to 3 years old,^{97,98} but transient erythroblastopenia of childhood can occur in the first year of life and through adolescence. Rare complications include seizures and transient neurologic abnormalities.^{99–101}

LABORATORY EVALUATION

In both syndromes, anemia is the hallmark, and hemoglobin levels may be markedly depressed. Reticulocytes usually are absent from the blood, and erythroid precursor cells are not present or markedly decreased in the marrow. Red cell indices are normal. White blood cell and platelet counts are normal or elevated. Occasionally, neutropenia and thrombocytopenia of mild or moderate degree are present (especially if splenic function is intact, as in hereditary spherocytosis and in transient erythroblastopenia of childhood).⁹⁷ If the episode is brief and diagnosed during marrow recovery, patients may present with reticulocytosis, and nucleated red blood cells may be seen on the blood film.

DIFFERENTIAL DIAGNOSIS

The reticulocyte count readily distinguishes the cause of increasing anemia in a patient with hemolytic disease as transient aplastic crisis. The most important differential diagnosis for transient erythroblastopenia of childhood is inherited pure red cell aplasia. For the former, the age at presentation is older, the patient usually has no family history (but transient erythroblastopenia of childhood may be familial and can occur simultaneously in siblings),¹⁰² physical anomalies are absent, and the syndrome resolves spontaneously.

In transient erythroblastopenia of childhood (in contrast to inherited red cell aplasia), erythrocyte adenosine deaminase levels are normal, and red cells do not show “stress” patterns of fetal hemoglobin and i antigen (red cell antigen expressed primarily on fetal erythrocytes) expression. The patient’s medical history, the red cell indices, and appropriate serum assays should allow prompt exclusion of more common causes of anemia in children, such as iron deficiency or other nutritional deficiencies. When transient erythroblastopenia is associated with neutropenia, acute lymphoblastic leukemia and aplastic anemia may be suspected: marrow examination clarifies the diagnosis.¹⁰³ A record of current medications, more important in adults, may provide the basis for a tentative diagnosis of drug-induced rather than idiopathic disease.

THERAPY, COURSE, AND PROGNOSIS

Transient aplastic crisis resolves as neutralizing antibodies to B19 parvovirus are made, usually within 1 to 2 weeks of infection. Ensuing reticulocytosis may be brisk, and the hemoglobin may transiently rise to higher-than-normal values. White cell and platelet numbers may “rebound,” and some bone pain from marrow expansion may be present. Severe anemia may require transfusion of red blood cells (Chap. 138). No established role for administration of immunoglobulin exists.

Transient erythroblastopenia of childhood typically terminates after a few weeks, but anemia may persist occasionally for months.⁹⁸ Transfusions may be required during that interval. Overtreatment of a self-limited illness and misdiagnosis of a more serious disease are to be avoided.

For drug-associated transient failure of erythropoiesis, the suspected offending drug is discontinued and the diagnosis established from subsequent clinical improvement.

ACQUIRED PURE RED CELL APLASIA

DEFINITION AND HISTORY

Acquired pure red cell aplasia is an uncommon cause of anemia that occurs principally in older adults. The blood counts and marrow appearance are indistinguishable from the picture of Diamond-Blackfan anemia, that is, anemia, severe reticulocytopenia, and absent marrow erythroid precursor cells. The nosologic origins of acquired pure red cell aplasia are obscure. Early descriptions are intermixed with those of aplastic anemia (in retrospect, a poor term for generalized marrow failure). Kaznelson¹⁰⁴ is credited with the first case report in 1922. Early distinction of the two syndromes was stimulated by the relationship of red cell aplasia to thymoma. Although red cell aplasia shares with aplastic anemia an immune pathophysiology and responsiveness to immunosuppressive therapies, the absence of involvement of neutrophils, monocytes, and platelets makes the diagnostic distinction evident. Many of the diverse clinical associations (Table 36–1) are consistent with an immune-mediated pathophysiology. The mechanism

TABLE 36–1. Classification of Pure Red Cell Aplasia

Fetal red cell aplasia (nonimmune hydrops fetalis)
Parvovirus B19 <i>in utero</i>
Inherited (Diamond-Blackfan anemia)
<i>RPS19</i> and other <i>RPS</i> mutations
Acquired
Transient pure red cell aplasia
Acute B19 parvovirus infection in hemolytic disease (transient aplastic crisis; ~100% of cases)
Transient erythroblastopenia of childhood
Chronic pure red cell aplasia
Idiopathic
Large granular lymphocytic leukemia
Chronic lymphocytic leukemia
Clonal myeloid diseases (especially 5q-syndrome)
Persistent B19 parvovirus infection in immunodeficient host (~15% of cases)
Thymoma
Collagen vascular diseases
Post-stem cell transplantation
Anti-ABO antibodies
Drug induced
Antierythropoietin antibodies
Pregnancy

of red cell failure is best understood for T cell–mediated autoimmune destruction and persistent B19 parvovirus infection.

ETIOLOGY AND PATHOGENESIS

Immune-Mediated Erythropoietic Failure

Clinical and laboratory evidence supports both antibody and cellular mechanisms of inhibition of erythropoiesis. Red cell aplasia is associated with autoimmune diseases, such as rheumatoid arthritis, systemic lupus erythematosus, myasthenia gravis, autoimmune hemolytic anemia, acquired hypogammaglobulinemia, autoimmune polyglandular syndrome, and especially thymoma, and with lymphoproliferative processes, such as chronic lymphocytic leukemia (CLL) and Hodgkin disease, in which immune dysregulation is common. Serum inhibitors can be detected in the laboratory. Krantz and colleagues showed that immunoglobulin fractions from the patient's blood inhibited heme synthesis and red cell progenitor assays *in vitro*.⁸⁷ Antibodies that inhibit BFU-E and CFU-E colony formation are present frequently in patients with red cell aplasia. A pathophysiologic role can be inferred, first from the response of patients to specific treatments directed at antibodies, such as plasmapheresis and a monoclonal antibody to a cluster of differentiation molecule expressed on the surface of all mature B cells, CD20, and second from decreased or absent plasma antibody in recovered patients. Antibodies may be involved in the red cell aplasia of pregnancy.¹⁰⁵

Autoantibodies to erythropoietin rarely have caused this disease.^{106,107} More frequently, red cell aplasia secondary to antibodies is elicited by administration of recombinant erythropoietin to patients undergoing renal dialysis.^{108–113} Anemia can be profound, and some patients remain transfusion dependent despite discontinuation of hormone therapy. Glycosylation of recombinant erythropoietin is different from the native molecule, but antibodies are directed against conformational epitopes of the protein and not to the sugar moieties. Erythropoietin immunogenicity associates with human leukocyte antigen (HLA) specificities.¹¹⁴ The second example of antibodies of known specificity causing red cell aplasia occurs after hematopoietic stem cell transplantation using donors mismatched at a major ABO locus, which can lead to delayed donor erythroid engraftment or late erythropoietic failure.^{115–118} In most instances, however, the target antigen(s) responsible for this outcome is(are) not known.

Suppression of erythropoiesis by T cells may be more common than antibody inhibition as a mechanism of erythropoietic failure.¹¹⁹ Suggestive clinical observations include the frequent association of red cell aplasia with CLL (Chap. 92) in approximately 6 percent of cases¹²⁰; CLL is also associated with autoimmune hemolytic anemia and idiopathic thrombocytopenic purpura¹²¹ and with large granular lymphocytic leukemia (LGL; Chap. 94) in approximately 7 percent of cases.¹²² In a series of 47 red cell aplasia patients, four had CLL and nine had LGL.¹²³ More sensitive flow cytometric and molecular methods may detect clonal T-cell expansion in patients with normal numbers of circulating lymphocytes.^{124,125} An attractive molecular mechanism underlying CD8 cell expansion is signal transducer and activator of transcription 3 gene mutations (*STAT3*), leading to constitutive activation of a clone of cytotoxic T cells, which is relatively frequent in patients with large granular lymphocytosis¹²⁶ and has been described in patients with pure red cell aplasia.^{127–129} Functionally, lymphocytes from patients with idiopathic pure red cell aplasia^{130–132} or red cell aplasia associated with CLL,^{133,134} LGL,^{135–137} thymoma,¹³⁸ other lymphoid malignancies,^{139,140} Epstein-Barr virus infection,¹⁴¹ and human T-cell leukemia virus 1 infection¹⁴² suppressed erythropoiesis in colony assays. Several mechanisms of cell killing have been suggested.^{122,143} When effector cells show histocompatibility locus A class I–restricted killing, recognition of a specific antigen peptide is implied by a T cell with an $\alpha\beta$ T-cell receptor.¹⁴⁴

In one man with red cell aplasia and LGL, erythropoiesis was inhibited by non-MHC (major histocompatibility) antigen-restricted $\gamma\delta$ T cells that lysed CFU-E. T cells downregulated class I histocompatibility antigens and thus were unable to engage the natural killer cell's inhibitory receptors.¹³⁷

Persistent B19 Parvovirus Infection

B19 parvovirus specifically infects and is toxic to erythroid progenitor cells. Parvovirus infection normally is terminated within 1 to 2 weeks of infection by the humoral immune response. Linear neutralizing epitopes are localized to a relatively small region of the capsid protein.¹⁴⁵ In the absence of an effective antibody response, infection persists and causes pure red cell aplasia.^{65,145} Erythropoietic failure may be the only evidence of parvoviral infection. Persistence of B19 parvovirus infection may occur in the setting of immunodeficiency (Chap. 80), most commonly caused by chemotherapeutic and immunosuppressive drugs,¹⁴⁶ human immunodeficiency virus 1 infection,¹⁴⁷ and occasionally with Nezelof syndrome's subtle immunologic abnormalities.¹⁴⁸ Parvovirus at one time may have accounted for approximately 15 percent of severe anemia in patients with AIDS,¹⁴⁹ but highly effective antiretroviral drug regimens have reduced its role.^{150,151} Persistent B19 parvovirus infection can occur in the fetus exposed during the midtrimester of pregnancy (Chap. 55). The infection can cause hydrops fetalis as a result of viral cytotoxicity for erythroid progenitors in the fetal liver and death of the newborn as a result of severe anemia and congestive heart failure.⁶⁵ In rare instances, parvovirus-infected or hydropic infants rescued by red cell transfusion show congenital red cell aplasia or dyserythropoietic anemia.³³

Intrinsic Cellular Defects Leading to Failed Red Blood Cell Production

Red cell aplasia can be the first or the major manifestation of myelodysplasia.¹⁵² Discrete genetic defects can lead to failure of erythropoiesis. Activating point mutations in *N-RAS*, an oncogene in the *RAS* family occur in some cases of myelodysplastic syndrome.^{153,154} Mutant *N-RAS in vitro* can induce a proliferative defect in erythroid progenitor cells.¹⁵⁵ Loss of the *RPS14* gene in 5q– deletions leads to red cell aplasia in this myelodysplastic syndrome.^{22,156} *In vitro* colony formation may distinguish such intrinsic cellular defects from immune mediated marrow failure, with higher BFU-E numbers predicting response to immunosuppressive therapies.¹⁵⁷

Medications

Idiosyncratic drug reactions account for a far smaller proportion of red cell aplasia than of agranulocytosis (Chap. 65). Case reports have implicated various agents, such as diphenylhydantoin, sulfa and sulfonamide drugs, azathioprine, allopurinol, isoniazid, procainamide, ticlopidine, ribavirin, and penicillamine. Causality is impossible to assign from case reports; with nonsteroidal antiinflammatory drugs, gold, and colchicine, the underlying rheumatic syndrome may be the etiologic link.

CLINICAL FEATURES

Symptomatic anemia in the older patient may manifest as pallor, fatigue, lassitude, pulsatile tinnitus, and anginal chest pain (Chap. 34). Iatrogenic Cushing syndrome and the physical stigmata of secondary hemochromatosis are seen in patients after prolonged glucocorticoid administration and long-term red cell transfusion therapy. Concomitant diseases include CLL and lymphomas, collagen vascular disorders, myasthenia gravis, especially in the setting of thymoma, and some cancers. Red cell aplasia also occurs with pregnancy. Persistent B19

parvovirus infection should be suspected in the anemic cancer patient after stem cell transplantation, in patients treated with immunosuppressive drugs, in patients with AIDS, and in patients with a family or personal history suggestive of inherited immune disorder. Other viral infections have been implicated in pure red cell aplasia, including infectious mononucleosis and an unknown agent in seronegative hepatitis.

LABORATORY FEATURES

Anemia is either normocytic or macrocytic, reticulocytopenia is profound, and white cell and platelet counts are generally normal. The marrow shows absent or very few erythroid precursor cells, but normal granulopoiesis and megakaryocytopoiesis. Iron saturation and ferritin level frequently are elevated and rise further after repeated red cell transfusions. Erythroid colony assays may predict responsiveness to immunosuppressive treatment. The presence of marrow or blood BFU-E and CFU-E correlates with hematologic improvement,^{130,158,159} but these tests may not be generally available.

Thymomas are frequently associated with autoimmune disease, myasthenia gravis most prominently and occasionally with marrow failure syndromes.¹⁶⁰ In pure red cell aplasia, a thymoma should be sought by chest imaging, including computed tomographic scan. The association of thymoma and pure red cell aplasia has been emphasized but is uncommon: thymoma in only two of 37 red cell aplasia patients,¹⁶¹ and only two instances of red cell aplasia in a series of 29 thymoma patients.¹⁶² The thymomas usually are encapsulated and have a spindle cell histology. In one series, 10 of 56 cases were considered malignant because of their locally infiltrating character¹⁶³; therefore, the tumors should be surgically excised, if feasible.

CLL should be evident based on elevated lymphocyte count and immunophenotyping for monoclonality. LGL (Chap. 94), which frequently underlies red cell aplasia, may be more subtle. Its diagnosis requires careful examination of the blood film for typical lymphocytic forms, flow cytometry for cell surface markers characteristic of natural killer and cytotoxic lymphocytes, and demonstration of monoclonal T-cell proliferation by molecular studies.

Persistent parvovirus infection can be difficult to diagnose. Giant pronormoblasts scattered on the marrow film are the most characteristic of the condition (see Fig. 36-1), but such typical cells may not be observed. Marrow morphologies that are dysplastic or suggestive of leukemia also have been described. Serum antibodies specific to the virus are absent or only IgM is positive. Parvovirus DNA should be present in high concentrations in the blood and readily detected by molecular techniques.

DIFFERENTIAL DIAGNOSIS

Distinction between inherited and acquired red cell aplasia may be impossible in the younger patient. Rarely, pure red cell aplasia is difficult to distinguish from more generalized marrow failure if other blood counts are borderline. A dysmorphic marrow smear and abnormal chromosomes point to myelodysplasia as responsible for isolated anemia and reticulocytopenia. B19 parvovirus infection should always be suspected and searched for in any immunosuppressed individual who is anemic because the infection can be treated.

THERAPY, COURSE, AND PROGNOSIS

Treatment

Transfusion Therapy As with inherited red cell aplasia, transfusions and iron chelation are basic to management.¹⁶⁴ In an adult, 1 unit of packed erythrocytes per week can replace marrow erythropoiesis, which

for convenience usually is transfused as 2 units every 2 weeks. The goal of preventing symptoms of anemia is achievable in most patients if the nadir hemoglobin is greater than 7 g/dL (70 g/L). A goal greater than 9 g/dL (90 g/L) may be preferable in patients with cardiac or pulmonary disease and in older patients. Even refractory pure red cell aplasia is consistent with a prolonged and perhaps even normal life expectancy, and iron-chelation therapy can be initiated based on the ferritin level (Chap. 43).

Immunosuppression Immunosuppressive agents are used to treat disease of suspected immune origin. Response is likely in the majority of patients, but sequential treatment with a variety of agents often is required. Some patients, however, remain refractory to treatment.^{119,164-166} Typically, oral prednisone 1 to 2 mg/kg/day is given first, and about half of patients improve. A 1- to 2-month trial can be associated with significant toxicity and evidence of Cushing syndrome. Higher response rates have been cited for cyclosporine, and some investigators advocate using this drug first.^{53,167-171} Cytotoxic agents, especially azathioprine and cyclophosphamide,¹⁷² can be beneficial but are not first-choice because of their mutagenic and leukemogenic properties. These drugs may be preferred for red cell aplasia associated with LGL, in which cytoreduction is required.^{124,173,174} Acquired pure red cell aplasia often responds to antithymocyte globulin.^{130,159,175} More specific monoclonal antibodies have less toxicity than does antilymphocyte globulin, and can be administered without hospitalization.¹⁷⁶ Daclizumab, a monoclonal antibody directed against the IL-2 receptor, is effective in approximately 40 percent of patients.¹⁷⁷ Success has been reported also using rituximab (anti-CD20 monoclonal antibody)¹⁷⁸⁻¹⁸⁰ and alemtuzumab (anti-CD52).¹⁸¹⁻¹⁸³ Some patients with resistant disease respond to fludarabine and cladribine.^{184,185} Plasmapheresis^{186,187} has produced long-lasting improvement in a few patients, presumably by removing pathogenic antibodies.¹⁸⁶ The absence of randomized trials and even case series of adequate sample size makes the extrapolation of case reports to quantitative estimates of response problematic for many of these therapies.¹⁶⁴

A thymoma should be excised to prevent local spread of a malignant tumor, but thymectomy does not necessarily improve marrow function.¹⁶³ Red cell aplasia can follow thymectomy. Cyclosporine appears the most effective drug to treat pure red cell aplasia associated with thymoma.¹⁸⁸ Red cell aplasia is rarely an indication for stem cell transplantation because the anemia usually can be managed with less drastic approaches. Unresponsive patients have been cured by infusion of allogeneic stem cells after cyclophosphamide conditioning.^{189,190}

Other Therapies Despite early favorable case reports, androgens, erythropoietin, and splenectomy are not routinely used to treat pure red cell aplasia.

Immunoglobulin for Persistent B19 Parvovirus Infection Persistent parvovirus infection results from the inability of the host to mount an effective humoral immune response. It can be effectively treated in almost all cases by administration of commercial immunoglobulin,^{191,192} an excellent source of neutralizing antibodies present in a large proportion of the normal population. Infusion of immunoglobulin at 0.4 g/kg/day for 5 to 10 days should produce brisk reticulocytosis and restore a hemoglobin level appropriate for the patient. A single course may be adequate to cure longstanding red cell aplasia resulting from an underlying inherited immunodeficiency syndrome,¹⁹³ but patients with AIDS may not show complete clearance of parvovirus from the circulation and may relapse, requiring retreatment¹⁴⁷ or maintenance immunoglobulin injections (Fig. 36-2).^{147,194} Patients suffering from persistent B19 parvovirus infection do not have typical manifestations of a viral infection, such as fever. In these patients, immunoglobulin infusions can induce fifth disease symptoms of variable severity, including cutaneous eruptions and arthritis. Older case reports of red cell aplasia

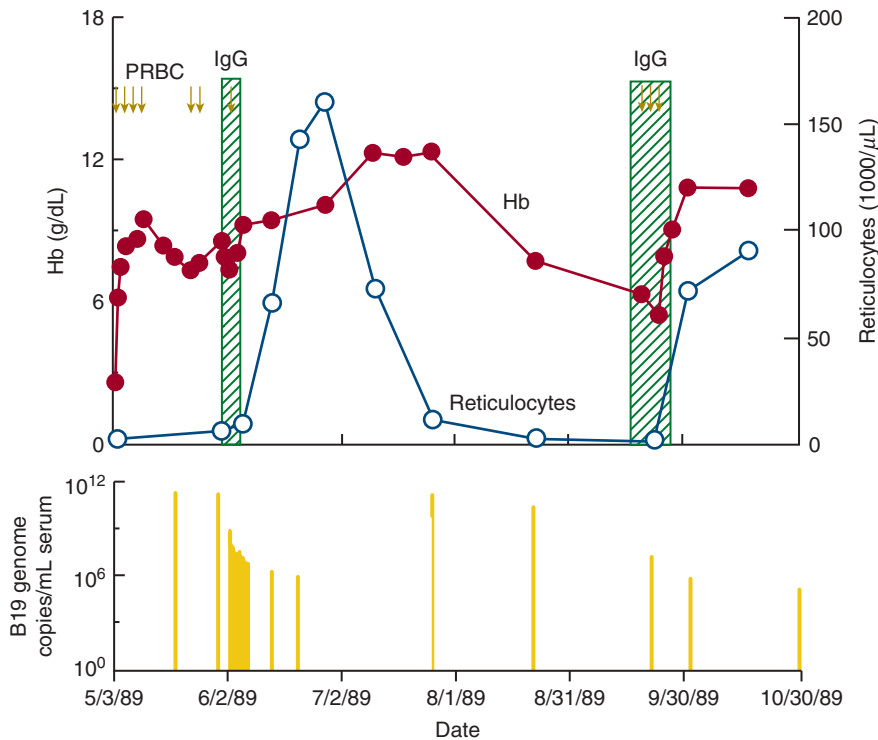

Figure 36-2. Diagram of the clinical course of a HIV-1-infected patient with red cell aplasia caused by B19 persistent parvovirus.¹²³ Note the increase of the reticulocyte count (*open circles*) to the first infusion of immunoglobulin (Ig) G (*hatched bar*) and the subsequent decline in parvovirus titers. Thereafter, the reticulocyte count and the hemoglobin (Hgb) concentration (*closed circles*) decrease, reflecting the return of the anemia. A second IgG treatment increases the reticulocyte count and Hgb concentration and decreases the parvovirus titers. PRBC, packed red blood cells.

responsive to immunoglobulin infusions likely represent treatment of patients with previously unrecognized parvovirus infection.

CHAPTER 37

ANEMIA OF CHRONIC DISEASE

Tomas Ganz

SUMMARY

Most patients suffering from chronic infection, chronic inflammation, or some with various malignancies develop a mild to moderate anemia. This anemia, designated *anemia of chronic disease* or *anemia of chronic inflammation*, is characterized by a low serum iron level, a low to normal transferrin level, and a high to normal ferritin level. The anemia is caused by the direct and indirect inhibitory effects of inflammatory cytokines on erythrocyte production. Among the cytokines, interleukin-6 has a central role, acting by increasing hepatocyte production of the iron-regulatory hormone hepcidin. Hepcidin then blocks the release of iron from macrophages and hepatocytes, causing the characteristic hypoferrinemia associated with this anemia, and limiting the availability of iron to the developing erythrocytes. Effective treatment of the underlying disease restores normal erythropoiesis. When this is not possible, and treatment is necessary, therapeutic trials have revealed that the anemia is often responsive to pharmacologic doses of erythropoietin.

Anemia of chronic kidney disease presents similarly to anemia of inflammation but because the kidneys are the predominant site of erythropoietin production, the pathogenesis of this anemia is frequently dominated by relative erythropoietin deficiency, where erythropoietin concentrations in serum are lower than expected for the severity of anemia. Systemic inflammation from underlying renal disease, or induced by dialysis treatments and their complications, contributes to pathogenesis in a manner similar to anemia of inflammation. Circulating hepcidin concentrations may also rise because of its decreased renal clearance. Suppressing effects of uremia on erythropoiesis and blood losses from hemodialysis may contribute to anemia in end-stage renal disease. A combination of erythropoiesis-stimulating agents and intravenous iron is usually effective in reversing anemia but overtreatment may worsen overall outcomes.

DEFINITION AND HISTORY

The term *anemia of chronic disease* (ACD) or *anemia of chronic disorders* refers to mild to moderately severe anemia (hemoglobin [Hgb] 7 to 12 g/dL) associated with chronic infections and inflammatory disorders and some malignancies.¹ The newer name, *anemia of inflammation*

(AI), is not only more reflective of the pathophysiology of ACD but also includes *anemia of critical illness*,² a condition that presents similarly to ACD but develops within days of the onset of illness. An anemia similar to AI is seen in some older individuals in the absence of an identifiable chronic disease; this condition is sometimes referred to as *unexplained anemia of elderlies* or *anemia of aging* (Chap. 9).³

AI is characterized by inadequate erythrocyte production in the setting of low serum iron and low iron-binding capacity (i.e., low transferrin) despite preserved or even increased macrophage iron stores in the marrow. The erythrocytes are usually normocytic and normochromic but can be mildly hypochromic and microcytic. Anemia of critical illness² can develop acutely (within days) in intensive care settings where the effects of infection or inflammation are exacerbated by disease-related or iatrogenic blood loss or red cell destruction, which by themselves are not sufficiently severe to cause anemia. Anemia of aging³ is diagnosed in the older when a normocytic normochromic anemia with low serum iron and preserved iron stores develops without an identified underlying disease. Older patients in this defined subset typically have an elevated sedimentation rate and/or elevated C-reactive protein (CRP), a high plasma interleukin (IL)-6 concentration, and frailty.

Anemia of chronic kidney disease (CKD) usually develops as chronic renal disease progresses and generally becomes more severe with decreasing creatinine clearance (Fig. 37-1). The anemia presents similarly to AI but because the kidney is the main site of erythropoietin (EPO) production in adults, the progressive destruction and fibrosis of the kidneys causes relative EPO deficiency, which frequently dominates the pathogenesis of this anemia. Patients with polycystic kidney disease are often at least partially spared of the anemia, whereas patients with bilateral nephrectomy are particularly severely affected by EPO deficiency. Systemic inflammation, true iron deficiency and decreased clearance of hepcidin are common consequences of the underlying disease and dialysis treatments, and one or more of these factors frequently worsen anemia or diminish the response to EPO therapy.

Physicians have known about the pale appearance of patients with chronic infections for hundreds of years. In 19th-century Europe, tuberculosis was the major killer and the pallor associated with this disease was romanticized in the art literature of the time. The first measurements of red cell mass revealed the association between inflammation and anemia. Discussing “the alterations in the condition of the Blood in Inflammation” in Section 372 of the 1859 edition of the *Principles of Human Physiology*, William B. Carpenter⁴ described this connection between inflammation and anemia (author’s parentheses): “With this increase in the proportion of fibrin and colorless corpuscles (leukocytes), separately or in combination, there is a diminution of the proportion of the red corpuscles, albumen and the salts of the blood.” In 1961, 100 years later, Maxwell Wintrobe, in the fifth edition of *Clinical Hematology*,⁵ used the term “simple chronic anemia” for the normocytic anemia associated with the majority of infections and chronic systemic diseases. He described anemia associated with inflammation as a common subtype. Wintrobe proposed “profound alterations in iron and porphyrin metabolism” as the likely cause, and referred to his own experiments that showed a decrease in erythrocyte survival of only 27 percent, which “could easily be met by increased erythropoiesis if the bone marrow functional capacity were not impaired.” Despite advances in our understanding of the pathophysiology of this very common form of anemia, our knowledge is incomplete.

Anemia of CKD became a common problem in the 1960s when hemodialysis became widely available and allowed prolonged survival of patients with end-stage renal failure. Anemia of CKD was usually severe enough to limit activities of daily living and was treated by blood transfusions until the late 1980s when recombinant EPO became widely available, and alleviated the most severe forms of this anemia.

Acronyms and Abbreviations: ACD, anemia of chronic disease; AI, anemia of inflammation; CKD, chronic kidney disease; CPG, clinical practice guideline; CRP, C-reactive protein; EPO, erythropoietin; ESA, erythropoiesis-stimulating agent; IDA, iron-deficiency anemia; IL, Interleukin; KDIGO, The Kidney Disease Improving Global Outcomes; sTfR, soluble transferrin receptor; TfR, transferrin receptor; TNF, tumor necrosis factor.

Figure 37-1. Relationship between hematocrit (Hct) and creatinine clearance in patients with CKD. Anemia worsens with decreasing creatinine clearance. (Reproduced with permission from Radtke HW, Claussner A, Erbes PM, et al: Serum erythropoietin concentration in chronic renal failure: relationship to degree of anemia and excretory renal function. *Blood* 54(4):877–884, 1979.)

EPIDEMIOLOGY

The high prevalence of infectious diseases worldwide and the high prevalence of inflammatory and malignant disorders in industrialized countries would suggest that AI is the second or third most common form of anemia after iron-deficiency anemia (IDA) and possibly thalassemia.⁶ Although the prevalence of iron deficiency in the industrialized countries is now rapidly decreasing,^{6,7} AI is expected to increase as the population ages. Table 37-1 lists the most common diseases associated with AI.

Although anemia can develop early in the progression of CKD, it generally worsens as the kidneys fail.^{8–10} Accordingly, the prevalence of patients with anemia of CKD worldwide is influenced by the availability of life-sustaining dialysis therapies. It is estimated that there are currently approximately 600,000 patients with end-stage renal disease in the United States, and approximately 100,000 new patients each year,¹¹ the majority of whom are anemic or receive treatment for anemia.⁹ Additional patients with milder anemia of CKD are found among the estimated 6.7 percent of the U.S. population (or approximately 20 million) identified as having likely CKD (estimated glomerular filtration rate [eGFR] <60 mL/min/1.73 m²) in the 2007–2010 National Health and Nutritional Examination Surveys (NHANES) study.¹¹

TABLE 37-1. Common Conditions Associated with Anemia of Inflammation

Category	Diseases Associated with Anemia of Inflammation
Infection	AIDS/HIV, tuberculosis, malaria (contributory), osteomyelitis, chronic abscesses, sepsis
Inflammation	Rheumatoid arthritis, other rheumatologic disorders, inflammatory bowel diseases, systemic inflammatory response syndrome
Malignancy	Carcinomas, multiple myeloma, lymphomas
Cytokine dysregulation	Anemia of aging

ETIOLOGY AND PATHOGENESIS

In the chronic setting, AI predominantly results from the body's inability to increase erythrocyte production to compensate for relatively small decrements in erythrocyte survival (reviewed in Ref. 1). In the steady state, erythrocyte production is sufficiently high so that the resulting anemia is mild to moderate. The anemia associated with acute critical illness has the same pathogenesis as other forms of AI but it develops more rapidly perhaps because of the more extensive erythrocyte destruction and intensive diagnostic phlebotomy common in this setting. The key questions about the pathogenesis of AI, still only partially answered, are: (1) What accounts for the inability of the AI marrow to increase erythropoiesis? and (2) How is this deficit connected to the characteristic hypoferrremia and sequestration of iron in macrophages and hepatocytes? Anemia of CKD is similar to AI but the underlying renal pathology also impairs the ability of the kidneys to produce enough EPO leading to insufficient compensatory erythropoiesis.

RED CELL DESTRUCTION

Human studies indicate that transfused AI erythrocytes have a normal life span in normal recipients but transfused normal erythrocytes have a decreased life span in AI recipients.¹ This finding suggests that increased erythrocyte destruction is caused by the activation of hosts factors such as macrophages that prematurely remove aging erythrocytes from the bloodstream. The explanation is consistent with the predominance of young erythrocytes in AI. Whether extrinsic factors, such as bacterial toxins and medications, or host-derived antibodies or complement contribute to this process is unknown.

SUPPRESSIVE EFFECTS OF INFLAMMATION ON ERYTHROPOIETIC PRECURSORS

Some cytokines, chiefly tumor necrosis factor (TNF)- α , IL-1, and the interferons, exert a suppressive effect on erythroid colony formation.¹² Interferon- γ overproduction suppresses erythropoiesis in a mouse model¹³ by reducing erythrocyte life span and decreasing erythropoiesis without any evidence of iron restriction. It is not known to what extent and under what conditions these mechanisms contribute to human AI.

INADEQUATE ERYTHROPOIETIN SECRETION AND RESISTANCE TO ERYTHROPOIETIN

The normal response to increased destruction of erythrocytes is transient anemia followed by an increase in EPO production and subsequent compensatory increase in erythropoiesis. One proposed explanation for the inadequate marrow response in AI is less EPO production than expected based on other types of anemia. Studies of patients with rheumatoid arthritis and AI indicated that EPO levels are increased but less so than in IDA.^{14–19} The findings were similar in patients with anemias associated with solid tumors or hematologic malignancies.^{20,21} However, these comparisons did not take into account the potentiating effect of iron deficiency on hypoxia sensing (Chaps. 32 and 42).²² This effect could increase EPO production in IDA above that in other types of anemia, and make EPO production in AI appear low in comparison. In support of the EPO suppression hypothesis are experiments with EPO-producing cell lines indicate that production of the hormone is inhibited by inflammatory cytokines including TNF- α and IL-1. The inhibition is mediated by the effects of the transcription factor GATA-1 on the EPO gene promoter, and the suppression of EPO production can be reversed by a GATA inhibitor.²³ Moreover, both baseline and hypoxia-induced EPO gene expression is suppressed in rats treated with

bacterial lipopolysaccharide or IL-1 β to mimic a septic state.²⁴ However, suppression of EPO production is not the major mechanism of AI. If it were, administration of relatively small amounts of EPO should be sufficient to reverse the AI.

In contrast, relative EPO deficiency is often a major contributor to anemia of CKD. Most destructive diseases affecting the kidneys also decrease the release of EPO.^{25,26} In the kidney, interstitial fibroblasts of neural crest origin^{26,27} are probably the main source of EPO, but the identity of EPO-producing cells in the kidney remains controversial, mostly because the basal production of EPO is very low and ultrasensitive methods are required to detect the source of the hormone. In response to anemia or hypoxia, the number of renal cells producing EPO increases. In advanced CKD, the kidneys undergo end-stage fibrosis, during which these fibroblasts may transdifferentiate into myofibroblasts and lose their ability to produce appropriate amounts of EPO in response to hypoxia.^{26,27} However, these or other renal cells can be activated to increase their EPO output by the administration of therapeutic prolyl-hydroxylase inhibitors²⁸ (Chap. 32), as indicated by the lower stimulated EPO production by anephric patients compared to those with end-stage renal disease and retained kidneys. Studies in animal models indicate that the impairment of EPO production in end-stage kidneys may be reversible and could be therapeutically restored.^{26,27}

Inflammation is also a strong contributor to the pathogenesis of anemia of CKD. Patients who had renal disease with inflammation, as measured by increased serum CRP greater than 20 mg/L, required on the average 80 percent higher doses of EPO than patients with simple primary EPO deficiency from renal disease.²⁹ In another study, patients with CRP greater than 50 mg/L reached lower concentrations of Hgb than patients with CRP less than 50 mg/L, despite higher doses of erythropoiesis-stimulating agents.³⁰ Inflammation thus induces a state of relative resistance to EPO, contributing to the pathogenesis of anemia of CKD.

ERYTHROPOIESIS RESTRICTION AS A RESULT OF IRON UNAVAILABILITY

Interleukin-6, Hepcidin, and Hypoferremia

Hypoferremia, one of the defining features of AI, develops within hours of the onset of inflammation.¹ Although previous studies of cytokine mediators of hypoferremia of inflammation were inconclusive, subsequent work³¹ indicates that the response is dependent on IL-6 which induces the iron-regulatory hormone, hepcidin.³² Unlike wild-type mice, mice deficient in either hepcidin³³ or IL-6³⁴ do not become hypoferremic during turpentine-induced inflammation. In human hepatocyte cell cultures, IL-6 is a potent and direct inducer of hepcidin and neither IL-1 nor TNF- α share this activity. The central role of IL-6 is further indicated by the observation that IL-6-deficient mice do not acutely induce hepcidin in response to turpentine inflammation. Infusion of IL-6 into human volunteers induces hepcidin release within hours and causes concomitant hypoferremia.³⁵ The IL-6–hepcidin axis now appears to be responsible for the induction of hypoferremia during inflammation. However, these studies do not exclude the potential contribution of other cytokines, including activin B and interferon- γ ,^{13,36} to AI in human diseases or more complex mouse models. In support of multiple pathways of AI in a mouse model of inflammation, either the ablation of hepcidin or the ablation of IL-6 ameliorated the anemia, but neither restored normal Hgb concentration.^{37,38}

Serum Iron Concentration Is Dependent on Iron Released from Macrophages and Hepatocytes

In the steady state, almost all of the approximately 20 to 25 mg of iron that daily enters the plasma iron/transferrin pool comes from

macrophage recycling of senescent erythrocytes and from hepatocyte iron stores; only approximately 1 to 2 mg come from dietary iron. Only approximately 2 to 4 mg of iron is bound to transferrin but the entire daily iron flow transits through this compartment; thus, the iron in this pool turns over every few hours. During inflammation the release of iron from macrophages and probably also from liver stores is markedly inhibited.^{39–45} Studies in transgenic mice lacking hepcidin and mice overexpressing hepcidin indicate that the peptide is a negative regulator of iron release from macrophages and of intestinal iron uptake.^{46,47} During inflammation, IL-6 induces hepcidin production, which in turn inhibits iron release from macrophages (and probably from hepatocytes), leading to hypoferremia (Fig. 37–2). Hepcidin acts by binding to cell membrane-associated ferroportin molecules that are the only conduits for iron export, and inducing ferroportin internalization and degradation.⁴⁸ As hepcidin concentrations increase, less and less ferroportin is available for iron export and the iron release into plasma from macrophages, hepatocytes, and enterocytes decreases.

Erythropoiesis in Anemia of Inflammation Is Limited by Iron

As an intermediate step during the synthesis of heme, iron becomes incorporated into protoporphyrin IX. Zinc is an alternative protoporphyrin ligand. In iron deficiency, increased amounts of zinc are incorporated into protoporphyrin. In AI, zinc protoporphyrin is also increased.⁴⁹

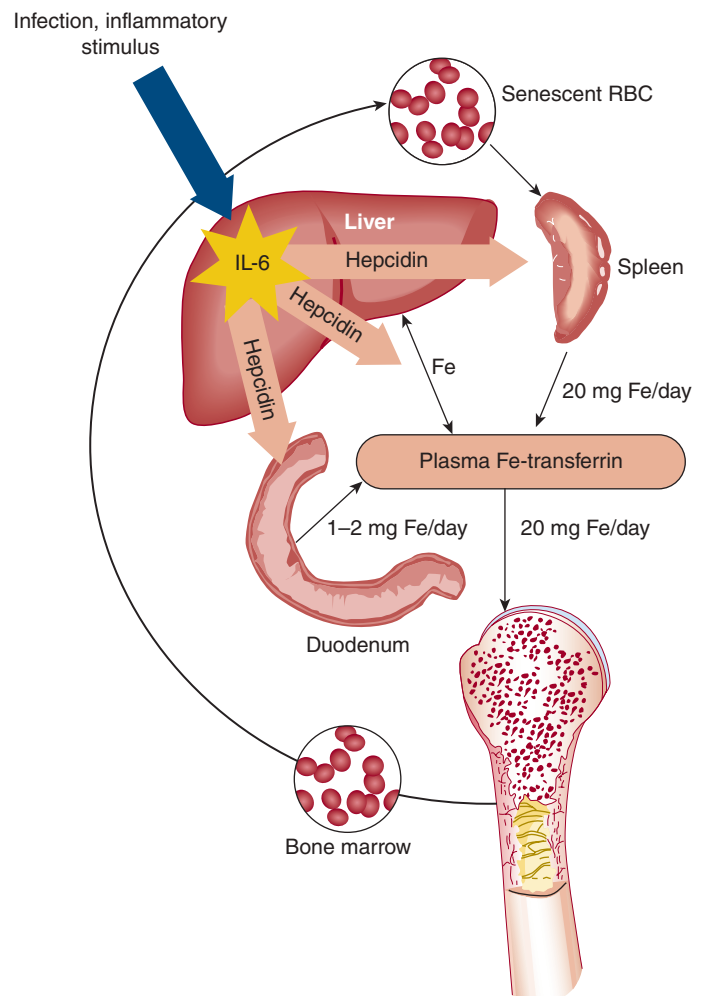

Figure 37–2. Diagram of the effect of inflammation on iron concentrations in plasma. Arrows labeled “Hepcidin” indicate control points where hepcidin inhibits iron flow into the plasma transferrin compartment.

Insufficient iron reaches the sites of heme synthesis in developing erythrocytes, leading to the substitution of zinc. Moreover, the number of sideroblasts, nucleated erythrocyte precursors that stain for iron with Prussian blue, is decreased in AI.¹ A further indication of the limiting role of iron in patients with AI but no evidence of iron deficiency is that coadministration of parenteral iron can resolve the resistance of AI to EPO.^{50,51} Attempts to treat AI with iron alone generally have been less successful, as iron became rapidly trapped in the macrophage compartment.^{1,52,53}

In the context of anemia of CKD, increased zinc protoporphyrin and decreased reticulocyte Hgb is also characteristic of functional iron deficiency during intense bursts of erythropoiesis stimulated by pharmacologic doses of EPO derivatives.⁵⁴

Inhibition of Intestinal Absorption of Iron and Other Factors Leading to Systemic Iron Deficiency

In longstanding AI, erythrocytes can become hypochromic and microcytic, partly because progressive depletion of iron stores worsens the iron restriction. Intestinal absorption of iron is inhibited^{55–57} during inflammation by an IL-6 and hepcidin-mediated mechanism.^{58–62} Only 1 to 2 mg of the daily iron needed for erythropoiesis comes from the diet and most adults have 400 to 2000 mg of iron stores (Chap. 42); therefore, a considerable amount of time is needed to deplete the stored iron. True iron deficiency can eventually develop in chronic inflammatory diseases, especially in children who have smaller iron stores and an additional requirement for iron because of body growth, or in conditions where IL-6 levels are particularly high, such as systemic-onset juvenile chronic arthritis.⁶³ The anemia in these children was accompanied by an appropriate EPO increase, but was unresponsive to oral iron replacement. The anemia was corrected, at least partially, by parenteral iron.

In anemia of CKD, several additional factors may contribute to true iron deficiency, including the blockade of intestinal iron absorption by higher hepcidin concentrations from its decreased renal clearance and the blood losses from hemodialysis, phlebotomy for laboratory studies, and occult gastrointestinal bleeding.

Summary of Pathogenesis

AI is primarily the result of slightly decreased red cell survival and of macrophage iron sequestration leading to iron-restricted erythropoiesis. Depending on the underlying disease, the condition is compounded by inadequate EPO production, suppressive effect of inflammation on erythropoietic precursors, or depletion of iron stores. Anemia of CKD is dominated by the effects of relative EPO insufficiency but inflammation and blood loss also contribute to its pathogenesis.

CLINICAL FEATURES

The clinical manifestations of AI and anemia of CKD are usually obscured by the signs and symptoms of the underlying disease. Moderate anemia (Hgb <10 g/dL) can exacerbate the symptoms of preexisting ischemic heart disease or respiratory disease, or contribute to fatigue and exertional intolerance. More severe untreated anemia seen mainly with CKD may cause extreme fatigue, dyspnea on exertion, and high-output congestive heart failure. The diagnosis is based on clinical features found in conjunction with typical laboratory abnormalities.

LABORATORY FEATURES

The erythrocytes in AI and anemia of CKD are usually normocytic and normochromic but, with increasing severity or duration, can sometimes become hypochromic and eventually microcytic.¹ The absolute reticulocyte count is normal or slightly elevated.

HYPOFERREMIA AND INCREASED SERUM TRANSFERRIN

Hypoferremia, a decrease in serum iron concentration, is a defining feature of AI and, in the absence of iron therapy, is also commonly seen in anemia of CKD. It develops within hours of the onset of infection or severe inflammation. The concentration of the iron-binding protein, transferrin (measured as total iron binding capacity), is moderately decreased in AI, unlike in IDA in which transferrin concentration is increased. The decrease in transferrin concentrations develops more slowly than the decrease in serum iron levels because of the longer half-life of transferrin (8 to 12 days)⁶⁴ compared to the turnover of plasma iron (approximately 90 minutes).

INCREASED SERUM FERRITIN

Serum ferritin concentrations, which reflect iron stores and inflammation, are increased in AI but decreased in iron deficiency. Thus, serum ferritin is useful in differential diagnosis in patients with low serum iron concentrations.⁶⁵ Depleted iron stores in patients with coexisting inflammation may result in intermediate ferritin levels (Table 37–2 and Fig. 37–3) because ferritin is an acute-phase protein and inflammatory cytokines increase ferritin synthesis. In this situation, iron deficiency should be suspected if ferritin concentrations are less than 60 mcg/L. Soluble transferrin receptor (sTfR) levels (Table 37–2) increase with increased demand of the erythroid marrow for iron but inflammation may have a direct suppressive effect on sTfR. As a result, sTfR is increased in iron deficiency but, unlike ferritin, it is unchanged or decreased during infection or inflammation.⁶⁶ Although these properties should make sTfR a useful diagnostic parameter alone or in combination with ferritin,⁶⁷ the use of sTfR in practice has been hampered by inadequate standardization and inconsistent reports of its clinical utility. Another promising marker that may differentiate AI from systemic iron deficiency is serum hepcidin, as very low serum hepcidin levels in the setting of hypoferremia are diagnostic of systemic iron deficiency. However, the assays have not yet been standardized and the clinical utility of hepcidin measurements in differential diagnosis of anemia has not yet been tested in large heterogeneous patient populations.⁶⁸

Low serum ferritin concentrations are indicative of iron deficiency in anemia of CKD but normal or even high ferritin concentrations do not preclude a clinical response (increased Hgb) after parenteral iron therapy. In these settings, high ferritin levels may largely reflect inflammation, and augmented iron supply may be needed to overcome “functional iron deficiency,”⁵⁴ that is, to provide sufficient iron supply for pulsatile erythropoiesis stimulated by intermittently administered pharmacologic doses of EPO or its derivatives.⁶⁹

MARROW IRON STAIN

Marrow aspiration or biopsy is rarely required for the diagnosis of AI. In general, the marrow is normal, unless the underlying disease alters the picture. The most important information obtained from marrow examination is the content and distribution of iron. Iron in a marrow preparation can be found as storage iron in the cytoplasm of macrophages or as functional iron in nucleated red cells. In normal individuals, a few Prussian blue–staining particles can be found inside or adjacent to many macrophages. Approximately one-third of nucleated red cells contain one to four blue inclusion bodies and such cells are called *sideroblasts*. Both sideroblasts and macrophage iron are absent in iron deficiency. In contrast, sideroblasts are decreased or absent but macrophage iron is increased in AI. The increase in storage iron in association with a decreased level of circulating iron and a decreased

f, Females; m, males; TfR, transferrin receptor.

Diagnosis was defined by marrow iron stain and appropriate coexisting disease. Patients with a combination of no stainable marrow iron and either coexisting disease or elevated CRP were classified as “COMBI.” Normal ranges for this laboratory for males (m) and females (f) are indicated. Measurements are presented as mean ± SD (median).

number of sideroblasts is characteristic of AI. Although marrow stain could be considered the gold standard for differential diagnosis of AI and iron deficiency, the discomfort to the patient associated this procedure, reports of variability in interpretation⁷⁰ and the wide availability of the serum ferritin assay have decreased the use of marrow stain in this setting.

Figure 37-3. Distribution of serum ferritin measurements in patients with iron-deficiency anemia (IDA), anemia of chronic disease (ACD = anemia of inflammation [AI]) and combined IDA and ACD (COMBI). The horizontal lines indicate lower normal values for healthy men and women. (Reproduced with permission from Punnonen K, Irjala K, Rajamaki A: Serum Transferrin Receptor and Its Ratio to Serum Ferritin in the Diagnosis of Iron Deficiency. *Blood* 89(3):1052–1057, 1997.)

DIFFERENTIAL DIAGNOSIS

Most patients with chronic infections, inflammatory diseases, or neoplastic disorders are anemic. The diagnosis of AI should only be made if the anemia is mild to moderate, the serum iron and iron-binding capacity are low, and the serum ferritin is elevated. Anemia of CKD is rare in mild renal disease but common and often severe in end-stage renal disease. Underlying diseases, comorbidities, and their treatments can cause many types of anemia, so other potential causes should be considered.

1. *Drug-induced marrow suppression or drug-induced hemolysis* can complicate infections, inflammatory disorders, CKDs, and cancer. When the marrow is suppressed by cytotoxic drugs or idiopathic toxic reaction, serum iron tends to be high and reticulocyte count low. In hemolysis, reticulocyte counts, haptoglobin, bilirubin, and lactate dehydrogenase often are elevated.
2. *Chronic blood loss* depletes iron stores and decreases serum iron and serum ferritin but increases transferrin (Chap. 43). When AI and chronic blood loss coexist, serum ferritin usually indicates the predominant disorder, although the level can increase as a result of inflammation itself. Chronic blood loss from hemodialysis or occult gastrointestinal bleeding is common in anemia of CKD and its lowering effect on ferritin may be masked by coexisting inflammation. Testing stool for occult blood and looking for other sources of overlooked blood loss, including phlebotomy, urinary loss and menorrhagia, often identify the source of bleeding. Once this issue is addressed, a successful trial of iron repletion confirms the diagnosis of iron deficiency complicating AI or anemia of CKD.
3. *Endocrine disorders*, including hypothyroidism and hyperthyroidism, testicular failure, and diabetes mellitus, can be associated with a chronic normocytic, normochromic anemia (Chap. 38). Unless inflammation or associated iron deficiency is present, serum iron should be normal in these disorders.
4. *Anemia resulting from metastatic invasion of the marrow* by tumors can be the presenting symptom of malignancy. The anemia can develop in the setting of a previous diagnosis of carcinoma or lymphoma and by itself is accompanied by normal or increased serum iron (Chap. 45). It often develops in the setting of preexisting malignancy-related AI. The blood film often is abnormal, with poikilocytes, teardrop-shaped red cells, normoblasts, or immature

myeloid cells. Direct marrow examination is necessary to establish the diagnosis.

5. *Thalassemia minor* is a common cause of mild anemia in many parts of the world. It can be confused with AI (Chap. 48). Microcytosis is a life-long condition and usually is more severe in this group of disorders than in AI.
6. *Dilutional anemia* is seen in pregnancy and in patients with severely increased plasma protein levels as a result of multiple myeloma or macroglobulinemia (Chap. 109).

● THERAPY, COURSE, AND PROGNOSIS

Anemia that presents in the setting of infection, inflammation, or malignancy requires sufficient diagnostic studies to rule out reversible and potentially more threatening causes, such as occult hemorrhage; iron, vitamin B₁₂, and folate deficiencies; hemolysis; and drug reaction. If the anemia can be designated as AI after such studies, effective treatment of the underlying disease resolves the anemia. If treatment of the underlying disease is not effective and the patient has symptoms or medical complications attributable to anemia, one or more of the available anemia-specific treatment modalities should be considered (Table 37–3). These recommendations are also applicable to anemia of CKD where, for most patients, only renal transplantation can reverse the underlying pathology. However, although anemia generally resolves or improves after renal transplantation, 30 to 40 percent patients continue to be anemic, mainly because of pathologic changes in the transplanted kidney and adverse effects of immunosuppressive drugs.^{71–78}

Specific therapy for AI and anemia of CKD employs erythrocyte transfusions, erythropoiesis-stimulating agents (ESAs) and intravenous iron (see Table 37–3). Transfusion of erythrocytes is used to correct AI or anemia of CKD when anemia is moderate to severe and the patient is acutely symptomatic. Because treatment with ESAs often effectively treats chronic anemia but may increase the risk of thromboembolic events,^{79–82} guidelines have been proposed for appropriate use of these agents. The widespread adjunctive use of intravenous iron with ESAs may increase their effectiveness and reduce the required doses but

evidence to date has not resulted in a consensus on specific indications for intravenous iron or its optimal dosing.⁸³

THERAPY FOR ANEMIA OF INFLAMMATION

EPO therapy for the treatment of AI has been tested in the setting of various cancers,^{84,85} multiple myeloma and other hematologic malignancies,^{21,86,87} rheumatoid arthritis,^{88–91} and inflammatory bowel diseases.^{92,93} In most reports, more than 50 percent of the patients experienced Hgb increases greater than 2 g/dL. Guidelines for the use of EPO in anemia associated with hematologic and nonhematologic malignancy were published in 2002⁹⁴ and updated in 2007⁹⁵ and again in 2010.⁹⁶ Because of shared pathogenesis between anemia of cancer and AI, and the absence of more specific recommendations, these form a reasonable guide for the EPO treatment of AI. The guidelines (used and quoted or paraphrased here with permission) recommend treating patients with Hgb less than 10 g/dL when necessary to avoid red blood cell transfusions, and after discussion of the patient's preferences between transfusion and EPO treatment. Furthermore, the FDA recommends that dosing should be "titrated for each patient to achieve and maintain the lowest hemoglobin level sufficient to avoid the need for blood transfusion." Because of reports of increased risk of thromboembolism in patients receiving these agents, clinicians should carefully weigh the risks of thromboembolism in patients for whom ESAs are prescribed. An optimal target Hgb concentration cannot be definitively determined from the available literature. Modification to reduce the ESA dose is appropriate when Hgb reaches a level sufficient to avoid transfusion or the increase exceeds 1 g/dL in any 2-week period to avoid excessive ESA exposure. The FDA-approved starting dose of epoetin is 150 U/kg three times a week or 40,000 U weekly subcutaneously. The FDA-approved starting dose of darbepoetin is 2.25 mcg/kg weekly or 500 mcg every 3 weeks subcutaneously. Alternative starting doses or dosing schedules have shown no consistent difference in effectiveness on outcomes, including transfusion and Hgb response, although they may be considered to improve convenience. Dose escalation should follow FDA-approved labeling; no convincing evidence exists to suggest differences in dose escalation schedules are associated with different effectiveness. Continuing the ESA treatment

beyond 6 to 8 weeks in the absence of response (e.g., <1 to 2 g/dL rise in Hgb), does not appear to be beneficial and EPO therapy should be discontinued. The most recent specific guidelines for dose reduction are contained in the FDA-approved package insert. Baseline and periodic monitoring of iron, total iron-binding capacity, transferrin saturation, or ferritin levels and instituting iron repletion when indicated may be valuable in limiting the need for EPO, maximizing symptomatic improvement for patients, and determining the reason for failure to respond adequately to EPO.

THERAPY FOR ANEMIA OF CHRONIC KIDNEY DISEASE

The most current recommendations are The Kidney Disease Improving Global Outcomes (KDIGO) clinical practice guideline (CPG) for anemia in CKD,⁹⁷ based upon systematic literature searches last conducted in October 2010 and supplemented with additional evidence through March 2012. For adult patients, these guidelines recommend that a newly anemic patient with CKD should have laboratory studies to rule out vitamin B₁₂ and folate deficiencies (Chap. 41), and a therapeutic trial of IV iron if their transferrin saturation is equal to or less than 30 percent and ferritin is equal to or less than 500 ng/mL. After the guidelines were published, the recommendation for a trial of IV iron received some support from a randomized trial showing that IV iron therapy delays or reduces the need for other anemia management including ESAs.⁹⁸ However, the entry criteria for this trial were more restrictive than those in the guidelines. The guidelines go on to recommend that individualized therapy with ESAs may be started when Hgb concentrations fall below 10 g/dL and are adjusted to maintain Hgb not exceeding 11.5 g/dL unless the patient perceives an increased quality of life at higher Hgb levels (not exceeding 13 g/dL) and is willing to accept increased risks.

ADJUNCTIVE USE OF INTRAVENOUS IRON WITH ERYTHROPOIETIN

This use of IV iron is an empiric therapeutic strategy based on the idea that iron becomes limiting when marrow production of erythrocytes is pharmacologically stimulated. In some cases occult iron deficiency coexists with AI.^{66,93} In other situations, limited iron stores may become depleted when EPO is initiated.⁹¹ In hemodialysis patients with high ferritin, low transferrin saturation (less than 25 percent), and above average EPO requirements, iron supplementation of EPO treatment with a 1-g loading course of intravenous ferric gluconate was shown to lead to a small increase in Hgb and decreased dosage of EPO.^{99,100} It is not yet certain whether this strategy is applicable to other AI settings. Pending additional studies, the coadministration of iron with EPO in AI in the absence of demonstrated iron deficiency remains investigational.⁵¹ Because of its ability to decrease the use of ESAs, the use of IV iron is now common practice in CKD patients on hemodialysis, without a clear consensus about the indications and potential risks of this strategy.⁸³ Concerns exist that iron supplementation in AI or CKD may increase susceptibility to infections,^{101,102} but epidemiologic studies have not come to consistent conclusions on this risk.^{83,103,104} The use of high bolus doses of iron in patients with intravenous catheters¹⁰⁵ may be associated with increased infections.

CHAPTER 38

ERYTHROPOIETIC EFFECTS OF ENDOCRINE DISORDERS

Xylina T. Gregg

SUMMARY

Anemia is the most common hematopoietic abnormality in endocrine disorders and may be the first manifestation of an endocrine disorder. Polycythemia/erythrocytosis is less common, but occurs in certain endocrine disorders. The pathophysiologic basis of the anemia is often multifactorial, but a direct influence of hormones on erythropoiesis in some instances may contribute to anemia. A decreased plasma volume in some of these disorders may mask the severity of anemia. It has been proposed that anemia in endocrine-deficiency states may be physiologic to adjust for decreased oxygen requirements. Some endocrine disorders are associated with an impaired response to the therapeutic use of erythropoietin.

● THYROID DYSFUNCTION

HYPOTHYROIDISM

Anemia is a well-recognized complication of thyroidectomy and other causes of hypothyroidism and may also occur in subclinical hypothyroidism.¹ In a retrospective review, anemia defined as a hemoglobin less than 13 g/dL in men and less than 12 g/dL in women was present in 57 percent of patients with hypothyroidism.² The anemia in hypothyroidism has been described variably as normocytic, macrocytic, or microcytic³ coexisting deficiencies of iron, vitamin B₁₂, and folate may explain some of this heterogeneity. In a study of approximately 60 anemic patients with untreated primary hypothyroidism, 10 percent had a macrocytic anemia, all of whom had vitamin B₁₂ deficiency, 43 percent had a microcytic anemia and iron deficiency, and the remainder had a normocytic anemia.⁴ However, even when these deficiencies have been excluded, some hypothyroid patients have a macrocytic anemia.⁵ In addition, although most hypothyroid patients have a significant reduction in their red cell mass, anemia is not always evident from hemoglobin and hematocrit values owing to a concomitant reduction of plasma volume.^{6,7}

Hypothyroidism may contribute to the development of iron deficiency (Chap. 43) due to associated menorrhagia, although this association is less common than previously thought.⁸ Because thyroid hormone may augment iron absorption,^{9,10} iron deficiency in hypothyroidism may also be caused by impaired iron absorption, either directly from a lack of thyroid hormone or an associated achlorhydria.^{11,12} Conversely, iron deficiency impairs thyroid hormone synthesis by reducing the activity of heme-dependent thyroid peroxidase.¹³ In patients with coexisting iron-deficiency anemia and subclinical hypothyroidism, the anemia often does not adequately respond to oral iron therapy. Combined treatment with oral iron and levothyroxine results in superior improvement in hemoglobin and ferritin levels compared with levothyroxine alone in these patients.^{14,15}

Although the macrocytosis seen in hypothyroid patients may be due to deficiencies of vitamin B₁₂^{4,5} or folate¹⁶ (Chap. 41), hypothyroidism

also causes macrocytosis that resolves with thyroxine treatment.⁵ The mean corpuscular volume of hypothyroid patients with low vitamin B₁₂ levels is similar to those with uncomplicated hypothyroidism, so this is not a sensitive means of identifying patients with hypothyroidism complicated by B₁₂ deficiency.⁵ Although there is an established association of hypothyroidism and pernicious anemia,^{17,18} the underlying mechanism is unclear. In one analysis of 116 hypothyroid patients, 40 percent had low serum vitamin B₁₂ levels.¹⁹ Although the mean hemoglobin was slightly lower in the vitamin B₁₂-deficient group (11.9 g/L vs. 12.4 g/L), the mean corpuscular volume and prevalence of antithyroid antibodies did not differ between the two groups.¹⁹

However, even when iron deficiency, vitamin B₁₂ deficiency, and other confounding causes of anemia have been excluded, anemia can be a direct consequence of thyroid hormone deficiency.^{5,16} Dogs subjected to thyroidectomy have a normocytic, normochromic anemia that is associated with reticulocytopenia and marrow erythroid hypoplasia.²⁰ In hypothyroid humans and thyroidectomized animals, the red cell life span is normal, and results of ferrokinetic studies are compatible with hypoproliferative erythropoiesis.^{20,21} Administration of thyroid hormones increases the rate of red cell production in experimental animals,²² whereas thyroidectomy decreases red cell production.²³ Because thyroid hormones affect the cellular needs for oxygen, these responses are compatible with an appropriate physiologic adjustment. Evidence of a direct effect of thyroid hormones on erythropoiesis exists. Some *in vitro* studies show that triiodothyronine, thyroxine, and noncalorigenic resin triiodothyronine all potentiate the effect of erythropoietin on erythroid colony formation.²⁴ Thyroid hormones also increase hypoxia-induced production of erythropoietin in the rat kidney and a human hepatoma cell line.²⁵ However, other *in vitro* studies show an inhibitory effect of triiodothyronine on erythroid colony formation, particularly in combination with all-*trans* retinoic acid.²⁶

Hypothyroidism may also affect the response to erythropoietin therapy. After adjusting for other variables, the mean monthly erythropoietin dose required to maintain a target hemoglobin level in hemodialysis patients was significantly higher in hypothyroid compared with euthyroid patients.²⁷

Improvement in the hemoglobin concentration in response to thyroid hormone therapy is seen over a several-month period.⁵ White blood cell and platelet counts usually are unaffected in hypothyroidism. However, pancytopenia in association with marrow hypoplasia has been reported in a patient with myxedema coma; the hematologic abnormalities in this patient resolved with thyroid hormone replacement.²⁸

HYPERTHYROIDISM

Although thyroid hormone administration increases red cell production in animals,²⁹ humans with hyperthyroidism generally do not have erythrocytosis. Anemia is present in 10 to 25 percent of these patients.³⁰⁻³² This finding may be the result of increased plasma volume⁷; however, decreased red cell survival³³ and ineffective erythropoiesis³⁴ also have been described. Antithyroid treatment ameliorates the anemia.^{31,32} A patient with autoimmune hemolytic anemia and hyperthyroidism has been described; the hemolysis in this patient abated with treatment of the hyperthyroidism.³⁵ Pancytopenia rarely occurs but also may respond to treatment of hyperthyroidism.^{36,37}

● ADRENAL GLAND DISORDERS

ADRENOCORTICAL INSUFFICIENCY

A normocytic normochromic anemia may be seen in primary adrenal insufficiency (Addison disease),^{12,38} but the anemia may also be masked by the concomitant reduction in plasma volume that is common in

this disease.³⁸ In a series of patients with Addison disease, some patients with normal hemoglobin levels developed transient anemia after initiation of hormone replacement therapy, presumably secondary to an increased plasma volume.³⁸

In experimental animals, adrenalectomy causes a mild anemia that responds to glucocorticoids.³⁹ However, the pathophysiologic basis of the anemia and any influence of adrenal cortical hormones on erythropoiesis are not well defined.

Pernicious anemia occurs in patients with autoimmune adrenal insufficiency, but is seen primarily in patients with type I polyglandular autoimmune syndrome, whose other manifestations include mucocutaneous candidiasis and hypoparathyroidism.⁴⁰ Anemia as a result of primary erythropoietin deficiency was reported in one patient with this syndrome.⁴¹

CUSHING DISEASE AND ALDOSTERONISM

Glucocorticoids interact with erythropoietin *in vitro* to enhance erythroid colony proliferation.⁴² Glucocorticoid receptors, activated by their cognate ligand, initiate Janus kinase 2 phosphorylation-mediated cytoplasmic signal transduction, which may stimulate erythropoiesis by a mechanism shared with erythropoietin (Chaps. 32 and 57). Erythrocytosis has been reported in Cushing syndrome,⁴³ primary aldosteronism,⁴⁴ and Bartter syndrome.⁴⁵

However, a study of 63 women and 17 men with Cushing disease found that although the hemoglobin levels in the females were evenly distributed over the normal range, the hemoglobin levels were in the lowest quartile in 14 of the 17 men, and 3 of these 14 were anemic.⁴⁶ The reduced hemoglobin levels in the male patients correlated with a low testosterone level and slowly improved after treatment of Cushing disease.

CONGENITAL ADRENAL HYPERPLASIA

The most common cause of congenital adrenal hyperplasia is 21-hydroxylase deficiency, which impairs conversion of 17-hydroxyprogesterone to 11-deoxycortisol.⁴⁷ Patients with the “classic form” present during the neonatal period with adrenal insufficiency, but others have a late onset presentation with findings of androgen excess. Erythrocytosis, likely a consequence of increased androgen levels, has been reported in patients with congenital adrenal hyperplasia resulting from 21-hydroxylase deficiency,⁴⁸ and erythrocytosis has also been described as the presenting manifestation of this disease.⁴⁹

PHEOCHROMOCYTOMA

Pheochromocytomas and the closely related tumor, paraganglioma, are rarely associated with erythrocytosis. This finding is believed to be a result of autonomous erythropoietin production by the tumor,⁵⁰ often mediated by von Hippel-Lindau mutations that cause or contribute to pheochromocytoma development (Chaps. 32 and 57).

However, several individuals with congenital polycythemia have developed recurrent pheochromocytomas, paragangliomas, and sometimes somatostatinomas.^{51,52} Their tumors are heterozygous for a heterogeneous gain-of-function mutation of hypoxia-inducible factor-2 α gene and erythropoietin transcript is present in tumor tissues (Chaps. 32 and 57). However, these mutations are generally not found in non-tumor tissues, so the etiology of the association of these tumors with polycythemia is unknown.^{51,52}

A syndrome of congenital polycythemia associated with a mutation in the proline hydroxylase type 2 gene and recurrent paragangliomas has also been described in a single family.⁵³

GONADAL HORMONES

ANDROGENS

Sexually mature males have higher hemoglobin levels than prepubertal males, older males, and females.⁵⁴ This difference is attributed to androgen production. Testosterone levels directly correlated with hemoglobin levels in a community population of males 30 to 94 years of age.⁵⁵ Another study of males 70 to 81 years of age also found a correlation between hemoglobin and testosterone levels, but when individuals with hemoglobin less than 13 g/dL and/or a testosterone level less than 8 nmol/L were excluded, the association was no longer significant.⁵⁶ Orchiectomy results in a median decrease in hemoglobin concentration of 1.2 g/dL.⁵⁷ “Medical” castration with combined androgen blockade by gonadotropin-releasing agonists and antiandrogens also causes anemia.⁵⁸

The erythropoietic effects of androgens have been widely exploited for the treatment of various anemias, especially before the development of recombinant erythropoietin. Testosterone therapy in hypogonadal men increased the mean hematocrit from 38.0 percent to 43.1 percent within 3 months.⁵⁹ Two meta-analyses found that erythrocytosis (defined as a hematocrit greater than 50 or 52 percent) was greater than three times more likely to occur in a testosterone-treated group compared to placebo.^{60,61} Erythrocytosis was reported in a woman treated for breast cancer with an aromatase inhibitor, which prevents the conversion of androstenedione and testosterone to estrogen.⁶²

The mechanism of androgen action appears to be complex, with evidence for stimulation of erythropoietin secretion⁶³ and a direct effect on the marrow.⁶⁴ Androgen receptors have been identified in the marrow cells of human males and females. However, the cells expressing the receptors included stromal cells, endothelial cells, macrophages, and myeloid precursors, but not erythroid cells,⁶⁵ thus the pathophysiologic significance of this association is unclear. Testosterone administration is associated with an increase in erythropoietin levels and a decrease in hepcidin levels.⁶³ Although erythropoietin levels declined with continued testosterone administration, they remained inappropriately high despite improved hemoglobin levels, suggesting a new setpoint.⁶³

ESTROGENS

Data regarding the role of estrogens is conflicting. Administration of large doses of estrogen led to a moderately severe anemia in rats.^{66,67} However, hematopoietic stem cells express estrogen receptor- α and estrogen signaling via this receptor promotes hematopoietic stem cell self-renewal and stimulates erythropoiesis.⁶⁸

PITUITARY GLAND DISORDERS

PITUITARY INSUFFICIENCY

The most common cause of pituitary insufficiency is pituitary tumors or consequences of their therapy.⁶⁹ Other etiologies include hypothalamic tumors or dysfunction, sarcoidosis or other infiltrative diseases, pituitary hemorrhage or infarct, genetic causes, and idiopathic pituitary failure. Regardless of the cause, hypopituitarism results in a moderately severe normochromic normocytic anemia, with an average hemoglobin level of 10 g/dL.^{12,70} Anemia and erythroid hypoplasia have also been described in hypophysectomized animals.^{71,72}

In rats, removal of the posterior lobe of the pituitary, which secretes vasopressin and oxytocin, does not result in anemia.⁷³ Thus, the anemia of hypopituitarism presumably results from the absence of the anterior lobe hormones, adrenocorticotropic hormone, thyroid-stimulating hormone, follicle-stimulating hormone, luteinizing hormone, growth

hormone, and prolactin, although the exact role of each of these hormones in the pathogenesis of anemia is unknown. The resulting deficiencies of thyroid hormones, adrenal hormones, and androgens are likely the major contributors to anemia. Combined adrenalectomy and thyroidectomy in animals results in an anemia that is similar but not identical to that seen after hypophysectomy.⁷⁴ A correlation between low testosterone levels and anemia has been observed in human males with hypopituitarism resulting from nonfunctioning pituitary adenomas.⁷⁵

Red cell survival is normal in hypopituitarism, but the marrow is hypoplastic. The results of ferrokinetic studies are consistent with decreased erythropoiesis.¹² In addition to anemia, leukopenia and even pancytopenia can occur.⁷⁶ Replacement therapy with a combination of thyroid, adrenal, and gonadal hormones usually effectively corrects anemia and other cytopenias.^{76,77} Erythropoietin therapy also was effective in one case of postoperative hypopituitarism refractory to hormone replacement therapy.⁷⁸

OTHER PITUITARY HORMONES

Growth Hormone

Growth hormone stimulates erythropoietin-induced erythropoiesis *in vitro*,^{79,80} and children with isolated growth hormone deficiency become anemic.⁸¹ Growth hormone replacement therapy in both children and adults with growth hormone deficiency increases hemoglobin levels.^{82–84}

Prolactin

There is limited information about the influence of prolactin. Prolactin administration in mice increased the number of erythroid and myeloid progenitor cells and partially corrected anemia induced by azidothymidine.⁸⁵ Metoclopramide, which stimulates prolactin secretion, improved hemoglobin levels or reduced transfusions in three of nine patients with Diamond-Blackfan anemia.⁸⁶ The prolactin receptor can substitute for the erythropoietin receptor in *in vitro* studies of erythroid differentiation.^{87,88}

However, macroprolactinomas have not been associated with erythrocytosis, but with anemia, likely the result of a concomitant decrease in testosterone levels.⁸⁹ In a retrospective review of 26 males with prolactinomas, a mild anemia was present in one-third, all of whom had a macroprolactinoma.⁹⁰ Hemoglobin levels did not correlate with serum prolactin levels, but did correlate with the presence of hypogonadism.⁹⁰

Gonadotropins

Pituitary adenomas that secrete gonadotropins are rare, but have been associated with erythrocytosis, likely due to testosterone excess.⁹¹

● HYPERPARATHYROIDISM

Anemia not attributable to other causes is present in 3 to 5 percent of patients with primary hyperparathyroidism; these patients usually have severe hyperparathyroidism.^{92,93} The anemia is normochromic and normocytic and resolves or improves after parathyroidectomy.^{92,93} The cause of the anemia is unknown; marrow fibrosis is present in some but not all patients.^{92,94} Although there is no correlation with marrow fibrosis and the duration of hyperparathyroidism, the presence of marrow fibrosis may positively correlate with improvement in anemia after parathyroidectomy.⁹⁴

Although anemia in patients with renal failure is multifactorial, secondary hyperparathyroidism may contribute to refractoriness to erythropoietin therapy. Parathyroidectomy or medical treatment of hyperparathyroidism may improve anemia and decrease requirements for exogenous erythropoietin therapy.^{95–98}

CHAPTER 39

THE CONGENITAL DYSERYTHROPOIETIC ANEMIAS

Achille Iolascon*

SUMMARY

The congenital dyserythropoietic anemias (CDAs) are a heterogeneous group of rare disorders characterized by anemia, the presence of erythroid hyperplasia with multinuclear erythroid precursors in the marrow, ineffective erythropoiesis and secondary iron overload. Only the erythroid series shows significant abnormalities, with rare exceptions. Patients have been classified as types I, II, and III, but several patients appearing with these general characteristics do not fit into any of the three groups. CDA types I and II are inherited as autosomal recessive disorders, and type III disease is inherited as an autosomal dominant disorder. Type I disease is caused by mutations of the *CDAN1* gene. Codanin-1, the gene product, is a cell-cycle-regulated protein of currently unknown function. In codanin-negative cases, *C15ORF41* mutations can cause type I CDA. Type II CDA is also known as hereditary erythroblastic multinuclearity with a positive acidified serum test, or by its acronym HEMPAS. The vast majority of CDA type II cases are caused by mutations of the *SEC23B* gene. This gene encodes the cytoplasmic COPII (coat protein) component

Acronyms and Abbreviations: AE1, band 3 anion transport protein; Arf6, adenosine diphosphate (ADP)-ribosylation factor 6; Asf1a, a protein that is a member of the H3/H4 family of histone chaperones; *C15ORF41*, gene encoding a protein with two predicted helix-turn-helix domains of unknown function; CDA, congenital dyserythropoietic anemia; *CDAN1* gene, codanin-1; COP, cytoplasmic coat protein; *COX4I2*, gene encoding cytochrome c oxidase subunit IV isoform; E2F1, transcription factor 1; ER, endoplasmic reticulum; G6PD, glucose-6-phosphate dehydrogenase; GATA1, hematopoietic transcription factor; GDF15, growth differentiation factor 15; HEMPAS, hereditary erythroblastic multinuclearity associated with a positive acidified serum test; HJV, hemojuvelin gene; HLA, human leukocyte antigens; HS, hereditary spherocytosis; KIF23, mitotic kinesin-like protein 1; *LPIN2* (18p11.31), encoding lipin 2; KLF1, a hematopoietic transcription factor; MCV, mean cell volume; MKD, mevalonate kinase deficiency; *MKLP1*, gene encoding mitotic kinesin-like protein 1; *SARTB*, a gene encoding a small guanosine triphosphatase (GTPase) protein; SDS-PAGE, sodium dodecylsulfate polyacrylamide gel electrophoresis; *UGT1A1*, bilirubin uridine diphosphate (UDP)-glucuronosyltransferase 1A1 gene.

SEC23B, which is involved in the secretory pathway of eukaryotic cells. CDA type III disease is rarer than the other two forms and its erythroid production failure is accompanied by a tendency for the development of retinal angioid streaks and of myeloma in the long term. It is caused by *KIF23* mutations, a gene encoding mitotic kinesin-like protein 1, which plays a critical role in cytokinesis. There is no specific treatment for these disorders. Management includes red cell transfusion, removal of excess body iron by chelation therapy or judicious phlebotomy, splenectomy, and allogeneic hematopoietic stem cell transplantation. Only in severe forms of type I CDA does interferon- α decrease transfusion needs.

DEFINITION AND HISTORY

The term *congenital dyserythropoietic anemia* (CDA), coined by Heimpel and Wendt,¹ applies to a group of rare hereditary refractory anemias characterized by ineffective erythropoiesis, erythroid hyperplasia, abnormal morphology of erythroid precursors, and secondary accumulation of tissue iron.

Dyserythropoiesis is a result of derangement of the multistep process of normal erythroid maturation caused by a maturation arrest at early and late polychromatic erythroblasts and a consequent reduction of daily red cell production (Fig. 39-1A). Depending on the degree of the cellular defect, variable degrees of anemia can result.

Dyserythropoiesis can be considered a subtype of marrow failure syndromes characterized by monolineage involvement and abnormalities in erythroid precursor cells (see Fig. 39-1B). Microscopic morphologic characterization defines the heterogeneity of these syndromes (Fig. 39-2). Indeed, the appearance of abnormal morphology of erythroid progenitors can be from other hereditary defects (such as thalassemias) and acquired causes (rapid regeneration of marrow, myelodysplasia, etc.), but these are usually readily apparent from the history, blood examination, and laboratory tests in the former and multilineage involvement and the absence of prevalent multinuclearity in the latter. Furthermore, the term *congenital* could be confusing, as the clinical appearance of hereditary dyserythropoietic anemias can be present during different ages. In addition, it is an archaic residual of older nomenclature and should be replaced by “hereditary” as it has been in diseases such as congenital spherocytosis (now hereditary spherocytosis).

Anemia is usually first noted in infancy or childhood. The life span of circulating erythrocytes is moderately reduced, and the dominant factor in pathogenesis is a large component of ineffective erythropoiesis (intramedullary cell death as a result of precursor cell apoptosis) resulting in anemia of variable severity, normal or slightly elevated reticulocytes, moderate increase in indirect bilirubin, low haptoglobin, and, typically, a gradual increase in ferritin levels. Splenomegaly is common. Congenital dyserythropoietic anemias have been classified into three types—types I, II, and III. In addition, a number of cases that do not fit clearly into any of these three categories have been described.²

EPIDEMIOLOGY

The prevalence of CDAs is likely higher than reported as a result of their clinical heterogeneity and diagnostic difficulties, as demonstrated by the fact that the correct diagnosis is often delayed into adulthood.

Merging of information from European registries suggests that the prevalence of CDA I and CDA II in Europe is approximately

*Dr. Jean Delaunay wrote this chapter in the 8th edition of this textbook. Some of the material from the 8th edition has been retained. Dr. Roberta Russo collaborated in the preparation of this manuscript.

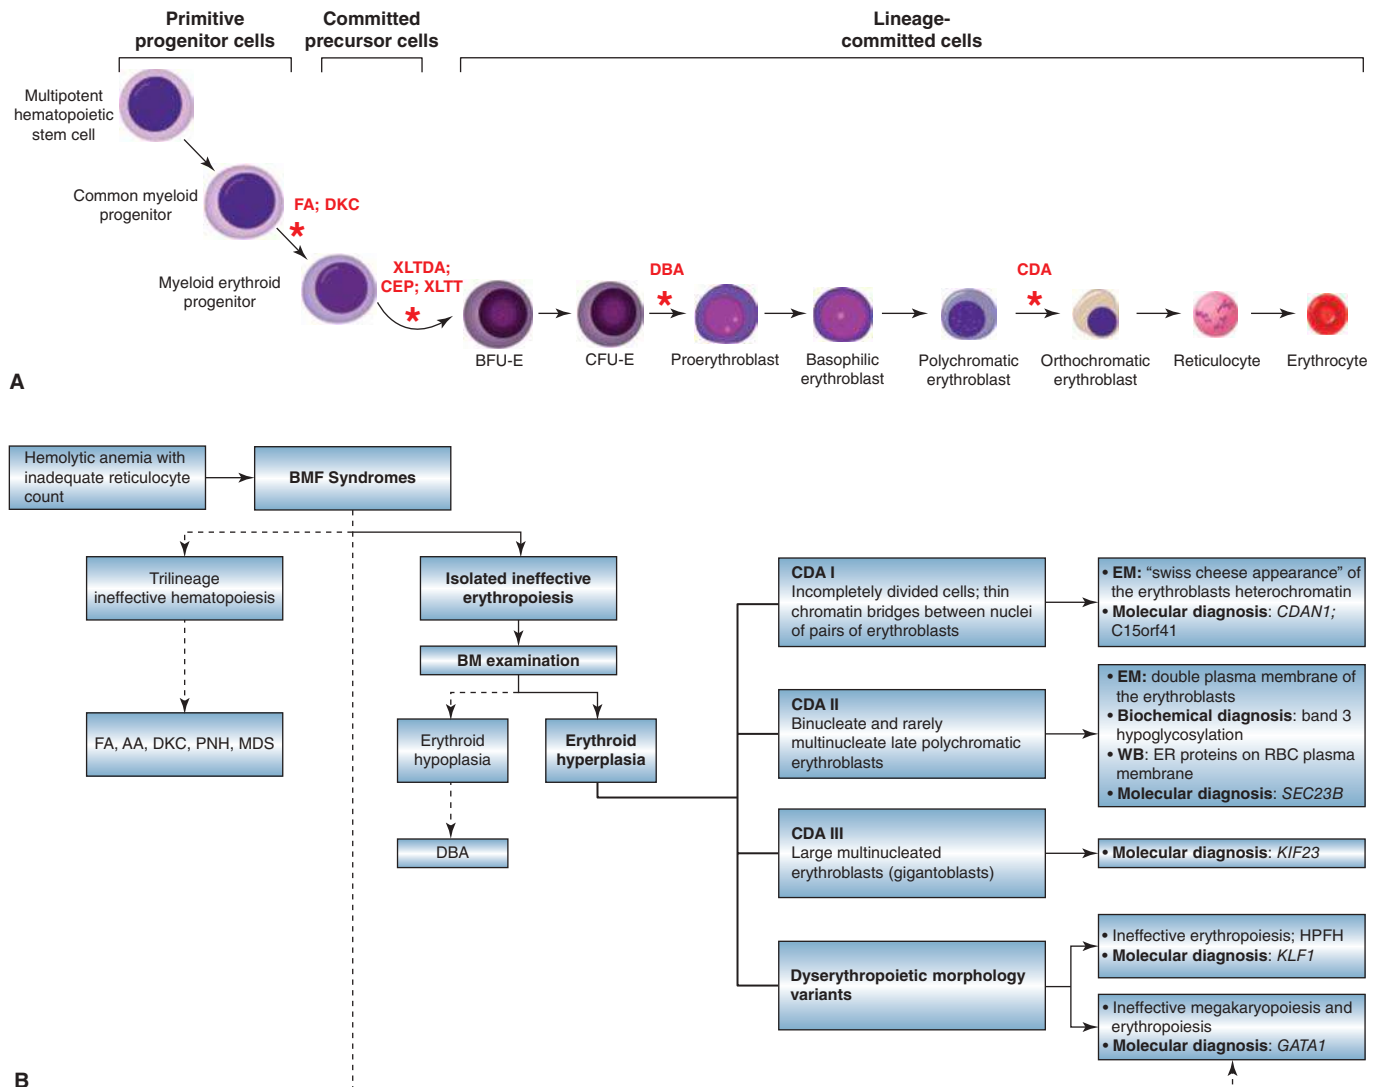

Figure 39–1. Differential diagnosis of congenital dyserythropoietic anemias (CDAs) among marrow failure syndromes. **A.** Erythroid maturation arrest can occur at several stages and can result in different marrow failure syndromes. CDA marrow is characterized by erythroid hyperplasia because the maturation arrest occurs later in these patients. **B.** Flow diagram for differential diagnosis of CDA subtypes based on clinical, morphologic, biochemical, and molecular findings. AA, aplastic anemia; BFU-E, burst-forming unit–erythroid; BM, marrow; BMF, marrow failure; CEP, congenital erythropoietic porphyria; CFU-E, colony-forming unit–erythroid; DBA, Diamond-Blackfan anemia; DKC, dyskeratosis congenita; EM, electron microscopy; ER, endoplasmic reticulum; FA, Fanconi anemia; HPFH, hereditary persistence of fetal hemoglobin; MDS, myelodysplastic syndromes; PNH, paroxysmal nocturnal hemoglobinuria; RBC, red blood cell; WB, western blotting; XLTTA, X-linked thrombocytopenia with dyserythropoietic anemia; XLTT, X-linked thrombocytopenia with β -thalassemia.

0.24 and 0.71 cases/million, respectively, whereas CDA III is even less common.^{3,4} In 2011, 712 cases from 614 families were included in the German CDA Registry, whereas in the Italian CDA registry 206 cases from 183 families were enrolled. In the literature, 169 cases from 143 families with CDA I and 454 cases from 356 families with CDA II worldwide have been recorded. Hence, CDA I is approximately one-third as frequent as CDA II. Most reported families were from Western European and Middle Eastern countries, but single cases have been also reported in the United States, India, Japan, and China.

The wide variation of incidence of CDA in Europe could be owing to genetic factors and also to the existence of reference centers for the diagnosis of CDA. However, molecular studies have established, at least for CDA type II, the presence of a founder effect in Europeans for the two most common mutations of the *SEC23B* gene.^{5,6}

● CONGENITAL DYSERYTHROPOIETIC ANEMIA, TYPE I

CLINICAL FEATURES

CDA I is inherited as an autosomal recessive disorder. It can manifest in any year of pediatric age, but may not be diagnosed until adulthood. There is a continuous spectrum between moderate and severe forms; more severe presentations are predictably diagnosed at earlier ages.⁷

Anemia, usually macrocytic, is typically moderate and associated with intermittent jaundice, splenomegaly, and, sometimes, hepatomegaly. Hemoglobin values fluctuate around 9 to 10 g/dL. The patient usually does not require transfusion.^{7–9}

Figure 39-2. Marrow morphologic features of congenital dyserythropoietic anemia (CDA) erythroblasts. **A.** Marrow light microcopy of CDA patients almost always shows erythroid hyperplasia (*inset 1*). However, specific morphologic abnormalities in erythroid precursor cells are used as hallmarks for discerning different types of CDAs. The presence of internuclear chromatin bridging is a mark of CDA type I (*inset 2*), whereas the presence of bi- or multinucleated late erythroid precursors is the discriminating feature of CDA type II (*inset 3*). Giant multinucleated erythroblasts (*inset 4*) and multinucleate erythroblasts (*inset 5*) are typical features of CDA types III and IV, respectively. **B.** Marrow electron microscopy of CDA I erythroblasts show a typical Swiss cheese-heterochromatin pattern in the nucleus (*inset 1*), whereas CDA type II erythroblasts display the characteristic double plasma membrane (*inset 2*). CDA type IV has nonspecific features, shared among different CDA types, such as marked heterochromatin, invagination of nuclear membrane, intranuclear precipitated material, and nuclear blebbing (*inset 3*).

Patients diagnosed in the neonatal period often have hepatomegaly and jaundice, and may have exhibited intrauterine growth retardation. Spleen size increases with age. Cholelithiasis is a common complication, and jaundice may be aggravated by the coinheritance of A[TA]₇TAA polymorphism in the promoter of the *UGT1A1* gene, the main cause of Gilbert syndrome.¹⁰

The disease is occasionally associated with a variety of dysmorphic features (4 to 14 percent of affected individuals), the most common of which involves the bones of the hand and the foot (syndactyly, hypoplasia of one or several phalanges, presence of supplementary metatarsal bones, and clubfoot) (Fig. 39-3).¹¹ Small stature, almond-shaped blue eyes, hypertelorism, micrognathism, and other abnormalities may also be present.

LABORATORY FEATURES

Anemia is a common finding, usually in the range of 8 to 10 g/dL of hemoglobin. The blood film usually exhibits macrocytosis (mean cell volume [MCV] of approximately 90 to 100 fL), marked poikilocytosis, and occasional nucleated erythrocytes, elliptocytes, and basophilic stippling. The reticulocyte count is inappropriately low for the degree of anemia.⁷⁻⁹ The marrow has intense erythroid hyperplasia. Binucleate polychromatic erythroblasts are evident at a frequency of approximately 3 to 7 percent. A highly specific feature is the presence of chromatin bridges linking two nuclei in more or less incompletely separated polychromatic erythroblasts with 0.6 to 2.8 strands per 100 erythroblasts (see Fig. 39-2A).¹² Ultrastructural abnormalities consist of a spongy (“Swiss cheese”) appearance in the nucleus of up to 60 percent of early and late polychromatic erythroblasts. Nuclei exhibit areas of electrolucency within electron-dense heterochromatin and contain nuclear membrane-lined cytoplasmic intrusions, occasionally with retained cytoplasmic organelles (see Fig. 39-2B).^{9,11}

GENETICS

The most frequent mutated gene in CDA I patients, *CDANI* (chromosome 15q15.1–15.3), spans 15 kb and is composed of 28 exons.^{13,14} The encoded protein, codanin-1, contains 1227 amino acids and it is ubiquitously expressed. Codanin-1 is a cell-cycle-regulated protein. The proximal *CDANI* gene-promoter region appears to be a direct target of transcription factor E2F1, and high levels of codanin-1 are observed in the DNA synthesis (S) phase of the cell mitotic cycle.¹⁵ At mitosis, codanin-1 undergoes phosphorylation and it is excluded from condensed chromosomes. Moreover, codanin-1 binds to Asf1a, a protein involved in chromatin structure dynamics by its role in nucleosome assembly and disassembly.¹⁶

More than 30 unique mutations have been found in the *CDANI* gene, and affected subjects are either homozygotes or compound heterozygotes for the mutation(s) they carry. A genotype–phenotype correlation has not been established. A homozygous patient for null-type mutations has not been described, suggesting that an absence of codanin-1 is lethal. Indeed, CDA I knockout mice embryos die *in utero* at 6.5 days before erythropoiesis onset, presumably as a result of the critical role of this protein in developmental processes other than erythropoiesis.¹⁷ In approximately 20 percent of families with the CDA I phenotype, *CDANI* mutations were not found.¹⁸ One founder mutation, R1042W, was observed in Bedouins.^{2,8,19}

A new CDA I causative gene, *C15ORF41*, has been identified in three unrelated pedigrees of Middle Eastern and Southeast Asian origin by whole-genome sequencing.²⁰ The cellular role of the restriction endonuclease encoded by the *C15ORF41* gene is unknown. This protein interacts with Asf1b, the paralogue of Asf1a, which may support the hypothesis that the primary defect in CDA I is confined to DNA replication and chromatin assembly.

In the erythroid lineage during normal maturation, cell division ceases at the polychromatophilic erythroblast stage and cell size

Figure 39-3. Foot dysmorphism in congenital dyserythropoietic anemia (CDA) type I. *Left:* Photograph showing hypoplastic nails, a broad first toe, hypoplastic third toe, and brachysyndactyly of the fourth and the fifth toes. *Right:* Radiograph showing a duplication of the fourth metatarsal bone (both bones being hypoplastic), a duplication of the fourth proximal phalanx, a single middle phalanx for the fourth and fifth toe, and the absence of the fourth distal phalanx. is progressively reduced.²¹ Cell mitotic cycle defects in mice result in S-phase arrest, ineffective erythropoiesis, and macrocytosis.²² Based on the probable involvement of CDA I mutated genes in DNA replication and chromatin assembly, it can be speculated that CDA I pathogenesis may involve disruption of the intrinsic connection between cell cycle dynamics and erythroid maturation.

Knowledge of the molecular defects in CDA patients permits detection of carriers for prenatal diagnosis.

TREATMENT, COURSE, AND PROGNOSIS

Severe forms of CDA I may present with hydrops fetalis.²³ Pulmonary hypertension was reported in three Bedouin newborns with CDA I.²⁴ Iron overload as a result of transfusion, hemosiderosis, and/or enhanced iron absorption characteristic of inefficient erythropoiesis is the main concern as patients age. Monitoring for iron overload is required; the following assessments are recommended: (1) annual measurement of serum ferritin concentration, and (2) myocardial T2* magnetic resonance imaging (MRI) and hepatic R2* MRI starting in adolescence (Chap. 43). Inappropriately low serum hepcidin levels could account for iron overload. High levels of *s-hemojuvelin* (*HJV*) in patients affected with CDA I, compared with controls, have been documented.²⁵ Hepcidin-to-ferritin ratio was negatively correlated with *s-HJV*, suggesting that *s-HJV* may suppress hepcidin.²⁶ Rare patients develop retinal angiod streaks.²⁷

Fertility in patients is not affected. However, fetal anemia during pregnancy in affected women is associated with some morbidity. In some cases, intrauterine transfusions are warranted by the severity of anemia as judged by fetal blood sampling.²³

Transfusions should be avoided whenever possible because of the risk of iron overload. When anemia is mild and does not require transfusion, small-volume regular phlebotomies may be used to decrease

body iron. Iron chelation or phlebotomies should be instituted when ferritin levels exceed 500 to 1000 mg/L. Iron chelation may be required for iron overload in those patients who cannot tolerate iron depletion by phlebotomies. Splenectomy is usually not beneficial.²⁹ Cholecystectomy for cholelithiasis is commonly performed.

Interferon- α was once used in a child with hepatitis C and CDA I; it was associated with an increase in hemoglobin level. A 9-year followup showed that the treatment remained effective and, on repeated liver biopsies, iron overload was normalized. In this case, the effective dose of interferon- α was 2 million units twice a week. Pegylated interferon could be used as well, at a dose of 30 mcg/wk.²⁸ The mechanism behind this response is unknown. Allogeneic hematopoietic stem cell transplantation was successful in several transfusion-dependent children.²⁹

● CONGENITAL DYSERYTHROPOIETIC ANEMIA, TYPE II

CLINICAL AND LABORATORY FEATURES

CDA II is an autosomal, recessively inherited condition in which the severity of anemia varies from mild to severe and in which approximately 7 percent of cases are transfusion-dependent.^{2,8,30,31} This disorder becomes variably manifest in infancy, childhood, or adolescence. Very few cases are characterized by clinical manifestations during intrauterine life, but hydrops fetalis caused by severe anemia has been reported.^{32,33} More commonly, anemia is mild and, in several cases, diagnosis has been based on the appearance of complications (mainly iron overload) during adulthood.^{2,8}

Erythrocytes of CDA II patients lyse in acidified serum (Ham test; Chap. 40) because of a naturally occurring immunoglobulin M class antibody that recognizes an antigen present on CDA II red cells but

which is absent on normal cells. Thus, the acronym HEMPAS (hemolytic anemia with a positive acidified serum test) is commonly used as a synonym for CDA II. The technical difficulty of this test, and the fact that cross-testing of more than 30 normal sera is needed to obtain a reliable result, has undermined its usefulness.³⁴

The clinical picture of CDA II includes hemolytic anemia with marrow erythroid expansion, commonly with splenomegaly, hepatomegaly, intermittent jaundice, and cholelithiasis.^{30,31} The blood film exhibits moderate to marked anisocytosis and anisochromia and a number of spherocytes. This, along with the patient's clinical appearance, may lead to confusion of CDA II with hereditary spherocytosis (HS; Chap. 46). However, typically in HS, the reticulocyte count in comparison to hemoglobin level is higher and the serum transferrin receptor level is lower. Moreover, the majority of HS cases are inherited as autosomal dominant and, thus, a parent is likely to have findings of spherocytosis on blood examination, whereas CDA II is invariably an autosomal recessive condition. Despite these differentiating features, CDA II is at times only diagnosed after the failure of splenectomy to normalize anemia when performed for suspected HS. In the marrow, 10 to 30 percent of intermediate and late erythroblasts have two or more nuclei or lobulated nuclei (see Fig. 39–2A). Karyorrhexis (fragmentation of the nucleus) is common. Gaucher-like cells may develop as a result of phagocytosis of erythroblasts by macrophages. Ringed sideroblasts are present in severe forms.¹² Electron microscopy shows structures that have been misnamed as “double membrane” (see Fig. 39–2B). These are cisternae of the endoplasmic reticulum (ER) that run along the red cell plasma membrane inner surface, and which contain ER-specific proteins, as shown by immunochemistry labeling.³⁵ Sodium dodecylsulfate polyacrylamide gel electrophoresis (SDS-PAGE), followed by immunoblots, reveals the presence of calreticulin, glucose-regulated protein 78, and disulfide isomerase; these are specific for the ER and are not detected in normal individuals.³⁵

The diagnostic hallmark of CDA II is analysis of erythrocyte membrane proteins by SDS-PAGE identifying narrower band size and faster migration of erythrocyte anion transporters (AE1 or band 3) and band 4.5 proteins.^{36,37} Increased destruction of red blood cells in CDA II is associated with hypoglycosylation of AE1, which causes clustering of this protein on the red cell surface and contributes to erythrocyte destruction in the spleen.³⁸ Rare patients have been reported without this characteristic SDS-PAGE pattern; it is recommended that these should be classified as CDA II–like conditions.

GENETICS

Pathognomonic hypoglycosylation of AE1 protein is the outcome of the expression of the mutated gene *SEC23B*.³⁹

Sequencing analysis in 33 patients from 28 unrelated families showed heterogeneous mutations in the *SEC23B* gene, either in compound heterozygous or homozygous states.^{2,8,39} An *in vitro* model of gene silencing demonstrated that suppression of *SEC23B* expression recapitulates the cellular defects in *SEC23B*-silenced cells.³⁹ Knockdown of zebrafish *SEC23B* also leads to aberrant erythrocyte development.³⁹

SEC23B is a cytoplasmic coat protein (COP) II component involved in the secretory pathway of eukaryotic cells. COPII is a multibunit complex essential for transport of correctly folded proteins from the ER toward the Golgi apparatus.⁴⁰ This pathway is critical for membrane homeostasis, localization of proteins within cells and secretion of extracellular factors.^{40,41}

CDA II belongs to COPII-related human genetic disorders.⁴² Alterations in *SAR1B*, a paralogue of *SEC23B*, are identified as the cause of chylomicron retention disease (Anderson disease),⁴³ while a specific mutation in the *SEC23A* gene causes craniolethinosutural dysplasia

(Boyadjiev-Jabs syndrome).⁴⁴ The specificity of the CDA II phenotype seems to be determined by tissue-specific expression of *SEC23B* versus *SEC23A* during erythroid differentiation.³⁹ Alternatively, this specificity could be explained by the presence of tissue-specific proteins (such as band 3 in red blood cells) which might require high levels and full function of a specific COPII component to be correctly transported.^{42,45}

So far, more than 60 different causative mutations have been described worldwide.^{2,8} A genotype–phenotype correlation seems to exist. Particularly, compound heterozygosity for missense and non-sense mutations tends to produce more severe clinical presentations than homozygosity or compound heterozygosity for two missense mutations. Homozygosity or compound heterozygosity for two non-sense mutations has not been reported, suggesting it may be lethal.⁴⁶ *Sec23b*-deficient mice (*Sec23b* *gt/gt*) have been generated and are born without anemia but die shortly after birth, with degeneration of secretory organs, including the pancreas and salivary glands.⁴⁷

The disparate phenotypes in mouse and human could result from residual *SEC23B* function associated with the hypomorphic mutations observed in humans, or, alternatively, might be explained by species-specific functional differences.⁴⁸

TREATMENT, COURSE, AND PROGNOSIS

The clinical course of this condition is quite heterogeneous. Treatment approaches depend on age, severity of phenotype and comorbidity. Most patients have only mild or moderate anemia and do not require medical intervention. Approximately 10 percent of neonates need at least one erythrocyte transfusion, and some remain transfusion-dependent.^{8,31} In most adolescents and adults, transfusional needs are limited to aplastic crises, pregnancy, coexistent infections, or major operations.

The more common, moderate forms may only be diagnosed in adult life because of iron overload (Chap. 43) that is consistently observed even in the absence of transfusions.^{2,8,49} Patients with severe forms of CDA II may be transfusion-dependent. In some cases, severe phenotypes could be the result of additional genetic abnormalities, such as coinheritance of glucose-6-phosphate dehydrogenase (G6PD) deficiency or thalassemic trait.⁵⁰

The iron overload is associated with high levels of growth differentiation factor 15 (GDF15).⁵¹ However, GDF15 concentrations are significantly lower in CDA II compared to CDA I patients, despite a similar degree of iron overload in both patient groups. It can be speculated that additional signals may determine hepatic hepcidin expression and the degree of iron overload in CDA II.⁵¹

Ferritin levels should be controlled at least annually, even in patients with only mild anemia. Achievement of normal ferritin concentrations is desirable.⁵² Iron chelation should be instituted when ferritin level exceeds 500 to 1000 cg/L (Chap. 43). If phlebotomies are tolerated, this is the preferred treatment. In instances where the patient cannot tolerate phlebotomy, chelating agents may be used.

Cholelithiasis and splenomegaly are common complications. Coinheritance of the *UGT1A* (TA)7/(TA)7 genotype could account for the increased rate of gallstones.⁵³ Cholelithiasis, which is frequent in all types of CDA, may require cholecystectomy; decision making should follow therapy guidelines for cholelithiasis.⁵⁴ Splenectomy is not universally recommended for CDA II or CDA I; individual decisions should be influenced by transfusion dependency and the presence of a massively enlarged spleen. Generally accepted criteria for splenectomy have not been defined. Splenectomy leads to a moderate, sustained increase in hemoglobin concentrations and decrease of serum bilirubin levels, but it does not prevent iron overload, and hemoglobin levels postsplenectomy generally do not reach normal values.⁵⁶ In non-transfusion-dependent patients, it is advisable to follow the guidelines for mild cases of HS.⁵⁴

Allogeneic marrow transplantation from an human leukocyte antigen (HLA)-identical sibling has been successful in transfusion-dependent children with very severe CDA II and in one adult with CDA II and β -thalassemia trait.^{32,33,55,56}

● CONGENITAL DYSERYTHROPOIETIC ANEMIA, TYPE III

CLINICAL AND LABORATORY FINDINGS

Type III is the least-common form of CDA. This condition, which is dominantly inherited, was initially coined “hereditary benign erythrocytosis.” One dominantly inherited form was reported as early as 1951 in a woman and her three children, in whom 16.0 to 22.7 percent of hematopoietic stem cell erythroblasts were multinucleated. Giant-size erythrocytes were present in the blood.

Most of our knowledge about CDA III stems from a large family from the province of Västerbotten in northern Sweden.⁵⁷ The diagnosis was made in the adults and older children. The spleen was not palpable, nor was iron overload recorded. The large size of this family made it possible to map the responsible gene to 15q22–25.⁵⁸ In addition, a number of sporadic cases of CDA III have been reported.⁵⁹

In another case, a number of stillbirths, including at least one stillborn with hydrops fetalis, were noted in an Indian family in which the mother, who initially required transfusions, became transfusion-independent after splenectomy.⁶⁰

Blood films from these patients show macrocytes, occasional extremely large forms (gigantocytes), and poikilocytes. Patients are generally asymptomatic, with no or moderate anemia, mild jaundice, and, commonly, cholelithiasis. The reticulocyte count is typically less than 3 percent.^{57,61} Marrow shows marked erythroid hyperplasia, with large multinucleate erythroblasts with large, lobulated nuclei, and giant multinucleate erythroblasts with up to 12 nuclei (see Fig. 39–2A). On electron microscopy, clefts within heterochromatin, autophagic vacuoles, iron-laden mitochondria, and myelin figures in the cytoplasm have been reported.⁶²

GENETICS

The causative mutation was found to be 2747C>G (P916R) in the *KIF23* gene.⁶³ The same mutation was also found in CDA III patients from an American family without any known relation to the Swedish kindred.⁶³ *KIF23* encodes a kinesin-superfamily molecule, mitotic kinesin-like protein 1 (MKLP1), a mitotic protein essential for cytokinesis.^{64,65} MKLP1 interacts with Arf6 (adenosine diphosphate (ADP)-ribosylation factor 6), ultimately forming an extended β -sheet that interacts with the membrane surface at the cleavage furrow. The Arf6–MKLP1 complex plays a crucial role in cytokinesis by connecting the microtubule bundle and membranes at the cleavage plane.⁶⁴ Knockdown of Arf6 results in binucleated and multinucleated cells, a hallmark of CDA III erythroblasts.⁶⁶ In knockdown and rescue experiments with *in vitro* cell lines, cytokinesis failure and binucleated cells were seen more frequently with the P916R mutant than wild-type GFP-MKLP1, indicating that the P916R mutation impairs the function of MKLP1 in cytokinesis.⁶³

COURSE AND PROGNOSIS

In spite of an apparently benign course, CDA III is prone to various long-term complications, including intravascular hemolysis, increased risk of myeloma and other monoclonal gammopathies,⁶⁷ and development of angiod streaks.⁶⁸

● OTHER CONGENITAL DYSERYTHROPOIETIC ANEMIAS

A number of cases of CDA that do not have specific features of types I, II, or, to some extent, III disease have been reported.^{69–74} Classification has been proposed based largely on cell morphology.⁷⁵ In addition, several genes have been associated with CDA variants, including mutations in the *GATA1* and *KLF1* genes, which are critical for development of specific blood cell lineages (outlined in Table 39–1).^{69–74,76}

Alterations in the erythroid hematopoietic transcription factor *KLF1* gene are associated with CDA type IV,⁷⁷ characterized by severe hemolytic anemia, elevated fetal hemoglobin, and deficiency of erythroid proteins CD44 and aquaporin 1 (see Table 39–1).⁷⁸

Additionally, syndromes have been described in which CDA accounts only for one feature of a syndrome phenotype (see Table 39–1). For instance, Majeed syndrome, is comprised of chronic recurrent multifocal osteomyelitis, inflammatory dermatosis, and CDA. The responsible gene is *LPIN2* (18p11.31), encoding lipin 2, an ER-phosphatidate phosphatase.⁷⁹ Additionally, dyserythropoiesis associated with exocrine pancreatic insufficiency and calvarial hyperostosis resulting from *COX4I2* gene mutations has been described in two Arab families.⁸⁰ Mevalonate kinase deficiency (MKD) resulting from a missense mutation in the *MVK* gene and showing morphologic marrow cell abnormalities similar to CDA II has also been reported.⁸¹

● DIFFERENTIAL DIAGNOSIS

Congenital dyserythropoietic anemias may be confused with thalassemias and other hemolytic anemias. Marked anisocytosis, including a

TABLE 39–1. A Classification Frame for Atypical Congenital Dyserythropoietic Anemias

Group	Main Features
IV	Transfusion-dependent anemia Pronounced normoblastic erythroid hyperplasia with a slight to moderate increase in the nonspecific dyserythropoietic erythroblasts with irregular or karyorrhectic nuclei No precipitated protein within erythroblasts
V	Near-normal hemoglobin with normal or slightly increased mean corpuscular volume Predominantly unconjugated hyperbilirubinemia Marked normoblastic/slightly megaloblastic hyperplasia Little or no erythroid dysplasia
VI	Normal or near-normal hemoglobin with marked macrocytosis Erythroid hyperplasia with cobalamin- and folate-independent florid megaloblastic erythropoiesis
VII	Severe transfusion-dependent anemia Severe normoblastic erythroid hyperplasia with irregular nuclear shapes in many erythroblasts Intraerythroblastic inclusions that resemble precipitated globin but do not contain globin

Data from Wickramasinghe SN and Wood WG: Advances in the understanding of the congenital dyserythropoietic anaemias. *Br J Haematol* 131(4):431–446, 2005.

normomacrocytic component, and low or moderate reticulocyte count out of keeping with the degree of anemia will point to a diagnosis of CDA. Indeed, CDAs are a subtype of marrow failure syndromes characterized by ineffective erythropoiesis and heterogeneous, type-specific morphologic abnormalities in erythroid precursor cells (see Fig. 39–1). Thus, marrow examination is essential if family history is unrevealing. The marrow, if needed, is quite different than in other types of hemolytic anemia or the thalassemias as multinuclearity of erythroblasts is not a feature of the latter two types of anemia.

CHAPTER 40

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Charles J. Parker

SUMMARY

In contrast to all other intrinsic abnormalities of the erythrocyte, paroxysmal nocturnal hemoglobinuria (PNH) is an acquired, not an inherited, disorder. PNH arises as a consequence of somatic mutation, involving one or more hematopoietic stem cells, of *PIGA*, a gene located on the X chromosome that is required for synthesis of the glycosylphosphatidylinositol (GPI) moiety that anchors some proteins to the cell surface. Consequently, all GPI-anchored proteins (GPI-APs) that are normally expressed are deficient on the mutant hematopoietic stem cells and their progeny. The complement-mediated intravascular hemolytic anemia and the resulting hemoglobinuria that are the clinical hallmarks of PNH are a consequence of deficiency of the GPI-anchored complement regulatory proteins, CD55 and CD59. Although PNH is a neoplastic (clonal) disease, it is not a malignant disease in that there is no exaggerated proliferation of neoplastic cells and replacement of marrow or spread to other tissues, and the extent to which the mutant clones expand varies greatly among patients. Thus, the blood cells of patients with PNH are a mosaic of phenotypically normal and abnormal cells. The size of the mutant clone is an important determinant of the clinical manifestations of the disease, which include hemolysis, thrombophilia, and, in many patients, pancytopenia as a result of marrow failure. The diagnosis of PNH is confirmed using flow cytometry to detect and quantify the percentage of blood erythrocytes and leukocytes (i. e., neutrophils and monocytes) that lack GPI-APs measured as intensity of CD55 and CD59 on the cell surface. The intravascular hemolysis of PNH can be controlled with eculizumab, a humanized monoclonal antibody that blocks formation of the cytolytic membrane attack complex of complement.

Acronyms and Abbreviations: APC, alternative pathway of complement; CD55, an antigen encoding DAF; CD59, an antigen encoding MAC-inhibitory protein; DAF, decay-accelerating factor; GPI, glycosylphosphatidylinositol; GPI-APs, glycosylphosphatidylinositol-anchored proteins; GVHD, graft-versus-host disease; HLA, human leukocyte antigen; INR, international normalized ratio of prothrombin assay data; LDH, lactate dehydrogenase; MAC, membrane attack complex of complement; MDS, myelodysplastic syndrome; MIRL, membrane inhibitor of reactive lysis; *PIGA*, phosphatidylinositol glycan class A; PMN, polymorphonuclear cell; PNH, paroxysmal nocturnal hemoglobinuria; PNH-sc, subclinical PNH; RA, refractory anemia; RAEB, refractory anemia with excess of blasts; RAEB-t, refractory anemia with excess of blasts in transformation; RA-PNH+, RA with a population of PNH cells; RA-PNH-, RA without a population of PNH cells; RARS, refractory anemia with ringed sideroblasts; RBCs, red blood cells; RCMD, refractory cytopenias with multilineage dysplasia; WHO, World Health Organization.

Although treatment with eculizumab favorably modifies the natural history of PNH, it has no effect on the underlying disease process (i. e., the *PIGA*-mutant hematopoietic stem cell clone). The *PIGA*-mutant clone can be eradicated and normal hematopoiesis restored by allogeneic hematopoietic stem cell transplantation, but the relatively benign natural history of PNH in patients treated with eculizumab has tempered enthusiasm for transplantation because of concerns about subjecting patients to the risk of treatment-related morbidity.

DEFINITION AND HISTORY

Although commonly regarded as a type of hemolytic anemia, paroxysmal nocturnal hemoglobinuria (PNH) is properly categorized as a hematopoietic stem cell disorder. PNH arises as a result of clonal expansion of *one or several* hematopoietic stem cells that have acquired a *somatic mutation* of the X-chromosome gene *PIGA* (phosphatidylinositol glycan class A). As a consequence of mutant *PIGA*, any progeny of affected stem cells (erythrocytes, granulocytes, monocytes, platelets, and lymphocytes) are deficient in all glycosylphosphatidylinositol-anchored proteins (GPI-APs) that are normally expressed on hematopoietic cells. The clinical manifestations of PNH are hemolytic anemia, thrombophilia, and marrow failure, but only the hemolytic anemia is unequivocally a consequence of somatic mutation of *PIGA*. It is not a malignant neoplasm in the classical sense of uncontrolled proliferation of cells, spread to tissues other than marrow, or spatial replacement of hematopoiesis. Its effects can be lethal and it can uncommonly undergo clonal evolution to acute myelogenous leukemia.

Comprehensive, scholarly reviews of the history of PNH have been published.¹⁻⁴ The first published clinical description of PNH is attributed to William Gull in 1866, but he failed to distinguish definitively PNH from paroxysmal cold hemoglobinuria. Paul Strübing, in 1882, clearly recognized PNH as a distinct entity and undertook prescient experiments designed to test his hypothesis that the nocturnal hemoglobinuria was a consequence of acidification of plasma that occurred when carbon dioxide and lactic acid accumulated because of slowing of respiration during sleep. In 1911, A.A. Hijmans van den Berg demonstrated that the hemolysis of PNH is caused by a defect in the red cell rather than by the presence of an abnormal plasma factor (as is the case with paroxysmal cold hemoglobinuria; Chap. 54). Thomas Hale Ham is credited with discovering, in the late 1930s, that complement mediates the hemolysis of PNH erythrocytes, although it was not until the alternative pathway of complement was identified and characterized in the mid-1950s by Louis Pillemer that the basis of Ham's original observations became apparent. Ham developed the acidified serum lysis test (Ham test) that, along with the sucrose lysis test (*sugar water test*) of Robert Hartmann and David Jenkins, was used as the standard diagnostic test for PNH until being supplanted in the early 1990s by flow cytometry. Both Hartmann and William Crosby brought attention to the important role that thrombosis (particularly the Budd-Chiari syndrome) plays in the natural history of PNH, and John Dacie and his student and colleague S.M. Lewis were the first to systematically characterize the relationship between PNH and marrow failure.

EPIDEMIOLOGY

The prevalence of PNH is not known with certainty. Prevalence estimates are influenced by bias in study design and results differ considerably, in large part, because of the heterogeneous nature of the disease. The blood of patients with PNH is a mosaic of normal and abnormal

cells, and the extent of the mosaicism varies widely among patients (see “Phenotypic Mosaicism is Characteristic of Paroxysmal Nocturnal Hemoglobinuria” below). Patients with small PNH clones have few or no symptoms related to hemolysis. Thus an argument can be made that asymptomatic patients with small clones do not have clinically significant PNH and should be excluded from prevalence estimates. Others, however, may argue that any patient with flow cytometric evidence of a population of GPI-AP-deficient cells, regardless of clone size, has PNH and should be included in prevalence estimates. Well-designed, rigorous studies of prevalence that address the issue of disease heterogeneity are needed, but, by any definition, PNH is a rare disease. The prevalence of clinically significant PNH (i.e., classic PNH) plus patients with relatively large clones that arise in the setting of another marrow failure syndrome, (see “Clinical Features” and Table 40–2 below) is likely in the order of less than 1 case per 200,000 population, easily fulfilling criteria (<1 case per 50,000 population) for classification as an ultraorphan disease.⁵ There is a close association between PNH and aplastic anemia, and environmental factors, drugs, and toxins, that cause aplastic anemia, concordantly increase the risk of developing PNH. Although PNH is reported in all age groups, the peak incidence is in the third and fourth decades of life, similar to that of aplastic anemia (Chap. 35). PNH is an acquired disorder, and there is no known inherited risk for developing the disease. A number of cases have been reported in which only one of a pair of identical twins was affected.

ETIOLOGY AND PATHOGENESIS

COMPLEMENT AND PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

The chronic intravascular hemolysis that is the hallmark clinical manifestation of PNH is mediated by the alternative pathway of complement (APC) (Fig. 40–1).⁶ The APC is a component of innate immunity (Chap. 20).⁷ This ancient system evolved to protect the host against invasion by pathogenic microorganisms. Unlike the classical pathway of complement that is part of the system of acquired immunity and requires antibody for initiation of activation, the APC is in a state of continuous activation, armed at all times to protect the host (Chap. 19 provides a detailed review of the complement system). The APC cascade can be divided into two functional components: the amplification C3 and C5 convertases and the membrane attack complex (MAC). The C3 and C5 convertases (Fig. 40–1, top panel) are enzymatic complexes that initiate and amplify the activity of the APC. Generation of C5b by enzymatic cleavage of C5 by the APC C5 convertase activates the terminal pathway of complement that results ultimately in assembly of the cytolytic MAC.

Because the APC is primed for attack at all times, elaborate mechanisms for self-recognition and for protection of the host against APC-mediated injury have evolved. Both fluid-phase and membrane-bound proteins are involved in these processes. Normal human erythrocytes are protected against APC-mediated cytolysis primarily by decay-accelerating factor (DAF, CD55)^{8–10} and membrane inhibitor of reactive lysis (MIRL, CD59).¹¹ These proteins act at different steps in the complement cascade (see Fig. 40–1, top panel). CD55 regulates the formation and stability of the C3 and C5 convertases, whereas CD59 blocks the formation of the MAC. Deficiency of CD55 and CD59 on the erythrocytes of PNH is the pathophysiologic basis of the Coombs-negative, intravascular hemolysis that is the clinical hallmark of the disease (see Fig. 40–1, bottom panel). But why are PNH erythrocytes deficient in the two complement regulatory proteins?

Figure 40–1. Complement-mediated lysis of paroxysmal nocturnal hemoglobinuria (PNH) erythrocytes. *Upper panel.* The hemolytic anemia of PNH is Coombs test–negative because the process is mediated by the antibody-independent alternative pathway of complement (APC). The C3 convertase of the APC consists of activated C3 (C3b), activated factor B (Bb, the enzymatic subunit of the complex), and factor P (a protein that stabilizes the complex, formally called properdin). The C5 convertase has the same components as the C3 convertase except that two C3b molecules are required to bind and position C5 for cleavage by activated factor B (Bb). C3a and C5a are bioactive peptides that are generated by cleavage of C3 and C5, respectively, by their specific activation convertases. The C3 and C5 convertases greatly amplify complement activation by cleaving multiple substrate molecules. The membrane attack complex (MAC) consists of activated C5 (C5b), C6, C7, C8, and multiple molecules of C9 (C9_n). The MAC is the cytolytic unit of the complement system. The glycosylphosphatidylinositol (GPI)-anchored complement regulatory protein CD55 restricts formation and stability of both the C3 and the C5 amplification convertases by destabilizing the interaction between activated factor B (Bb) and C3b (indicated by the blue arrow), whereas GPI-anchored CD59 blocks formation of the MAC by inhibiting the binding of C9 to the C5b-8 complex (indicated by the brown arrow). Inhibition of MAC formation by the humanized monoclonal anti-C5 antibody eculizumab (indicated by the red arrow) ameliorates the intravascular hemolysis of PNH. *Lower panel.* Normal erythrocytes (left) are protected against complement-mediated lysis primarily by CD55 (blue circles) and CD59 (green circles). Deficiency of these GPI-anchored complement regulatory proteins results in APC activation on PNH erythrocytes (right). Because of deficiency of CD55 and CD59, the complement cascade activates on the cell surface. Consequently, MACs form pores in the red cell membrane resulting in colloid osmotic lysis and release of hemoglobin (red circles) and other contents of the red cell including lactate dehydrogenase (LDH) into the intravascular space. RBC, red blood cell. (Modified with permission from Parker CJ: *The pathophysiology of paroxysmal nocturnal hemoglobinuria*. Exp Hematol 35(4):523–533, 2007.)

THE MOLECULAR PATHOGENESIS AND GENETIC BASIS OF PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

PNH is a consequence of clonal expansion of one or more hematopoietic stem cells with mutant *PIGA* (located on Xp22.1).¹² The protein product of *PIGA* is a glycosyl transferase^{12–16} that is an obligate constituent of a complex biochemical pathway required for synthesis of the glycosylphosphatidylinositol (GPI) moiety that anchors individual proteins belonging to diverse functional groups to the cell surface (Fig. 40–2). As a result of mutant *PIGA*, progeny of the affected stem cells are deficient in all GPI-APs. Although more than 20 GPI-APs are expressed by hematopoietic cells, it is deficiency on red blood cells

Figure 40–2. The molecular and genetic basis of paroxysmal nocturnal hemoglobinuria (PNH). There are two types of anchoring mechanisms for plasma membrane proteins: transmembrane and glycosylphosphatidylinositol (GPI). Transmembrane proteins are anchored into the lipid bilayer of the cell by a short series (approximately 25 amino acids) of hydrophobic residues (*blue rectangle*). Transmembrane proteins typically have a short cytoplasmic tail that usually has signaling properties (*red rectangle*). The ectoplasmic portion of the protein is illustrated by the series of *gray-blue squares*. The GPI-anchored protein (AP) consists of the following components: phosphatidylinositol (inositol is represented by the *blue hexagon* labeled I and phosphate is represented by the *red oval*); glucosamine (GlcN, *yellow circle*); three mannose (Man, *green circles*); ethanolamine phosphate (EtN, *blue square* with attached phosphate represented by the *red oval*); the protein entity (*blue circle*). The lipid component (indicated by the series of *diagonal lines* within the lipid bilayer) is usually 1-alkyl,2-acylglycerol for mammalian GPI-APs. PNH cells are deficient in all GPI-APs because somatic mutation of the X-chromosome gene *PIGA* disrupts the first step in the biosynthetic pathway (transfer of the nucleotide sugar UDP-GlcNAc [uridine diphosphate-*N*-acetylglucosamine] to GlcNAc-PI [phosphatidylinositol]) indicated by the *arrow*.

(RBCs) of the two GPI-anchored complement regulatory proteins, CD55 and CD59, that underlies the hemolytic anemia of PNH.¹⁷ RBCs lacking CD55 and CD59 undergo spontaneous intravascular hemolysis as a consequence of unregulated activation of the APC (see Fig. 40–1, *bottom panel*). Thus, the hallmark clinical manifestation of PNH (intravascular hemolysis and the resultant hemoglobinuria) occurs because the two proteins that regulate complement on erythrocytes happen to be GPI-anchored.

Hypothetically, the PNH phenotype would result from inactivation of any of the more than 25 genes involved in synthesis of the GPI-anchor (see Fig. 40–2), but, with one exception,¹⁸ somatic mutation of no gene involved in GPI-AP synthesis other than *PIGA* has been reported in patients with PNH. This phenomenon is accounted for by the fact that, of the genes involved in the GPI-anchor synthesis pathway, only *PIGA* is located on the X-chromosome. Therefore, somatic mutation of only one allele is required for expression of the phenotype as males have one X-chromosome and, as a consequence of X-inactivation during embryogenesis, females have only one functional X-chromosome in somatic tissues (Chap. 10). On the other hand, mutation of two alleles would be required for inactivation of any of the autosomal genes involved in the GPI-anchor synthesis pathway.¹⁸

Cells with *PIGA* mutations do not appear to have a proliferative advantage *in vitro* or in hybrid animal models made with *PIGA* knock-outs.¹⁹ They have been found to be relatively resistant to apoptosis in some studies,^{20–23} but not in others.^{24,25} Thus, the basis of clonal selection and clonal expansion of *PIGA* mutant stem cells in patients with PNH remains largely enigmatic²⁶ although a number of hypotheses have been proposed (reviewed in Ref. 17).

PHENOTYPIC MOSAICISM IS CHARACTERISTIC OF PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

The blood of patients with PNH is a mosaic of normal and abnormal cells (Fig. 40–3). Although PNH is a clonal disease, the extent to which the *PIGA*-mutant clone expands varies widely among patients.¹⁷ As an example, in some cases, greater than 90 percent of the blood cells may

be derived from the *PIGA*-mutant clone, whereas in others, less than 10 percent of the blood cells may be GPI-AP deficient. This unique feature (variability in extent of mosaicism) is clinically relevant because patients with relatively small PNH clones have minimal or no symptoms and require no PNH-specific treatment, whereas those with large clones are often debilitated by the consequences of chronic complement-mediated intravascular hemolysis and respond dramatically to complement inhibitory therapy.

Another remarkable feature of PNH is phenotypic mosaicism (see Fig. 40–3A) based on *PIGA* genotype²⁷ (see Fig. 40–3B) that determines the degree of GPI-AP deficiency.¹⁷ PNH III cells are completely deficient in GPI-APs, PNH II cells are partially (approximately 90 percent) deficient and PNH I cells express GPI-APs at normal density (putatively, these cells are progeny of residual normal stem cells; see Fig. 40–3A). Phenotype varies among patients (Fig. 40–4). Some patients have only type I and type III cells (the most common phenotype), some have type I, type II, and type III (the second most common phenotype), and some patients have only type I and type II cells (the least-common phenotype). Furthermore, the contribution of each phenotype to the composition of the blood varies. Phenotypic mosaicism is clinically important because PNH II cells are relatively resistant to spontaneous hemolysis, and patients with a high percentage of type II cells have a relatively benign clinical course with respect to hemolysis (Fig. 40–4).

The anemia of PNH is multifactorial as an element of marrow failure is present in all patients, although the degree of marrow dysfunction is variable.²⁸ In some patients, PNH arises in the setting of aplastic anemia. In this case, marrow failure is the dominant cause of anemia. In other patients with PNH, evidence of marrow dysfunction may be subtle (e.g., an inappropriately low reticulocyte count) with the degree of anemia being determined primarily by the rate of hemolysis that is, in turn, determined by PNH clone size.

CLINICAL FEATURES

The primary clinical manifestations of PNH are hemolysis, thrombosis, and marrow failure.²⁸ Constitutional symptoms (fatigue, lethargy, malaise, asthenia) dominate the history, with nocturnal hemoglobinuria

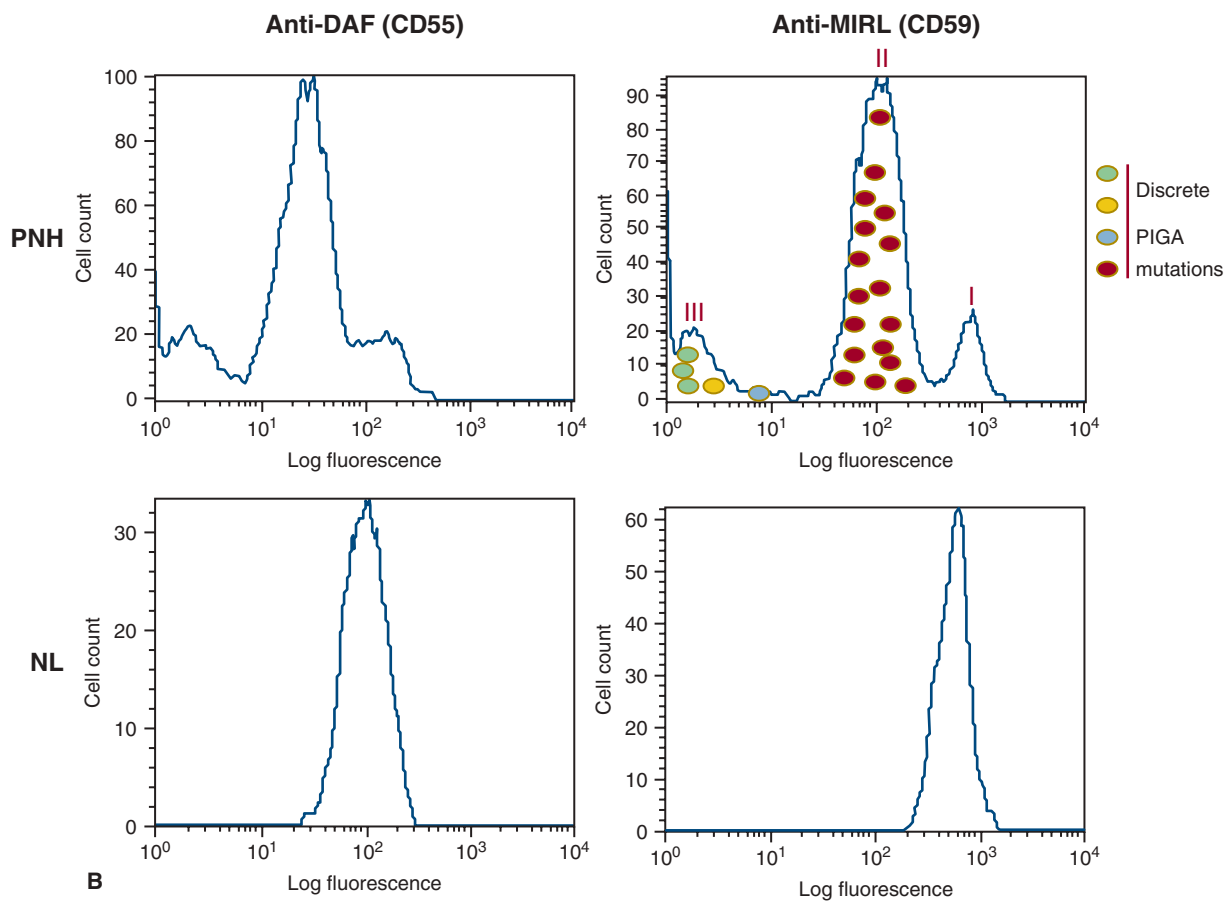

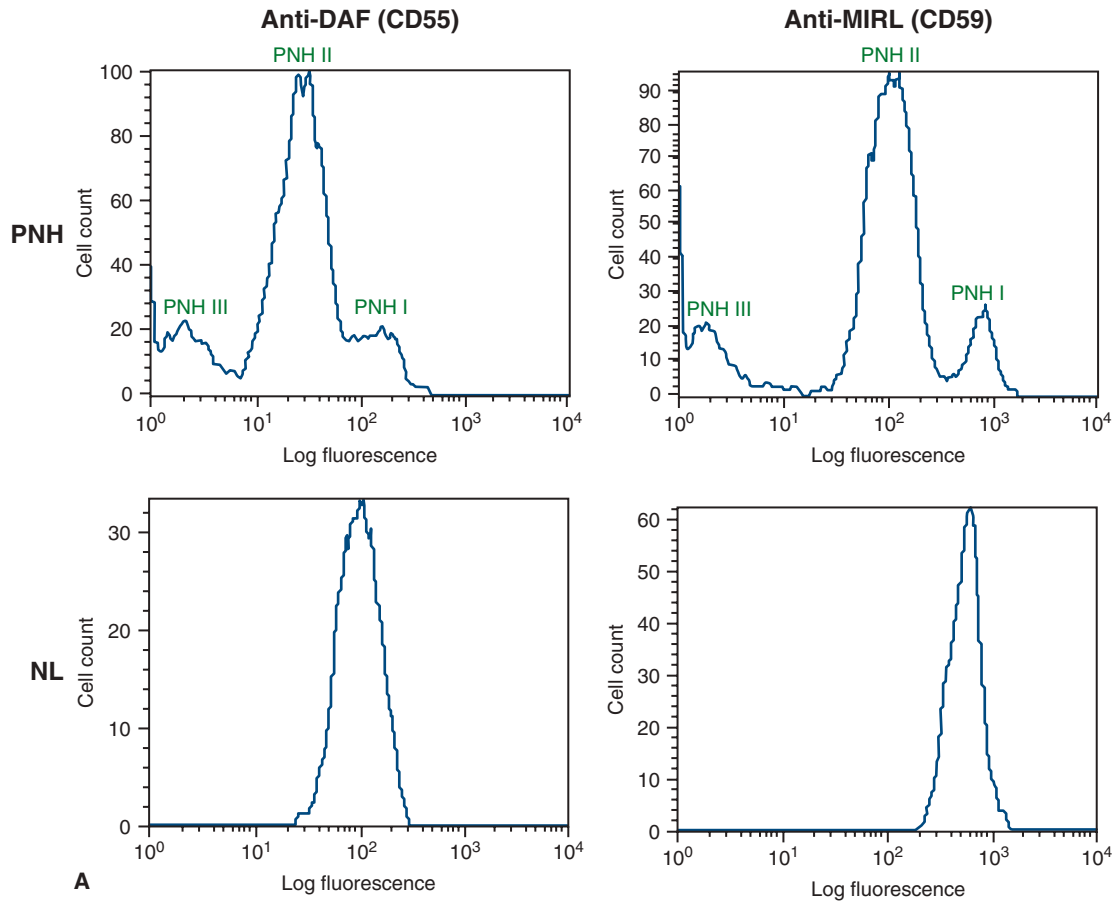

TABLE 40-1. Recommendation for Screening Patients for Paroxysmal Nocturnal Hemoglobinuria*

History of episodic hemoglobinuria
Evidence of nonspherocytic, Coombs-negative intravascular hemolysis (must have high serum lactate dehydrogenase)
Patients with aplastic anemia (screen at diagnosis and once yearly even in the absence of intravascular hemolysis)
Patients with refractory anemia or refractory cytopenias with multilineage dysplasia variants of myelodysplastic syndrome†
Patients with venous thrombosis involving unusual sites (usually have evidence of intravascular hemolysis)
<ul style="list-style-type: none"> • Budd-Chiari syndrome • Other intraabdominal sites • Cerebral veins • Dermal veins

*Screening by flow cytometric analysis of glycosylphosphatidylinositol-anchored proteins on red blood cells and polymorphonuclear cells.

†There is no indication for screening patients with other myelodysplastic syndrome classifications.

being a presenting symptom in only approximately 25 percent of patients.²⁹ Direct questioning frequently elicits a history of episodic dysphagia and odynophagia, abdominal pain, and male impotence. Venous thrombosis, often occurring at unusual sites (Budd-Chiari syndrome, mesenteric, dermal, or cerebral veins), may complicate PNH. Arterial thrombosis is less common.

LABORATORY FEATURES

PNH should be suspected in all patients with nonspherocytic, Coombs-negative intravascular hemolysis (Table 40-1).

Although the clinical manifestations of PNH depend in large part on the size of the *PIGA*-mutant clone, the extent of the associate marrow failure also contributes significantly to disease manifestations. Thus, PNH is not a binary process and based on clinical features, marrow characteristics, and the size of the mutant clone as determined by the percentage of GPI-AP-deficient polymorphonuclear cells (PMNs), the International PNH Interest Group recognizes three disease subcategories (Table 40-2).²⁸

Reticulocytosis reflects the response to hemolysis, although the reticulocyte count may be lower than expected for the degree of anemia because of underlying marrow failure (see Table 40-1). Serum lactate

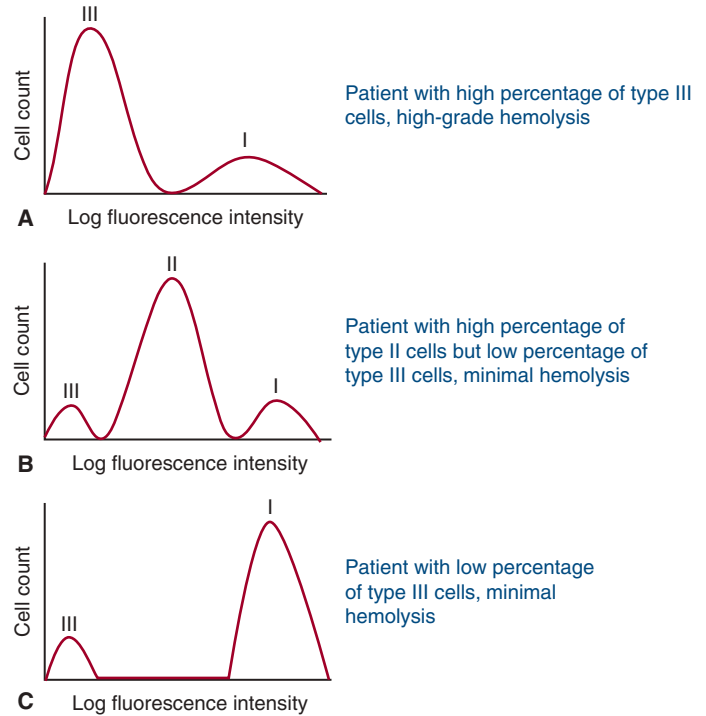

Figure 40-4. Clinical manifestations of paroxysmal nocturnal hemoglobinuria (PNH) are determined by clone size and erythrocyte phenotype. Mock flow cytometry histograms of erythrocytes from hypothetical patients with PNH stained with anti-CD59 are illustrated. Both the proportion and type of abnormal erythrocytes vary greatly among patients with PNH and these characteristics are important determinants of clinical manifestations. In general, patients with a high percentage of type III erythrocytes have clinically apparent hemolysis (A). If the erythrocytes are partially deficient in glycosylphosphatidylinositol-anchored protein (PNH II cells), hemolysis may be modest even if the percentage of the affected cells is high (B). A patient may have a diagnosis of PNH, but if the proportion of type III cells is low, only biochemical evidence of hemolysis may be observed (C). (Modified with permission from Parker C, Omine M, Richards S, et al: *Diagnosis and management of paroxysmal nocturnal hemoglobinuria*. Blood 106(12):3699–3709, 2005.)

dehydrogenase (LDH) concentration is always abnormally high in patients with clinically significant hemolysis and serves as an important surrogate marker for estimating and following the rate of intravascular hemolysis. A close association exists between PNH and aplastic anemia, and to a lesser extent between PNH and low-risk myelodysplastic syndromes (MDSs) (Chaps. 35 and 87 and see “Paroxysmal Nocturnal Hemoglobinuria and Marrow Failure” below). By using high-sensitivity flow cytometry, approximately 50 percent of patients with aplastic

Figure 40-3. Phenotypic mosaicism is a characteristic feature of paroxysmal nocturnal hemoglobinuria (PNH). A. The blood of patients with PNH is a mosaic of phenotypically normal and abnormal cells. In some patients, erythrocytes that are partially deficient in glycosylphosphatidylinositol-anchored proteins (GPI-APs) (called PNH II) are present in the blood along with cells that are completely deficient (PNH III) and cells that are phenotypically normal (PNH I). In the case illustrated, erythrocytes from a patient with PNH (PNH, upper panels) and from a healthy volunteer (NL, lower panels) were stained with fluorescently labeled antibodies (anti-CD55, left panels; CD59, right panels) and analyzed by flow cytometry. B. *PIGA* genotype determines PNH phenotype. The PNH II phenotype is a consequence of *PIGA* mutation that partially inactivates enzyme function (red circles), whereas any *PIGA* mutation that causes complete loss of enzyme function generates the PNH III phenotype (green, yellow, and blue circles). PNH I cells, have wild-type *PIGA* and are the progeny of normal residual hematopoietic stem cells. In a single individual, multiple discrete *PIGA* mutations can be identified, accounting for the phenotypic mosaicism based on GPI-AP expression. DAF, decay-accelerating factor; MIRL, membrane inhibitor of reactive lysis.

TABLE 40–2. Classification of Paroxysmal Nocturnal Hemoglobinuria*

Category	Rate of Intravascular Hemolysis [†]	Marrow	Flow Cytometry	Benefit from Eculizumab
Classic	Florid (macroscopic hemoglobinuria is frequent or persistent)	Cellular marrow with erythroid hyperplasia and normal or near-normal morphology [‡]	Large population (>50%) of GPI-AP–deficient PMNs [§]	Yes
PNH in the setting of another marrow failure syndrome [§]	Mild to moderate (macroscopic hemoglobinuria is intermittent or absent)	Evidence of a concomitant marrow failure syndrome [§]	Although variable, the percentage of GPI-AP deficient PMNs [§] is usually relatively small (<30%)	Dependent on the size of the PNH clone
Subclinical	No clinical or biochemical evidence of intravascular hemolysis	Evidence of a concomitant marrow failure syndrome [§]	Small (<1%) population of GPI-AP–deficient PMNs detected by high-resolution flow cytometry	No

GPI-AP, glycosylphosphatidylinositol-anchored protein; MDS, myelodysplastic syndrome; PMN, polymorphonuclear cell; PNH, paroxysmal nocturnal hemoglobinuria; RBC, red blood cell.

[†]Based on macroscopic hemoglobinuria, serum lactate dehydrogenase concentration, and reticulocyte count.

[‡]Karyotypic abnormalities are uncommon.

[§]Aplastic anemia and refractory anemia/MDS are the most commonly associated marrow failure syndromes.

[¶]Analysis of PMNs is more informative than analysis of RBCs because of selective destruction GPI-AP–deficient RBCs.

anemia and 15 percent of patients with low-risk MDS have been found to have a detectable population of GPI-AP–deficient erythrocytes and granulocytes.^{30–33} In approximately 80 percent of these cases, the proportion of GPI-AP deficient cells is <1.0 percent of the total. These patients with very small populations of GPI-AP–deficient erythrocytes have no clinical or biochemical evidence of hemolysis and are designated as subclinical PNH (PNH-sc; see Table 40–2). Varying degrees of leukopenia, thrombocytopenia, and relative reticulocytopenia reflect the extent of marrow insufficiency (see “Paroxysmal Nocturnal Hemoglobinuria and Marrow Failure” below).

Once suspected, diagnosing PNH is straightforward as deficiency of GPI-APs on blood cells is readily demonstrated by flow cytometry (Fig. 40–5).^{34,35} Although they have much biologic and historic importance, the acidified serum lysis test (Ham test) and the sucrose lysis test (sugar water test) have largely been abandoned as diagnostic assays because they are both less sensitive and less quantitative than flow cytometry. Flow cytometric analysis of both RBCs and PMNs is warranted, as clone size will be underestimated if only RBCs are examined because GPI-AP–deficient red cells are selectively destroyed by complement. Recent transfusion will also affect the estimate of clone size, if only RBCs are analyzed, but delineation of PNH phenotypes (i.e., the percentage of types I, II, and III cells) requires flow cytometric analysis of the erythrocyte population.

In addition to flow cytometric analysis, the basic initial evaluation of a patient with PNH should include complete blood count to assess the effects of the disease on production of leukocytes and platelets, as well as on erythrocytes (Table 40–3). In patients with classic PNH, the leukocyte and platelet counts are usually normal or nearly normal, whereas leukopenia, thrombocytopenia, or both invariably accompany PNH/aplastic anemia and PNH/MDS. The reticulocyte count is needed to assess the ongoing capacity of the marrow to respond to the anemia. Although the reticulocyte count is elevated in patients with classic PNH, as noted above, it may be inappropriately low for the degree of anemia, reflecting underlying relative insufficiency of hematopoiesis that is characteristic of the disease. The reticulocyte count is decreased in patients with PNH with concomitant aplastic anemia or low-risk MDS.

Serum LDH is always markedly elevated in classic PNH. The degree of serum LDH elevation is variable in patients with PNH/aplastic anemia and PNH/MDS, depending on the size of the PNH clone (see Table 40–2). By definition, patients with PNH-sc have neither clinical nor biochemical evidence of hemolysis (see Table 40–2). Patients with classic PNH are often iron deficient as a result of chronic iron loss in the form of hemoglobinuria and hemosiderinuria (Chap. 43). Marrow aspirate and biopsy are needed to distinguish classic PNH from PNH in the setting of another marrow abnormality. Nonrandom cytogenetic abnormalities are rare in PNH.²⁶

● DIFFERENTIAL DIAGNOSIS

PAROXYSMAL NOCTURNAL HEMOGLOBINURIA AND MARROW FAILURE

Although the marrow of patients with classic PNH appears relatively normal morphologically (see Table 40–2), numerous *in vitro* studies have shown that the growth characteristics of marrow-derived stem cells are aberrant.^{21,36,37} Moreover, when stem cells are sorted into GPI-AP– and GPI-AP+ populations, compared to the GPI-AP+ population, the growth characteristics of the GPI-AP– population more closely approach those of normal control cells.^{21,36} One plausible explanation for this observation is that the GPI-AP– cells are relatively protected from the pathophysiologic process that mediates the marrow injury, thereby providing a basis for natural selection of the *PIGA* mutant clone. In this view of PNH, outgrowth of the *PIGA* mutant clone is seen as an example of Darwinian evolution occurring within the microenvironment of the marrow. Although appealing, definitive experimental support for this hypothesis is lacking.

A close association exists between PNH and aplastic anemia and to a lesser extent between PNH and low-risk MDSs. By using high-resolution flow cytometry,³⁴ approximately 50 to 60 percent of patients with aplastic anemia and 15 to 20 percent of patients with low-risk MDS have been found to have a detectable population of GPI-AP–deficient erythrocytes and granulocytes.^{30,31,33,38,39} In approximately 90 percent of

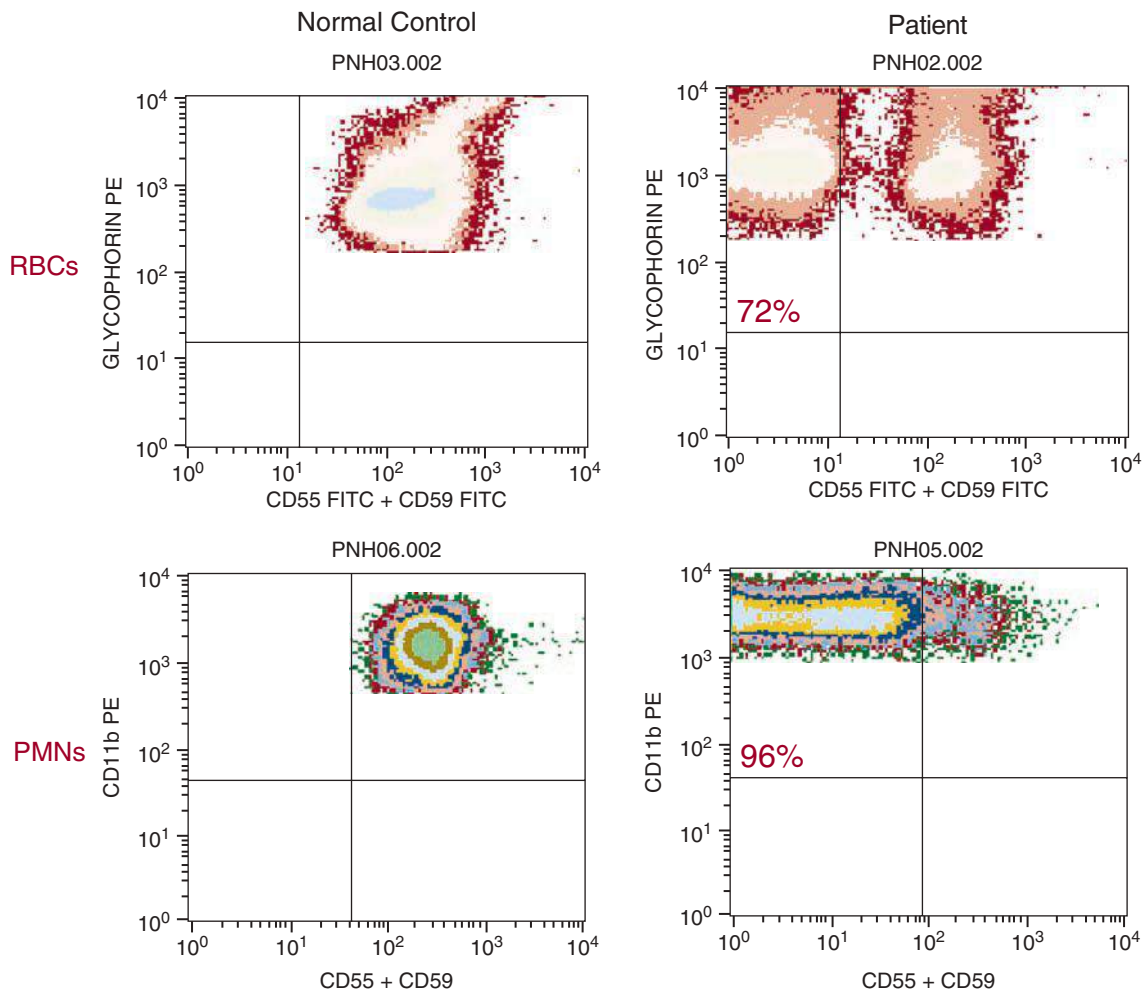

Figure 40-5. Diagnosis of paroxysmal nocturnal hemoglobinuria (PNH) by flow cytometry. Erythrocytes (RBCs) and neutrophils (PMNs) from a healthy volunteer and a patient with PNH were analyzed by flow cytometry using anti-glycophorin A (*top row, vertical axis*) to identify RBCs and anti-CD11b (*bottom row, vertical axis*) to identify PMNs. Glycosylphosphatidylinositol-anchored protein (GPI-AP) expression was detected using a combination of anti-CD55 and anti-CD59 (*top and bottom rows, horizontal axis*). PNH cells are deficient in both CD55 and CD59 (*upper left quadrant of each histogram*). The percentage of GPI-AP-deficient (PNH) cells is shown for each sample.

Marrow aspirate, biopsy, and cytogenetics‡

*Paroxysmal nocturnal hemoglobinuria (PNH) clone size is determined by the percentage of GPI-AP-deficient polymorphonuclear cells.

†The most important surrogate marker for intravascular hemolysis.

‡Marrow aspirate and biopsy are used to distinguish classic PNH from PNH in the setting of another marrow failure syndrome. Nonrandom karyotypic abnormalities are rare in PNH.

these cases, the proportion of GPI-AP-deficient blood neutrophils is less than 25 percent of the total.³⁸ Those patients with very small populations of GPI-AP-deficient erythrocytes (designated PNH-sc) have no clinical or biochemical evidence of hemolysis and require no specific treatment for PNH (see Table 40-2).

Studies have investigated the natural history of PNH clones in the setting of marrow failure.^{38,40,41} The threshold that separates PNH-sc from clinical PNH is reached when the neutrophil clone size is in the range of 20 to 25 percent with a corresponding GPI-AP-deficient erythrocyte population of 3 to 5 percent.⁴⁰ Longitudinal studies indicate that clonal expansion occurs in 15 to 50 percent of cases.^{38,40,41} In 10 to 25 percent of cases the clone disappears, and in 25 to 60 percent of cases the clone size persists unchanged.^{38,40,41} Available evidence indicates that patients who present with PNH-sc do not progress to clinical PNH.^{38,40,41} Among patients who present with clinical PNH in the setting of marrow failure, treatment for complications of PNH (eculizumab for hemolysis or anticoagulation for thrombosis) is required in approximately 50 percent

of cases.⁴¹ There is no evidence that treatment with immunosuppressive therapy influences clonal expansion either positively or negatively.

The basis of the relationship between PNH and aplastic anemia is speculative. The vast majority of patients with PNH have some evidence of marrow failure (e.g., thrombocytopenia, leukopenia, or both) during the course of their disease.^{26,42,43} Therefore, marrow injury may play a central role in the development of PNH by providing the conditions that favor the growth/survival of *PIGA*-mutant, GPI-AP-deficient stem cells. Finding a population of GPI-AP-deficient erythrocytes in patients with aplastic anemia is clinically relevant, as these patients have a particularly high probability of responding to immunosuppressive therapy, and the onset of the response appears to be more rapid compared to patients with aplastic anemia without a population of GPI-AP-deficient erythrocytes.^{31,33,44}

The presence of PNH cells has also been observed in patients with MDS.^{30,33,39,45} Notably, the association between PNH and MDS appears to be confined to low-risk categories of MDS, particularly the refractory anemia (RA) variant.^{30,33,39} Using high-sensitivity flow cytometry in which equal to or greater than 0.003 percent GPI-AP-deficient RBCs or PMNs was classified as abnormal, Wang and colleagues reported that 21 of 119 (18 percent) patients with RA MDS had a population of PNH cells, whereas GPI-AP-deficient cells were not detected in patients with RA with ringed sideroblast (RARS), RA with excess of blasts (RAEB), or RA with excess of blasts in transformation (RAEB-t). Compared to patients with RA without a population of PNH cells (RA-PNH-), patients with RA with a population of PNH cells (RA-PNH+) had a distinct clinical profile characterized by the following features: (1) less-pronounced morphologic abnormalities of blood cells; (2) more severe thrombocytopenia; (3) lower rates of karyotypic abnormalities; (4) higher incidence of HLA-DR15; (5) lower rate of progression to acute leukemia; and (6) higher probability of response to cyclosporine therapy.

That a population of PNH cells is associated only with low-risk MDS was confirmed in a North American study of 137 patients classified by World Health Organization (WHO) criteria.^{39,46} The study found a population of PNH cells in 1 of 5 (20 percent) patients with 5q-syndrome, in 6 of 17 (35 percent) patients with RA, and in 2 of 37 (5 percent) patients with refractory cytopenias with multilineage dysplasia (RCMD), whereas no patient with RARS (0 of 9), RCMD-ringed sideroblasts (0 of 6), RAEB (0 of 26), MDS unspecified (0 of 10), myelodysplastic/myeloproliferative disease (0 of 10), primary myelofibrosis (0 of 5), chronic myelomonocytic leukemia (0 of 5), or acute myeloid leukemia (0 of 6) had a detectable population of GPI-AP-deficient blood cells.³⁹

When combined with evidence of polyclonal hematopoiesis (based on the pattern of X-chromosome inactivation in female patients), the presence of a population of PNH cells in patients with MDS predicts a relatively benign clinical course and a high probability of response to immunosuppressive therapy in patients.³⁰ A relatively good response to immunosuppressive therapy for patients with MDS and aplastic anemia was also predicted by expression of HLA-DR15 in studies of both North American and Japanese patients.^{47,48} Together, these observations provide compelling indirect evidence that aplastic anemia and a subgroup of low-risk MDS are immune-mediated diseases and that the immune pathophysiologic process provides the selection pressure that favors the outgrowth of *PIGA* mutant, GPI-AP-deficient stem cells.

THERAPY

ECULIZUMAB

The complement-mediated intravascular hemolysis of PNH can be inhibited by blocking formation of the terminal complement pathway generated MAC, the cytolytic component of the complement system

(see Fig. 40-1). The MAC consists of complement components C5b, C6, C7, C8, and multiple molecules of C9. Eculizumab (Soliris) is a humanized monoclonal antibody that binds to complement C5, preventing its activation to C5b and thereby inhibiting MAC formation (see Fig. 40-1).⁴⁹ In 2007, eculizumab was approved by both the FDA and the European Union Commission (now the European Medicines Agency) for treatment of the hemolysis of PNH. Treatment with eculizumab reduces transfusion requirements, ameliorates the anemia of PNH, and markedly improves quality of life by resolving the debilitating constitutional symptoms (fatigue, lethargy, asthenia) associated with chronic complement-mediated intravascular hemolysis.⁵⁰ Following treatment, serum LDH concentration returns to normal, but mild to moderate anemia and reticulocytosis usually persist, likely the result of ongoing extravascular hemolysis mediated by opsonization of PNH erythrocytes by activated complement C3, as eculizumab does not block the activity of the APC C3 convertase (see Fig. 40-1).^{51,52} In some cases, extravascular hemolysis is sufficiently severe so as to require therapy.⁵³

Thromboembolic events are the major cause of morbidity and mortality in PNH,²⁸ and eculizumab appears to ameliorate the thrombophilia of PNH, although the studies that support that conclusion had suboptimal design.⁵⁴

Eculizumab is given by intravenous infusion on a biweekly schedule following an initial loading period consisting of five weekly treatments. In general, the drug is well tolerated; however, patients with congenital deficiency of complement C5 have an increased risk of infection with *Neisseria* species. For this reason, patients treated with eculizumab (which blocks the function of C5; see Fig. 40-1) are at risk for meningococcal septicemia. All patients must be inoculated with a meningococcal vaccine 2 weeks before starting therapy, but the vaccine is not 100 percent protective. Whether prophylactic antibiotic therapy aimed at preventing meningococcal infection is justified for a patient receiving eculizumab remains to be determined. Despite the fact that the percentage of GPI-AP-deficient erythrocytes increases during treatment with eculizumab,⁵⁵ there have been no reports of catastrophic hemolytic crises in the relatively few PNH patients who have discontinued treatment with eculizumab.^{54,56}

Eculizumab is expensive (approximately \$400,000/year in the United States), and it has no effect on either the underlying stem cell abnormality or the associated marrow failure. Consequently, treatment must continue indefinitely and leukopenia, thrombocytopenia, and reticulocytopenia, if present, persist.

OTHER TREATMENT FOR PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Other than eculizumab, there is no specific treatment for PNH, and for patients who are not being treated with eculizumab, management is largely supportive (reviewed in Ref. 28). Although hemolysis is ameliorated in some patients by treatment with glucocorticoids or androgens, the use of steroids in the management of patients with PNH is controversial.²⁸ The main value of glucocorticoids may be in attenuating acute hemolytic exacerbations. Under these circumstances, brief pulses of prednisone may reduce the severity and duration of the crisis. The value of glucocorticoids in treating chronic hemolysis is limited by toxicity, and the harm that can accrue from long-term use cannot be overemphasized. An every-other-day schedule may attenuate some of the adverse effects of chronic glucocorticoid use,⁵⁷ but patients may note worsening of symptoms on the off day.

Androgen therapy, either alone or in combination with glucocorticoids, has been used successfully to treat the anemia of PNH.^{57,58} As with glucocorticoids, the mechanism by which androgenic steroids ameliorate the anemia of PNH is not fully understood, although the

rapid onset of action is consistent with complement inhibition.⁵⁸ Potential complications of androgen therapy include liver toxicity, prostatic hypertrophy, and virilizing effects. The toxicity profile is more favorable for attenuated synthetic androgens such as danazol, making long-term use of this drug a reasonable management option in responding patients. A starting dose of 400 mg twice a day is recommended, but a lower dose (100 to 400 mg/day) may be adequate to control chronic hemolysis.²⁸

Patients with PNH frequently become iron deficient as a result of both hemoglobinuria and hemosiderinuria.^{57,58} Clinically important iron loss from hemosiderinuria can occur (Chap. 43), even in the absence of gross hemoglobinuria. Replacement is often associated with exacerbation of hemolysis, regardless of the route of administration.^{57,58} Compared with parenteral replacement, oral administration of iron may be accompanied by less-severe hemolytic exacerbations, but urinary iron loss may be so great that repletion may not be achieved.⁵⁷ Concern for inducing a hemolytic exacerbation should not deter iron repletion.⁵⁷ If a hemolytic exacerbation occurs in the setting of iron repletion, the episode can be controlled by treatment with glucocorticoids or androgens or by suppression of erythropoiesis by transfusion. There is no concern about iron-replacement therapy inducing a hemolytic exacerbation in patients being treated with eculizumab as hemolysis is inhibited by the drug.

Because the hemolysis is a consequence of a defect intrinsic to patient's erythrocytes, the anemia of PNH responds to red cell transfusion. Concerns about inducing a hemolytic exacerbation as a consequence of infusion of small amounts of donor plasma that may be included in red cell preparations appear unwarranted.⁵⁹ However, hemofiltration is recommended to prevent transfusion reaction arising from the interaction between donor leukocytes and recipient antibodies. Iatrogenic hemochromatosis from chronic transfusion may be delayed in patients with PNH as a result of iron loss from hemoglobinuria/hemosiderinuria,⁵⁷ but iron overload remains a concern in patients who require chronic transfusion when the anemia is primarily a consequence of marrow failure rather than intravascular hemolysis.

Supplemental folate (1 mg/day) is recommended to compensate for increased use (Chap. 41) associated with heightened erythropoiesis that is a consequence of ongoing hemolysis.²⁸

The role of splenectomy in the management of patients with PNH has not been investigated systematically. Reports of amelioration of hemolysis and improvement in cytopenias following splenectomy are anecdotal. Concerns about lack of proven efficacy and the potential for postoperative complications, particularly thrombosis, have led some to argue that splenectomy has no role in the management of PNH.²⁸

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Prior to the availability of eculizumab, the primary indications for transplantation were marrow failure, recurrent, life-threatening thrombosis, and uncontrollable hemolysis (Table 40-4).²⁸ The latter process can be eliminated by treatment with eculizumab and the thrombophilia of PNH may also respond to inhibition of intravascular hemolysis by eculizumab.^{54,60} Nonetheless, transplantation is the only curative therapy for PNH, and the availability of molecularly defined, matched, unrelated donors, less-toxic conditioning regimens, reduction in transplantation-related morbidity and mortality, and improvements in post-transplantation supportive care make this option a viable alternative to medical management. Studies (see "Course and Prognosis" below) indicate a normal survival for patients with PNH treated with eculizumab, making the decision of whether to recommend medical management or hematopoietic stem cell transplant particularly complex.⁶⁰

TABLE 40-4. Hematopoietic Stem Cell Transplantation for Paroxysmal Nocturnal Hemoglobinuria

Indications for transplantation

- Marrow failure—approach to management depends primarily on the underlying marrow abnormality (e.g., aplastic anemia) but the treatment regimen must be sufficient to eradicate the paroxysmal nocturnal hemoglobinuria (PNH) clone
- Major complications of PNH
- Refractory, transfusion-dependent hemolytic anemia*
- Recurrent, life-threatening, thromboembolic complications†

Conditioning regimens and donors

- Ablative and reduced intensity conditioning regimens have been successful
- For transplantations involving syngeneic twins, an ablative regimen is recommended‡
- Matched unrelated donor transplantations have been successful but experience is limited

Outcomes

- There are no PNH-specific adverse events. Severe, acute graft-versus-host disease occurs in approximately 33% of patients and the incidence of chronic graft-versus-host disease is roughly 35%
- Overall survival for unselected PNH patients who undergo transplantation using an human leukocyte antigen (HLA)-matched sibling donor is in the range of 50–60%

*Treatment with eculizumab controls the intravascular hemolysis of PNH. Mild to moderate extravascular hemolytic anemia persists in most patients with PNH treated with eculizumab, likely as a consequence of opsonization of erythrocytes by activation and degradation products of complement C3.

†Eculizumab may ameliorate the thrombophilia of PNH.

‡Absence of graft-versus-host effect may render nonablative approaches inadequate.

An understanding of the unique pathobiology of PNH and the input of physicians experienced in transplantation and medical management of PNH are essential to develop an appropriate management plan for transplantation-eligible patients.⁶¹

For patients who are receiving transplantation for marrow failure, the focus of management is on the etiology of the marrow failure (see Table 40-4). For patients with aplastic anemia and a small PNH clone who undergo matched sibling donor allotransplantation, the conditioning regimen of antithymocyte globulin and cyclophosphamide coupled with graft-versus-host effects appear sufficient to eradicate the PNH clone.²⁸ However, in the unusual situation in which the patient has a syngeneic twin, a more intense conditioning regimen is required, as graft-versus-PNH effect does not contribute to clonal eradication in this circumstance.⁶² In the event that a patient with low-risk MDS with a PNH clone requires allotransplantation, the conditioning regimen (marrow ablative or reduced intensity) in combination with graft-versus-tumor effects usually is sufficient to eradicate the PNH clone.

Transplantation for classic PNH is aimed at eradicating the PNH clone, and both marrow ablative^{63–65} and reduced-intensity^{66,67} conditioning regimens are effective, although experience with the latter is more limited. Successful outcomes have been reported using matched, unrelated donors, as well as matched, sibling donors.^{66,68} There are no PNH-specific adverse events associated with transplantation; severe, acute graft-versus-host disease (GVHD) occurs in more than one-third of the patients and the incidence of chronic GVHD is

approximately 35 percent. Overall survival for unselected PNH patients who undergo transplantation using an human leukocyte antigen (HLA)-matched sibling donor is in the range of 50 to 60 percent.²⁸

MANAGEMENT OF THE THROMBOPHILIA OF PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Thromboembolic complications are the leading cause of morbidity and mortality in PNH.⁶⁹ Prophylaxis against thromboembolic events in patients with PNH is an issue of active debate.⁶⁹ Current estimates of risk are based on retrospective analysis,^{54,70-73} but risk appears to correlate with size of the PNH clone (based on flow cytometric determination of the percentage of GPI-AP-deficient PMNs), leading to the recommendation that patients with greater than 50 to 60 percent GPI-AP-deficient PMNs be offered prophylactic anticoagulation.^{70,71} Treatment with warfarin with a goal international normalized ratio (INR) of between 2.0 and 3.0 is recommended for patients with PNH who require chronic anticoagulation either for treatment of a thromboembolic event or for prophylaxis. There are no empiric data to guide the use of low-molecular-weight heparin or novel oral anticoagulants in these settings, but their use can be considered in patients with adequate renal function who fail warfarin or in patients have difficulty maintaining a consistent therapeutic INR.

Although arterial thrombosis may be observed,⁵⁴ thromboembolic events in patients with PNH usually involve the venous system. Acute thrombotic events require anticoagulation with heparin. Systemic thrombolytic therapy,^{74,75} or thrombolytic therapy delivered via canalization directly to the affected site,⁷⁶ should be strongly considered in patients with acute onset of Budd-Chiari syndrome.

Thrombocytopenia often complicates PNH, and this issue should be addressed when formulating an anticoagulation management plan. Thrombocytopenia is a relative contraindication to anticoagulation, and transfusions should be given to maintain the platelet count in a safe range rather than withholding therapy.⁷⁷ Patients with PNH who experience a thromboembolic event should be anticoagulated indefinitely. Recurrent, life-threatening thrombosis merits consideration of marrow transplantation, but such patients are at high-risk for transplantation-related adverse events (see Table 40-4).⁶¹

Eculizumab reduces the risk of thromboembolic complications.⁵⁴ For patients being treated with eculizumab who have no prior history of thromboembolic complications, prophylactic anticoagulation may not be necessary.

PREGNANCY AND PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

Women with PNH can have serious morbidity and increased mortality during pregnancy.^{77,78} Because of concerns about fetal/maternal risks from exposure to potentially toxic therapy, anticoagulation and transfusion have been the mainstay of management. Eculizumab has been assigned to pregnancy category C (risk cannot be ruled out) by the FDA. There are no controlled studies of the use of eculizumab in human pregnancy; however, anecdotal reports and small series have identified no significant adverse effects when eculizumab is used during pregnancy, including early in gestation and, in one case, from the time of conception.^{51,79,80} Nonetheless, until more is known about the safety of eculizumab in pregnancy, it seems prudent to restricted use of the drug to the third trimester and then only for patients who are at high-risk for thrombosis and who have no acceptable therapeutic alternatives.

Moderate to severe thrombocytopenia may complicate the pregnancy, and clinically significant bleeding in this setting necessitates platelet transfusion. The incidence of clinically apparent venous

thromboembolism during pregnancy in women with PNH is approximately 10 percent,⁷⁷ and these events are associated with a high risk of mortality.^{77,78} Similar to nonpregnant patients with PNH, cerebral and hepatic veins are commonly involved sites of thrombosis. Thrombolytic therapy should be considered for those with Budd-Chiari syndrome.

The role of prophylactic anticoagulation for pregnant women with PNH has not been studied prospectively; however, because of the significant morbidity and mortality associated with thromboembolism in this setting, prophylaxis is recommended. Coumadin is contraindicated because of teratogenic potential in the first trimester and hemorrhagic risks later in gestation (Chap. 8). Anticoagulation with heparin should begin immediately once the pregnancy is documented. Low-molecular-weight heparin has a hypothetical advantage over unfractionated heparin because of a lower incidence of drug-induced thrombocytopenia and less osteopenia (Chap. 118). Careful monitoring of the platelet count is required because thrombocytopenia may worsen during the period of anticoagulation. Anticoagulation can be discontinued briefly around the time of delivery. However, it should be restarted as soon as is feasible and continued for at least 6 weeks into the postpartum period, as thrombosis during the puerperium is a major concern.^{77,78} Most deliveries can be accomplished vaginally, although premature delivery may be necessary. Despite the many concerns surrounding PNH and pregnancy, successful outcomes appear to be the rule rather than the exception^{72,77}; however, management is complicated and should involve the combined efforts of a knowledgeable hematologist and an obstetrician experienced in dealing with high-risk pregnancies.²⁷

PEDIATRIC PAROXYSMAL NOCTURNAL HEMOGLOBINURIA

PNH can occur in the young (approximately 10 percent of patients are younger than age 21 years at the time of diagnosis).²⁸ A retrospective analysis of 26 cases, underscored the many similarities between childhood and adult PNH.⁸¹ Signs and symptoms of hemolysis, marrow failure, and thrombosis dominate the clinical picture, although gross hemoglobinuria as a presenting symptom may be less common in young patients. A generally good response to immunosuppressive therapy was observed,⁸¹ but based on poor long-term survival, hematopoietic cell transplantation is the recommended treatment for childhood PNH. One study⁸² confirmed the common presentation of marrow failure in 11 children with PNH, and reported that five patients eventually underwent hematopoietic cell transplant (three matched unrelated donors and two matched family donors), of whom four were long-term survivors. In another study of 12 young patients over an 18-year period, 10 presented with evidence of marrow failure and only one with hemoglobinuria.⁴⁰ There were six children with thrombosis and five with myelodysplastic features, indicating that the clinical presentation may be more similar to adult PNH than previously recognized. The safety and effectiveness of eculizumab in pediatric patients below the age of 18 years has not been established, however, there are anecdotal reports of its use in pediatric patients with PNH.⁸³ Although eculizumab is not approved for PNH patients younger than age 18 years, approval will likely be sought once pharmacodynamic and pharmacokinetic characteristics of the drug are defined for the pediatric/adolescent population.⁸⁴ The availability of eculizumab for pediatric PNH may be particularly advantageous as a bridge prior to implementation of more definitive therapy.

COURSE AND PROGNOSIS

The clinical course of PNH is enormously variable. In rare instances, the patient may succumb to this disease within a few months of the first onset of symptoms. Most patients experience a chronic course in which the

severity of the disease waxes and wanes as the normal cells and the PNH clone alternately appear to gain ascendancy. Rarely, the abnormal clone disappears altogether, and the patient appears to be cured. Transformation to acute leukemia is uncommon (in the range of 1 percent). In some instances, but not in others, leukemic blasts are GPI-AP-deficient.⁴⁶

As with so many other diseases, initial reports on PNH tended to emphasize the more severely affected patients, so the prognosis was generally deemed to be very grave. As physicians developed a higher index of suspicion concerning this disorder, and as simplified methods for diagnosis became available, milder cases were diagnosed with a better long-term outlook. Nonetheless, even today, the disease must be considered a very serious one. The most common lethal event is a thrombotic episode such as the Budd-Chiari syndrome,^{69,73,85} but the various complications of pancytopenia also may lead to death,^{29,43} and in a few patients, the terminal process is development of acute leukemia.⁴⁶ In a study of 220 patients with PNH followed for up to 46 years in the preculizumab era, the Kaplan-Meier survival estimate was 65 percent at 10 years and 48 percent at 15 years after diagnosis.⁸⁵ In another preculizumab era study of 80 consecutive patients the outlook was similar: the median survival after diagnosis was 10 years, with 28 percent of patients surviving for 25 years.⁴³ Eight-year cumulative incidence rates of the main complications of pancytopenia, thrombosis, and MDS were 15 percent, 28 percent, and 5 percent, respectively. Poor survival was associated with age older than 55 years at the time of diagnosis, the occurrence of thrombosis as a complication, evolution to pancytopenia, MDS or acute leukemia, and thrombocytopenia at diagnosis. The prognosis of patients in whom aplastic anemia antedated PNH was better than in those in whom it did not.⁸⁵

In addition to symptomatic benefit, treatment with eculizumab appears to influence the natural history of PNH. In a retrospective study of the clinical history of 79 patients with classic PNH or PNH/marrow failure treated with eculizumab, the median age at diagnosis was 37 years (range: 12 to 79 years) and the median age at the time of initiation of treatment with eculizumab was 46 years (range: 14 to 84 years).⁶⁰ The mean duration of treatment with eculizumab was 39 months (range: 1 to 98 months). Based on flow cytometric analysis of blood neutrophils, the average clone size among the treated patients was 96.4 percent (range: 41.8 to 100 percent). Twenty-four patients (30 percent) had a history of a marrow failure syndrome at the time of diagnosis (23 with aplastic anemia and one with MDS). Thrombotic episodes were reported in 27 percent of patients prior to starting eculizumab (including 12 cases of Budd-Chiari syndrome, four cases of mesenteric vein thrombosis, three cases of cerebral vein thrombosis). The investigators found that treatment with eculizumab reduced the mean yearly transfusion requirement from 19.3 units to 5.0 units. Of 61 patients who had been on eculizumab for more than 1 year, 40 (66 percent) became transfusion-independent. Thrombosis was observed in two patients while on eculizumab. No thrombotic events were reported in 21 patients who discontinued prophylactic anticoagulation after starting treatment with eculizumab.

Survival of the 79 patients treated with eculizumab was the same as that of a group of age- and sex-matched controls from the general population. Two eculizumab patients developed documented meningococcal infection with *Neisseria meningitidis* serogroup B, and thereafter, a program of antibiotic prophylaxis was instituted by the investigators.

A multicenter study involving 195 patients followed for 66 months largely confirmed these findings.⁸⁶

Together, these results demonstrate that treatment with eculizumab alters the natural history of PNH both by reducing or eliminating transfusion requirements through inhibition of intravascular hemolysis and by virtually eradicating thromboembolic complications. Eculizumab treatment may also reduce disease related mortality although the extent

to which the drug enhances survival cannot be accurately determined from these studies as the experimental design did not include a randomized control group of patients. Eculizumab does not appear to affect either the marrow failure component of the disease or the clonal hematopoiesis that underlies disease pathophysiology. Although PNH is a clonal disease, it is not a malignant disease, as previously discussed, and it is this characteristic of PNH that allows for successful long-term symptomatic management in the absence of a treatment strategy aimed at eradicating the PIGA mutant hematopoietic stem cells.

CHAPTER 41

FOLATE, COBALAMIN, AND MEGALOBlastic ANEMIAS

Ralph Green

SUMMARY

Deficiency of either folate or cobalamin (vitamin B₁₂) leads to macrocytic anemia with or without other cytopenias as a result of megaloblastic hematopoiesis, a manifestation of defective DNA synthesis. Folate in its tetrahydro form is a transporter of one-carbon fragments, which it can carry at any of three oxidation levels: methanol, formaldehyde, or formic acid. The oxidation levels of the folate-bound one-carbon fragments can be altered by oxidation and reduction reactions that require nicotinamide adenine dinucleotide phosphate in its oxidized (NADP) or reduced (NADPH) form. The primary source of the folate-bound one-carbon fragments is serine, which is converted to glycine as its terminal carbon is transferred to folate. The one-carbon fragments are used for biosynthesis of purines, thymidine, and methionine. During biosynthesis of purines and methionine, free folate is released in its tetrahydro form. During biosynthesis of thymidine, tetrahydrofolate is oxidized to the dihydro form and must again be fully reduced by dihydrofolate reductase to continue functioning in one-carbon metabolism. Methotrexate acts as an anticancer agent because it is an exceedingly powerful inhibitor of dihydrofolate reductase, thereby interdicting the generation of reduced folate.

In the cell, folates are conjugated by the addition of a chain of seven or eight glutamic acid residues. These residues enable the retention of folates in the cell. When folates are absorbed from the intestine, a process that occurs chiefly in the duodenum and proximal jejunum, all but one of the glutamates is removed by the enzyme glutamate carboxypeptidase II (folate hydrolase). Resulting monoglutamate forms are then taken up by one of two folate-specific transporters located on the apical brush border small bowel epithelium, the reduced folate carrier or the proton-coupled folate transporter. Blood folates are taken up by cells, mainly in the form of methyltetrahydrofolate monoglutamate. The newly absorbed folates are rapidly reglutamylated in the cell by the enzyme folyl-polyglutamyl synthase (FPGS). If glutamylat

is prevented, the folates cannot be retained in the cell, resulting in an intracellular folate deficiency.

Cobalamin is required for two reactions: intramitochondrial conversion of methylmalonyl coenzyme A (CoA), a product of catabolism of branched-chain amino acids, and ketogenic amino acids to succinyl CoA, a Krebs cycle intermediate and cytosolic conversion of homocysteine to methionine, a reaction in which the methyl group of methyltetrahydrofolate is donated to the sulfur atom of homocysteine. In cobalamin deficiency, methyltetrahydrofolate accumulates because, for practical purposes, donation of the methyl group to homocysteine is the only method of generating free tetrahydrofolate from methyltetrahydrofolate. Free tetrahydrofolate is an excellent substrate for FPGS; methyltetrahydrofolate is a poor substrate. Consequently, much of the methyltetrahydrofolate taken up by a cobalamin-deficient cell leaks out of the cell before it can be polyglutamylated. The megaloblastic anemia of cobalamin deficiency results from an intracellular folate deficiency that arises because of the cell's limited ability to polyglutamylate methyltetrahydrofolate.

Absorption of cobalamin is a highly complex process. Upon arriving in the stomach, cobalamin is taken up by haptocorrin (HC) binder (also called *R binder* or *cobalophilin*), a glycoprotein found in virtually all secretions. When the cobalamin HC complex enters the duodenum, the HC is digested and the cobalamin is released into the intestinal lumen, where it is taken up by intrinsic factor, a glycoprotein secreted by the gastric parietal cells. The cobalamin-intrinsic factor complex is absorbed by cells in the ileum through receptor-mediated endocytosis, involving cubilin and other proteins. The cobalamin is released within lysosomes and transported to the blood where it circulates bound to transcobalamin (TC), which delivers its cargo of cobalamin to cells throughout the body. Folate (vitamin B₉) and cobalamin (vitamin B₁₂) play key roles in the metabolic machinery of proliferating cells.

Megaloblastic anemia most commonly results from folate or cobalamin (vitamin B₁₂) deficiency. Folate deficiency often was nutritional in origin. It may be seen in alcoholics, the elderly, the poor, but also is seen in patients on hyperalimentation, with hemolytic anemia, or hemodialysis. In the many countries that now practice folic acid fortification of the diet, such as the United States and Canada, the prevalence of folate deficiency has been dramatically reduced and nutritional folate deficiency has been virtually eliminated. In pregnancy, even a mild folate deficiency may be associated with defects in neural tube closure in the fetus, so pregnant women should always receive folate supplements. The incidence of neural tube defects has fallen considerably in North America since the introduction of folic acid fortification. Diagnosis of folate deficiency is based on measurements of folate in serum, which furnishes information about the current level of folate, and in red cells, which provide data on aggregate folate status over the preceding period during which those red cells were produced. Nutritional folate deficiency is treated with folic acid by mouth.

Folate deficiency as a result of malabsorption occurs in tropical and nontropical sprue. Folate deficiency as a result of tropical sprue is treated with folate supplements and antibiotics. In nontropical sprue, the treatment is folate plus a gluten-free diet.

The most common cause of clinically apparent cobalamin deficiency is pernicious anemia (PA), a condition in which the portion of gastric mucosa that contains the parietal cells is destroyed through an autoimmune mechanism. The parietal cells secrete intrinsic factor, which is essential for physiologic cobalamin absorption. Without intrinsic factor, a state of cobalamin deficiency develops over the course of years. Cobalamin deficiency leads not only to megaloblastic anemia but also to a demyelinating disease that manifests itself

Acronyms and Abbreviations: AdoCbl, adenosylcobalamin; AICAR, 5-amino-4-imidazole carboxamide ribotide; ATPase, adenosine triphosphatase; AZT, azidothymidine; CnCbl, cyanocobalamin; CoA, coenzyme A; CUB, cubilin; CUBAM, the binary ileal cubilin receptor complex consisting of cubilin and amnionless; dTMP, deoxythymidine monophosphate; dU, deoxyuridine; dUMP, deoxyuridine monophosphate; FH₄, tetrahydrofolate; FPGS, folylpoly-γ-glutamyl synthase; [³H]Thd, [³H]thymidine; HC, haptocorrin; HCl, hydrochloric acid; IM, intramuscular; LDH, lactate dehydrogenase; MCV, mean corpuscular volume; MeCbl, methylcobalamin; MRI, magnetic resonance imaging; MTHFR, methylenetetrahydrofolate reductase; NADP, nicotinamide adenine dinucleotide phosphate; NADPH, nicotinamide adenine dinucleotide phosphate (reduced form); N₂O, nitrous oxide; OHCbl, hydroxocobalamin; PA, pernicious anemia; PteGlu, pteroylglutamic acid (folic acid); SAH, S-adenosylhomocysteine; S-AdoCbl, S-adenosylmethionine; TC, transcobalamin.

as peripheral neuropathy, spastic paralysis with ataxia (so-called combined system disease of the spinal cord), dementia, psychosis, or some combination of these features. "Subtle" cobalamin deficiency, which may manifest as neurologic symptoms without anemia, appears to be relatively widespread among the elderly. The incidence of gastric cancer is increased by a factor of two to three in patients with PA. Other causes of cobalamin deficiency are gastric resection; stasis of the small intestinal contents as a result of blind loops, strictures, or hypomotility; and disease or resection of the terminal ileum, the site of vitamin B₁₂-intrinsic factor complex absorption. Individuals on a vegan diet can become cobalamin deficient. Cobalamin deficiency is diagnosed by measuring the level of either total or TC-bound vitamin in the blood or by measuring serum methylmalonic acid, which accumulates in the bloodstream in patients with cobalamin deficiency. The cause of cobalamin deficiency was determined by the Schilling test, a measure of cobalamin absorption, but the test is obsolete and no replacement is currently available. In patients with nutritional megaloblastic anemia, folate or cobalamin deficiency as the cause of the anemia must be determined. If a patient with cobalamin deficiency is treated with folic acid, the anemia may be corrected but the neurologic abnormalities persist, progress or may be aggravated. Patients with cobalamin deficiency usually are treated with parenteral cobalamin but large doses of oral cobalamin may be used.

Megaloblastic anemia can develop as an acute disorder with rapid development of leukopenia and/or thrombocytopenia. Nitrous oxide anesthesia or abuse is responsible for some cases of acute megaloblastic anemia. The anemia is rarely also seen in patients with a marginal folate status in intensive care units or severe hemolytic anemia through increased folate demand for augmented erythropoiesis. The condition resembles an immune cytopenia but can be ruled out by examining the marrow, which exhibits a floridly megaloblastic picture.

Other causes of megaloblastic anemia include drugs (e.g., hydroxyurea, nucleoside analogues) and certain inborn errors of metabolism. Of the inherited conditions, TC deficiency is singled out because it causes a severe megaloblastic anemia in infants who respond completely to high-dose cobalamin. Irreversible neurologic complications supervene if the deficiency is not detected in time. Megaloblastic-like morphologic features of varying degree are seen in the myelodysplastic syndromes, and in acute leukemia of the erythroleukemia type. Megaloblastic anemia seen in association with refractory anemia with excess sideroblasts occasionally responds to very high doses of pyridoxine.

FOLATE

Folate and cobalamin (vitamin B₁₂) play key roles in the metabolism of all cells, particularly proliferating cells.

CHEMISTRY

The group of compounds referred to as folates consists of folic acid and its various derivatives. *Folic acid* (pteroylglutamic acid) is composed of a pteridine moiety, a *p*-aminobenzoate residue, and an L-glutamic acid residue (Fig. 41-1A). The first two together are called *pteroic acid*.¹ In nature, folates occur largely as conjugates in which multiple glutamic acids are linked by peptide bonds involving their γ -carboxyl groups (Fig. 41-1B). Additionally, the naturally occurring polyglutamated folates are reduced in the 5, 6, 7, and 8 positions of the pteridine ring (as described below, Fig. 41-1B). Conjugates are named according to the length of the glutamate chain (e.g., pteroylmonoglutamate,

pteroyldiglutamate, pteroylhexaglutamate). Therapeutic folic acid (pteroylglutamic acid, abbreviated PteGlu, or F) has one glutamic acid and the pteridine ring is not reduced.

To form a functional compound, folate must be reduced to tetrahydrofolate (FH₄; see Fig. 41-1B). In this reduction, dihydrofolate (FH₂) is an intermediate. A single enzyme, *FH₂ reductase*, catalyzes both F→FH₂ and FH₂→FH₄.

The folate family consists largely of FH₄ derivatives bearing a one-carbon substituent (symbolized as FH₄-C). The varieties of FH₄-C differ with regard to the identity of the one-carbon unit and the site of its attachment to FH₄. Figure 41-2 shows one-carbon substituents of biochemical significance and their major interconversions.

These substituents are attached to FH₄ through N⁵,N¹⁰, or both (see Fig. 41-2). Specific enzymes interconvert these various FH₄ derivatives through oxidations that require nicotinamide adenine dinucleotide phosphate (NADP) and reductions that utilize the reduced form of NADP, NADPH.²

Reduced derivatives of folic acid usually are sensitive to air oxidation. An important exception is N⁵-formyl FH₄, also called *citrovorum factor*, *leucovorin*, or *folinic acid*, which, because of its stability, is the form preferred for clinical use.

NUTRITION

Sources

Folic acid comes from many sources. The richest vegetable sources are asparagus, broccoli, endive, spinach, lettuce, and lima beans. Each vegetable contains more than 1 mg of folate per 100 g dry weight. The best fruit sources are oranges, lemons, bananas, strawberries, and melons. Folates also are abundant in liver, kidney, yeast, mushrooms, and peanuts. Since the advent of folic acid fortification of the food supply, the median daily intake of folate from an average American diet is estimated to be 350 mcg.³ Foods are readily depleted of folate by excessive cooking, especially with large amounts of water, discarded before ingestion.

Daily Requirements

In the normal adult, the minimum daily requirement for folic acid is approximately 50 mcg. The average diet contains many times this amount, but some of the folate may be unavailable. Accordingly, the officially recommended dietary allowance of *food* folate for an adult is 0.4 mg.³ This figure is derived through considerations of the nutrient requirements to satisfy the needs of 97 to 98 percent of healthy individuals and the relative differences in absorption and bioavailability between dietary folate and the more bioavailable synthetic folic acid. One microgram of food folate is the dietary equivalent of 0.6 mcg folic acid added to food. The body is thought to contain approximately 5 mg of folate.⁴ When folate intake is reduced to 5 mcg/day, megaloblastic anemia develops in approximately 4 months.⁵

Folic acid requirements increase in hemolytic anemia, leukemia, and other malignant diseases, in alcoholism⁶ and during growth; in pregnancy and during lactation requirements increase threefold to sixfold.⁷ Adequate folate supplies are particularly important in pregnant and lactating women, in whom the recommended daily allowance is increased to 600 and 500 mcg/day, respectively, to meet requirements.⁸

METABOLISM

Folate-Dependent Enzymes

FH₄ is an intermediate in reactions involving the transfer of one-carbon units from a donor to an acceptor. Table 41-1 summarizes the metabolic systems of animal tissues known to require folic acid coenzymes.

One-carbon units enter the folate pool principally via the serine hydroxymethyltransferase (SHMT) reaction which requires pyridoxal

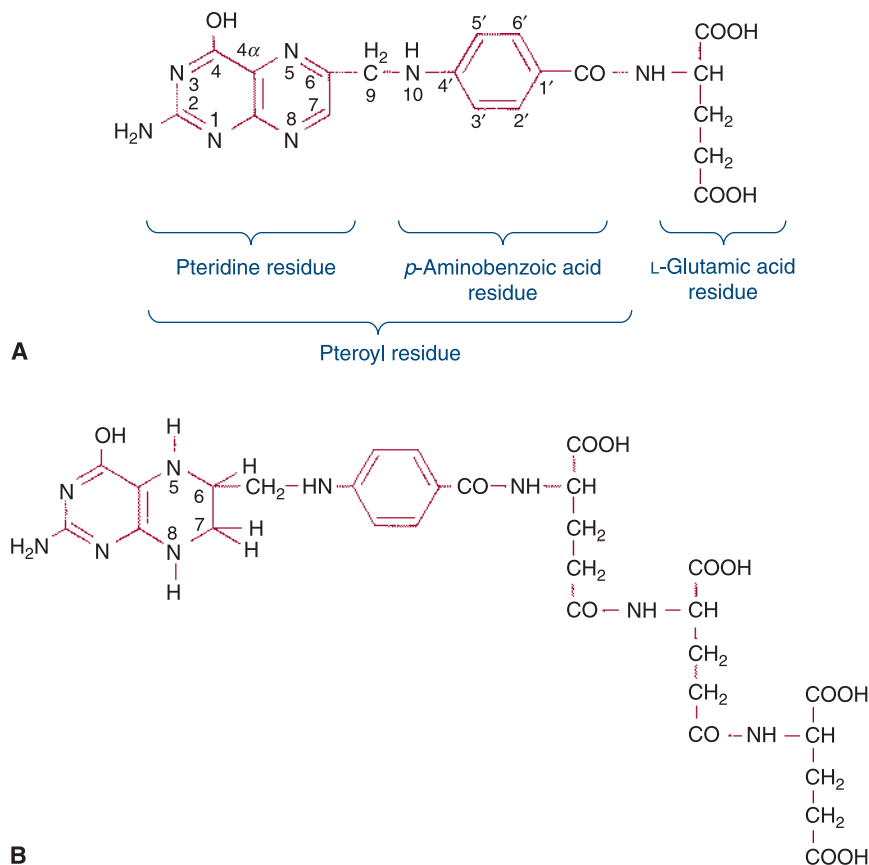

Figure 41-1. Folic acid. **A.** Folic acid (pteroylglutamic acid) and its components. **B.** Tetrahydrofolate triglutamate.

phosphate as a cofactor.⁹ There are both cytoplasmic (SHMT1) and mitochondrial (SHMT2) isoforms of SHMT which impart a state of functional redundancy for this important enzyme, which is the primary source of one-carbon units for purine and pyrimidine biosynthesis. The cytoplasmic form can undergo sumoylation during S-phase, allowing nuclear localization.¹⁰

Among the several one-carbon transfers mediated by folic acid, the transfer that appears to be the most important clinically is the methylation of deoxyuridylylate to thymidylylate, catalyzed by the enzyme thymidylylate synthase.^{2,10,11} This reaction is an essential step in the synthesis of DNA (Fig. 41-3). In carrying out this reaction, $\text{N}^5, \text{N}^{10}$ -methylene FH_4 simultaneously transfers and reduces a one-carbon group, itself serving as the hydrogen donor for the reduction.¹² The reaction generates FH_2 , which must be reduced again to FH_4 by FH_2 reductase and NADPH before it can again be utilized as a coenzyme:

where dUMP = deoxyuridine monophosphate; dTMP = deoxythymidine monophosphate; and NADP = nicotinamide adenine dinucleotide phosphate. Limitation of thymidylylate synthesis in folic acid deficiency causes incorporation of uracil instead of thymine into DNA.¹³

A key enzyme, methylenetetrahydrofolate reductase (MTHFR) regulates the distribution of reduced folates by controlling the rate of NADPH-mediated conversion of $\text{N}^5, \text{N}^{10}$ -methylene FH_4 to N -methyltetrahydrofolate. Because $\text{N}^5, \text{N}^{10}$ -methylene FH_4 is the obligate one-carbon donor for thymidylylate synthesis, its conversion to N -methyltetrahydrofolate serves as a brake on DNA synthesis and repair, while diverting more folate to the methionine synthase reaction (see

Fig. 41-2). The activity of MTHFR therefore serves as a checkpoint for intracellular folate trafficking and distribution, and thus becomes more critical in states of folate depletion.

A polymorphic form of MTHFR, MTHFR 677C→T, is of some clinical importance. The mutation results in a thermolabile form of the enzyme with a higher K_m (Michaelis-Menten dissociation constant) for its methylene- FH_4 substrate. Retardation of the folate methylation cycle makes more methylene- FH_4 available for thymidylylate synthesis (Fig. 41-4), and also affects the levels of homocysteine, an amino acid whose rate of production depends on both folate and cobalamin.

Folate deficiency diminishes purine biosynthesis by slowing (1) the folate-dependent formylation of glycinamide ribotide to N -formylglycinamide ribotide, the reaction that places the C-8 in the purine ring, and (2) the folate-dependent conversion of 5-amino-4-imidazole carboxamide ribotide (AICAR) to 5-formamido-4-imidazole carboxamide ribotide, the reaction that places the C-2 in the purine ring.¹⁴ Additional reactions dependent on biopterin, a nonfolate pteridine derivative, that are of potential metabolic importance are hydroxylation of phenylalanine to tyrosine, oxidation of long-chain alkyl ethers of glycerol to fatty acid, hydroxylation of tryptophan to 6-hydroxytryptophan (a precursor of serotonin), 17 α -hydroxylation of progesterone,¹⁵ and production of nitric oxide.¹⁶ Tetrahydrofolic acid is weakly active in some of these systems *in vitro*¹⁷; whether it plays any such role *in vivo* is unknown.

Significance of Folylpolyglutamates

Intracellular folates exist primarily as polyglutamate conjugates.¹⁸ Approximately 75 percent of the folate in human erythrocytes and leukocytes is polyglutamylated.¹⁹ Plasma folate consists largely of the monoglutamate N^5 -methyltetrahydrofolate and is transported into the cells in this form.²⁰ Inside the cells, the polyglutamate chain is sequentially built up by an ATP-dependent *folylpoly- γ -glutamyl synthase* (FPGS).²¹

Figure 41-2. Derivatives of tetrahydrofolic acid (FH_4), their interconversions, and the metabolic pathways in which they participate. One-carbon substituents are shown in blue.

TABLE 41-1. Metabolic Systems Requiring Folic Acid Coenzymes in Animal Cells

System	Related Transformations of Folic Acid Coenzymes
Serine \rightarrow glycine	Serine + tetrahydrofolate (FH_4) \rightarrow N^5, N^{10} -methylene FH_4 + glycine
Thymidylate synthesis	Deoxyuridylate (dUMP) + N^5, N^{10} -methylene $\text{FH}_4 \rightarrow \text{FH}_2$ + thymidylate (dTMP)
Histidine catabolism	Formiminoglutamate + $\text{FH}_4 \rightarrow N^5$ -formimino FH_4 + glutamate
Methionine synthesis	Homocysteine + N^5 -methyltetrahydrofolate $\rightarrow \text{FH}_4$ + methionine
Purine synthesis	Glycinamide ribotide + N^{10} -formyl $\text{FH}_4 \rightarrow \text{FH}_4$ + formylglycinamide ribotide
Purine synthesis	5-Amino-4-imidazole carboxamide ribotide + N^{10} -formyl $\text{FH}_4 \rightarrow \text{FH}_4$ + 5-formamido-4-imidazolecarboxamide ribotide

The activity of human FPGS depends strongly on the form of the folate substrate, declining in the order $\text{FH}_4 > N^{10}$ -formyl $\text{FH}_4 > N^5$ -methyltetrahydrofolate, toward which the enzyme is almost inert.²² In humans, conjugated folates carry on average seven to eight glutamyl residues.²³ Intracellular folylmonoglutamates leak out of the cells at a fairly rapid rate whereas polyglutamates do not, presumably because of the highly charged polyglutamate tail.²⁴ Therefore, attachment of the polyglutamate chain is essential for retaining folates within cells. Folylpolyglutamates are superior to monoglutamates as substrates for folate-dependent enzyme reactions.¹⁹

PHYSIOLOGY

Intestinal Absorption

The duodenum and proximal jejunum is the principal site of folate absorption. Absorption of a dose of either monoglutamate or polyglutamate forms of folate begins within minutes. Peak plasma levels are reached in 1 to 2 hours. Because only folylmonoglutamate appears in plasma, all folylpolyglutamates must first be hydrolyzed by the enzyme glutamate carboxypeptidase II (folate hydrolase)²⁵ during absorption across the intestine.²⁶ This enzyme (previously referred to as “conjugase”) is located on the brush-border membrane and plays an important role in the intestinal absorption of folate.²⁷ Folylpolyglutamate is hydrolyzed at the brush-border of the intestinal cell (Fig. 41-5). Folate

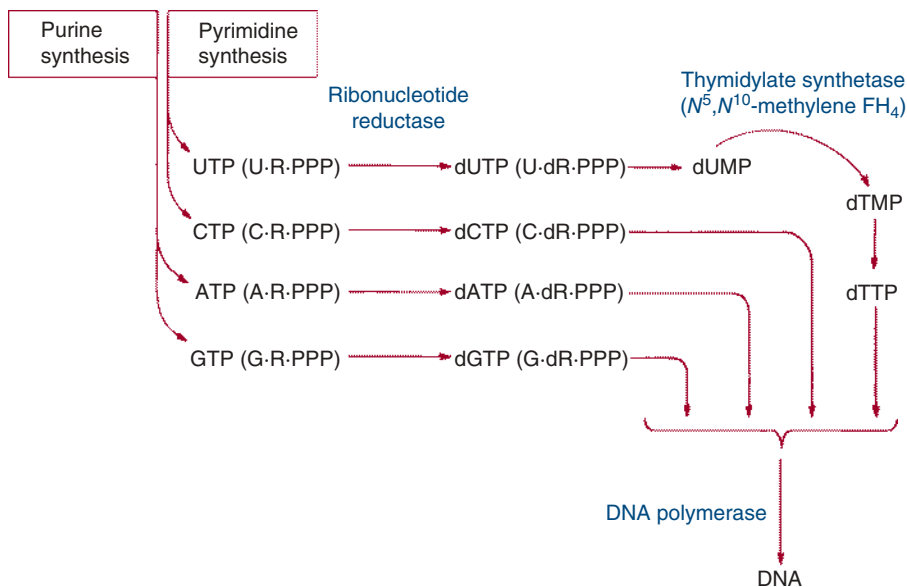

Figure 41-3. Pathways of deoxynucleotide and DNA synthesis.

Figure 41-4. N^5 -methyltetrahydrofolate-homocysteine methyltransferase reaction.

hydrolase purified from human jejunum catalyzes the Zn^{2+} -dependent deconjugation of folate polyglutamates ranging from PteGlu₂ to at least PteGlu₇.²⁸ It is an exopeptidase that successively removes single glutamate residues from the end of the polyglutamate chain, ultimately yielding the folylmonoglutamate. The monoglutamate forms are then taken up by one of two folate-specific transporters located on the apical brush-border, the reduced folate carrier (RFC) or the proton-coupled folate transporter (PCFT).²⁵ Although RFC has a pH optimum of 7.4, PCFT is a high-affinity folate transporter that uses a proton-coupled system to facilitate folate absorption and shows maximum transport activity at a low pH.^{25,29} This property is consistent with the observation that cancer cells retain a high affinity for the new-generation antifolate pemetrexed. Defects in the PCFT are the underlying cause of hereditary folate malabsorption.³⁰

Folate hydrolases also are found outside the intestine. For example, human plasma contains sufficient hydrolase activity to convert polyglutamates containing more than three glutamyl residues to monoglutamates. Other γ -glutamyl hydrolases appear to be lysosomal carboxypeptidases³¹ that are not involved in absorption of folates from the intestine but that play a role in the release of folate from storage sites in the liver and kidney.²⁵

Folate monoglutamates are actively transported across the intestinal epithelium by PCFT-mediated transport ($K_m = 1$ to $2 \mu M$) that is independent of Na^+ , K^+ , and transmembrane potential.³² The mechanism uses the pH gradient between the jejunal lumen (pH ~6) and the interior of the epithelial cell to drive folate into the cell against a concentration gradient.³³ Passive transport also may occur.³⁴ In the intestinal cell, the absorbed folate monoglutamates are reduced if necessary, and then converted to N^5 -methyltetrahydrofolate (some N^{10} -formyl FH_4 also is made) and transported into the bloodstream without further change.³⁵

Folate undergoes an enterohepatic cycle in which it is first secreted against a concentration gradient into the bile, appearing there chiefly as N^5 -methyltetrahydrofolate monoglutamate, and then is reabsorbed from the small intestine.³⁶ Bile contains approximately two to 10 times the folate concentration of normal serum, with biliary excretion accounting for up to 0.1 mg of folate per day. This quantity is sufficiently large that interruption of the enterohepatic cycle by biliary diversion causes serum folate levels to fall by more than 50 percent in less than 1 day.³⁷ The enterohepatic cycle has been proposed to redistribute folate between hepatic stores and peripheral tissues according to the state of the exogenous folate supplies.³⁸

Figure 41-5. Digestion and absorption of folate polyglutamate by the intestine. The polyglutamate (in this case, PteGlu_n) is hydrolyzed in the intestinal lumen or at the brush-border. The resulting pteroylglutamate (PteGlu) is transported into the intestinal cell, where it is reduced and methylated, appearing in the circulation chiefly as N^5 -methyltetrahydrofolate.

METABOLISM

Tritiated foylmonoglutamate ($^3\text{H-F}$) administered intravenously is almost completely removed from the bloodstream in a few minutes.³⁹ Uptake involves two classes of folate-binding proteins⁴⁰: *high-affinity folate receptors*⁴¹ that concentrate folate in intracellular vesicles and a *membrane folate transporter* that transports folate from the vesicles into the cytosol. The high-affinity receptors, which are attached to the outer surface of the cell membrane by glycosyl-phosphatidylinositol linkages and lack an intracytoplasmic portion,⁴² bind very tightly (K_d [distribution coefficient] in the nanomolar range) to most physiologic folate monoglutamates,⁴³ particularly N^5 -methyltetrahydrofolate, the major circulating folate.⁴⁴ The folate receptors exist in various isoforms (of which α and β are the most important). Folate receptor- α , despite its missing cytoplasmic extension, is effective in mediating endocytosis.⁴⁵ Their very high affinity enables the receptors to take up N^5 -methyltetrahydrofolate from the plasma, even at its ambient concentration of approximately 10 nM. The membrane folate transporter is a probenecid-inhibitable organic anion carrier that, among other functions, carries reduced folates and methotrexate in and out of the cytoplasm.⁴⁰ Its K_m for folate is in the micromolar range. Once internalized, the folates are retained by the cells partly through polyglutamylation⁴⁶ as well as through tight association with a set of intracellular folate-binding proteins.⁴⁷ Three of these proteins are enzymes involved in methyl group metabolism: sarcosine dehydrogenase and dimethylglycine dehydrogenase (mitochondrial)⁴⁸ and glycine N -methyl transferase (cytosolic).⁴⁹ Why these enzymes bind folate so avidly or whether this binding affects overall methyl group metabolism is unknown, although glycine N -methyl transferase is speculated to regulate methyl group metabolism by controlling the tissue concentration of S -adenosylhomocysteine (SAH), one of its reaction products and a potent inhibitor of most methyltransferases.

Folates have been found in all body tissues that have been analyzed. The principal form of the vitamin in tissues and in blood appears to be the N^5 -methyl form.⁵⁰ The total folate pool turns over very slowly.⁵¹ Degradation accounts for a portion of this turnover. *p*-Aminobenzoylglutamate has been identified as a breakdown product. The fate of the pteridine moiety is unknown.

FOLATE-BINDING PROTEINS OF SERUM AND MILK

The soluble folate-binding proteins of serum and milk are high-affinity folate receptors that are released from cell membranes by proteolysis.⁵² These proteins can be detected in approximately 15 percent of normal individuals⁵³ and are found at increased levels in some pregnant women, women taking oral contraceptives, folate-deficient alcoholics (but not patients with cobalamin deficiency),⁵⁴ and patients with uremia, hepatic cirrhosis, and chronic myelogenous leukemia.⁵⁵ In normal subjects, the proteins are approximately two-thirds saturated and have a total folate-binding capacity of approximately 175 pg/mL of serum.⁵⁶ The proteins may not be detected in some subjects because of complete saturation of the proteins with endogenous unlabeled folate.⁵⁷ Serum folate-binding protein has an Mr of 40,000 and prefers oxidized to reduced folates.⁵⁵

Folate-binding proteins have been found in milk and in normal granulocytes.⁵⁸ Folate bound to the milk folate binder in suckling animals is absorbed chiefly in the ileum⁵⁹ rather than the jejunum, the principal site of absorption of free folate. The milk folate binder, a glycoprotein, also promotes folate transport into the liver via the asialoglycoprotein receptor.⁶⁰ The milk folate binder is speculated to protect an infant's folate supply by preventing bacteria from sequestering the vitamin away from the intestinal absorptive surface. The folate-binding

protein in granulocytes has been localized to the specific granules, from which it is released when the granulocytes are stimulated.

EXCRETION

Folates are both resorbed and secreted by the kidney. Resorption is accomplished by a membrane-bound high-affinity folate receptor (K_m for N^5 -methyltetrahydrofolate = 0.4 nM) located in the brush-borders of the proximal tubules.⁶¹ Filtered folate may thus be returned to the bloodstream. There is resorption of most, but not all, of the filtered folate.

In humans, intact folates and their cleavage products are excreted by the kidney at a rate of 2 to 5 mcg/day.⁶² A small percentage of parenterally administered labeled folate is recoverable in the feces and mainly represents unreabsorbed folate from the enterohepatic cycle.⁶³

ASSAY OF SERUM FOLATE

Folates are measured by chemiluminescent methods using various folate binders. These assays are identical in principle to the radioligand binding assays that they have replaced.

COBALAMIN

CHEMISTRY

Structure and Nomenclature

The cobalamin molecule has two major portions: a porphyrin-like near-planar macrocycle known as corrin, and a nucleotide that lies almost perpendicular to the corrin ring (Fig. 41-6). The corrin moiety contains four reduced pyrrole rings that bind a central cobalt atom whose two remaining coordination positions are occupied by a 5,6-dimethylbenzimidazolyl (5,6-DMB) group, below the ring and various ligands (in this case, —N in the form of CN) above the ring.⁶⁴

Compounds containing the corrin ring are known as *corrinoids*. The cobalamins are corrinoids whose nucleotide contains 5,6-DMB. Two connections exist between the corrin and the nucleotide: (1) a bond between the nucleotide phosphate and a side chain in ring D, and (2) a bond between cobalt and a nitrogen atom of benzimidazole. Figure 41-7 summarizes the numbering and ring designations of the corrin system.

The term *vitamin B₁₂* is sometimes used as a generic term for the cobalamins. The term probably is best reserved, however, as an alternative name for cyanocobalamin, the usual therapeutic form of cobalamin.

Figure 41-6. A. Structure of cyanocobalamin (CnCbI; vitamin B₁₂). B. Partial structure of CnCbI showing the relationship between the corrin ring and the nucleotide.

Figure 41-7. Corrin ring showing ring designations and standard numbering of the atoms.

Four cobalamins are important in animal cell metabolism. Two are *cyanocobalamin* (CnCbI; vitamin B₁₂) and *hydroxocobalamin* (OHCbI) or *aquocobalamin* (HOHCbI). The other two cobalamins are alkyl derivatives that are synthesized from OHCbI and serve as coenzymes. In one, *adenosylcobalamin* (AdoCbI), a 5'-deoxyadenosyl replaces OH as the cobalt ligand above the ring (Fig. 41-8).⁶⁵ In the second, *methylcobalamin* (MeCbI), the upper ligand is a methyl group. MeCbI is the major form of cobalamin in human blood plasma.⁶⁶

NUTRITION

Sources

Cobalamin is synthesized only by certain microorganisms; animals ultimately depend on microbial synthesis for their cobalamin supply. Foods that contain cobalamin are of animal origin: meat, liver, seafood, and dairy products. Cobalamin has not been found in plants.

Daily Requirements

The average daily diet in Western countries contains 5 to 30 mcg of cobalamin, of which 1 to 5 mcg is absorbed.⁶⁷ Less than 250 ng appears in the urine; the unabsorbed remainder appears in the feces. Total body content is 2 to 5 mg in an adult,⁶⁸ with approximately 1 mg in the liver. The kidneys also are rich in cobalamin.⁶⁹ Relative to the daily requirement, body reserves of cobalamin are much larger than those of folate.

Cobalamin has a daily rate of obligatory loss of approximately 0.1 percent of the total-body pool, irrespective of the pool size. For this reason, a deficiency state does not develop for several years after cessation of cobalamin intake. The officially recommended dietary allowance (RDA) for adults is 2.4 mcg²; growth, hypermetabolic states, and pregnancy increase daily requirements. The RDA for children ages 1 to 13 years is 0.9 to 1.8 mcg. Because of insufficient data, no RDA has been established for infants. Instead, adequate intakes of 0.4 mcg for age 0 to 6 months and 0.5 mcg for age 7 to 12 months have been estimated.

ROLE IN METABOLISM

The only two recognized cobalamin-dependent enzymes in human cells are AdoCbI-dependent *methylmalonyl CoA (coenzyme A) mutase* and MeCbI-dependent *methyltetrahydrofolate-homocysteine methyltransferase*.

Methylmalonyl Coenzyme A Mutase

Methylmalonyl CoA mutase is a mitochondrial enzyme that participates in the disposal of the propionate formed during breakdown of valine, isoleucine, and odd-carbon fatty acids. The enzyme is a homodimer of a 78-kDa subunit that is encoded by a gene on chromosome 6.⁷⁰ In the reaction catalyzed by methylmalonyl CoA mutase, methylmalonyl CoA, which is produced during catabolism of propionate,⁷¹ is converted to succinyl CoA, a Krebs cycle intermediate. In the course of this reaction, a hydrogen on the methyl carbon of the substrate exchanges places with the —COSC oA group (Fig. 41-9).

The coenzyme serves as an intermediate hydrogen carrier, accepting the hydrogen from the substrate in the initial phase of the reaction and returning it to the product after migration of —COSC oA.

N⁵-Methyltetrahydrofolate-Homocysteine Methyltransferase

MeCbI participates in cobalamin-dependent synthesis of methionine from homocysteine by the enzyme N⁵-methyltetrahydrofolate-homocysteine methyltransferase. S-adenosylmethionine (SAMe) and a second enzyme, methionine synthase reductase are required for methyltransferase activity.⁷² The reductase converts the oxidized cobalt to

Figure 41-9. Methylmalonyl coenzyme A (CoA) mutase reaction. AdoCbI, adenosylcobalamin.

Figure 41-8. Adenosylcobalamin (AdoCbI). R = CH₂CONH₂; R' = CH₂CH₂CONH₂.

the readily alkylizable Co^+ , which then accepts a methyl group from SAMe, a powerful biologic methylating agent, thereby restoring activity of the methyltransferase. In humans, this pathway also serves as a mechanism critical for converting N^5 -methyltetrahydrofolate to FH_4 required for synthesis of polyglutamates as well as other important one-carbon adducts of folate. The demethylation of N^5 -methyltetrahydrofolate is a prerequisite for attachment of the polyglutamate chain to newly acquired folate, which is largely taken up by the cell in the form of N^5 -methyltetrahydrofolate monoglutamate.²⁴ Nitrous oxide (N_2O) impairs the methyltransferase by oxidizing cob(I)alamin (a catalytic intermediate in the methyltransferase reaction) to cob(II)alamin. This reaction depletes MeCbl and produces a cobalamin deficiency-like state.

Nonenzymatic Metabolism

Because cobalamin has the capacity to bind cyanide, it may participate in detoxification of cyanide. Tobacco and certain foods (fruits, beans, tubers, and nuts) contain cyanide in the form of thiocyanate. Although the evidence is inconclusive, cobalamin is believed to play a role in neutralizing cyanide taken in via these substances.⁶⁴

FOLATE-COBALAMIN RELATIONSHIP

In both folate deficiency and cobalamin deficiency, the megaloblastic anemias are fully corrected by treatment with the appropriate vitamin. The megaloblastic anemia of cobalamin deficiency also is variably corrected by folic acid supplementation even if no cobalamin is given, although the remission may be partial and only temporary. Conversely, the anemia of folate deficiency is generally not helped at all by cobalamin although partial responses to high doses of cobalamin have been reported in some patients with folate deficiency.⁷³ These clinical observations indicate that the megaloblastic anemia in cobalamin deficiency actually results from an abnormality in folate metabolism.²⁴ The observation that urinary excretion of formiminoglutamic acid (FIGlu) and AICAR, normally regarded as a sign of folate deficiency, is seen occasionally in pure cobalamin deficiency⁷⁴ provides further evidence that folate metabolism is deranged by cobalamin deficiency. Two explanations have been proposed to account for the folate responsiveness of cobalamin-deficient megaloblastic anemia: (1) the *methylfolate trap* hypothesis, which is accepted by the majority of authorities, and (2) the *formate starvation* hypothesis (Fig. 41–10).

METHYLFOLATE TRAP HYPOTHESIS

The methylfolate trap hypothesis⁷⁵ is based on the fact that the folate-requiring enzyme N^5 -methyltetrahydrofolate–homocysteine methyltransferase is also dependent on cobalamin. The hypothesis states that in cobalamin deficiency tissue folates are gradually diverted into the N^5 -methyltetrahydrofolate pool because of slowing of the methyltransferase reaction,⁷⁶ the only route out of that pool for folate. As N^5 -methyltetrahydrofolate levels increase, the levels of other forms of folate decline, with a consequent fall in the rates of reactions in which those forms participate. In particular, because the MTHFR reaction is irreversible, methylene- FH_4 becomes depleted, the synthesis of dTMP is slowed, and megaloblastic anemia ensues.

In its simplest form, the hypothesis predicts that in cobalamin deficiency tissue levels of N^5 -methyltetrahydrofolate are abnormally high and those of other forms of folate are abnormally low. Although serum N^5 -methyltetrahydrofolate levels are frequently elevated in cobalamin deficiency,⁷⁷ tissue folate levels, predominantly polyglutamates, decline.⁷⁸ The decreased level appears to be related to the substrate specificity of the folate-conjugating enzyme. This enzyme works very poorly with N^5 -methyltetrahydrofolate; therefore, it is unable to carry out normal γ -glutamyl transfer of newly internalized N^5 -methyltetrahydrofolate monoglutamate in cobalamin-deficient cells because the freshly acquired folate cannot be converted into a suitable substrate (i.e., free FH_4 or formyl FH_4). Thus, although sequestration of tissue folates in an expanded N^5 -methyltetrahydrofolate pool may account for some of the effects of the blockade in methyltransferase activity, the major problem seems to be a failure to convert newly acquired folate into a form that can be retained by the cell. The upshot is development of tissue folate deficiency as the unconjugated folate leaks out (see Fig. 41–10). The whole process is aggravated by a drop in tissue levels of SAMe as the methionine supply is curtailed because of the diminished activity of the methyltransferase.⁷⁹ SAMe, which is necessary for methyltransferase activity, is also a powerful inhibitor of N^5, N^{10} -methylene FH_4 reductase MTHFR,⁸⁰ the enzyme responsible for production of N^5 -methyltetrahydrofolate. The relief of this inhibition as SAMe levels fall accelerates the flow of folates toward N^5 -methyltetrahydrofolate, further aggravating the metabolic imbalance resulting from impairment in methyltransferase activity.

This problem could be overcome if N^5 -methyltetrahydrofolate were converted into a substrate for the conjugating enzyme by another route. In theory, this could be accomplished by reversal of

Figure 41–10. Methods by which cobalamin deficiency decreases intracellular folate levels. Methyltetrahydrofolate (MeFH_4), the principal form of folate in the bloodstream, circulates in the unconjugated form (i.e., it has no polyglutamate side chain). This and other forms of unconjugated FH_4 can be taken into cells but leak out again unless they are conjugated. MeFH_4 is not a substrate for the conjugating enzyme, so conjugation cannot occur until the MeFH_4 is converted to another form of folate. Cobalamin is necessary for this process because it is the cofactor for the reaction that converts MeFH_4 to FH_4 . In cobalamin deficiency, the conversion of MeFH_4 to FH_4 is defective. Newly transported folate remains in the form of MeFH_4 , which cannot be conjugated and leaks back out of the cell. **A.** According to the *methylfolate trap hypothesis*, all forms of FH_4 other than MeFH_4 can be conjugated, so MeFH_4 is the only folate species that leaks out of the cell. **B.** The *formate starvation hypothesis* differs from the methylfolate trap hypothesis solely in assuming that only the formylated folates (N^{10} -formyl FH_4 and/or N^5, N^{10} -methenyl FH_4) can be conjugated, so newly transported MeFH_4 , N^5, N^{10} -methylene FH_4 and free FH_4 leak out of the cell. $(\text{CHO})\text{FH}_4 = N^{10}$ -formyl FH_4 . Homocys met, homocysteine methyltransferase.

the N^5,N^{10} -methylene FH_4 reductase reaction. For practical purposes, however, the N^5,N^{10} -methylene FH_4 reductase reaction is irreversible *in vivo*.⁸¹

FORMATE STARVATION HYPOTHESIS

This hypothesis holds that formate starvation is the basis for folate-responsive megaloblastic anemia of cobalamin deficiency.⁸² This theory is based on the diminished capacity of cobalamin-deficient lymphoblasts to incorporate formaldehyde into purine and methionine⁷⁹ and on experiments showing that N^5 -formyl FH_4 is more effective than FH_4 at correcting some of the abnormalities in folate metabolism seen in cobalamin deficiency.⁸³ The hypothesis states that with the decrease in methionine production in cobalamin-deficient conditions, the generation of formate is depressed (because normally the methyl group of excess methionine is rapidly oxidized to formate),⁸⁴ leading to a decline in the production of N^5 -formyl FH_4 .

INTESTINAL ABSORPTION

Intrinsic Factor

Intrinsic factor is one of a number of binding proteins in which cobalamin is ensconced as it makes its way through the body (Table 41–2). Intrinsic factor is needed for the absorption of cobalamins taken orally at physiologic dosage levels. Human intrinsic factor is a glycoprotein (Mr approximately 44,000) encoded by a gene on chromosome 11.⁸⁵ It has binding sites for cobalamin and a specific ileal receptor, the former situated near the carboxy-terminus and the latter near the aminoterminus of the intrinsic factor molecule.⁸⁶ Binding to cobalamin is very tight, and involves the 5,6-DMB lower axial ligand of the molecule. This specificity allows for the exclusion of other noncobalamin corrinoids during the tightly regulated absorptive process.⁶⁴ The entrapment of the vitamin alters the conformation of intrinsic factor, producing a more compact form that is resistant to proteolytic digestion.

In humans, intrinsic factor is synthesized and secreted by the parietal cells of the cardiac and fundic mucosa.⁸⁷ Secretion of intrinsic factor usually parallels that of hydrochloric acid (HCl). It is enhanced by the presence of food in the stomach, vagal stimulation, histamine, and gastrin. Gastric juice also contains other cobalamin-binding glycoproteins.⁸⁸ These proteins were known as the *R proteins* because of their rapid electrophoretic mobility compared with intrinsic factor. Elucidation of the primary protein structure of the R proteins reveals that they belong to the same family of isoproteins as the plasma haptocorrin (HC) binder (previously known as transcobalamins I and III). These HC-like proteins are produced mainly by the salivary glands.

Absorption of Cobalamin: Cubilin

Cobalamins in foods are liberated in the stomach by peptic digestion.⁸⁹ They are then bound not to intrinsic factor but to the HC-like protein

because cobalamin binds much more tightly to HC than to intrinsic factor at the acid pH of the stomach.⁹⁰ Upon entering the duodenum, cobalamin is released from the cobalamin–HC protein complex through digestion by pancreatic proteases, which in normal subjects act by selectively degrading HC and the cobalamin–HC complex while sparing intrinsic factor.⁹⁰ Only at this point can cobalamin bind to intrinsic factor to form the intrinsic factor–cobalamin complex.

The intrinsic factor–cobalamin complex, which is very resistant to digestion,⁹¹ traverses the intestine until it reaches the intrinsic factor receptor, *cubilin*,⁹² a 460-kDa peripheral membrane glycoprotein located in the microvillus pits of the ileal mucosa brush-border. Cubilin forms part of a multifunctional epithelial receptor complex also found in the yolk sac and renal proximal tubule cells.⁹³ In the kidney, it appears to serve a role in the overall body economy through tubular reabsorption of cobalamin,⁹⁴ but the function of the cubilin receptor complex in the kidney and other polarized epithelial surfaces extends beyond cobalamin. The ileal cubilin receptor complex consists of two proteins, cubilin (CUB) and amnionless (AMN), the product of two distinct genes, *CUB* and *AMN*. Both proteins, which together have been designated the “CUBAM complex,” colocalize in the endocytic compartment and are required for the process of assimilation of cobalamin,⁹⁵ AMN serving as a chaperon for endosomal targeting. Mutations affecting either of the two proteins disrupt the normal process of the intestinal phase of cobalamin absorption. In addition to the tightly embracing components of the CUBAM complex, a distinct large multifunctional protein, megalin, which belongs to the low-density lipoprotein family,⁹⁶ also participates in the conformational changes that accompany internalization. The concentration of the CUBAM complex rises progressively to a maximum near the terminal ileum.⁹⁷ A specific site on the intrinsic factor molecule avidly attaches to the receptor in a binding reaction that requires a pH of 5.4 or greater and Ca^{2+} (or other divalent cations) but no energy.⁹⁸

The intrinsic factor–cobalamin receptor complex is taken into the ileal mucosal cells over 30 to 60 minutes by endocytosis,⁹⁹ where the vitamin is processed and released into the portal blood over many hours. The receptors recycle to the microvillus surface to shuttle another load of intrinsic factor–cobalamin complex.⁹⁹ That this process has a limited capacity is evident from estimates of the maximum amount of cobalamin that can be absorbed from a single dose via this physiologic pathway.^{64,100} Defects in the genes that regulate the complex mechanism of ileal absorption are implicated in autosomal recessive megaloblastic anemia (MGA1), caused by intestinal malabsorption of cobalamin (see “Selective Malabsorption of Cobalamin, Autosomal Recessive Megaloblastic Anemia, Imerslund-Gräsbeck Disease” below).

During its sojourn in the ileal enterocyte, the vitamin first appears in the lysosomes, but by 4 hours most of the vitamin is located in the cytosol.¹⁰¹ During absorption, the entire intrinsic factor–cobalamin complex appears to be taken into the cell, where the cobalamin is released while the intrinsic factor is degraded.¹⁰²

Cobalamin from a small oral dose (10 to 20 mcg) starts to appear in the blood after 3 to 4 hours, and the vitamin reaches a peak level in 6 to 12 hours. In the portal blood, the cobalamin is complexed with a cobalamin-transporting protein known as *transcobalamin* (TC) previously known as TC II.¹⁰³ There is evidence that cobalamin leaves the enterocyte through a portal that is part of the ABC drug transport system, ABCC1 (also known as the multidrug resistance protein1 [MRP1]) located on the basolateral surface of the intestinal epithelium, as well as other polar cells and nonpolar cells (macrophages).¹⁰⁴ The cobalamin–TC complex is now believed to be formed as it exits the ileal enterocyte, one of a variety of cells that synthesize TC, including the neighboring vascular endothelial cells in the submucosa.¹⁰⁵ Large oral doses (1 mg) of cobalamin are absorbed inefficiently (1 to 2 percent of an oral dose)

TABLE 41–2. Cobalamin-Binding Proteins

Protein	Source	Function
Intrinsic factor	Gastric parietal cells	Promotes absorption uptake of cobalamin by ileum
Transcobalamin	Probably all cells	Promotes uptake of cobalamin by cells
Haptocorrin	Exocrine glands, phagocytes	Helps dispose of cobalamin analogues (?)

Figure 41–11. Biosynthesis of adenosylcobalamin (AdoCbl).

by simple diffusion that is not mediated by intrinsic factor.¹⁰⁰ In these instances, the vitamin appears in blood within minutes, again as the cobalamin–TC complex.

Like the folates, the cobalamins undergo appreciable enterohepatic recycling.¹⁰⁶ In humans, between 0.5 and 9 mcg/day of cobalamin is secreted into the bile, where it is bound to HC.¹⁰⁷ After entering the intestine, the cobalamin–HC complexes of biliary origin are treated exactly like those delivered from the stomach. The cobalamin is released by digestion of the HC by pancreatic proteases, and then is taken up by intrinsic factor and reabsorbed. From 65 to 75 percent of biliary cobalamin is estimated to be reabsorbed by this mechanism.¹⁰⁸ Because of the size of the cobalamin storage pool and the existence of this enterohepatic circulation, a very long time—as long as 20 years—is required for a clinically significant cobalamin deficiency to develop from a diet providing insufficient cobalamin (e.g., a strictly vegetarian diet).¹⁰⁹ Patients who are unable to absorb the vitamin, however, become clinically deficient in only 3 to 6 years because the absorption of both biliary and dietary cobalamin are interdicted.¹¹⁰

COBALAMIN IN THE CELL: TRANSCOBALAMIN

Uptake of Cobalamin By Cells

TC is the plasma protein that mediates the transport of cobalamin into the tissues.¹¹¹ A β -globulin protein with a calculated molecular weight of 45,538 from the deduced amino acid sequence,^{112,113} TC binds cobalamin with exceedingly high affinity ($K_a = 10^{-11} M$).¹¹⁴ Unlike intrinsic factor, whose binding is highly specific for cobalamins, TC shows some promiscuity and also can bind certain corrins that are chemically related to the cobalamins but have no function in mammalian systems and are known as cobalamin “analogues.”¹¹⁵ TC is synthesized by many types of cells, including enterocytes, hepatocytes, endothelial cells, mononuclear phagocytes, fibroblasts, and hematopoietic precursors in the marrow.⁶⁴ Although circulating TC carries only a minor fraction of the cobalamin in the plasma, it is the protein on which cobalamin absorbed through the intestine and is transported into the portal blood as the preformed cobalamin–TC complex. It also is the protein with which cobalamin given parenterally associates almost immediately.¹¹⁶ These cobalamin–TC complexes are transported into the tissues within minutes of appearing in the bloodstream.¹¹⁷ The transport process begins with binding of the cobalamin–TC complex to a specific membrane receptor that is present on a wide variety of cells.¹¹⁸ The protein and gene encoding the TC receptor has been purified from placental membranes and characterized.¹¹⁹ Designated as CD320, the receptor belongs to the low-density

lipoprotein receptor family and its internalization involves megalin. The receptor-bound complex is internalized by receptor-mediated endocytosis and delivered to a lysosome, where the TC is digested and the cobalamin is freed.^{120,121}

Formation of Adenosylcobalamin and Methylcobalamin

To become metabolically active, CnCbl and OHcbl must first be converted to AdoCbl and MeCbl, the coenzymatically active cobalamins. The conversion is accomplished by reduction and alkylation. CnCbl and OHcbl are first reduced to the Co^{++} form [cob(II)alamin] by NADPH- and NADH (nicotinamide adenine dinucleotide phosphate)-dependent reductases that are present in mitochondria and microsomes.¹²² CN- and OH- are displaced from the metal during reduction. Some of the cob(II)alamin is reduced further in the mitochondria to the intensely nucleophilic Co^+ form [cob(I)alamin]. This is then alkylated by ATP to form AdoCbl in a reaction in which the 5'-deoxyadenosyl moiety of ATP is transferred to the cobalamin and the three phosphates of ATP are released as inorganic triphosphate (Fig. 41–11). The rest of the cobalamin binds to cytosolic N^5 -methyltetrahydrofolate–homocysteine methyltransferase, where it is converted to MeCbl. The several steps involved in the conversion of cobalamin to its coenzymatically active forms are regulated by genes that play a critical role in the processing of the vitamin. There are a number of inherited metabolic errors that correspond to one or more of these specific steps and that result in characteristic syndromes affecting aspects of cobalamin metabolism that are discussed later in this chapter.

PLASMA HAPTOCORRIN (TRANSCOBALAMINS I AND III; “R” PROTEINS)

The HCs (previously known as R proteins) are a group of immunologically related proteins of apparent Mr approximately 60,000, consisting of a single polypeptide species variably substituted with oligosaccharides that terminate with different quantities of sialic acid.¹²³ They are found in milk, plasma, saliva, gastric juice, and numerous other body fluids. They appear to be synthesized by mucosal cells of the organs that secrete them¹²⁴ and by phagocytes.¹²⁵ Although the HCs bind cobalamin, they lack intrinsic factor activity, that is, they are unable to promote the intestinal absorption of the vitamin.

Plasma HC carries most (70 to 90 percent) of the circulating cobalamin. It contains nine potential glycosylation sites¹²⁶ and is encoded by a gene on chromosome 11, the same chromosome that carries the intrinsic factor gene.¹²⁷ In contrast to TC, HC clearance from the plasma is

very slow (half-life [$T_{1/2}$]: 9 to 10 days).¹²⁸ The asialoglycoprotein receptor carries the cobalamin-HC complexes into the hepatocytes, where they are chiefly eliminated. The complexes are degraded, and their load of cobalamins is excreted in the bile.^{106,129} HC binds its ligands more tightly than does either intrinsic factor or TC. Furthermore, HC is less restrictive than either intrinsic factor or TC with respect to ligand specificity; it avidly takes up corrinoids of widely varying structure.¹³⁰ The ligand-binding properties of HC and its mode of clearance by the liver suggest that HC helps clear the system of nonphysiologic cobalamin analogues that may have been acquired or may have arisen through degradation of cobalamin.^{131,132} As the liver metabolizes analogue-HC complexes, it secretes the analogues into the bile. Because these analogues are bound poorly by intrinsic factor,¹³⁰ they are poorly reabsorbed from the intestine and are eliminated in the feces. The precise role of HC is unknown, although it may play a role in the body economy of cobalamin by facilitating excretion of cobalamin analogues while conserving cobalamin through enterohepatic recycling. Additionally, it has been proposed that HC may serve an antimicrobial role.⁶⁴

ASSAY OF SERUM COBALAMIN AND THE TRANSCOBALAMINS

As with folate, cobalamin is usually measured with automated competitive displacement assays using intrinsic factor as a cobalamin-binding protein. The misleading results previously provided by competitive ligand displacement assays were explained by the discovery in serum and tissue of a class of cobalamin analogues that are detected by the radioisotope assay when HC-type proteins and not intrinsic factor were used as the binding protein.¹³³ Current assays use intrinsic factor as the binder and give more reliable values for serum cobalamin. The chemical nature and biologic significance of the analogues are unknown,¹³⁴ but recent evidence suggests that they may arise in the gastrointestinal tract.^{131,132}

TC and HC are present in plasma in trace quantities (approximately 7 and 20 mcg/L, respectively). In fasting plasma, at least 70 percent of the circulating cobalamin is bound to HC.¹³⁵ TC binds only 10 to 25 percent of the total plasma cobalamin,¹³⁶ but provides the majority (approximately 75 percent) of the total unsaturated cobalamin-binding capacity of plasma.¹³⁵ Table 41-3 lists alterations in unsaturated cobalamin-binding capacity and in HC and TC levels in various disease states. In recent years, assays have been developed that measure the fraction of the plasma cobalamin that is bound to TC. This component, known as holotranscobalamin (holoTC), shows improved specificity compared with the standard cobalamin assay for identifying true cobalamin deficiency, although the assays appear to be generally comparable with respect to sensitivity.¹³⁷⁻¹⁴³

MEGALOBlastic ANEMIAS

DEFINITION

Megaloblastic anemias are disorders caused by impaired DNA synthesis. The presence of megaloblastic cells is the morphologic hallmark of this group of anemias. Megaloblastic red cell precursors are larger than normal and have more cytoplasm relative to the size of the nucleus. Promegaloblasts show a blue granule-free cytoplasm and a fine “salt and pepper” granular chromatin that contrasts with the ground-glass texture of its normal counterpart. As the cell differentiates, the chromatin condenses more slowly than normal into darker aggregates that coalesce, but do not fuse homogeneously, giving the nucleus a characteristic fenestrated appearance. Continuing maturation of the cytoplasm as it acquires hemoglobin contrasts with the immature-looking nucleus—a feature termed *nuclear-cytoplasmic asynchrony*.

TABLE 41-3. Levels and Binding Capacity of Cobalamin-Binding Proteins in Disease

Binder	Disease
Increased HC (TCI, R protein)	Myeloproliferative disorders
	Polycythemia vera

Unsaturated cobalamin binders	
Increased	Transient neutropenia
	Elevated HC
Decreased	Liver disease
	Elevated serum cobalamin

Data from Lawler S, Roberts P, Hoffbrand A: Chromosome studies in megaloblastic anaemia before and after treatment. *Scand J Haematol* 8(4):309-320, 1971.

Megaloblastic granulocyte precursors are also larger than normal and show nuclear-cytoplasmic asynchrony. A characteristic cell is the *giant metamyelocyte*, which has a large horseshoe-shaped nucleus, sometimes irregularly shaped, containing ragged open chromatin.

Megaloblastic megakaryocytes may be abnormally large and polyplobated, with deficient granulation of the cytoplasm. In severe megaloblastosis, the nucleus may show detached lobes. Further details are provided in “Laboratory Features” below and in Figs. 41-12 and 41-13.

ETIOLOGY AND PATHOGENESIS

Table 41-4 lists the causes of megaloblastic anemia. By far the most common causes worldwide are folate deficiency and cobalamin deficiency. There has, however, been a marked reduction in the prevalence of folate deficiency in North America and a growing number of other countries that have implemented folic acid fortification of the food supply.

Megaloblastic cells have much more cytoplasm and RNA than do their normal counterparts, but they have a relatively normal amount of DNA,¹⁴⁴ suggesting that cytoplasmic constituents (RNA and protein) are synthesized faster than is DNA. Evidence that maturation is retarded in megaloblastic precursors supports this conclusion.¹⁴⁵ DNA synthesis is impaired,¹⁴⁶ and migration of the DNA replication fork and the joining of DNA fragments synthesized from the lagging strand (Okazaki fragments) are delayed,¹⁴⁷ and the S-phase is prolonged.¹⁴⁶

Slowing of DNA replication in the megaloblastic anemias of folate and cobalamin deficiency appears to arise from failure of the folate-dependent conversion of dUMP to dTMP. Because of this failure, deoxyuridine triphosphate (dUTP) levels become abundant and because DNA polymerase is promiscuous with respect to its substrate specificity, allows dUTP to become incorporated into the DNA of folate-deficient cells in place of deoxythymidine triphosphate (dTTP).¹⁴⁸ DNA excision-repair mechanisms to repair the DNA by replacing uridine with

Figure 41-12. **A.** Pernicious anemia. Blood film. Note the striking oval macrocytes, wide variation in red cell size, and poikilocytes. Despite the anisocytosis and microcytes, the mean red cell volume is usually elevated, as in this case (mean corpuscular volume [MCV] = 121 fL). **B.** Marrow precursors in pernicious anemia. Note very large size of erythroblasts (megaloblasts) and asynchronous maturation. Cell on *right* is a polychromatophilic megaloblast with an immature nucleus for that stage of maturation. Cell on *left* is an orthochromatic megaloblast with a lobulated immature nucleus. An orthochromatic megaloblast with a condensed nucleus is between and above those two cells. **C** and **D.** Two examples of hypersegmented neutrophils characteristic of megaloblastic anemia. The morphology of blood and marrow cells in folate-deficient and vitamin B₁₂-deficient patients is identical. The extent of the morphologic changes in each case is related to the severity of the vitamin deficiency. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

thymidine fail for the same reason that uridine triphosphate was incorporated into the DNA in the first place. The result is a repetitive iteration of flawed DNA repair that ultimately leads to DNA strand breaks, fragmentation, and apoptotic cell death.¹⁴⁹

Addition of deoxyuridine (dU) to marrow cells in culture normally decreases the incorporation of tritiated thymidine into DNA, because the dU is converted via dUMP→dTMP to unlabeled dTTP, which competes with the tritiated thymidine. In megaloblastic cells, this effect of added dU is greatly diminished. This finding is consistent with impairment in the dUMP→dTMP reaction in the megaloblastic cells and was the basis for the now defunct *dU suppression test*.¹⁵⁰ The failed excision–repair model following dUTP misincorporation into DNA also explains the chromosome breaks and other abnormalities that occur in megaloblastic cells.¹⁵¹

CLINICAL FEATURES

All megaloblastic anemias share certain general clinical features. Because the anemia develops slowly, with opportunity for cardiopulmonary

and intraerythrocytic compensatory changes,¹⁵² it produces few symptoms until the hematocrit is severely depressed. Symptoms, when they appear, are those of anemia: weakness, palpitation, fatigue, lightheadedness, and shortness of breath. The blending of severe pallor and slight jaundice caused by a combination of intramedullary and extravascular hemolysis produce a characteristic lemon-yellow skin. Leukocyte and platelet counts may be low, but rarely cause clinical problems. Details of the clinical manifestations are given in the sections on the specific forms of megaloblastic anemia later in this chapter.

LABORATORY FEATURES

Blood Cells

All cell lines are affected. Erythrocytes vary markedly in size and shape, often are large and oval, and in severe cases can show basophilic stippling and nuclear remnants (Cabot rings and Howell-Jolly bodies). Erythroid activity in the marrow is enhanced, although the megaloblastic cells usually die before they are released, accounting for the reduced reticulocyte count. The more severe the anemia, the more pronounced

Figure 41-13. Marrow films. Megaloblastic anemia. Patient with pernicious anemia (vitamin B₁₂ deficiency). **A.** Basophilic megaloblasts. Large cell size, very characteristic nuclear chromatin pattern with exaggerated proportion of euchromatin. **B.** Polychromatophilic megaloblast. Very large cell size for maturational stage. Large nuclear size and abnormally large proportion of euchromatin without appropriate nuclear condensation at this stage of maturation. Adjacent lymphocyte. **C.** Polychromatophilic megaloblast with small nuclear fragment. Arrow indicates giant band neutrophil. At lower left is orthochromatophilic megaloblast with multiple nuclear fragments. **D.** Oblique arrow indicates promegaloblast. Horizontal arrow indicates giant band neutrophil. To the left of and below the asterisk are four orthochromatophilic megaloblasts—large cell size for maturational stage: two with delayed nuclear condensation and two with condensed nuclei with abnormal nuclear margins showing small or large budding nuclei. To the right of the asterisk are two giant band neutrophils. On the right at midfield is a plasma cell below which is a lymphocyte. (Reproduced with permission from Lichtman's Atlas of Hematology, www.accessmedicine.com.)

the morphologic changes in the red cells. When the hematocrit is less than 20 percent, erythroblasts with megaloblastic nuclei, including an occasional promegaloblast, may appear in the blood. The anemia is macrocytic (mean corpuscular volume [MCV] is 100 to 150 fL or more), although coexisting iron deficiency, thalassemia trait,¹⁵³ or inflammation can prevent macrocytosis.¹⁵⁴ Slight macrocytosis may be the earliest sign of megaloblastic anemia. Because of the progressive nature of gradual replacement of normocytic red cells with the macrocytic progeny of a megaloblastic marrow, the earliest observable change in red cell indices is an increase in the red cell distribution width (RDW), reflecting an increase in anisocytosis.

Neutrophil nuclei often have more than the usual three to five lobes (see Fig. 41-12).¹⁵⁵ Typically, more than 5 percent of the neutrophils have five lobes. Cells may contain six or more lobes, a morphology rarely seen in normal neutrophils but not pathognomonic of megaloblastic hematopoiesis. In nutritional megaloblastic anemias caused by folate deficiency, hypersegmented neutrophils are an early sign of megaloblastosis⁵ and persist in the blood for many days after treatment.¹⁵⁵ Neutrophil hypersegmentation was not found to be a sensitive test for mild cobalamin deficiency.¹⁵⁶ Cytogenetic studies are non-specific and show chromosomes that are elongated and broken. Specific therapy corrects these abnormalities, usually within 2 days, although some abnormalities do not disappear for months.^{151,157} Platelets are often

reduced in number and slightly smaller than normal with a wider variation in size (increased platelet distribution width [PDW]).¹⁵⁸ The morphologic features of megaloblastic anemia may be grossly exaggerated in patients who have been splenectomized or lack a functional spleen as occurs in celiac disease or sickle cell anemia. Numerous circulating megaloblasts and bizarre red cell morphology may be present.¹⁵⁹

Marrow

Aspirated marrow is cellular and shows striking megaloblastic changes, especially in the erythroid series with well-hemoglobinized erythroblasts containing nuclei that possess less-mature, more-open nuclear chromatin than their normal counterparts. There is a preponderance of earlier basophilic erythroblasts over more mature forms which gives the overall impression of a maturation arrest (see Fig. 41-13). Sideroblasts are increased in number and contain increased numbers of iron granules. The ratio of myeloid to erythroid precursors falls to 1:1 or lower, and granulocyte reserves may be decreased. In severe cases, promegaloblasts containing an unusually large number of mitotic figures are plentiful. Macrophage iron content often is increased. Megaloblastic features in the granulocytic series is also usually present with giant forms and large horseshoe-shaped nuclei. Occasionally megakaryocytes with hyperlobated nuclei are present.

Coexisting Microcytic Anemia

Many features of megaloblastic anemia may be masked when megaloblastic anemia is combined with a microcytic anemia.¹⁵⁴ The anemia can be normocytic or even microcytic, whereas the blood film may show both microcytes and macroovalocytes (a "dimorphic anemia"). The marrow may contain "intermediate" megaloblasts¹⁶⁰ that are smaller and look less "megaloblastic" than usual. In this kind of mixed anemia, the microcytic component usually is iron-deficiency anemia,¹⁵⁴ but it may be thalassemia minor¹⁵³ or the anemia of chronic disease. Even megaloblastic anemia masked by a severe microcytic anemia usually shows hypersegmented neutrophils in the blood and giant metamyelocytes and bands in the marrow. Neutrophil myeloperoxidase levels are high.¹⁶¹

Less commonly, the megaloblastic component of a mixed iron-deficiency anemia can be overlooked, and the patient may be treated only with iron. In this situation, the anemia may respond only partly to therapy, and megaloblastic features become more conspicuous as iron stores fill. The masking of macrocytosis in these situations may

be responsible for delay or difficulty in diagnosis of pernicious anemia, particularly in certain geographic areas and ethnic groups where there is a high incidence of thalassemia and microcytic hemoglobinopathies.^{153,162,163} There are several situations that favor the coexistence of a megaloblastic state with iron deficiency. Both folate and iron deficiency occur in celiac disease,¹⁶⁴ and cobalamin and iron deficiency both complicate gastric reduction surgery for morbid obesity.¹⁶⁵ Furthermore, *Helicobacter pylori* infection is associated with gastric atrophy that can result first in iron deficiency and later lead to cobalamin malabsorption and perhaps even predispose to pernicious anemia.^{166,167}

Incomplete Megaloblastic Anemia

If a patient with a full-blown megaloblastic anemia receives cobalamin or folate before marrow aspiration, the anemia persists but the megaloblastic changes may be obscured. Attenuated megaloblastic changes also are seen in patients with early megaloblastic anemia, in patients with coexisting infection,¹⁵⁴ or in patients after transfusion.

Megaloblastic Anemia Misdiagnosed as Acute Leukemia

Occasionally, very severe megaloblastic anemia produces marrow morphology so bizarre as to be mistaken for acute leukemia. In some cases, the erythroid series does not mature, and the megaloblastic pronormoblast dominates the marrow with prominent mitotic figures and dysmorphic forms, raising the possibility of erythroid leukemia.

Megaloblastic Changes in Other Cells

In most forms of megaloblastic anemia, cytologic abnormalities resembling megaloblastosis may appear in other proliferating cells. Epithelial cells from the mouth, stomach, small intestine, and cervix uteri may look megaloblastic, appearing larger than their normal counterparts and containing atypical immature-looking nuclei. Distinguishing these “megaloblastic” changes from the changes of malignancy may be difficult.¹⁶⁸

Chemical Changes in Body Fluids

Plasma bilirubin, iron, and ferritin levels are increased.¹⁶⁹ Serum lactate dehydrogenase-1 (LDH-1) and LDH-2, both found in red cells, are markedly elevated as a result of rapid intramedullary erythroblast turnover and increase with the severity of the anemia.¹⁷⁰ In megaloblastic anemia LDH-1 is greater than LDH-2, whereas in other anemias LDH-2 is greater than LDH-1.¹⁷¹ Serum muramidase (lysozyme) levels are high,¹⁷² whereas serum glutamic oxaloacetic transaminase (aspartate transaminase [AST]) is normal.¹⁷³ Erythropoietin levels rise, but less than in other anemias of similar severity.¹⁷⁴ Surprisingly, the elevated erythropoietin levels fall sharply within 1 day of beginning treatment, an interval too short either to have been mediated by the hematocrit or to affect it.

Cytokinetics

Megaloblastic anemia is associated with two pathophysiologic abnormalities: *ineffective erythropoiesis* and *hemolysis*. Ineffective erythropoiesis increases the red cell precursor to reticulocyte ratio, plasma iron turnover,¹⁷⁵ LDH-1 and LDH-2 levels,¹⁷¹ and “early labeled” bilirubin.¹⁷⁶ Both intramedullary and extramedullary hemolysis occurs in megaloblastic anemia, with red cell life span decreased by 30 to 50 percent.¹⁷⁷

Increased serum muramidase in megaloblastic anemia can be caused by increased granulocyte turnover,¹⁷² possibly induced by disintegration of granulocyte precursors in the marrow (ineffective erythropoiesis). In cobalamin deficiency, platelet production is only 10 percent of that expected from the megakaryocyte mass,¹⁷⁸ perhaps reflecting ineffective thrombopoiesis. Platelets in severe cobalamin deficiency are functionally abnormal.¹⁷⁹

FOLIC ACID DEFICIENCY

Etiology and Pathogenesis

Folate deficiency is caused by (1) dietary deficiency, (2) impaired absorption, and (3) increased requirements or losses (see Table 41–4).

Decreased Intake Caused by Poor Nutrition Prior to the mid-1990s, inadequate dietary intake was the major cause of folate deficiency. However, in the era of folic acid fortification, the prevalence of folate deficiency has fallen dramatically. In the United States, the prevalence of low plasma folate has dropped from 22 to 1.7 percent of the population.¹⁸⁰ Because folate reserves are limited, deficiency develops rapidly in malnourished persons, typically the old, the poor, and the alcoholic. Folate deficiency can also occur during hyperalimentation¹⁸¹ and subclinical folate deficiency has been reported in subtotal gastrectomy.¹⁸² Folate deficiency can occur in premature infants, especially with infection, diarrhea, or hemolytic anemia¹⁸³; in children on a synthetic diet because of inborn errors¹⁸⁴; and in infants raised on goat's

milk, which is poor in available folate.¹⁸⁵ Destruction of folate through excessive cooking can aggravate folate deficiency.

In alcoholic cirrhosis, megaloblastic anemia usually is caused by folate deficiency.¹⁸⁶ Alcohol may acutely depress serum folate, even if folate stores are replete,¹⁸⁷ and accelerates the development of megaloblastic anemia in persons with early folate deficiency.¹⁸⁸ Alcohol causes acute marrow suppression, decreases in reticulocyte, platelet, and granulocyte levels¹⁸⁹; reversible vacuolation of erythroid and myeloid precursors; and dysfunction of granulocytes.¹⁹⁰ These changes occur even if large doses of folate are given with the alcohol.¹⁹¹

Decreased Intake Caused by Impaired Absorption Nontropical Sprue Nontropical sprue (*celiac disease* in children) is related to ingestion of wheat gluten.¹⁹² Pathologically, nontropical sprue shows atrophy and chronic inflammation of the small intestinal mucosa that is most severe proximally. Findings include weight loss; glossitis (typical of folate deficiency); other signs of a generalized vitamin deficiency; diarrhea; and passage of light-colored, bulky stools with a particularly foul odor caused by steatorrhea. Iron deficiency, hypocalcemia, osteoporosis, and osteomalacia may occur.

Folate malabsorption occurs in most patients with this disorder.¹⁹³ Serum folate levels are low,¹⁹⁴ and megaloblastic anemia occurs frequently.

Tropical Sprue Tropical sprue is endemic in the West Indies, southern India, parts of Southern Africa, and Southeast Asia. It can be acquired by travelers to those regions and persists for many years after the travelers return.¹⁹⁵ Tropical sprue is rapidly corrected by folate therapy, even though folate deficiency does not cause the disease. The precise etiology of tropical sprue is unknown, although the response of the disease to antibiotics suggests infection.¹⁹⁶

Clinically and pathologically, tropical sprue is like nontropical sprue, except that tropical sprue is more severe in the distal small intestine.¹⁹⁷ Therefore, tropical sprue eventually also leads to cobalamin deficiency¹⁹⁸ and should be strongly considered as a cause of cobalamin deficiency in former residents of the tropics, even though they have been away from the tropics for 20 years or more. Folate malabsorption may occur,¹⁹⁹ possibly because the diseased intestine fails to deconjugate folate polyglutamates.²⁰⁰ Consequently, megaloblastic anemia is very common in patients with this disease,²⁰¹ and may result from both folate and cobalamin deficiency.

Other Intestinal Disorders Malabsorption of folic acid commonly occurs in regional enteritis,²⁰¹ after extensive resections of the small intestine,²⁰² and in conditions such as lymphomatous or leukemic infiltration of the small intestine,²⁰³ Whipple disease,²⁰³ scleroderma and amyloidosis,²⁰⁴ and diabetes mellitus.²⁰⁵ Systemic bacterial infections impair folate absorption.²⁰⁶

Increased Folate Requirements in Pregnancy During pregnancy (Chap. 8),²⁰⁷ folate requirements increase five- to 10-fold because of transfer of folate to the growing fetus,²⁰⁸ which draws down maternal folate stores even in the face of severe maternal folate deficiency.²⁰⁹ Further increases in requirements may result from the presence of multiple fetuses, a poor diet, infection, coexisting hemolytic anemia, or anticonvulsant medication. Lactation aggravates folate deficiency.²¹⁰ Consequently, folate deficiency is very common in pregnancy and is the major cause of the megaloblastic anemia of pregnancy,²¹¹ particularly in developing countries.²¹²

Folate deficiency is difficult to diagnose in pregnancy because the signs of deficiency are obscured by the normal hematologic changes of pregnancy. During pregnancy, a physiologic “anemia” develops because of increased plasma volume that is only partly offset by an accompanying increase in red cell mass. Hemoglobin levels may fall to 10 g/dL. The anemia is associated with a physiologic macrocytosis; MCV may increase to 120 fL, although the average at term is 104 fL.²¹³ Serum

and red cell folate levels fall steadily during pregnancy, even in well-nourished women who are not taking a folic acid supplement.²¹⁴ Conversely, hypersegmented neutrophils, usually a reliable clue to early megaloblastic anemia, are inconspicuous in early megaloblastic anemia of pregnancy.²¹⁵

Increased Cell Turnover Because of increased marrow cell turnover, the folate requirement rises sharply in chronic *hemolytic anemia*.²¹⁶ During bouts of acute hemolysis that can occur in these anemias, the marrow may become megaloblastic within days.

Folic acid deficiency may arise in chronic *exfoliative dermatitis*, in which folate losses of 5 to 20 mcg/day may occur.²¹⁷ Patients with psoriasis who are treated with methotrexate have an added reason for developing signs of folate deficiency. Pretreating such patients with folate may prevent these signs without impairing the therapeutic effect of methotrexate.²¹⁷ During hemodialysis, folate is lost in the dialysis fluid.²¹⁸

Clinical Features

The clinical picture of folate deficiency includes all the general manifestations of megaloblastic anemia *plus* the following specific features: (1) a history and laboratory studies indicating folate deficiency, (2) absence of the neurologic signs of cobalamin deficiency (see “Cobalamin Deficiency” below), and (3) a full response to *physiologic* doses of folate.

Laboratory Features

The earliest specific indicator of folate deficiency is a low serum or plasma folate. Raised plasma levels of homocysteine may precede the lowering of plasma folate. However, elevated homocysteine has poor specificity as there are several causes of a raised plasma homocysteine.²¹⁹ Plasma folate follows folate intake closely, so an isolated low serum folate (less than approximately 3 ng/mL) may simply indicate a drop in folate intake over the preceding few days.⁵ Similarly, a low plasma folate, except in malabsorption, rises quickly on refeeding.

A better indicator of the tissue folate status is the red cell folate,²²⁰ which remains relatively unchanged while a red cell is circulating and thus reflects folate status over the preceding 2 to 3 months. Red cell folate usually is quite low in folate-deficient megaloblastic anemia. However, red cell folate also is low in more than 50 percent of patients with cobalamin-deficient megaloblastic anemia¹⁰⁰ owing to the poor retention of methyltetrahydrofolate monoglutamate within the cells; consequently, red cell folate cannot be used to distinguish between folate and cobalamin deficiencies. Conversely, red cell folate may be normal in the megaloblastic state that occurs, often with little accompanying anemia, in rapidly developing folate deficiency (see “Acute Megaloblastic Anemia” below).²²¹

The dU suppression test has been used in research on pathogenic mechanisms in megaloblastic states. It adds little to the clinical evaluation of a megaloblastic anemia. The test is further discussed in “Deoxyuridine Suppression” below.

Differential Diagnosis

Macrocytosis without megaloblastic anemia occurs in alcoholism, liver disease, hypothyroidism, aplastic anemia, certain forms of myelodysplasia, pregnancy, and any condition associated with reticulocytosis (e.g., autoimmune hemolytic anemia). Macrocytosis has also been reported among smokers.²²² However, MCV rarely exceeds 110 fL in these conditions, whereas in folate deficiency, uncomplicated by causes of microcytosis, the MCV is usually over 110 fL.

A full hematologic response to physiologic doses of folate (i.e., 200 mcg daily) distinguishes folate deficiency from cobalamin deficiency, in which a response occurs only at pharmacologic doses of folate (e.g., 5 mg daily). This is not recommended as a diagnostic test because

neurologic problems may develop in cobalamin-deficient patients treated with folate alone. High doses of cobalamin may produce a partial response in folate deficiency.⁷³

The diagnosis of nontropical sprue rests on (1) the demonstration of malabsorption, (2) noninvasive serologic testing including detection of antibodies to gliadin, endomysium, tissue transglutaminase, and deamidated gliadin,²²³ (3) a jejunal biopsy showing villus atrophy, and (4) the response to a gluten-free diet. In 80 percent of patients, a gluten-free diet gradually reverses the functional disorder by correcting folate malabsorption.²²⁴

Nonhematologic Effects of Folate Deficiency

The hematologic problems associated with folate deficiency have been recognized for decades. However, folate deficiency has been associated with a number of serious disorders not involving the hematopoietic system. Moreover, these disorders occur at folate levels usually regarded as low normal. They include developmental, neurologic, cardiovascular, and neoplastic diseases.²²⁵

Abnormalities of Neural Tube Closure

A close association exists between mild folate deficiency and congenital anomalies of the fetus, most notably defects in neural tube closure, but also abnormalities involving the heart, urinary tract, limbs, and other sites.²²⁶ A portion of the neural tube closure defects appear to be associated with antibodies against folate receptors that may be overcome by higher folate intake.²²⁷ Mutations and polymorphisms affecting enzymes of folate metabolism, especially the common 677C→T polymorphism of the *MTHFR* gene (also designated as *MTHFR* 677C→T),²²⁸ also predispose to congenital anomalies. As noted above, this polymorphism results in diminished conversion of its substrate methylene FH₄ to methyltetrahydrofolate, supporting the view that it is the role of folate in methylation through methionine synthesis (see Table 41–1) that is critical in embryonic development. Folic acid fortification programs, which were mandated in the United States and Canada in the mid-1990s, have been highly successful as a public health measure in reducing the incidence of neural tube defect births by between 20 and 50 percent.^{229,230}

Cobalamin also plays a significant role as a risk factor for neural tube defects. Levels of TC in normal pregnant women correlate with their likelihood of bearing an infant with a defect in neural tube closure. Patients in the lowest quintile of TC concentration are five times more likely to give birth to a defective infant as patients in the highest quintile.²³¹ Evidence indicates that in populations exposed to folic acid fortification, there is an approximately threefold increase in the risk of neural tube defects in offspring of mothers in the lowest quartile of TC.²³²

Several poorly defined neuropsychiatric abnormalities that respond to folate therapy have been reported in patients with folate deficiency. The most convincing associations are with depressive illness.^{225,233}

Vascular Disease

Even a mildly elevated homocysteine level is a major independent risk factor for atherosclerosis and venous thrombosis, possibly because of an effect on the vascular endothelium.²³⁴ In folate deficiency, homocysteine levels may rise considerably, resulting in varying degrees of hyperhomocysteinemia. This is true also in cobalamin and pyridoxine deficiencies; consequently, the notion of seeking to ameliorate hyperhomocysteinemia and thus diminish the risk of cardiovascular disease has seemed appealing. However, the effect of lowering homocysteine levels by the use of folate, cobalamin, and pyridoxine supplements, on the risk of recurrent vascular disease is unclear. Although there is some evidence that such supplements reduce risk,²³⁵ contradictory evidence suggests that supplement use may actually increase the risk of in-stent

coronary restenosis²³⁶ or other adverse cardiovascular outcome.²³⁷ On the other hand, an accelerated rate of decrease in stroke mortality has been observed in the United States and Canada that coincided with the introduction of folic acid fortification in these countries.²³⁸ The disparate designs of these studies makes it difficult to draw firm conclusions regarding the question of whether lowering of plasma homocysteine in subjects at risk for cardiovascular disease has any ameliorative or deleterious effect on outcome. In a meta-analysis of eight randomized trials involving over 37,000 individuals, the authors concluded that supplementation with folic acid in various combinations with vitamin B₁₂ and vitamin B₆ for periods of up to 7.3 years, despite an overall reduction of plasma homocysteine of 22 percent and 25 percent in folic acid fortified and non-fortified populations, respectively, there were no significant effects on cardiovascular events, overall cancer, or mortality.²³⁹ Critical factors might relate to several considerations including the preexisting degree of vascular damage in relation to the time of the intervention and the form and dosage of administered vitamins.

Another potential link between folate deficiency and morbidity risk that relates to hyperhomocysteinemia is the association between elevated homocysteine levels and incident dementia or cognitive impairment without dementia, independent of the vascular complications of hyperhomocysteinemia.^{240,241} The *MTHFR* polymorphism *MTHFR* 677C→T leads to increased homocysteine levels in subjects with low folate or cobalamin levels,²⁴² although controversy exists as to whether *MTHFR* 677C→T contributes to an increased incidence of vascular disease. Like folate, cobalamin seems to be important in decreasing the risk of vascular disease.²⁴³ A 1561C→T polymorphism in the gene for glutamate carboxypeptidase-II increases serum folate and decreases serum homocysteine in the homozygote, possibly protecting against vascular disease.²⁴⁴

HELLP Syndrome

Severe folate deficiency reportedly mimics the hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome (preeclampsia with liver swelling and abnormal liver function studies in pregnant women; Chap. 8).²⁴⁵ In these patients, the diagnosis of severe folate deficiency can be made based on the presence of anemia and a megaloblastic blood film and marrow. Serum and red cell folate, serum cobalamin, homocysteine, and methylmalonic acid levels all should be assayed before treatment is started.²⁴⁶ The patient should immediately be given high doses of folate plus cobalamin, the latter in case the megaloblastic anemia actually results from cobalamin deficiency, a possibility rendered more likely in folic acid-fortified populations. A major goal of treatment is preventing preterm delivery of the fetus.

Colon Cancer

A large study of nurses in the United States indicated that supplementation with more than 400 mcg of folic acid per day reduces the incidence of colon cancer by 31 percent.²⁴⁷ Furthermore, individuals who are homozygous for the 677C→T *MTHFR* mutation also have a decreased incidence for colon cancer compared with 677C→T heterozygotes and normal controls.²⁴⁸ Other evidence points to possible deleterious effect of folic acid on colon cancer incidence. Although only circumstantial, a recent epidemiologic study reported that after several successive years of a declining incidence of colorectal cancer in the United States and Canada, there was a significant increase in the rate in both countries that coincided with and followed the introduction of folic acid fortification.²⁴⁹ These apparently contradictory observations may be reconcilable because of the several roles of folate on cellular proliferation and repair as well as on the stage of tumorigenesis.²⁵⁰ Because folate is critical for *de novo* thymidine synthesis, it plays an important part in DNA repair, thus correcting mutations and DNA strand breaks that could

potentially initiate cancer. On the other hand, the growth of established neoplastic clones might be accelerated by additional folate, allowing more rapid tumor progression. The situation is rendered even more complex if the potential role of folate in epigenetic regulation of gene expression is considered. Folate is necessary for synthesis of the universal methyl donor, SAMe, which is required for both cytosine and histone methylation. In this pathway, too, the role of folate theoretically may be cancer promoting or cancer protective, depending on whether oncogenes or tumor-suppressor genes are silenced by methylation of CpG islands in DNA or by conformational changes in chromatin resulting from histone methylation. The question of a possible effect of increased folate intake through the use of folic acid supplements on overall and site-specific cancer incidence was recently examined in a meta-analysis of 50,000 individuals. The authors concluded that there was no substantial increase or decrease in incidence over a 5-year period of folic acid supplement use.²⁵¹

Therapy, Course, and Prognosis

Folate, usually in the form of folic acid, 1 to 5 mg/day, is given orally, although 1 mg usually is sufficient. At this dose, anemia usually is corrected even in patients with malabsorption. A parenteral preparation containing 5 mg/mL of folate also is available.

Treatment for *tropical sprue* consists of the usual doses of folate, plus cobalamin if indicated. To prevent relapse, treatment should be maintained for at least 2 years. Broad-spectrum antibiotics are helpful adjuncts, although antibiotics alone fail to correct the condition.

Pregnant women must be given at least 400 mcg of folate per day.²⁵² As to the possibility of overlooking cobalamin deficiency resulting from folate administration, although pernicious anemia (PA) in women of childbearing age is rare in whites, this is not the case among persons of African and Hispanic descent.^{253,254} In pregnant women at risk for cobalamin deficiency (e.g., vegans or patients with malabsorption), the risk of an associated cobalamin deficiency is easily prevented with vitamin B₁₂, 1 mg given parenterally every 3 months during the pregnancy.

Therapeutic doses of folate partially and temporarily correct the hematologic abnormalities in cobalamin deficiency, but the neurologic manifestations can progress, with disastrous results.²⁵⁵ Therefore, both folate status and cobalamin status must be evaluated early in the workup of a megaloblastic anemia. If treatment is urgent and the nature of the deficiency is unclear, both folate and cobalamin can be given after suitable specimens have been obtained for assay.

Patients who receive low-dose methotrexate therapy as an immunosuppressant may develop side effects, the worst of which is hepatotoxicity. The incidence of side effects, including hepatotoxicity, has been correlated with reduced folate levels.²⁵⁶ Administration of folic or folinic acid can prevent or greatly diminish the major side effects without reducing the therapeutic effect of low-dose methotrexate. Coadministration of folic acid together with vitamin B₁₂ also reduces side-effects without adversely affecting the therapeutic efficacy of the newer multi-targeted antifolate drug, pemetrexed.²⁵⁷

COBALAMIN DEFICIENCY

Etiology and Pathogenesis

There are several causes and varying degrees of severity of cobalamin depletion and deficiency. From the hematologic standpoint, it is convenient to divide the causes of B₁₂ deficiency into those that frequently lead to megaloblastic anemia and those that usually do not.^{64,258}

Table 41–4 lists disorders that lead to cobalamin deficiency.

Decreased Uptake Caused by Impaired Absorption Cobalamin deficiency most often results from defective absorption, most commonly PA, a condition characterized by failure of gastric intrinsic

factor production. Many other causes of defective cobalamin absorption involve mainly the stomach, or small intestine and to lesser extent, the pancreas.

Gastric Disorders in Pernicious Anemia PA is a disease of insidious onset that generally begins in middle age or later (usually after age 40 years).²⁵⁹ In this condition, intrinsic factor secretion fails because of gastric mucosal atrophy. PA is an autoimmune disease. The gastric atrophy of PA probably results from immune destruction of the acid- and pepsin-secreting portion of the gastric mucosa. The term *pernicious anemia* sometimes is used as a synonym for cobalamin deficiency, but it should be reserved for the condition resulting from defective secretion of intrinsic factor by an atrophic gastric mucosa caused by an autoimmune process primarily directed against the parietal cells and their products.

In patients with PA, antibodies occur that recognize the H⁺/K⁺-adenosine triphosphatase (ATPase), which resides in the secretory membrane of the parietal cell and is responsible for acidifying the stomach contents. These antiparietal cell antibodies occur in approximately 60 percent of patients with simple atrophic gastritis and in 90 percent of patients with PA, but in only 5 percent of a random 30- to 60-year-old population.²⁶⁰ Antiparietal cell antibodies also occur in a significant percentage of patients with thyroid disease.²⁶¹ Conversely, patients with PA have a higher than expected incidence of antibodies against thyroid epithelium, lymphocytes, and renal collecting duct cells.²⁶²

Antiparietal cell antibodies are not thought to be responsible for the pathogenesis of PA. Rather, studies in mice suggest the gastric atrophy in PA is caused by CD4⁺ T cells whose receptors recognize the H⁺/K⁺-ATPase. Thus, thymectomized BALB/c mice develop an autoimmune atrophic gastritis similar to that seen in PA patients. CD4⁺ T cells from these mice produce atrophic gastritis when injected into nude mice.²⁶³

Antibodies to intrinsic factor ("type I," or "blocking," antibodies) or the intrinsic factor–cobalamin (Cbl) complex ("type II," or "binding," antibodies) are highly specific to PA patients.²⁶⁴ Blocking antibodies, which prevent formation of the intrinsic factor–Cbl complex, are found in up to 70 percent of PA sera.²⁶⁴ Binding antibodies, which prevent the intrinsic factor–Cbl complex from binding to its ileal receptors, are found in about half the sera that contain blocking antibody. Some findings in humans support the idea that T cells are responsible for the gastric atrophy in PA. First, lymphocytes from patients with PA are hyperresponsive to gastric antigens.²⁶⁵ Second, the incidence of PA is higher than expected in patients with agammaglobulinemia, even though their sera contain none of the antibodies typical of PA.²⁶⁶

Other Autoimmune Diseases The coexistence of several other autoimmune diseases and PA is further evidence that PA is an autoimmune disease. Antiparietal cell antibodies and PA are unexpectedly frequent in patients with other autoimmune diseases,²⁶⁷ including autoimmune thyroid disorders (thyrotoxicosis, hypothyroidism, and Hashimoto thyroiditis),²⁶⁸ type I diabetes mellitus, hypoparathyroidism,²⁶⁹ Addison disease, postpartum hypophysitis,²⁷⁰ vitiligo,²⁷¹ acquired agammaglobulinemia,²⁶⁶ infertile female patients younger than age 40 years,²⁷² and hypospermia and infertility in males.^{273,274} Infertility may, however, relate to impairment of DNA synthesis in gonadal cells rather than to an autoimmune mechanism.

Inherited Predisposition to Pernicious Anemia Predisposition to PA can be inherited. The disease is associated with human leukocyte antigen types A2, A3, B7, and B12,²⁷⁵ and with blood group A.²⁷⁶ PA and antiparietal cell antibodies occur more frequently than expected in the families of PA patients.²⁷⁷ In one study, gastric atrophy was found in more than 30 percent of the relatives of patients with PA; of these relatives, 65 percent had antiparietal cell antibodies and 22 percent had antiintrinsic factor antibodies.²⁷⁸ PA occurs relatively frequently

in northern Europeans (especially Scandinavians)²⁷⁹ as well as Africans,^{163,280} but is uncommon in Asians. In Americans of African descent, the disease tends to begin early, occurs with high frequency in women, and often is severe.^{163, 254}

Stomach and Intestine in Pernicious Anemia Gastric manifestations of PA include achlorhydria, acquired intrinsic factor deficiency previously demonstrable by the Schilling test, and an increased incidence of certain malignancies. There is an approximately twofold increase in the incidence of gastric cancer, similar increases in the incidence of certain hematologic malignancies, and an increase in the incidence of gastric carcinoid.²⁷⁹ Achlorhydria may precede by many years the loss of intrinsic factor secretion and the development of PA.²⁸¹ The absence of achlorhydria excludes the diagnosis of PA. *H. pylori*, a microorganism that infects the gastric mucosa, is a major cause of gastritis and peptic ulcers. Evidence is conflicting regarding the role of *H. pylori* in PA. In two studies, cultures of gastric biopsies showed a very low incidence of *H. pylori* infection in PA patients.²⁸² One study reported that anti-*H. pylori* antibodies were found in only a small fraction of the sera from these patients. The other study reported that these antibodies were present in most of the PA sera, indicating that most of the patients described in the study had been infected previously. Whether *H. pylori* participates in the pathogenesis of PA is an open question. An intriguing hypothesis has been advanced that chronic infection with *H. pylori* may be responsible for triggering an autoimmune reaction directed against the host H⁺/K⁺-ATPase protein as a result of molecular mimicry.^{167, 283}

Fasting plasma gastrin levels are high in most patients with PA, whereas somatostatin levels are low.²⁸⁴ In biopsies from PA stomachs, however, fundal gastrin and somatostatin levels were high, correlating with increases in argyrophilic cells in the basal crypts; antral gastrin and somatostatin were normal. Gastrin levels are high in simple achlorhydria without PA.²⁸⁵

The stomach shows characteristic histologic abnormalities in PA (Fig. 41–14). The mucosa of the cardia and fundus is atrophic, containing few chief (i.e., pepsin-secreting) or parietal cells. The withered mucosa is infiltrated with lymphocytes²⁸⁶ and plasma cells. In contrast, the antral and pyloric mucosa are normal. Gastric atrophy is partly reversible by glucocorticoid treatment, with some regeneration and return of intrinsic factor secretion, further evidence for the autoimmune nature of PA.²⁸⁷ Clinical response to administration of glucocorticoids or adrenocorticotrophic hormone in patients with neurologic disease may reflect temporary amelioration of underlying and undiagnosed PA.²⁸⁸

Megaloblastic changes reversible by cobalamin are seen in the gastrointestinal epithelium. Cells recovered by lavage are large¹⁶⁸ and show atypical nuclei resembling early malignant change.²⁸⁹ Small intestinal biopsy shows decreased mitoses in crypts, shortening of villi, megaloblastic changes in epithelial cells, and infiltration in the lamina propria.²⁹⁰ These changes may account for the malabsorption of D-xylose and carotene observed in PA.²⁹¹

Recognizing PA may be difficult. PA combines the general features of megaloblastic anemia and features specific for cobalamin deficiency with unique clinical features related to its (probable) autoimmune etiology and gastric pathology. The disease is easily missed because of its (1) insidious onset, (2) tendency to be masked by the use of multivitamin preparations containing folic acid,²⁹² and (3) many atypical presentations,²⁹³ including its presentation as a neurologic disease without hematologic findings,^{77,294} and its tendency to be overlooked in patients with another autoimmune disease.

Antiparietal cell and antiintrinsic factor antibodies are rarely measured, even though antiintrinsic factor antibodies in particular could be of considerable diagnostic value.²²¹ In the absence of a reliable method to assess vitamin B₁₂ absorption, following the Schilling test becoming obsolete, measurement of antiintrinsic factor antibodies in serum

Figure 41-14. Gastric histology in pernicious anemia. (Left) Normal fundus. The thick mucosa is packed with gastric glands composed mostly of chief cells and parietal cells. The mucus-secreting cells are concentrated in the necks of the glands. (Right) Fundus in pernicious anemia. Gastric glands in the atrophic mucosa are sparse and consist mainly of mucus-secreting cells. The mucosa is densely infiltrated by lymphocytes.

represents the only available method to confirm a diagnosis of PA. Anti-intrinsic factor antibody is highly specific for PA (although its sensitivity is only modest); its presence in a megaloblastic anemia makes the diagnosis of PA almost certain.

Gastrectomy Syndromes Gastric surgery often leads to anemia. Iron-deficiency anemia is most common, but cobalamin deficiency with megaloblastic anemia can occur. After *total gastrectomy*, cobalamin deficiency develops within 5 or 6 years because the operation removes the source of intrinsic factor.²⁹⁵ The delay between surgery and the onset of cobalamin deficiency reflects the time needed to exhaust cobalamin stores after cobalamin absorption ceases. This may occur more rapidly because of abrogation of the enterohepatic reabsorption of biliary cobalamin.

After *partial gastrectomy*, few patients show frank cobalamin deficiency, but approximately 5 percent have intermediate megaloblastosis, approximately 25 to 50 percent have low serum cobalamin levels, and

many have varying degrees of decreased cobalamin absorption.²⁹⁶ Achlorhydria not present before surgery often develops some years after gastrectomy. Postgastrectomy patients with low serum cobalamin levels usually have low serum iron levels,²⁹⁷ in contrast to the high iron levels otherwise typical of cobalamin deficiency.

Cobalamin deficiency after partial gastrectomy can be caused by mucosal atrophy in the unresected remnant of the stomach²⁹⁸ or, if a gastrojejunostomy was performed, by bacterial overgrowth in the afferent loop (see “Competing Intestinal Flora and Fauna: ‘Blind Loop Syndrome’” below). A surgical procedure that has gained popularity for the treatment of morbid obesity is gastric reduction surgery. This procedure results in multiple deficiencies of micronutrients including cobalamin.²⁹⁹

Of the various causes of cobalamin malabsorption described, those that most often lead to megaloblastic anemia include PA, total or partial gastrectomy, intestinal blind loop syndrome, fish tapeworm, ileal resection, regional enteritis (Crohn disease) and tropical sprue.⁶⁴ In addition, several of the inherited disorders affecting cobalamin absorption and metabolism, such as congenital intrinsic factor deficiency, selective cobalamin malabsorption and congenital TC deficiency can also result in megaloblastic anemia.

Zollinger-Ellison Syndrome In Zollinger-Ellison syndrome, a gastrin-producing tumor, usually in the pancreas, stimulates the gastric mucosa to secrete immense amounts of HCl. The major clinical problem is a severe ulcer diathesis. Malabsorption of cobalamin occurs when the vast quantities of HCl secreted by the overactive gastric mucosa cannot be completely neutralized by the pancreatic secretions. The resulting acidification of the duodenal contents prevents transfer of Cbl from HC binder to intrinsic factor and also inactivates pancreatic proteases.³⁰⁰

Intestinal Diseases Because the terminal ileum is the site for physiologic cobalamin absorption, a number of intestinal disorders can lead to cobalamin deficiency, including (1) extensive resection of the ileum³⁰¹; (2) inflammatory bowel disease or regional ileitis or other disease affecting the ileum (e.g., lymphoma, radiation damage³⁰²); (3) cobalamin malabsorption associated with hypothyroidism,³⁰³ or certain drugs³⁰⁴; (4) the effects of cobalamin deficiency itself³⁰⁵; and (5) sprue, either tropical or, less often, nontropical.¹⁹⁸ In each of these disorders, administration of exogenous intrinsic factor, as was carried out in the Schilling test, would fail to correct subnormal cobalamin absorption.

Competing Intestinal Flora and Fauna: “Blind Loop Syndrome” The *blind loop syndrome* is a state of cobalamin malabsorption with megaloblastic anemia caused by intestinal stasis from anatomic lesions (strictures, diverticula, anastomoses, surgical blind loops) or impaired motility (scleroderma, amyloid).³⁰⁶ Serum cobalamin is low, but intrinsic factor secretion is normal. Cobalamin malabsorption is not corrected by exogenous intrinsic factor but may be corrected by antibiotic treatment. The defect in cobalamin absorption is caused by colonization of the diseased small intestine by bacteria that take up ingested cobalamin before it can be absorbed from the intestine.³⁰⁷ Steatorrhea is also seen in the blind loop syndrome.

Another cause of cobalamin deficiency is infestation with the fish tapeworm *Diphyllobothrium latum*. Prevalence is highest near the Baltic Sea, Canada, and Alaska, where raw or undercooked fish is consumed. Cobalamin deficiency results from competition between the worm and the host for ingested cobalamin.³⁰⁸ The clinical picture of *D. latum* infestation ranges from no symptoms to a full-blown megaloblastic anemia with neurologic changes. The infestation is diagnosed by finding tapeworm ova in the feces.

Acquired Immunodeficiency Syndrome A substantial number of patients with AIDS have low serum cobalamin levels with associated evidence of cobalamin malabsorption.³⁰⁹ In addition, individuals testing seropositive for HIV infection may also have low serum cobalamin and

evidence of cobalamin malabsorption.³⁰⁹ The cause of the malabsorption may be intestinal or gastric or a combination of both.^{310, 311}

Pancreatic Disease Some degree of cobalamin malabsorption has been demonstrated in 50 to 70 percent of patients with exocrine pancreatic insufficiency.³¹² Cobalamin malabsorption in pancreatic insufficiency is caused by a deficiency in pancreatic proteases, resulting in a partial failure to destroy HC-Cbl complexes whose destruction is a prerequisite for the transfer of cobalamin to intrinsic factor.³¹³ Pancreatic insufficiency rarely causes clinically significant cobalamin deficiency.³¹⁴

Dietary Cobalamin Deficiency Dietary cobalamin deficiency was previously considered very unusual and restricted largely to complete vegetarians who also do not consume dairy products and eggs (vegans).³¹⁵ Low serum cobalamin levels occur in 50 to 60 percent of individuals in this group. The onset of cobalamin deficiency in vegans is slower than in conditions associated with cobalamin malabsorption. Thus it may take 10 to 20 years for an individual consuming a vegan diet to manifest features of cobalamin deficiency.³¹⁶ This is because the enterohepatic pathway for biliary cobalamin absorption remains intact, thus conserving body cobalamin stores.⁶⁴ Breastfed infants of vegan mothers also may develop cobalamin deficiency.³¹⁷ Cobalamin deficiency in vegans presents with mild megaloblastic anemia, glossitis, and neurologic disturbances. In addition to vegans, however, there is mounting evidence of cobalamin inadequacy in children and young adults in developing countries that cannot be explained on the basis of cobalamin malabsorption, and has therefore been attributed to inadequate dietary intake.³¹⁸

Cobalamin deficiency may occur in severe general malnutrition. A megaloblastic anemia not related to cobalamin deficiency may accompany kwashiorkor or marasmus.³¹⁹

Neurologic Effects of Cobalamin Deficiency

Previously, the neurologic abnormalities of cobalamin deficiency were attributed to disordered metabolism of myelin lipids caused by an impaired methylmalonyl CoA mutase reaction.³²⁰ Similar neurologic abnormalities do not, however, occur in patients with inherited methylmalonyl CoA mutase deficiency.^{260, 321} Authentic combined system disease has occurred in a patient with nutritional folate deficiency³²² and in a patient with MTHFR deficiency.³²³ The latter reports suggest the neurologic lesions of cobalamin deficiency result from deranged methyl group metabolism. Animal studies support this hypothesis. Neurologic disorders closely resembling combined system disease develop in cobalamin-deficient fruit bats,³²⁴ pigs, and monkeys.³²⁵ The development of these disorders is prevented by methionine, which is produced in a cobalamin-dependent reaction and is the precursor of the biologic methylating reagent SAME. A finding that further supports a methylation defect is that brains from cobalamin-deficient pigs contain increased levels of SAH,³²⁶ a powerful methylation inhibitor produced in SAME-dependent methylation reactions:

where RH is any unmethylated compound and RCH₃ is its methylated form. Against the methylation defect hypothesis is the finding that cobalamin deficiency had no effect on SAME, SAH, or methylation of phospholipids or myelin basic protein³²⁷ in the brains of fruit bats.

CLINICAL FEATURES

The more typical clinical picture of cobalamin deficiency includes the nonspecific manifestations of megaloblastosis, such as anemia, thrombocytopenia, neutropenia, smooth tongue, cardiomyopathy, pale yellow skin and/or weight loss, plus specific features caused by the lack of cobalamin, chiefly neurologic abnormalities. Disturbances in either or both cellular and hormonal immune functions have been reported

Figure 41-15. Degeneration of spinal cord in combined system disease. (Reproduced with permission from JW Harris, RW Kellermeyer: *The Red Cell: Production, Metabolism, Destruction: Normal and Abnormal*, rev ed. Harvard University Press, Cambridge, 1970.)

in cobalamin deficiency.^{328, 329} Cobalamin deficiency may also contribute to the risk of vascular disease through elevation of homocysteine levels. Other disease associations with cobalamin deficiency have been described. These include a possible increase in breast cancer risk in premenopausal women³³⁰ and in osteoporosis.^{331, 332} Because cobalamin reserves are large, years may pass between the cessation of cobalamin absorption and the appearance of deficiency symptoms.

Neurologic Abnormalities

Cobalamin deficiency causes a neurologic syndrome that is particularly dangerous because the syndrome can develop in isolation,³³³ with no megaloblastic anemia to suggest a lack of cobalamin,^{294, 334} and because the syndrome cannot be reversed by treatment when it is sufficiently far advanced. The syndrome usually begins with paresthesias in feet and fingers as a result of early peripheral neuropathy and disturbances of vibratory sense and proprioception. The earliest signs, which precede other neurologic findings by months, are loss of position sense in the second toe and loss of vibration sense for a 256-Hz but not a 128-Hz tuning fork.³³⁵ Left untreated, the neurologic disorder progresses to spastic ataxia resulting from demyelination of the dorsal and lateral columns of the spinal cord, so-called *combined system disease* (Fig. 41-15).³³⁶

The peripheral nerves, the spinal cord, and the brain are affected by cobalamin deficiency. Somnolence and perversion of taste, smell, and vision with occasional optic atrophy are accompanied by slow waves on the electroencephalogram. A dementia mimicking Alzheimer disease can develop.³³⁷ There is recent evidence linking low cobalamin status with brain volume loss and cerebral white matter lesions.^{338, 339} Psychological derangements, including psychotic depression and paranoid schizophrenia, can occur.³⁴⁰ Frank psychosis in cobalamin deficiency has been given the sobriquet *megaloblastic madness*.³⁴¹

The neurologic lesions of cobalamin deficiency can be detected by magnetic resonance imaging (MRI). Demyelination appears as T2-weighted hyperintensity of the white matter.³⁴² MRI is particularly useful for confirming the diagnosis of a neurologic disorder resulting from cobalamin deficiency. MRI also has been used to follow the progress of neurologic abnormalities during treatment of cobalamin-deficient patients.³⁴²

Subtle Cobalamin Deficiency

Some observations suggest the existence of a large group of patients who are hematologically normal, with a normal hematocrit and MCV, but who have cobalamin-responsive neuropsychiatric disease.²⁹⁴

Neuropsychiatric findings include peripheral neuropathy, gait disturbance, memory loss, and psychiatric symptoms, often with abnormal evoked potentials. Serum cobalamin may be normal, borderline, or low, but tissue cobalamin deficiency is suggested by consistently high levels of serum methylmalonic acid and/or homocysteine. Most of the neuropsychiatric abnormalities appear to respond to cobalamin therapy.

LABORATORY FEATURES

Plasma or Serum Cobalamin Levels

Plasma or serum cobalamin is low in most but not all patients with cobalamin deficiency.²¹⁹ Cobalamin levels are usually normal in cobalamin deficiency resulting from exposure to nitrous oxide, TC deficiency, and inborn errors of cobalamin metabolism. Levels also may be normal in cobalamin-deficient patients with high HC levels resulting from myeloproliferative diseases. Conversely, plasma cobalamin levels may be low in the presence of normal tissue cobalamins in vegetarians, in subjects taking megadoses of ascorbic acid,³⁴³ in pregnancy (25 percent), in the presence of HC deficiency,^{344,345} and in megaloblastic anemia resulting from folate deficiency (30 percent).²¹⁹ Plasma folate may be high in cobalamin deficiency because of retardation in conversion of methyltetrahydrofolate, which is the predominant form in plasma. Patients deficient in both cobalamin and folate may show normal serum folate levels.

Plasma or Serum Holotranscobalamin

The fraction of the cobalamin in plasma that is bound to TC constitutes only 10 to 30 percent of the total plasma cobalamin. Even so, it is this fraction that is functionally important and also better reflects the integrity of the cobalamin absorptive status of an individual.^{142,346,347} The major fraction of plasma cobalamin bound to HC is considered functionally inert and is therefore less relevant for the consideration of cobalamin status. Consequently, and with the development of assays to measure the TC-bound fraction of the plasma cobalamin, an increasing body of evidence has accumulated to support the usefulness of TC-associated cobalamin (holoTC).^{64,137,140, 346}

Methylmalonic Acid

Except when caused by an inborn error, methylmalonic aciduria is a reliable indicator of cobalamin deficiency.³⁴⁸ Normal subjects excrete only traces of methylmalonate (0 to 3.4 mg/day). In cobalamin deficiency, urine methylmalonate usually is elevated.³⁴⁹ Cobalamin therapy restores excretion to normal in a few days. Another possible advantage of measurement of urine rather than plasma methylmalonic acid is that in conditions of impaired renal function, when plasma methylmalonic acid may give misleadingly elevated levels, measurement of the metabolite in urine when correlated with creatinine obviates this problem.³⁵⁰

Serum or Plasma Methylmalonic Acid and Homocysteine

Elevated plasma or serum methylmalonic acid and homocysteine levels are indicators of *tissue* cobalamin deficiency. Their levels are high in more than 90 percent of cobalamin-deficient patients and rise before plasma cobalamin falls to subnormal levels.^{219,351} Elevated plasma methylmalonic acid and/or elevated homocysteine are both indicators of cobalamin deficiency in patients without a congenital disorder in their metabolism. Of the two, methylmalonic acid measurement is both more sensitive and more specific, and elevated methylmalonic acid will persist for several days, even after cobalamin treatment is instituted. Unlike homocysteine levels that rise in folate and pyridoxine deficiencies, as well as in hypothyroidism, methylmalonic acid elevation is seen only in cobalamin deficiency.²¹⁹ In renal diseases however, both homocysteine and methylmalonate, acid levels are frequently elevated. Additionally,

intestinal bacteria synthesize propionate, a precursor of methylmalonate, and in conditions of bacterial overgrowth, microbially derived methylmalonic acid may contribute to elevations in plasma methylmalonic acid.^{351,352} Although measurement of these metabolites may be used for population screening for evidence of cobalamin deficiency, the finding of an isolated elevation of plasma methylmalonate cannot be taken as *a priori* evidence of clinically attributable cobalamin deficiency, absent any demonstration of a therapeutic response to the administration of cobalamin.^{352, 353}

Spinal fluid methylmalonic acid levels are markedly elevated in cobalamin deficiency.³⁵⁴

Assays of Cobalamin Absorption and Intrinsic Factor

Despite its numerous shortcomings the previous “gold standard” for assessment of cobalamin absorption was the Schilling test. The Schilling test assessed cobalamin absorption by measuring urinary radioactivity after an oral dose of radioactive cobalamin. The test could be performed even after cobalamin deficiency had been corrected. The test consisted of administering a physiologic dose of radiolabeled Co-CnCbl by mouth followed 2 hours later by injection of a large “flushing” dose of unlabeled CnCbl and determination and radioactivity in a 24-hour collection of urine. Subjects with normal absorption excreted 7 percent or more of the radioactivity in the urine. Subjects with subnormal urinary excretion would have the test repeated with addition of an animal-derived intrinsic factor to determine whether the malabsorption could be corrected.³⁵⁵ The use of the Schilling test has dropped to a point of obsolescence as a consequence of reduced availability of the test components, cost, radioactive waste disposal, and concern about the use of animal-derived tissues for human use, which were required for the intrinsic factor administered in the second part of the test.⁶⁴ Replacements for the Schilling test are currently under development. One approach uses measurement of the change in holoTC following oral administration of non-radiolabeled cobalamin.^{346,347,356} A different approach involves the use of accelerator mass spectrometry and microbially produced ¹⁴C at attomolar concentrations.³⁵⁷ In this approach, ¹⁴C is measured in blood at the time of peak appearance 6 to 8 hours following the dose. Both methods show promise but have not been approved or validated for routine clinical use.

Deoxyuridine Suppression Test

The dU suppression test is based on the finding that unlabeled dU can suppress the uptake of [³H]thymidine ([³H]Thd) into the DNA of cultured lymphocytes or marrow cells through dilution of the label in the thymidine pool.³⁵⁸ This occurs when the thymidylate synthase reaction is functionally intact, which requires adequate quantities of both folate and cobalamin.

The dU suppression test is chiefly a research tool. It can help diagnose certain special clinical problems,³⁵⁸ but these problems also can be diagnosed using other laboratory tests, therapeutic trials with vitamins or iron, or watchful waiting. Furthermore, in more than 40 years of use, the test has not moved from the research laboratory into the clinic. The dU suppression test seems unlikely to enjoy more widespread clinical use in the future.

THERAPY, COURSE, AND PROGNOSIS

Treatment of cobalamin deficiency consists of parenteral CnCbl (vitamin B₁₂) or OHCbl to replace daily losses and refill storage pools, which normally contain 2 to 5 mg of cobalamin.³⁵⁹ Toxicity is highly unusual, and there is no defined upper limit.² Doses exceeding 100 mcg saturate the cobalamin-binding proteins (TC and HC), and the excess is lost in the urine. A typical treatment schedule consists of 1000 mcg cobalamin

intramuscular (IM) daily for 2 weeks, then weekly until the hematocrit is normal, and then monthly for life. For neurologic manifestations, 1000 mcg every 2 weeks for 6 months is recommended. Higher doses are given for certain inherited disorders (e.g., TC deficiency). *Transfusion* occasionally is required when the hematocrit is less than 15 percent or the patient is debilitated, infected, or in heart failure. In such instances, packed cells should be given slowly to avoid pulmonary edema. Infections can impair the response to cobalamin and must be treated vigorously.

Response to Treatment and Therapeutic Trial

Following parenteral administration of cobalamin to deficient patients, elevated plasma bilirubin, iron, and LDH levels fall rapidly (Fig. 41-16).³⁶⁰ Decreasing plasma iron turnover and fecal urobilinogen reflect cessation of ineffective erythropoiesis. Within 12 hours, the marrow begins to change from megaloblastic to normoblastic, a process that is complete in 2 to 3 days. Consequently, morphologic diagnosis may be difficult after treatment is initiated. Reticulocytosis begins on days 3 to 5 and peaks on days 4 to 10.³⁶¹ The new red cells come from new normoblasts, not from the old megaloblasts, most of which die before leaving the marrow.¹⁴⁹ Blood hemoglobin concentration becomes normal within 1 to 2 months. If normal values are not achieved by 2 months, another cause of anemia should be sought.

Other changes include the following: (1) prompt and dramatic improvement in the sense of well-being; (2) normalization of leukocyte and platelet counts, although neutrophil hypersegmentation may

persist for 10 to 14 days; (3) rise in serum cobalamin and folate. Cobalamin deficiency does not respond to a physiologic dose of folate (100 to 400 mcg/day), although this dose produces a maximal response in folate deficiency. Larger doses of folate (5 to 15 mg/day) can produce a reticulocytosis and partially or temporarily correct the anemia in cobalamin deficiency. To avoid the risk of masking an underlying cobalamin deficiency by inducing a hematologic remission in response to folate, doses in excess of 1 mg folic acid daily should be shunned until an underlying cobalamin deficiency has been ruled out.³

Special Circumstances

After Gastrectomy Cobalamin should always be given after total gastrectomy. Cobalamin administration is not necessary after partial gastrectomy, but patients need to be watched for megaloblastic anemia, bearing in mind that this anemia can be masked by postgastrectomy iron deficiency.^{352,362}

Blind Loop Syndrome The anemia of the blind loop syndrome can be treated by parenteral cobalamin therapy. It also responds after approximately 1 week to oral broad-spectrum antibiotics (cephalexin monohydrate [Keflex] 250 mg QID plus metronidazole 250 mg TID for 10 days),³⁶³ and cobalamin absorption is restored. Successful surgical correction of an anatomic lesion also cures the syndrome.

Fish Tapeworm Treatment consists of a single oral dose of a 50 mg/kg of niclosamide or a dose of 5 to 10 mg/kg of praziquantel.

Rekindled Use of Oral Cobalamin

Much interest has been kindled³⁶⁴ regarding the possibility of treating cobalamin deficiency with oral cobalamin as had been proposed previously.³⁶⁵ Oral cobalamin can be used not only for treatment of dietary cobalamin deficiency that occurs in vegans and in patients with very severe general malnutrition, but also for patients with food cobalamin malabsorption³⁶⁶ and for patients with PA, provided the patients are followed carefully.³⁶⁷ In patients lacking intrinsic factor, approximately 1 percent of an oral dose of the vitamin crosses the intestinal epithelium by mass action. Therefore, 1000 to 2000 mcg/day of oral cobalamin supplies most PA patients with their daily cobalamin requirement without the need for injections and their accompanying pain and expense. Cobalamin should be given by mouth to patients with dietary cobalamin deficiency and patients (e.g., hemophiliacs, the frail elderly) who cannot take IM injections.

ACUTE MEGALOBlastic ANEMIA

Megaloblastic anemia usually is a chronic condition that requires weeks or months to develop, but a potentially fatal megaloblastic state resulting from acute tissue folate or cobalamin deficiency can arise over the course of only a few days. Patients with acute megaloblastic anemia present with rapidly developing thrombocytopenia and/or leukopenia and counts that sometimes fall to very low levels, but little change in red cell levels unless another cause of anemia is present. The discrepancy between platelet and leukocyte counts on the one hand and red cells on the other hand is a reflection of the much longer red cell life span. The clinical picture can suggest an immune cytopenia. The diagnosis is made from the marrow aspirate, which is floridly megaloblastic, and confirmed by the rapid response to appropriate replacement therapy.

The most common cause of acute megaloblastic anemia is nitrous oxide (N₂O) anesthesia.³⁶⁸ N₂O rapidly destroys MeCbl,³⁶⁹ leading to a megaloblastic state. AdoCbl eventually is lost, SAME and total folate levels decline, and the proportion of folate in the form of N⁵-methyltetrahydrofolate increases.³⁷⁰ Clinical findings develop quickly. Grossly megaloblastic changes are seen in the marrow after 12 to 24 hours.³⁷¹ Hypersegmented neutrophils do not appear until 5 days after exposure but then persist for several days.³⁷² The effects of N₂O disappear

Figure 41-16. Effect of cyanocobalamin on reticulocyte count, serum iron, serum bilirubin, stool urobilinogen, and plasma iron turnover. (Adapted with permission from Coleman D, Donohue D, Finch C, et al: Erythrokinetics in pernicious anemia. *Blood* 11(9):807-820, 1956.)

spontaneously after a few days; disappearance can be hastened by folinic acid or cobalamin.³⁷³ Fatalities resulting from N₂O-induced megaloblastosis have occurred in tetanus patients given N₂O for weeks.³⁶⁸ Long-term recreational use of N₂O has led to a neurologic disorder similar to combined system disease.³⁷⁴

Acute megaloblastic anemia occurs in other clinical settings. A rapidly developing megaloblastic state with acute thrombocytopenia has occurred in seriously ill patients, often in intensive care units.³⁷⁵ Especially at risk are patients who are transfused extensively at surgery,³⁷⁶ those on dialysis or total parenteral nutrition, and those receiving weak folate antagonists such as trimethoprim. Morphologic clues to the diagnosis (e.g., hypersegmented neutrophils) often are absent from the blood film. Both red cell folate and serum cobalamin levels may be normal, but the marrow is always megaloblastic. A rapid response to therapeutic doses of parenteral folate (5 mg/day) and cobalamin (1 mg) is the rule.

MEGALOBlastic ANEMIA CAUSED BY DRUGS

Table 41-5 lists the drugs that cause megaloblastic anemia. *Aminopterin* and *methotrexate* are almost structurally identical to folic acid. After they enter cells via the folate carrier³⁷⁷ and acquire a polyglutamate chain,³⁷⁸ they act as very powerful inhibitors of FH₂ reductase.³⁷⁹ By blocking the FH₂→FH₄ reaction and perhaps inhibiting other enzymes of folate metabolism, they effect the rapid withdrawal of folates from the one-carbon fragment carrier pool, causing a fall in nucleotide (especially thymidine) biosynthesis that leads to a major derangement in DNA replication (Chaps. 10 and 22).³⁸⁰
